Chest pain or discomfort relieved by sitting up and leaning forward and intensified by lying supine is typical. Respiratory symptoms of cough and dyspnea can dominate the clinical picture. The physical exam reveals a pericardial friction rub, heard most frequently during expiration with the patient upright and leaning forward [24]. The friction rub may not be heard in patients with large effusions. Tachypnea, tachycardia, widened pulse pressure, and

hepatojugular reflux are signs of impending hemodynamic compromise. The classic Beck triad of pericardial tamponade includes hypotension, muffled heart sounds, and jugular venous distension [25]. Pulsus paradoxus, defined as an exaggerated decrease in systolic blood pressure (>10 mmHg) with inspiration, is a sign of falling cardiac output. Late findings are cyanosis and decreased level of consciousness.

Post-pericardiotomy syndrome typically occurs after cardiac surgery and is usually mild. The patient can suffer from fatigue and low-grade fever. Anterior precordial chest pain that increases on deep inspiration is common. The typical clinical finding is that of a pericardial friction rub. When a pericardial effusion is associated, the friction rub can disappear, the heart sounds are attenuated and tamponade is a possibility.

Diagnostic Workup

- Laboratory

Blood work should be directed toward identifying the etiology (Tables 131.2 and 131.3). Diagnostic studies can be performed on the pericardial fluid including cell count and differential, protein, lactate dehydrogenase, glucose, gram stain, bacterial and fungal cultures, viral PCR, mycobacterial acid-fast stain, and tumor cytology. When connective tissue disease is suspected, rheumatoid factor, antinuclear antibodies, and complement levels can be added. Specific bacterial antigens may be identified with immunologic techniques. In tuberculous pericarditis, the pericardial fluid will be serosanguineous with a predominance of lymphocytes, and pericardial fluid adenosine deaminase activity, a T-lymphocyte product, has been shown to be useful in the diagnosis of tuberculous pericarditis [26]. Acid-fast bacilli are present on auramine-rhodamine fluorescent stained smears in 15–40 % of patients, and incubation of Mycobacterium tuberculosis may require 6 weeks using standard cultures. In chylopericardium, pericardial fluid triglyceride levels are elevated. In patients with post-pericardiotomy syndrome, elevated white blood cell count with a left shift and elevated erythrocyte sedimentation rate (ESR) are usual. Analysis of pericardial fluid should include cell count.

Table 131.3 Causes of pericardial effusion

Causes of pericardial effusion	
Idiopathic	
Viral	Coxsackievirus A and B
	Hepatitis
	HIV
Pyogenic	Pneumococci
	Streptococci
	Staphylococci
	Neisseria species
	Legionella species
	Haemophilus influenzae
Tuberculous	Mycobacterium tuberculosis
Fungal	Histoplasmosis
	Coccidioidomycosis

	Procainamide
Postradiation therapy	
Post-cardiac transplant	
Others	Hypercholesterolemia
	Sarcoidosis
	Whipple disease

Picture 131.2 Chest X-ray in pericardial effusion: water bottle-shaped heart

- Chest X-Ray

An increased cardiac silhouette that is globular (water bottle-shaped heart) can be seen with excessive pericardial fluid accumulation (Picture 131.2) [27]. Another finding is visualization of the pericardial fat stripe within the cardiac silhouette. The lung fields are usually oligemic and a pleural effusion is often associated.

- Electrocardiogram

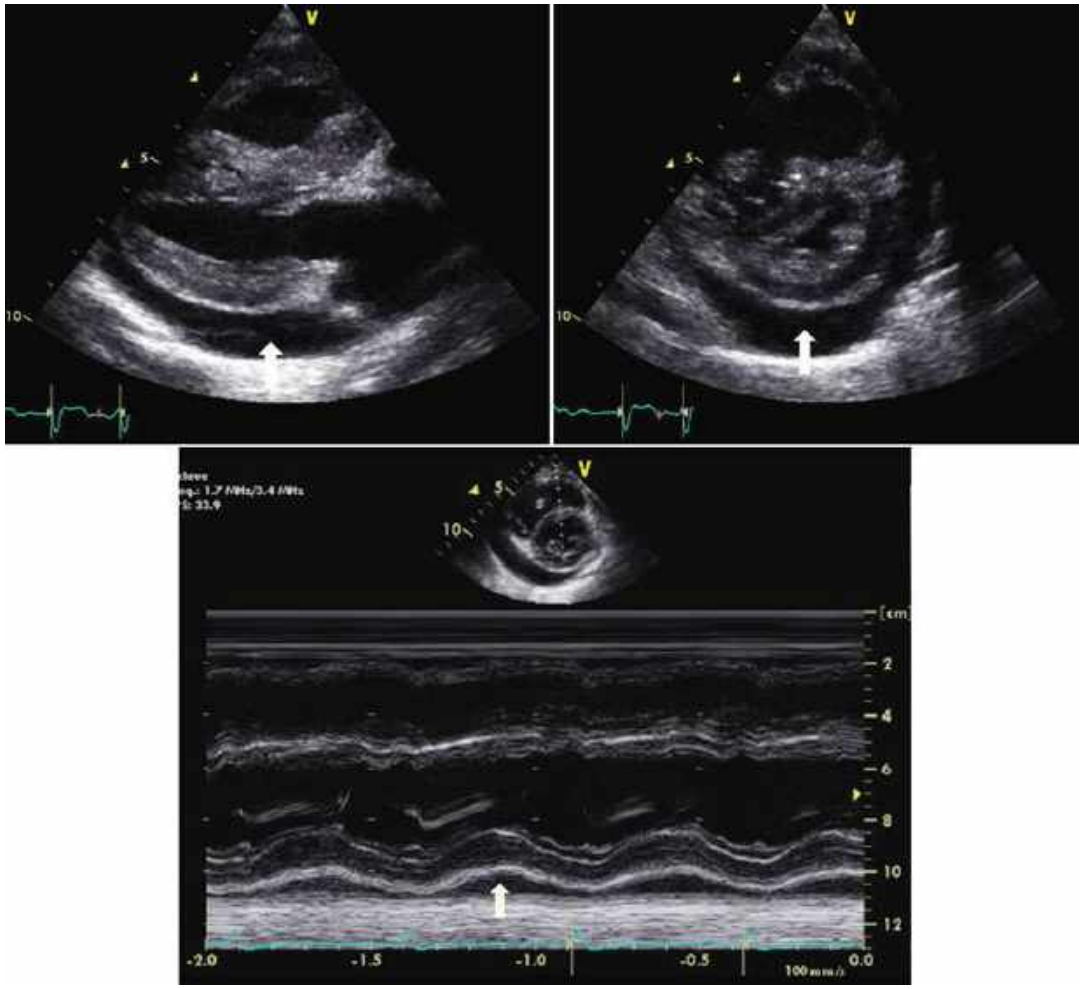
Low voltage QRS with diffuse nonspecific ST-segment changes are present with large effusions. Electrical alternans is pathognomonic of cardiac tamponade and is characterized by alternating P wave, QRS complex, and T wave voltages attributable to swinging motion of the heart [28, 29]. In patient with post-pericardiotomy syndrome, nonspecific abnormalities of the T waves (flattening in leads I and lateral chest) and decrease in voltage are common findings, especially with large pericardial effusions.

- Echocardiography

Pericardial effusion appears as an "echo-free" space between the visceral and parietal pericardium on M-mode echocardiography (Picture 131.3) [30]. Effusions tend to accumulate posterior and inferior to the left ventricle initially. However, on echocardiographic imaging, fluid visualized above the right atrium in the four chamber view is the most sensitive indication as this is the first place where a pericardial effusion is seen. Moderate effusions (10–20 mm in size) extend toward the apex of the heart, and large effusions (more than 20 mm) circumscribe the heart (Picture 131.3, Videos 131.1 and 131.2).

The rapidity of fluid accumulation and the compliance of the pericardium influence the hemodynamic significance for a given fluid volume. As pericardial fluid accumulates, intrapericardial pressure increases until it exceeds normal filling pressure of the heart, leading to tamponade. The first sign of hemodynamic compromise is *expiratory right ventricular free wall collapse early in diastole*, reflecting the brief period when intrapericardial pressure is greater than the right ventricular transmural distending pressure [31, 32]. The right ventricle is the first to collapse due to its lower intracardiac pressure compared to the left ventricle. Although right ventricular collapse is generally a specific indicator of tamponade, the sensitivity can be reduced in conditions with increased right ventricular pressure [33]. *Expiratory right atrial collapse* occurs in *late diastole* (Picture 131.4). The sensitivity of expiratory diastolic right atrial collapse for diagnosing tamponade is low (55 %), but the specificity is high (90 %). Extension of collapse greater than 1/3 of the cardiac cycle increases the sensitivity of this finding to more than 90 % [34, 35]. Absence of expiratory right atrial collapse virtually excludes tamponade. Another sensitive marker of tamponade by echocardiogram is absence of inspiratory collapse (plethora) of the inferior vena cava, defined by less than 5 mm decrease in diameter during inspiration [36]. The sensitivity of inferior vena cava plethora is high (97 %), but the specificity is low (66 %). Diastolic collapse of the left atrium and rarely the left ventricle occurs during inspiration, related to the increased right heart inflow and abrupt expansion of the right ventricle.

Doppler echocardiography shows large swinging amplitudes of the mitral and tricuspid inflow, the aortic and pulmonary outflow, and the hepatic veins. Normally, there is no more than 10 % variation in the amplitude of inflow and outflow signals with respiration, but this exceeds 30 % in tamponade (Picture 131.5). The classic



Picture 131.3 Parasternal long and short axis 2D-echocardiography: large pericardial effusion (*arrow*) circumscribing the heart. M-mode echocardiography: echo-free space (*arrow*) between the visceral and parietal pericardium, posterior to the left ventricle

Doppler patterns of cardiac tamponade (Fig. 131.4) [37, 38] are as follows:

- Mitral inflow: During inspiration, E wave velocity decreases by more than 30 % compared with expiration.
- Pulmonary veins: During inspiration, D wave velocity decreases.
- Tricuspid inflow: During inspiration, E wave velocity increases more than 50 % compared with expiration.
- Hepatic veins: During inspiration, S is greater than D and during expiration, there is a very limited or absent D wave with prominent reversal.
- Cardiac CT and MRI

CT can potentially determine composition of fluid and may detect as little as 50 mL of fluid. MRI can detect as little as 30 ml of pericardial fluid and may be able to distinguish hemorrhagic and nonhemorrhagic effusions. Both MRI and CT scan may be superior to echocardiography in detecting loculated pericardial effusions and pericardial thickening.

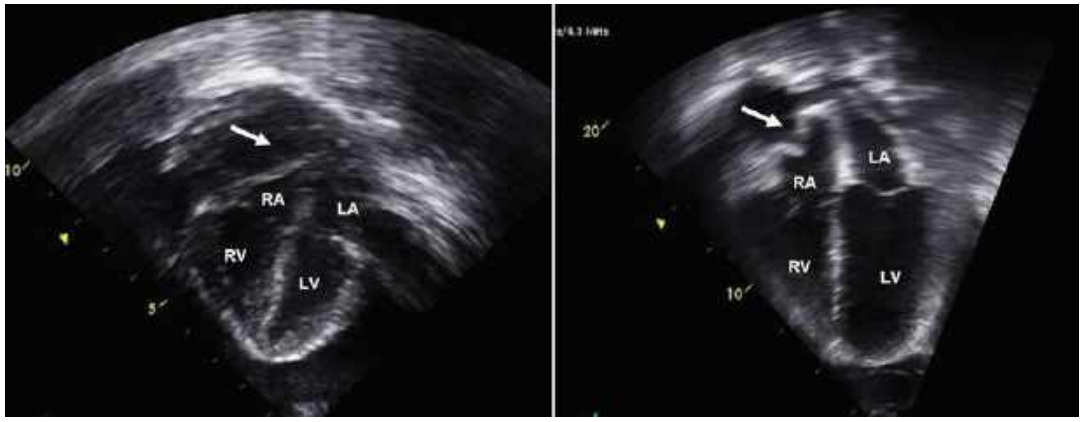
Video 131.1 Implantation of Artificial Chordae. The mitral valve is exposed through a left atriotomy, and anterior and posterior mitral leaflets are tested for mobility and coaptation using 2 nerve hooks. The prolapse and increased mobility of the anterior mitral leaflet when compared to the posterior leaflet is noted here. Since the size of the mitral annulus corresponds to the surface area of the anterior mitral leaflet, this equates to the inter-trigonal distance. The anterior mitral leaflet is unfurled, and the corresponding sizer, that matches the surface area of the anterior leaflet and inter-trigonal distance, is chosen as the correct size for the annuloplasty ring. Pledgeted 4-0 poly-tetra-fluoro-ethylene (PTFE, Gortex, USA) sutures are inserted through the body of the anterior and posterior papillary muscles below, and through the free-margin of the anterior mitral leaflet at the appropriate distance. Any clefts/indentations in the posterior mitral leaflet are closed using interrupted 5-0 polypropylene sutures. One of the needles of the biodegradable annuloplasty ring is inserted into the posterior mitral annulus along an intra-annular plane, starting from the level of the posterior commissure. The ring is gently pulled through and advanced along the entire length of the posterior annulus, until it exits at the level of the anterior mitral commissure. The length of the artificial chordae are measured such that the coaptation height of both the leaflets are equal, and the anterior leaflet prolapse is corrected. Saline injection testing of the valve, and intra-operative trans-esophageal echocardiography confirm adequacy of mitral valve repair, and obliteration of mitral regurgitation.

Video 131.2 Fundoplasty. Inspection of the mitral valve using 2 nerve hooks demonstrates a typical stenotic "fish mouth" rheumatic valve, characterized by thickened, fibrotic leaflets with markedly limitation in mobility, and commissural fusion. Anterior and posterior commissurotomies are performed using a No. 11 blade, leaving a 2 mm margin between the incision and the annulus. Fused sub-valvular tissue is also divided and released. Re-inspection of the valves demonstrates retraction of the P2-P3 scallops of the posterior mitral leaflet. A 3-4 cm incision is made on the posterior mitral annulus, extending from P3 to P2, leaving a 2 cm rim away from the free margin of the posterior leaflet. Full thickness polypropylene sutures are taken through the 3 O'clock and 9 O'clock positions of the incision. Similarly, multiple interrupted sutures are taken through the 10 O' clock and 2 O' clock, 8 O'clock and 4 O'clock positions, etc. When these sutures are tied down, the orientation of this incision changes from a horizontal incision into a vertical incision, thereby improving the coaptation height of the P2 and P3 segments. The mitral annulus is then supported by conventional ring annuloplasty. Saline injection testing and intra-operative trans-esophageal echocardiography confirm adequacy of repair, with good leaflet coaptation and no mitral regurgitation.

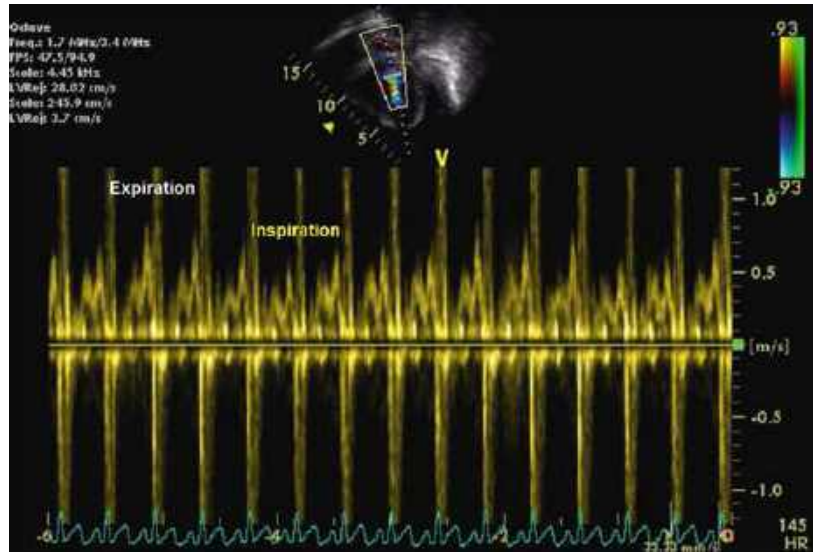
Medical Management

In the case of a small pericardial effusion in the postoperative period, an increase in the diuretic regimen can be attempted. Nonsteroidal anti-inflammatory drugs or acetylsalicylic acid is usually used to decrease the inflammatory reaction. Aspirin (80–100 mg/kg/day) during 7–10 days, tapered down over 3–4 weeks, is usually the first-line treatment. Steroids are reserved for severe and recurrent cases, as cases of corticoid-dependent pericardial effusion has been described. *Post-pericardiotomy syndrome* is usually self-limited, but relapses can occur. Medical treatment includes bed rest and anti-inflammatory drugs:

- Acetylsalicylic acid (aspirin 80–100 mg/kg/day or 800 mg every 6 h in adults) is thought to reduce inflammation and fever and is administered for 10 days and then gradually tapered down over 3 weeks. High-dose acetylsalicylic acid should be associated with gastroduodenal prophylaxis.
- Nonsteroidal anti-inflammatory drugs (NSAIDs), like ibuprofen (10 mg/kg/day), is an alternative to acetylsalicylic acid therapy.



Picture 131.4 Apical four-chamber and subcostal 2D-echocardiography views in pericardial effusion right atrial collapse (*arrow*)



Picture 131.5 Doppler echocardiography in pericardial effusion: respiratory variation in mitral inflow with increased E wave velocity during expiration

- Colchicine has been shown to be safe and effective in the treatment and prevention of recurrent pericarditis after failure of conventional treatment, especially in idiopathic cases [16]. The dose for adults is 1–2 mg for the first day followed by a maintenance dose of 0.5–1 mg daily for 3 months. No data are available in children.
- Corticosteroids (prednisone 1–2 mg/kg/day) are preferably avoided but can be used in severe or recurrent cases during 2–4 weeks followed by gradual tapering off.
- High doses intravenous immunoglobulins (IVIG) have been described in the treatment of recurrent post-pericardiotomy syndrome [39].

In pericarditis associated with acute rheumatic fever, treatment with anti-inflammatory agents usually effects a rapid reduction in the amount of pericardial effusion.

Percutaneous Management

- Echocardiography-guided pericardiocentesis

The approach is to assess the size, distribution, and ideal needle entry site and trajectory to safely evacuate the pericardial fluid.

The echocardiographic transducer is placed approximately 3–5 cm from the parasternal border, and the area of maximal pericardial fluid accumulation is identified. The needle trajectory is established by the angle of the transducer [40–42]. The precordium is entered in the angle formed between the xiphoid process and the left costal cartilages using an 18-mm gauge needle directed at an approximate 15° posterior angle toward the shoulder. The needle is advanced with the tip bent downward, while continuous suction is performed with a syringe until fluid is obtained. Adequate drainage of the pericardial fluid is assessed by echocardiography. Echocardiography-guided pericardiocentesis is simple, safe, and effective for primary treatment of clinically significant pericardial effusion, even in the postoperative period [43]. Complications include transient arrhythmia and cardiac injury with possible hemopericardium.

- Percutaneous pericardial drainage

Frequently, pericardiocentesis is accompanied by insertion of a drainage catheter to reduce the rate of recurrence that may complicate simple needle drainage. The precordium is entered from the standard subxiphoid approach using an 18-mm gauge needle until fluid is obtained. To assess the position of the needle in the pericardial sac, saline solution can be injected and monitored via echocardiography [44]. A 0.035″ guide wire is advanced into the pericardial space, under echoguidance. The needle is subsequently removed and the tract is dilated with a 7F or 8F dilator. A 7F or 8F pigtail catheter is then inserted over the guide wire, positioned in the posterior pericardial space at the level of the left atrioventricular groove.

- Percutaneous balloon pericardiotomy

The initial part of the procedure is similar to percutaneous pericardial drainage but is performed in the catheterization laboratory under fluoroscopic guidance. The parietal pericardium is dilated using a 10F dilator. Further dilation is performed using either a single balloon (20 mm wide, 3 cm long) or trefoil (triple) balloons. The balloon is filled with a mixture of contrast and saline and is manually inflated to a maximum pressure of 3.5 atm until the balloon "waist" disappears. Three inflations of 15 s each are recommended. At the end of the procedure, a pigtail catheter is exchanged over the wire and left in place to allow complete drainage of the effusion [45]. Complications include fever, pneumothorax, pleural effusion, and severe chest pain. The success rate of this procedure is high, and yet many would disagree that this technique is successful or durable [46].

- Pericardial sclerosing therapy

When significant pericardial effusion recurs, a more definitive intervention is needed. Pericardiocentesis with instillation of sclerosing agents has been shown to be successful for malignant pericardial effusions, with a low recurrence rate. Most commonly used are tetracyclin or bleomycin, instilled through a pigtail catheter [47, 48]. Common side effects include transient pyrexia, severe retrosternal chest pain, and transient atrial arrhythmia. Few data are available in children [49].

Surgical Management

- Subxiphoid pericardial drainage

Subxiphoid pericardiotomy is often preferred to percutaneous pericardiocentesis in critically ill patients or when echo-guided pericardiocentesis has failed. It is performed via a midline incision from the xiphisternal junction to 6–8 cm below the tip of the xiphoid. The xiphisternal junction is split and the xiphoid process removed to expose the diaphragm. The sternum is lifted so the pericardium can be reached. The pericardium is incised allowing the fluid to drain freely and a pericardial drain is left in place [44]. Minor complications include wound dehiscence and transient pneumothorax.

- Pleuropericardial window

Limited pericardiectomy is performed via a left thoracotomy. No attempt is made to excise all pericardial tissue, the main objective being to provide drainage of the pericardial sac into the left pleural space. This procedure can also be performed under direct thoracoscopic vision with excellent visualization of the pericardium and pleura.

Constrictive Pericarditis

Etiology and Epidemiology

Constrictive pericarditis is rare in children in developed countries, but as mentioned above, the incidence in undeveloped countries is much higher due to higher rates of tuberculosis. Clinical presentation depends on etiology and the rate of onset and severity of disease (Table 131.4) [50, 51].

Table 131.4 Causes of constrictive pericarditis

Causes of constrictive pericarditis

Post-cardiac surgery	
Uremia	
Neoplasia	
Metabolic disorders	
Genetic disorders	

Signs and Symptoms

The history reveals symptoms of congestive heart failure, such as dyspnea, orthopnea, paroxysmal nocturnal dyspnea, diaphoresis, easy fatigability, and tachycardia. Precordial pain is unusual in chronic constrictive pericarditis, as opposed to acute pericarditis. The hallmarks of physical diagnosis include absence of a drop in jugular venous pulsations during inspiration (Kussmaul sign) and elevated jugular pressure with prominent y descent (Friedreich's sign). Unlike other forms of pericardial disease, such as acute pericarditis, a friction rub is usually not audible. A protodiastolic knock, usually heard along the left sternal border, corresponds to the abrupt cessation of ventricular filling during diastole. As the systemic venous pressure becomes elevated, signs of right-sided heart failure develop, such as neck vein distention, hepatomegaly, ascites, hepatojugular reflux, and peripheral edema [52, 53]. Signs of diminished cardiac output include diminished pulse pressure, pulsus paradoxus, and a prominent third heart sound.

Diagnostic Workup

- Laboratory

Brain natriuretic peptide (BNP) is usually normal or just above normal in patients with constrictive pericarditis as opposed to elevated (>600 pg/ml) in patients with restrictive cardiomyopathy, helping differentiate between these two conditions [54]. No data on BNP levels in this setting are available in children.

- Chest X-Ray

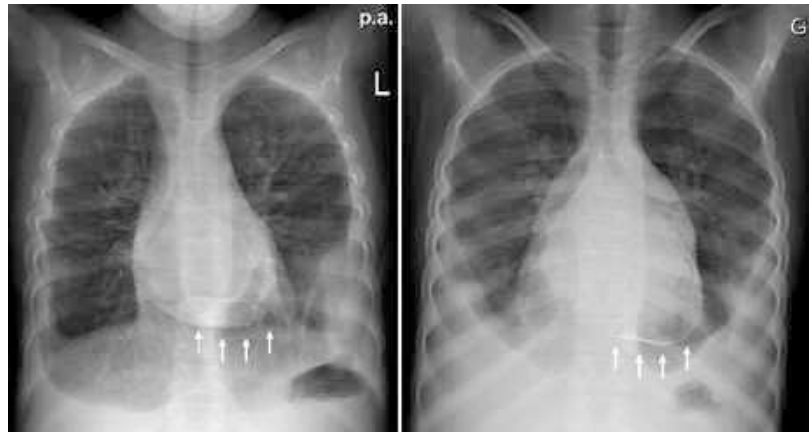
The chest X-ray is usually unremarkable. Pericardial calcifications are present in 40–50 % of patients, giving an eggshell appearance of the cardiac silhouette [55] (Pictures 131.6 and 131.7). The right superior mediastinum may be enlarged owing to dilation of the superior vena cava. Pleural effusions may be present, reflecting chronic elevation of right heart filling pressures. Pulmonary infiltrates are uncommon.

- Electrocardiogram

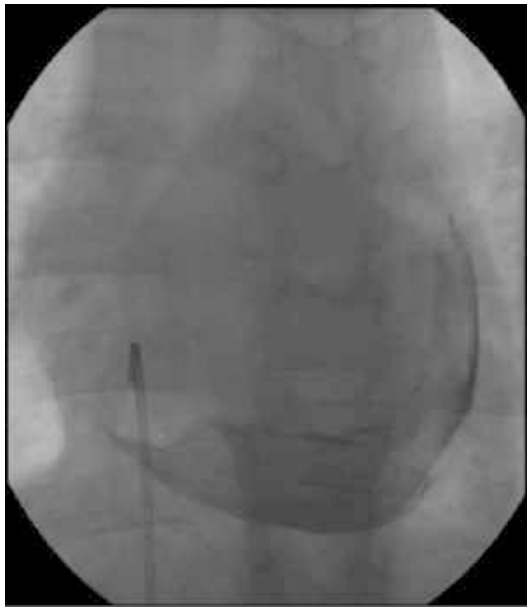
ECG is nonspecific but usually demonstrates diffuse low voltage and nonspecific ST-T wave changes. Atrial dysrhythmias are common.

- Cardiac catheterization

The hallmark finding in constrictive pericarditis is elevation and near equalization of end-diastolic pressures in the right atrium, right ventricle, pulmonary capillary wedge (left atrium), and left ventricle. The jugular venous or right atrial pulse waveform is characterized by a prominent A wave, reflecting rapid early diastolic filling of the ventricle, a sharp x descent, due to accelerated atrial relaxation, and a sharp y descent reflecting the early resistance free right



Picture 131.6 Chest X-ray in constrictive pericarditis: eggshell appearance of the cardiac silhouette with calcification of the pericardium (*arrows*)



Picture 131.7 Cardiac catheterization in constrictive pericarditis: calcification of the cardiac silhouette

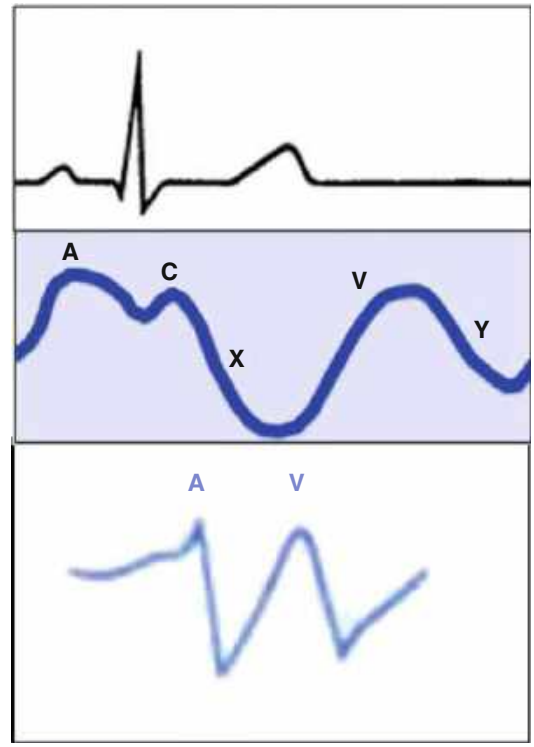


Fig. 131.5 Jugular venous pressure and atrial wave form: normal (*upper tracing* below the ECG) and in constrictive pericarditis (*bottom tracing*) with rapid x and y descents described as an "M-" or "W-" shaped pattern

ventricular filling (Fig. 131.5). The mean jugular venous and right atrial pressures are elevated.

The right ventricular waveform is distinctive, with a "dip and plateau" or "square-root sign" pattern (Fig. 131.6), reflecting the rapid relaxation, followed by a sharp increase in filling pressure as the expanding ventricle meets the constraints of the pericardium [56]. The left ventricular pressure tracing is usually similar. Other hemodynamic findings include a right ventricular diastolic pressure exceeding one third of the right ventricular systolic pressure and a pulmonary artery pressure of less than 50 mmHg [57].

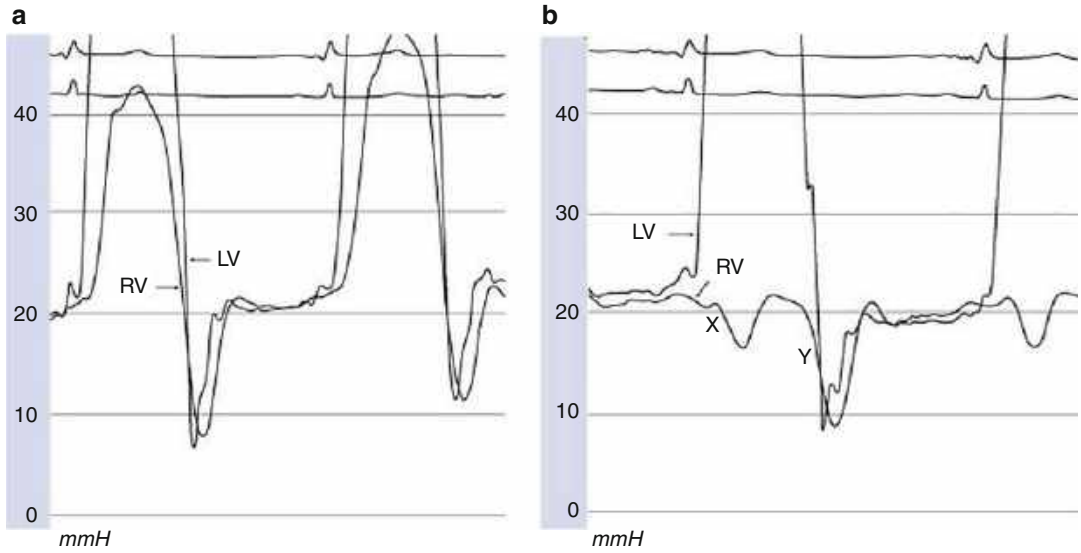

Fig. 131.6 Cardiac catheterization pressure tracings in constrictive pericarditis: (**a**) Simultaneous right and left ventricular pressure showing equalization of diastolic pressures and characteristic "dip and plateau" or "square-root" pattern of the right ventricular pressure curve. (**b**) Simultaneous left ventricular and right atrial pressure showing equalization of diastolic pressures and characteristic waves of the right atrial pressures with sharp x and y descents. *Abbreviations*: *RV* right ventricle, *LV* left ventricle, *RA* right atrium

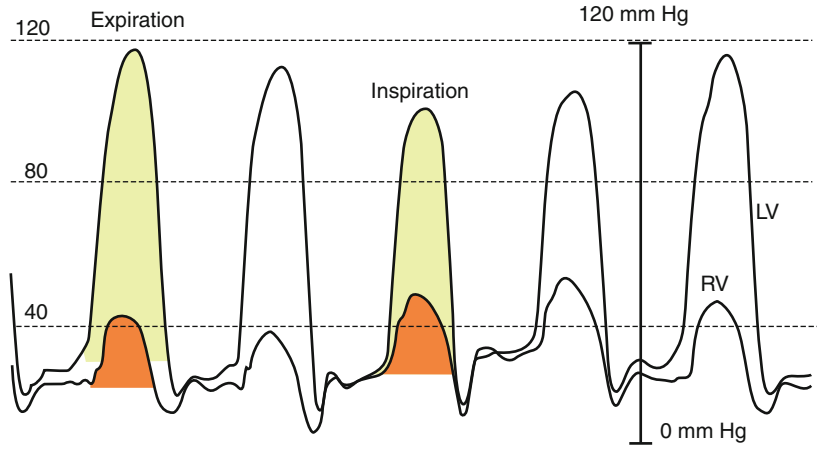

Fig. 131.7 Pressure tracing in constrictive pericarditis: during inspiration, there is an increase in the area under the RV pressure curve (*orange-shaded area*) compared with expiration, the area of the LV pressure curve (*yellow-shaded area*) decreases during inspiration as compared with expiration (Adapted from Talreja et al. [89]). *Abbreviations*: *RV* right ventricle, *LV* left ventricle

Another hallmark of constriction is increased ventricular interdependence. Because pericardial constraint limits total cardiac volume, there is a reciprocal relation between left and right heart filling due to enhanced septal interaction. There is opposite directional changes in ventricular systolic pressure and reciprocal changes with respiration, with inspiration inducing an increase in right ventricular but a decrease in left ventricular pressure, a phenomenon called ventricular discordance (Fig. 131.7). The opposite changes occur during expiration, with increased left heart filling and reduced right heart filling. This may be the most reliable hemodynamic indicator of

constriction [58]. When hemodynamic studies are equivocal, a bolus fluid can be administered and reveals striking elevation of the filling pressures in the case of constrictive pericarditis [59, 60].

- Echocardiography

Echocardiography remains the best tool in the initial assessment of constrictive pericarditis [61]. A thickened pericardium with some degree of pericardial effusion may be observed by 2D-echocardiography [62]. Transthoracic echocardiography is insensitive, as mildly increased pericardial thickening can be missed and false positives can be obtained if the gain is set too high. Pericardial calcifications with localized tethering of atrial or ventricular cavities may be noted, while separation of the entire pericardium by a small fixed space is known as the "halo sign." The systemic veins are usually dilated, with the inferior vena cava showing absent collapse with inspiration (plethora). Septal "bounce" is typical, defined as abrupt posterior movement of the interventricular septum in early diastole during inspiration, and is caused by underfilling of the left ventricle and redistribution of blood from the left to the right ventricle. This "bounce" represents the first and best clue for the presence of constriction [63].

The right and left ventricular size is decreased, and both atria are mildly enlarged, related to the compliance abnormality of the ventricles. The ventricles have an elongated appearance giving the heart a tubular shape. The biventricular systolic function is usually normal. Interventricular septal motion may be paradoxical or flat as a sign of ventricular interdependence. A characteristic septal notch has been described in early diastole (Picture 131.6), corresponding to the septal bounce seen by 2D-echocardiography [64, 65]. Extensive areas of adhesions seen posteriorly by M-mode provide evidence for generalized pericardial thickening and constriction.

The hallmark of Doppler examination is reciprocal respiratory variation of right and left heart flows caused by interventricular dependence. The classical Doppler pattern consists of the following (Fig. 131.8) [66–68]:

– Mitral inflow: During inspiration, E wave to A wave ratio (E > A) is lower, while during expiration, there is larger E wave to A wave (E > A) ratio. E wave is typically increased more than 25 % with expiration and the IVRT increased more than 25 % with inspiration (Picture 131.8).
– Pulmonary veins: During inspiration, S and D waves are near equal in size. During expiration, larger S and D waves are noted.
– Tricuspid inflow: It shows the same pattern with reciprocal changes compared to the mitral inflow. During expiration, smaller E wave to A wave (E > A) ratio is noted, while during inspiration, there is larger E wave to A wave (E > A) ratio. E wave is typically increased more than 40 % with inspiration.
– Hepatic veins: During inspiration, S wave is greater than D wave, with a small A wave reversal. During expiration, S wave is greater than D wave, with small or absent D wave and larger A wave reversal.

Also described in constrictive pericarditis is an inspiratory increase in the tricuspid regurgitant jet velocity and duration of the signal [58]. As opposed to restrictive cardiomyopathy, respiratory variation in the filling phase is more pronounced in constrictive pericarditis. Tissue Doppler echocardiography shows a normal or high early mitral annular velocity (Em wave) in constrictive pericarditis (Picture 131.9), as opposed to restrictive cardiomyopathy where it is reduced [69]. The usually positive linear relation between mitral Doppler E and tissue Doppler Em (E/Em) is useful to assess left atrial pressure and is found to be reversed in constrictive pericarditis [70].

- Cardiac MRI and CT

Both CT and MRI can detect a thickened pericardium (≥4 mm), but this is an insensitive finding. An advantage of CT is the ability to detect calcification (Picture 131.10), indicative of constrictive pericarditis [71, 72]. However, CT may have difficulty differentiating pericardial fluid from thickened pericardium. The absence of pericardial thickening does not rule out hemodynamically significant constrictive pericarditis.

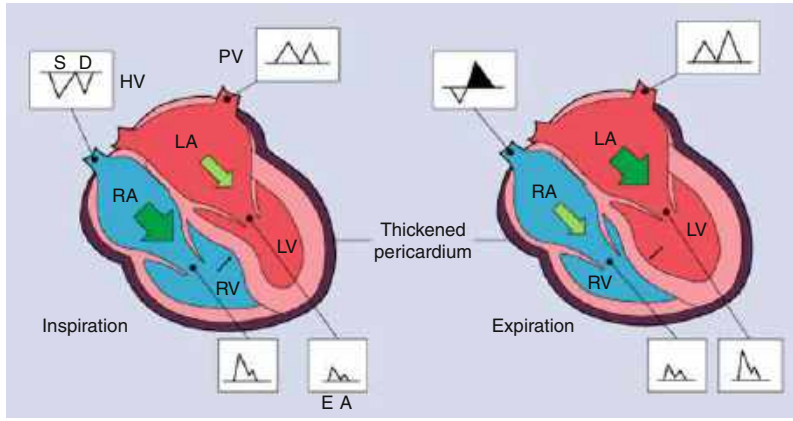

Fig. 131.8 Ventricular interdependence and respiratory variation in transvalvular and central venous flow velocities in constrictive pericarditis. With inspiration, the driving pressure gradient from the pulmonary bed to the left cardiac chambers decreases, resulting in a decrease in mitral inflow and diastolic pulmonary venous velocities. Decreased left ventricular filling results in ventricular septal shift to the left, allowing increased flow to the right-sided cardiac chambers, resulting in increased tricuspid inflow and diastolic hepatic venous velocities. The opposite changes occur during expiration (Adapted from Oh [90]). *Abbreviations*: *A* late diastolic (atrial reversal) Doppler wave, *D* diastolic Doppler wave, *E* early diastolic Doppler wave, *HV* hepatic vein, *LA* left atrium, *LV* left ventricle, *PV* pulmonary vein, *RA* right atrium, *RV* right ventricle, *S* systolic Doppler wave

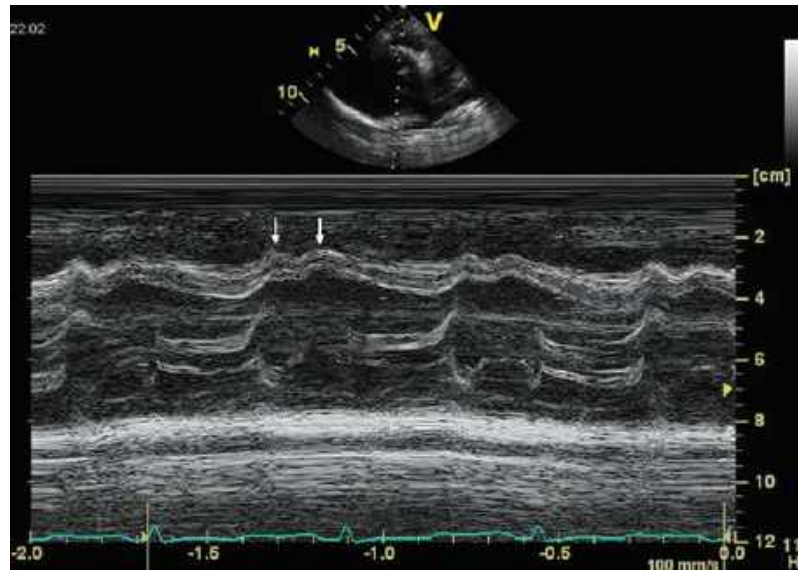


Picture 131.8 M-mode echocardiography in constrictive pericarditis: notched interventricular septum (*arrow*)

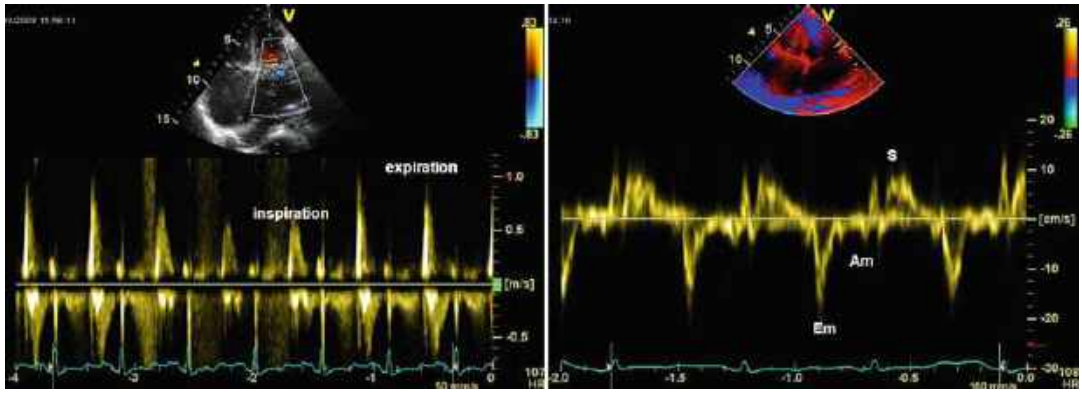
Medical Management

The treatment is essentially symptomatic, with diuretics to reduce right heart failure and pulmonary edema. The only curative treatment is pericardiectomy.

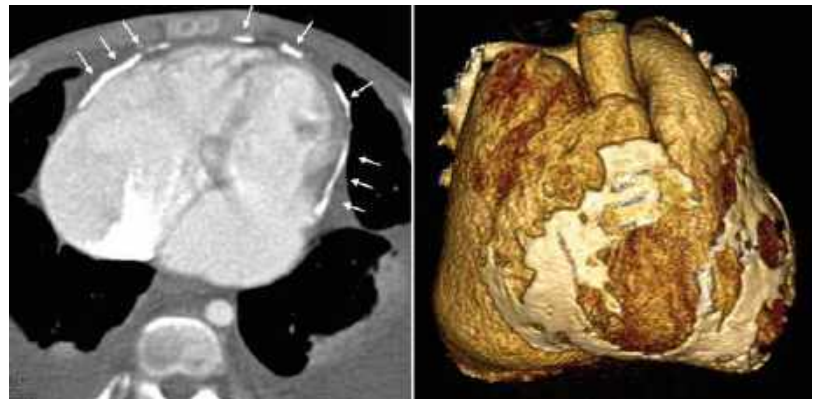
Surgical Management

- Pericardiectomy

Pericardiectomy is the treatment of choice for symptomatic patients with typical constrictive hemodynamics. Limited pericardiectomy is usually



Picture 131.9 Doppler echocardiography in constrictive pericarditis: respiratory variation in mitral inflow with increased E wave velocity with expiration, secondary to ventricular interdependence. Tissue Doppler imaging (TDI): normal or increased early diastolic (Em) wave velocity



Picture 131.10 Cardiac computed tomography (CT): pericardial calcifications (*arrows*). 3D reconstruction: calcified pericardium

performed via a left thoracotomy, but does not allow access to the right atrium and vena cava. Total pericardiectomy is defined as wide excision of the pericardium from around both ventricles, the great vessels, the vena cava, and the right atrium. It is important to include pericardium both anterior and posterior to the phrenic nerves, which must be properly identified and spared. It is usually performed via a median sternotomy or bilateral trans-sternal anterior thoracotomy. A median sternotomy with cardiopulmonary bypass standby is usually the preferred approach as it offers better exposure to the right side of the heart [73].

Poor results with persistent elevation of ventricular filling pressures have been attributed to inadequate decortication and remodeling of the ventricles after pericardiectomy. Complications include excessive bleeding and low cardiac output syndrome, thought to be secondary to fibrosis and atrophy of the myocardial fibers. Reoperation for recurrent constrictive pericarditis after partial pericardiectomy is common [74]. Improvement of symptoms and normalization of the intracardiac pressures occurs more quickly after extensive pericardiectomy [75].

Congenital Anomalies of the Pericardium

Etiology and Epidemiology

Congenital anomalies of the pericardium are uncommon but should be considered in children. *Pericardial cyst* is rare and usually congenital but may also be acquired after cardiothoracic

surgery. Cysts are typically located at the right cardiophrenic angle (50–70 %) or at the left cardiophrenic angle (28–38 %). *Congenital absence of the pericardium* can be complete or partial and can be isolated or associated in one third of the cases with other congenital cardiac anomalies (patent ductus arteriosus, atrial septal defect, mitral stenosis, tetralogy of Fallot) or congenital pulmonary anomalies (sequestration, bronchogenic cyst, diaphragmatic hernia). Eighty percent of defects occur on the left side and are related to premature atrophy of the left duct of Curvier during embryologic development.

Signs and Symptoms

Although most *pericardial cysts* are asymptomatic, patients may present with atypical chest pain, dyspnea, or persistent cough [76]. Complete *congenital absence of the pericardium* is often an incidental finding with chest imaging demonstrating deviation of the heart into the left chest. In those with symptoms, paroxysmal stabbing chest pain, largely nonexertional and mimicking coronary artery disease, dyspnea, and syncope can be associated [77]. Life-threatening complications include herniation of a cardiac chamber through the defect, most commonly the left atrial appendage, torsion of the great arteries, or constriction of a coronary artery at the rim of the defect. Displacement of the left ventricular impulse on clinical exam is the most common feature.

Diagnostic Workup

- Chest X-Ray

  A *pericardial cyst* is typically suspected after an abnormal chest X-ray consisting of a round, discrete mass in the right cardiophrenic angle, which is the most common location of these cysts [78]. In *congenital absence of the pericardium*, the chest X-ray reveals levoposition of the heart with loss of the right heart border hidden by the spine [77]. Prominence of the main pulmonary artery and interposition of a tongue of lung tissue between the pulmonary artery and the aorta (opacification of the aortopulmonary window) or between the inferior border of the heart and the left hemidiaphragm are other findings.
- Electrocardiogram

  In *congenital absence of the pericardium*, right bundle branch block is common. Right axis deviation with leftward displacement of the transition zone in the precordial leads can be seen.
- Echocardiography

  Pericardial cysts are difficult to detect with transthoracic echocardiography. They present as an echo-free space which is more localized and spherical than a pericardial effusion [79].

  Complete absence of the pericardium leads to enlargement of the right ventricle, excessive motion of the posterior left ventricular wall, paradoxical motion of the interventricular septum, and a shift of the heart to the left resulting in more of the right ventricle being seen on the left parasternal long axis view. All of these findings mimic right ventricular volume overload and thus this diagnosis should be excluded [80]. Partial absence of the pericardium sometimes results in herniation of a chamber through the defect, with the false appearance of wall motion abnormality. The biventricular function is usually normal. True wall motion abnormality is seen if a coronary artery is compressed.
- Cardiac CT and MRI

  CT and MRI are the preferred methods to confirm a suspected diagnosis of *pericardial cyst* [76, 81]. On CT scan, pericardial cysts are thin-walled, sharply defined, oval homogeneous masses. Their attenuation is slightly higher than water density, 30–40 HU, and the cyst fails to enhance with intravenous contrast [82]. The most reliable finding in *congenital absence of the pericardium* is interposition of lung tissue between the main pulmonary artery and the aorta. The heart can be completely displaced in the left hemithorax and its apex elevated. The main pulmonary artery and the left atrial appendage can be seen extending far beyond the mediastinal margins.

Surgical Management

Surgical procedures employed for patients with *absence of the pericardium* include left atrial appendectomy, division of adhesions, pericardiectomy, or pericardioplasty. The latter is usually reserved for symptomatic patients, as the symptoms are thought to be secondary to excessive cardiac motion. It is controversial as to whether asymptomatic patients with moderate-sized pericardial defects should undergo prophylactic operation to reduce the risk of death from cardiac structure herniation or incarceration [83]. Surgical reconstruction of the pericardium (pericardioplasty) can be performed with PTFE (polytetroflouroethylene) material or xenograft pericardium. The lateral and anterior surfaces of the newly reconstructed pericardium are then sutured to the lateral and medial aspect of the diaphragmatic surface to avoid excessive cardiac motion. Careful attention must be paid to the left phrenic nerve [77].

For patients with *pericardial cyst*, surgical excision is recommended only in symptomatic patients, while asymptomatic patients can be managed conservatively [84]. Minimally invasive thoracoscopic resection of the cyst is a good alternative, as it minimizes postoperative pain and has a better cosmetic outcome [85].

Postoperative Management

Among the pericardial disease processes, a common postoperative strategy may be employed. In large part, postoperative care is supportive with additional treatment directed at the underlying etiology of the disease. Management of the patient in ICU consists of fluid balance monitoring, sedation and analgesia, respiratory management, inotropic and vasodilator therapy, and recognition of anticipated complications.

In many patients, the duration of the pericardial disease process will impact their postoperative course.

- Monitoring

Continuous cardiorespiratory monitoring remains standard for these patients. Attention should be paid to alterations in heart rate, blood pressure, and respiratory rate. Most patients should be maintained in the physiologic range after returning to the intensive care unit.

- Fluid Management

The fluid status of a patient with pericardial disease returning to the ICU environment should be monitored carefully. Many postoperative patients may have undergone aggressive diuresis prior to surgery, and a few may be diuretic dependent. Maintenance intravenous fluid therapy should be initiated on patients unless contraindicated by concurrent illness. Most will not need the aggressive fluid management of other postoperative cardiac patients. The exceptions are those patients with restrictive physiology in whom fluid balance will become important as their disease process progresses.

- Sedation and Analgesia

Most patients should be extubated in the operating room or upon return to the intensive care unit (ICU). Sedation should not be a significant issue in the postoperative period. Pain control can be achieved with continuous narcotic infusion or boluses. Pain from thoracotomy should not be underestimated, especially in the older patients, as atelectasis secondary to shallow breathing can be a serious complication. The transition to oral pain management should occur when the patient is tolerating an oral diet. In the older child or adolescent, intermittent oral or intravenous benzodiazepines may be used for anxiolysis. Additionally, intravenous ketorolac or nonsteroidal anti-inflammatory drugs (NSAIDs) may be useful in patients with an inflammatory component to their pericardial disease.

- Respiratory Management

Most patients are extubated in the operating room or immediately upon return to the intensive care unit. Adequate pain control helps to avoid one of the most common complications after thoracotomy or sternotomy: atelectasis.

- Inotropic and Vasodilator Therapy

A low cardiac output state may be treated with volume resuscitation, inotropic support, and afterload reduction. Additionally, vasoactive medications may be used depending upon the patient's clinical state.

- Anticipated Complications

In-hospital mortality after pericardiectomy for constrictive pericarditis is not negligible, around 15 %. Complications after surgery include low cardiac output syndrome and hemorrhage. Patients should be monitored for persistent effusion or restrictive physiology after surgical intervention.

Long-Term Outcome

Pericardiectomy improves symptomatology in the majority of patients during late follow-up. A subgroup of patients do not experience an amelioration in clinical symptoms, probably because myocardial function does not completely recover [86]. This is particularly true for patients with long-standing constriction, especially in the setting of tuberculosis. Right ventricular dysfunction has been associated with myocardial involvement and absence of clinical improvement after pericardiectomy [87]. Recurrence is the most troublesome complication of pericarditis, occurs in 15–50 % of patients and is probably an autoimmune process. The overall prognosis in idiopathic recurrent pericarditis is excellent and complications are uncommon. Even after numerous recurrences of pericarditis, constrictive pericarditis as a complication is extremely rare. The risk of evolution to constrictive pericarditis in idiopathic acute pericarditis is estimated to be around 1 % [88]. The risk of progression to constriction is higher in tuberculous, neoplastic, or purulent pericarditis.

Cardiac Traumatic Lesions in Children

132

Alexandre Cazavet, Hanane Ouald Ali, and Bertrand Leobon

Abstract

Cardiac traumatic lesions in children are a relatively rare event but imply specific attention considering their potentially life-threatening consequences. Mechanisms of cardiac traumatisms are various but can be divided into three categories: blunt traumatisms, penetrating thoracic wounds, and iatrogenic injuries. All anatomical cardiac structure can be involved. Cardiac lesions are often associated with other thoracic or extra-thoracic lesions requiring a global management. Their clinical presentation is also very variable from minor asymptomatic lesions to dramatic conditions requiring emergent resuscitation. Unstable patients require prompt interventions including standard advanced trauma life support and emergent thoracotomy for surgical procedure. For stable patients, when a cardiac lesion is suspected, careful clinical examination and diagnostic studies are required. The early diagnosis of cardiac lesions and their management are crucial to determine the best treatment and improve outcome. This chapter will discuss their epidemiology, initial evaluation, diagnostic, and specific treatments, limited to the injuries implicating directly the heart and the great vessels.

Introduction

Cardiac traumatic lesions in children are a relatively rare event but imply specific attention considering their potentially life-threatening consequences. This chapter will discuss their epidemiology, initial evaluation, diagnostic, and specific treatments, limited to the injuries implicating directly the heart and the great vessels. Mechanisms of cardiac traumatisms are various but can be divided into three categories: blunt traumatisms, penetrating thoracic wounds, and iatrogenic injuries. Their clinical presentation is also very variable from minor asymptomatic lesions to dramatic conditions requiring emergent resuscitation. Cardiac lesions are often associated with other thoracic or extra-thoracic lesions requiring a global management. Their early diagnosis and management are crucial to determine the best treatment and improve outcome.

Epidemiology

General Considerations

Trauma is the leading cause of death in children, and the incidence of traumatic death in children is estimated to be about 20,000 each year in the United States [1]. Among injured children, thoracic traumas are rare and concern up to 8 % of injured children [2]. The overall mortality rate for children with severe thoracic trauma is between 15 % and 26 % [3–6]. Most children who undergo serious blunt traumas die of associated injuries. In contrast, most children who have thoracic penetrating trauma die because of these thoracic injuries.

Blunt Cardiac Trauma

Blunt traumatic injuries are the most frequent mechanism of injury in pediatric population and are involved at least in 80 % of cases [2–4]. Mainly, children are victims of blunt traumatic injuries being passenger or pedestrian involved in car crashes, or because of important falls [7]. Cardiovascular lesions after blunt traumatic injuries may be as frequent as 15 % in a postmortem study [8], but among patient admitted for blunt traumatic injuries, their incidence is reported to be as low as about 1 % [7, 9, 10]. This difference is due to the severity of some cardiac lesions responsible for a rapid death, often on the scene of the crash. Moreover, in high-energy blunt traumatic injuries, cardiovascular lesions are often associated with other severe lesions. The first cause of mortality after blunt traumatic injuries is a central nervous system injury [5]. These data underline the requirement of a global management of severe blunt traumas, giving priority to the most life-threatening lesions.

Penetrating Cardiac Trauma

Penetrating traumas are less frequent in children than blunt traumas but account for more than 10 % of admissions to most major North American pediatric trauma centers [11]. However, when the overall mortality rate for children injured from penetrating mechanisms is 14 %, those with thoracic injuries account for 97 % of those deaths [6]. Firearm injuries and stab wounds are the major causes of penetrating thoracic trauma in children [5].

Iatrogenic Injuries

Iatrogenic cardiac injuries can also be induced by insertions of central venous lines [12] or by cardiac catheterization procedures [13]. Those events are rare, but they must be considered when those kinds of procedures are planned.

Initial Evaluation and Stabilization of Children with Cardiac Trauma

Approach to the Initially Stable Child with Blunt or Penetrating Injury

General Considerations

A stable child refers to a patient who has normal vital signs and functions (neurological status, breathing, and circulation) during the initial

evaluation. However, physicians must be wary of children appearing initially stable, who secondarily may need hospitalization and/or surgical intervention. Initial assessment is critical to distinguish children at low or high risk of cardiac injury based on the mechanism of the trauma and the physical findings. In any child admitted for trauma, determination of the extent of the injuries (multiple or single), their nature (blunt or penetrating), and severity (mild, moderate, or severe) are important in the assessment and management of the patient.

Blunt Cardiac Trauma

The initial evaluation of children with suspected cardiac injury as the result of thoracic trauma should include an exhaustive medical history and a complete physical examination. A history of minimal trauma to the chest with normal vital signs and only superficial chest wall injuries is unlikely to require complementary investigations and may be discharged rapidly.

The presence of a history of mild to severe thoracic trauma, abnormal vital signs, or abnormal breath or cardiopulmonary examination suggests potential life-threatening intrathoracic injury. Those patients must have additional evaluation exams including chest radiography, electrocardiograms (EKG), and blood sample for troponin level.

Chest radiography may demonstrate chest wall lesions, pleural effusion, mediastinal enlargement, or anomalies of the cardiac area. Nonspecific abnormalities can also be noted on EKG including ST-segment changes, arrhythmias, and conduction disturbances [14]. A retrospective study found that more than half of children with cardiac trauma had an abnormal EKG [9]. The interest of cardiac troponin quantification in the evaluation of children who have sustained blunt thoracic trauma is uncertain because it can be elevated in patients with minor cardiac injury [15]. However, those with normal troponin levels who are hemodynamically stable and have normal EKGs are unlikely to have significant myocardial injury. Children with thoracic blunt injury presenting hypotension have elevated cardiac troponin level, or abnormal EKG should have cardiac monitoring and additional imaging studies. For children, FAST exam (focused assessment with sonography in trauma) or oriented echocardiography should be preferred to CT scan to identify cardiac injury [16]. FAST exam is a bedside ultrasound examination consisting in rapid analysis of four areas (peri-hepatic space, peri-splenic space, pericardium, and the pelvis) in order to find the presence of intraperitoneal or pericardial free fluid. For some physicians, CT scan must be reserved to children with suspected tracheobronchial or great vessel injuries [17], but for others, its indication is less restrictive and should be considered in case of abnormal chest radiography or history of high-energy blunt traumas (like the death of another passenger in a car crash).

Penetrating Cardiac Trauma

Even if a child with a penetrating wound to the thorax appears stable at the initial evaluation, he/she must be considered as a high-risk patient for major injury, including cardiac tamponade or internal hemorrhage. He/she requires rapid transfer to a surgical center and emergent surgical consultation. The initial management consists of hemodynamic restoration, but immediate surgical intervention is necessary in most cases. There, a FAST exam may be helpful to identify cardiac injuries with associated hemopericardium. In case of doubt about a cardiac lesion, some surgeons will perform an exploratory thoracoscopy before sternotomy. In cases of stab wounds, it is recommended not to remove the penetrating agent from the chest of the victim until in the operating room and ideally not until the pericardium is opened. The ability to utilize cardiopulmonary bypass is optimal in the case of severe cardiopulmonary injuries. Some children with penetrating wounds can undergo a nonsurgical management and careful monitoring, only if advanced imaging studies (echocardiography and CT scan) and surgical examination can exclude any pericardial penetration.

Approach to the Unstable Child

Advanced Trauma Life Support (ATLS)

The initial management of unstable trauma patients follows the standardized approach consisting in airway, breathing, and circulation management. It starts immediately on the scene and during transportation, with insertion of large venous access for vascular filling and drug infusion and tracheal intubation for ventilation. Persistent hypotension suggests massive hemorrhage or cardiac tamponade. Pericardiocentesis may restore circulation, but rapid thoracotomy will be required to control the source of bleeding.

Emergent Procedure

Emergency Thoracotomy

An emergency thoracotomy (ET) can be used in patients arriving in the Emergency Department (ED) without hemodynamic activity despite correct resuscitation maneuvers (CPR) are started before or during transportation. It consists of a large left anterolateral thoracotomy allowing clamping of the descending aorta, pericardial opening, cardiac massage, and defibrillation before addressing the intrathoracic lesions. The use of this technique has been proposed for patient after blunt or penetrating thoracic wounds. After the ET, the child must be taken immediately to the operating room for definitive surgery.

The analysis of a pediatric cohort of 23 patients treated in the Davis Medical Center of Sacramento [18] reports a transient restoration of spontaneous circulation in four children (17.4 %) and only one survival to discharge (4.4 %) despite optimal care (74 % of these patients were intubated, and vascular access was achieved on the field. They were transported within 10 min to the trauma center. Thoracotomy and open cardiac massage were performed within 5 min of arrival in the ED). The authors underline the absence of survival after blunt trauma and in case of absence of vital signs on the field for penetrating traumas. They conclude that children arriving at the ED following blunt or penetrating trauma with no cardiac rhythm are unsalvageable and should not undergo ET and that indications for ET in pediatric trauma victims should therefore be the same as those currently used for adult trauma victims. These results are consistent with those from adult series such as the Denver Health Medical Center [19] including over 26 years, 959 patients who underwent ET, with 62 survivors. The authors underline the same worst prognosis for blunt trauma requiring CPR. They conclude that ET is futile in patients with blunt trauma requiring prehospital CPR longer than 5 min and in patients with penetrating trauma with more than 15 min of prehospital CPR.

Two systematic reviews on ET confirm these indications, and the latest one proposes an algorithm directing the use of ET [20, 21].

Extra Corporeal Life Support

Extracorporeal life support (ECLS) or extracorporeal membrane oxygenation (ECMO) has been used in severe multisystem traumas including respiratory distress syndrome [22–24]. In blunt lesion, cardiac injuries responsible for hemodynamic failure are often associated with respiratory failure. In these severe situations, venoarterial ECMO provides hemodynamic and respiratory support and can allow recovery. The institution of the ECMO is usually accomplished by cannulation of the jugular vein and carotid artery in small patients, but can also be central in case of emergent sternotomy, or axillary or femoral in adolescent patients. ECMO has been reported in the emergency management of cardiac contusion [25] or traumatic ventricular septal defect [26]. A case of rupture of the carina with respiratory and hemodynamic failure stabilized and successfully treated under venoarterial ECMO will soon be published. This procedure has important limitations such as intracranial hemorrhage, or uncontrollable bleeding.

Diagnostic, Pathophysiology, and Specific Treatment

Blunt Cardiac Trauma

General Considerations

Consequences of thoracic trauma in children are different from those seen in adults because of special anatomic and physiologic characteristics. The chest of a child is more compliant because its skeleton contains more cartilage [6]. As a result, children may have serious intrathoracic trauma without obvious injuries to the chest wall [4] and myocardial contusion (MC) is the most common [27].

Clinical Features and Diagnostic Criteria

Myocardial Contusion

Myocardial contusion (MC) is the most frequent cardiovascular traumatic lesion despite a high frequency of failed diagnosis [9]. MCs are attributed to direct crush or brutal deceleration. The pathologic lesions combine intramyocardial hemorrhage and myocardial fiber necrosis. The result of cicatrization of this initial lesion will depend on the size of the area of contusion. It ranges from a complete healing, termed cardiac concussion, to a transmural fibrous scar formation responsible of a dyskinetic area that can lead to a ventricular aneurysm [7].

The very severe MC can result in a ventricular free wall rupture in the pericardium that is immediately lethal or to a contained rupture leading to a pseudoaneurysm [28]. In some cases, a septal contusion can lead to a secondary rupture and creation of a traumatic ventricular septal defect [7]. MCs can also induce coronary occlusion followed by late ischemic complications [29].

In most cases, MCs are asymptomatic but can result in arrhythmia (mostly ventricular), pericardial effusion, or myocardial dysfunction. Diagnosis is based on continuous EKG monitoring and serial cardiac enzymes determination [30]. An echocardiography is recommended if myocardial dysfunction is suspected and will also check the absence of associated valvular or pericardial lesions before discharge. Follow-up by a cardiologist is mandatory in case of any anomalies detected on the initial evaluation.

Cardiac Rupture

Traumatic rupture of any chamber of the heart usually results in rapid death and is the most common cause of death from thoracic injury [8]. The right ventricle is the most commonly ruptured cardiac chamber. The majority of these are due to high-energy impacts such as motor vehicle collisions or falls from great heights. Most of these patients die at the scene, and survivors represent only rare case reports [31, 32].

Commotio Cordis

Commotio cordis is defined as the combination of ventricular fibrillation and sudden cardiac death secondary to relatively innocent chest wall impact. Despite its traumatic appearance, sudden death due to commotio cordis appears to be a primary electrical event, with ventricular fibrillation occurring immediately upon chest wall impact [33]. The National Commotio Cordis Registry established in the mid-1990s reports that children are most commonly affected and most of cases occurred during sports with blunt projectiles and/or more physical contact [34]. The diagnosis is based upon the history composed of blunt chest trauma followed by collapse, ventricular fibrillation, and the absence of structural heart damage on imaging studies or autopsy. Survival remains poor, with a reported survival of only 25 % in all patients [34]. However, over time it appears to improve, presumably due to earlier resuscitation maneuvers and earlier defibrillations.

Ventricular Septal Defect

There are also only rare cases of traumatic VSD secondary to blunt chest trauma reported [35]. VSD occurring from blunt trauma is divided in two mechanisms. The first considers that the rupture occurs due to acute compression during the late diastolic phase, closing the atrioventricular

valves. The second proposes that a myocardial contusion causes myocardial necrosis secondary to localized interruption of coronary blood flow within the ventricular septum leading to infarction and rupture of the septum. The size of the defect determines the hemodynamic condition. If the patient is symptomatic due to the VSD, a surgical closure is indicated. If associated lesions prohibit a cardiopulmonary bypass, temporary improvement by the use of percutaneous techniques has been described [36]. If the hemodynamic state remains good during the early posttraumatic period, repair can be delayed.

Atrial Septal Defect

Traumatic atrial septal defects occur less commonly than ventricular septal defects because the interatrial septum is better protected by being located behind the sternum. The mechanisms of atrial septal rupture have been described by Getz et al. [37]; in youths with pliable chests, bidirectional forces from compression of the heart between the sternum and vertebral bodies may result in chamber rupture. Rupture of the atrial septum seems to require a massive force that usually results in severe associated injuries mostly leading to death. For those patients who survive, a significant delay is usual between initial traumatism and recognition of the cardiac defect which will be diagnosed by echocardiography and treated classically with a patch closure [38].

Atrioventricular Valve Rupture

Valvular lesions after blunt traumatic injury are very rare [9, 39], and two different mechanisms seem to be implicated in the damage of the atrioventricular valve apparatus [40]. The acute damage seems to be the result of a hyper pressure mechanism when the ventricles are loaded (end of the diastole). This generates a marked traction on the valvular and subvalvular apparatus leading to rupture and acute regurgitation becoming rapidly symptomatic. Less frequently, the leaflets themselves can be damaged either by laceration or by an abrupt rupture near the annulus. The mitral valve is more often concerned [41], but some rare cases are described involving the tricuspid valve [42]. The second mechanism consists of papillary muscle contusion with hemorrhage followed by inflammation and late necrosis with subsequent disruption and is implicated in delayed rupture. This severe complication usually happens during the first week after the injury, although a delayed rupture later than 1 week has been reported [43]. For mitral valve rupture, operative repair is often urgently indicated, whereas it can be delayed for tricuspid valve rupture. Valve repair is always preferred to replacement.

Aortic Cusp Rupture

Aortic valve rupture is thought to be a relatively rare event [39]. Aortic valve injuries are thought to occur in early ventricular diastole, whereas tricuspid and mitral valve injuries can occur in late diastole or at the beginning of systole [44]. Acute aortic insufficiency is even less well tolerated than acute mitral insufficiency. Consequently, pulmonary edema and pulmonary hypertension develop early, requiring urgent surgical repair.

Pericardial Effusion

Pericardial effusions after nonpenetrating cardiac traumatisms are often related to a myocardial contusion and in most cases will regress but require follow-up [45]. Some rare cases of acute pericardial effusions after nonpenetrating chest traumatisms are consequences of ventricular attrition or perforation by fractured ribs. They may be treated as penetrating wounds by emergent surgery to prevent the risk of cardiac arrest. Finally, some pericardial ruptures have been described, and the main risk is cardiac herniation through the defect causing hypotension and cardiac arrest. Otherwise, symptoms may be mild or absent consisting of signs associated in chronic pleural effusion [46].

Isthmic Aortic Rupture

Isthmic aortic ruptures are less common in children than in the adult population; their pathophysiology is the same, caused by a brutal deceleration, but elasticity of vessels in children could explain a lower incidence compared to

adults. The diagnostic is suggested by a history of violent deceleration, a left pleural effusion, or a mediastinal enlargement on chest radiography and confirmed by CT scan. Unlike adults, the uses of stent graft techniques are limited by the size of the patient. Repair usually requires thoracotomy with resection and repair. There are some patients in whom nonoperative observation may be safe.

Penetrating Cardiac Trauma

General Considerations

A child with a penetrating wound to the thorax is at high risk for major injuries, including lung and/or cardiac lesions, and requires emergent surgical consultation. Most cases are associated with hemopericardium. Penetrating chest injuries can be schematically split in two categories: penetrating lesions (intentional or accidental) and firearm injuries.

Stab Wounds

Cardiac perforation by sharp objects can be intentional (stabbing) or accidental by projection of the wounding agent (glass, metal, wood) or by a fall on any type of sharp object like scissors or tools. In most cases, if a cardiac perforation is not lethal in a few minutes, it is because the hemostasis of the lesion is favored by its small size, the thickness of the free wall, and containment of hemorrhage by the pericardium with compensated tamponade. To maintain this tenuous balance, it is recommended not to remove the penetrating agent from the chest of the victim until in the operating room and ideally not until the pericardium is opened.

When the patient is in refractory shock but has vital signs, tamponade is highly suspected, and a pericardiocentesis can be performed. These children require rapid transfer to a surgical center and emergent surgical consultation and intervention. When the patient's condition is stable and a cardiac stab wound is only suspected, investigation by echocardiography can be quickly accomplished in the ED or in the operating room (Fig. 132.1).

Once in the operating room, the patient is rapidly anesthetized, prepared, and draped for operation. Median sternotomy is made and the pericardium opened. Blood is rapidly aspirated from the pericardial space. Ventricular wounds are best controlled immediately by digital compression, whereas atrial and caval wounds are generally best controlled with wide clamps. Ventricular wounds are directly sutured with pledgets horizontal mattress sutures. Occasionally, a ventricular laceration is so extensive that it requires cardiopulmonary bypass and repair with patch material. Wounds near a major coronary artery are sutured with pledgets on both sides of the artery and the sutures passing beneath it. If a main coronary artery has been damaged, a coronary artery bypass graft may be required. After control of the hemorrhage, an intraoperative transesophageal echocardiography can be used to diagnose intracardiac injury that can be repaired with the aid of cardiopulmonary bypass. Both pleural spaces are widely opened, and chest tubes are placed in each pleural space and one in the pericardial space. The sternotomy is closed in the usual manner, and follow-up is mandatory, as secondary lesions may develop like coronary aneurism (Fig. 132.2).

Coronary artery fistulae, either arteriovenous or arterio-cameral, are typically sequelae of penetrating trauma [47]. Fistulae most commonly involve the anterior descending artery. The right atrium and ventricle are most commonly involved in arterio-cameral fistulae. Complications of fistulae include progressive cardiomegaly, ischemia due to coronary steal, and bacterial endocarditis. Traumatic coronary artery fistulae have an excellent prognosis after successful closure of the fistula [48].

Cardiac injuries are not always limited to the free wall of the heart or epicardial arteries. It can cause damage in more profound cardiac structures involving the conduction system, interventricular and interatrial septa, or cardiac valves, requiring surgical repair [49].

Firearm Injuries

In the United States, firearm injuries are the major cause of penetrating thoracic injury among

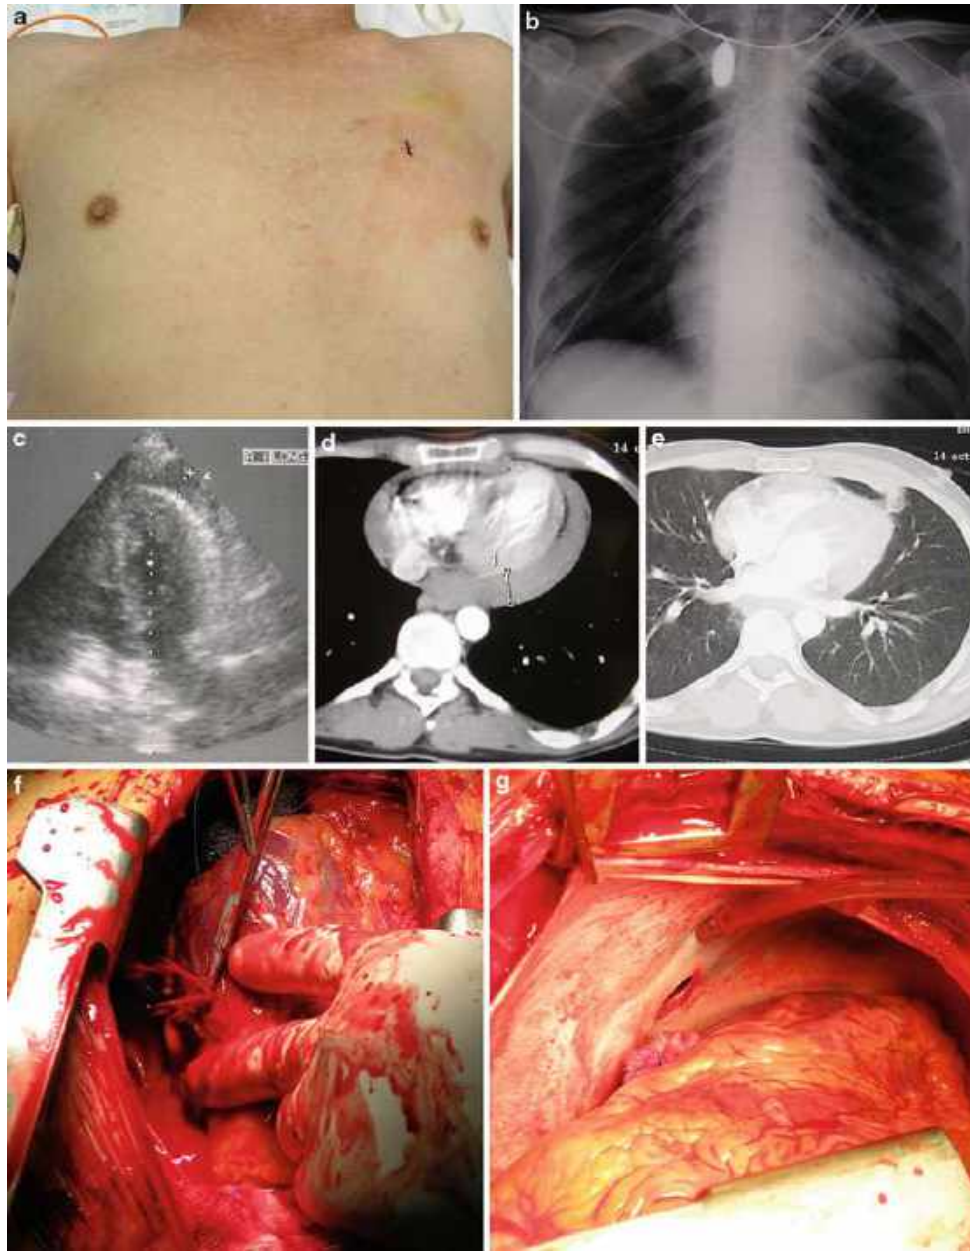

Fig. 132.1 Case report of a left ventricle wound by knife stabbing in a young psychotic patient attempting suicide. Initial evaluation found a stable patient. Despite the very small parietal wound (**a**) and a normal chest radiography (**b**), the location of the wound in the cardiac area required advanced imaging studies. The patient underwent echocardiography (**c**) and CT scan (**d**) showing an important pericardial effusion and a pulmonary contusion from the chest wall to the pericardium (**e**), confirming a cardiac wound. After emergent sternotomy, pericardial opening, and clots removal, a reactivated important bleeding was found on the left ventricle (**f**), 1 cm on the left side of the left descending artery (LDA). Bleeding was controlled by digital compression, while the repair was achieved by U stitches on pledgets (**f**, **g**). After the cardiac repair, the left pleural cavity was explored and drained, as the knife had passed through the left lung before penetrating the pericardium (note the pericardial wound facing the repair, on the *left* side of the LDA)

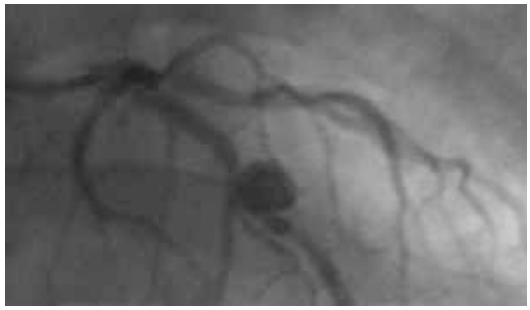

Fig. 132.2 Angio-coronarography 3 months after a wound of the left descending artery by stabbing in an adolescent patient. Note the coronary false aneurism

children [5]. The site of injury, velocity of the bullet, and its distance to the patient are important factors in determining the extent and severity of injury.

Firearm injuries are divided in two groups: high-velocity gunshot wounds (HVGSW) and low-velocity gunshot wounds (LVGSW). Other injury types include shotgun wounds (SGW) and explosives wounds (EW). HVGSW causes severe tissue damage beyond the tract of penetration producing more intense and evident cavitation, laceration, and contusion. In general, there is more extensive damage at the exit point of the bullet. LVGSW produces less extensive lacerations and contusions on the way of the bullet. With SGW, multiple pellet entries are scattered over a wide area and usually induce multiorgan injuries. EW affects a wide area of the body and can cause multisystem trauma as the result of the initial blast despite few damages to the chest wall as in blunt trauma [50].

Principles of management are the same as described for penetrating wounds, but the result is less often successful [51]. In three large pediatric retrospective studies, authors report no survival following cardiac firearm injuries [50, 52, 53]. In another North American retrospective study of 51 children having thoracic gunshot wounds, six were admitted with cardiac injuries and only two survived. Those children presented with cardiac tamponade (one due to a right ventricular perforation and the other with a left ventricular penetration). Authors concluded that survival is possible for the subset of patients with cardiac wounds who have clinical deterioration related to a reversible event (as a tamponade); conversely, survival is unlikely for patients with cardiac wounds who present with an exsanguination [54].

Iatrogenic Cardiac Trauma

General Considerations

A significant etiology of cardiac traumatic lesion in pediatric population is iatrogenic. Peripheral vascular lesions (venous or arterial) are not rare, including immediate complications (such as hemorrhage, dissection, or occlusion) or delayed such as false aneurisms or arteriovenous fistulas. Lesions of the heart or great vessels can also prompt due to endovascular maneuvers. These accidents may occur during central venous access for line insertion and pacemaker leads placement or during catheterization examination for diagnosis or interventional procedure mainly in congenital heart disease.

Central Venous Access

Central venous access in children, usually for central line insertion or catheterization procedures, can result in serious complications, as presented in a recent review [12]. These complications include early (dysrhythmia, cardiac and vessel injury, lung injury, device rupture) or late complications (septic, thrombotic, embolic, device dysfunction, vascular or cardiac erosion). Regarding the heart, arrhythmias are very frequent. In most cases, pulling back the guidewire or catheter is efficient to restore a sinus rhythm, but in some reported cases, medications or cardioversions have been required to control arrhythmias [55–57].

Iatrogenic cardiac perforations involve mainly the right atrium or the right ventricle [58] but can also be located in the left atrium, superior vena cava, or subclavian veins. Acute perforation may lead to rapid tamponade requiring emergent surgical repair by a median sternotomy. After clot removal, inspection will find the perforation, and repair will be achieved by sutures with pledgets under lateral clamping for the atrium or digital

Fig. 132.3 Intraoperative picture of a right atrial perforation after pacemaker lead implantation

compression for ventricles. Sometimes a perforation will be revealed by a delayed pericardial effusion or tamponade [59] due to repeated or permanent pressure of the catheter on the myocardium. The same complications may occur with pacemaker leads (Fig. 132.3).

Embolic migration to the heart of guidewires or ruptured catheters may also happen. In many cases, an endovascular procedure will be able to capture and remove the foreign body, and in cases of failure, a surgical procedure will be discussed.

Congenital Catheterization

Compared to central venous access, the cardiac catheterization presents specificities and own risks of cardiac lesions. They are dedicated to patients with congenital heart diseases including newborn to adults, sometime presenting unstable conditions. These procedures are achieved in specialized centers and should benefit a surgical backup. These catheterizations for diagnosis or interventional purposes present specific risk of complications. Several studies have analyzed these complications aiming to identify risk factors and to allow comparisons in the results.

A prospective study [60] identified, among consecutive pediatric catheterizations, several complications including rare deaths, cardiac perforations, cardiac tamponade, and device embolizations. Those major complications were most frequent during interventional procedures, whereas vascular complications were the most frequent. Risk factors associated with major complication included patient's weight and the type of procedure. Another retrospective study on catheterizations for congenital heart diseases [61] concluded that patient weighting less than 5 kg remains a significant risk factor for complications irrespective of the type of procedure performed and that balloon dilation interventions carried the highest risk.

The Congenital Cardiac Catheterization Project on Outcomes (C3PO) has recently proposed [13] to use CHARM (Catheterization for Congenital Heart Disease Adjustment for Risk Method) to adjust case mix complexity and allow comparisons of adverse events among institutions performing catheterization for congenital heart disease. They have defined four categories of procedures according to their risks and five severity levels of adverse events. This analysis resulted in a multivariable model (CHARM) including procedure risk category, number of hemodynamic indicators, and age. On this recent work, it is remarkable that interventional catheterization is now more frequent than diagnostic and that the complexity, the lower age, and the weight remain risk factors of adverse event.

Conclusion

Cardiac traumas in children are rare but serious and life-threatening events. They can be the consequences of blunt, penetrating, or iatrogenic injuries. All anatomical cardiac structure can be involved. Life-threatening injuries such as cardiac tamponade or injury to the great vessels must be rapidly identified and treated. Unstable patients require prompt interventions including standard advanced trauma life support and emergency thoracotomy for surgical procedure. For stable patients, when cardiac lesion is suspected, careful clinical examination and diagnostic studies are required.

Trypanosomiasis and Cardiac Disease

133

Lísia Esper, Fatima Brant, Louis M. Weiss, Herbert Bernard Tanowitz, and Fabiana Simão Machado

Abstract

American trypanosomiasis or Chagas disease is caused by the protozoan parasite *Trypanosoma cruzi* and is found only in the Western Hemisphere. Human African trypanosomiasis is found only on the African continent and is caused by other members of the genus Trypanosoma, *Trypanosoma brucei rhodesiense* (in east and southern Africa) and *Trypanosoma brucei gambiense* (in west and central Africa). Congenital transmission may occur with either American or African trypanosomiasis. While cardiovascular manifestations can occur with all of these species of trypanosomes, it is much more common with American trypanosomiasis, i.e., Chagas disease, due to *T.* cruzi.

Keywords

African trypanosomiasis • American trypanosomiasis • Cardiomyopathy • Myocarditis • Neglected tropical diseases • Sleeping sickness • *Trypanosoma brucei gambiense* • *Trypanosoma brucei rhodesiense* • *Trypanosoma cruzi* • Trypanosomiasis

Introduction

Both human African trypanosomiasis (HAT) and American trypanosomiasis were described in the early twentieth century. These neglected tropical diseases (NTD) of humankind were likely present millions of years ago as enzoonotic diseases of wild animals [1]. American and African trypanosomiasis are regarded by the World Health Organization (WHO) as NTD because they are found in tropical and/or subtropical regions of low- and middle-income countries and lead to disabilities, social stigma, premature mortality, and disfigurement [2]. Both of these infections are associated with cardiovascular abnormalities [3]. In addition, latent infections with these parasites can reactivate in the setting of immunosuppressive therapy or HIV/AIDS [3]. Although *Trypanosoma cruzi*, the cause of Chagas disease, and *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*, the causes of HAT, are in the genus Trypanosoma, they have different epidemiological, biological and clinical characteristics [4].

Human African Trypanosomiasis

The Parasite and Mechanisms of Transmission

Human African trypanosomiasis (HAT), also known as "sleeping sickness," is the result of infection with *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense*. Both are transmitted by the bite of an infected tsetse fly (*Glossina spp.*) during its feeding on mammalian hosts [5, 6]. Tsetse flies are found exclusively in Africa in a belt that stretches south of the Sahara and north of the Kalahari Desert, mainly in riverine forests and savanna [7, 8]. *Trypanosoma brucei gambiense* (Gambian or West African) and *Trypanosoma brucei rhodesiense* (Rhodesian or East African) are morphologically indistinguishable but cause diseases that differ in their epidemiology, clinical presentation, and prognosis [3, 9, 10]. Numerous other *Trypanosoma*

Fig. 133.1 Trypomastigote of *Trypanosoma brucei rhodesiense* (Figure 1 is from the collection of Herman Zaiman, "A Presentation of Pictorial Parasites" permission of the American Society of Tropical Medicine and Hygiene and the Zaiman Family)

species are found in other mammals; however, normal human plasma contains a trypanosome lytic factor that destroys animal trypanosomes [11]. Both *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense* are resistant to this plasma factor [11]. *Trypanosoma brucei rhodesiense* is a zoonosis usually transmitted from animal to fly to animal, and humans are accidental hosts, while cattle and game animals are important reservoir hosts. In Uganda, up to 40 % of cattle carry infective *Trypanosoma brucei rhodesiense* in some endemic areas [12]. In contrast, *Trypanosoma brucei gambiense* is an anthroponotic infection with its cycle being fly-man-fly, and therefore humans are the reservoir host [6, 11]. HAT is found where infected humans and vectors cohabit [6].

The fly ingests blood from trypomastigotes during a blood meal, and these enter the insect's digestive tract. In tsetse flies, midgut trypomastigotes transform into procyclic trypomastigotes which multiply by binary fission. Procyclic trypomastigote forms leave the midgut and change into epimastigotes in the salivary glands. Epimastigotes multiply and transform into metacyclic trypomastigotes, which are inoculated into the mammalian host. Metacyclic trypomastigotes convert into bloodstream trypomastigote that are carried to other sites. Trypomastigotes (Fig. 133.1) then multiply by binary fission in various body fluids (e.g., lymph, blood, and spinal fluid) [13]. In the initial phase

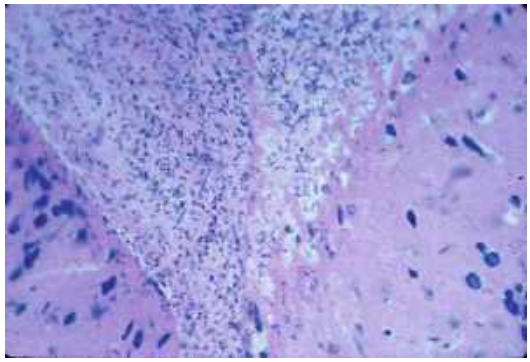

Fig. 133.2 Brain parenchyma with trypomastigotes of *Trypanosoma brucei rhodesiense* (Figure 2 is from the collection of Herman Zaiman, "A Presentation of Pictorial Parasites" permission of the American Society of Tropical Medicine and Hygiene and the Zaiman Family)

of infection, trypomastigotes are restricted to the lymph and blood systems. At a later stage, these forms are also observed in brain parenchyma (Fig. 133.2) and cerebrospinal fluid (CSF) [11].

Epidemiology

HAT has been a major public health problem in sub-Saharan Africa for many years. Initially, this infection was controlled through intensive efforts in vector control and treatment of infected individuals; however, since the 1980s, there has been a significant upsurge in the incidence of HAT [8]. There are multiple reasons for this resurgence such as population shifts of humans and animal reservoirs, poor disease surveillance, wars, civil strife, drug resistance, changes in host susceptibility to the disease, and vegetation and climate changes [14]. In sub-Saharan Africa, there are 60 million people at risk for HAT [15]. Since 2006, WHO has intensified its support for HAT control. There are over 35 countries where HAT is endemic, and over 90 % of the cases have been reported from Angola, Democratic Republic of Congo, southern Sudan, and Uganda [8, 10, 11, 16]. Gambian and Rhodesian HAT are geographically separated, and it is believed that Uganda is the only country where both forms occur [6, 11].

Approximately 5 % of all HAT cases are caused by the more acute and aggressive *Trypanosoma brucei rhodesiense*, and 95 % due to the more chronic *Trypanosoma brucei gambiense* [15].

HAT caused by *Trypanosoma brucei gambiense* is rare among travelers, but has been sporadically reported in immigrants, refugees, and expatriates residing in rural areas for long periods of time [11]. In contrast, *Trypanosoma brucei rhodesiense* HAT is mainly observed in short-term travelers such as tourists on safaris and hunting trips in endemic areas [6].

Clinical Manifestations

HAT is a challenging and deadly disease owing to its complex clinical presentation and, if left untreated, invariably results in death [6]. The disease involves two distinct successive stages, but there is considerable overlap. The first phase is the hemolymphatic stage that happens when trypanosomes remain in the blood and the lymph systems, causing a variety of nonspecific symptoms such as fever, headache, malaise, and weakness [6, 17]. The second phase, that may occur years later, is the meningoencephalitic stage, which is characterized by invasion of the central nervous system [6, 14, 17]. Clinical presentation of HAT depends on the parasite species, the stage of the disease, and the host response [6]. The incidence of the disease and the distribution of symptoms and signs are equal for both genders [18]. The clinical manifestations of HAT in travelers are different from native Africans, in that travelers usually present as an acute febrile illness with a chancre at the inoculation site and a rash [6, 11].

Trypanosoma brucei gambiense

The disease caused by *Trypanosoma brucei gambiense* is usually chronic resulting in death after a period ranging from three years to decades. After the tsetse fly bite, a chancre is rarely seen. A typical sign of *Trypanosoma brucei gambiense* is lymphadenopathy, also termed "Winterbottom's sign," that develops after several weeks, frequently in the posterior triangle of the neck [7]. The first-stage symptoms

are often nonspecific. Fever is intermittent, with attacks lasting from a day to a week, separated by intervals of a few days to a month or longer, and is rarely seen in the second stage. The infection is chronic and presents with headache, mobile or rubbery lymphadenopathies, facial and limb edema, and, to a lesser extent, splenomegaly or hepatomegaly [17, 19]. In the second stage, sleep disturbances and neuropsychiatric disorders dominate the clinical presentation. The neurologic symptoms are varied and include a diversity of movement and speech disorders [6, 13]. The characteristic sleep disturbances include daytime somnolence, nocturnal insomnia, "narcoleptic crises," and – in the final stages – uncontrollable urges to sleep [14]. In addition, there are associated psychiatric disorders including depression, suicidal ideation, and psychosis [14, 17].

Trypanosoma brucei rhodesiense

Trypanosoma brucei rhodesiense causes an acute febrile illness accompanied by anemia and thrombocytopenia leading to death within 6–9 months in the absence of treatment [6, 17]. A chancre is found at the initial bite site and is characterized by local erythema and edema. There is generalized lymphadenopathy. Sleep disorders, reduced consciousness, tremors, and movement disorders occur later [6, 13].

Infection in Children

Children with HAT often present with nonspecific signs and symptoms [20, 21], and the incidence in young children is lower than in adults [20]. The signs and symptoms in children are similar to those seen in adults, but in the first years of life, headache, sleeping disorders, or motor weakness are difficult to evaluate [18]. In young children, infection may be totally asymptomatic or they may present with severe neuropsychiatric manifestations [18, 20, 21]. Lymphadenopathy is less frequently reported in children younger than 7 years compared to adults [18]. There seems to be a higher proportion of second-stage illness in very young children (<2 years) [20]. This may be explained by the fact that these nonspecific clinical features may be difficult to differentiate from other febrile illnesses such as malaria. The latter may contribute to a delay in diagnosis and treatment resulting in brain damage [20]. The existence of congenital trypanosomiasis (vertical transmission) is controversial due to the small number of reported cases. Abortion or perinatal death of the infected fetuses may lead to undetected cases and therefore to the low number of reported congenital cases [21]. The diagnosis of HAT in newborns should be established through direct parasite detection. Serological screening with the card agglutination test (CATT) is considered less reliable in newborns since the presence of maternal antibodies may lead to false positive results. An immature immune response in newborns may also yield false negative results [22].

Cardiac Manifestation

Clinically significant cardiac manifestations are not a prominent feature of African trypanosomiasis, but these have been described [11, 13]. For example, alterations in the electrocardiogram (ECG) appear early in the infection and usually precede central nervous system involvement [23]. Importantly, trypomastigotes do not invade cells in the cardiovascular system and are rather found in the interstitial spaces. A pancarditis accompanied by a diffuse interstitial lymphocytic infiltrate and edema in the pericardium, myocardium, and endocardium, without myocardial necrosis, has been reported [13]. Fibrosis of the heart valves and alterations in the conductive system have also been described [3]. This cardiac involvement rarely causes severe congestive heart failure. The most frequent ECG changes are QTc prolongation which may pose added risk of death due to uncontrolled ventricular arrhythmias [3, 9, 23]. ECG findings may also be characterized predominantly as low voltage with repolarization changes and to a lesser extent as PR depression with repolarization changes [3, 6, 10, 11, 13]. The ECG changes are neither associated with clinical signs and symptoms nor with deterioration of pro-brain natriuretic peptide (NTpro-BNP) levels or elevation of troponin levels [3, 10]. Signs and symptoms consistent with

cardiac involvement, such as palpitations, chest pain, exertional dyspnea, distant cardiac sounds, and hypotension, are more frequently observed in patients with *Trypanosoma brucei gambiense* HAT [3, 13]. In *Trypanosoma brucei rhodesiense* infection, myopericarditis can be more severe [11], but very few patients have been studied, not allowing an in-depth understanding of cardiac involvement. Histological examinations have revealed myocardial degeneration and interstitial hemorrhage [3, 11, 13]. In *Trypanosoma brucei gambiense* infection, the early occurrence of myocarditis indicates a poor prognosis [17].

Pathology and Pathogenesis

The metacyclic infective trypomastigote forms are inoculated into the skin by the tsetse fly and multiply there. A characteristic hard and sometimes painful chancre is formed. At approximately the tenth day, long, slender forms are found in the bloodstream and lymphatics, and for the next several days (Fig. 133.1), their numbers increase logarithmically. Soon thereafter, the organisms nearly disappear from the bloodstream, only to reappear later. The interval between waves of parasitemia may vary from 1 to 8 days, with clinical symptoms accompanying each bout of parasitemia. Each successive parasitemic wave represents a new antigenic variant that has emerged to elude the antibody response of the host to the previous antigen. The parasite is covered with a variable surface glycoprotein (VSG). Each peak of parasitemia contains a predominant variable antigen type. The specific antibody response to this coat leads to the destruction of the predominant variable antigen type or homotype. However, within each population of parasites are a number of heterotypes, one of which then becomes the next homotype that is not recognized by the host's immune response. The parasite in each successive wave of parasitemia bears a different variable antigen type. A single trypomastigote may contain many genes, each encoding for a specific VSG [3, 17, 24, 25].

A significant early humoral antibody response, (predominantly IgM), is observed. These macroglobulins not only contain antitrypanosomal antibodies that are directed against the surface antigens but also a variety of other antibodies such as heterophil and rheumatoid factor. As a result of polyclonal B cell activation, there also are many antibodies produced to a wide variety of antigens, including brain-specific autoantibodies. In addition, antibodies directed against myelin basic protein, gangliosides, and cerebrosides have been found in experimental models. Circulating immune complexes have been reported regularly, and these may be responsible for the glomerulonephritis often accompanying acute and chronic disease. Cell-mediated immunity also is important in this disease, and nitric oxide may be important in depression of T cell responsiveness and generalized immunodepression. This may result in increased susceptibility to malaria and bacterial infections.

The principal pathologic lesions especially involve the posterior cervical, submaxillary, supraclavicular, and mesenteric lymph nodes, as well as the central nervous system. Lymphatic tissues usually reveal generalized hyperplasia with diffuse proliferation of lymphocytes. Initially, they are markedly hemorrhagic and contain large numbers of trypomastigotes; later, nodes may become small and fibrotic. A progressive, chronic leptomeningitis then develops. The brain becomes edematous, and there is prominent perivascular cuffing by glial cells, lymphocytes, and plasma cells. Morula cells, reactive astrocytes, and hyperplasia of microglial cells all have been reported. In addition, demyelination is said to occur in chronic cases. Organisms may be found in the brain tissue near vessels and in the cerebrospinal fluid (Fig. 133.2). There is a striking lymphocytosis in the cerebrospinal fluid with predominant B cells. Glomerulonephritis, myocarditis, pericardial effusion, pulmonary edema, and hypoplastic bone marrow with an associated anemia may be seen. The pathogenesis of the neuropsychiatric manifestations is poorly understood. Studies in experimental models suggest that a variety of factors may be responsible, such as

deposition of immune complexes and increased levels of brain neurotransmitters [26], prostaglandins, and cytokines.

In the blood and tissues of infected individuals, trypomastigotes are visualized in the interstitial areas, and there is an intense inflammatory reaction most evident in the brain (Fig. 133.2). Trypomastigotes can be seen in the CSF, and there is also an intense upregulation of the inflammatory response. In patients with *Trypanosoma brucei rhodesiense* in Uganda, both early- and late-stage infections are characterized by elevated levels of IFN-γ, TNF-α, and IL-10, although IFN-γ levels diminish in the late-stage cases [24]. Once the parasites invade the brain, IL-6, IL-8, TNF-α, and IL-10 levels are elevated in the CSF during the late-stage disease [3].

Diagnosis

Diagnosis of HAT is obtained by identification of the parasite in blood smears (Fig. 133.1), lymph node aspirates, or CSF. The major obstacle to this is the characteristically low parasitemia, especially in *Trypanosoma brucei gambiense* HAT, necessitating concentration methods or animal inoculation. Different centrifugation techniques can be applied to increase the sensitivity of the detection of trypanosomes from both blood and CSF [3, 6, 8]. Diagnosis and management of *Trypanosoma brucei gambiense* infection involve screening, parasitological confirmation, and staging [17]. The diagnosis of patients with *Trypanosoma brucei rhodesiense* differs from that of patients with *Trypanosoma brucei gambiense* [12]. Diagnosis follows the same general principles (screening, diagnostic confirmation, and staging), but differs in the absence of a serological screening test for *Trypanosoma brucei rhodesiense*. Screening is based on the recognition of nonspecific clinical features (e.g., fever) and history of exposure (e.g., tsetse fly bite during a safari in East Africa). Parasitological confirmation is easier, however, due to the high density of blood circulating trypomastigotes and abnormal hemoglobin, platelets, and coagulation profile [6, 17].

The card agglutination test for trypanosomiasis (CATT) is a rapid serological screening test used in the HAT control programs for *Trypanosoma brucei gambiense* [8, 17]. Typically, all diagnostic algorithms start with CATT screening, followed by parasitological confirmation and staging. Accurate serological tests also exist in immunofluorescence or ELISA formats, but they are usually employed in non-endemic countries [17]. There are studies on newer methods to detect trypanosome antigens in blood and CSF, LAMP (loop-mediated isothermal amplification, which is similar to PCR) to detect parasites in blood and CSF [27], and other new markers that are specific for the second stage of disease [6, 28]. After successful treatment, the IgM level declines gradually, disappearing after approximately 1 year. However, if 1 year after therapy there is a constant high level or an abrupt rise in the IgM, these features may indicate relapse. However, the IgM level should not be used routinely as the sole method of diagnosis or prognosis.

Treatment

First-Stage Treatment

- *Pentamidine* is used for the treatment of the *Trypanosoma brucei gambiense* sleeping sickness. Undesirable side effects include pain at the injection site, hypoglycemia, and hypotension; nonetheless, this medication is in general well tolerated by patients**.** Pentamidine treatment for first-stage illness has been reported as very safe and effective in preschool children [20].
- *Suramin* is used for the treatment of the *Trypanosoma brucei rhodesiense*. Undesirable side effects include fever, photophobia, lacrimation, hyperesthesia, kidney injury, and proteinuria. Rare side effects may include allergic dermatitis, polyneuropathy, agranulocytosis, and hemolytic anemia [6].

Second-Stage Treatment

- *Melarsoprol*: This compound crosses the hematoencephalic barrier and is used in both forms of HAT. Reactive arsenical

encephalopathy may be fatal in 3–10 % of patients. An increase in resistance to the drug has been observed in several zones particularly in central Africa.

- *Eflornithine*: This molecule, albeit less toxic than melarsoprol, is only effective against *Trypanosoma brucei gambiense*. The main problems associated with this drug are the short half-life and the increasing rate of resistance to monotherapy.
- *Combination treatment with Nifurtimox and Eflornithine (NECT)*: This combined therapy has been recently introduced (2009) [17]. With regards to undesirable side effects, although hematotoxic effects are reduced by half, nausea and vomiting increased to 50 % [6]. Cases of resistance against NECT have already been reported [6].
- *Fexinidazole*: is an oral drug active against *Trypanosoma brucei gambiense* and *Trypanosoma brucei rhodesiense* in animal studies and has shown an excellent safety profile. It should be effective in both stages of sleeping sickness because it penetrates the hematoencephalic barrier [6].

The treatment of congenital cases of HAT does not differ from the treatment of other children [22], but formal treatment protocols for infected newborns and infants need be established [21].

American Trypanosomiasis (Chagas Disease)

The Parasite and Mechanisms of Transmission

Chagas disease or American trypanosomiasis is caused by the protozoan parasite *Trypanosoma cruzi* and is recognized as an important NTD [29]. This lifelong and persistent infection was described in 1909 by the Brazilian physician-scientist, Carlos Chagas (1879–1934) [30]. Within a short period of time, he described in detail the etiologic agent, mode of transmission, principal reservoirs, pathology, and clinical manifestations [31, 32]. Unfortunately, he never received the Nobel Prize for his outstanding achievements. Interestingly, paleoparasitological studies have revealed that *Trypanosoma cruzi* was present in mummy tissues in Chile from the period 4000 BC to 1400 AD [33–35].

Fig. 133.3 Blood form trypomastigotes of *Trypanosoma cruzi* (Figure 3 is from the collection of Herman Zaiman, "A Presentation of Pictorial Parasites" permission of the American Society of Tropical Medicine and Hygiene and the Zaiman Family)

The life cycle of *Trypanosoma cruzi* is complex and involves mammalian hosts and insect vectors. Most infections occur in areas of endemicity through vector-borne transmission by triatomine insects but can also occur via blood transfusion, organ transplantation, vertically from mother to infant (congenital transmission), breast feeding, and uncommonly by ingestion of food or liquid contaminated with the parasite [4, 32]. The triatomines or kissing bugs become infected when they take a blood meal from mammals that have circulating trypomastigotes (Fig. 133.3). Once in the insect vector, the trypomastigotes transform into epimastigotes (Fig. 133.4) and undergo binary fission to convert into nondividing but infectious metacyclic trypomastigotes in the hindgut. These forms are then excreted with the feces of the vector during blood meals. The transmission to a new mammalian host occurs when the parasite-laden feces contaminate oral or nasal mucous membranes, the conjunctivae or wounds, and the skin, including vector bite sites. Once in the mammalian host, the trypomastigotes (Fig. 133.3) enter host cells

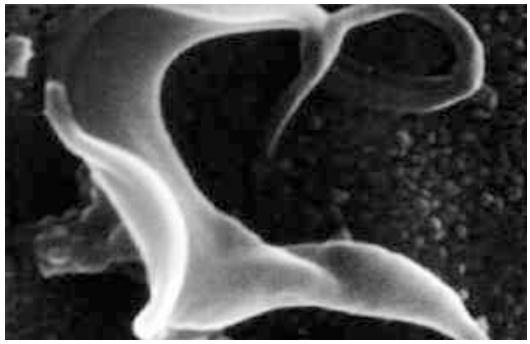

Fig. 133.4 Scanning electron micrograph of an epimastigote form of *Trypanosoma cruzi*

and transform into amastigotes which proliferate within host cell cytoplasm. Amastigotes convert into bloodform trypomastigotes (Fig. 133.3) and are released when the host cell ruptures. Blood form trypomastigotes infect adjacent cells or disseminate via the lymphatics and blood stream to distant sites and the cycle is repeated. Any nucleated mammalian cell can be parasitized, including cardiac myocytes, endothelial and vascular smooth muscle cells, peripheral muscle cells, cells of the central and peripheral nervous systems, cells of the reticuloendothelial system, and adipocytes [35, 36]. Studies in humans and mice indicate that the adipose tissue is an early target and a reservoir site for persistence of this parasite [36, 37].

Epidemiology

According to WHO, 8–10 million people are chronically infected with *Trypanosoma cruzi*, and 10,000–14,000 deaths are caused by Chagas disease per year [32, 38]. In the past 20 years, vector control programs and blood bank screening have reduced new cases of infection and decreased the burden of Chagas disease in Latin America [31, 39]. Chagas disease is endemic in Mexico, Central, and South America. Naturally occurring Chagas disease has been described among dogs in southern United States. In endemic areas, natural transmission of Chagas disease occurs in poverty-stricken rural areas where people live in contact with potential vectors. In Latin America, there has been a migration of chronically infected individuals to cities. In addition, the migration of individuals from endemic areas of Latin America to non-endemic areas has made Chagas disease a worldwide public health concern [32, 39] with an increased recognition of Chagas disease in North America, Europe, Australia, and Japan. Congenital Chagas disease has now been described in non-endemic areas [31, 40].

Clinical Manifestations

Acute and Indeterminate Phases of Chagas Disease

The acute phase lasts 4 to 8 weeks and is usually asymptomatic or may present as an acute febrile illness. The vast majority of cases remain undiagnosed or else misdiagnosed as an intercurrent viral or bacterial illness of childhood. Symptoms may appear within 1–2 weeks after infection. Signs and symptoms include fever, malaise, hepatosplenomegaly, lymphadenopathy, and a rash. At the site of the bite, a "chagoma" (Fig. 133.5a), a localized raised skin lesion may appear. In addition a "Romaña sign," which is unilateral periorbital edema, may be observed (Figs. 133.5a, b). The most severe manifestations of the disease are myocarditis accompanied by arrhythmias and congestive heart failure (Fig. 133.6) [31, 32]. ECG abnormalities include first-degree atrioventricular block, sinus tachycardia, low voltage, and T-wave changes [3, 41, 42]. The chest x-ray may show variable degrees of cardiomegaly, and the serial ECG and chest x-rays are important for the management of these patients [32]. Another important serious manifestation of acute Chagas disease is meningoencephalitis. The signs and symptoms of acute Chagas disease resolve within 1 or 2 months even if untreated. The mortality rate of acute infection is less than 1 %. These infected individuals who survive enter the indeterminate phase, which is characterized by the presence of antibodies against the parasite, lack of signs and symptoms, and lifelong sub-patent parasitemia [32].

Fig. 133.5 *Left panel* shows a young boy with a "chagoma" on the lip. *Right panel* shows a young girl with unilateral periorbital edema (Romaña sign) (Figure 5 is from the collection of Herman Zaiman, "A Presentation of Pictorial Parasites" permission of the American Society of Tropical Medicine and Hygiene and the Zaiman Family)

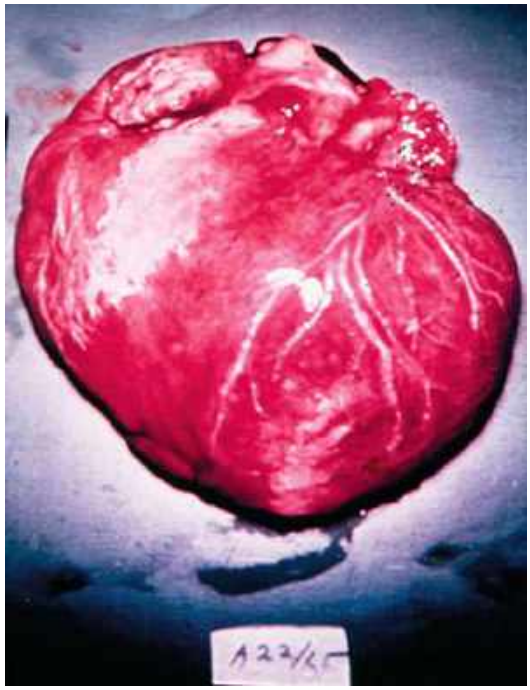

Fig. 133.6 Heart of a child who died of acute myocarditis (Figure 6 is from the collection of Herman Zaiman, "A Presentation of Pictorial Parasites" permission of the American Society of Tropical Medicine and Hygiene and the Zaiman Family)

Congenital Chagas Disease

Congenital *Trypanosoma cruzi* infection is an acute infection in newborns. This mode of infection is by vertical transmission from an infected mother to her child [43]. Once diagnosed, if left untreated, it may lead to chronic disease later in life [43]. Epidemiological data from Latin America indicates that the number of congenital cases of *Trypanosoma cruzi* infection is greater than 15,000 per year [44]. Transmission from mother to child has been described both in endemic and non-endemic areas. Most cases are asymptomatic, but some congenital cases can present with signs and symptoms compatible with the TORCH syndrome, including fever, hypotonicity, anemia, and hepatosplenomegaly. There are no specific measures to be taken to prevent congenital infection for infected pregnant women, and antiparasitic treatment is not recommended during pregnancy. Additionally, there are no factors that predict which mothers will transmit the infection to their fetuses [43]. During pregnancy, it is possible to detect the infection by two serological tests [43, 45]. The diagnosis of congenital infection in neonates is made by detecting trypomastigotes by PCR in venous or in cord

blood [46]. Detection of blood parasites at any time after birth or a positive *Trypanosoma cruzi*-specific serology in infants greater than 8 months of age is diagnostic of congenital Chagas disease and requires therapy.

Chronic Chagas Cardiomyopathy

Chronic Chagas disease is observed in 20–30 % of infected individuals [3, 47]. The factors that determine which individuals transition into the chronic form are not known. While any arrhythmia can be observed, the most common ECG changes are right bundle branch block (RBBB), RBBB and left anterior fascicular block, and premature ventricular beats. Others include left bundle branch block, atrial fibrillation, and various degree of heart block which may require the placement of a pacemaker [3, 31, 48]. Chronic Chagasic cardiomyopathy is a dilated cardiomyopathy associated with congestive heart failure and stroke. Symptoms may include syncope, palpitations, and chest pain [3, 49]. Sudden death, heart failure, and thromboembolic disorders are not uncommon, even in younger individuals (Fig. 133.7) [31, 50]. Individuals with HIV/AIDS or treated with immunosuppressive drugs may experience an exacerbation of chronic infection, leading to increased or recurrent parasitemia [31].

Digestive Form

Alterations in the motor, secretory, and absorptive functions of the esophagus and the gastrointestinal tract characterize the digestive form of Chagas disease [32]. The mega-syndromes result from destruction of the ganglia of the enteric nervous system, and the structure most affected is the myoenteric plexus of Auerbach, located between the longitudinal and circular muscular layers of the digestive tract. The most compromised segments are the esophagus and the distal colon. Denervation leads to loss of motor coordination and achalasia of the sphincters, and these are the mechanisms underlying Chagasic megaesophagus and megacolon [32, 35]. Surgery is indicated in advanced stages. Mega-syndromes are not commonly observed in children.

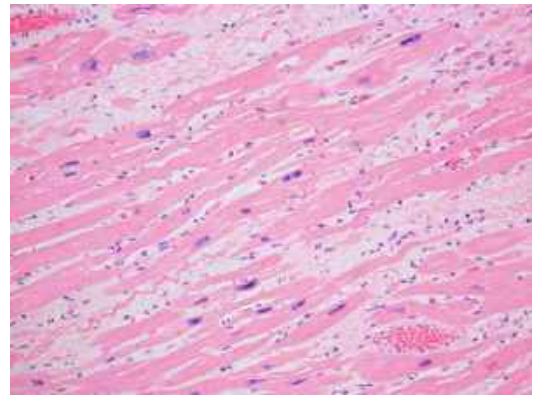

Fig. 133.7 Microscopic view of the heart of a patient age 31 who had Chagasic cardiomyopathy and died awaiting heart transplant. Note the fibrosis (This figure is obtained through the Courtesy of Dr. Randin Nelson, Department of Pathology, Albert Einstein College of Medicine)

Cardio-Digestive Form

This form is a combination of heart disease with megacolon, megaesophagus, or both. The prevalence of the cardio-digestive form is not known, but in most countries, the development of megaesophagus precedes heart and colon disease.

Pathology and Pathogenesis

Acute *Trypanosoma cruzi* infection results in an exuberant inflammatory response in the heart accompanied by increased expression of proinflammatory cytokines, chemokines, nitric oxide synthase, and endothelin-1 [51, 52]. There are parasite pseudocysts associated with myonecrosis, myocytolysis, and intense vasculitis. Trypomastigotes invade the endothelium and the interstitial areas of myocardium. Cardiac myocytes and cardiac fibroblasts are then invaded and destroyed. The degradation of the cardiac extracellular matrix is likely due to contributions from host and parasite. There are structural changes associated with inflammation, fibrosis, necrosis, and ventricular dilation and hypertrophy. There are bands of fibrous tissue replacing cardiac myocytes (Fig. 133.7). These changes lead to thinning of the myocardium and cardiac hypertrophy. Infection-associated vasculitis, vasospasm, vasoconstriction, platelet aggregation, and a reduction in myocardial blood

flow have been described in Chagasic heart disease. In the myocardium, CD4+ and CD8+ cells are present in the inflammatory infiltrate, but during chronic Chagasic cardiomyopathy, CD8 + T cells are predominant [35, 53]. The balance between damage inflammation of the host tissue and immune-mediated parasite containment is required to establish the course of the disease during the chronic phase. Parasite persistence is responsible for the development of the disease [31, 54]. Even autoimmunity is likely dependent, at least to some extent, on parasite persistence. Some *Trypanosoma cruzi* antigens that cross-react with noncardiac and cardiac host components have been identified, but only some have been shown as functionally active [3, 54]. Chronic Chagasic heart disease is characterized by four chamber enlargement of the heart and the presence of an apical aneurysm, and other wall motion abnormalities are common and usually appear at early stages [31, 55].

Diagnosis and Prevention

Diagnosis of acute infection is made by finding trypomastigotes in the blood or CSF (Fig. 133.3). In congenital Chagas disease, detection of trypomastigotes in cord or peripheral blood of the neonate by smear or PCR is diagnostic [31, 56]. Parasites can be seen in Giemsa-stained thick and thin blood smears. Serologic testing may not be helpful in the diagnosis of acute Chagas disease. In chronic Chagas disease, the identification of immunoglobulin G (IgG) antibodies against *Trypanosoma cruzi* antigens requires the use of two different serological methods, namely, an enzyme-linked immunosorbent assay, indirect immunofluorescence, or indirect hemagglutination [57]. PCR is sensitive but not always helpful in routine diagnosis. As noted, PCR is very helpful in making the diagnosis in the setting of congenital Chagas disease or Chagas disease in the setting of immune-compromised patients [32, 56]. The routine screening of blood banks stocks in many countries currently identifies individuals who are potential sources of infection, and they are removed from the blood donor pool.

Treatment

The treatment of Chagas disease is not entirely satisfactory and involves parasite-specific therapy and adjunctive therapy for the management of the clinical manifestations [35, 58]. Only benznidazole (Rochagan, Roche 7-1051) and nifurtimox (Lampit, Bayer 2502) are recommended for Chagas disease treatment [31, 35]. Both of these drugs are available in endemic countries. In the Unites States, they are available under investigational protocols. Benznidazole, a nitroimidazoe derivative, has been extensively investigated in clinical studies and has the best efficacy profile. For adults the doses are 5 mg/Kg benznidazole per day for 60 days or 8–10 mg/Kg nifurtimox per day for 60–90 days [32]. Children should be given 5–10 mg/Kg benznidazole in 2 or 3 divided doses per day for 60 days or 15 mg/Kg nifurtimox in 3 divided doses per day for 60–90 days. Both drugs should be administered after meals [32]. The drugs have variable efficacy, must be taken for extended periods of time, and patients may experience severe side effects such as vomiting, nausea, and anorexia [58]. These drugs are most effective for treatment of acute and congenital infection, and the parasitological cure is believed to occur in 60–85 % of persons with acute infection who complete a full course of either drug. The management of patients in the indeterminate stage to prevent transition to the chronic phase and whether they should be treated with these drugs is the focus on ongoing studies, and currently there is no standard for the antiparasitic treatment of these indeterminate cases.

Conclusions

In the past few years, the interest in neglected tropical diseases (NTDs) has increased as a result of several developments including new approaches to the control or elimination of these diseases, commitment from pharmaceutical donors to provide drugs, transformed government commitment, and the recognition that these diseases should be addressed as part of the Millennium Development Goal (MDG).

Historically, HAT and Chagas disease have been serious public health problems in their respective endemic regions, but recently Chagas disease has become a worldwide problem due to emigration from endemic countries. Diagnosis and treatment of these diseases are complex and require specifically skilled staff. There is no vaccine or drug for prophylaxis for either African or American trypanosomiasis. Preventive measures are targeted at minimizing contact with vectors. However, it is necessary to understand immune mechanisms involved in the control of these infections, and the development of new candidate therapeutic or prophylactic targets that are effective and substantially free of side effects is realistic goal. In fact, there are many unanswered points that urge for future scientific investigations. There are no reliable biomarkers for the diagnosis of the infection and the assessment of the parasitological cure, or markers to predict the transition to chronic disease. However, most experts believe that once the disease has progressed to the chronic clinical stage, current antiparasitic treatment is not justified as structural damage to the heart in Chagas Disease appears irreversible. Vaccine development is in its infancy.

Endomyocardial Fibrosis

134

Ana Olga H. Mocumbi

Abstract

Endomyocardial fibrosis (EMF) is an idiopathic disorder of the tropical and subtropical regions of the world. It is the commonest cause of restrictive cardiomyopathy and affects an estimated 10 million people worldwide mainly children and adolescents from Africa, South America, and Asia.

The etiology and pathogenesis of EMF remain unknown, since none of the factors that have been postulated for its origin can fully explain the occurrence worldwide. EMF might be caused by one or several environmental factors acting upon genetically predisposed individuals. Attempts to relate the condition to infections, dietary factors, and toxic agents failed to unveil the exact etiology and pathogenesis.

The pathological hallmark of EMF is the deposition of a thick layer of fibrous tissue underneath the endocardium, which interferes with the diastolic and systolic function of one or both ventricles, and thickening and fibrosis of the components of the atrioventricular valves causing valve malfunction. Mild tissue inflammation, predominant in the interface between the endocardium and the myocardium, is a common feature.

To date, there are no specific drugs to treat EMF. Endocardial decortication and atrioventricular valve repair/replacement seems to be beneficial in a subset of patients, but surgery is associated with high morbidity and mortality. Surgery is technically and financially very demanding and has been performed in only few centers treating a small number of patients, which leads to slow improvement in knowledge about the condition. The rate of recurrence after surgery is controversial. The overall prognosis is poor.

EMF is probably the most neglected disease in cardiovascular medicine. Despite constituting a big burden to the families and health systems in endemic areas, due to its preponderance in poor sectors of the society, few human and material resources are made available for research onto its

mechanisms. However, there is need to fully understand the pathogenesis and pathophysiology of EMF in order to improve the management and outcome of the affected patients.

Keywords
Idiopathic • Neglected cardiovascular disease • Restrictive cardiomyopathy • Tropical disease

Definition

Endomyocardial fibrosis (EMF) is a restrictive cardiomyopathy of unclear etiology that is characterized by endocardial fibrous thickening, affecting predominantly the ventricular wall and the atrioventricular valves, which results in ventricular cavity reduction with abnormal diastolic filling and severe tricuspid or mitral regurgitation.

Historical Perspective

The first description of the correlation between the pathological features and clinical signs of EMF was done by Jack Davies, allowing the diagnosis of the entity in life [1]. The term *Davies disease* was initially used to describe the condition. Other designations have also been used in the literature, namely, tropical endomyocardial disease, endocarditis parietalisfibroplastica, endocardial fibrosis, constrictive endocarditis, and endocardial fibroelastosis. The expression *Heart of Africa* has been used due to the similarity between the map of Africa and the heart shape in right ventricular EMF with retraction of the apical region and also because EMF occurred mainly in Uganda, a country located in a central position in Africa. *Endomyocardial fibrosis* is the term that best describes the pathological abnormalities in this condition and is the most widely used.

Epidemiology

EMF occurs mainly in the tropical parts of Africa, South America, and India [2, 3], but is sporadically reported from other parts of the world. Most cases have been reported from the African continent, namely, from Uganda, Nigeria, Ivory Coast, Mozambique, and Egypt [3]. In recent years, there have been case reports from other African countries, suggesting that the disease is disseminated along the continent.

In the absence of population-based studies, worldwide prevalence can only be estimated. EMF is thought to affect an estimated 10–12 million people [4]. It is the most widely prevalent form of restrictive cardiomyopathy worldwide [5], considering its high prevalence in highly populated areas of the world.

Geographical Distribution

The highest prevalence of EMF is found in certain regions of sub-Saharan Africa where it accounts for up to 20 % of cases of heart failure [6]. For unclear reasons, there are marked variations in the distribution of EMF in the different countries where the disease has been reported [7]. In India the highest prevalence was reported in the coastal areas of Kerala [8]. In Nigeria, the majority of cases originated from the Southwest region [9]. Reports from Uganda showed preponderance of patients from two neighboring countries Rwanda and Burundi immigrating to the Southwest of Uganda [10]. Finally, in Mozambique there is an area of striking high prevalence in a rural coastal area in the South [11, 12].

Community-based prevalence studies were performed in Mozambique, in a rural coastal area with a striking high attack rate [11]. Initially, 948 inhabitants between 4 and 45 years of age were screened through cardiac auscultation and then submitted to transthoracic echocardiography,

showing a prevalence of 8.9 % in this population. More recently, echocardiographic screening was used on a random sample of 1,063 individuals of all ages from the same region; the overall prevalence of EMF was 19.8 % (95 % confidence interval, 17.4–22.2), confirming this disease as a major public health problem in the area [12].

Age and Sex Distribution

EMF affects predominantly children and adolescents [5, 13], with a peak incidence at ages 11–15 years in both sexes [14]. Women show a second peak incidence in childbearing age [15]. The disease may also occur in infants or very young children, although rarely [16].

There seems to be no clear gender predominance in prevalence of EMF. Whereas in Uganda there is female preponderance [10], in Nigeria no gender difference was found, and male predominance was found in Mozambique [12].

Etiology and Pathogenesis

The cause of EMF is unknown and the mechanisms involved in its pathogenesis are incompletely understood. Social deprivation seems to be an important factor since the disease rarely affects communities with high socioeconomic standards [15]. The factors most commonly proposed to explain the origin of the disease are ethnicity, poverty, malnutrition, dietary factors, infections (viral and parasitic), autoimmunity, allergy (eosinophilia), toxic agents (cerium, cassava, serotonin, plant toxins, and vitamin D), and heredity [3]. There seems to be a preponderance of environmental factors playing a role in the pathogenesis, but none of the hypotheses studied can fully explain the pathological findings and its peculiar geographic distribution.

The Role of Eosinophils

Hypereosinophilia, a frequent finding in EMF, has also been considered an etiologic factor. EMF might be a variant of the hypereosinophilic syndrome seen in temperate climate, since the late fibrotic lesions are identical for both diseases [17]. An inverse relationship between hypereosinophilia and the duration of EMF symptoms has been reported [18], suggesting that the eosinophil might be involved in earlier stages or in episodes of recrudescence and that fibrotic lesions would represent the end result of an acute eosinophilic endocardial injury.

Hypereosinophilia is probably induced by parasitic infections, such as by helminthic, Schistosoma [19], microfilarial loa loa [20], or filarial [21]. However, this has been difficult to prove as several studies failed to show increased prevalence of these infections in EMF patients when compared to the general population of endemic areas [9, 17, 22]. Moreover, eosinophilia is usually absent in both thrombotic and fibrotic endocardial lesions [23, 24].

Infectious Agents

The role of infectious agents has been postulated in the etiology of EMF due to the climatic restrictions of the disease and reports of sporadic cases after short stays in endemic areas [20, 25]. Possible causes or triggers for disease are *Plasmodium* species [26], *Schistosoma* [19], *microfilaria* [20], *helminths* [27], *Coxsackie B virus*, *arboviruses*, and *Toxoplasma gondii* [28].

The finding of endomyocardial fibrotic lesions mimicking human EMF in mice infected with *Plasmodium berghei* [29] supports the hypothesis of malaria being involved in the pathogenesis of this condition and has been reinforced by reports of rebound eosinophilia after acute Plasmodium falciparum malarial infection [30]. However, there are no studies confirming this hypothesis in humans.

Autoimmunity

While some EMF patients have increased levels of anti-heart antibodies [26], particularly strong IgG reactivity against myocardial proteins [31],

suggesting a role of autoimmunity in its pathogenesis, others failed to confirm this finding [32]. Similarly, pathological studies did not show large numbers of immunologically competent cells at the endomyocardial junction, where EMF lesions are more prominent [33].

Geochemical Factors

The equatorial distribution of EMF suggests the role of ultraviolet radiation in its pathogenesis. Since EMF lesions are often calcified and some tropical plants can synthesize vitamin D on exposure to sunlight, it was thought that the practice of drying staple foods in the sun, which is very common in poorer regions in the tropics, would increase the levels of vitamin D in plants exposing those who eat them to increased levels of calcium [34]. Vitamin D-induced calcinosis would be the basis for cellular hyperplasia and excessive production of collagen in the endomyocardium and would explain the fibrosis and calcification. To date no systematic studies have confirmed this hypothesis for human endomyocardial fibrosis.

Children from low-income groups in equatorial regions of endemic areas for EMF in Africa, Brazil, and India are prone to hypomagnesemia, associated with insufficient intake and chronic diarrhea related to protein-calorie malnutrition [35]. In mouse heart, magnesium deficiency induces intolerance to hypoxia injury [36]. In rabbits, recurrent episodes of Mg deficiency lead to myocardial fibrosis similar to the pattern observed in human EMF [37]. Also, deficiency in magnesium promotes the absorption of cerium, a major constituent of monazite mineral present in tropical soils, enhancing its toxicity and forming potentially the basis for the initial heart injury in EMF. Interestingly, cardiac tissue of EMF patients showed low concentrations of magnesium and high levels of cerium [8].

Dietary Factors

Studies on the role of nutritional deficiencies on the etiopathogenesis of EMF had deceiving results [38], and EMF has been reported in well-nourished people [20]. Plantains and bananas containing high levels of serotonin, consumed in large quantities in some communities from India where EMF is common [39], were proposed as the trigger for EMF since excess of serotonin causes lesions resembling those found in human EMF in guinea pigs [40]. Similarly, diet based on dried cassava, and therefore rich in vitamin D, was thought to be the critical background to EMF in Uganda [34, 41].

Genetic Susceptibility

Hereditary factors, possibly immunological in nature, may contribute to genetic susceptibility in EMF. Furthermore, host-related factors may explain the dissimilarities in clinical features and expression of the disease. However, at the present, there is no compelling evidence supporting the contribution of inherited factors to the pathogenesis of EMF.

The role of ethnicity was suggested because in Uganda the disease affected almost exclusively individuals from certain ethnics groups of immigrants from Rwanda and Burundi, while there was an extremely low prevalence among the relatively affluent indigenous Ganda tribe [10, 15]. Familial occurrence was later found in clinical series from Uganda and Zambia [42, 43] as well as confirmed in population studies in a rural area of Mozambique [12], but may be due to genetic or environmental factors.

Natural History

EMF appears to evolve in three successive stages after an unknown stimulus or trigger. Initial endocardial necrosis would be followed by thrombosis, and later, fibrosis develops in the area adjacent to the thrombus leading to the characteristic lesions found in advanced disease [17]. This proposed sequence of events has been difficult to prove because initial and acute EMF is rarely reported, as clinical series include mainly patients with advanced disease. Moreover, most

studies of the natural history of EMF have been done retrospectively and took place before the advent of echocardiography, making it difficult to document and monitor the progression of intracardiac lesions.

Pathological Findings

The cardinal feature in EMF is endocardial fibrous thickening more prominent in the ventricles. Fibrosis is due to abnormal stimulation of cardiac fibroblast leading to enhanced collagen synthesis that may represent a reactive stromal change. The macroscopic appearance and the sites of ventricular involvement are distinctive and differentiate this condition from any other form of cardiac disease. There is no primary involvement of extra-cardiac organs.

The classical descriptions of the pathology of EMF have been based on autopsies performed in two sets of patients: those with advanced disease who died as a result of complications of long-term heart failure or those with acute disease who died after febrile episodes with rapidly progressive heart failure [10, 33]. Recently, there have been descriptions of histological findings in vivo using endomyocardial biopsies from patients submitted to cardiac catheterization [44] or surgery [24, 45, 46]. These failed to show a dominant lesion such as necrosis, inflammation, thrombosis, or small vessel lesions but revealed increased interstitial cellularity even in the absence of macroscopic lesions [23, 24, 33, 46].

Macroscopic Appearance

The pericardial sac is usually distended by a moderate to large effusion. There is usually cardiomegaly due to aneurismal atria, and adhesions between the parietal and visceral layers of the pericardium are frequent. A *right border notch* is usually seen in hearts with severe affection of the right side.

The endocardium shows thrombosis and fibrosis, which are characteristically prominent in the ventricular apices and the posterior wall of the left ventricle (Fig. 134.1). In the right ventricle, scar tissue may be massive, engulfing and fusing the trabeculae carneae, causing obliteration of the trabecular portion and fixation of papillary muscles, chordae tendineae, and leaflets of the tricuspid valve; the tricuspid annulus is usually severely dilated as a result of right atrial dilatation. On the left ventricle, thrombus and scar tissue may engulf and obliterate the posterior leaflet of the mitral valve, its attached chordae and papillary muscle, but no clear left ventricular retraction occurs (Fig. 134.1); the apex is frequently scarred. Endocardial calcification may be present embedding the tricuspid or mitral papillary muscles [47].

Fig. 134.1 Moderate endocardial thickening of the left ventricle corresponds to diffuse whitening of the endocardial surface with thicker fibrous tissue visible in the apex and surrounding the papillary muscles; the fibrosis spares the aortic cusps

The semilunar valves may be thickened and mild regurgitation may occur in some patients. The great vessels are never involved in the process.

Microscopy

All three layers of the heart are involved in the pathological process in EMF [48]. The hallmark of established disease is endocardial thickening due to acellular fibro-collagen tissue deposition underneath the endothelial layer of the endocardium (Fig. 134.2) [33, 44, 49]. Deep in the

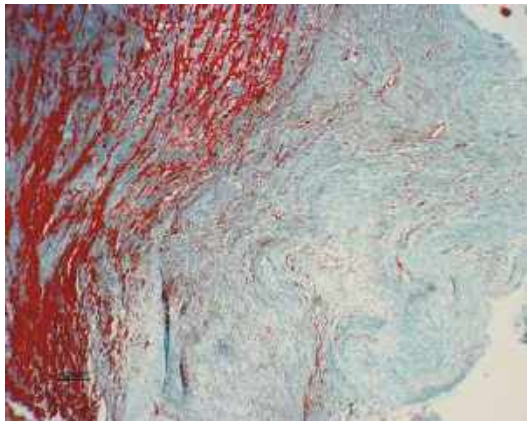

Fig. 134.2 Microscopic evaluation of the cardiac tissue reveals endocardial thickening and fibrosis, which penetrates the myocardium, seen as blue on Masson's trichrome staining

sub-endocardium, there are foci of intense neovascularization associated with chronic inflammation; the latter is composed mainly of mononuclear cells, namely lymphocytes, macrophages, and plasma cells. There are myocytolytic lesions in the sub-endocardium and increase in interstitial cellularity, but marked degree of myocardial loss is rare. Intense inflammatory infiltrates, including eosinophils, are usually absent. Small vessel disease is unusual.

Other Findings

Cardiotropic infective agents may be found in the endomyocardium of patients with EMF, but their role in the pathogenesis of EMF is still controversial. Infective agent's genome was detected in the ventricular endomyocardium, namely, for enterovirus, cytomegalovirus, and *T. gondii* [50].

Pathophysiology

EMF appears to start as a febrile syndrome triggered by unknown factors. Intraventricular thrombosis, pancarditis, hypereosinophilia, facial swelling, body itching, urticaria, and neurological features caused by thromboembolism have been described in the initial phases [51]. Mural and valvar thrombi evolve to organization and subsequent endocardial fibrosis develops [17].

Endocardial fibrosis reduces ventricular cavity size and impedes adequate diastolic filling leading to restrictive physiology. By affecting the papillary muscles, chordae, and leaflets, endocardial fibrosis causes severe atrioventricular valve dysfunction. Restriction to ventricular filling and valve distortion are responsible for the characteristic features of advanced EMF, namely, small ventricles with severely dilated atria, the so-called *Mickey Mouse heart*.

The mechanism of right ventricular cavity obliteration corresponds to compaction of trabeculae between the thickened endocardium and the epicardium, with no thrombus or blood in between them [52]. The moderator band is lost, engulfed in the endocardial fibrosis, and a false floor of the right ventricle excludes the trabecular portion from the circulation. This isolation of right ventricular trabecular portion and the progressive fusion of trabeculae between the thickened endocardium and the epicardium apparently lead to retraction of the ventricular wall towards the false floor and causing the typical right apical notch.

The sustained low cardiac output that occurs in advanced stages of EMF results in finger and toe clubbing, growth retardation, testicular atrophy, cachexia, and failure to develop secondary sexual characters [53–55]. In right ventricular EMF, chronic systemic venous hypertension is responsible for exophthalmos, elevated jugular pressure, gross hepatomegaly, and congestive splenomegaly [5, 54, 55].

Some distinctive features of EMF are not fully understood and cannot be explained exclusively by decreased output or systemic venous hypertension. These include central cyanosis in the absence of patent *foramen ovale*, absence of pedal edema in right heart failure, parotid swelling, retardation of sexual maturation, asthma-like episodes in the absence of hypereosinophilia, and hyperpigmentation of lips and gums but not the tongue [54, 55].

Diagnosis and Classification

Symptoms and Physical Examination

The clinical picture of EMF depends on the ventricle affected, the duration of disease, and the presence of active disease [53]. Although not clearly defined, active, chronic, and steady stages of EMF have been described [27, 53, 56]. *Active* EMF is suggested by fever, abdominal distension, facial or periorbital swelling, body itching, urticaria, neurological features, hypereosinophilia, and myopericarditis [47, 57], usually associated with absolute eosinophil count greater than 1.5×10^9/L and increased inflammation markers [27]. *Chronic* disease is defined as duration of symptoms for more than six months and is characterized by finger and toe clubbing, growth retardation, testicular atrophy, failure of the development of male secondary sexual characters, and cachexia [27]. Finally, *steady or inactive* EMF corresponds to the absence of amelioration or deterioration of the clinical picture for several months or years [53].

EMF patients may be mildly symptomatic, despite severe structural abnormalities detected on echocardiography [56, 58]. They usually give a poor clinical history and few recall a febrile illness at the beginning of the disease [7, 56].

Isolated or dominant right ventricular EMF: Patients with predominant right heart lesions often present with exophtalmus, jaundice, peripheral cyanosis, finger clubbing, atrial fibrillation, and ascites in the absence of pedal edema (Fig. 134.3) [53, 56]. A heave at the left upper parasternal area is seen as the result of the dilated and pulsatile right ventricular outflow tract. Cardiac auscultation can be unremarkable when free atrioventricular regurgitation is present and the tricuspid leaflets are immobile, but a third sound is usually detected even in advanced stages.

Isolated or dominant left ventricular EMF: Patients with predominance of lesions on the left side of the heart usually come to medical attention in a better general and nutritional status, having usually shorter duration of the disease [56], but severe cachexia may be present in some cases. On cardiac auscultation, there is a systolic murmur that is typically soft, short, and confined to early systole. A delayed opening snap and loud pulmonary component of the second sound may be heard, indicating increased pulmonary pressures.

Fig. 134.3 Ascites is a common finding in right EMF, usually with little or no edema of the lower limbs

Biventricular EMF: This group includes the majority of EMF patients. The right-sided lesions, by reducing pulmonary perfusion, avoid the hazards of severe pulmonary hypertension caused by left-sided lesions, allowing longer survival. Ascites is less prominent than in isolated right ventricular forms.

In endemic areas, the most common causes for acute decompensation are nonadherence to medication, changes in diet with increased salt intake, arrhythmia, thromboembolism, and acute illnesses such as malaria, diarrhea, or pneumonia.

Laboratory Findings

The laboratory profile changes of EMF patients are unspecific, with no evidence of infection or parasitism in the majority of cases [7].

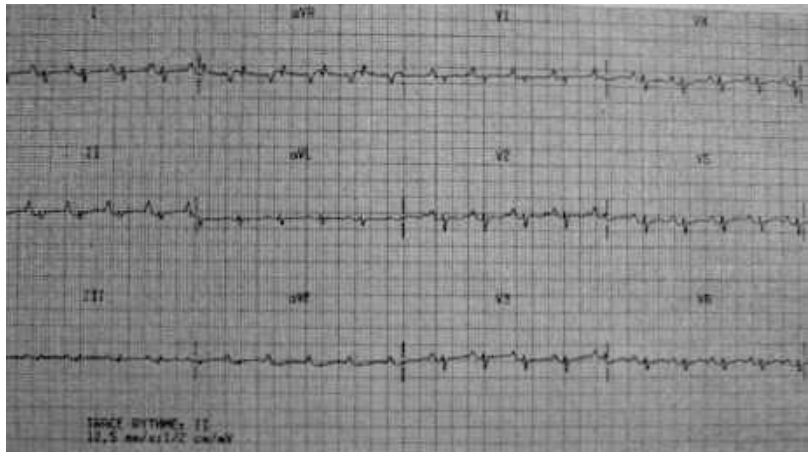

Fig. 134.4 Electrocardiographic features in advanced right EMF include giant right atrium and the characteristic qr pattern in lead V1. Notice the low voltage of the QRS complexes

Severe hypereosinophilia is a common finding [7, 17, 59, 60], and mild hypoproteinemia is sometimes seen in advanced disease [5]. Erythrosedimentation rate and C-reactive protein may be increased. The effusions are typically exudates, with higher protein content than expected in right heart failure [53] and present increased cellularity, predominantly lymphocytes.

Electrocardiography

The electrocardiogram shows no constant pattern. Atrial fibrillation is present in a considerable number of cases upon presentation [5, 56, 61]. Low-voltage QRS complexes, nonspecific ST-T wave changes, and conduction disturbances are characteristic of advanced disease [62]. In advanced right EMF, the electrocardiogram shows a tall and broad right atrial wave and a characteristic *qr* pattern in the leads V3R or V1 (Fig. 134.4) [53]. The ECG of left-sided EMF shows signs of left atrial hypertrophy and pulmonary hypertension.

Chest X-ray

Severe increase in the cardiac silhouette is typical of advanced disease, due to aneurismal atria and/or large pericardial effusions. The chest X-ray in right forms of EMF depicts severe right atrial enlargement, a bulge over the left heart border related to infundibular dilatation, and hypoperfused lungs. In EMF with predominant left lesions, the main pulmonary artery is prominent; there is exaggeration of the blood vessels in the lung fields and signs of left atrial enlargement. Rarely, endocardial calcification may be detected.

Echocardiography

Echocardiography is the main tool for diagnosis of EMF in endemic areas. This noninvasive imaging technique allows the diagnosis of EMF, the evaluation of its severity, as well as pre- and postoperative management [63]. It can demonstrate the presence of thickened endocardium in different parts of the ventricular wall, atrioventricular valve and subvalvar apparatus abnormalities, restrictive filling pattern, and complications such as thrombi and signs of heart failure. The echocardiographic features of established EMF are summarized in Table 134.1.

The two-dimensional echocardiography shows inversion of the normal size of the cavities, with obliterated ventricles and dilated atria, together with a thickened endocardium and

Table 134.1 Common echocardiographic findings in advanced endomyocardial fibrosis

Right ventricular EMF	Left ventricular EMF
Thickening and brightening of the endocardium, especially at septal and apical portions	Endocardial thickening at the apex and recess of the posterior leaflet of the mitral valve wall
Endocardial calcification may be found in the apical or trabecular portion	Endocardial calcification at the apex and valve apparatus
Reduction of the trabecular portion (apical notch) with dilated and hypercontractile outflow tract	Reduced longitudinal dimension with dilated and hypercontractile basal portion
Fixed or immobile tricuspid valve apparatus with severe non-turbulent tricuspid regurgitation	Restricted motion or plastered posterior mitral leaflet with eccentric mitral regurgitation
Interventricular and interatrial septa bulging to the left side, compressing the left cavities	M-movement of interventricular septum and/or posterior wall
Low-velocity waves on tricuspid Doppler	Tall E-wave and small A-wave
Free tricuspid regurgitation	Severe eccentric mitral regurgitation
Dilated right atrium and inferior vena cava; spontaneous contrast or large multiple thrombi	Dilated left atrium and pulmonary veins; rarely left atrial thrombi may be present
Pulmonary valve diastolic opening; difficult to estimate pulmonary pressures	Functional pulmonary regurgitation allowing estimation of elevation in pulmonary pressure
Large pericardial effusion	Mild to moderate pericardial effusion

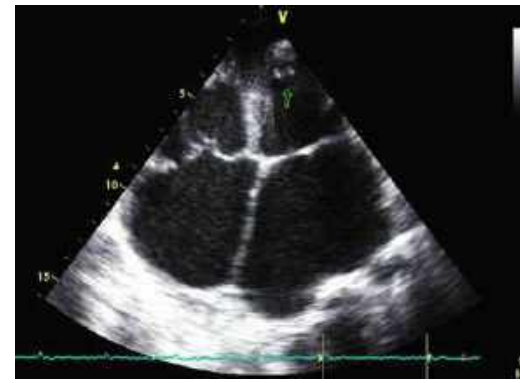

Fig. 134.5 Moderate left EMF with marked endocardial thickening in the ventricular apex and septum, spherical ventricle, thickening of the anterior leaflet of the mitral valve, and increased echos at the posterior papillary muscle

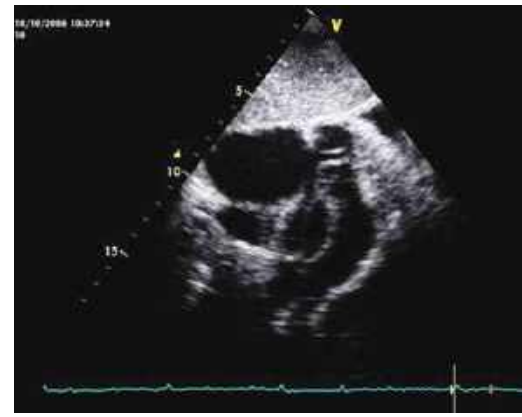

Fig. 134.6 Initial stages of right EMF with reduction of ventricular cavity size, due to obliteration of the trabecular portion of the right ventricle well seen in the longitudinal view of the right ventricle

fibrous thrombus, usually in the apex. In patient with balanced disease on both sides of the heart, the typical feature of biatrial dilatation with small ventricles, the so-called *Mickey Mouse heart*, can be found (Fig. 134.5). There is usually marked dilatation of the hepatic veins with little change in diameter with respiration. The pulmonary veins are dilated in left-sided EMF and relatively small in right-sided EMF.

Obliteration of the trabecular portion of the right ventricle is a typical feature of right-sided EMF (Fig. 134.6), which is associated with tricuspid annulus dilatation, massive regurgitation, and reduction in cavity volume. The typical finding of *apical notch* represents right ventricular retraction in severe cases. Free tricuspid regurgitation, spontaneous contrast, multiple right atrial thrombi, and pericardial effusion are usual features in advanced right-sided EMF (Fig. 134.7). Bulging of the interventricular and interatrial septa to the left compresses left cavities and contributes to impairment of left ventricular filling, difficult evaluation of the mitral valve, and low cardiac output.

The left ventricle presents usually patchy thickening of the ventricular endocardium, but large plaques are also seen mainly in the apex, the basal septum, and the posterior wall. The long

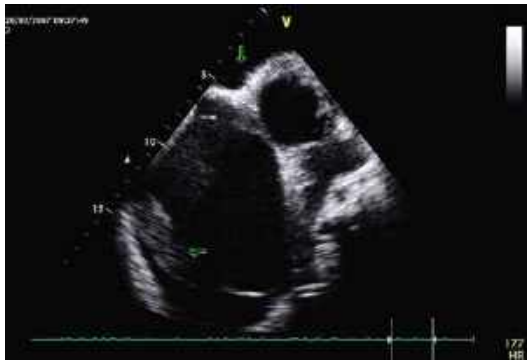

Fig. 134.7 Right atrial dilatation stretches the tricuspid ring, causing free tricuspid regurgitation. In later stages, the atrium and the ventricle become a single chamber with spontaneous contrast and thrombi

Fig. 134.8 Mitral regurgitation is usually severe with the jet directed to the left atrial posterior wall. The right cavities are dilated due to passive pulmonary hypertension

axis of the ventricle is shortened, resulting in a round shape of the cavity (Fig. 134.8). There is usually obliteration of the recess behind the posterior mitral leaflet, which is frequently fused to the posterior wall leading to mitral regurgitation (Fig. 134.9). Severe dilatation of the left atrium is common, and tricuspid regurgitation is usually present, allowing confirmation of pulmonary hypertension.

M-mode echocardiography provides evidence of restriction by the square root sign shown in the movement of the interventricular septum and the posterior wall, as well as the *merlon sign*, characterized by a hypercontractile basal ventricle

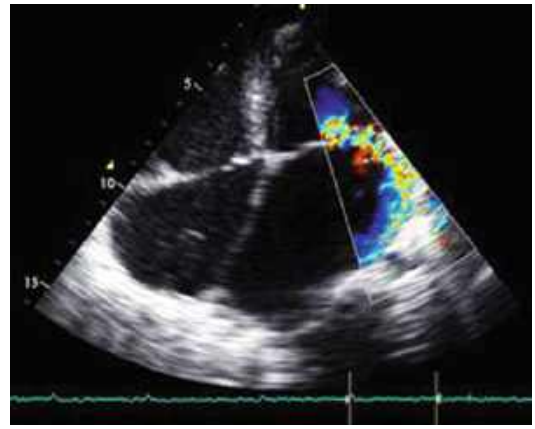

Fig. 134.9 Echocardiographic features of bilateral EMF include atrioventricular valve thickening and organized thrombus in the left ventricular apex. Reduction of ventricular cavity size with increased biatrial enlargement gives origin to the classical feature of the so-called Mickey Mouse heart

opposing an obliterated apex [64]. Mitral and tricuspid Doppler flow analysis shows a restrictive flow pattern, consisting of high and narrow E-wave, short A-wave, and short deceleration time. The velocity of change in velocity from inspiration to expiration in tricuspid and mitral valves has the same minimal percentage seen in healthy individuals. Continuous wave and color Doppler are helpful in establishing the severity of atrioventricular valve regurgitation. The pulmonary veins show marked diastolic D-wave and broad reversal A-wave.

Transesophageal echocardiography may be useful for more accurate study of the pulmonary veins and severity of mitral regurgitation [64].

Computed Tomography

Computed tomography is seldom used in clinical practice for it adds little to echocardiographic evaluation. It depicts morphologic features of EMF, by allowing direct visualization and mapping of fibrosis in the endocardium and within the myocardial wall. EMF is suggested by linear calcification distal to the pericardium, along the inner border of the myocardium [65].

Magnetic Resonance Imaging

Magnetic resonance imaging is the ideal tool for the diagnosis and management of EMF, giving exact anatomic and hemodynamic information, as well as allowing diagnosis and monitoring of the response to medical and surgical treatment [66]. It is particularly helpful in patients with severe structural abnormalities that lead to distorted anatomy and compromise transthoracic echocardiographic evaluation. It confirms the presence of thrombus or calcifications and allows an exact delineation of hypo-perfused areas that correspond to fibrosis [67]. Myocardial suppression scans are useful for exact appreciation of disease extension through delayed hyperenhancement of the pathologic areas [66, 67].

Cardiac Catheterization

Cardiac catheterization confirms hemodynamic abnormalities in EMF patients, but can be misleading in localized or mild forms of the disease. It is also technically challenging and dangerous in advanced disease. Endomyocardial biopsy is technically difficult in areas of dense endocardial fibrous thickening and gives false results when tissue is obtained from unaffected sites. Due to the imbalance between the information obtained and the risk of the procedure, and the ability to assess the lesions through echocardiography and Doppler, cardiac catheterization and endomyocardial biopsy are rarely performed.

In right-sided EMF, the pressures are equal both in form and amplitude in the right atrium, right ventricle, and pulmonary artery. The right ventricular angiogram shows loss of trabeculated pattern, flattened apex, reduction of the ventricular volume, dilated and hypercontractile infundibulum, free tricuspid reflux, large right atrium, and dilated cava veins [68].

Left disease is characterized by elevated left ventricular end-diastolic pressure with dip-plateau pattern and pulmonary hypertension that is variably damped by the presence of the right ventricular disease. The left ventricular angiogram shows left apical obliteration with varying degree of mitral regurgitation.

The increased distance from coronary arteries to the contrast inside the ventricular cavity demonstrates the obliteration of the apices, while in earlier stages a right ventricular diverticulum may be present [16].

Differential Diagnosis

EMF must be differentiated from several entities that are prevalent in young people from tropical regions, namely, rheumatic heart disease, constrictive pericarditis, tuberculous pericarditis, dilated cardiomyopathy, lymphomas with neoplastic infiltration of the heart, and also from Ebstein malformation of the tricuspid valve [5, 7, 69, 70].

The distinction between EMF with predominance of lesions on the left side of the heart and mitral regurgitation due to RHD can be particularly challenging. Fusion of the posterior leaflet of the mitral valve to the ventricular wall, leaflet thickening not restricted to the free extremities, and reduction of the longitudinal dimension of the left ventricle are distinct features of EMF.

Principles of Management

There is no specific treatment aimed at arresting or reversing the structural heart defects in patients with EMF. Medical therapy is aimed at treating acute disease, heart failure, and its complications, while surgery partially corrects some of the structural and hemodynamic abnormalities.

Medical Therapy

The medical management of EMF includes the use of diuretics, ACE inhibitors, digitalis, β-blockers, anticoagulants, and corticosteroids (Table 134.2). These drugs aim at controlling heart failure, arrhythmias, and inflammation, as well as preventing thromboembolism.

Table 134.2 Drugs commonly used for management of EMF in endemic areas of Africa

Drug	Initial daily dosage	Common problems
Furosemide	2–3 mg/kg	Hypovolemia
		Hyponatremia
Spironolactone	50–100 mg	High cost
Captopril	12.5–25 mg	Intolerance (cough)
		Hypotension
Propranolol	20–80 mg	Bronchospasm
Digoxin	0.125–0.25 mg	No titration available
Prednisolone	1 mg/kg	Immunosuppression
		Fluid retention
Warfarin	2.5–5.0 mg	Difficult monitoring
		Bleeding
Aspirin	100–150 mg	Gastrointestinal bleeding

Oral therapy has little success in patients with severe ascites, due to increase in intraperitoneal pressure and subsequent reduction in absorption of the intraluminal content of the bowel, and therefore, intravenous diuretics may be needed.

Management of Heart Failure

Furosemide at high doses 3–4 mg/kg/day may be needed initially, but metolazone and hydrochlorothiazide are needed in some cases. Potassium-sparing diuretic spironolactone and vasodilators acting on the renin-angiotensin-renin system must be privileged due to their effects in modulating fibrosis.

Management of Hypereosinophilia

Although not validated by clinical trials, short courses of oral corticosteroids are used for management of hypereosinophilia, usually 1 mg/kg/day of prednisolone for 10 days. Some reports show that they have no or little influence on the natural course of EMF [5], and therefore, their use must always be balanced against the known disadvantages and risks, particularly reactivation of tuberculosis and parasitic diseases that are prevalent in endemic areas for EMF.

Management of Arrhythmia and Anticoagulation

Control of arrhythmias and prevention of thromboembolism is poor, due to severe impediment to ventricular filling resulting in progressive atrial dilatation and stasis. Electrical cardioversion is indicated as a lifesaving procedure for treatment of arrhythmias, usually recent onset atrial fibrillation, after exclusion of the presence of intracavitary thrombi. Most patients in atrial fibrillation are managed through heart rate control strategy, usually using digoxin and beta-blockers.

Chronic anticoagulation should be started to prevent systemic and/or pulmonary thromboembolism in patients with extremely dilated atria or non-turbulent tricuspid regurgitation. Aspirin at low doses is preferred in patients who cannot afford or survey oral anticoagulation. Low-molecular-weight heparins, unfractionated heparin, and thrombolysis are seldom used but should be considered.

Management of Effusions

Effusions in EMF patients are usually resistant to medical treatment and require periodical drainage. Marked clinical improvement is obtained after peritoneal, pericardial, and/or pleural drainage, due to alleviation of one of the components contributing to reduce atrial filling and lowering cardiac output. Surgical procedures such as pericardio-pleural window, pericardio-peritoneal shunt, and drainage of the ascites into the femoral vein [54] have been tried for the management of tense ascites, with disastrous results. These procedures are not routinely recommended and patients with large effusions, particularly ascites, benefit from repeated evacuation of fluid for symptomatic relief. These procedures must be performed with close monitoring of blood pressure and caution to avoid excessive protein depletion.

Surgical Management

Surgery is indicated in all EMF patients in NYHA class III and IV who have structural lesions

suitable for correction since it increases survival and improves quality of life when compared to medical therapy [68, 71, 72]. However, surgery is associated to high morbidity and mortality [71, 73].

The surgical treatment is currently based on several facts. Firstly, severe disease is fatal if untreated, while restriction of the diastolic filling and atrioventricular regurgitation can be corrected. Secondly, in some cases, the myocardium remains healthy and unaffected, allowing endocardectomy to be done through a relatively well-preserved cleavage plan. Finally, low rates of recurrence have been reported after surgery [73] supporting prompt treatment before shrinking of the ventricles, or irreversible cardiac and hepatic damage occurs. The usual contraindications for surgery are large long-standing ascites refractory to medical therapy, extreme cachexia, fixed pulmonary hypertension, extensive endocardial fibrosis, or calcification with impaired myocardial function.

Corrective surgery initially consisted of total resection of the endocardial fibrous membrane, excision of the damaged papillary muscles, and replacement of the damaged atrioventricular valves and was associated mortality of around 20 % mainly due to low cardiac output syndrome, complete atrioventricular block, and valve prostheses-related events [71–73]. Reduction in perioperative mortality and improvement in prognosis have been achieved through changes to the operative technique, namely, the use of subtotal right ventricular endocardial resection to avoid atrioventricular block, atrioventricular valve repair to treat mitral and tricuspid incompetence [74], and new techniques of myocardial protection.

Surgical Technique

Endocardial resection is usually done through atriotomy on both sides of the heart, but ventriculotomy may be necessary on the left side to access the apex [75]. Mobilization of the obliterated right ventricular trabecular portion in right-sided EMF and additional procedures such as Glenn procedure and atrial reduction have been recently used with promising results [52, 76, 77].

Fig. 134.10 Surgical picture of the right ventricle during endocardial resection, which allows the release of the myocardium underneath the fibrotic tissue improving both systolic and diastolic function

Mobilization of the trabecular portion of the right ventricle: After right atriotomy, ventricular cavity obliteration is exposed through the markedly dilated tricuspid valve. Endocardial resection is started near the tricuspid annulus by retracting the leaflets of the valve or separating them if they are fused. Following the development of a cleavage plane by sharp dissection, a combination of sharp and blunt dissection is used to excise the thick fibrous endocardial lining, a process that is continued into the ventricular cavity ensuring preservation and mobilization of the tricuspid valve chordae and papillary muscles. After removal of the fibrous tissue covering the entry into the trabecular part, the fused muscular tissue is exposed underneath it (Fig. 134.10), and recreation of the cavity is done by separating the fused *trabeculae* while taking care not to perforate the ventricular wall [52].

Perioperative Evaluation and Care

Transthoracic echocardiography allows detailed characterization, description of the location, and assessment of severity of the lesions in most cases [24]. It helps defining the mechanism of ventricular cavity reduction (thrombus, obliteration,

or retraction), the extension of fibrosis and/or calcification, the severity of atrioventricular leaflet shortening, and the presence of other structural abnormalities on a given patient. This can be confirmed on intraoperative evaluation of the pathological lesions and allows the design of surgical approaches tailored to patient's pathological features.

After surgery, close follow-up of myocardial function, presence of thrombi, and pericardial effusion is mandatory. Transient atrioventricular block may occur. Inotropic support and anticoagulation may be needed in the first 48 h. Diuretics, ACE inhibitors, and low doses of aspirin are given for at least 6 months.

Prognosis

The overall prognosis of EMF is poor. The disease has a high incidence of sudden death from arrhythmias and thromboembolism. Deaths are also the consequence of progressive chronic heart failure with protein-losing enteropathy, cardiac cirrhosis, and hepatic failure. Complications such as pulmonary hypertension and systemic thromboembolism determine earlier fatality in isolated or predominant left ventricular EMF.

The mean survival after the onset of symptoms, initially at 2 years [61], seems to be improving with the use of new drugs for heart failure and arrhythmias as well as the use of surgical treatment before the advent of irreversible complications. Rapidly progressive heart failure may occur but evolution towards a long steady period without any deterioration is also possible.

Personal Perspective and Future Directions

Although known since the middle of twentieth century, EMF remains one of the most neglected diseases in cardiology. It has received little attention from the scientific community and did not benefit from modern management approach. Despite major developments in imaging techniques that allow better characterization of heart disease and its progression, the early phases of EMF are not clearly defined because these imaging techniques remain expensive and not readily available in most endemic areas.

Research on the mechanisms of this disease is mandatory in order to identify new therapeutic targets and explore preventive measures to avoid progression to severe disease states. Although not clearly defined, chronic inflammation and hypereosinophilia seem to be major determinants of the natural history of EMF. Understanding their role in pathogenesis will probably allow targeting them with drugs already available that might have a major impact on management and improve prognosis.

Hypereosinophilic Heart Disease 135

Pierre-Emmanuel Séguéla and Philippe Acar

Abstract

Eosinophilia may be responsible for heart damage with a wide spectrum of severity, ranging from myocarditis to endomyocardial fibrosis. This section focuses on the molecular pathophysiological aspects of the hypereosinophilic heart disease. Etiologies of eosinophilia are discussed and the different heart lesions are described. Because cardiac involvement may be extremely severe, it should be systematically considered in case of eosinophilia. Thus, echocardiography should always be performed in this context and appropriate therapeutics should be started rapidly in order to limit the progression of the disease.

Introduction

Hypereosinophilic heart disease is a relatively rare condition that was first described in 1936 by Löffler who called it "fibroplastic parietal endocarditis with blood eosinophilia" [1]. In fact, several types of insults may be encountered in the context of eosinophilia. Mechanisms that underlie these lesions and their different clinical and paraclinical aspects are presented in this section.

Eosinophils

Eosinophils are normally found in the blood and in certain tissues. These cells are involved in the normal antimicrobial immunity [2]. Since, when stimulated, eosinophils have the ability to elaborate substances that are toxic to a wide variety of parasites [3], their usual location in the body (respiratory tract, gastrointestinal tract, and skin) may be explained by their antiparasitic activity. Eosinophils measure 12–15 μm in diameter and are characterized by a bilobed nucleus and numerous eosin-staining specific granules in their cytoplasm [4]. These granules contain high concentrations of hydrolases and cationic and basic proteins (Fig. 135.1) [5, 6].

Eosinophil Production and Kinetics

As the other polymorphonuclear leukocytes, eosinophils are produced by the bone marrow, where they represent up to 6 % of the resident nucleated cells [7]. Under the influence of several cytokines, the hematopoietic stem cells gradually differentiate into eosinophilic myelocytes and then into mature eosinophils (Fig. 135.2). This maturation process takes approximately 8 days. The main cytokines responsible for the increase in eosinophil number are granulocyte macrophage colony–stimulating factor (GM-CSF), interleukin-3 (IL-3), and interleukin-5 (IL-5). IL-5 is specific for the production of eosinophils and is considered to be their major growth factor [8]. IL-5 is produced by Th2 lymphocytes. It is also involved in survival, chemotaxis, and degranulation. Eosinophils remain briefly in the peripheral blood (8–12 h) before migrating preferentially to certain tissues where they are concentrated: the respiratory tract, the gastrointestinal tract, the skin, and the urogenital tract (for females) (Fig. 135.2). Eosinophils survive 1–2 weeks, unless apoptosis is prevented by cytokines (GM-CSF, IL-3, IL-5) [7].

Composition of Eosinophils

The cytoplasm of eosinophils is filled with many eosin-staining specific and non-eosinophilic granules. As eosinophils are involved in the inflammation process and in the innate and the adaptive immunity, the specific granules contain cationic proteins: major basic protein (MBP), eosinophil cationic protein (ECP), eosinophil-derived neurotoxin (EDN), and eosinophil peroxidase (EPO) (Fig. 135.1) [8]. These proteins have several effects including production of free radicals, cell necrosis, and apoptosis induction. These eosinophilic constituents are very deleterious to the endothelial cell [9]. Finally, the endocardium appears to be very sensitive to the release of these cardiotoxic agents, especially MBP and ECP [10].

Definition of Eosinophilia

Normal count of circulating eosinophils is $\leq$350/mm^3, both for adults and children. Mild eosinophilia is defined by a level of 500–1,500 eosinophils/mm^3. A count of 1,500–5,000 eosinophils/mm^3 is considered as moderate and >5,000 eosinophils/mm^3 as a significant eosinophilia [7].

Cardiac Toxicity of Eosinophils

The degree of damage associated with tissue eosinophilic infiltration appears related to the stimulus attracting the eosinophils, the duration

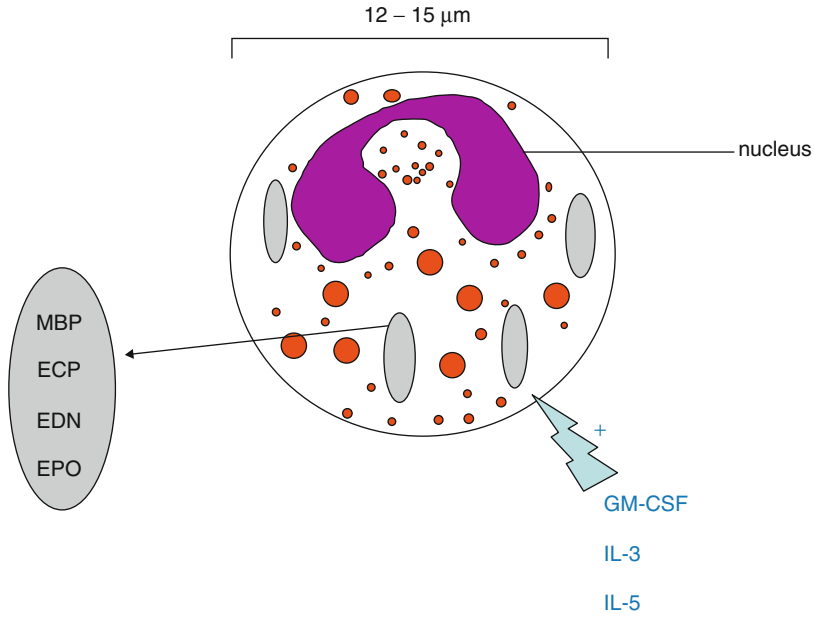

Fig. 135.1 Eosinophil characteristics. Eosinophil contains numerous *red-orange* granules in their cytoplasm. These granules are composed of various cationic proteins, cytokines, and lipid mediators. The cationic proteins, especially MBP, ECP, EDN, and EPO, are potent mediators of antimicrobial immunity. These proteins are extremely toxic for the heart cells. The production of eosinophils is stimulated by cytokines such as GM-CSF, IL-3, and IL-5. *ECP* eosinophil cationic protein, *EDN* eosinophil-derived neurotoxin, *EPO* eosinophil peroxidase, *GM-CSF* granulocyte macrophage colony–stimulating factor, *IL-3* interleukin 3, *IL-5* interleukin 5, *MBP* major basic protein

of eosinophilia, and the degree of eosinophil activation. Indeed, deleterious effects on tissues, particularly on the heart, are more common in case of profound eosinophilia (>5,000/mm^3). According to Gottdiener and colleagues, three phases are classically described [11]. The first stage is due to the eosinophilic infiltration in the tissues and leads, after the release of the granular proteins, to cells necrosis. When biopsies are performed, they consistently show deposits of MBP, ECP, and EPO. The second phase is represented by the thrombosis formation. Because the cationic proteins of eosinophils bind to the anion-binding exosite of thrombomodulin, the complex thrombomodulin-thrombin cannot form. Thus, it loses its anti-thrombotic role. Indeed, thrombomodulin, by binding to the circulating thrombin, is a potent physiological inhibitor of coagulation (Fig. 135.3). The third stage corresponds to the fibrotic scarring. In the final stage, cardiac endothelium and valves become fibrotic and thickened resulting in a noncompliant ventricle, initially defined as the Löffler's fibroplastic endocarditis [1].

Causes of Profound Eosinophilia in Children

Many diseases (most common are reported in Table 135.1) are responsible for eosinophilia, but profound eosinophilia cannot be attributed to all of these. The first diagnostic step is to exclude reactive eosinophilia [12]. Indeed, some drugs (anticonvulsants, nonsteroidal anti-inflammatory drugs, antimicrobial agents, sulfonamides) are well known to trigger an abnormal production of eosinophils. Eosinophilia may be the sole manifestation of a drug-induced hypersensitivity reaction. When a drug-related eosinophilia is associated with a morbilliform

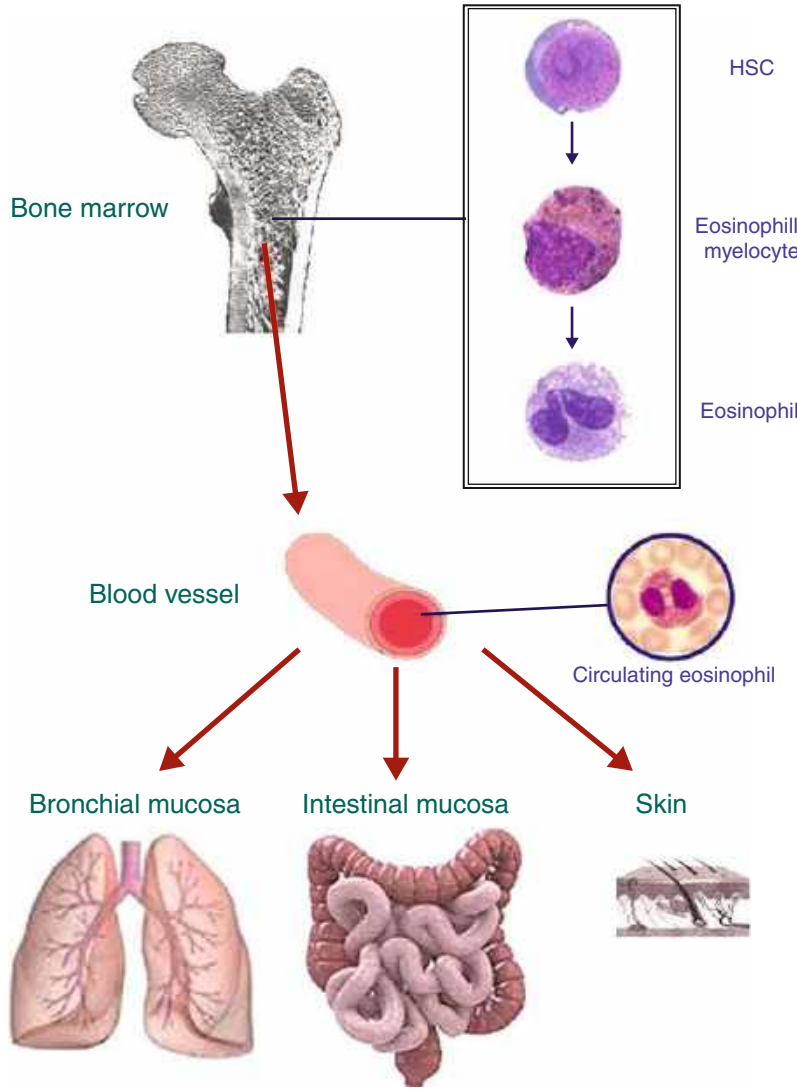

Fig. 135.2 Normal kinetics of eosinophil. After being produced by the bone marrow, eosinophils stay few hours in the peripheral blood before migrating to specific organs which are involved in antimicrobial immunity. *HSC* hematopoietic stem cell

eruption and severe tissue damage, this condition is called Drug Rash with Eosinophilia and Systemic Symptoms (DRESS syndrome) [13]. In the latter condition, the eviction of the offending drug usually results in normalization of the eosinophil count within 7–10 days [7]. Infections, and particularly helminthic, should also be ruled out. Thereby, in the presence of significant eosinophilia, an empirical anti-helminthic drug therapy should be started immediately. Other etiologies are mainly represented by systemic diseases, malignancies, and hypereosinophilic syndrome.

Hypereosinophilic Syndrome (HES)

HES is a heterogeneous group of rare hematological disorders defined by an unexplained and sustained blood eosinophilia. Chusid and colleagues defined HES as an eosinophilia >1,500/mm^3 for longer than 6 months, without any secondary cause and with evidence of organ involvement [14]. Albeit more common between 20 and 50 years of age, this entity is sometimes encountered in children [15–17]. As for adults, there is a slight male predominance (55 % of cases)

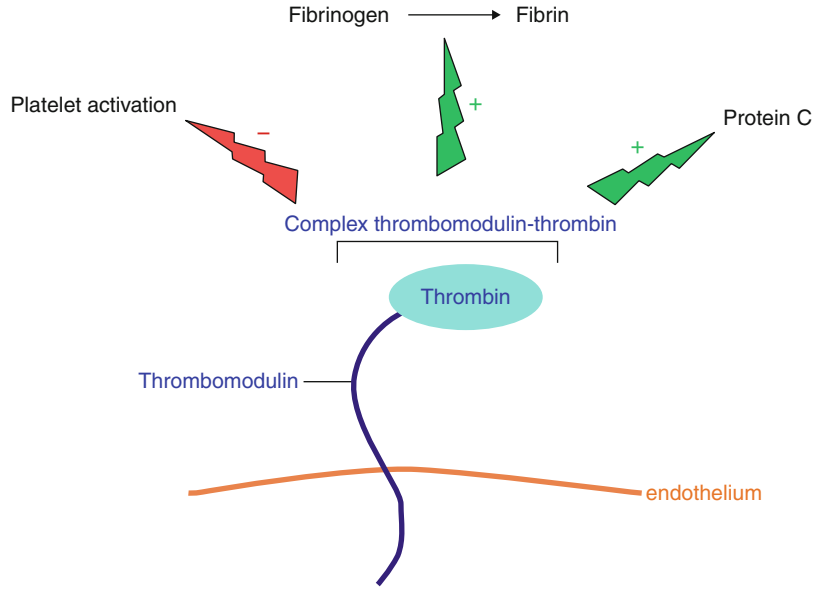

Fig. 135.3 Actions of thrombomodulin. Thrombomodulin, a cell surface protein of endothelium, normally binds to thrombin to form the complex thrombomodulin-thrombin. This complex inhibits the platelet activation, activates the conversion of fibrinogen to fibrin, and activates protein-C which is a major physiological anticoagulant. By binding to the extracellular anionic domain of thrombomodulin, the cationic proteins of eosinophil prevent the formation of the complex and cause thrombosis

[15, 16]. The involvement of the cardiovascular system is the major source of morbidity and mortality. However, dermatologic, pulmonary, and gastrointestinal involvement seems to be more common [16]. In children, HES is commonly associated with chromosomal abnormalities. A new classification [18], introducing the concepts of variants, was recently proposed. As their clinical presentation, treatment, and prognoses are different, two subtypes of HES must be recognized: a lymphocytic variant of HES (L-HES) and a myeloproliferative variant or chronic eosinophilic leukemia (CEL). Bone marrow cytogenetic analysis and fluorescent in situ hybridization (FISH) are essential for this differential diagnosis. Indeed, a FIP1L1-PDGFRA (FP) fusion gene created by an 800-kb deletion on chromosome 4q12 was discovered in the majority of myeloproliferative variants [19]. Thus, patients with FP mutation are likely to have the myeloproliferative variant of HES, as opposed to L-HES. The product of this fusion gene is a constitutively active protein-tyrosine kinase capable of transforming hematopoietic cells into eosinophil precursors. It explains the fact that a well-known tyrosine kinase inhibitor, imatinib, is completely effective in 88 % of FP-positive patients [19, 20]. However, some patients with myeloproliferative variant are FP-negative and therefore do not respond to imatinib. The L-HES variant is characterized by a deregulation of the lymphocyte homeostasis, resulting in an increased secretion of cytokines (IL-5). In this case, corticosteroids are the first-line therapeutic agents. For the resistant forms, an anti-IL-5 therapy (mepolizumab) is recommended [20]. Whereas the L-HES variant is less deleterious for the heart, the transformation into acute leukemia seems to be more common [15].

Eosinophilic Heart Injuries

The heart is one of the most frequently involved organs in case of sustained eosinophilia in children [15]. In the Löffler's postmortem examination of two patients with chronic eosinophilia, cardiac involvement was characterized by fibrosis that obliterated the ventricles [1]. It is now recognized that this endomyocardial fibrosis is the ultimate form of hypereosinophilic heart disease. Classically, the cardiac pathology of eosinophilia is divided into three chronologic phases: eosinophilic infiltration, thrombosis, and fibrosis [11].

Eosinophilic Myocarditis = Acute Necrotic Stage

The early phase is characterized by an eosinophilic endomyocarditis with eosinophil and lymphocyte infiltration [20]. When infiltrating tissues, eosinophils degranulate and release toxic cationic proteins, thus inducing necrosis and apoptosis. However, most of the time, patients have no cardiac symptoms during this stage [21] and may present only nonspecific signs. When performed, ECG may show sinus tachycardia, supraventricular tachycardia, nonspecific ST segment anomalies or conduction delays, but is often unremarkable [22]. Echocardiography reveals an increased left ventricular wall thickness because of the interstitial myocardial edema (Fig. 135.4, Video 135.1). Endomyocardial biopsy is necessary to make the diagnosis. Histological sections show eosinophilic infiltration of the endocardium and subendocardial interstitium, evidence of myocardial necrosis and sometimes eosinophilic granulomas (Fig. 135.5) [22, 23]. At this stage of the disease, the aim of the treatment is to rapidly lower the eosinophil count in order to limit myocardial necrosis.

Acute necrotizing eosinophilic myocarditis represents the most severe form of acute eosinophilic heart disease and may be rapidly fatal without early diagnosis and appropriate treatment [21, 24]. Patients present acute heart failure symptoms or may have rapidly evolving cardiogenic shock. ECG shows conduction abnormalities and diffuse ST segment elevation. The level of troponin is elevated, mimicking acute myocardial infarction [25, 26]. Echocardiography shows left ventricular systolic dysfunction with wall

Video 135.1 Transthoracic echocardiographic apical four-chamber view of eosinophilic myocarditis in a 5-year-old child. The free wall of the left ventricle is thickened because of the interstitial myocardial edema

motion abnormalities. In this context, cardiac MRI seems to be very efficient to depict the endomyocardial involvement [27]. Indeed, the endocardial inflammation is well detected by the use of delayed-enhancement sequences (Fig. 135.6), showing extensive eosinophilic infiltrates, and, sometimes, a patchy distribution of the gadolinium enhancement. Moreover, cine sequences can accurately assess ventricular function.

Symptoms of congestive heart failure ought to be treated with conventional drugs. Because corticosteroid therapy inhibits the degranulation of eosinophils, it has been proposed as a first-line treatment for eosinophilic myocarditis, in order to limit the myocardial necrosis. However, the efficacy of corticosteroids remains controversial [28, 29]. In case of fulminant heart failure, mechanical support may be necessary.

Thrombotic Stage

The second stage is represented by the formation of mural thrombi along the damaged endocardium. Several mechanisms are proposed to explain this thrombosis. As previously pointed, eosinophilic proteins can bind to thrombomodulin, thus impairing the anticoagulant property of the endothelial membrane [30]. Furthermore, coagulation factors may be activated by the granular proteins of eosinophils [20]. Thrombi most commonly involve both ventricles at the apex, ventricular outflow tracts, subvalvular regions, and occasionally the atrium. Mural thrombi are well recognized both by echocardiography (Fig. 135.7) and cardiac MRI.

According to authors, thromboembolic events occur in 4–29 % of adult patients with idiopathic hypereosinophilia [14, 31, 32]. Thus, in case of organized thrombi, an oral anticoagulation therapy appears to be legitimate even if no data are available in children [33, 34]. Antiplatelet therapy has also been proposed to prevent the formation of thrombus at the stage of eosinophilic myocarditis. However, no study has been conducted to evaluate both effectiveness and modalities of these treatments.

Fibrotic Stage = Scarring Stage

Finally, the formation of thrombi is followed by the fibrotic stage which corresponds to endomyocardial scarring. Fibrosis, an irreversible damage, involves the two ventricles (Fig. 135.8)

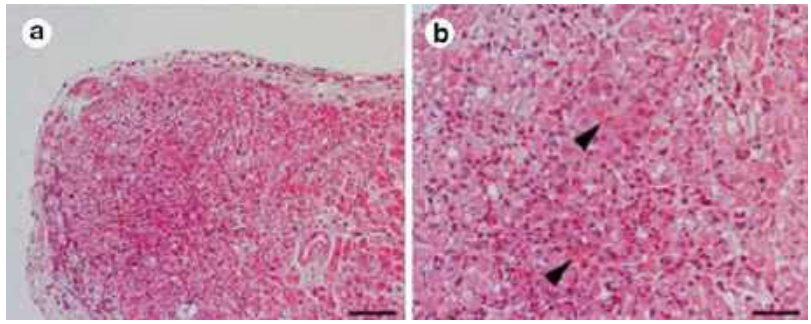

Fig. 135.5 Endomyocardial biopsy of eosinophilic myocarditis. (**a**) Extensive eosinophilic infiltrate involving the endocardium and the myocardium (hematoxylin and eosin). (**b**) Subendocardial granulomas consisting of central amorphous granular material (*arrowheads*) surrounded by histiocyte-like elements and a marked eosinophilic infiltrate with signs of myocyte necrosis (hematoxylin and eosin) (Reproduced with permission from [23])

and may include subvalvular apparatus of both mitral and tricuspid valves [35, 36]. In their echocardiographic series, Gottdiener and colleagues found a mitral regurgitation in 43 % of patients with HES [11]. The accumulation of thrombofibrotic material between the mural endocardium of left ventricular free wall and the ventricular aspect of the posterior mitral leaflet limited the posterior mitral leaflet motion (Fig. 135.9) [37]. In addition to these valvular attachments, endomyocardial fibrosis is responsible for restrictive cardiomyopathy whose prognosis is very poor. Endomyocardial fibrosis may also alter the cardiac conduction system, leading to severe ventricular arrhythmias [38].

At this stage, echocardiography allows visualization of atrioventricular valve regurgitation, and spectral Doppler flow patterns across the

mitral valve and pulmonary veins are consistent with restrictive filling. Endomyocardial biopsy shows marked endocardial fibrosis, classically in the absence of any residual eosinophilic infiltrate [39] (Fig. 135.10). Endomyocardial fibrosis is well depicted by cardiac MRI, and cine sequences are useful to demonstrate the diastolic dysfunction [40–43] (Fig. 135.11, Video 135.2). On cardiac catheterization, the typical hemodynamic feature is the dip-and-plateau or square root sign [44, 45]. This restrictive filling pattern can also be well analyzed by strain echocardiography [46].

Fig. 135.8 Gross anatomy of endomyocardial fibrosis. Cross section of an expanded heart with marked left ventricular hypertrophy and endocardial fibrosis with multiple superficial hemorrhages. The patient had a hypereosinophilic syndrome and was positive for the FIP1L1-PDGFRα gene rearrangement (Reproduced with permission from [39])

Surgery is often the only efficient treatment at this stage of the disease. Endocardial decortication provides acceptable results by prolonging survival [47–49]. When valvular regurgitation is important, valvular surgery may be required and bioprosthetic valve replacement is commonly preferred to mechanical prosthesis [50, 51], because recurrent thrombotic events are more common with the use of mechanical valves [52]. Ultimately, orthotopic heart transplantation should be considered. Only three heart transplantations have been reported in case of eosinophilic heart disease, with good results [39]. In any case, it is necessary to control eosinophilia by medical treatments before considering any surgical therapy.

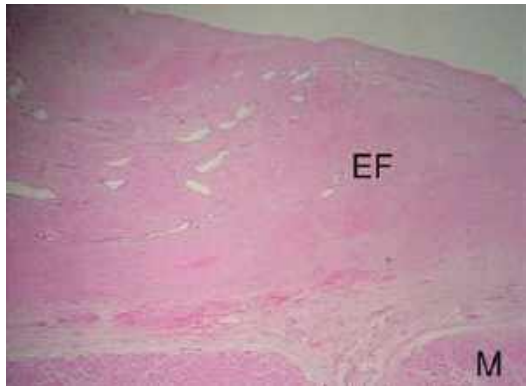

Fig. 135.10 Endomyocardial biopsy of Loffler's disease. Gross endocardial fibrosis with no cellular infiltrates. *EF* Endocardial fibrosis, *M* Myocardium (Reproduced with permission from [39])

Pericardial Effusion

Endomyocardial involvement is often associated with pericardial effusion, thus characterizing the myo-pericarditis. However, isolated acute eosinophilic pericarditis has also been reported [53, 54] as well as eosinophilic cardiac tamponade [55]. Finally, pericardial involvement of eosinophilia may occur as constrictive pericarditis [56].

Focus on Tropical Endomyocardial Fibrosis

Tropical endomyocardial fibrosis (EMF) is the most common cause of restrictive cardiomyopathy worldwide and is further discussed in a specific chapter in this book section [57]. As Davies was the first author to describe the clinicopathologic features of tropical EMF in 1948, this cardiomyopathy is sometimes called Davies disease [58]. Tropical EMF is endemic in tropical and subtropical areas, especially in Africa. Because the cardiac lesions are similar to those observed in eosinophilic EMF, some authors suggested that the two diseases have a common pathogenesis involving eosinophilic toxicity [59–61]. Indeed, the high prevalence of parasitic infections in the tropics was assumed to be the

cause of a transient or sustained eosinophilia, leading to the cardiac lesions. This hypothesis was supported by observations of visitors of subtropical regions who developed tropical EMF [62]. However, the variable association with eosinophilia and the frequent absence of eosinophils on endomyocardial biopsies, even in the early stages, are arguments against this assumption [57, 63]. Thus, exact mechanisms of tropical EMF remain unknown. New hypothesis involves an infective trigger in genetically susceptible individuals [63].

Conclusion

Eosinophils may be particularly toxic to the heart in case of eosinophilia. Clinical and echocardiographic signs of hypereosinophilic heart disease may vary widely. As an early treatment can limit irreversible damages, echocardiography should be systematically performed in case of eosinophilia, especially if sustained. First-line treatment should include anti-helminthic therapy, corticosteroid therapy, and anticoagulant therapy. The goal of these therapeutics is to rapidly lower the eosinophil count and to prevent thromboembolic events. Surgery may be necessary at the fibrotic stage of the disease. The prognosis is related to the severity of cardiac injuries but also to the cause of eosinophilia.

The Adult With Congenital Cardiac Defects

Gary Webb

Controversies in Our Current Decade Surrounding the Management of the Adult with Congenital Heart Disease

136

Scott Cohen, Peter Bartz, Tejas Shah, and Michael G. Earing

Abstract

Heart defects occur in 75 of 1,000 live births, 25 % of which are at least moderate in severity. Less than 33 % of infants born with congenital heart disease 50 years ago survived to adulthood. With current advances in pediatric cardiology and surgery, it is now estimated in developed countries that up to 95 % are expected to reach adulthood. As life expectancy improves, the population of adults with congenital heart disease continues to grow. For the first time, it is now estimated that the number of adults with congenital heart disease has surpassed the number of children with congenital heart disease. While this is a remarkable achievement in the field of medicine, it is now apparent that early surgical interventions were reparative and not curative. Adults with congenital heart disease are increasingly requiring medical services and late complications are becoming increasingly apparent. As result, healthcare systems are now challenged to meet the demands of this complex and largely underserved population. This chapter discusses and highlights some of the important advances and controversies in the modern era in the management of the adult with congenital heart disease.

Introduction

Epidemiologic studies suggest that heart defects occur in 75 of 1000 live births, 25 % of which are at least moderate in severity. Less than 33 % of infants born with congenital heart disease 50 years ago survived to adulthood. With current advances in pediatric cardiology and surgery, it is now estimated in developed countries that up to 95 % are expected to reach adulthood. As life expectancy improves, the population of adults with congenital heart disease continues to grow. For the first time, it is now estimated that the number of adults with congenital heart disease has surpassed the number of children with congenital heart disease. While this is a remarkable achievement in the field of medicine, it is now apparent that early surgical interventions were reparative and not curative. Adults with congenital heart disease are increasingly requiring medical services and late complications are becoming increasingly apparent. These complications may arise from hemodynamic or hypoxic stress, postoperative sequelae, residual defects, and acquired comorbidities. As result, healthcare systems are now challenged to meet the demands of this complex and largely underserved population. This chapter discusses and highlights some of the important advances and controversies in the modern era in the management of the adult with congenital heart disease.

Elective Pulmonary Valve Replacement for Severe Pulmonary Regurgitation in the Asymptomatic Patient

Physiological pulmonary valve regurgitation (PR) is a common finding in adults with normally structured hearts. Severe PR, however, is often the result of a prior surgical repair for various types of congenital heart disease. These include tetralogy of Fallot, congenital pulmonary stenosis, or in repair of congenital defects utilizing the Rastelli procedure. Commonly thought to be benign and well tolerated by the right ventricle (RV), various studies have demonstrated that the long-standing volume loading of the RV caused by severe pulmonary regurgitation can lead to a number of adverse effects that can significantly impact a patient's quality of life and survival.

Pathophysiology of Chronic Pulmonary Valve Regurgitation

Although significant PR may be seen in a variety of forms of repaired congenital heart disease, the effects of concomitant cardiac defects, cyanosis, or poor ventricular compliance may influence the RV's response to severe PR in various ways. Examining the RV response to isolated congenital pulmonary regurgitation (a rare form of congenital heart disease) is one way to assess the effects of chronic severe PR without the confounding effects of other pathology. In a review of 72 cases of congenital pulmonary valve incompetence, Shimazaki et al. found that only 6 % of patients had symptoms develop by the age of 20 years. By age 40, this number, however, had increased to 29 % and there were 3 deaths [1]. This study reinforces the concept that the RV can accommodate the significant volume overload of PR for a period of many years or decades; however, eventually the RV compensatory mechanisms fail, symptoms develop, and the risk of further morbidity and mortality increases.

The ability of the RV to adapt to the volume overload imposed by chronic, severe PR is influenced by the degree and duration of the PR and particular characteristics of the RV and pulmonary arteries [2]. These characteristics include the diastolic pressure gradient between the main pulmonary artery (PA) and the RV, the capacitance of the PAs, and the duration of diastole [3]. For example, at the time tetralogy of Fallot repair, the RV is hypertrophied and restrictive, the PA is often small with a low compliance, and the time in diastole is usually short due to high heart rates. These factors tend to limit the degree of PR. However, over time, the increase in RV stroke volume eventually leads to an increased diameter and capacitance of the PA; there is an increase

in RV compliance; and there is longer duration of diastole with the decreasing heart rate seen with aging. This process leads to a progressive increase in the degree of PR over time [3].

RV dilation due to severe PR may also dilate the tricuspid valve annulus and lead to significant tricuspid valve regurgitation. Tricuspid regurgitation may further add to the volume load on the RV and contribute to further dilation. RV dilation from volume overload has been associated with exercise intolerance, arrhythmias, and sudden cardiac death [4–6]. It has also been found to correlate with QRS prolongation. A QRS duration on a resting ECG of $\geq$180 ms has been shown to be a sensitive predictor of life-threatening ventricular arrhythmias [2, 7].

Need for Pulmonary Valve Replacement

Because of continued surgical and medical advances, there are an increasing number of adult congenital patients surviving into adulthood with severe pulmonary regurgitation and facing the effects of chronic volume overload on the RV. Because of the worsened morbidity and association with sudden cardiac death, many of these patients will undergo pulmonary valve replacement (PVR). Approximately 15 % of patients following tetralogy of Fallot repair will need PVR [4]. The perioperative mortality after PVR has been shown to be 1–4 % with a 10-year survival of 86–95 % [8]. PVR has been the treatment of choice for symptomatic patients. It has been shown to improve ventricular volumes, improve NYHA functional class [9, 10], stabilize the QRS duration, and in conjunction with intraoperative cryoablation, decrease the incidence of preexisting atrial and ventricular tachyarrhythmias [11].

Many adults with severe pulmonary regurgitation often report being asymptomatic. Unfortunately, for various reasons (fear of inducing complications related to their congenital heart disease or being given exercise restrictions earlier in life), many of these patients have learned to limit themselves. Although they may be able to perform their daily activities without difficulty, they often will be found to have poor exercise capacity when objective measures are used. The results of an exercise stress test can be useful in these patients who feel asymptomatic. The data obtained can objectively quantify a patient's exercise capacity and peak oxygen consumption. These results may indicate that a patient who feels asymptomatic may actually be functionally limited due to their heart disease.

The decision as to when to intervene on severe pulmonary regurgitation in the asymptomatic patient has been the subject of much controversy. In making this decision, one must have the knowledge of the natural history of severe pulmonary regurgitation and risk factors associated with poor clinical outcomes. The difficulty of balancing the risks posed by long-standing severe pulmonary regurgitation with the risks posed by surgical PVR and the lack of longevity of various bioprosthetic valves (possibly exposing the patient to multiple future surgeries) contributes significantly to this controversy.

When considering the timing of PVR in the asymptomatic patient, the physician's goals of intervention should include the reduction of RV size, its beneficial effect on the electrical instability and incidence of tachyarrhythmias [12], and improving the patient's overall prognosis. Given the association between RV dilation and eventual RV dysfunction with increased morbidity and mortality in patients with chronic volume overload caused by severe PR, the optimal time to perform PVR in the asymptomatic patient would seem to be prior to the point of irreversible RV damage. This irreversible damage may be due to scarring and fibrosis and prevent ventricular remodeling after PVR [9]. Therefore, this decision becomes an important balancing act of performing PVR prior to irreversible RV dysfunction and delaying the need for reoperation by not performing PVR too early.

Cardiac magnetic resonance (cMRI) is the current gold standard in assessing RV size and function due to its tomographic nature and three-dimensional reconstruction capabilities. The RV volumes are determined in post-processing analysis by tracing the contour of the RV

endocardium in contiguous ventricular short axis images in both systole and diastole. Each of these images is of a specified thickness, and the volumes of each short axis image are summed to reach the end-systolic and end-diastolic volumes. There are three issues related to tracing the contours that commonly arise that may lead to imprecision in tracing the RV endocardial borders. These include the lack of a clear border between RV outflow tract and main pulmonary artery, inclusion versus exclusion of RV trabeculations, and differentiation of the RV from right atrial blood pool at the atrioventricular junction [13]. Despite these potential limitations, when experienced cMRI clinicians perform the measurements, estimated RV volumes have good reproducibility. When two expert cMRI clinicians evaluated RV volumes in patients with congenital heart disease involving the RV, Walsh et al. found the variability for indexed RV end-diastolic volumes to be 3.2 % and 3.3 % for intra- and inter-observer comparisons, respectively [13].

cMRI is the focus of many studies evaluating the optimal timing of PVR. Although many of these studies included fairly small numbers of patients, the majority of these studies have demonstrated a size threshold at which the RV normalizes in size after PVR. Therrien et al. demonstrated that in 17 adults with repaired tetralogy of Fallot evaluated by cMRI before and after PVR, there was a significant decrease in RVEDVI of 163 ml/m^2 prior to PVR to 107 ml/m^2 after PVR, and that in no patients with a RVEDVI of $>$170 ml/m^2 or a RVESVI of $>$85 ml/m^2 prior to PVR were RV volumes normalized after surgery [14]. Dave et al. showed similar results. In this study, 39 patients had a valved conduit placed when the RVEDVI on cMRI exceeded 150 ml/m^2. Twenty-one of these patients had a cMRI 6 months postoperatively. Of the 21 patients who had a cMRI postoperatively, only 7 of these patients had normalization of their RVEDVI. These 7 patients' preoperative RVEDVI was significantly lower than the other 14 patients who had some improvement, but no normalization (170+/−21.1 ml/m^2 vs. 203.6+/−35.6 ml/m^2). Their data also showed that the group of patients who had the lower preoperative RVEDVI not only normalized their RVEDVI after PVR but also improved their LV ejection fraction, whereas the group with higher preoperative RVEDVI did not. The authors hypothesize that this is likely due to improved LV filling by restoring the septal shift toward the RV [15]. These studies are in concordance with a cMRI study performed in children, by Buechel et al., in which cMRI 6 months after PVR showed that the decreased RV volumes, RV mass, and normalization of RV volumes after PVR were related to the preoperative RVEDVI. They found that RV remodeling occurred when the RVEDVI was $>$150 ml/m^2, but none of the patients with a RVEDVI $>$200 ml/m^2 had normalization of their RV volume after PVR [16]. Van Straten et al. showed that in 16 patients who underwent PVR, their postoperative RVEDVI was significantly decreased compared to their preoperative RVEDVI (164.2 ml/m^2 to 112.7 ml/m^2), and their RVESVI decreased significantly after PVR from 93.7 ml/m^2 to 60.9 ml/m^2 6 months after PVR. There was also evidence of improved diastolic function late 22 months after PVR [17]. Finally, Vliegen et al. showed that in 26 adults after tetralogy of Fallot repair who underwent PVR for severe PR, there was a decrease in RV end-diastolic volume index (RVEDVI) from 166.8 ml/m^2 prior to PVR to 114.3 ml/m^2 after PVR, a decrease in RV end-systolic volume index (RVESVI) from 99 ml/m^2 prior to PVR to 66.3 ml/m^2 after PVR, and an increase in RV ejection fraction when corrected for regurgitation and shunting (25.2 % prior to PVR and 43.3 % after PVR) [18]. These studies demonstrate the importance of monitoring preoperative RV volumes by cMRI, as there seems to be a RVEDVI and RVESVI threshold after which the RV has irreversible damage, and its volume will not normalize after PVR.

Percutaneous Pulmonary Valve Implantation

Recently, percutaneous pulmonary valve implantation (PPVI) has become available and may be

an alternative to surgery for some patients [19]. In this procedure, the replacement valve is implanted through a catheter, which is inserted through the skin into the femoral vein and then advanced into the pulmonary artery [19]. This approach currently is used only in patients who have had previous treatment using an RV outflow tract conduit or a bioprosthetic valve. The procedure also is limited by available valve size, with patients previously treated with larger homografts or bioprosthetic valves often not being candidates [19–23]. Initial series of PPVI as treatment for pulmonary valve dysfunction show good short-term efficacy [19–23]. These series have shown that PPVI is associated with decreased RV systolic pressure, decreased RV outflow tract gradients, and decreased degree of pulmonary regurgitation. Importantly, PPVI has also been associated with improved RV volumes by cMRI as well as improved functional class as measured by cardiopulmonary exercise testing [19–23]. Unfortunately, at this point there is little evidence of long-term efficacy. This procedure is also associated with several well-recognized complications, particularly stent fractures. Other complications include bacterial endocarditis, valve migration, conduit rupture or tear, coronary artery compression, and complete heart block [20–23]. As the availability and experience with PPVI increases, the decision when to perform PVR in the setting of the asymptomatic patient with severe pulmonary regurgitation will likely also continue to evolve. Clearly, if multiple surgeries can be avoided and that this is a safe and durable option, its role in the treatment of pulmonary regurgitation will grow.

Summary

Because of the improving survival rates of children with congenital heart disease, there are an increasing number of adult congenital heart disease patients that live with severe PR. Longstanding, chronic, severe PR can be tolerated by the RV for years; however, eventually the volume overload can have deleterious effects on the RV leading to symptoms (exercise intolerance, progressive arrhythmias, and signs of RV failure), but the need and timing of PVR in asymptomatic patients has been the subject of controversy. Over the past decade, studies using cMRI to assess RV volumes and function have demonstrated that PVR improves RV size and function, but the RV's ability to remodel and normalize (thereby, hopefully, preventing some of the morbidities associated with a dilated RV) is dependent on pre-PVR volumes (such as RVEDVI). Because of the low operative mortality, and the advancements in PPVI, PVR based on RV volumes measured on CMR in asymptomatic patients is becoming a widely accepted practice in many large adult congenital centers. Future research may focus on advancements in imaging (such as echocardiographic strain and strain rate) that may better indicate the appropriate timing of PVR and whether the practice of PVR (both surgical and PPVI) impacts mortality. PPVI short-term efficacy is clear, but studies documenting long-term efficacy are still needed.

The Ross Procedure

The Ross operation, first performed in 1967, involves replacing the aortic valve with a pulmonary autograft (the patient's own pulmonary valve) and then reconstructing the right ventricular outflow tract with an aortic or pulmonary homograft [24]. This was first performed using the subcoronary technique in which the pulmonary sinuses of the pulmonary root are partially excised and the pulmonary valve was secured in the recipient's aortic root with two suture lines, one below and one above the aortic annulus, leaving the coronary artery orifices unobstructed [25]. Initially, the Ross operation did not gain support among surgeons. This was due to its technical complexity, early failure of the autograft due to its need to be adapted to the geometry of the native aortic root, and the need to replace the pulmonary valve with a homograft [26–28]. However, due to technical variations, the Ross operation gained popularity during the 1980s and 1990s. These variations included the aortic root

replacement technique, in which the aortic root is excised, the pulmonary root is sutured to the aortic annulus and ascending aorta, and the coronary arteries are reimplanted into the neo-aortic root [25]. The inclusion cylinder technique is similar to the aortic root replacement technique, but with this technique, the pulmonary root is placed inside of the aortic root [25]. With these variations in technique and potential advantages, such as low thrombogenicity and avoidance of anticoagulation, favorable hemodynamic profile, low endocarditis risk, and the potential for growth in children [24, 28], the Ross operation became the operation of choice for children and young adults who required aortic valve replacement in the 1980s and 1990s [29]. However, outcomes seen in some of the more recent long-term studies have caused some controversy regarding the Ross operation.

Mortality

Early, midterm and late survival rates for the Ross operation are excellent. Elkins et al. showed an operative mortality of 2.7 % [29], and Luciani et al. showed an in-hospital death rate of 1 % [27]. Sievers et al. demonstrated a 30-day mortality rate after the subcoronary technique of 0.6 %, and a 99 % survival at 1 year, 97 % at 5 years, and 94 % at 8 years [28]. Finally, David et al. found a survival rate at 15 years to be 96.6 % [25]. At the end of the first decade, the survival for patients after the Ross operation has been found to be similar to the general population. This is likely due to the low risk of valve- and cardiac-related deaths because of the autograft's hemodynamic and biological features [19]. Importantly, when the survival in adults patients who underwent the Ross operation (mean age 47.3 years) was compared to the survival achieved for a matched cohort of adults who underwent mechanical aortic valve replacement (mean age 48 years) with optimal self-management of anticoagulation therapy, there was no difference between the two cohorts at 10-year follow-up [30].

Autograft Dilation

Autograft root dilation is the most common adverse event late after Ross operation occurring in up to one-third of patients [31, 32]. In a study by Luciani et al., freedom from root dilation was 99 %, 65 %, and 42.8 % at 1, 5, and 7 years, respectively. Freestanding root replacement had significant increases at all aortic root levels with equalization of the sinuses, sino-tubular junction, and ascending aorta as an almost uniform finding, while the inclusion cylinder technique had reverse remodeling. Factors predictive of late root dilation were younger age, larger preoperative dimension of root, use of root replacement technique, absence of pericardial strip buttressing, and length of follow-up [33]. The presence of a bicuspid aortic valve has not been found to correlate with an increased risk for neo-aortic root dilation [33].

The dilation seen in the root replacement technique may be because the pulmonary root is intrinsically different than the aortic root. These structural differences include thickness of the media layer and the orientation and fragmentation of elastic fibers [32]. Structural changes in the neo-aortic root due to devascularization (causing ischemic injury) and subjection to systemic arterial pressures have also been noted. These include cystic medial necrosis, elastic fiber fragmentation, and deficiency of smooth muscle cells [28, 32].

Autograft dissection has been reported in the literature [31, 34]. The anastomotic suture lines of the autograft and the native aorta limit the extension of the dissection distally and proximally into the coronaries. Because the autograft is denervated, dissections can be painless. The time to intervene on a dilated root is not well described, but reoperation is generally indicated when the aortic dimension exceeds 55 mm, when there is moderate or severe valvular regurgitation, or in the presence of RVOT complications (such as homograft stenosis or regurgitation) [31]. The prevalence of root dilation and the possibility of rupture or dissection have caused some to advocate for a more aggressive approach by considering root replacement in the setting of

a severely dilated neo-aortic root. If the autograft valve is functioning well, valve-sparing root replacement has been described [31].

Valve Dysfunction

Aortic autograft valvular regurgitation has been reported to occur in 14 % of patients at 10 years after the Ross operation [27]. In a study by Elkins et al., the predicted numbers of patients with at least moderate autograft regurgitation increased from 3.3 % at 5 years to 7.9 % at 10 years and 21.5 % at 16 years in a cohort in which root replacement was performed in the majority of patients. Independent variables associated with the development of at least moderate aortic autograft regurgitation were time elapsed since operation, immediate postoperative regurgitation of grade 1 or higher, and the patient's age at the time of operation [35]. David et al. found a freedom from moderate or severe autograft regurgitation of 90 % at 15 years in a cohort in which the operative techniques of modified subcoronary implantation and aortic root inclusion were the primary techniques used. Preoperative regurgitation was the only predictor of late regurgitation [25]. Incidence of autograft dysfunction due to regurgitation affects a minority but increases over time and is more prevalent in patients with neo-aortic root dilation. This may be due to remodeling of the root, loss of the sino-tubular junction, and aortic sinus dilation [33].

Reoperation

The need for reoperation on the autograft after the Ross operation increases with time. In a study in which patients had the Ross operation using the root replacement technique, at 5, 7, and 10 years postoperatively, freedom from reoperation on the aortic autograft was 95 %, 80 %, and 75 %, respectively [36]. In a study of patients who had the subcoronary autograft and root inclusion procedure with 8-year follow-up, freedom from reoperation was 98 % at 7 years for the autograft and 97 % for the homograft [26]. David et al. found freedom from autograft reoperation to be 93 % at 15 years. The majority of these patients had the root inclusion and the modified subcoronary implantation techniques as their original operations [25]. In comparison, the median interval to reoperation of contemporary, stented aortic bioprostheses has been found to be 7.74 years in patients less than 40 years of age and 12.93 years in patients 40–60 years of age. Multivariable risk factors associated with reoperation following bioprosthetic aortic valve replacement were found to include age and concomitant coronary artery bypass grafting [37].

Reintervention on the RV outflow tract may also become necessary following the Ross operation. A study by Klieverik found the freedom from reoperation on the pulmonary homograft was 87 % at 13 years [38]. Pasquali et al. found that during a median follow-up period of 6.5 years (2.5–10.4 months), there was a 14 % rate of reintervention. Small RV outflow tract homograft size was the strongest predictor of RV outflow tract reintervention. Younger age at the time of the Ross was found to be a univariate predictor of RV outflow tract reintervention [39].

Summary

Since first performed in 1967, the Ross operation has gone through various modifications in technique which has led to resurgence in use. These three techniques each have advantages and disadvantages, and many factors are considered when deciding which technique is best for an individual patient. These include native aortic annulus diameter, presence of aortic regurgitation, and surgeon's preference. Because of the risk of autograft dysfunction and root dilation in patients with preoperative aortic regurgitation and root dilation, some now believe that the Ross operation is best suited for young adults with aortic stenosis and a normal aortic root size [25]. Studies have demonstrated that the Ross operation has excellent long-term survival and quality of life, but the potential for long-term

complications such as autograft dysfunction, root dilation, and reoperation (including pulmonary homograft intervention) exists. Therefore, it is clear that lifelong surveillance is necessary.

Stent Versus Surgical Repair of Coarctation of the Aorta in the Adult

Introduction

Coarctation of the aorta occurs in approximately 6–8 % of patients with congenital heart disease. Anatomically, coarctation of the aorta is typically a discrete stenosis of the proximal descending aorta. However, many anatomic variations exist, including long-segment stenosis and transverse arch hypoplasia. In addition to anatomic variation, clinical presentations can vary considerably. The majority of patients present in infancy or childhood with congestive heart failure, systemic hypertension, or a murmur. Adults most commonly present with systemic hypertension. Moreover, adult patients with native coarctation may have significant comorbidities, including bicuspid aortic valve disease, ascending aortopathy, left ventricular dysfunction, a vast network of collateral vessels, coronary artery disease, and intracranial aneurysms. Choice of optimal treatment for adults found to have a significant coarctation of the aorta is somewhat controversial due to a number of factors including anatomic variations of the coarctation as well as comorbidities [40].

Surgical Intervention

Surgical intervention for coarctation of the aorta has seen continuous refinement since first described by Drs. Crafoord and Nylin in 1944 [41]. Modifications of surgical techniques have included patch aortoplasty, end-to-end anastomosis, subclavian flap aortoplasty, interposition graft, and extra-anatomic bypass graft. Each technique has specific advantages, disadvantages, and long-term outcome profiles. The choice of procedure has depended on several variables, including the specific anatomy of the coarctation, the patient's age, the era, and the surgeon's preference.

The outcomes of surgical intervention for coarctation of the aorta have been well documented. Rothman reviewed 11 series, comprising 2,355 patients who underwent surgical repair between 1946 and 1994. The operative mortality in all series ranged from 3 % to 32 % [42]. Toro-Salazar and coworkers reported the outcome of 274 patients who underwent surgical repair between 1948 and 1976. Twenty patients (7 %) died in the immediate postoperative period [43]. Cohen et al. reported results for 646 patients who underwent surgical repair from 1946 to 1981. The perioperative mortality was 2.6 %, despite the early era in which many of the procedures occurred [44]. More recently, Forbes et al. reported no operative deaths in 72 patients who underwent surgical repair between June 2002 and July 2009 [45]. Difficulty arises in direct extrapolation of surgical results to the adult congenital patient since most large studies include infants, children, and adults. Estimated surgical mortality in the adult with coarctation in the current era is very low, probably about 1 %.

The long-term outcomes after surgical invention have been well described. Once again, Cohen et al. reported survival rates of 91 % at 10 years, 84 % at 20 years, and 72 % at 30 years. The 20-year survival rate was 91 % if surgery was performed by the age of 13 years and 79 % if surgery was at an older age. Of 571 patients with long-term follow-up, there were 87 late deaths at a mean age of 38 years [44]. In the Toro-Salazar and coworkers series, of the 252 survivors, 45 (18 %) died at a mean age of 34.4 years. The survival rate was 95 % at 10 years after surgery, 89 % at 20 years, and 82 % at 30 years. Mean age of the 252 survivors at follow-up was 40 years [43]. In both studies, causes of late mortality included coronary artery disease, sudden death, heart failure, stroke, and ruptured aortic aneurysm.

Catheter Intervention

More recently, transcatheter intervention has been successfully utilized to treat native coarctation. Balloon angioplasty was first described by Singer et al. in 1982 [46]. The addition of intravascular stenting to balloon angioplasty gained acceptance throughout the 1990s. Currently, a combination of balloon angioplasty and stent placement is considered the treatment of choice in most centers for recurrent coarctation following surgical repair. However, for the treatment of native aortic coarctation, controversy exists.

Initial trials comparing surgery to angioplasty for native coarctation demonstrated similar results when comparing mortality and immediate reduction in gradient. However, concerns remained for medium- and long-term complications of aneurysm and recoarctation. In 1993, Shaddy et al. compared balloon angioplasty and surgery results for treatment of native coarctation. On follow-up, aneurysms were seen only in the angioplasty group (20 %) and not in the surgery group (0 %). In addition, although not statistically different, the incidence of restenosis (peak systolic pressure gradient $\geq$20 mmHg) tended to be greater in the angioplasty group (25 %) than in the surgery group (6 %) [47].

In 2010, the Congenital Cardiovascular Interventional Study Consortium reported the results of the first prospective multi-institutional registry evaluating the short- and long-term effectiveness and safety of aortic coarctation stenting. A total of 302 patients were enrolled from 34 centers in the United States, Canada, Europe, and South America from 2000 through 2009. Aortic imaging was encouraged during the follow-up period to screen for late aortic wall injuries, with mean follow-up of 1.1 years and the longest follow-up being 4.8 years. Patients were distributed among native (55 %) and recurrent (45 %) coarctation, with a mean age of 15 years. There were no deaths associated with the procedure. Adverse events were reported in 5 % of the patients and included aortic wall complications, balloon rupture, stent migration, stent fracture, and femoral artery injury. No adverse event required surgical intervention. Overall, this study confirmed the short- and long-term safety and effectiveness of coarctation stenting for the treatment of native and recurrent coarctation of the aorta [48].

The first multicenter observational study evaluating acute and follow-up outcomes of surgery, stenting, or balloon angioplasty for the treatment of native coarctation of the aorta in children, adolescents, and adults was published by the Congenital Cardiovascular Interventional Study Consortium in 2011. Between June 2002 and July 2009, 350 patients from 36 institutions were enrolled: 217 underwent stent placement, 61 underwent balloon angioplasty, and 72 underwent surgery. All three arms showed significant improvement acutely and at follow-up in resting systolic blood pressure and upper to lower extremity systolic blood pressure gradient. Stent placement was superior to balloon angioplasty in reducing upper to lower extremity systolic blood pressure gradient acutely. Surgery and stent placement were superior to balloon angioplasty at short-term follow-up in reducing the upper to lower extremity systolic blood pressure gradient. Stent patients had shorter hospitalization than surgical patients (2.4 vs. 6.4 days) and fewer complications than surgical and balloon angioplasty patients (2.3 %, 8.1 %, and 9.8 %, respectively). The balloon angioplasty patients were more likely to encounter aortic wall injury, both acutely and at follow-up. Almost 44 % of patients treated with balloon angioplasty developed an aneurysm or dissection within 5 years of treatment. Overall, complication rates at 60 months follow-up were 25.0 % for surgery, 43.8 % for balloon angioplasty, and 12.5 % for stenting. Unplanned reintervention procedures were necessary in 5.5 % of the surgical group, 6.5 % of the balloon angioplasty group, and 4.1 % of the stent group. However, 16.1 % of the stent group had planned reinterventions, which were performed either because of a staged approach or secondary to patient somatic growth. Overall, this study demonstrates that stent patients had significantly lower acute complications compared with surgery patients or balloon angioplasty patients, although they were more likely to

require a planned reintervention. At short- and intermediate-term follow-up, stent and surgical patients achieved superior hemodynamic and aortic arch imaging outcomes compared with balloon angioplasty patients [45].

Recently, covered stents have become available. Covered stents were first used in 1999 to treat a young adult male with a residual coarctation of the aorta and an associated aneurysm [49]. Since then, an array of covered stents have become available for clinical use and include the covered Cheatham-Platinum (CP) stent (NuMED, Inc., Hopkinton, NY), the Jomed covered stent (Jomed International AB, Helsingborg, Sweden), the Advanta stent (Atrium Medical Corporation, Hudson, NH), the Braile stent (Braile Biomedical, São José do Rio Preto, Brazil), and various stent grafts [49]. Covered stents offer the advantage of excluding any stretch-induced wall trauma from the endoluminal aspect of the aorta, particularly in the catastrophic event of aortic rupture which has been reported [49]. Some covered stents (i.e., CP covered stent) have rounded edges that are considered less traumatic to the native vessel.

Covered stents are most commonly employed as a rescue treatment in patients with aneurysms, acute dissection, localized rupture, and bare-metal stent-related complications. Covered stents have also been used as primary treatment in patients with complex anatomy: long-segment coarctation, near interruption, tortuous aortic arch, or advanced age defined as >30 years of age. Over the past decades, there have been several studies on the use of the covered stent in the treatment of coarctation of the aorta [50–52]. The largest study to date has been the study by Tzifa et al. In this study, 33 covered stents were placed in 30 patients. The mean age of the patients was 28 years (range 8–67 years); by computed tomography or magnetic resonance imaging, all stents were patent and were in good position 3–6 months following implantation [50].

While the use of covered stents has gained widespread acceptance in other countries, the device has not been approved in the United States. As a result, novel approaches like applying a Gore-Tex covering to a bare-metal stent have been reported when covered stents were unable to be used [49]. There are currently two large studies underway in the United States designed to assess the use of the CP stent for the treatment of CoA. The first, entitled the Coarctation of the Aorta Stent Trial (COAST), is charged with evaluating its use in patients weighing at least 35 kg. The second study, COAST II (Covered Cheatham Platinum CP Stents for the Prevention or Treatment of Aortic Wall Injury Associated with Coarctation of the Aorta), addresses patients with clinical situations that pose a high risk of aortic wall injury during bare-metal stenting. These include extreme narrowing, genetic aortic wall weakness, and advanced age. Patients with nearly atretic descending aorta 3 mm or less in diameter, acute or chronic aortic wall injury (i.e., descending aorta aneurysm/pseudo-aneurysm, contained aortic wall rupture, and non-contained rupture of the aortic wall), advanced age (men and woman aged 60 years or older), and genetic syndromes associated with aortic wall weakening, such as Marfan Syndrome, Turner Syndrome, familial bicuspid aortic valve, and ascending aortic aneurysm, are included. Patient enrollment for both of these trials is completed and preliminary results are expected to be published in the near future [49].

Summary

With greater than 6 decades of experience with treatment of aortic coarctation, the optimal therapy continues to evolve. The studies clearly demonstrate that the mortality for treatment of coarctation of the aorta appears to be very low (<1 %) and comparable among surgical, balloon angioplasty and stent interventions. Additionally, acute relief of obstruction appears to be similar, but slightly favoring stent therapy. Unfortunately, comparison of intermediate- and long-term outcomes continues to be difficult. Long-term outcomes in surgical patients are currently measured in decades, whereas catheter-based long-term outcomes are measured in years. In addition, the modality of follow-up has

changed over the years and makes comparison difficult. Early surgical patients were followed clinically without routine imaging. Currently, greater emphasis is placed on follow-up imaging especially within the catheter-based intervention cohort. Furthermore, it is evident that with longer follow-up, regardless of technique, a risk for sequelae exists, including systemic hypertension, aortic aneurysms, recoarctation or stenosis, aortic valve disease, and risk of endocarditis or endarteritis. Finally, whether covered stents will limit these sequelae and what their role will be in the future remains unknown.

Conclusion

Increasing numbers of CHD patients are now surviving to adulthood. Although early interventions have transformed the outcome for these patients, many of them have ongoing problems that require tertiary cardiac care in adult life. Numerous studies over the past decade have increased our understanding of repaired congenital heart defects and have deepened our appreciation of potential late complications. The purpose of this chapter was to review three controversial topics in our current decade surrounding the management of the adult with congenital heart disease. By no means are these the only controversies in our current era. They only serve as examples and emphasize the need for continued research in the management of this complex group of patients in efforts to offer future therapy that can be tailored to the individual needs of the adult with congenital heart disease.

Congenital Heart Disease: A Life-Cycle Condition – Understanding Demographic Trends and Estimating Disease Burden

137

Ariane Marelli

Abstract

The adult congenital heart disease population is one of the fastest growing populations in cardiology. Strides in diagnosis and management of children born with congenital heart lesions have changed the demographic landscape of those born with congenital lesions. Previously almost exclusively in the domain of pediatric cardiology, congenital heart disease is now a life-cycle condition. The demographics of the congenital heart disease population are characterized by the distribution of age, sex, and disease severity. These are in turn determined by the *incidence* and *survival* of patients with CHD resulting in the *prevalence* of disease in adults as we observe it. *Modifying factors* of incidence and survival of CHD are both *primary* or biological affecting birthrates and *intervening* including surgical and medical care as well as health-care behavior.

This chapter will review cornerstone notions of the epidemiology of congenital heart disease and the impact of the epidemiology on the demographics of the congenital heart disease population in terms of age, sex, and severity of disease distribution.

Introduction

The adult congenital heart disease population (ACHD) is one of the fastest growing populations in cardiology. Strides in diagnosis and management of children born with congenital heart lesions (CHD) have changed the demographic landscape of those born with congenital lesions [1]. Previously almost exclusively in the domain of pediatric cardiology, CHD is now a life-cycle condition. Figure 137.1 provides a conceptual model bridging epidemiology and clinical care both of which determine demographics and prevalence of lesions carried from birth. This figure illustrates the demographic ***characteristics and determinants*** of the CHD population as well as the ***primary and intervening pathways*** impacting them. The demographics of the CHD population are characterized by the distribution of age, sex, and CHD disease severity. These are in turn determined by the ***incidence*** and ***survival*** of patients with CHD resulting in the ***prevalence*** of disease in adults as we observe it. ***Modifying factors*** of incidence and survival of CHD are both ***primary*** or biological affecting birthrates and ***intervening*** including surgical and medical care as well as health-care behavior.

This chapter will be divided in two parts. **Part I** will review cornerstone notions of the epidemiology of CHD. The aim is to familiarize the reader with principles of population science that provide the basis for understanding the changing demographics of CHD. This should facilitate critical thinking and understanding of the publications aimed at estimating the size of the CHD population. **Part II** will review the impact of the epidemiology on the demographics of the CHD population in terms of age, sex, and severity of disease distribution.

The data sources used below drew predominantly from population-based administrative and surveillance data sources that have been published in industrialized countries. Specifically data was presented from the Quebec CHD database in Canada, from the Center for Disease Control (CDC) in the USA, and from the European Congenital Anomalies Surveillance of Congenital Anomalies (EUROCAT) in Europe.

Part I. The Epidemiology of CHD

Figure 137.2 uses a beaker to visually illustrate how the size of a population during any given observation period can be quantified (Fig. 137.2: Panels A, B; Fig. 137.3). The size of population (prevalent cases) results from the difference between the number of cases entering (new or incident cases) and those exiting (surviving cases) during the duration of the observation. During the observation period in Panel A when mortality of CHD is high, the long vertical arrow indicates that majority of cases entering the cohort die. Thus, the number of surviving cases is small. During the observation period in Panel B, the mortality is reduced and the number of survivors has thus increased.

Figure 137.3 models these elements contributing to the observed changes in prevalence of ACHD showing the interplay between incidence and mortality over time. What has been observed in the last several decades is a rise in prevalence of adults with CHD that has been directly influenced by the incidence and mortality of CHD (Fig. 137.3). Prevalence is thus the product of incidence and survival (Fig. 137.1). What then among these elements have we been able to accurately measure and what does this tell us about future trends?

Birth Prevalence of CHD: The Most Accurate Proxy for Incidence of CHD

The incidence of CHD cannot be accurately measured because it would have to track the number of new cases of CHD in utero. Since this measurement cannot be systematically obtained, what has been reported is measurement and report of the number of observed *cases at birth* following in utero attrition due to spontaneous or planned pregnancy termination. What is really being reported then is prevalence at birth as the best possible proxy for incidence of CHD.

The reported birth prevalence of CHD varies widely depending on the lesions included, the

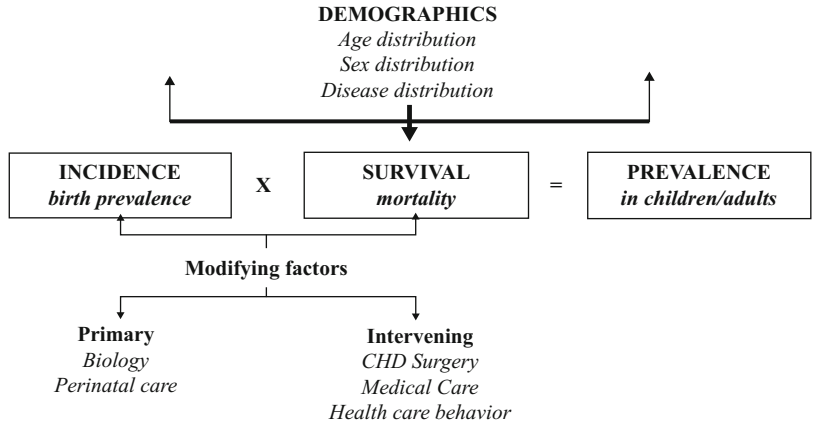

Fig. 137.1 Schematic representation of the demographics of the congenital heart disease population. The demographic characteristics of the CHD population (age, sex, and disease distribution) and their epidemiologic determinants (incidence, survival, and prevalence) and associated modifying factors (primary and intervening) are schematically illustrated

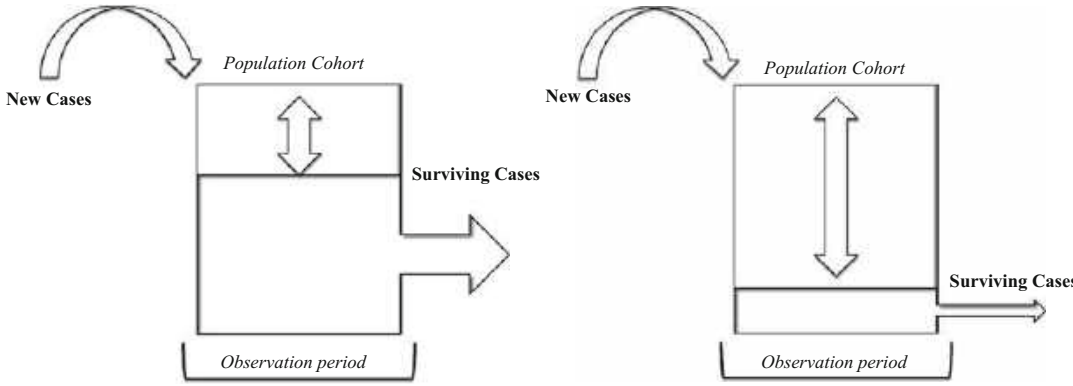

Fig. 137.2 Visual representation of the number of cases entering cohorts of the congenital heart disease population. Visual representation of the size of the CHD population based on new cases entering and surviving cases exiting the population cohort over an observation period when the number of surviving cases is small (*Panel A*) and when the number of surviving cases is large (*Panel B*)

surveillance method used, and the geographical area of source and accounts for the large variation in published rates. Most commonly the reported rates of birth prevalence cluster around 8/1,000 live births but vary between 4/1,000 and 50/1,000 [2]. In the USA the most recent report using data from the CDC has reported birth prevalence rates between 8 and 10/1,000 live births [3]. Variations in birth prevalence have also been analyzed using the EUROCAT registry that assembles data from 16 European countries. In 26,598 cases observed from 2000 to 2005, the prevalence at birth of CHD was reported up to 13/1,000 live births [4].

Using birth prevalence rates of CHD to estimate the number of ACHD patients is further limited by the assumption that birthrates have remained constant over time. Figure 137.1 draws attention to some of modifying factors impacting birth prevalence of CHD. Primary modifiers may be biologically determined or may act through prenatal care including pregnancy termination and prevention. Biological determinants of birth prevalence are related to the proportion of infants

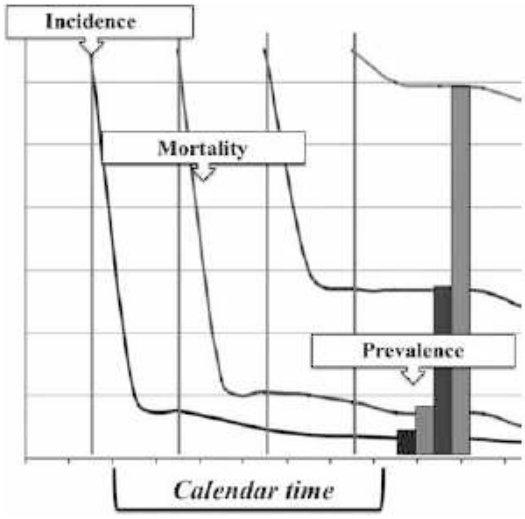

Fig. 137.3 Modeling the change in prevalence of congenital heart disease over time. Conceptual model illustrating the contribution of changing incidence and mortality to the growing prevalence of the congenital heart disease population over calendar time. Assuming the prevalence of CHD at birth remains constant, as mortality decreases over time, the number of surviving patients increases and the observed prevalence of CHD increases

born with chromosomal abnormalities associated with a higher frequency of CHD [5, 6]. The EUROCAT registry is one of the only data sources that examines the impact of perinatal mortality and pregnancy termination rates on birthrates of CHD in the same population [4]. In this registry, perinatal mortality due to CHD in the fetus is most commonly reported from .2 to .4/1,000 births. Not surprisingly, pregnancy termination rates susceptible to cultural trends varied more widely occurring in up to 1–1.3/1,000 births depending on the country [4]. Using the Quebec CHD database, the authors examined the impact of policy aimed at reducing birth defect rates at a population level. In a time-series analysis of 2,050 births with severe CHD of 1,247,623 infants born in Quebec from 1990 to 2004, it was observed that there was a significant decrease in birth prevalence of severe CHD from 1.68 to 1.57/1,000 before and after the introduction of mandatory folic acid supplementation in grain products [7].

Thus, prevalence at birth is the best proxy available to estimate incident or new cases of CHD born each year. As modeled in Fig. 137.3, even if assuming constant rates of birth prevalence of CHD, the next challenge is estimating sequential variations in death rates of CHD patients over the last several decades (cohort effect). Looking back at Fig. 137.1, the measurements and pitfalls of the first part of the prevalence equation have therefore been reviewed. What about survival, and what do we know of the change in survival over time?

Mortality: A Shift Away from the Young and Towards Adulthood

The reciprocal of survival is mortality. Although estimating survival itself over time with a uniform methodology is difficult, mortality of CHD patients has been measured. Using CDC data in the USA, the age-adjusted yearly infant mortality decreased 40 % from nearly 2.6 to 1.8/100,000 live births between 1979 and 1993 [8]. Although death from CHD remains the most common cause of infant mortality from birth defect in the USA, CDC data from 1979 to 1997 indicated that mortality due to CHD decreased most dramatically in children and infants 0–10 years of age from a rate of 100/100,000 to <1/100,000 population during the observation period [8]. Also, using CDC registry data, all age mortality rates in cyanotic and cyanotic CHD decreased 40 % in patients with tetralogy of Fallot and 60 % in those with VSD as observed between 1980 and 2005 [9]. Using the Quebec CHD database, in 8,123 patients followed for 1,008,835, we showed that median age of death in the CHD patients increased from 2 years of age in 1997–1998 to 23 years of age in 2004–2005 [10]. Thus, mortality from CHD changed from a bimodal distribution of death to a distribution skewed towards the elderly espousing that of the normal population (Fig. 137.4) [10].

As illustrated in Fig. 137.1, mortality is likely to be the element where the largest number of modifying factors manifest by way of intervening pathways was observed. Surgical and percutaneous intervention, medical care pertinent to diagnosis, and complications of CHD and

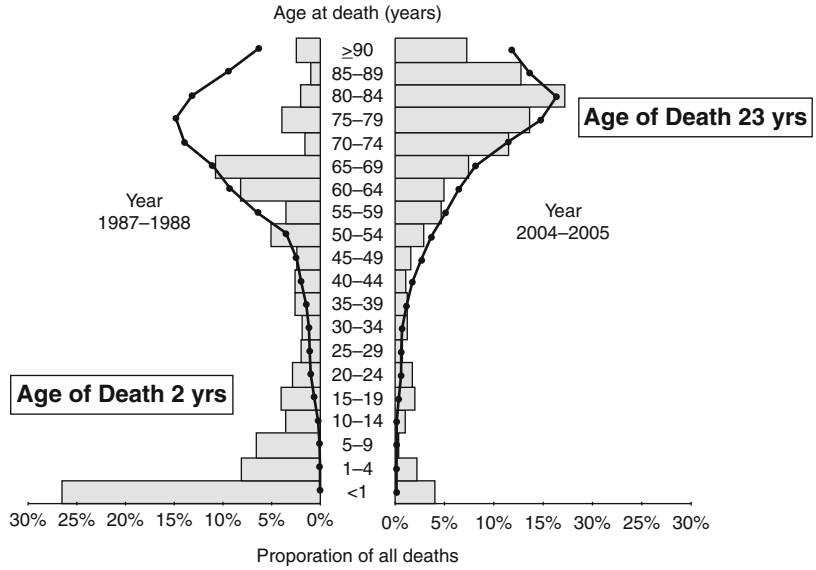

Fig. 137.4 Change over time in age distribution of death in the congenital heart disease population as measured by the proportion of deaths stratified by age. In l987–1988 the pattern of death in the CHD population was bimodal with a predominant peak in childhood during which time the median age of death for patients with severe CHD was 2 years. By 2004–2005, the peak in childhood had disappeared and the shape of the age distribution of death espouses that of the normal population (*dotted black line*). During this latter observation period, the median age of death in those with severe CHD increased to 23 years

health-care behavior as determined by insurance, access, and psychosocial determinants have all made significant contributions to the change in mortality of CHD over time [11].

Thus, going back to Fig. 137.3, the chronological decrease in mortality is expected to result in a sequential increase in survival rates contributing to an increasing pool of prevalent CHD patients. From an epidemiologic perspective, as illustrated in Fig. 137.1, the product of incidence and survival is prevalence. What then have we observed on the changing prevalence of CHD on a population level? Specifically we turn our attention to the prevalence of the CHD population across the life span.

Prevalence of CHD Throughout the Life Span

The challenge in measuring prevalence in children and adults beyond birth is obtaining a meaningful denominator. The number of CHD patients can be counted in various jurisdictions, but a prevalence rate requires the judicious choice of denominators. To the author's knowledge, the Québec CHD database is one of the only data sources that attempt a prevalence estimate of CHD in the general population [1]. Where health insurance is universal and health services are tracked using a single unique identifier throughout an individual's life, the authors measured the prevalence of CHD in children, adults, and overall in the same population (Fig. 137.5). In a population of 7,357,029 in Québec in the year 2000, the prevalence of CHD in patients 0–18 years of age was 11.89/1,000 children and 4.09/1,000 adults with an overall prevalence of CHD across the life span of 5.78/1,000 in the general population [1]. The estimated prevalence in children is higher than published estimates of prevalence at birth, but this is not surprising if considering the number of cases of CHD that can be detected after birth, over an observation period of up to 18 years and particularly with the advent of cardiac ultrasound since the mid-1980s. Although the prevalence rates are higher in

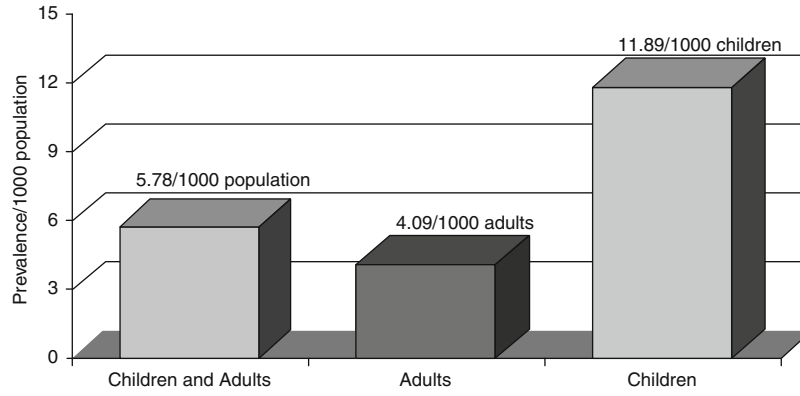

Fig. 137.5 Prevalence of congenital heart disease in the general population of Québec in 2000. Prevalence rates of CHD are reported overall, in adults and in children measured in the same population in the same year

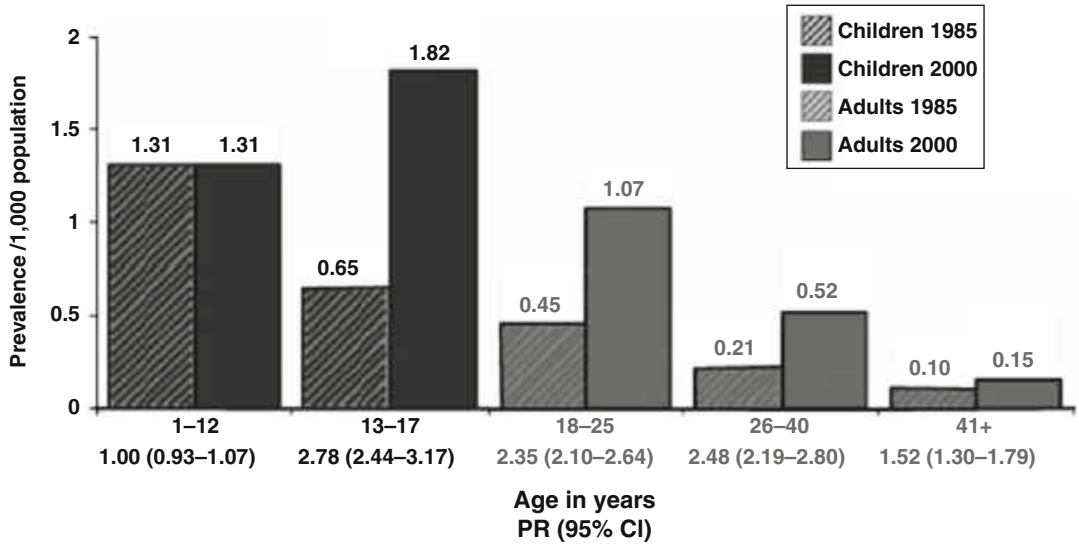

Fig. 137.6 The change in prevalence of congenital heart disease (CHD) between 1985 and 2000 stratified by age. On the y-axis the prevalence rate is expressed per 1,000 population. On the x-axis, the age strata are shown with the change in prevalence ratios (*PR*) and 95 % confidence intervals between 1985 and 2000. The increase in PR is significant in all age groups above age 12, but the greatest increase occurs in those 13–25 years of age

children than adults, since there are more adults than children in most industrialized nations, the absolute number of adults with CHD is now at least equal to the number of children with CHD. In the same study, it was showed that the prevalence of severe CHD increased by 22 % in children and 85 % in adults from 1985 to 2000 [1]. This differential rise in children and adults over the same observation period is less likely to be influenced by ascertainment using cardiac ultrasound as there is no reason to suspect that adults had more access to ultrasound diagnosis than children in the same jurisdiction. When the data was stratified for the increase in prevalence by age group, as shown in Fig. 137.6, it was seen that the largest increase in prevalence ratios over time occurred in those 13–18 followed by those 18–25 years of age [1]. It is therefore expected that a further increase occurred in the number of CHD patients entering adult cohorts in the last decade.

Can the Burden of CHD Be Estimated: What Are the Numbers?

In 2000, the total number of adults living with CHD in the USA was estimated to be 800,000 with the estimated number of children living with CHD being 600,000 [11]. There are no population-based longitudinal CHD data on children, adolescents, and adults living with CHD. Based on Canadian data from 1990 to 2000 [12] extrapolated to US Census data in 2010, it is estimated that 2–3 million people of all ages may potentially be living with CHD in the USA in 2010 [13]. The estimated number of children living with CHD is between 975,000 and 1.4 million, while the estimated number of adults is between 959,000 and 1.5 million [13].

Figure 137.7 shows the index of Canadian data to the age distribution of populations by continental areas based on World Health Organization data [14, 15]. As can be seen in Fig. 137.7, Panel A, there are expected to be over 20 million children with CHD worldwide who are less than 15 years of age using a prevalence rate of 11/1,000, which is probably conservative given the higher rates of consanguineous marriages in developing compared to non-developing countries [16]. In Fig. 137.7, Panel B, the prevalence of CHD in children and adults to the age distribution of the respective continental areas is indexed. As can be seen in industrialized regions where there are more adults than children in the general population such as Europe, the USA, and Canada, the number of adults with CHD is expected to be at least equal to or to exceed the number of children. Although this calculation is limited by the absence of measured prevalence that is region specific worldwide, it allows the estimation that the global burden of CHD is substantial.

Thus, where exact survival estimates are unavailable, a direct *calculation* of the product of incidence and survival (Fig. 137.1) cannot be obtained. Nonetheless, it is possible to *observe* the changing prevalence of CHD (Fig. 137.3) in different age groups where population-based denominators are available.

Part II. The Demographics of CHD: Impact of Epidemiology

The Aging of the CHD Population

As mortality shifts away from the young and towards adults (Fig. 137.4), the median age of those alive with CHD has increased. Figure 137.8 illustrates the increase in median age of patients who are alive with severe CHD. In 1985 the median age was 11 years (IQR 4,22), while in 2000, the median age was 17 years (IQR 10,28). At the other end of the spectrum, the authors analyzed 3,239 geriatric ACHD patients from 1990 to 2005 [1]. In 2005, the prevalence of ACHD was 3.7 per 1,000 in the elderly adults [17]. Using 1990 as a reference, the prevalence remained constant in the elderly, whereas it increased in nonelderly adults [17]. As the population ages, what is known about the sex distribution of ACHD adults?

A Predominance of Females in Adults with CHD?

Sex distribution in the CHD population has received relatively little attention. In Canada in over 45,000 adults with CHD, females accounted for 57 % of patients, a proportion which was significantly higher than the predominance of females observed in the general population [1]. The prevalence was 4.55 per 1,000 for females compared to 3.61 per 1,000 in males (Fig. 137.9). Consistent with these findings, using death registry data in 11,040 adults in the USA, the CDC demonstrated lower mortality rates in females with CHD compared to males [18]. Potential causes of a shift in demographics towards a predominance of females in the ACHD population include milder lesions in females born with CHD, differences in mortality related to CHD surgery, or sentinel effects related to a decrease in the proportion of males in the general population of industrialized nations [19]. Using Healthcare Cost and Utilization Project (HCUP) data in the USA, this author analyzed the KIDs' Inpatient Database in 2000,

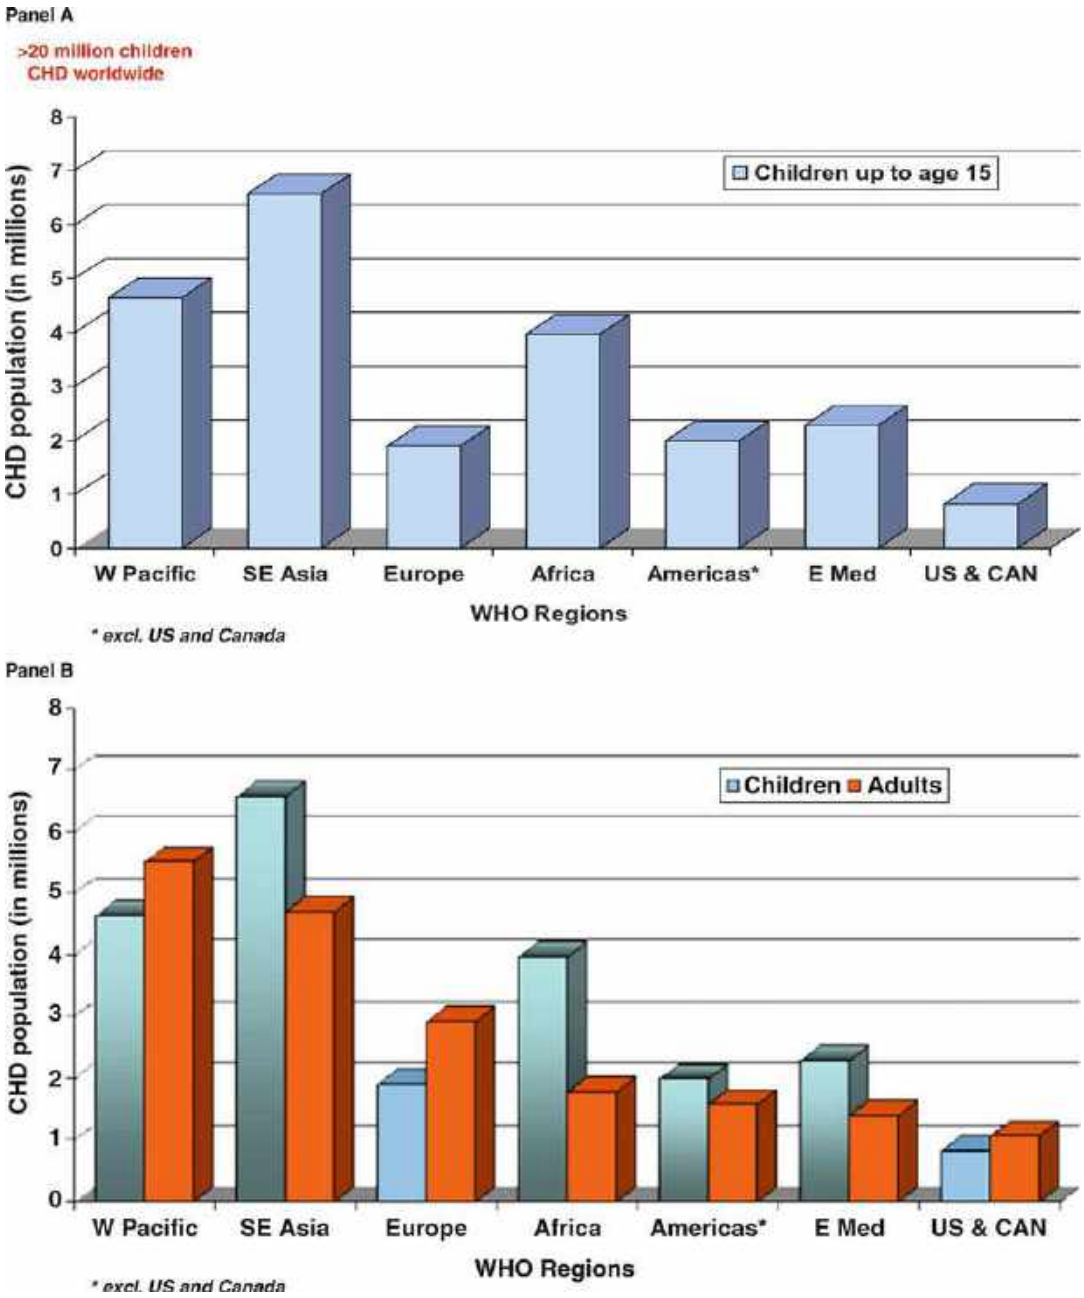

Fig. 137.7 *Panel A*: The expected number of children with CHD worldwide who are less than 15 years of age using a prevalence rate of 11/1,000. *Panel B*: In industrialized regions where there are more adults than children in the general population such as Europe, the USA, and Canada, the number of adults with CHD is expected to be at least equal to or to exceed the number of children

2003, and 2006 which samples pediatric discharges, up to 20 years of age in 38 US states, and showed that 55 % of all children having surgery were males and males were more likely to have high-risk procedures [19]. This is consistent with the observation that the most common CHD lesion, atrial septal defect, has a higher frequency in females while conotruncal anomalies such as

transposition of the great arteries are more common in males [20].

The interplay between factors impacting the sex distribution of the CHD population at birth and during adulthood is illustrated in Fig. 137.10. A predominantly female ACHD population is likely to result in increased transmission rates of CHD to offspring. The effect will be further magnified if surviving adult females are less likely to have severe disease both because of biologically driven distribution of lesions at birth and potential differences in mortality during adult years. Thus, the proportion of females and the disease distribution of CHD among them may result in *increasing* numbers of patients with CHD in the future.

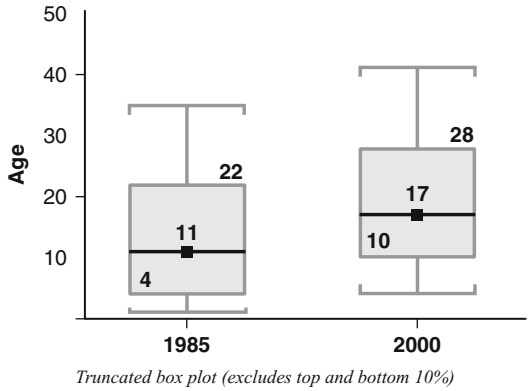

Fig. 137.8 Age of those alive with congenital heart disease. The increase median age of those alive with severe CHD increasing from 11 to 17 years from 1985 to 2000

On the other hand, these trends may be offset by CHD prevention and pregnancy termination as discussed above in the context of prevalence of CHD. We have seen that grain fortification may decrease the birth prevalence of severe defects [7]. Voluntary or involuntary pregnancy termination may also result in decreasing rates of infants with severe CHD at birth. It is interesting to speculate then that a larger proportion of surviving healthy females with less severe lesions, in addition to prevention and pregnancy termination of fetuses with severe lesions, will conspire to decrease the number of patients with severe CHD from one generation to the next. From an evolutionary point of view, this would be consistent with biology's natural intelligence. What then do we know about the distribution of disease severity in the ACHD population at the current time?

Distribution of Disease Severity in ACHD Patients

There continues to be debate about what proportion of the ACHD population has severe or complex CHD. As seen above, this number is subject to change over time due to factors as outlined in Fig. 137.1, and in all probability it is likely to evolve in the coming decades. The nature of the debate results at least in part from the interdependence between *advocacy* and *data*. There is a need for the numbers required for our

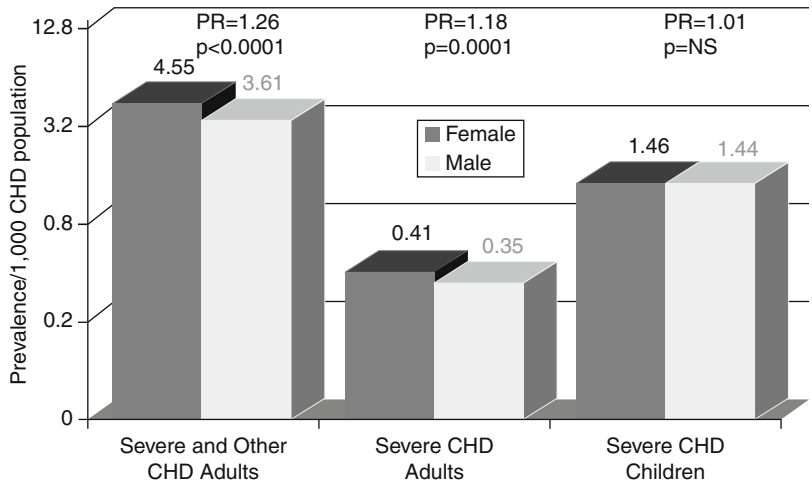

Fig. 137.9 Sex distribution in the congenital heart disease population. Difference in prevalence between females and males with CHD per 1,000 population in adults and children. Although there is no significant difference in the prevalence ratio (*PR*) between females and males in children, there is a predominance of females among adults with severe and other forms of CHD

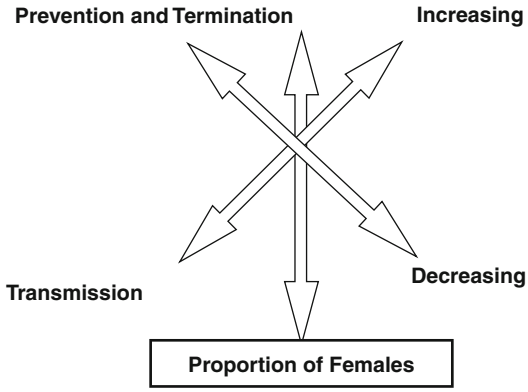

Fig. 137.10 Interplay of factors affecting the prevalence at birth of congenital heart disease. This diagram illustrating the interplay of the factors that can result in increasing or decreasing birth prevalence of CHD in future generations. With a higher proportion of females, the increasing transmission rates may result in increasing prevalence, while prevention and pregnancy termination may have the opposite effect thereby decreasing the prevalence of CHD

advocacy platforms to move us forward in order to overcome the existing limitations of the data currently available. One cannot occur without the other. In addition, the language of this debate suffers from *definitional* and *methodological* uncertainty.

The definition of disease severity and the question of who should be followed in ACHD centers are related but are different and often used interchangeably. The first is traditionally based on anatomy and physiology, the second is based on health services requirements. The definition of the *severity of CHD* has undergone several modifications over the last 70 years [20, 21]. In children severe or complex CHD has been linked with cyanosis. The authors have previously defined "severe" CHD as that which has the highest probability of being associated with cyanosis at birth. For adults, during the 32nd Bethesda conference, lesions were classified as "complex," "moderate," or "simple" based on a combination of anatomy and surgical interventions [11]. Although it is generally agreed that ACHD with lesions of great complexity should receive specialized services [11], making recommendations for those with mild and moderate disease is thus more problematic. For example, when looking at surgical trends in ACHD patients between 1990 and 2000, the fastest growing segment of patients requiring interventions were those classified as having "moderate" disease as defined at the 32nd Bethesda conference [22]. Not surprisingly, with evolving percutaneous procedures paralleling a growing need to *prevent* rather than to treat complications, specialized ACHD care may need to be delivered to a wider range of ACHD patients.

Despite these limitations, the proportion of ACHD patients having complex or severe disease is one of several important metrics of disease burden. The proportion of ACHD patients with complex or severe lesions has been *estimated* and *measured* [1, 2, 11, 23] and are summarized in Table 137.1. Estimates are based on prevalence at birthrates with assumptions about survival. The range of reported estimates of adults with CHD of great complexity varies from 5 % to 14 % depending on if the assumption is made that no patients with severe CHD at birth are treated or if all are treated. Using estimates of survival by cohort and the Bethesda disease severity classification, an approximate 15 % of adults are expected to have lesions of great complexity, while those with moderate lesions were estimated to account for approximately one-third of patients. Using the general population as the denominator, we measured a proportion of 9 % of ACHD patients with severe disease as defined with administrative data sources.

Using *birth prevalence* rates CHD requiring referral for specialized care, the NERCP determined that in 1976 there were 2.4 NERICP infants per 1,000 live births identifiable in the New England states referred for definitive treatment [20]. It is reasonable to suppose that these infants represent the sickest children from that era. Using 2000–2005 as a measurement period, the EUROCAT registry identified between 2 and 3/1,000 infants who had severe and moderately severe CHD lesions at birth [4]. Accepting that the birth prevalence of CHD is 8–10/1,000, this suggests that up to 25 % of infants born with CHD require early attention.

It would therefore be reasonable to suppose that the proportion of adults with advanced

Table 137.1 Estimated and measured proportion of patients with complex or severe CHD in the ACHD population

	Complex or severe CHD
Estimated (assuming all treated) Hoffman et al. 2004 [23]	14 %
Estimated (assuming none treated) Hoffman et al. 2004 [23]	5 %
Estimated Warnes et al. 2001 [11, p. 116]	15 %
Measured in the general population Marelli et al. 2007 [1]	9 %

forms of heart disease is between 10 % and 25 % depending on the method of estimation, measurement, and jurisdiction. The limitations of this statement underscore the need for more uniform disease severity definitions, based on anatomy *and* health services utilization across the life span as well as measurement-based studies in the USA.

Summary and Future Directions

Prevalence at birthrates is the best proxy available to estimate incident or new cases of CHD born each year. Available population data from industrialized nations suggest that birthrates of CHD are between 8 and 10/1,000 live births with CHD patients requiring intervention at an early age accounting for up to 25 % of these. Ultimately, disease distribution in adults is determined disease distribution at birth and survival. The proportion of adults with severe or complex CHD is probably between 10 % and 25 %.

The sex distribution of the CHD population at birth and during adulthood will impact future trends in the total number of patients with CHD as well as the sex and disease distribution of CHD in generations to come. This is likely to be influenced by preventive measures aimed at decreasing congenital malformations in the fetus and variations in laws governing pregnancy termination.

Where exact survival estimates are not available, the closest approximation remains mortality. Using CDC data in the USA, infant mortality due to CHD, death from CHD, and death from specific cyanotic and acyanotic lesions have been shown to consistently decrease between 1979 and 2005. Using Canadian data the authors observed a shift in mortality away from the young and towards older adults. Thus, the pediatric CHD population is aging with the median age of those with severe disease on the cusp of adulthood. At the other end of the spectrum, there are sufficient numbers to turn our attention to geriatric ACHD patients, perhaps with more simple forms of CHD but with a growing burden of acquired disease.

Measuring the prevalence of CHD across the life span remains a challenge. These authors observed a significant rise in the prevalence of severe CHD in adults compared to children consistent with the notion of increased survival and observed decrease in mortality of the CHD population. Extrapolating Canadian data to the USA, it is estimated that 2–3 million people are living with CHD in the USA of which adults constitute at least half.

The unique needs of this population center around lifelong comorbidities. Using the Quebec CHD database, we have documented the impact of ongoing disease burden including atrial arrhythmias [24], pulmonary hypertension [25], and repeated need for interventions [26] resulting in significant increases in health services utilization during childhood [27], transition years [28], and adulthood [29] extending into the geriatric populations [17] which are at the crossroads between congenital and acquired lesions. The demographics of this population will continue to evolve requiring a growing need for expertise CHD that crosses age groups and spans general and subspecialty care. The trends in long-term outcomes and health services utilization are an important departure point for studies measuring and improving quality of care for these patients. Studies are needed to generate robust estimates of the global burden of CHD in industrialized and nonindustrialized countries.

Eisenmenger Syndrome and Other Types of Pulmonary Arterial Hypertension Related to Congenital Heart Disease

138

Konstantinos Dimopoulos, Matina Prapa, and Michael A. Gatzoulis

Abstract

This book chapter summarizes the pathophysiology, clinical presentation, and management of adult patients with congenital heart disease and pulmonary arterial hypertension with an emphasis on differences between congenital heart disease-related and other types of pulmonary arterial hypertension. Eisenmenger syndrome, the extreme manifestation of pulmonary vascular disease in congenital heart disease, is a progressive multi-organ entity which impacts the quality of life and survival of affected patients. Over the past few years, disease-targeting pulmonary arterial hypertension therapies have become available and can be administered to patients with congenital heart disease, despite limited available evidence. Supportive measures remain key to the management of Eisenmenger patients with an aim of reducing symptoms and treating or preventing related complications. Regular follow-up of these patients is essential in specialist centers with expertise in both congenital heart disease and pulmonary arterial hypertension due to the syndrome's complex pathophysiology.

Introduction

Despite recent advances in the diagnosis and management of congenital heart disease (CHD), 5–10 % of adult patients develop pulmonary arterial hypertension (PAH) [1, 2]. PAH, in turn, impacts the quality of life and the survival prospects of these patients, especially those who develop near-systemic pulmonary arterial pressures and cyanosis (Eisenmenger syndrome) [1]. Improved understanding of the pathophysiology of PAH along with the development of new oral disease-targeting therapies is currently leading to improved care of these patients.

Eisenmenger Syndrome: Definition, Pathophysiology, and Differences from Other PAH Etiologies

Eisenmenger syndrome is the extreme manifestation of PAH associated with CHD and consists of pulmonary hypertension in the presence of reversed or bidirectional shunting and cyanosis. Shunting may occur at different levels and associated defects can be divided into pretricuspid, i.e., atrial septal defects (ASDs), or post-tricuspid, i.e., nonrestrictive ventricular septal defects (VSDs), patent ductus arteriosus (PDA), and aortopulmonary windows (Figs. 138.1 and 138.2). Large uncorrected communications between the systemic and pulmonary circulation result in increased pulmonary blood flow, which over time leads to pulmonary obstructive arteriopathy and increased pulmonary vascular resistance. When pulmonary vascular resistance equals or exceeds systemic vascular resistance, left-to-right shunting becomes bidirectional or reversed and Eisenmenger syndrome is established.

Structural alterations of the pulmonary vascular bed in Eisenmenger syndrome start in early childhood due to persistent exposure of the pulmonary circulation to high pressure and flow. Typical histopathologic changes include intimal proliferation, medial hypertrophy, and "plexiform lesions" of the medium and small-sized muscular pulmonary arteries. The exact mechanism behind the development of PAH in CHD remains unknown but is likely multifactorial. Vasoconstriction, proliferative, and obstructive remodeling of the pulmonary vascular bed, inflammation, and thrombosis all appear to be involved [2]. As discussed later, only three molecular pathways implicated in the above processes have been successfully targeted by PAH-specific therapies to date: the endothelin, nitric oxide, and prostacyclin pathways.

The rate of progression of pulmonary arterial disease in CHD varies according to the type and size of the defect [3]. Large VSDs and PDAs expose the pulmonary circulation to high pressures and flows and are more likely to induce early severe pulmonary vascular disease (Fig. 138.1). Large ASDs, on the other hand, can also cause PAH but do so at a much slower rate and rarely does pulmonary arterial pressure reach systemic levels. Occasionally, patients with an ASD can present with severe PAH, which may suggest a different genetic or other type of predisposition to the disease [4].

Patients with previous repair of CHD may also present with various degrees of PAH. This can be secondary to late repair of the defect, when pulmonary vascular disease was already established, or residual defects. Occasionally CHD patients may present with PAH for no obvious reason (e.g., after atrial switch repair for transposition of great arteries). Finally, patients with complex pulmonary atresia and multiple aortopulmonary collaterals often develop segmental PAH, affecting segments of the lung perfused by large collateral arteries or oversized Waterston or Blalock-Taussig shunts.

In the Venice classification of PAH, patients with CHD are classified together with idiopathic PAH (iPAH) and PAH related to systemic diseases [2]. However, CHD-related PAH and especially Eisenmenger syndrome differ significantly from other types of PAH in terms of cardiac anatomy, physiology, clinical presentation, and natural history, despite

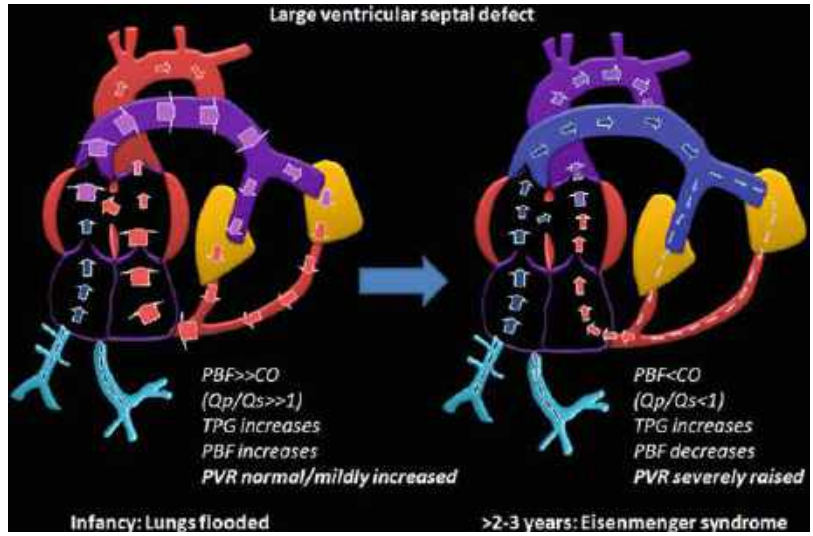

Fig. 138.1 Development of Eisenmenger syndrome in a large ventricular septal defect (Drawn according to Rudolph A.M. [71]). Abbreviations: *PBF*: pulmonary blood flow; *Qp*: pulmonary blood flow; *Qs*: systemic blood flow; *TPG*: transpulmonary gradient; *PVR*: pulmonary vascular resistance *CO*: cardiac output.

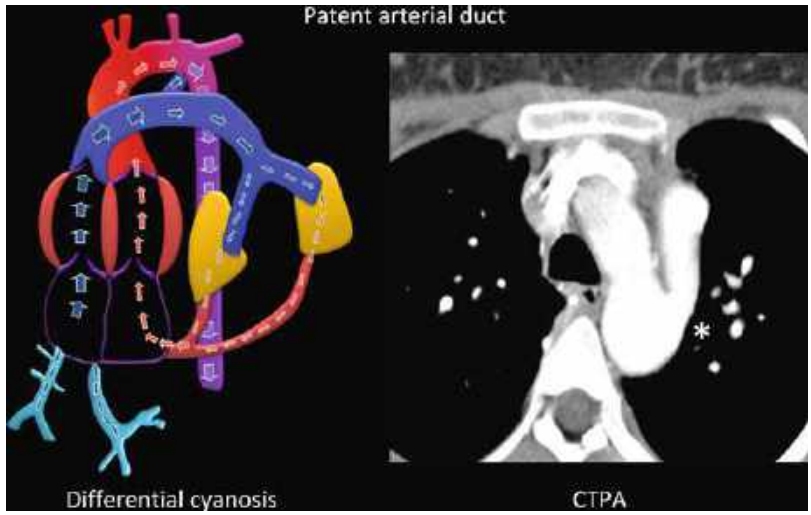

Fig. 138.2 Schematic representation of Eisenmenger patent ductus arteriosus (*PDA*). The right-to-left shunt at the level of the isthmus of the aorta results in differential cyanosis, and thus physical examination and measurement of saturations in the toes is essential in these patients. Moreover, assessment of Qp:Qs is complicated by the location of the shunt, visualized by computed tomography pulmonary angiogram (*CTPA*) on the right side of the panel; the asterisk denotes the communication between the distal aortic arch and the left pulmonary artery

similarities in the pulmonary anatomical findings (Table 138.1) [5]. These differences should be taken into consideration both when caring for Eisenmenger patients and designing or interpreting clinical trials.

One of the most important distinctions between Eisenmenger syndrome and other types of PAH is the nature of the right ventricular response to elevated pulmonary pressures. While right ventricular dysfunction is a major contributor to the adverse prognosis of patients with other types of PAH, the right ventricle in Eisenmenger syndrome is typically able to sustain an elevated afterload over much longer

Table 138.1 Differences between idiopathic pulmonary hypertension (PAH) and Eisenmenger syndrome

Differences	Eisenmenger syndrome	Idiopathic PAH
Clinical		
Perception of limitation	Underestimation as present from childhood	No underestimation
Systemic complications	Common	Uncommon/late
Physiological		
RV response	Often preserved (VSD) and relatively stable RV function with typical hypertrophy in post-tricuspid defects	RV dilatation with rapid deterioration in systolic function
Cardiac output	Sustained via R-L shunting	Significantly reduced
Cyanosis	Typical, often severe at rest and especially on exercise, associated secondary erythrocytosis	With low cardiac output ± PFO/ASD, rarely severe at rest, rare hematologic manifestations
RA pressures	May rise also due to causes independent of PAH (e.g., intracardiac communication, valve disease)	Increased with decompensation
Left-sided myocardial/valve disease	Common (e.g., univentricular heart, AVSD)	Rare until functional TR develops
Prognosis		
Survival after diagnosis	Decades	Limited to few years without therapies
Associated genetic syndromes	Common (e.g., Down syndrome)	None
Transplantation	Slow progression, unsuitable candidates due to systemic complications and complex cardiac disease	Rapid progression, likely to benefit

Abbreviations: *ASD* atrial septal defect, *AVSD* atrioventricular septal defect, *PAH* pulmonary arterial hypertension, *RV* right ventricle, *R-L* right to left, *PFO* patent foramen ovale *RA* right atrium; *TR* tricuspid regurgitation; *VSD* ventricular septal defect

periods of time [6]. The response of the right ventricle to CHD-related PAH varies according to etiology: in the most common form of Eisenmenger syndrome secondary to a large VSD, the right ventricle adapts to the rise in pressure through hypertrophy and preservation of a "fetal-like" phenotype [7, 8]. However, in Eisenmenger ASD the response of the right ventricle resembles that of iPAH, with dilation and progressive, marked systolic dysfunction. This resemblance to iPAH, and the "disproportionate" response of the pulmonary circulation to an atrial communication, raises questions as to whether the PAH observed is secondary to the cardiac defect or a coexisting condition (i.e., iPAH with coexisting ASD). Against a mere coexistence of the two conditions is the fact that patients with Eisenmenger ASDs have a better prognosis compared to iPAH.

Another major point of divergence between the Eisenmenger syndrome and other forms of PAH is the presence and extent of cyanosis. While cyanosis can be present in iPAH and other forms of PAH, especially with a coexisting atrial communication (patent foramen ovale or ASD), it is not as common or as severe as in Eisenmenger syndrome and is usually the result of low cardiac output. Cyanosis in CHD-related PAH results from significant right-to-left shunting at rest and especially during exercise. This results in significant long-standing hypoxia, an increase in ventilation/perfusion (V/Q) mismatch and physiological dead space, and contributes to the marked ventilatory inefficiency and exercise intolerance characteristic of

the Eisenmenger syndrome. Shunting, however, contributes to the maintenance of cardiac output at rest and especially during mild-moderate exercise.

Clinical Manifestations of CHD-Related PAH and Eisenmenger Syndrome

Common manifestations of PAH of any etiology include marked exercise intolerance with dyspnea and fatigue. The clinical manifestations of PAH in CHD, however, vary significantly according to the type and severity of the underlying cardiac lesion, patient age, prior repair or palliation, and the magnitude and direction of the shunt (Fig. 138.3). Patients with Eisenmenger syndrome may also have a different perception of their symptoms compared to those with iPAH, due to the later onset and absence of prior disease in the latter. In Eisenmenger syndrome, exercise limitation is present from childhood and leads to chronic adaptation of everyday activities to a lower intensity. Adult patients may remain clinically stable and report minimal exercise limitation, but when interrogated on their activities, they are typically found to avoid strenuous efforts and tend to perform activities at a slower pace than the average individual [9–11]. Therefore, assessment of functional class can be difficult.

Long-standing cyanosis in patients with Eisenmenger syndrome results in a high prevalence of peripheral organ dysfunction, such as renal and liver disease, and multiple systemic complications, which may also manifest clinically and independently affect prognosis, as discussed below (Table 138.2).

Chronic cyanosis is typically associated with significant hematologic changes such as secondary erythrocytosis, a physiological adaptation to chronic hypoxia aimed at a compensatory increase in tissue oxygenation. This is an isolated rise in red cell blood count due to increased erythropoietin production and should not be confused with polycythemia rubra vera, as they do not share the significantly increased predisposition of thrombosis characteristic of polycythemia. Venesections are, thus, very rarely required in patients with secondary erythrocytosis.

Patients with Eisenmenger syndrome are, however, at an increased risk for both bleeding and thrombosis, imposing important therapeutic dilemmas as discussed later. Hemoptysis is

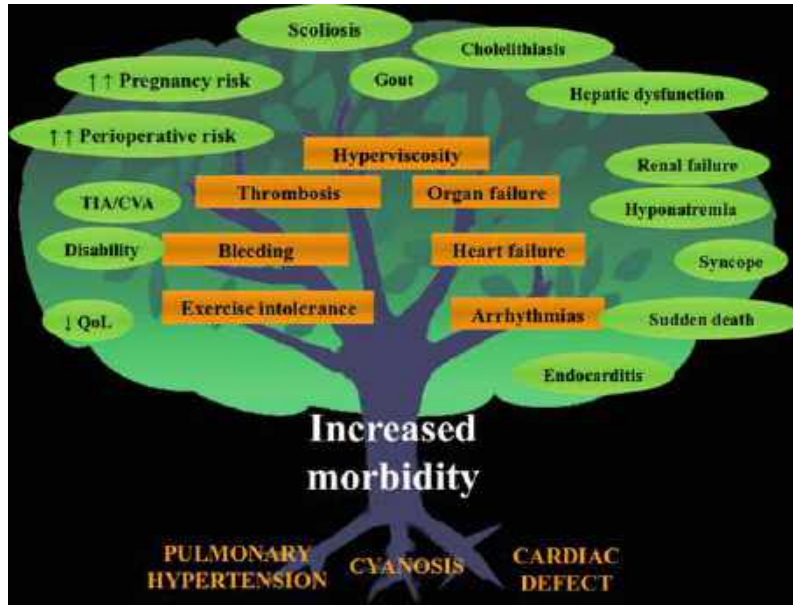

Fig. 138.3 The clinical picture of Eisenmenger syndrome relates not only to pulmonary arterial hypertension but also to the coexisting cardiac defect and chronic cyanosis, all of which contribute to morbidity and also mortality in this population. Abbreviations: *CVA*: cerebrovascular accident; *QoL*: quality of life; *TIA*: transient ischemic attack

Table 138.2 Complications of Eisenmenger syndrome

Eisenmenger syndrome	
Complications	Management
Cardiac:	
• Progressive heart failure • Endocarditis • Arrhythmias • Paradoxical embolism • Angina • Syncope • Progressive dilatation of the large elastic pulmonary arteries	• Heart failure: medical treatment (diuretics with care to avoid dehydration) • Endocarditis: meticulous prophylaxis • Arrhythmias: consider anticoagulation, antiarrhythmics, unknown role of implantable defibrillators
Hematologic:	
• Secondary erythrocytosis • Hyperviscosity • Iron deficiency • Thrombocytopenia • Bleeding disorders	• Hyperviscosity: routine venesections are contraindicated and restricted to patients with hemoglobin >20 g/dl and hematocrit >65 %, severe hyperviscosity symptoms, and in the absence of dehydration and iron deficiency •Avoidance and prompt treatment of relative anemia and dehydration • Iron deficiency: iron profile and appropriate supplementation
Pulmonary:	
• Hemoptysis • Intrapulmonary bleeding • Pulmonary artery thrombosis	• Hemoptysis: chest X-ray and CT scan to determine extend of hemorrhage; embolization of culprit vessels if severe and recurrent • Thrombosis: consider anticoagulation
Central nervous system:	
• Stroke/TIA • Cerebral abscess	• Stroke: inappropriate repeated venesections increase risk • Cerebral abscess: urgent contrast enhanced CT and blood cultures, may require urgent evacuation
Renal:	
• Proteinuria and hematuria • Mildly elevated creatinine • Progressive renal failure	• Judicious use of diuretics • Avoid iatrogenic renal dysfunction
Metabolic:	
• Hyperuricemia and gout • Hyperbilirubinemia and gallstones • Nephrolithiasis	• Treat symptomatic hyperuricemia

CT computed tomography; *TIA* transient ischemic attack

common in this setting and is the cause of death in 11–30 % of patients, even though in most occasions, it is mild and self-limited [12]. Thrombocytopenia is one of the many mechanisms by which bleeding can occur and is attributed to reduced platelet release from megakaryocytes, increased peripheral platelet consumption, thrombasthenia, and decreased platelet life [13]. Other factors contributing to the high bleeding risk of Eisenmenger patients include primary fibrinolysis and coagulation factor deficiencies, secondary to chronic liver dysfunction and abnormal gastrointestinal absorption [14–16].

The increased iron requirements, predisposition to bleeding, and, possibly, reduced iron absorption in cyanotic CHD patients often result in iron deficiency, affecting up to one in three patients. Iron deficiency can have similar symptoms to those of hyperviscosity and can have detrimental effects on oxygen delivery to tissues, possibly promoting cerebrovascular events. Patients who present with symptoms of hyperviscosity, such as headache, visual disturbances, and paresthesias should, thus, be assessed for iron deficiency or dehydration before considering venesection [17–19]. Serum ferritin, transferrin saturation, or, when available, transferrin

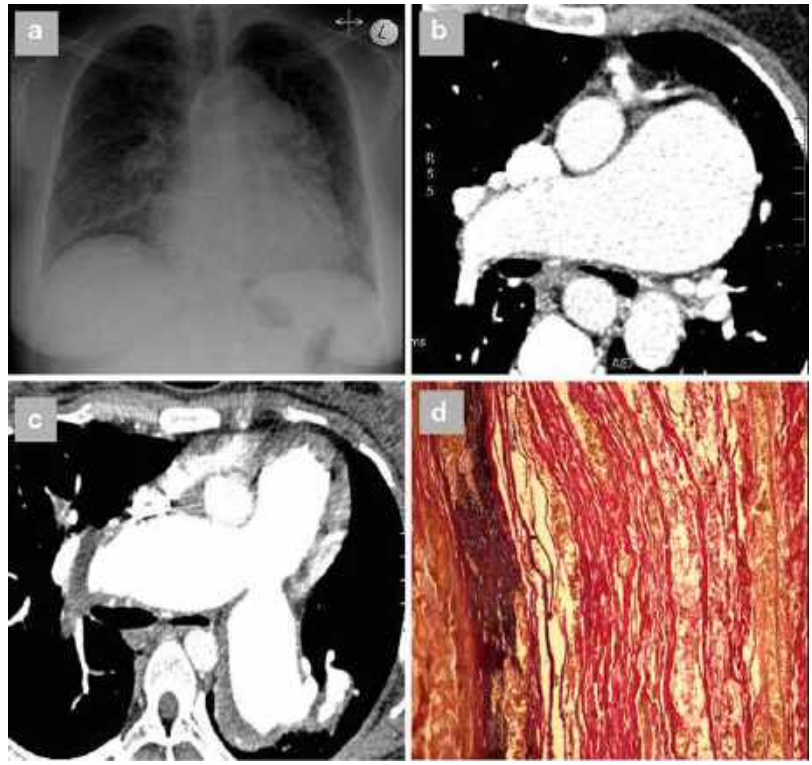

Fig. 138.4 Pulmonary arterial dilatation is common in Eisenmenger syndrome and typically evident on chest X-ray (**a**) and computed tomography pulmonary angiogram (**b**). In situ thrombosis (**c**) can be observed in 20–30 % of patients. Multiple layers of organized thrombus formation can be seen on histological examination of the pulmonary arteries (**d**) hematoxylin and eosin, magnification ×20

receptor level should be used for the diagnosis iron deficiency in this cohort, as mean cellular volume is often normal and can even be increased.

Increased pulmonary arterial pressures in Eisenmenger syndrome typically causes aneurysmal dilatation of the elastic pulmonary arteries, which may become severely atherosclerotic and develop in situ thrombosis [12, 20] (Fig. 138.4). The prevalence of advanced thrombosis of the central pulmonary arteries of Eisenmenger patients ranges between 20 % and 30 % [12, 21, 22]. Potential mechanisms of thrombosis include local vascular injury, hypercoagulability, sluggish blood flow with red cell aggregation, and distal embolic sources [12]. While almost certainly in situ rather than embolic in origin, central pulmonary artery thrombi may be the source for peripheral pulmonary thrombi and pulmonary infarction leading to hemoptysis (Fig. 138.5).

In Eisenmenger patients, the effects of long-standing PAH and hypoxia are superimposed to those relating to the underlying cardiac lesion. Myocardial dysfunction, valve disease, and arrhythmias are not uncommon and contribute to morbidity and mortality. History of clinical arrhythmia has been found to be a predictor of death in this population, which is sudden in most cases [18]. The presence of severe PAH makes cardiac intervention and cardiac surgery very high risk in most such cases.

Prognosis

Eisenmenger syndrome, at a first glance, would appear to be a devastating disease due to the coexistence of a cardiac defect, long-standing severe pulmonary vascular disease, and the deleterious systemic effects of cyanosis. However, Eisenmenger patients may survive into

Fig. 138.5 Computed tomography pulmonary angiogram (CTPA) of a patient with recent hemoptysis. Bleeding in the right lower lung can be seen as well as significant cardiomegaly with marked right ventricular hypertrophy and prominent pulmonary vasculature

adulthood, decades after the diagnosis has been established [18, 23], and have a significantly slower disease progression compared to iPAH [24]. In a retrospective case–control study of 171 adult Eisenmenger patients, survival at 40, 50, and 60 years of age was 94 %, 74 %, and 52 %, respectively, with markers of heart failure and arrhythmia adversely affecting their prognosis [18]. The better prognosis compared to other types of PAH has been attributed to the adaptation of the right ventricle from childhood, possibly preserving the fetal phenotype, and to the presence of a defect that allows systemic cardiac output to be maintained at the expense of cyanosis [6]. Moreover, a large ventricular septal defect may allow the left and right ventricle to function in unison and allow the right ventricle to relieve some pressure load through the defect in diastole. In patients with previously repaired CHD and those with pretricuspid shunts, some of the above mechanisms are lacking, which may explain the different prognosis.

Clinical Management

Patients with PAH secondary to CHD should be followed up in tertiary centers with expertise in both CHD and PAH [25]. Clinical assessment should include history-taking, with emphasis on exercise capacity, hyperviscosity symptoms, bleeding or thrombotic complications, syncopal or pre-syncopal episodes, and infection. Particular attention should be made to assessing functional status, interrogating patients with regard to ordinary activities such as walking, climbing stairs, cleaning, gardening, and dancing, so as not to overestimate their exercise tolerance. On physical examination, the presence and extent of cyanosis, nutritional status, and evidence of heart or liver failure should be noted. Oxygen saturations should be measured by pulse oximetry after at least 3 min of complete rest. In patients with a PDA, resting saturation should be measured in the right hand and feet to detect differential cyanosis (Fig. 138.2). Electrocardiography and chest X-ray provide valuable information on the heart, great vessels, and lung parenchyma. Periodic blood testing is required and should include full blood count, hematocrit, platelet count, clotting profile, markers of liver and kidney function, uric acid, and screening for iron deficiency (with serum ferritin in a stable patient or transferrin saturation). Also, neurohormonal levels such as BNP or NT-proBNP can prove useful in assessing progression of disease and prognosis [26].

Objective assessment of exercise tolerance should also be performed periodically with

a 6-min walk test (6MWT) and/or cardiopulmonary exercise testing. Although the 6MWT has become the standard for routine assessment of PAH patients and an accepted endpoint for trials, it may not detect changes in mildly limited patients [27] and cannot substitute for formal cardiopulmonary exercise testing, the latter providing a wealth of information on exercise pathophysiology. On the other hand, appropriately "mild" exercise protocols should be used when performing cardiopulmonary exercise tests in patients with CHD-related PAH, in order to obtain a long-enough exercise period.

Transthoracic echocardiography confirms the underlying CHD lesion and site of the shunt and monitors biventricular function and valvular competence [28]. In particular, measures of right ventricular function (tricuspid annular plane excursion and peak systolic velocity), myocardial performance (total isovolumic time, systolic to diastolic duration ratio), and raised central pressures (right atrial area and estimated pressure as well as right-to-left atrial area ratio) appear to be related to outcome in patients with Eisenmenger syndrome. High-resolution chest computerized tomography and magnetic resonance can be used to assess the lung parenchyma, aneurysmal dilation, and in situ thrombosis of the proximal pulmonary arteries, right ventricular dimensions and function, and associated cardiac or extracardiac lesions.

Therapy

Despite the lack of definitive treatment for patients with Eisenmenger syndrome, numerous management measures and precautions should be taken aimed at improving quality of life and reducing complications in this population.

Supportive Measures and Precautions

Supportive measures remain key to the management of Eisenmenger patients with an aim of reducing symptoms and treating or preventing complications related to hypoxia, hematological or coagulation disorders, congestive cardiac failure, rhythm disturbances, and infection. Avoidance of dehydration with adequate fluid replacement is critical for these patients due to their delicate physiology depending on adequate preload and their tendency to hyperviscosity. Hyperviscosity symptoms, although common, can mimic symptoms and signs of iron deficiency anemia [19]. Iron deficiency should be sought and corrected wherever possible to ensure adequate hemopoiesis and erythrocytosis appropriate to the level of cyanosis. Venesections induce or augment iron deficiency, increase the risk of stroke, and should, therefore, be avoided [19]. Intravenous iron can be used, especially when iron deficiency is severe or the patient is intolerant to oral preparations, as long as adequate measures are taken to avoid air embolism.

Oxygen therapy may have a role for nocturnal use in selected patients; however, its round-the-clock use in young individuals may lead to "oxygen dependency" and physical deconditioning and should be discouraged [29, 30]. In fact, even in this very symptomatic cohort, patients should be encouraged to remain physically active within their capacity, without having to carry with them a heavy oxygen cylinder. Avoidance of strenuous exercise and competitive sports are advisable as they impose a risk of sudden death. [31]. Commercial air travel appears safe and can be well tolerated without supplemental oxygen as long as patients avoid inactivity and dehydration [32].

Additional precautionary measures for Eisenmenger patients include annual immunization against influenza and pneumococcal infections and careful planning/avoidance of noncardiac surgery, which carries significant mortality risks. Endocarditis prophylaxis is still recommended in the AHA and ESC guidelines for cyanotic patients, and dental hygiene remains paramount. For patients with Down syndrome, dental procedures may need to be performed under general anesthesia. The benefits of such procedures should be weighed against the risks of the anesthesia, and careful planning in tertiary centers with adequate anesthetic support is paramount. Pregnancy in CHD-related PAH poses a high risk for both maternal and fetal

complications and is contraindicated [33]. Timely counseling and effective contraception measures are necessary in this population due to the high maternal mortality rate [34]. Estrogen-containing contraceptives should be avoided as they may promote thrombosis.

Heart Failure Medication, Antiarrhythmics, and Implantable Defibrillators

Heart failure medication can be used in patients with signs of cardiac decompensation, although there are limited data on their efficacy in Eisenmenger syndrome [2]. Special care should be taken when using diuretics to avoid dehydration, which may destabilize the delicate physiology of Eisenmenger patients.

Arrhythmias are frequent late complications of the Eisenmenger syndrome and may herald clinical and hemodynamic deterioration or sudden cardiac death. Supraventricular arrhythmias have been reported as independent predictors of mortality in this population, whereas ventricular arrhythmias are less common [18]. Antiarrhythmics, such as amiodarone, are often used to control these arrhythmias despite the lack of evidence supporting this approach. The role of implantable cardioverter-defibrillators in Eisenmenger syndrome also remains unknown and warrants further investigation [35]. Electrophysiology study and ablation can be indicated in carefully selected patients in expert tertiary centers, under expert anesthetic care, weighing the benefits of the procedure against the risks of an anesthetic or procedure-related complication (e.g., emboli, life-threatening arrhythmias).

Anticoagulation

Use of anticoagulation remains controversial in Eisenmenger syndrome due to the increased risk of thrombosis but also bleeding (e.g., hemoptysis) [36]. Evidence supporting anticoagulation in this population is extrapolated from studies in iPAH and the high risk of thrombosis in the pulmonary arteries [12, 22]. Additional parameters which should be taken into consideration include the presence of intracavitary thrombi, arrhythmias, and previous embolic phenomena versus the risk of hemoptysis. Attention is required when assessing coagulation parameters in cyanotic patients as secondary erythrocytosis increases hematocrit and decreases plasma volume. The amount of anticoagulant in vials used for blood collection should be reduced to match the decrease in plasma volume per unit of blood.

Disease-Targeting PAH Therapy

Available "advanced" therapies for PAH target vasoconstriction and proliferation of smooth muscle cells in the pulmonary arterial bed. To date, three identified major pathways controlling these processes have been translated into clinical practice: (a) the prostacyclin-mediated pathway, (b) the nitric oxide-mediated pathway, and (c) the endothelin-mediated pathway [37]. Targeted therapies acting on the prostacyclin-mediated pathway include synthetic prostacyclin and prostacyclin analogues such as intravenous prostacyclin (epoprostenol), subcutaneous treprostinil, inhaled iloprost, and oral beraprost. Phosphodiesterase inhibitor sildenafil acts on the nitric oxide-mediated pathway, whereas two drugs acting on the endothelin-mediated pathway are available: bosentan, and ambrisentan.

BREATHE-5 [38] is the first randomized, double-blind, placebo-controlled trial in patients with Eisenmenger syndrome; bosentan had a beneficial short-term effect on exercise capacity and cardiopulmonary hemodynamics in WHO class III patients without compromising systemic oxygen saturation. The beneficial effects of bosentan on exercise capacity were sustained to 1 year in the open-label extension study (40 weeks' follow-up) [39] and beyond this in other non-randomized studies (see below). Another small randomized trial of sildenafil in 10 Eisenmenger and 10 iPAH patients reported a significant improvement in functional

status, exercise capacity, and pulmonary pressures in the Eisenmenger subgroup [40]. A crossover randomized trial of tadalafil in Eisenmenger patients was recently reported, showing a significant improvement in exercise capacity and hemodynamic parameters [41].

A minority of patients with CHD has been included in the population of other large randomized trials using treprostinil [42], sildenafil [43], and previously sitaxentan (now withdrawn from the market) [44, 45] as well as the EARLY study assessing the effect of bosentan on PAH patients in functional class II [27]. A large number of non-randomized observational studies have reported a beneficial effect of advanced therapies in patients with CHD, both in terms of hemodynamic and functional improvement [38–40, 42, 45–62]. While many studies show that the benefit of advanced therapies persists beyond the first year, few studies show loss of benefit after 1 year, possibly due to progression of the disease [52, 53, 59, 63].

In most specialist centers, targeted therapies are used in combination when a single drug does not produce the desired effect or increased doses of a single medication are poorly tolerated [64–66], although their combined administration is supported only by observational studies. Intravenous prostanoids have also been used in Eisenmenger patients, even though there are concerns about line infection predisposing to endocarditis and enhanced systemic side effect due to drug shunting to the systemic circulation. Limited evidence exists on inhaled therapies. Recent evidence of a prognostic benefit of advanced therapies in Eisenmenger patients provides an additional stimulus for assessing patients early with regard to eligibility for advanced therapy [67].

Transplantation

Lung transplantation with repair of the underlying cardiac defect or heart and lung transplantation can be performed with an acceptable risk to eligible Eisenmenger patients with an improvement of symptoms and quality of life [68, 69]. In reality, transplantation is restricted to patients with end-stage disease with a 1-year survival rate <50 % who are, thus, likely to benefit from this procedure. However, most Eisenmenger patients remain clinically stable for many years, and by the time transplantation is considered, they are unsuitable candidates due to established multi-organ failure [70]. This, together with the chronic shortage of donors, highlights the importance of development of alternative therapies aimed at improving quality of life and survival of these patients.

Palliative Mustard Procedure

The palliative Mustard procedure is suitable for patients with transposition of the great arteries, large VSD, and PAH, and consists of an atrial switch procedure (Mustard or Senning procedure) in which the VSD is left open. This procedure offers the beneficial effect of reducing cyanosis via redirection of desaturated blood to the pulmonary artery and oxygenated blood to the aorta [71, 72].

Conclusions

Eisenmenger syndrome is a remarkable example of a disease which was considered until recently untreatable and irreversible and is currently amenable to medical therapy, although not curative. Further research is currently underway to define the long-term role of advanced PAH therapies in this population, whereas supportive measures and appropriate precautions remain key to the management of Eisenmenger patients.

Arrhythmias, Conduction Disorders and Electrophysiological Anomalies in the Adult with Congenital Cardiac Disease

139

Jeremy P. Moore, Ravi Mandapati, Kevin Shannon, Anjan S. Batra, and Seshadri Balaji

Abstract

Adult congenital heart disease has become an increasingly common issue in the cardiology community, with rhythm abnormalities being one of the most frequent comorbidities. Arrhythmia affects adult congenital heart disease patients in excess of the general population regardless of the congenital abnormality, but the degree of risk generally depends on the specific lesion. Postsurgical bradyarrhythmias include sinus node dysfunction and AV block and are seen with increased frequency among patients with complex repairs. Permanent pacing may require special consideration for various surgical subtypes, especially after atrial baffle repair. Atrial tachyarrhythmias also pose a particularly troublesome problem, with management strategies involving various combinations of antiarrhythmic medication administration, catheter ablation, and antitachycardia pacing. The general approach to catheter ablation in the setting of adult congenital heart disease is presented, with a focus on the most common substrates of

cavotricuspid isthmus-dependent atrial flutter and scar-based or intra-atrial reentry tachycardia. Finally, ventricular tachyarrhythmia and sudden cardiac death are discussed. Management strategies in this last category continue to evolve, but improved catheter ablation strategies and the now time-tested efficacy of implantable cardioverter-defibrillator placement have emerged as highly effective therapies for these patients. Although data remain incomplete, risk factors for sudden cardiac death have emerged in this population and evidence-based indications for device therapy of sudden cardiac death are presented.

Introduction

For the growing number of adults with congenital heart disease (ACHD), there still remain many long-term issues that require continued medical care, of which arrhythmia is one of the most common and most troublesome. It is not surprising that ACHD patients are prone to arrhythmias given the natural history of their underlying congenital heart disease (CHD), the long-standing nature of their hemodynamic alterations, and the consequences of surgical interventions. This chapter will review the arrhythmias most likely to be encountered in this population and their management.

Arrhythmia Incidence

Bradyarrhythmias requiring pacemakers are highly prevalent in adults with congenital heart disease, with an incidence that varies according to the type of defect and surgical correction. Sinus node dysfunction (SND) frequently occurs after cardiac surgery (e.g., intra-atrial baffle repair for transposition of the great arteries, Fontan-type palliations for single ventricles, and superior cavopulmonary connections) [1]. In patients with atrial baffles (Mustard or Senning palliations) for transposition of the great arteries, for example, symptomatic sinus node dysfunction is observed in 64 % and 82 % at 5 and 16 years of follow-up, respectively [2]. On the other hand, displacement of the atrioventricular (AV) node and conduction axis confers susceptibility to impaired AV conduction, with an estimated 2 % annual incidence of spontaneous AV block in congenitally corrected transposition of the great arteries [3].

A recent study showed that from the period 1998 to 2006, there was a 112 % increase in the number of ACHD patients that were admitted for emergency care in the United States with a diagnosis of arrhythmia [4]. Bouchardy et al. [5] reported that atrial arrhythmias occurred in 15 % of adults with congenital heart disease. The lifetime incidence increased steadily with age and was associated with a doubling of the risk of adverse events. Overall, the 20-year risk of developing atrial arrhythmia was 7 % in a 20-year-old patient and 38 % in a 50-year-old patient. More than 50 % of patients with severe congenital heart disease that reach 18 years of age will develop atrial arrhythmia by age 65 years.

The burden of atrial arrhythmias in the Fontan population depends on the type of Fontan, being the highest (50–60 % a decade after undergoing surgery) in those having an atriopulmonary connection [6]. Stephenson et al. [7] recently reported that the lateral tunnel and extracardiac Fontans have a lower prevalance of arrhythmia with a rate of 2–7 %. However, most of this specific population has not reached the adult age and the true late impact of surgery type is not yet known.

Ventricular arrhythmias usually occur after the second decade of life in certain types of ACHD patients. The greatest risk is in patients undergoing a ventriculotomy for repair such as tetralogy of Fallot and double-outlet right ventricle. The bulk of literature and clinical experience regarding ventricular tachycardia (VT) in CHD has centered on tetralogy of Fallot. The prevalence of VT after tetralogy repair has been estimated to be between 3 % and 14 % in several large clinical series [8–10].

A study by Khairy et al. [11] involving intermediate and high-risk patients with tetralogy of Fallot receiving implantable cardioverter-defibrillators (ICDs) showed that 3.8 % of patients with ICDs for primary prevention and 17.5 % of patients with ICDs for secondary prevention received appropriate shocks for ventricular arrhythmias each year.

VT is also seen in patients that have severely elevated ventricular wall stress due to either pressure or volume overload, such as is seen with aortic valve stenosis, l-transposition of great vessels, d-transposition of the great vessels undergoing a Mustard or Senning repair, severe Ebstein's anomaly, single ventricle physiology, Eisenmenger's syndrome, and unrepaired tetralogy of Fallot, among others.

Bradyarrhythmias

The most common bradyarrhythmias seen in ACHD are sinus node dysfunction (SND) and complete heart block (CHB).

SND occurs predominantly in patients who have had surgery near the sinoatrial (SA) node. The two operations that most commonly result in SND are the original surgeries for d-transposition of the great arteries (d-TGA) (Mustard and Senning operations) and the various iterations of the Fontan operation including some of the staged palliative operations [12–14]. However, there is a risk of SND after almost any operation for CHD due to superior vena cava (SVC) cannulation to achieve cardiopulmonary bypass in almost every intracardiac operation, at which time the sinoatrial (SA) node or its arterial supply may be damaged. Furthermore, the etiology of SND remains unknown after certain kinds of operation, as witnessed by the incidence of SND after the superior cavopulmonary connection (Glenn operation) and the extracardiac conduit Fontans, in which the surgeon operates in locations remote from the SA node [15].

Another interesting aspect of SND is that although it may occur in the immediate postoperative period, it more often appears insidiously after long-term follow-up. Studies of d-TGA and Fontan patients who have been followed for many years show steady loss of sinus rhythm [12–14]. Often the sinus rate falls below the junctional pacemaker rate and the patient is noted to be in junctional rhythm. It is rare (but possible) for patients to present with precipitous bradycardia needing urgent management due to this problem. However, junctional rhythm presents with different hemodynamic consequences for the two main groups mentioned above, namely, the d-TGA group and the Fontan group. In the d-TGA group, the creation of atrial baffles removes much of the reservoir function of the atria, and therefore, the loss of sinus rhythm does not result in severe hemodynamic consequence. Atrial systole does not augment cardiac stroke volume much in this setting and the bradycardia itself is the greater issue. For patients repaired by the Fontan operation, however, the loss of atrial contribution to cardiac output is felt very severely and the tolerance for junctional rhythm is much lower. These patients not only need improvement in heart rate but also every effort to create AV synchrony and reintroduce the atrial transport function for ventricular filling [16, 17].

As the occurrence of SND is often insidious, so is the way in which patients present. Most often there are either no symptoms or the symptoms are vague, such as fatigue or a gradual loss of exercise tolerance. Periodic electrocardiograms (ECG) and 24-h ECG monitoring are worthwhile in these specific subgroups of patients.

Chronotropic incompetence refers to the inability of the sinus node to provide an increased heart rate to compensate for increased metabolic needs. It can be difficult to diagnose and may only be unmasked with exercise stress testing. Furthermore, there are no age-specific norms for the extent of heart rate increase because the increase is highly dependent on prior conditioning, which can vary enormously between patients.

SND may also be not apparent until it is unmasked by antiarrhythmic drug therapy for tachyarrhythmia management. Any patient with the above surgeries (Mustard, Senning, or Fontan) being placed on antiarrhythmic drug therapy requires careful monitoring for SND and/or complete heart block (CHB).

CHB is less common overall in the adult congenital population and is most commonly seen in the immediate postoperative period. Rarely however, patients do present with late-onset CHB. While it can occur in almost any postoperative patient, the group that needs the closest vigilance is the patient with l-TGA. This group has an incidence of de novo CHB, at times precipitated by surgery [18].

Bradyarrhythmia Management

It is rare for ACHD patients to present with acute bradycardia. In general however, chronic bradycardia is treated by pacemaker placement. Pacemaker therapy in ACHD is fraught with complexity [19–21]. It is important to have a thorough understanding of the patient's anatomy and physiology with special attention to prior operative notes and cardiac catheterization procedures before implanting a pacemaker. In general, practitioners who are unfamiliar with a particular congenital heart defect should not attempt to place pacemakers in these patients.

The main aspects impacting pacemaker therapy are the patency of peripheral veins and the intracardiac anatomy, which may prohibit access to certain chambers. For instance, in patients with d-TGA who have had Mustard operation, the course of the ventricular lead will be posterior and leftward. Indeed, the lead must be anchored in the morphologic left ventricle. Being smooth walled, it is hard to anchor a tined lead and so it is important to choose an active fixation lead in these patients. Additionally, perhaps because of the smooth internal wall, lead dislodgement is more common in this group. Atrial lead placement in this group can also be a challenge. It is very important to check for baffle obstruction and/or baffle leak with venography (including follow-through) prior to implantation. Also, the natural course of the atrial lead as it courses through the SVC baffle will direct it to the lateral roof of the left atrium where it will often abut the left phrenic nerve, causing diaphragmatic stimulation. Avoiding this area can be challenging and may require multiple attempts at lead placement (Fig. 139.1).

Fontan patients are a unique challenge [19]. In almost all such patients, the Fontan baffle will preclude access to the endocardial surface of the ventricular mass. Placing a lead through a baffle puncture (with subsequent anticoagulation) has been described but this is not recommended because of the higher risk of thromboembolism in this group. Depending on the type of Fontan, it may also restrict access to the atrial myocardium. This is the usual finding in patients with the so-called extracardiac conduit style Fontan. If endocardial access is difficult or impossible, epicardial access may be required for lead placement. A congenital heart surgeon familiar with the relevant anatomy and physiology is best suited to perform this surgery.

An important aspect to bear in mind in patients with transvenous pacing or defibrillation leads who have an intracardiac shunt is the resultant risk of thromboembolism. In a multicenter study of 202 patients with intracardiac shunts followed for a mean of 12 years, those with transvenous

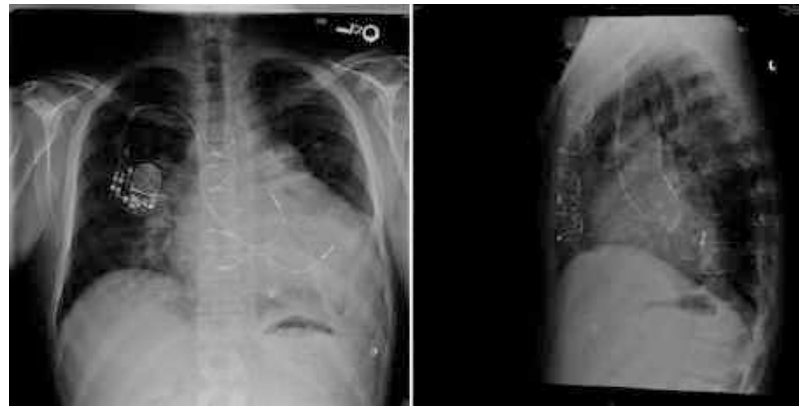

Fig. 139.1 AP (**a**) and lateral (**b**) chest x-ray of a patient with prior Mustard procedure for d-TGA. A dual chamber pacemaker has been placed with the atrial lead at the roof of the left atrium and the ventricular lead in the posterolateral LV wall. Note the posterior position of both leads.

leads had a higher risk of thromboembolic event compared to those with epicardial leads (2 % vs. 0.5 %). Among those with transvenous leads, factors associated with thromboembolism were older age, presence of atrial flutter or fibrillation, and ongoing phlebotomies. Importantly in this study, 9 of 14 thromboembolic events occurred while patients were taking warfarin. These findings suggest that intracardiac shunts should be closed if at all possible prior to placing transvenous leads [22].

Tachyarrhythmias

Supraventricular Tachycardia (SVT)

Supraventricular tachycardia (SVT) is an important cause of morbidity and mortality for many patients with congenital heart disease (CHD) irrespective of whether they have had prior surgery for their CHD. SVT mainly occurs after atrial surgery such as atrial septal defect repair (ASD), Mustard or Senning palliations for transposition of the great arteries (TGA), and the Fontan operation for single ventricle [12, 14]. However, some patients can develop SVT after "ventricular" surgery (e.g., tetralogy of Fallot) [23]. There is much to be learned with respect to the pathogenesis of supraventricular arrhythmia in congenital heart disease. Treatment is often complex and can further complicate patient care due to unwanted side effects.

Pathogenesis of SVT

The most important factor in the pathogenesis of SVT in CHD is the presence of scarring or fibrosis in the atrium. This usually represents surgical scar, but if the patient has not had prior surgery, the fibrosis may be secondary to the underlying CHD [24–27]. The atria in CHD patients are often hypertrophied due to long-standing pressure and volume overload, that may be the result of mitral or tricuspid valve dysfunction, ventricular hypertrophy with decreased compliance (in some instances, due to outflow tract obstruction), or residual left-to-right shunts. Both pressure and volume overloading play important roles in the pathogenesis of SVT. Another factor that can contribute to atrial arrhythmia is SND, which may be due to direct surgical trauma or trauma to the sinus node blood supply at the time of surgery. Less common, but important, modulating factors are electrolyte disturbances and proarrhythmic medications.

Atrioventricular Reentrant Tachycardia (AVRT) Secondary to a Bypass Tract or Wolff-Parkinson-White Syndrome

Wolff-Parkinson-White syndrome and bypass tracts can occur in almost any CHD but are most commonly seen in patients with Ebstein's anomaly. Up to 10–25 % of patients with Ebstein's anomaly have a bypass tract [28],

most commonly on the right side of the heart [29, 30]. Multiple pathways may also be present in these patients. In patients with congenitally corrected transposition of the great arteries associated with Ebstein's anomaly of the left-sided tricuspid valve, the bypass tracts are on the left side (associated with the AV junction between the morphologic left atrium and the morphologic right ventricle). In very rare instances, patients with the atriopulmonary Fontan operation develop an iatrogenic bypass tract, which may be associated with AVRT [31].

Atrioventricular Nodal Reentrant Tachycardia (AVNRT)

AVNRT is rare in patients with congenital heart disease [32, 33]. It has specifically been reported in some children with left ventricular outflow tract obstruction [32]. An interesting variant of AVNRT has been described in some patients with univentricular heart [34]. Most commonly seen in patients with atrioventricular discordance and complete atrioventricular septal defect (AVSD), these patients can have two distinct AV nodes that form an electrical "sling" (Monckeberg's sling) and can develop AVRT whereby the impulse travels from the atrium to the ventricle via one AV node and returns to the atrium through the other AV node. These patients often exhibit two distinct non-preexcited QRS morphologies and two distinct His bundle electrograms during invasive electrophysiologic testing.

Atrial Flutter (AFL)

Typical AFL can occur in almost all forms of CHD but is most often seen in the setting of unoperated ASD or other conditions associated with a dilated right atrium [35]. Examples include patients with tricuspid regurgitation or a noncompliant right ventricle (e.g., in repaired tetralogy of Fallot). The area between the inferior vena cava and the tricuspid valve (termed the cavotricuspid isthmus) is capable of slow conduction in patients with CHD similar to what is observed in many people with a normal heart. In patients with scar-based atrial tachycardia (IART, see below), typical AFL is a common associated arrhythmia often identified at the time of ablation [36].

Incisional Atrial Reentrant Tachycardia (IART)

IART is an arrhythmia which is mainly observed in patients who have undergone surgeries with extensive atrial scars, such as ASD repair, Mustard or Senning operation for d-TGA, or the Fontan operation. In patients with other types of surgery, IART can still occur since a right atriotomy is commonly performed in most CHD operations in addition to sites of SVC and inferior vena cava (IVC) cannulation for commencement of cardiopulmonary bypass. These surgical scars are potential barriers that may create the substrate for IART [37, 38].

Because of the complexity of the scars and the extensive areas of slow conduction that may result, IART can be a relatively slow tachycardia (with rates just above 100 bpm) and the p waves can be discrete and not "saw-toothed" as is seen with typical AFL (Fig. 139.2).

Focal Atrial Tachycardia

Focal atrial tachycardias are atrial arrhythmias that originate in a small nest of cells and spread outward in a centrifugal pattern [39]. Focal tachycardias may be due to abnormal automaticity, triggered activity, or microreentry, and as such they differ from the more common macroreentrant AFL and IART. Because the p waves are usually discrete, these foci are often more difficult to distinguish from IART based on the ECG appearance alone. The true nature of this arrhythmia is often only revealed during invasive electrophysiology study.

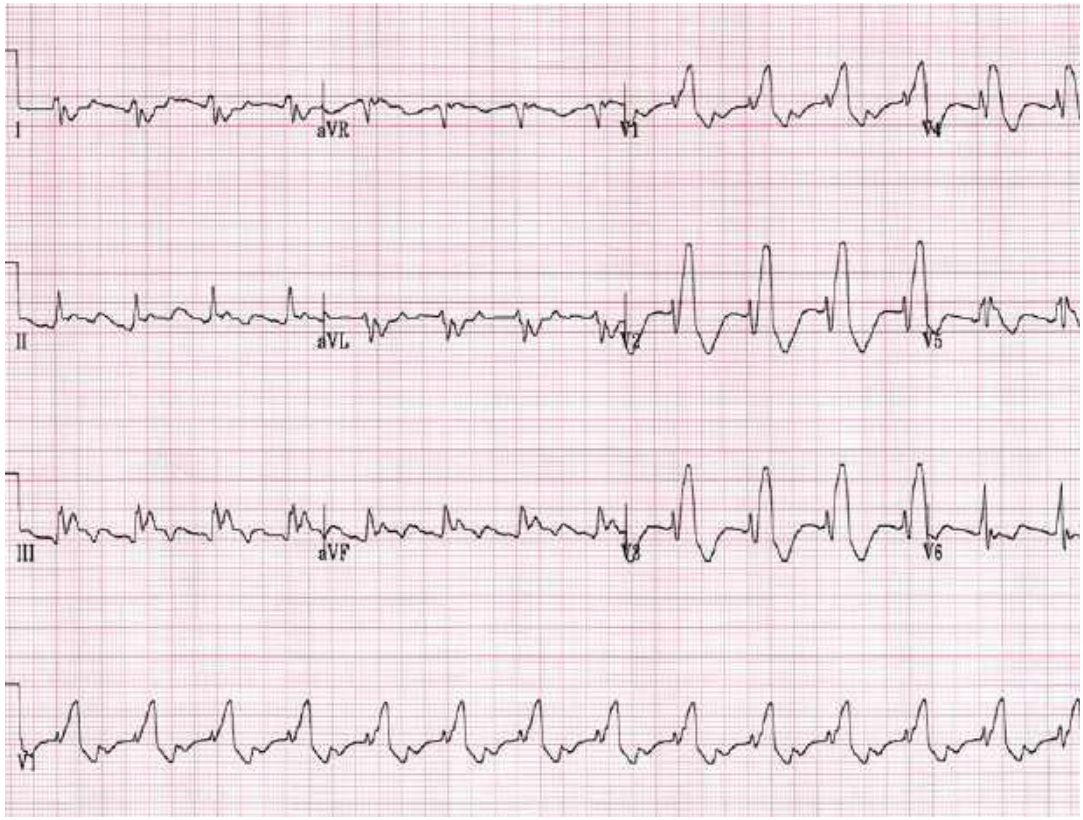

Fig. 139.2 IART in a patient with Ebstein's anomaly

Atrial Fibrillation (AF)

AF is an important arrhythmia in older individuals with CHD whether or not surgical repair has been performed. AF is well described in unoperated ASD patients [14, 40]. In addition, AFL or IART may occasionally degenerate into AF. AF is especially common in patients with mitral valve disease and Eisenmenger's syndrome.

Assessment of Atrial Arrhythmias

Adequate ECG documentation is an important first step for characterization of the arrhythmia. Electrophysiology study is rarely needed to make a reasonable and actionable diagnosis, and most arrhythmias can be diagnosed by noninvasive ECG techniques alone.

Some important clinical points for supraventricular arrhythmia management are as follows. An inappropriately high heart rate in a patient with complex CHD (Fig. 139.2) may indicate a tachyarrhythmia. Caregivers must be mindful that many adults with CHD have an element of SND and the resting ECG often shows relative bradycardia. Therefore, the symptomatic patient with palpitations and a higher than expected heart rate should raise concern, even if the heart rate is under 100 bpm. This is particularly true for patients who are already on medications that can induce bradycardia such as beta-blockers. An abrupt change to a higher heart rate is likely pathologic, while a gradual change is usually benign. An important clue to identifying p waves, especially in the presence of bundle-branch block, is to compare the ECG in tachycardia to that of sinus rhythm.

The cause and effect relationship between the hemodynamic state and arrhythmias can be difficult to discern. The occurrence of an arrhythmia often leads to abrupt hemodynamic worsening; however, an abrupt change in hemodynamic state may be a cause of arrhythmias. Because of this linkage, all patients with arrhythmia should undergo a thorough hemodynamic assessment which may include transthoracic and transesophageal echocardiography, cardiac magnetic resonance imaging, and, possibly, cardiac catheterization.

Management of SVT

Acute Therapy

In the setting of an adult with CHD, SVT can be poorly tolerated and acute management can be a challenge due to hemodynamic instability. As a general principle, it is important to convert to sinus rhythm in the most expeditious manner and a rate control strategy should be, at best, only a temporary one. Conversion to sinus rhythm can be achieved using the following techniques and the specific route chosen will depend mainly on the expertise of the local specialists. Transesophageal pace termination may be used for converting patients to sinus rhythm [41] (Fig. 139.3), but in practice it requires a high output pacing stimulator and a specialist knowledgeable with its use, which may not be possible. The two more commonly available options for conversion to sinus rhythm are the acute use of class Ia and class III drugs such as procainamide (class Ia) and ibutilide, amiodarone, and sotalol (class III), or otherwise synchronized DC cardioversion.

Ibutilide is a class III agent available for intravenous use only and is indicated for the acute conversion of AFL and AF to sinus rhythm [42]. It has been shown to be successful in converting IART to sinus rhythm with reasonable efficacy and low risk. Prominent side effects, however, include QT prolongation and torsade des pointes (TdP) and hence should be used with care with adequate monitoring and resuscitation and defibrillation equipment readily available. Hoyer et al. reported the use of ibutilide in children and patients with CHD [43]. In their report of a total of 19 patients, there were 15 with CHD. In this subgroup, they found that ibutilide successfully resulted in conversion to sinus rhythm in 9 of 15 patients with the first attempt. No patient with CHD experienced proarrhythmia in the form of TdP; however, one patient had nonsustained VT which terminated upon discontinuation of the drug.

There is little evidence in the literature for the use of intravenous procainamide or amiodarone specifically in adults with CHD although they have been used in many other settings.

Oral sotalol has been used to convert IART to sinus rhythm in adults with CHD [44]. However, acute bradycardia due to sinus node dysfunction has been noted with its use. One report described a single oral dose of sotalol 2 mg/kg in 19 patients with atrial tachycardias (4 AET, 15 IART, 9 Fontans) with successful conversion to sinus in 16/19 (84 %) within two and a half hours after the dose. They reported bradycardia needing pacer placement in two patients and lethal thromboembolism 2 days later in one patient.

In patients with AFL, IART, and AF, there is a major risk of thromboembolism. Therefore, whenever these rhythms have persisted for >48 h or when the duration of arrhythmia is unknown, it is important to perform transesophageal echocardiography (to determine if atrial thrombi are present) prior to cardioversion.

Chronic Therapy

Options for long-term treatment include drug therapy, pace termination, catheter ablation, and surgical ablation and are described in the following sections.

Drug Therapy

Arrhythmias such as AVRT and AVNRT can usually be effectively suppressed with drugs such as digoxin, beta-blockers, or calcium-channel blockers. Side effects of these three categories of drugs are usually minor. AFL, IART,

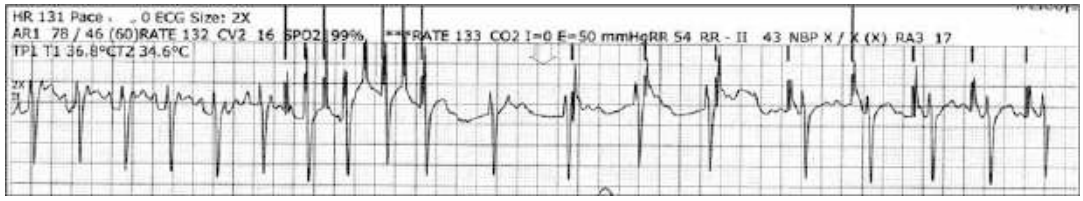

Fig. 139.3 Transesophageal pace termination of atrial tachycardia in a postoperative patient with history of AVSD. There is atrial tachycardia with 2:1 conduction (atrial rate 260 bpm) at the beginning of the tracing. Rapid atrial pacing through an esophageal catheter is initiated at a rate of 300 bpm which succeeds in terminating the tachycardia. Bradycardia pacing is instituted toward the end of the tracing

and AF are generally more difficult to treat and do not respond to the categories of drugs mentioned above. These arrhythmias are usually treated with class Ic or class III agents. The most commonly used group of drugs however is the class III agents (sotalol, amiodarone, dronedarone, and dofetilide). There is some experience with the use of the class Ic drugs such as flecainide and propafenone for patients with CHD, whereas there is very little experience with the use of the class Ia agents (quinidine or procainamide) in this patient group.

A major drawback to drug therapy is the possibility of adverse side effects. Of these, the most concerning is the development of proarrhythmia (i.e., the ability of the antiarrhythmic drugs to cause arrhythmias). The most important kind of proarrhythmia is QT prolongation and subsequent TdP that occurs mainly with the class III agents [45].

Class Ic drugs such as flecainide and propafenone can be associated with severe slowing of conduction, which in turn can cause a slowing of the atrial tachycardia rate. Paradoxically, this can be a major concern because the slower atrial tachycardia has a better chance of being conducted 1:1 to the ventricle via the AV conduction system compared to a faster atrial tachycardia [46]. For this reason, class 1 agents are not usually used as first-line therapy and are usually combined with an AV node slowing drug (digoxin or beta-blocker).

Sotalol is the most well studied of all the major antiarrhythmics in patients with CHD. Tanel et al. reported the use of sotalol in 45 patients who were either children or had CHD (or both) [47]. Of these, 13 had IART post CHD. Their mean age was 13 $\pm$ 7.5 years. Therapy was efficacious in the CHD subgroup with 12/13 success (complete 7, partial 5) with 1 death due to IART (not proarrhythmia) and with no patient having to discontinue the drug due to QT prolongation. Pfammatter et al. reported the use of sotalol in 27 patients with CHD (19 IART) [48]. They found excellent efficacy in 84 % of the patients (complete 48 %, partial 36 %) and no patient demonstrated TdP as a proarrhythmia. The main adverse effect was bradycardia due to high-grade AV block in two patients. Finally, Beaufort-Krol and colleagues reported the use of sotalol in 26 children all with CHD, most with AFL/AF and a mean age of 7.5 $\pm$ 5.8 years [49]. They noted excellent efficacy with recurrence-free survival of 96 % for all ATs and 81 % for AFL, with no patient exhibiting proarrhythmia.

Amiodarone has been used in ACHD patients with arrhythmias. The largest report so far has been from Villain and colleagues [50]. They reported its use in 27 CHD patients, all with AFL/IART (18 TGA, 6 Fontan, 3 other). Efficacy was excellent with full success in 18 and partial success in 7 (total 25/27, 93 %). There were six deaths: 2 with refractory AFL and 4 after stopping amiodarone. There were no tachyarrhythmias due to proarrhythmia. However, three patients exhibited severe bradycardia needing pacing, and three had rises in pacing thresholds. The main drawback with amiodarone is its long half-life and association with adverse effects [51]. Amiodarone is in a class of its own when it comes to its pharmacokinetics with the longest half-life in cardiovascular drug therapy. It also has a very

long list of potential complications mainly associated with chronic therapy such as the development of thyroid and liver dysfunction, pulmonary, and ophthalmic nerve toxicity. For these reasons it is usually used as a drug of last resort.

Dronedarone, a newer drug, is a non-iodinated derivative of amiodarone which seems to have a better safety profile and shorter half-life but is also less effective than amiodarone. Large multicenter trials in adults with AF suggest that it can be quite effective in that population but needs to be used cautiously in patients with heart failure [52]. The efficacy and safety of dronedarone in patients with CHD remains to be determined.

Dofetilide is a newer class III antiarrhythmic agent that selectively inhibits the rapid component of the delayed rectifier potassium current, thus prolonging refractory periods and the QT [53]. Its actions are similar to ibutilide, but it is available in an oral formulation. In randomized, double-blind, placebo-controlled studies of adults with AF, dofetilide was associated with higher rates of conversion and maintenance of sinus rhythm and fewer recurrences of AF compared to placebo. Experience in patients with CHD is limited. One multicenter report of 20 ACHD patients (median age 30 years; range 19–53 years) showed initial success rates of 85 %, with 55 % remaining on dofetilide at last follow-up. The main adverse effect was TdP in two patients, one with truncus arteriosus and the other with a single ventricle and Fontan palliation [54]. Both patients were taking 500 mcg twice daily. The authors recommended that in ACHD patients, it may be best to start a lower dose of 250 mcg bid initially and only go up to 500 mcg bid if necessary.

Pacing Therapy

Atrial antitachycardia pacing (ATP) is an important nonpharmacologic option in some patients with arrhythmias, especially IART in the setting of atrial surgery for transposition or Fontan operation. However, it is important to note that ATP may not convert all episodes of IART and that studies to date indicate a success rate for conversion to sinus rhythm of only about 50 %. The usefulness of ATP lies in its role as an important adjunctive therapy to reduce the number of hospital and emergency room visits in some patients. One of the currently available implantable pacemakers includes the Medtronic Enrhythm (Medtronic, Minneapolis, MN). This is a dual chamber device with atrial ATP capability. It has a built-in safety feature that will not allow high rate atrial pacing in patients with high ventricular rates or atrial tachycardias with a 1:1 AV nodal conduction response. For those patients, options include a software update or capping the ventricular lead, which is only possible in patients who have intact resting AV nodal conduction but are unable to sustain rapid conduction during periods of atrial tachycardia.

Catheter Ablation

Catheter ablation has become a valuable therapeutic modality for the treatment of arrhythmia in the setting of congenital heart disease. Catheter ablation was first utilized in the congenital heart population shortly after its development in the early 1990s [55]. Since then, major advancements have occurred, primarily by building on the knowledge of arrhythmia mapping and ablation from patients without structural heart disease. Along the way, the importance of surgically placed anatomic obstacles in the reentry circuits was realized [56–58], and the development of electroanatomic navigation for elucidation of the tachycardia substrate was developed [59], both of which have greatly improved the efficacy of these procedures.

Basic electrophysiologic techniques remain paramount to a successful procedure. Since the vast majority of arrhythmias in the setting of congenital heart disease are due to a reentrant mechanism (continuous wavefront propagation through a predefined circuit), fundamental properties of reentry can be utilized to determine the critical elements to target for ablation. Since the chances of successful ablation have been shown to be highest at narrow channels of impaired conduction [60], these areas are generally sought out with

Table 139.1 Electrophysiologic principles for catheter ablation of intra-atrial reentrant tachycardia

Mapping concept	Electrophysiologic characteristics
Activation sequence mapping	Local activation times recorded at sequential sites
Zone of slow conduction	Atrial activity in electrical diastole (distinct from p wave and systolic EGMs)
	Large shift in EGM timing with small catheter movement
	Low-amplitude, fractionated EGM
	Concealed entrainment possible
	Long stim to p-wave interval >50 ms
Double potentials	Disparate signals from same catheter >50 ms
	Convergence of signals toward the ends of an atriotomy
	Palpation of surgical ridge
Bystander versus participating site	Entrainment PPI-TCL < 30 ms
Nonconductive barrier	Electrically unexcitable regions
	Very low-amplitude signal (<0.3 mV)

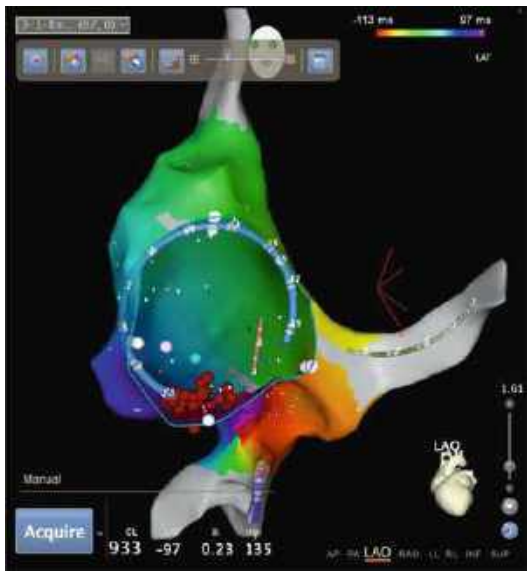

Fig. 139.4 Typical cavotricuspid isthmus-dependent atrial flutter. Activation proceeds in the counterclockwise direction around the tricuspid valve annulus with lesions placed between the TVA and the IVC to interrupt the reentrant circuit (*red circles*)

a series of well-described electrophysiologic techniques [58, 59, 61] (Table 139.1). Radiofrequency energy is subsequently delivered to transect the area of slow conduction, with the overall goal to connect two anatomic obstacles and produce complete conduction block in these regions.

Catheter Ablation of Atrial Tachycardia

Atrial tachycardia, including both typical (cavotricuspid isthmus-dependent) atrial flutter and incisional atrial reentrant tachycardia (IART), is the most common type of arrhythmia in the setting of congenital heart disease. Although typical flutter remains the most common mechanism in this population [62], the incidence of a particular tachycardia substrate varies dramatically with the type of congenital malformation. Mapping and ablation techniques for the treatment of atrial tachycardias are described in the following sections with an emphasis on the underlying congenital cardiac anatomy.

Tetralogy of Fallot and related lesions such as double-outlet right ventricle are the most common forms of cyanotic congenital heart lesion and are thus frequently seen in the electrophysiology laboratory [23, 63]. Most atrial arrhythmias in this group of patients are related to typical atrial flutter, although IART circuits around atriotomy incisions contribute significantly [64]. The circuit in typical atrial flutter often proceeds in the counterclockwise direction around the tricuspid valve annulus when viewed from the LAO projection (Fig. 139.4). Lesions placed between the tricuspid valve annulus and the IVC are effective for interruption of this circuit. In some patients, a combination of both circuits, known as dual-loop reentry, occurs, for which complete elimination of both circuits is essential in order to avoid recurrence of the clinical arrhythmia (Fig. 139.5) [65, 66].

The AV septal defect (AVSD) is another common congenital cardiac malformation associated with reentrant atrial tachycardias. Similar to tetralogy of Fallot and its variants, typical atrial flutter and periatriotomy (IART) circuits are common and are approached in a similar fashion

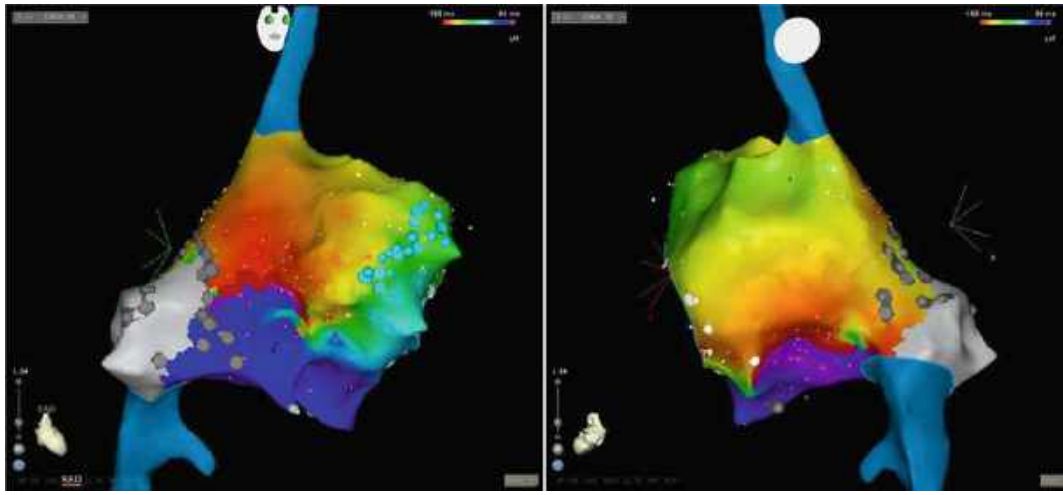

Fig. 139.5 Dual-loop reentry in a patient with tetralogy of Fallot. (**a**) shows RAO view and (**b**) shows a titled PA view. Simultaneous wavefronts are present, rotating in opposite directions around an atriotomy in the right atrial free wall (*clockwise*) and the tricuspid valve annulus (*counterclockwise*)

(Fig. 139.3) [62]. A vital consideration when performing catheter ablation in this population is the altered disposition of the conduction system. Depending on the degree of deficiency in the primum atrial septum, the compact AV node is variably displaced in the posterior direction to a new "nodal triangle" formed by the boundaries of the coronary sinus ostium, the bridging tendon of the primum atrial septum, and the attachment of the posterior bridging leaflet at the posterior fibrous area [67, 68]. Due to this abnormal location, lesions intended to transect the typical cavotricuspid isthmus should be placed more laterally than usual, to avoid permanent injury to the AV node and resultant AV block.

For patients who have undergone surgery with one of the modifications of the Fontan operation, the development of atrial arrhythmia is exceedingly common [69]. Tachycardia circuits in this group are rarely those of typical cavotricuspid isthmus-dependent atrial flutter and are more often the result of IART, with special predilection for sites involving the right atrial free wall [70, 71]. Depending on the underlying congenital heart disease, the substrate for typical atrial flutter may not even exist in this group of patients, and unique circuits such as pericaval reentry have instead been implicated [72]. The most recent modification of the Fontan operation, the extracardiac conduit, was designed to reduce overall arrhythmia burden in this population by rerouting blood flow through the systemic venous conduit. While its effectiveness in this regard is encouraging, this latest modification has introduced new challenges for catheter ablation. Not only is the systemic venous circulation separated from the atrium after this surgery, but the intervening material is often composed of Dacron or Gore-Tex which may or may not be directly adherent to the lateral atrial wall. A recently proposed technique for catheter ablation in this population involves a combination of conventional transseptal puncture technique and radiofrequency energy to perforate the surgical material and enter the atrial chamber (Fig. 139.6) [73]. Patients who have undergone Fontan operation presenting with IART are the most challenging group for catheter ablation. The underlying atrial anatomy is complex, there are often multiple scars and multiple circuits, and the excessive atrial thickness can make catheter ablation difficult if not impossible. Improvements over the past decade have included the availability of three-dimensional electroanatomic mapping techniques such as the CARTO system (Biosense Webster, Diamond Bar, CA) and the ESI system (Endocardial Solutions

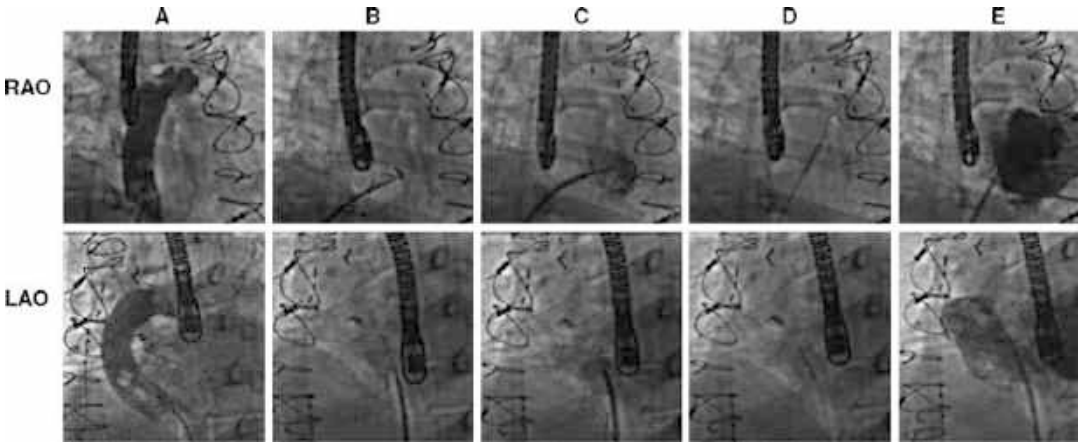

Fig. 139.6 Transbaffle perforation for access to the pulmonary venous atrium in a patient with an extracardiac Fontan. The baffle is stained with contrast and the cardiac chamber is entered with fluoroscopic and TEE guidance

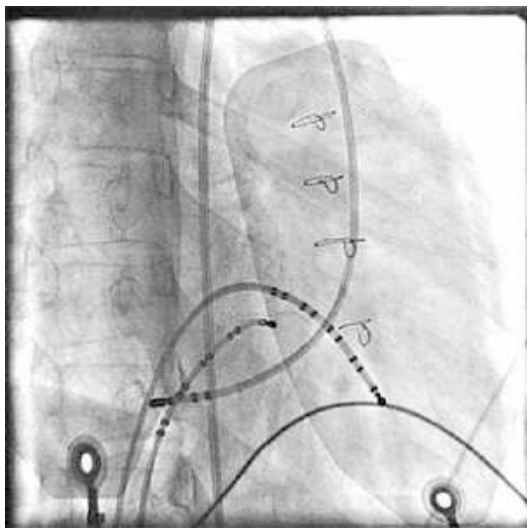

Fig. 139.7 RAO view of cavotricuspid isthmus ablation in a patient with Mustard repair: catheter position shows retrograde approach to pulmonary venous atrium. Note the catheter which has passed through the aortic and tricuspid valve with its tip situated posteriorly within the pulmonary venous atrium

Inc., St Paul, MN) which help with better characterization of the atrial anatomy including areas of scar and also help to develop a three-dimensional understanding of the activation and propagation of the IART circuit. The advent of cooling tip technology for the ablation catheter (e.g., Thermocool) has allowed the creation of larger and deeper lesions with ensuing improvement in acute and chronic success from ablation.

The Senning operation for transposition of the great arteries and later the Mustard procedure inevitably result in multiple suture lines in the right atrium, predisposing to the development of atrial arrhythmia [74, 75]. Arrhythmia in this population is most commonly the result of typical AFL and less frequently involves the morphologic right atrial free wall. As opposed to other forms of congenital heart disease, the cavotricuspid isthmus is partitioned into both systemic venous and pulmonary venous portions by nature of the surgical baffle which transects this region [76]. Depending on where the baffle suture line has been placed, typical AFL can occasionally be interrupted exclusively from the systemic venous side, although a complete line of block is usually only achieved by either the retrograde approach or transseptal puncture to reach the tricuspid valve annulus (Fig. 139.7) [77]. Similarly, the native right atrial free wall can only be reached by entering the pulmonary venous atrium, with improved catheter angulation and stability usually achieved by transseptal puncture. The latter approach is particularly useful for these patients, with the added benefit of a reduction in trauma to the aortic and tricuspid valves, which are necessarily crossed during the retrograde approach.

Table 139.2 Congenital cardiac lesions and associated arrhythmia

Congenital lesion	Associated arrhythmia
Ebstein's anomaly	AVRT, AT/AFL
l-transposition of the great arteries	AVRT, AV block
AV septal defect	AV block, AT/AFL
Heterotaxy syndrome	Twin AV node AVRT, SND, AV block
d-transposition of the great arteries (atrial baffle)	SND, AT/AFL
Tetralogy of Fallot	VT, AT
Left-sided obstruction	AF, VT
Univentricular heart	AF, AT

AVRT AV reentrant tachycardia, *AT* atrial tachycardia, *AFL* atrial flutter, *VT* ventricular tachycardia, *SND* sinus node dysfunction

Table 139.3 Location of the AV node according to congenital cardiac lesion

Congenital lesion	Location of the compact AV node
AV septal defect	Anterior to CS os, junction of primum septum and ventricular crest
L-transposition of the great arteries	Anterolateral mitral valve annulus
Double inlet LV	Anterolateral tricuspid valve annulus
Tricuspid atresia	Tricuspid valve "dimple" (coalescence of nodes)
Hypoplastic RV, overriding TV	Posterolateral tricuspid valve annulus
Heterotaxy syndrome	Variable

Catheter Ablation of Other SVT Mechanisms

Although less common than atrial tachycardia, patients with congenital heart disease and prior surgical palliation may present with other forms of supraventricular tachycardia (SVT). A close association often exists between the form of congenital heart disease and the type of SVT in these patients (Table 139.2).

As mentioned previously, AV reentrant tachycardia (AVRT) related to either a manifest or concealed accessory pathway is the most common ablation target in patients with Ebstein's anomaly of the tricuspid valve [78] and is frequently associated with l-transposition of the great arteries when Ebstenoid malformation of the left-sided tricuspid valve is present. Catheter ablation for these patients can be complicated by multiple accessory pathways as well as atrialization of ventricular tissue resulting in fragmentation of endocardial electrograms over a wide area, resulting in difficulty in discerning appropriate annular sites for ablation. These obstacles can usually be overcome with separation of atrial and ventricle signals using timed pacing maneuvers [79, 80]. Ablation of AVRT in other forms of congenital heart disease is usually performed via the usual techniques; however, issues such as difficulty with access to the accessory pathway related to baffles and other surgical obstacles can exist. The risk for AV block in patients with a congenitally abnormal disposition of the conduction system must also be carefully considered before delivering ablative therapy.

AV node reentry tachycardia (AVNRT) is seen increasingly with age and is the most common form of SVT in the general adult population [81]. Patients with repaired congenital heart disease are not spared from this process, but due to alterations in the location of the AV node in several congenital lesions, catheter ablation of AVNRT may be associated with increased complexity (Table 139.3). Two lesions that deserve mention here are AV septal defect and l-transposition of the great arteries in which abnormalities of AV node location are particularly common.

Although the true location of the slow pathway inputs is unknown for patients with AV septal defect, successful treatment of AVNRT has been described. Initial reports described placing the catheter in a posterior position below the location of the His bundle electrogram and using cryoenergy applications with progressively more septal lesion application [82, 83]. Modification of the slow pathway above the level of the His bundle (also using cryoenergy) has also been described [84], and finally, left-sided approaches to ablation of both the retrograde fast [85] and slow [86] pathways have also been reported using

radiofrequency energy when access to the right side of the septum was hindered by previously placed surgical patch material. Less information is available for patients with l-transposition of the great arteries in whom pathologic studies have generally demonstrated an anterolateral location of the compact AV node [87]. Whereas the slow pathway was successfully modified in the typical posteroseptal region in one study [88], a location above the His bundle in the anteroseptal region was successful in another [33].

Atrial Arrhythmia Surgery

Arrhythmia surgery can be a therapeutic option in a variety of situations in patients with CHD and atrial arrhythmias. First, the presence of a concomitant hemodynamic problem for which the patient needs surgery may make this an attractive option. For example, a patient with a Fontan operation who has an obstruction within the Fontan conduit who also has episodic atrial arrhythmias is likely to be a good candidate for such an approach. While it is potentially possible that improvement in the hemodynamic aspect may make the patient better able to tolerate the arrhythmia, it is wise to use the opportunity during surgery to address the arrhythmia which can be performed by variations of the Maze operation [89]. Also it is generally a clinical axiom that trying to manage the arrhythmia without addressing the underlying hemodynamic problem is unlikely to succeed. An example of such thinking would be to try to control AF without relieving the obstruction in a patient with significant mitral stenosis.

The most challenging patients are those with single ventricle and a Fontan operation with recurrent IART unresponsive to drug therapy or to catheter ablation. One important approach involves surgical conversion of the conventional atriopulmonary connection type of Fontan to an extracardiac conduit combined with a right atrial Maze procedure (including placement of a pacemaker to alleviate the expected sinus node dysfunction) [90]. Multiple groups have reported encouraging results using such an approach [91–94].

Ventricular Arrhythmias

There is a varied presentation of ventricular arrhythmia for the patient with congenital heart disease. As mentioned previously, ventricular arrhythmia is the presumed mechanism of sudden cardiac death in this population. Despite this, patients with nonsustained ventricular tachycardia may be completely asymptomatic, being detected only during ambulatory monitoring or intracardiac device monitoring. On the other hand, patients with sustained monomorphic ventricular tachycardia may present with severe hemodynamic disturbance or even cardiac arrest.

The pathophysiology of ventricular arrhythmia in the congenital heart population is incompletely understood, but available evidence would suggest that there is considerable overlap between sustained ventricular tachycardia (VT) and late sudden cardiac death (SCD). For most forms of repaired congenital heart disease, data suggests that reentrant VT is related to prior surgical scars and surrounding fibrosis that develop with time after surgery, exacerbated by ventricular dilation [3, 9, 95]. In patients with significant residual hemodynamic defects, however, these rhythms may be poorly tolerated and result in late mortality. Although initial studies evaluating the issue of SCD in patients with repaired tetralogy of Fallot stressed the importance of RV outflow tract obstruction as predisposing to SCD [95–97], LV dysfunction has recently emerged as a major risk factor in this population [11, 98]. Risk factors for both sustained ventricular tachycardia and SCD continue to be explored, and the ideal marker for these outcomes awaits the results of further large-scale clinical trials. The evaluation and management of SCD in the setting of congenital heart disease as well as the risk factors for this occurrence are discussed later in this chapter.

For the patient presenting with suspected ventricular arrhythmia, initial assessment should include careful examination of the 12-lead electrocardiogram. Features of monomorphic VT include the finding of VA dissociation, in which the ventricular rate is faster than, and independent of, the underlying sinus rhythm. This finding is

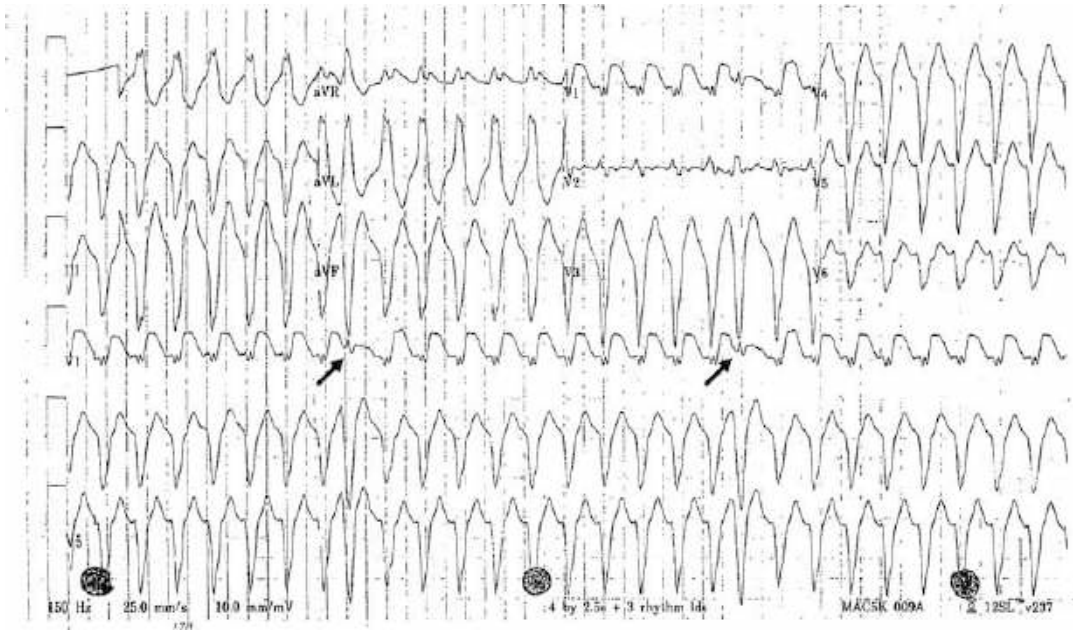

Fig. 139.8 Ventricular tachycardia at a rate of 170 bpm in a patient with prior surgical repair for tetralogy of Fallot. Note the LBBB morphology and left axis deviation (in contrast to RBBB in sinus rhythm), as well as intermittent sinus capture beats (*black arrows*), consistent with VA dissociation

essentially pathognomonic of VT in any setting and excludes the often-confusing situation of SVT with aberrancy. Findings associated with VA dissociation include fusion beats and sinus capture which further support the diagnosis (Fig. 139.8). Another supportive feature of sustained VT, especially in the patient with tetralogy of Fallot and related surgical populations, is the bundle-branch morphology. Approximately 75 % of ventricular tachycardias in the setting of tetralogy of Fallot are of left bundle-branch block (LBBB) morphology [9]. Since the vast majority of patients with tetralogy of Fallot have a right bundle-branch block (RBBB) morphology after surgical correction, the finding of LBBB during tachycardia essentially excludes the possibility of aberrant conduction of SVT. Similarly, inspection of the baseline ECG (if available) in the setting of other forms of congenital heart disease may be helpful if there is uncertainty regarding the diagnosis.

Depending on the hemodynamic status of the patient, initial management is likely to include either direct current cardioversion or sometimes antiarrhythmic therapy to restore sinus rhythm. Commonly used agents in the latter situation include procainamide, lidocaine, or amiodarone and are especially useful if there is a requirement for ongoing arrhythmia suppression for recurrent or incessant rhythms.

After stabilization of the patient, a search for correctable hemodynamic disturbances should take place. If a significant residual surgical lesion is identified, then the option of arrhythmia surgery in combination with the other indicated surgical procedure can be entertained. One well-described technique in the setting of tetralogy of Fallot includes mapping of the arrhythmia substrate in the operating room together with pulmonary valve replacement. With the use of a customized endocardial balloon and epicardial sock in such cases, cryoablation of the involved regions can be specifically targeted [9, 99, 100]. Excellent success rates have been described using these techniques with an associated decrease in arrhythmia burden after surgery [9, 101].

In most other situations, placement of an implantable cardioverter-defibrillator (ICD) is indicated in accordance with current secondary prevention guidelines [102]. ICD therapy has been validated in the setting of congenital heart disease but is unfortunately fraught with difficulties and potential negative consequences in this population. For most single ventricle patients, these devices require repeat sternotomy for epicardial placement of the pacing and defibrillation leads, which is a major hardship for the patient and is not without its own associated morbidity and mortality. For other patients with biventricular repair, transvenous placement of the high-voltage coil across the tricuspid valve may result in worsening tricuspid regurgitation in the setting of a hypertensive right ventricle, a common finding in this population. One approach to avoid both of these issues involves placement of a subcutaneous high-voltage coil for defibrillation in combination with a pace-sense lead in a branch of the coronary sinus [103].

Catheter ablation therapy can be used in combination with ICD placement. For VT that is hemodynamically stable (particularly in the biventricular population), catheter ablation may be performed concurrent with the ICD placement to modify or eliminate the arrhythmia substrate and decrease the likelihood of future shocks. Alternatively, for the patient who has previously undergone ICD placement and who receives multiple therapies that are refractory to medical treatment, catheter ablation can be utilized to lessen or potentially eliminate future shocks.

Chronic antiarrhythmic therapy should be used with caution in association with ICD therapy as the conduction slowing induced by many of these agents may slow the circuit such that it escapes detection by the ICD. In addition, many of the commonly used antiarrhythmic agents increase the threshold for defibrillation, so that repeat testing of the device may be warranted upon their initiation. One agent that lowers the defibrillation threshold is d-sotalol which can be effective in this population and useful in the appropriate setting. Unfortunately, sotalol is associated with an increased risk of sudden death in patients with ventricular dysfunction (EF < 40 %) [104] and should therefore be used with caution in this setting, even in the presence of an ICD. Conversely, amiodarone and beta-blockers have not been shown to have an adverse effect on mortality risk, but have been shown to cause a modest increase in defibrillation threshold in some studies [105].

Catheter Ablation of Ventricular Tachycardia

Catheter ablation of ventricular tachycardia (VT) in the setting of congenital heart disease has focused primarily on repaired tetralogy of Fallot and its variants, due to the close association of ventricular arrhythmia and late sudden death with this lesion. Early work in the preablation era demonstrated areas of slow conduction localized to regions of prior surgical repair [106–110], which suggested a reentrant mechanism for VT after repair of tetralogy of Fallot. Clinicopathologic correlation supported the notion that diseased myocardium near sites of prior surgical repair were responsible for maintaining reentry [100] and intraoperative mapping studies confirmed macroreentry around surgical scars during induced VT in the operating room [99].

Catheter mapping in this setting has utilized a variety of electrophysiologic techniques, many of which overlap those for atrial tachycardia as discussed previously. Since VT may be poorly tolerated in the congenital heart patient with ongoing hemodynamic disturbance, the technique of substrate mapping is often utilized (Fig. 139.9) [111, 112]. This involves careful sampling of tissue voltages in various regions of the right ventricle, with annotation of areas of low voltage as well as nearby structural landmarks. Based on prior work, a limited number of critical isthmuses can be found in the setting of tetralogy of Fallot, allowing for a focused evaluation at these sites [113]. After clarification of the relevant anatomic obstacles, tachycardia can briefly be induced and then followed by limited pacing techniques to verify critical participation of the suspected site in the tachycardia (Fig. 139.10). Ablation is then performed to connect anatomic obstacles and interrupt the reentrant circuit.

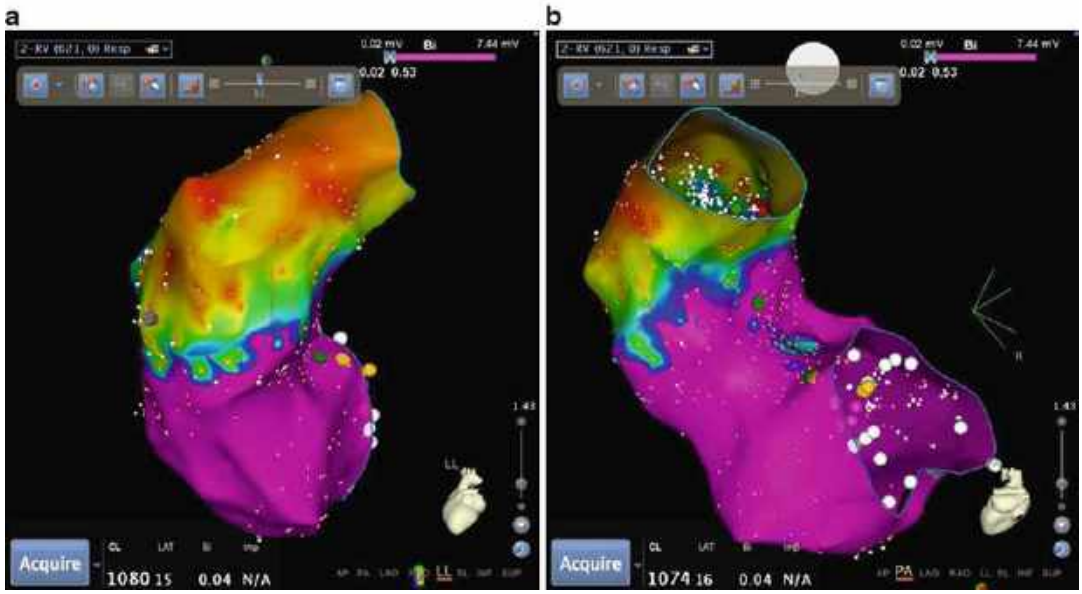

Fig. 139.9 (**a**) Voltage map of the right ventricle in a patient after repair of tetralogy of Fallot. There is aneurysmal dilation of the RVOT associated with diffuse scar surrounding the prior outflow tract patch site. (**b**) Mapping of the posteroseptal surface of the right venrtricle revealed a small ventricular septal patch located above the bundle of His (*yellow dot*) consistent with prior surgical closure of a perimembranous VSD with posteroinferior course of the conduction tissue as typically seen with this defect. A narrow channel of conduction is formed by the tissue between the posterior portion of the pulmonary valve and the septal patch.

Although there is a paucity of data for VT ablation in the setting of other forms of congenital heart disease, occasional examples do exist. One such situation is that of ischemic VT after coronary reimplantation in patients with d-transposition of the great arteries. Similar to post myocardial infarction VT as seen in the adult patient with coronary artery disease, classic substrate mapping and ablation techniques can be used to treat these tachycardias with satisfactory results [114, 115].

Sudden Death in Adult Congenital Heart Disease

As the operative mortality for congenital heart disease (CHD) has decreased over the decades, an increasing number of patients with CHD are entering adulthood. However, these adult survivors of repaired CHD remain at premature risk of death. Deaths in CHD have shifted away from infants and toward adults, with a steady increase in age at death [116]. Sudden cardiac death (SCD) is one of the leading causes of death in patients with CHD [117], but because of the low overall annual incidence of sudden death, it may be challenging to risk stratify these patients.

The modes of death for adults with CHD have not been well defined. The most frequent cause of SCD is believed to be arrhythmic, usually ventricular arrhythmia [118–120]. Factors shown to be associated with an increased mortality risk in adults with CHD include atrial arrhythmias [121] and severe subaortic ventricular systolic dysfunction [122]. However, the predictive value for any single risk factor for the occurrence of SCD is relatively low. Most studies investigating risk factors for ventricular arrhythmia and/or SCD have focused on patients with repaired tetralogy of Fallot, patients with Mustard or Senning repair for complete transposition of the great arteries, and patients with Fontan repair.

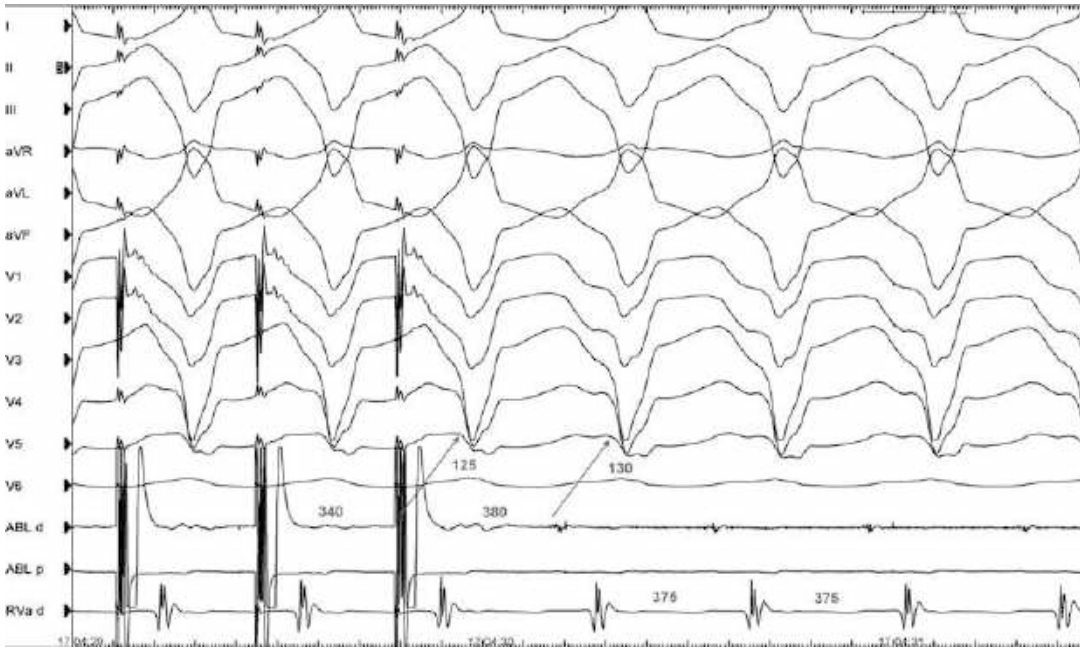

Fig. 139.10 Entrainment pacing in the same patient. Note that the QRS morphology is identical during pacing as well as during the subsequent native VT ("concealed fusion"), which suggests pacing from a protected isthmus. Also the postpacing interval (380 ms) is nearly identical to the subsequent tachycardia cycle length (375 ms) suggesting that the pacing site is within the tachycardia circuit, rather than a bystander site connected to the isthmus

Magnitude of the Problem

The estimated population of adults with CHD in the USA is approximately 850,000 and the overall annual incidence of SCD is estimated at 0.09 % per year (765 SCDs/year) [123, 124]. Although the incidence of SCD varies widely between specific lesions, surgical repair of most congenital heart defects is associated with lingering cardiac mortality. Silka et al. [124] found the highest annual incidence of SCD in patients with repaired aortic stenosis (0.54 % per year), complete transposition of the great arteries (0.49 % per year), tetralogy of Fallot (0.15 % per year), and aortic coarctation (0.13 % per year). A population-based cohort study [125] found late cardiac mortality at 25 years after surgery to be 5 % for tetralogy of Fallot and isolated ventricular septal defect, 10 % for coarctation of the aorta, 17 % for aortic stenosis, 5 % for pulmonic stenosis, and less than 1 % for patent ductus arteriosus; there were no late cardiac deaths after atrial septal defect repair. In a cross-sectional study [126] performed on a population of adults assessed at a CHD specialty clinic, mean age at death was 37 ± 15 years. Mortality was highest in patients with congenitally corrected transposition of the great arteries (26 %), tricuspid atresia (25 %), and univentricular connection (23 %). The youngest mean age at death was observed in patients with tricuspid atresia (27 ± 5 years), complete transposition of the great arteries (27 ± 7 years), pulmonary atresia (27 ± 6 years), and aortic coarctation (29 ± 6 years).

Tetralogy of Fallot

Sudden death of presumed arrhythmic etiology is the most frequent mode of demise in patients with surgically repaired tetralogy of Fallot, often in

early to mid-adulthood [127]. In the largest cohort study of 793 patients with repaired TOF, 11.9 % experienced sustained ventricular tachycardia and 8.3 % died suddenly at 35 years from repair [128]. Khairy et al. [11] performed a multicenter cohort study of patients with TOF and implantable cardioverter-defibrillators (ICD) in order to determine the rate of appropriate ICD discharges as a surrogate for sudden cardiac death. They reported a 7.7 % annual shock rate of appropriate discharges in primary prevention patients. Elevated LV end-diastolic pressure ($\geq$12 mmHg) and nonsustained VT independently predicted appropriate ICD discharges [11].

Transposition of the Great Arteries

The intra-atrial baffling procedure was commonly used between the 1970s and 1990s for transposition of the great arteries. Shortened life expectancy and increased risk of sudden death are well documented after atrial switch operations. The estimated incidence of SCD after the intra-atrial baffling procedure at 19 years of follow-up is 8.0 % [129]. Schwerzmann et al. showed that in an adult Mustard population, the incidence of sustained VT and/or SCD was 9 % during a follow-up of 9 $\pm$ 6 years after first presentation to an adult congenital cardiac clinic [130]. Risk factors for sustained VT and/or SCD included subaortic RV dysfunction (ejection fraction $<$ 40 %), congestive heart failure (NYHA class $\geq$ III), QRS duration of 140 ms or longer, severe tricuspid regurgitation, and associated cardiac lesions. Change from the atrial to the arterial switch has led to improved long-term survival after hospital discharge. Survival at 20 years after arterial switch operation has been reported to be high (96.6 % $\pm$ 1.3 %) [131].

Fontan Repair

Long-term sequelae associated with Fontan palliation are increasingly appreciated as the first recipients with univentricular physiology enter their fourth decade of follow-up. In a large single-center cohort of patients with various forms of Fontan surgery, Khairy et al. [132] report a gradual attrition after the perioperative period, predominantly from thromboembolic, heart failure-related, and sudden deaths, with 70 % actuarial freedom from all-cause death or cardiac transplantation at 25 years. Risk of death from thromboembolism increased 15 years after Fontan surgery and was predicted by clinically identified thrombus and lack of aspirin or warfarin therapy. Heart failure-related mortality was minimal the first 10 years. Independent risk factors were single RV morphology, higher postoperative RA pressure, and protein-losing enteropathy. The incidence of sudden death was 0.15 % per year, with most events of presumed arrhythmic origin. This is similar to reported rates in tetralogy of Fallot and aortic coarctation but lower than complete transposition of the great arteries with an atrial level repair and aortic stenosis [133]. Although the cause of sudden death is likely multifactorial, arrhythmias clearly are responsible for a subset of events as evidenced by documented intra-atrial reentrant tachycardia with rapid 1:1 conduction, leading to cardiac arrest [133].

Prevention of Sudden Cardiac Death

ICDs are the mainstay therapy for primary and secondary prevention of SCD. Current experience with ICDs in this patient population is limited to observational studies, and the selection of patients for prophylactic ICD implantation is impeded both by the absence of randomized trials and weak predictors. A probabilistic approach using a combination of noninvasive risk factors and programmed ventricular stimulation, as suggested by Khairy et al., may be a useful strategy to select patients for device implants. Consensus is that patients with CHD who are survivors of SCD are candidates for ICD therapy. Catheter ablation of ventricular tachycardia has emerged as a promising therapy for abolishing or reducing the burden of arrhythmia, but experience is still limited and the impact on long-term outcome uncertain.

Aortic Coarctation in the Adult

140

Barry A. Love, Gregory W. Fischer, Paul Stelzer, and Valentin Fuster

Abstract

Coarctation of the aorta is one of the more common congenital lesions that may be recognized for the first time in adulthood. Recurrent coarctation of the aorta first treated in childhood is also commonly encountered in the adult age-group. Unrepaired coarctation of the aorta or repaired coarctation with residual stenosis may lead to premature atherosclerotic disease of the carotid and coronary arteries, and early left ventricular systolic and diastolic dysfunction. Significant coarctation or recoarctation of the aorta presenting in adulthood is treated with surgery or with transcatheter stenting. Although serious complications are possible, in general, very good immediate and long-term outcomes are expected after successful intervention though ongoing surveillance is mandatory. Many adult patients with coarctation despite complete or near-complete gradient relief will require lifelong antihypertensive medical therapy and surveillance for early-onset coronary artery disease.

Introduction

Coarctation of the aorta is defined as a narrowing of the aorta distal to the transverse aortic arch. While most patients with coarctation have a discrete narrowing just distal to the left subclavian artery, there is great anatomic heterogeneity. Coarctation of the aorta is thought to arise from an extension of tissue from the fetal ductus arteriosus onto the adjacent aortic wall. With ductal constriction postnatally, the affected aortic wall also undergoes constriction leading to aortic luminal narrowing. While partially true, this explanation does not account for the posterior "shelf" seen on prenatal imaging of many patients with coarctation of the aorta (when the ductus is unconstricted) nor does it explain the frequent association with hypoplasia of the transverse arch. Earlier classifications used to describe coarctation in terms of the relationship to the ductus arteriosus (preductal, juxtaductal, or postductal). From a clinical standpoint, classification seems less important than understanding the relationship of the narrowed segment in relation to the head and neck vessels and the extent of the involved narrowing. An extreme form of coarctation may even be encountered in the adult with complete interruption of the aorta at the level of the isthmus (also called interrupted aortic arch type A). In this situation, the lower body is completely perfused by collateral vessels (Fig. 140.1). In this rare instance, the constriction at the isthmus to eventual obliteration is presumed to have occurred slowly over time allowing the left ventricle to adapt to an increased afterload without causing symptoms.

Coarctation can be described as being *simple* without other associated anomalies or *complex* with other associated abnormalities. When other associated lesions are present, they are typically left-sided obstructive lesions including bicuspid aortic valve (present in up to 85 %), aortic stenosis, subaortic membrane, and mitral valve abnormalities. Ventricular septal defects are also commonly associated with coarctation of the aorta.

Coarctation of the aorta may also be seen in association with other more complex forms of congenital heart disease including hypoplastic left heart syndrome (100 %), transposition of the great arteries (9–12 %) [1], and tricuspid atresia or double inlet left ventricle with transposed great arteries.

Epidemiology

Coarctation of the aorta with or without bicuspid aortic valve has a quoted incidence in the population of about 2 in 1,000 live births [2, 3]. This number underestimates the true incidence as it derives from data of newborns with congenital heart disease. As coarctation of the aorta is frequently diagnosed later in childhood or adulthood, this incidence number underrepresents the true incidence. The male to female ratio is approximately 1.5:1 [2]. There does not appear to be a geographic or ethnic predisposition.

Genetics

The genetics of coarctation of the aorta are not well understood. Nonetheless, it is one of the more heritable forms of congenital heart disease. Siblings of patients with coarctation have about a 1:200 risk of having coarctation themselves and 1 % of any form of congenital heart disease [4]. Offspring of mothers with a history of coarctation of the aorta have an increased chance of giving

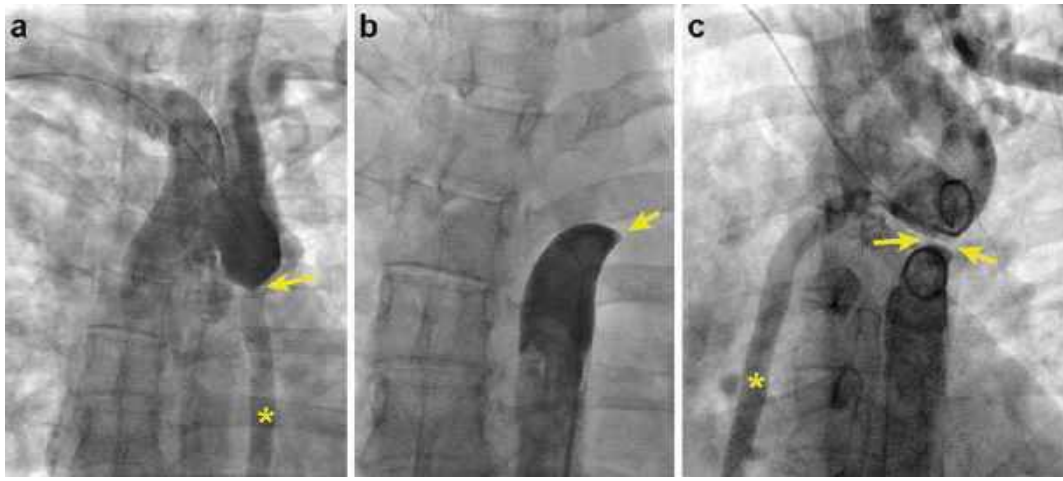

Fig. 140.1 Forty two-year-old woman with severe hypertension diagnosed for 20 years managed medically with three antihypertensive drugs. Despite medications, blood pressure in right arm 172/74. Underwent MRA to evaluate for renal artery stenosis and severe coarctation versus **interupted aortic arch type C** was discovered. After diagnosis, blood pressure in lower extremities performed (90/55). *Panel A* 4Fr pigtail catheter passed from right radial artery to distal aortic arch. Angiography in AP projection shows aortic atresia at isthmus (*arrow*). Note large tortuous collateral (*). *Panel B* 5Fr pigtail passed from right femoral artery to upper thoracic aorta. Angiogram in same AP projection shows atretic aorta (*arrow*). *Panel C* Simultaneous injection in proximal and distal pigtail catheters in LAO projection showing "gap" of 3 mm between the segments (*arrows*). Not the same large collateral (*) as shown in panel A. This patient underwent complete repair with 20 mm interposition graft. At 6 months post-procedure, she is normotensive (121/69 right arm) on no antihypertensive medications

birth to a child with congenital heart disease on the order of about 4 % [5]. Although the offspring of parents with coarctation may also have coarctation, there is a wide spectrum of other cardiac lesions including left-sided obstructive lesions that may be seen up to and including hypoplastic left heart syndrome.

Coarctation of the aorta is found much more frequently (about 15 %) in Turner's syndrome (45 XO) patients [6]. Patients with Turner's syndrome additionally have short stature, webbed neck, and primary amenorrhea.

Presentations

Extreme narrowing of the aorta may require the presence of the ductus arteriosus to perfuse the lower body and is deemed a *critical coarctation*. This extreme form of coarctation may present in the newborn with lower extremity desaturation as the ductus arteriosus supplies the lower half of the body with blood. As the ductus constricts in the first days to weeks of life, there is an acute rise in left ventricular afterload, absence of femoral pulses, progressive metabolic acidosis, and shock. In the era before prostaglandin (early 1980s in developed countries) and to this day in underdeveloped countries, this severe form of coarctation is typically fatal. In the modern era, prostaglandin is administered intravenously to reopen the ductus arteriosus and the constricting ductal tissue in the aorta. This restores lower body perfusion. After a period of stabilization, neonatal repair of coarctation is typically performed using a variety of methods (see "Surgical Approaches" section).

With the increasing application of fetal echocardiography, many fetuses with coarctation of the aorta are diagnosed prenatally, avoiding the reliance on signs and symptoms to alert the clinician to the diagnosis before clinical decompensation ensues.

If the narrowing of the aorta is less severe, ductal closure will acutely raise the left ventricular afterload, but there is sufficient lower body perfusion to avoid shock. Signs of tachypnea,

gallop rhythm, and weak or absent femoral pulses are the heralding clinical signs for the pediatrician. In the era prior to neonatal repair, infants were managed clinically with digitalis and diuretics, until surgical repair was feasible. With time, collateral arterial vessels will enlarge, lessening the volume of blood that is required to transverse the narrowed segment.

Moderate coarctation of the aorta typically presents with the finding of hypertension in the upper extremities or diminished femoral pulses in the child or adult.

Mild coarctation may present with hypertension. There is usually only a mild pressure difference across the coarctation. In these instances, there may be clinical uncertainty as to whether intervention is required.

Natural History

The first description of coarctation was a postmortem case report by Paris in 1791 [7]. In 1928, Maude Abbott compiled the largest postmortem case series of 200 of her own specimens and those appearing in the literature [8]. Reifenstein published another postmortem series in 1946 compiling another 104 cases [9]. Of these 304 cases, the median age of death was 31 years, and 76 % of those deaths were attributed to complications of coarctation. The most common cause of death was heart failure (26 %) and occurred at a mean age of 37 years. Other causes of death included aortic rupture (21 %), bacterial endarteritis (18 %), and intracranial hemorrhage (12 %). Of the patients with intracranial hemorrhage, 1/3 had ruptured cerebral aneurysms.

Campbell compiled data from three large case series of patients followed with coarctation in the era prior to surgical repair [10]. In 181 patients, 22 deaths were observed. The mortality rate was 1.6 %/year for patients younger than 20 years of age rising to 6.7 % for those aged 60 and older. Again, the most common etiologies for death were heart failure, bacterial endarteritis, and intracranial hemorrhage.

Since premature coronary artery disease has long been said to occur in coarctation patients, it is curious that coronary artery disease does not emerge as a cause of death in these early non-operated series. These patients certainly had significant coarctation to be represented in the pathological and clinical case series in this early, presurgical era. This likely parallels the relatively low incidence of coronary artery disease in the population in those era and lends support to a "multiple-hit" model of coronary artery disease where multiple risk factors (hypertension, obesity, hyperlipidemia, diabetes, smoking, and sedentary lifestyle) act in concert to produce coronary artery disease. As will be discussed in later sections, coronary artery disease becomes an important mode of death in patients with repaired and unrepaired coarctation likely due to the prolonged hypertension but only in the "baby boomer" generation and beyond where other risk factors were also becoming major public health issues.

Symptoms

The adult with coarctation of the aorta is usually asymptomatic. Patients may present with symptoms thought to be associated with hypertension (headaches) or rarely with angina associated with premature coronary artery disease. Shortness of breath as a presenting symptom due to left ventricular systolic and diastolic dysfunction is seen. Lower extremity claudication has been reported to be a presenting symptom though is infrequent. Rarely a ruptured cerebral aneurysm may be the presenting symptom. Adults with recoarctation of the aorta may present with symptoms similar to primary coarctation or those related to complications of repair such as a leaking or ruptured aneurysm of the aorta presenting with chest pain or with hemoptysis from erosion into a bronchus.

Physical Findings

General Appearance

Adults with coarctation of the aorta generally appear well. The presence of a surgical scar on the chest offers important clues if the patient had

prior surgical intervention as a child. A lateral thoracotomy scar will be present if the approach was end to end, left subclavian flap, or interposition graft, whereas a midline incision is indicative of a repair typically done on cardiopulmonary bypass requiring arch augmentation or some other intracardiac repair (e.g., VSD repair). In some patients, a thoracotomy approach as a child may have led to the development of scoliosis.

Blood Pressure

The most important physical finding in the adult with coarctation of the aorta is upper extremity hypertension and a blood pressure gradient between the upper and lower extremities. It cannot be stressed enough that four extremity blood pressures are critical for evaluation and management of the patient with coarctation of the aorta. The right arm blood pressure is usually the one that reflects the hypertension. However, in the presence of an aberrant right subclavian artery, the right arm blood pressure may be distal to the obstruction. The left arm blood pressure is usually elevated in most patients with coarctation with the left subclavian artery arising proximal to the stenosis; however the left subclavian may be within the stenosis or distal to it, making the left arm blood pressure lower than the ascending aortic pressure. The left arm blood pressure may also be decreased in patients having undergone repair of coarctation with acquired stenosis of the left subclavian or complete division of the artery if the subclavian flap technique was used.

Lower extremity blood pressures are easily obtained with an automated blood pressure cuff. Usually a large adult cuff on the leg will produce an accurate reading. A manual blood pressure cuff may be also be used using a long thigh cuff with a bladder size of 18 × 42 cm applying it midthigh. The cuff is centered so that the bladder is over the posterior aspect of the thigh. The stethoscope is applied over the popliteal artery, and the cuff is then inflated and deflated as usual listening for the Korotkoff sounds over the popliteal artery. The patient should be supine or with the leg flexed slightly when the lower extremity blood pressure is determined [11]. Although the leg blood pressures should be equally reduced in patients with coarctation of the aorta, femoral arterial injury due to prior catheterizations in infancy and childhood may lead to reduced blood pressure in the affected extremity and overestimate the degree of obstruction due to coarctation.

In the absence of coarctation, the lower extremity blood pressures are usually slightly higher than the arm blood pressures due to pulse amplification of the pressure wave [12]. Coarctation should be considered when the upper extremity blood pressures exceed the lower extremity ones, though this is not the only consideration favoring intervention.

In milder degrees of obstruction, upper extremity hypertension is an important factor in considering intervention. In equivocal cases, 24-h ambulatory blood pressure readings may be helpful.

Other Findings

The presence of short stature, webbing of the neck, widely spaced nipples, and absence of secondary sexual characteristics are suggestive of Turner's syndrome.

Cardiac Examination

The precordial impulse is often normal. In the case of significant left ventricular hypertrophy as might be seen in significant coarctation or recoarctation, the apical impulse may be displaced to the left.

The first heart sound is usually normal and the second heart sound is typically normal. There may be an early systolic ejection click associated with a bicuspid aortic valve. A systolic ejection murmur or diastolic decrescendo murmur at the right upper sternal border or towards the apex would be associated with aortic stenosis or regurgitation.

A bruit is often heard in the upper back to the left of the spine. Significant collateral formation with intercostal dilation will cause a bruit to be heard more widely over the back.

Examination of the pulses is critical in assessment of patients with coarctation. The radial and femoral pulses should be examined bilaterally. These areas should also be examined for scar. If the patient had previously undergone surgery, radial arterial line placement may diminish the pulse on that side, and a scar will often be present on the skin. Similarly, if catheterized, arterial occlusion or stenosis of the femoral artery may have occurred and give a diminished pulse at that location. If catheterized as an infant, femoral arterial occlusion may have led to leg-length discrepancy with the lower extremity with the arterial injury growing slightly less long and with less muscle and soft tissue mass than the contralateral lower extremity.

The typical finding in significant coarctation is a *radiofemoral delay*. That is, the radial pulse and the femoral pulse are about equidistant from the aortic valve, and the pulse wave arrives at both in the normal patient at about the same time. In the case of coarctation of the aorta, the femoral pulse is typically diminished and arrives slightly later than the radial pulse. In overweight patients, the physical finding is less easy to elicit because the femoral pulse is more difficult to feel through the subcutaneous fat. Even in the presence of significant coarctation in the adult, this finding may be relatively subtle. Modest exercise such as a minute or two of "jumping jacks" will accentuate the radiofemoral delay.

Electrocardiogram

The ECG will often show left ventricular hypertrophy often with a "strain" pattern, and left atrial enlargement may also be present. Right bundle branch block pattern, either complete or incomplete, may be seen in unoperated patients and more often in patients who have undergone prior intracardiac repairs.

Chest X-Ray

The anteroposterior chest X-ray in coarctation may show the classic "3 sign" above the left border of the heart representing a shadow of indentation in the descending aorta. In addition, notching of the undersurface of the posterior thoracic ribs may be seen as a result of enlargement of the intercostal arteries deforming the bony ridge of the rib (Fig. 140.2). In reality, these signs while considered "classic" are often absent even in severe coarctation, and their absence should not be considered as important.

Imaging

Transthoracic Echocardiography

Transthoracic echocardiography is helpful to assess patients with coarctation of the aorta and is a useful adjunct to the clinical examination in patients suspected to have coarctation.

Imaging from the suprasternal notch will often show the coarctation, and continuous wave Doppler interrogation will provide an estimate of the gradient across the narrowing using the modified Bernoulli equation (Fig. 140.3).

Especially in mild coarctation, it is important to correct for proximal velocity so as not to overestimate the true gradient. The modified Bernoulli equation uses velocity to estimate a pressure gradient and is usually expressed as the following: Pressure gradient $= 4 * (\text{Velocity})^2$.

However, because the normal velocity in the aorta is often up to about 2 m/s, even a normal patient without any obstruction would yield a "gradient" of $4*2^2 = 16$ mmHg!

The correction for proximal velocity involves measuring the velocity before the narrowing with pulse-wave Doppler (V1) and the velocity across the obstruction (V2). The corrected velocity is then: pressure gradient $= 4V_1^2 - 4V_2^2$.

Doppler interrogation of the abdominal aorta also yields helpful additional information. In coarctation, there is blunting of the upstroke of the waveform and a slow decay of the velocity (Fig. 140.4).

Fig. 140.2 AP projection chest X-ray of a 28-year-old man with newly diagnosed coarctation of the aorta. Note the three signs due to indentation of the aorta at the coarctation as well as rib notching (*arrows*) due to erosion of the undersurface of the rib due to enlargement of the intercostal arteries acting as conduits from the upper to lower aorta (Published with permission from LearningRadiology.com)

In milder cases, the only abnormality of the abdominal Doppler pattern is absence of the flow reversal seen in early diastole.

In addition to gradient estimation, the echocardiogram is important to look for other associated anomalies including bicuspid aortic valve with stenosis and or regurgitation, dilated ascending aorta, ventricular septal defect, and mitral valve abnormalities and to assess the left ventricular function and wall thickness. Diastolic left ventricular function parameters are often measured.

Magnetic Resonance Imaging (MRI) and Computed Axial Tomography (CT)

MRI and contrast CT give excellent anatomic imaging for coarctation in the adult both native and recurrent. In addition to the coarctation segment, both CT and MRI are used to evaluate the extent of collateral vessels.

Contrast CT is a more rapid modality that yields excellent anatomic imaging. Three-dimensional reconstruction yields additional information that is helpful in planning repair and assessing for complications post-repair including aneurysm formation. If stenting of the coarctation area is performed, CT provides an excellent modality for follow-up as the stent artifact is minimal (Fig. 140.5).

The MRI yields good anatomic images that are almost as good as contrast CT (Fig. 140.6, Movie 140.1). In addition, because flow patterns can be assessed, MRI can additionally predict coarctation severity and predict peak-to-peak gradients of less than or greater than 20 mmHg found at catheterization using a combination of anatomic and flow parameters [13]. MRI can also be used to follow patients after surgical repair and balloon dilation of coarctation for aneurysm formation. Because of metal artifact, the MRI is less useful to follow patients who have received stents to treat coarctation.

In addition to the great vessels, both CT and MRI can be used to assess the presence of cerebral aneurysms which are present in 3–10 % of patients with coarctation [14] and, if left untreated, are an important cause of mortality.

The 2008 American College of Cardiology/American Heart Association guidelines recommend that every patient with coarctation of the aorta receive at least 1 MRI or CT to evaluate the thoracic aorta and intracranial vessels (level of evidence B) [15].

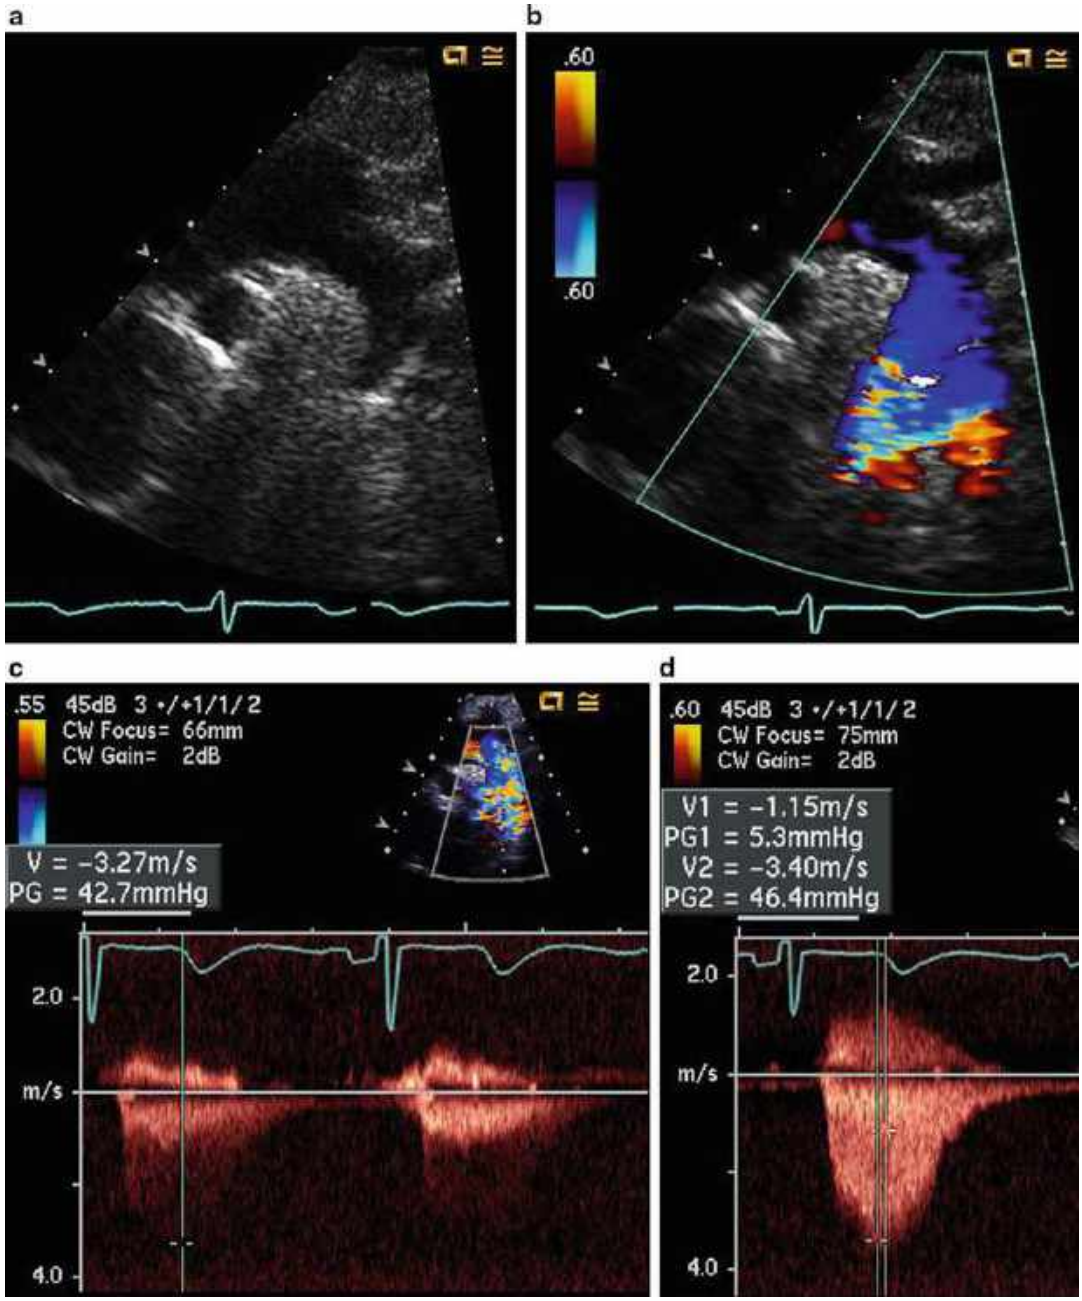

Fig. 140.3 Suprasternal notch echocardiographic imaging in a 32-year-old woman with native coarctation. *Panel A* Two-dimensional imaging shows the aortic arch with tapering of the aorta distal to the left subclavian artery. The coarctation site is not imaged well shadowed by the left bronchus as is typical in adult patients with coarctation. *Panel B* Color Doppler imaging of the distal transverse arch and aortic isthmus in patient with coarctation. Note the flow acceleration at the isthmus suggestive of coarctation. *Panels C and D* Continuous wave Doppler through the aortic isthmus showing a "double envelope." The proximal velocity (1.15 m/s) and the distal velocity (3.4 m/s) are shown. The modified Bernoulli equation estimates the gradient across the coarctation of 46 mmHg − 5 mmHg = 41 mmHg

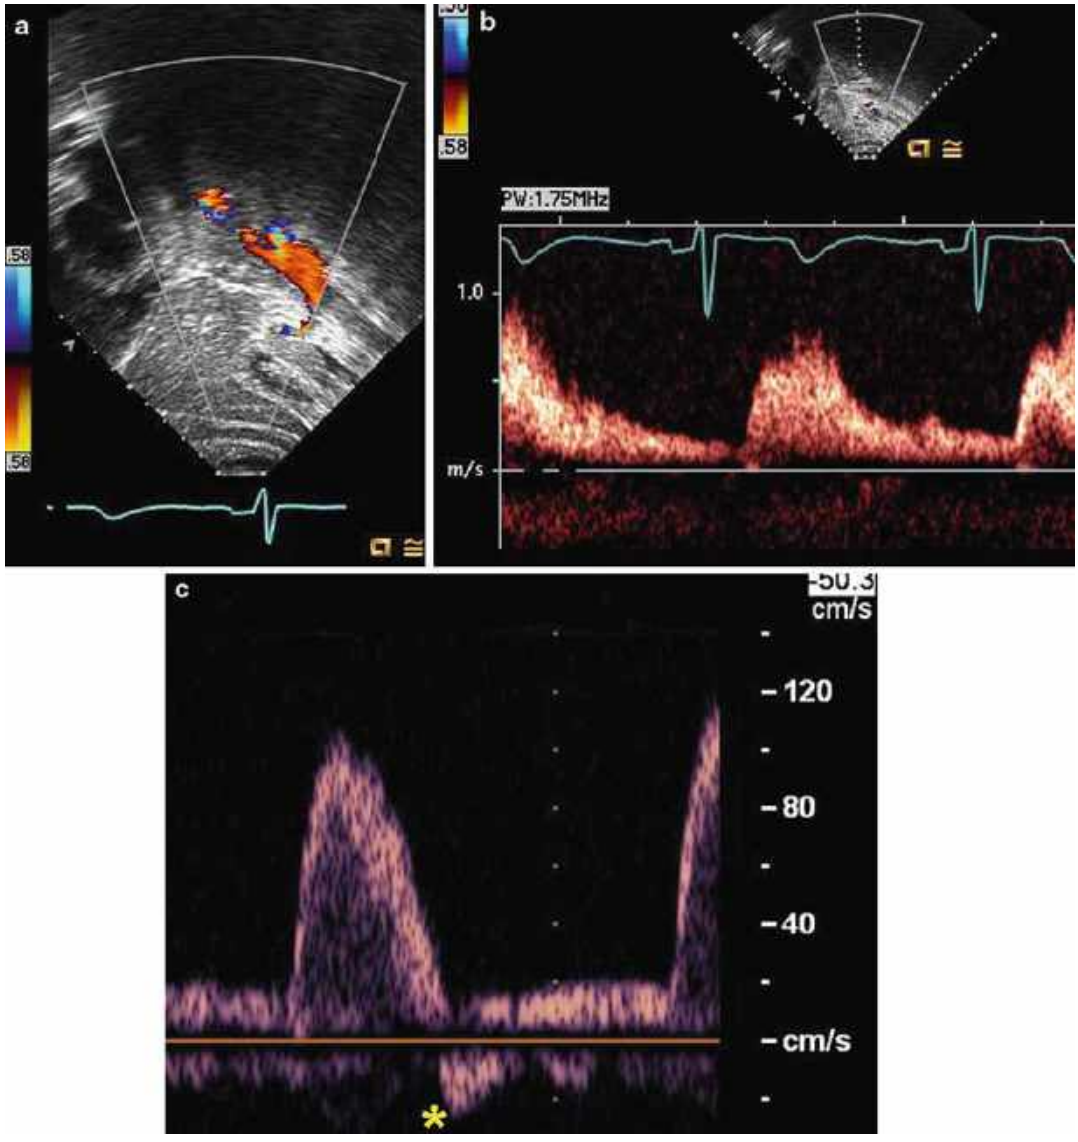

Fig. 140.4 Subcostal short axis echocardiography of the descending aorta in 32-year-old woman (*Panels A and B*). *Panel A* Color Doppler of the descending aorta at the level of the diaphragm. *Panel B* Pulse-wave Doppler of the descending aorta at the level of diaphragm showing blunted upstroke and continuous slow velocity decay in diastole confirming a significant coarctation. *Panel C* Normal abdominal aortic waveform in 36-year-old woman without coarctation. Note rapid upstroke of the velocity in early systole and rapid velocity decay in late systole as well as brief flow reversal after aortic valve closure (*)

Cardiac Catheterization

As a diagnostic modality, the role of cardiac catheterization has become limited as other non-invasive modalities (especially MRI) have emerged. Nonetheless, diagnostic cardiac catheterization is the "gold standard" for gradient assessment, and most of the guidelines for intervention are based on peak-to-peak gradients at catheterization. In addition to assessment of gradient, angiography also aids in planning surgical or catheter-based intervention. Left ventricle

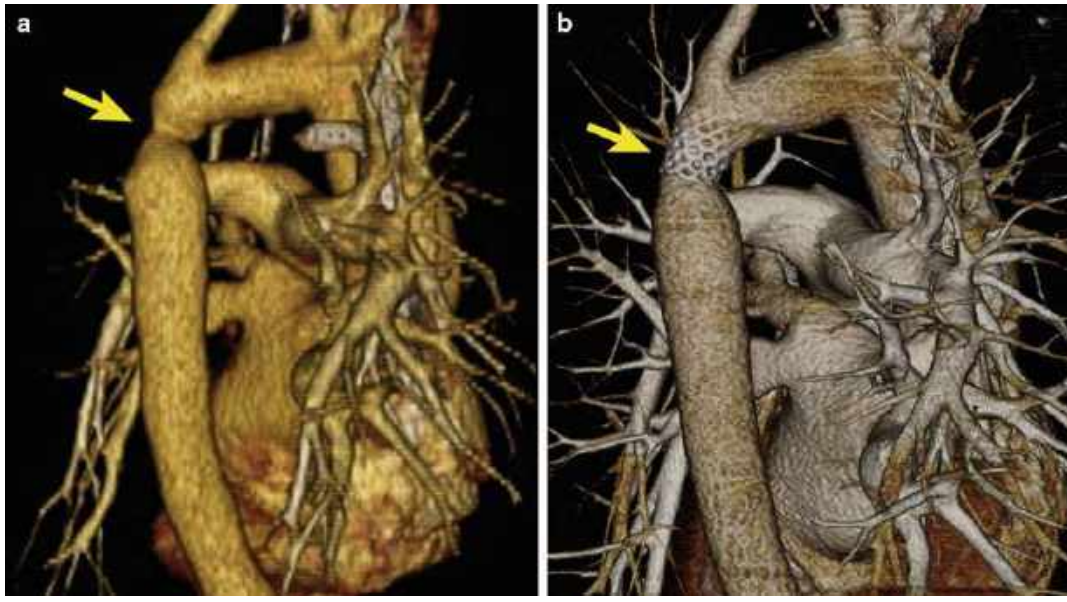

Fig. 140.5 CT angiogram with three-dimensional reconstruction of a 39-year-old woman with coarctation of the aorta status post-repair with end-to-end technique as a teenager. *Panel A* Residual coarctation of the aorta (*arrow*). *Panel B* After transcatheter stenting, the residual obstruction was relieved. Patient had atypical chest pain 2 years later. CT angiogram performed with 3D reconstruction for evaluation. No aneurysm present and stent in good position with no residual anatomic obstruction (*arrow*)

Fig. 140.6 MRI with 3D reconstruction in a 17-year-old patient with coarctation of the aorta. Note the tight coarctation of the aorta (*arrow*) and the multilobulated distal aortic arch proximal to the isthmus (*)

Movie 140.1 MRI with 3D reconstruction in a 17-year-old patient with coarctation of the aorta. Note the tight coarctation of the aorta (*arrow*) and the multilobulated distal aortic arch proximal to the isthmus (*)

end-diastolic pressure measurement as well as pulmonary artery wedge pressure gives an indication of LV diastolic compliance. Finally, in patients over 40 years of age, coronary angiography is important if contemplating surgical repair.

Indications for Intervention

Patients with significant coarctation or recoarctation of the aorta should undergo intervention to relieve the obstruction. Most consensus documents agree on a peak-to-peak gradient of 20 mmHg or more as an indication for intervention [15, 16]. In addition, lesser gradients should also be considered for intervention in the presence of significant anatomic narrowing with significant collaterals. In patients with borderline gradients, the presence of hypertension, an exaggerated blood pressure response with exercise, or left ventricular hypertrophy or dysfunction would be additional factors to weigh in clinical decision-making.

Treatment

Surgical Approaches

End to End

The first repair for coarctation of the aorta was performed in 1944 in Stockholm by Crafoord and Nylin using the end-to-end technique in a 12-year-old hypertensive boy [17] The end-to-end surgical repair for coarctation of the aorta is the simplest surgical method for coarctation of the aorta. The approach for the operation is from a left lateral thoracotomy. The aorta is exposed and the aorta above and below the narrowed segment is cross-clamped. The narrowing is excised and the ends are then sutured together (Fig. 140.7).

The initial results of this technique were unsatisfactory in that there was a high incidence (20–86 %) of restenosis at the repair site [18–20]. As a result, other surgical techniques were developed in an attempt to overcome this problem.

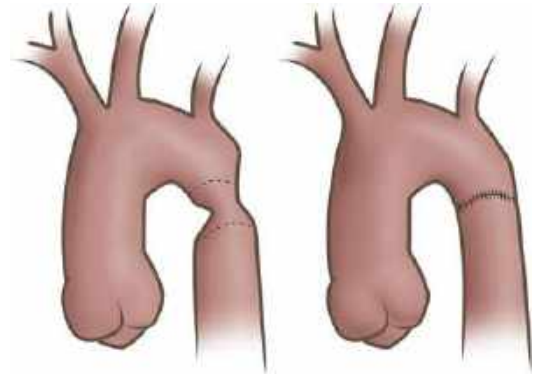

Fig. 140.7 Pre- and postoperative anatomy of coarctation of the aorta repaired with an end-to-end technique. The coarctation segment is excised (*dotted lines*) and the aortic ends are mobilized and sutured together

It was later found that recoarctation rates could be minimized if the aorta were sufficiently mobilized to allow for a tension-free anastomosis. In the infant and child undergoing primary coarctation repair, the descending aorta is more easily freed from the surrounding connective tissue and moved cranially. This method is now the preferred option for most congenital surgeons operating on infants and children with discrete coarctation because the incidence of recoarctation appears to be lowest compared with other methods (8 % vs. 35 % for other methods in aggregate) [21]. In the adult, it is more difficult to mobilize the aorta, and the end-to-end technique is limited to a very discrete coarctation where the amount of mobilization required will be minimal.

Patch Plasty

In this repair method, the aorta is cross-clamped, but rather than excising the narrowed segment, the posterior aortic wall is incised and enlarged with a patch (Fig. 140.8). Dacron, Goretex, Hemashield, and other patch materials have been used. While this method avoids the need for aortic mobilization, there appears to be a higher rate of residual coarctation left by this method. In addition, there also appears to be

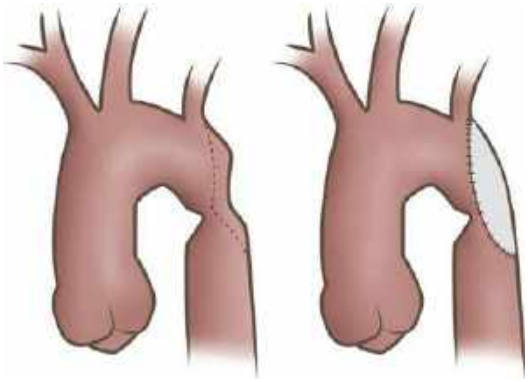

Fig. 140.8 Pre- and postoperative anatomy of coarctation of the aorta repaired with a patch-plasty technique. An incision is made in the posterior aortic wall and an elliptical patch is placed

a higher rate of aneurysm formation opposite the patch in late follow-up (Figs. 140.9 and 140.10). This is thought to be due to the differing compliances of the patch versus the native aorta.

Left Subclavian Flap

Recoarctation of the aorta was recognized to be a problem in some patients after end-to-end repair especially in childhood. Some believed that this was due to the presence of circumferential scar in the aorta that did not grow with the child leading to recurrent stenosis. It was thought that, by eliminating the circumferential scar, this would lead to a lower rate of recoarctation. The left subclavian flap repair was advanced as a way to address these issues and first described by Waldhausen and Nahrwold in 1966 [22]. In this repair, the left subclavian artery is divided proximal to the origin of the vertebral artery (Fig. 140.11). The posterior wall of the aorta is incised and the incision is carried up through the proximal left subclavian artery. The incised left subclavian artery is then "turned down" and used as a patch to augment the posterior aorta. The technique was popular in many centers in the 1970s and early 1980s but fell out of favor as it became clear with follow-up that there remained a significant incidence of residual stenosis [23, 24]. (Figs. 140.12 and 140.13). There does not appear to be a significant problem with vascular insufficiency to the left arm despite the ligated proximal left subclavian artery likely because the collateral vessels develop robustly in young patients. The left hand and arm may be slightly smaller than the opposite limb when compared closely. The majority of the supply to the left arm is usually retrograde from the ipsilateral vertebral artery (Fig. 140.14 and Movie 140.2) as well as other collateral vessels around the scapula. Even with the retrograde flow from the vertebral artery, it is rare to encounter a patient with a cerebral steal phenomenon.

Interposition Graft

For longer-segment stenosis, especially in the adult, excision of the narrowed segment and placement of an interposition graft remains an excellent surgical repair option (Fig. 140.15). It is the technique of choice where excision of a native, postsurgical, or mycotic aneurysm is required. This technique is usually avoided in growing children because of the problem of "outgrowing" the graft leading to recurrent stenosis. In addition, stenosis may develop at either end of the graft.

Arch Augmentation

In the case of transverse arch hypoplasia associated with coarctation, the aortic arch may be enlarged by incising the undersurface of the transverse arch down to the aortic isthmus and enlarging it by placement of a patch (Fig. 140.16). This repair is performed from a midline sternotomy under cardiopulmonary bypass with hypothermic circulatory arrest. Circulatory arrest may be avoided by cannulating the innominate artery to provide cerebral perfusion during the time the ascending and descending aorta are clamped. This type of repair is usually performed in infants and small children. In older children and adults, the isthmus becomes difficult to reach from a midline approach, and inadequate relief of stenosis at the isthmus may result.

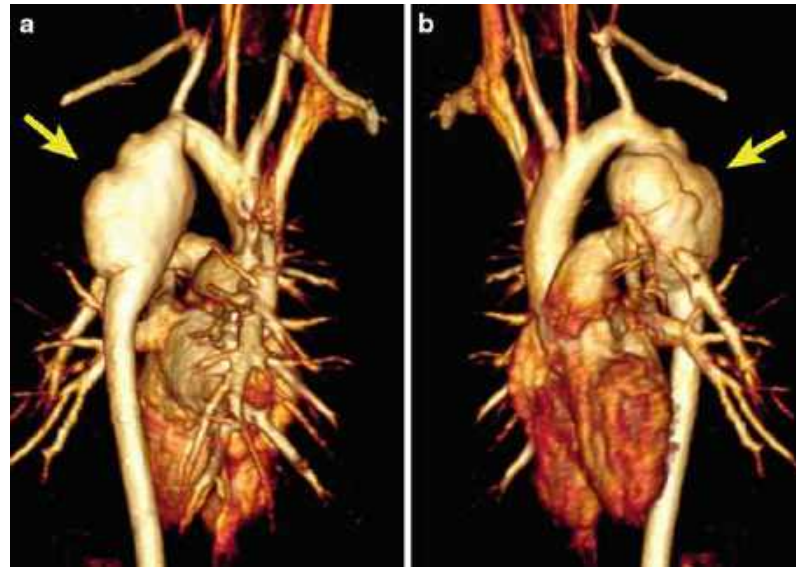

Fig. 140.9 MRI in a 22-year-old woman status post-coarctation repair at age 4 years with a patch-plasty technique. Now complaining of chest pain. MRI with 3D reconstruction shows large aneurysm of the aorta from the origin of the subclavian to the mid-thorax (*arrows*)

Ascending-Descending Aortic Conduit

The ascending to descending conduit repair is performed from a sternotomy rather than a thoracotomy and is typically performed on cardiac bypass. A long tube graft is anastomosed to the side of the descending aorta at the level of the diaphragm and then brought up to the right of the heart where it is anastomosed to the side of the ascending aorta. This repair is best suited for patients with transverse arch hypoplasia, complex arch anatomy, or when other cardiac repair or coronary bypass surgery is also required (Figs. 140.17, 140.18, and 140.19).

Complications of Surgical Repair

The most feared complication of surgical repair of coarctation of the aorta is spinal cord injury, with the worst outcome being paraplegia. The literature reports this occurring in between 0.9 % and 2.4 % of cases of repair of coarctation of the aorta, though the more recent experience probably has an even lower incidence due to awareness of the problem and improved surgical techniques including specific spinal cord protection strategies. The two mechanisms by which spinal cord ischemic injury occurs are prolonged cross-clamping of the aorta leading to a period of inadequate perfusion, and ligation of the arterial supply to the spinal cord itself. Anatomy textbooks have perpetrated the myth that the spinal cord is supplied by the "artery of Adamkiewicz" arising from the upper-mid thoracic aorta. More recent work has shown that the spinal cord arterial supply is complex and variable from numerous arterial vessels arising from the aorta at various points. It is therefore not possible to predict which vessels are critical for spinal cord function, and so care is taken to minimize the number of these vessels that are ligated from the aorta in the mobilization process. The duration that the aorta may be safely cross-clamped without causing spinal cord ischemia or ischemic injury to the distal organs is also highly variable and unpredictable. The presence of a well-developed collateral circulation in adult patients with coarctation of the aorta typically mitigates the effect of cross-clamping as the collaterals continue to perfuse the lower body. The typical time that the aorta remains cross-clamped for coarctation surgery is between 20 and 30 min. If the duration of cross-clamping is expected to be longer or if the collateral circulation appears underdeveloped, spinal cord protection techniques may be employed.

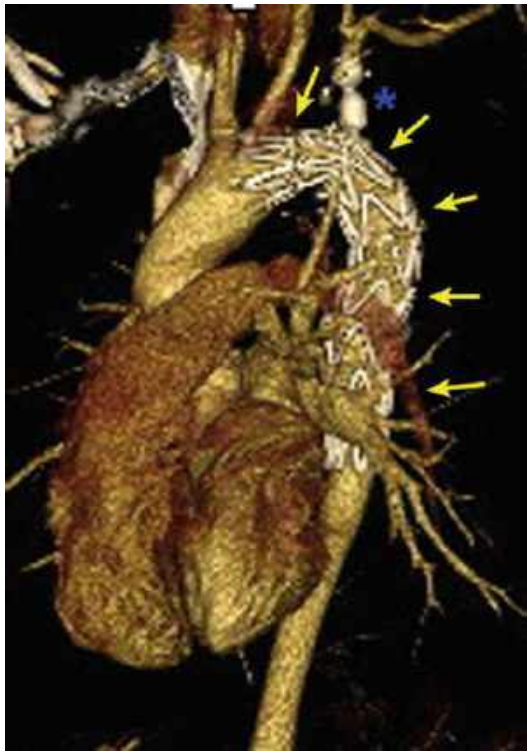

Fig. 140.10 Same patient as in Fig. 140.9. Aneurysm treated with percutaneous endograft (covered stent on self-expanding stent scaffold) placed from transverse arch to mid-thoracic aorta (*arrows*). Because the left subclavian artery would be covered by the stent graft, this vessel was intentionally occluded prior to the endograft placement with an Amplatzer Vascular Plug II (*). The left subclavian artery is now perfused retrograde from the left vertebral artery. At 6 months post-procedure, the patient remains asymptomatic and has no symptoms of cerebral steal or vascular insufficiency of the left arm

Several strategies to prevent spinal cord injury have been advocated. None are widespread and the techniques are employed variably by different centers depending on their individual clinical experiences. Some centers will incorporate spinal somatosensory evoked potential monitoring with the use of these techniques to further guide the adequacy of spinal cord protection.

Left Heart Bypass

The technique of left heart bypass is performed by cannulating the left atrial appendage or left

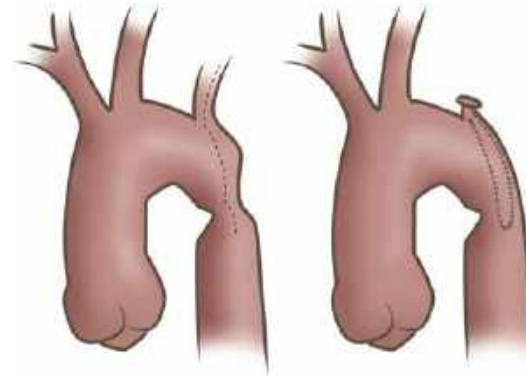

Fig. 140.11 Pre- and postoperative anatomy of coarctation of the aorta repaired with a left subclavian flap technique. The left subclavian artery is divided and ligated proximal to the origin of the vertebral artery. The proximal left subclavian artery is then opened longitudinally and the incision carried down the posterior wall of the aorta. The flap is then turned down and used to patch the incision on the aorta

lower pulmonary vein for the inflow, a pump (typically centrifugal) to augment the pressure and an outflow cannula placed in the aorta distal to the cross-clamp. Some centers also use a heat exchanger in the circuit to provide a mild degree of hypothermia (32–34 °C). This technique provides lower body perfusion and perfusion of the distal spinal arteries during the period of cross-clamping. Small studies have suggested a benefit to this technique for anticipated cross-clamp times greater than 30 min.

Epidural Cooling

With an epidural catheter placed at the T10-11 level and a second epidural catheter placed in the lumbar level, cooled saline (4 °C) may be continuously infused which cools the epidural space and presumably decreases the oxygen demand of the spinal cord, limiting the potential ischemic injury during cross-clamping.

Bleeding/Blood Loss/Transfusion

The presence of extensive collaterals, while decreasing the risk of spinal cord ischemia,

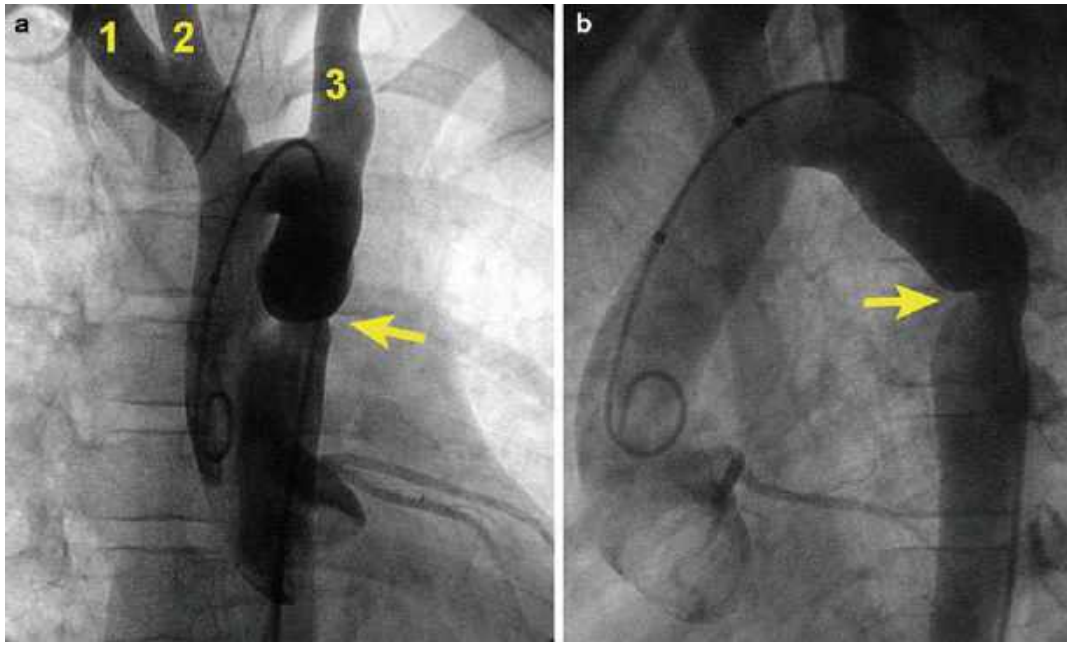

Fig. 140.12 A 19-year-old man with a history of coarctation of the aorta treated with a left subclavian flap repair at age 5 years. He has persistent hypertension and a 30 mmHg systolic blood pressure gradient between the right arm and the left leg. Ascending aortic injection in the anteroposterior (*AP*) and lateral (*Lat*) projections. *Panel A* AP projection. Note residual narrowing at the isthmus. Note the head and neck vessels and absence of the left subclavian artery seen on this angiogram: right subclavian artery (*1*), right carotid artery (*2*), left carotid artery (*3*). Panel B: Lat projection. Note the anterior "shelf" that persists in the left subclavian flap repair

increases the risk of bleeding complications which may be encountered by the surgeon. Hemostasis may be a challenge in patients as there may be multiple small collateral vessels encountered while entering the left chest that must be carefully controlled. Failure to adequately control hemostasis will result in a hemothorax or an extrapleural hematoma.

The suture line at the aortic repair must be meticulous to avoid bleeding or pseudoaneurysm formation.

For most adult patients undergoing coarctation repair, administration of blood products is not required.

Chylothorax

The thoracic duct returns chyle from the intestines to the venous circulation. The usual course of the thoracic duct is through the diaphragm adjacent to the aorta where it ascends to the right of the vertebral column before crossing to the left at about the T4 level where it continues its ascent to enter the left subclavian vein. The thoracic duct is generally invisible in the fasting state and may be disrupted during repair of coarctation of the aorta leading to chylothorax. Most patients with chylothorax may be managed conservatively with chest-tube drainage and fasting with parenteral nutrition or low-fat diet for several days or weeks. Rarely reoperation for thoracic duct ligation is required.

Recurrent Laryngeal Nerve Injury

The recurrent laryngeal nerve descends from the neck to loop around the left-sided ductus arteriosus/ligamentum arteriosus before ascending to supply the left vocal cord. In mobilizing the aorta, the ligamentum arteriosus is usually

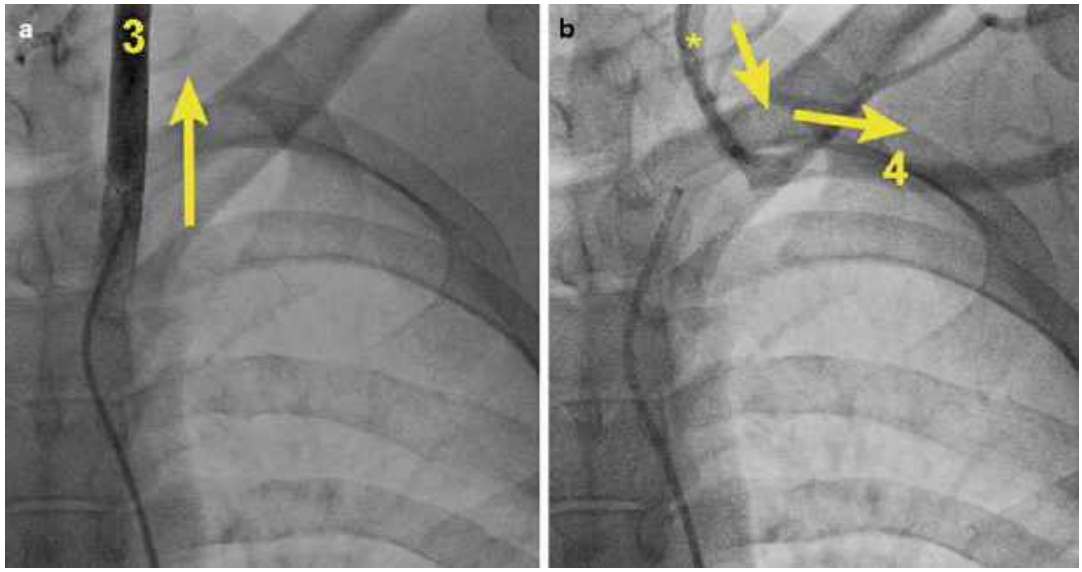

Fig. 140.13 Same patient as Fig. 140.12. *Panel A* AP projection of injection in the left common carotid artery (*3*) (*arrow* shows direction of flow). *Panel B* A few seconds after the injection in *Panel A*, dye is seen coursing retrograde in the left vertebral artery (*) and reconstituting the distal left subclavian artery (*4*) (*arrows* show direction of flow)

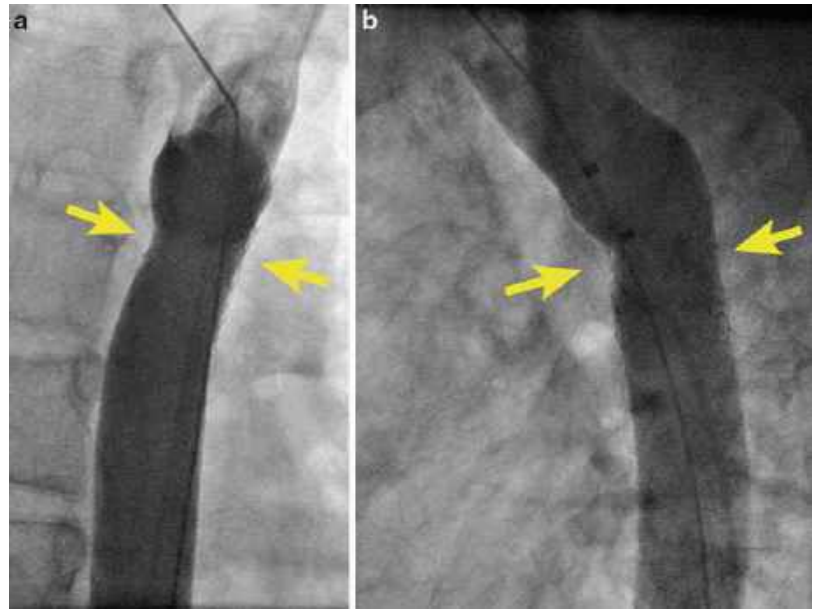

Fig. 140.14 Same patient as Fig. 140.12. The residual coarctation was treated with a balloon-expandable stent placed across the residual narrowing. *Panel A* (AP projection) *Panel B* (Lateral projection). The stent is shown (*arrows*) with no residual stenosis. The gradient was eliminated but the patient remains hypertensive at baseline but is normotensive on single-agent angiotensin-converting enzyme inhibitor

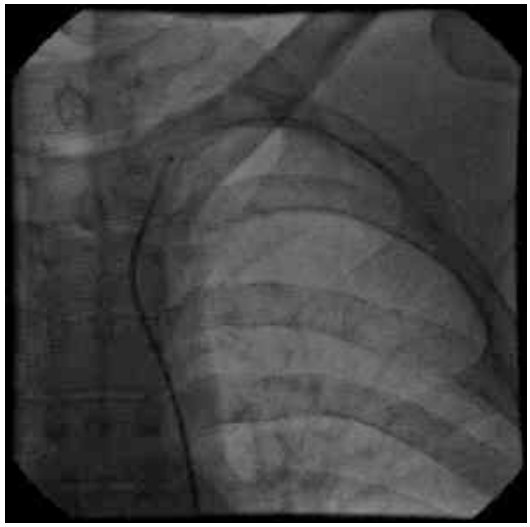
divided. Care should be taken prior to dividing the ligamentum to identify and protect the recurrent laryngeal nerve; however even traction on the nerve itself may led to unilateral vocal cord paresis that may be temporary or permanent. Difficulty speaking with hoarseness is the typical symptom. Aspiration is rarely seen with as the paretic vocal cord comes to rest in the closed



Movie 140.2 Same patient as Fig. 140.12. *Panel A* AP projection of injection in the left common carotid artery (*3*) (*arrow* shows direction of flow). *Panel B* A few seconds after the injection in *Panel A*, dye is seen coursing retrograde in the left vertebral artery (*) and reconstituting the distal left subclavian artery (*4*) (*arrows* show direction of flow)

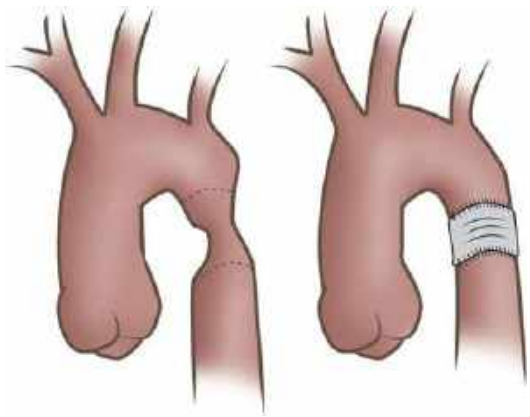


Fig. 140.15 Pre- and postoperative anatomy of coarctation of the aorta repaired with an interposition graft. The narrowed segment is excised and a tube graft of appropriate length is sutured to the proximal and distal segments to bridge the gap

position. The recurrent laryngeal nerve is not at risk with the ascending to descending bypass technique and has been used by one of the authors (Stelzer) in a patient where preservation of vocal cord function was integral to the patient's occupation (professional singer).

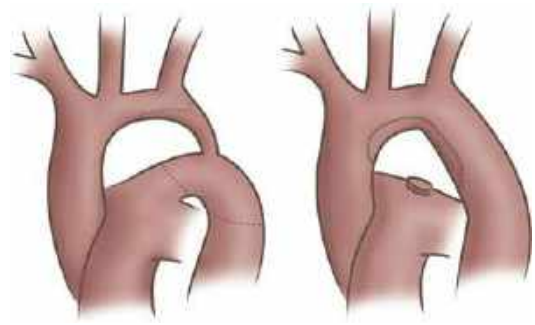

Fig. 140.16 Pre- and postoperative anatomy of critical coarctation of the aorta with aortic arch hypoplasia and a patent ductus arteriosus repaired with an aortic arch augmentation. The aortic arch is enlarged by incising the undersurface of the transverse arch down to the aortic isthmus and enlarging it by placement of a patch. The ductus arteriosus is ligated. This repair is performed from a midline sternotomy under cardiopulmonary bypass

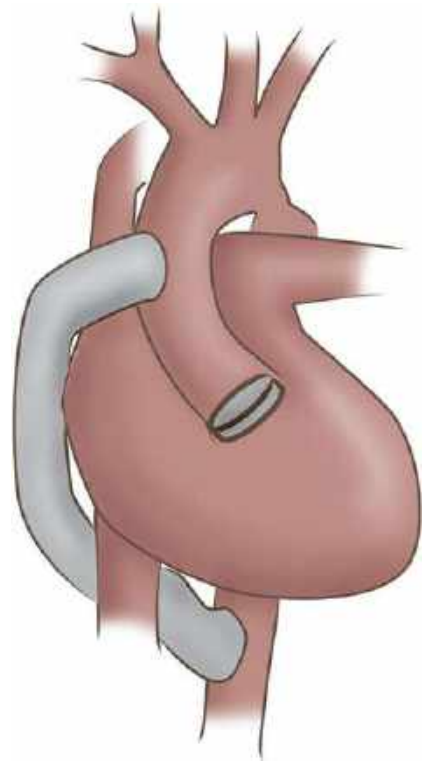

Fig. 140.17 Postoperative anatomy of coarctation of the aorta treated with an ascending to descending bypass. A large graft (*gray*) is anastomosed to the descending aorta at the level of the diaphragm and brought around the right side of the heart and anastomosed to the right of the ascending aorta. The repair is performed on cardiopulmonary bypass

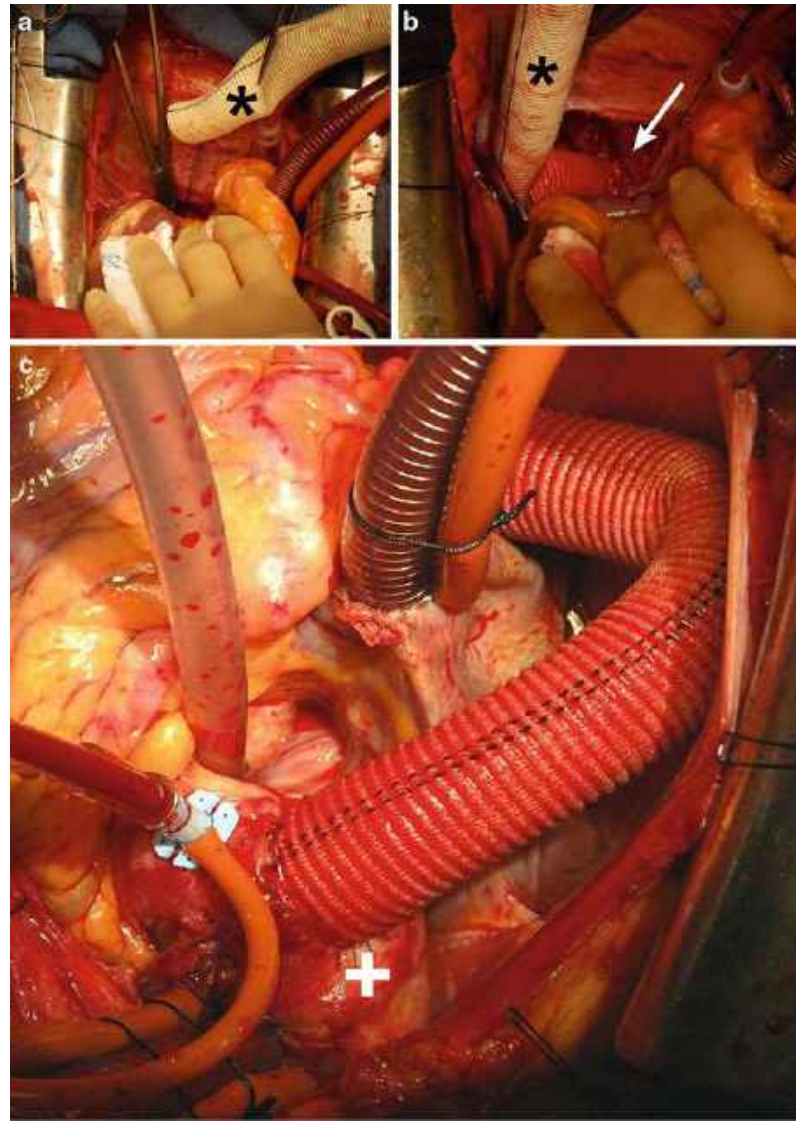

Fig. 140.18 A 58-year-old professional singer with long-segment coarctation of the aorta and coronary artery disease. Operative photographs of ascending-descending aortic graft technique. This technique was chosen so as to minimize risk to the recurrent laryngeal nerve. *Panel A* The heart is retracted superiorly and the descending aorta is exposed through the diaphragm. The graft (*) is first anastomosed to the descending aorta. *Panel B* The distal anastomosis (*arrow*) is shown of the graft (*) to the descending aorta. *Panel C* The graft is brought around the right of the heart, trimmed to the appropriate length, and anastomosed to the right side of the ascending aorta (+)

Post-coarctectomy Syndrome

In patients with coarctation of the aorta undergoing surgical repair, a number will develop paradoxical increase in systemic blood pressure in the first week after repair even in the absence of residual obstruction. The phenomenon is usually the worst in the first 48 h after surgery. The phenomenon is thought to be due to stimulation of sympathetic nerve fibers between the media and adventitia of the aortic isthmus stimulating the release of plasma norepinephrine as well as a spinal reflex that stimulates renin release [25]. The renin release is thought to constrict mesenteric vessels that can lead to abdominal pain and intestinal ischemia if left untreated. Interestingly, this finding is rarely observed in patients who have coarctation treated percutaneously with balloon dilation [26] and/or stenting. The incidence of

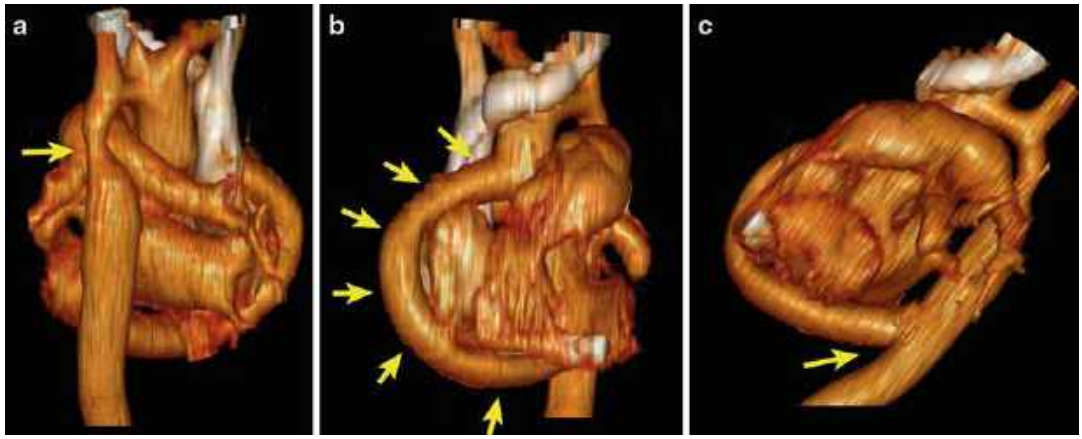

Fig. 140.19 CT angiogram with 3D reconstruction post-operatively of patient described in Fig. 140.18. *Panel A* Posterior view shows long-segment coarctation of the aorta (*arrow*). *Panel B* Anterior view showing graft coursing around the right heart border (*arrows*). *Panel C* Oblique view showing anastomosis of graft with descending aorta (*arrow*)

post-coarctectomy syndrome was reported to be as high as 56 % in surgical series with the syndrome more commonly seen in patients after adolescence [25]. Pretreatment with a nonselective beta-blocker (propanolol) was found to diminish the paradoxical hypertensive response and also blunt the rise in plasma renin levels [27].

Although adult patients undergoing surgical coarctation repair should ideally be pretreated with a nonselective beta-blocker prior to surgery, there has been less focus on the need for this pretreatment in the current era. This is likely because the postoperative medications to treat hypertension in the intensive care unit are much better than they were in the 1970s and 1980s when treatment of postoperative hypertension was more difficult.

Outcomes of Surgical Repair

The largest series to date describing the outcomes late after surgical repair for coarctation of the aorta was described by the Mayo clinic in 1989 [28]. In this important paper, the late outcomes of 571 patients who underwent surgical repair for coarctation in the early era (1946–1981) were characterized. By the nature of the surgical era, over half of the patients were operated after age 15 with 20 % of the patients older than age 30 at the time of repair. The striking finding of this paper was the relationship between survivorship and age at repair. For those less than 14 years at the time of repair, survivorship as measured at 20-year follow-up was 91 %, whereas in the group operated at more than 14 years, survivorship to 20 years was only was 79 %. The mean age at death was 38 years. The most common cause of death in this group was coronary artery disease in 37 % followed by sudden death in 13 %. Heart failure in 9 %, stroke in 7 %, and ruptured aortic aneurysm in 7 % were other modes of death.

There was a strong correlation with residual hypertension and age at repair. In those operated on beyond 9 years of age, about one quarter of patients had late hypertension compared with 6 % or less operated on at an earlier age. This data suggesting earlier repair leads to less risk of residual hypertension was also confirmed by studies that showed that early childhood repair led to most patients having normal blood pressure in follow-up [29].

Although the trend for earlier repair in childhood has been shown to reduce the incidence of

late resting hypertension, studies have shown that despite normal resting blood pressure, many patients (28 %) will have abnormal 24-h ambulatory blood pressure readings [30] and many will have severe hypertension with exercise [31]. This phenomenon is likely due to increased stiffness of the aortic wall at the site of the repair but also more globally in the aorta [31]. Some authors implicate coarctation as a diffuse arteriopathy [32].

Other late complications of surgical repair of coarctation include recoarctation and aneurysm formation at the level of the repair. The incidence of reintervention after successful surgical repair is between 7 % and 28 % [28, 33].

There is a low incidence of sudden death in patients with repaired coarctation of the aorta. Silka performed a population-based study evaluating patients who had undergone congenital heart surgery in the state of Oregon between 1958 and 1996 [34]. In this group, there were 536 patients with coarctation of the aorta who had a total of 6,706 patient-years of follow-up. There was an incidence of non-sudden cardiac death of 0.25 %/year and an incidence of sudden cardiac death of 0.13 %/year in the repaired coarctation group. Contrast this with a similar group of patients with tetralogy of Fallot in this study with an incidence of sudden cardiac death of 0.15 %/year (Tables 140.1 and 140.2).

Table 140.1 Interventional management for native and recurrent aortic coarctation

Surgery	Native coarctation	Recurrent coarctation
Resection and end-to-end anastomosis	Appropriate for short-segment coarctation only	Rarely performed to relieve recurrent coarctation
	Adequate mobilization of descending aorta is critical	
Subclavian flap	Rarely performed in the adult because of risk of aneurysm formation and loss of pulsatile flow to left arm	Rarely performed for recurrent coarctation
Interposition tube graft	Good technique for longer-segment coarctation	Often used if aneurysm present – resect abnormal tissue with placement of interposition graft
	Aorta should be at or near full growth	
Patch angioplasty	Rarely performed now because of increased risk of aneurysm formation	May be used if difficulty exposing aorta circumferentially. Less risk of aneurysm in recurrent coarctation because of prior scar tissue formation
Ascending-Descending bypass	Excellent option for patient who need concomitant cardiac procedure on bypass (e.g., aortic valve replacement) or for those with small transverse arch	Excellent option for patients with complex arch anatomy or for those who need other cardiac surgery
Interventional Catheterization	Native coarctation	Recurrent coarctation
Balloon angioplasty alone	Has been shown to be higher risk with poorer outcomes than stenting or surgery	Reasonable choice in patients where stent placement would be problematic (cover carotid or subclavian origin)
		Recoil leads to suboptimal gradient relief
Bare metal stent	Results comparable to those of surgery with respect to gradient relief	Procedure of choice in most instances for adult with recurrent coarctation
	May need a staged approach with subsequent balloon dilation to achieve desired final stent diameter	
Covered stent	Covering may decrease risk of dissection and rupture	
	Further studies needed	

Table 140.2 Follow-up for patients with repaired coarctation of aorta

	Baseline	Annually	Every 2–5 years	Situational
History and physical exam	X	X		
ECG	X	X		
Echocardiogram	X		X	X
Exercise test	X		X	X
CT/MRI	X		X[a]	X
24-h ambulatory blood pressure monitor				X
Cardiac catheterization				X

Transcatheter Treatment for Adults with Coarctation of the Aorta

Transcatheter approaches to treat adults with coarctation can be employed for primary coarctation (those for which no prior coarctation surgery has been performed) or for recurrent coarctation. The three techniques are balloon dilation alone, balloon dilation with stent deployment, and balloon dilation with covered stent deployment.

Balloon Dilation

The earliest reported attempts to treat primary coarctation with balloon dilation were in the early 1980s. Prior to attempting this in humans, Lock and colleagues took excised surgical coarctation specimens and subjected them to balloon dilation [35]. This preclinical experiment laid the foundation for the principle that the coarctation segment itself is very noncompliant and care must be taken to avoid overexpansion and rupture.

The method of balloon dilation is as follows: A relatively noncompliant balloon is inflated across the coarctation – usually from a femoral arterial approach. The intent of the dilation is to achieve an intimal and partial medial tear of the vessel wall. With healing, the lumen remodels to a larger inner diameter. The difficulty with balloon dilation alone is that the aorta, and especially the adult aorta in the area of the coarctation, is a relatively *noncompliant* region. This means that the balloon diameter must be less than or equal to the size of the normal aorta or one risks a complete adventitial tear leading to aortic rupture. Because of this, balloon dilation alone rarely eliminates the narrowing completely often leading to significant residual stenosis. Even with an appropriate-sized balloon, care must be taken to evaluate that there is not a very tight "waist" on balloon inflation. If so, this implies a very noncompliant coarctation segment that is also likely to rupture if the balloon inflation is carried up to the nominal diameter.

The biggest advantage of balloon dilation alone for primary coarctation is that it is the simplest of all therapies for coarctation and at the lowest cost. The disadvantages are that there is frequently incomplete relief of the narrowing and a higher risk of aortic rupture and also of aneurysm formation. The incidence of aneurysm formation following balloon dilation alone has been reported at between 7.5 % and 43.8 % [36, 37].

Nonetheless, for recoarctation of the aorta, especially in younger patients who have not yet reached their full growth, balloon dilation alone may be used to relieve the recurrent stenosis. There is much less chance of rupture and late aneurysm formation with scar tissue surrounding the repaired area from the prior surgical repair. However complete relief of stenosis is less likely with balloon dilation alone for recurrent coarctation.

Balloon Dilation Plus Stent Implantation

Given the disadvantages of balloon dilation for coarctation, bare metal stent implantation for primary repair of coarctation of the aorta in the adult was introduced in the 1990s [38] (Figs. 140.20 and 140.21).

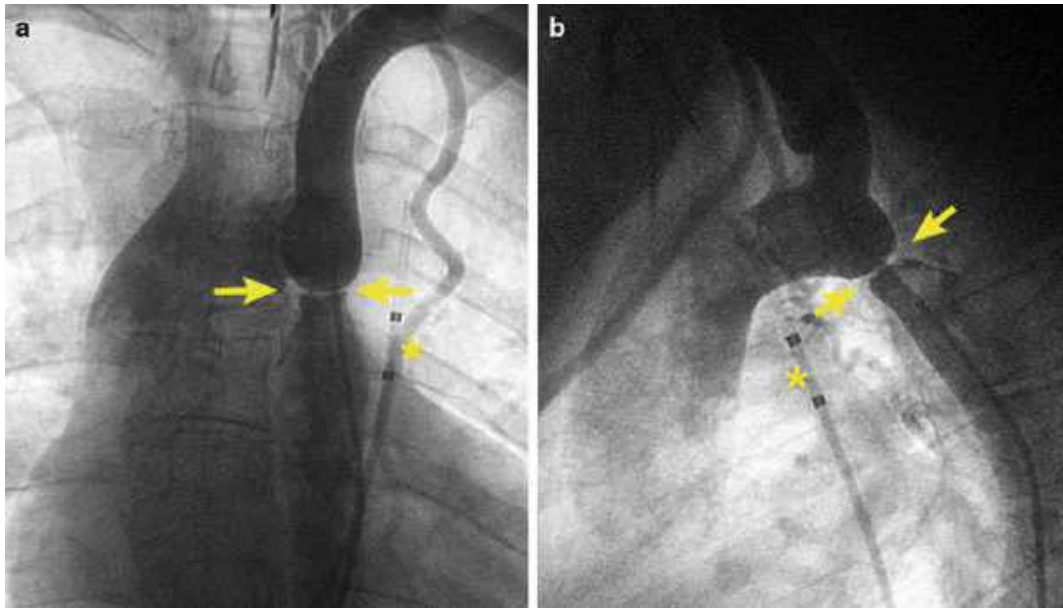

Fig. 140.20 AP (*Panel A*) and lateral (*Panel B*) aortic angiogram of a 33-year-old woman with Turner's syndrome and a severe native coarctation of the aorta (*arrows*). The patient has a persistent left superior vena cava to coronary sinus, and a marker catheter (*) was placed retrograde in this vessel to provide a sizing guide

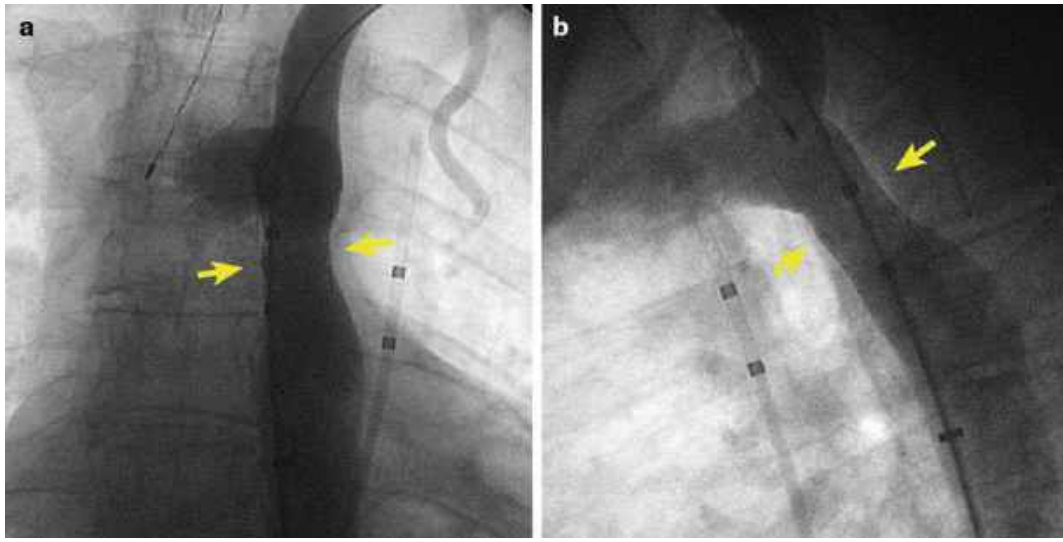

Fig. 140.21 Same patient as Fig. 140.20. AP (*Panel A*) and lateral (*Panel B*) aortic angiogram post-stenting of the coarctation with a Genesis XD stent expanded to 10 mm. The isthmus diameter is improved but not yet at the final diameter. The patient will require an additional 1–2 procedures to dilate the stent to the final diameter of the distal aortic arch (16 mm)

The advantage of stenting when added to balloon dilation of coarctation is that it prevents the recoil of vessel leading to larger final vessel diameter without the need to overexpand the aorta. Because of the noncompliant nature of the aorta, it may be planned as a two- or three-stage procedure with stent implantation at the first setting and further balloon expansion at

a second and possibly third stage separated by several months or more. There is controversy if balloon dilation should be first performed prior to stent implantation. Two nonrandomized studies suggested a higher incidence of aneurysm formation if balloon angioplasty was first performed [39]; however many feel that balloon dilation to a diameter less than the final planned stent diameter provides valuable information as to the compliance of the area. If a tight waist appears on the balloon during initial balloon expansion, a smaller balloon can be used.

Most operators choose balloon-expandable stents to treat coarctation because of the superior radial strength of balloon expandable as compared with self-expanding stents. The current generation of large-diameter balloon expandable stents that are available includes the Cordis Genesis XD (Cordis, Warren NJ), the eV3 Intrastent LD MAX (Covidiean, Plymouth MN), the Cordis Palmaz XL 3110, 4010 and 5010 (Cordis, Warren NJ), and the CP stent (NuMed, Hopkinton, NY). The Cordis Genesis XD stents have a low profile and can be inserted with a smaller arterial sheath; however the largest diameter they can sustain is about 18 mm, and they shorten dramatically at the limits of expansion. In addition, the Genesis stents have a propensity to wire fracture over time which then compromises the radial strength (Fig. 140.22). The Palmaz XL stents have excellent radial strength; however they have a large profile requiring a larger sheath and are very rigid with fairly sharp edges leading to a higher risk of balloon problems with insertion. The EV3 stents

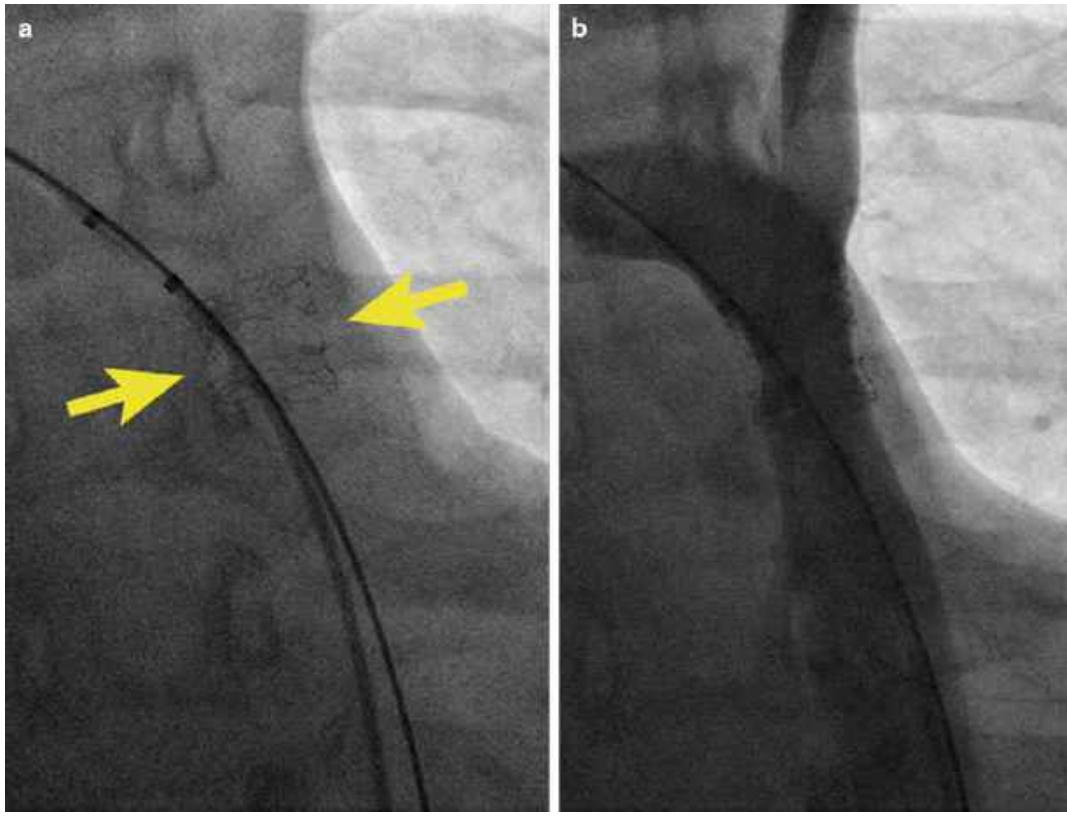

Fig. 140.22 A 16-year-old with coarctation of the aorta repaired with an end-to-end technique at age 1 year. He had recurrent coarctation and had a Genesis stent placed at age 11 years. At age 16 years, he presents with residual isthmus narrowing. *Panel A* Left anterior oblique fluoroscopy of the stent showing a circumferential fracture with separation of the proximal and distal segments arrows. *Panel B* Aortic angiogram showing residual narrowing at the (unsupported) site of stent fracture

have minimal foreshortening with expansion but have a lower radial strength. The open-cell design of the EV3 stents allows for balloon dilation and even stenting through the side branches if required. All these stents are FDA approved as "biliary" stents and are used off label in the aortic position in the United States.

The CP stent has a good combination of radial strength and flexibility. The CP stent received CE mark in Europe in 2007 but is still not FDA approved and only available in the United States in clinical trials.

Results of stenting for native coarctation of the aorta in the adult are quite good. Recent experience suggests the risk of aortic dissection or aneurysm with staged stenting procedures is about 1 % in the current era with other risks including femoral arterial injury and stent malposition in 0.5–2 % [36, 40]. Gradient relief appears to be very good with an acute success of 96 % and long-term gradient relief and freedom from unplanned intervention rate of 77 % at 18–60 months.

Patients who have undergone stenting for primary coarctation continue to have a significant incidence of residual hypertension with one study [40] showing 23 % of patients with hypertension and 32 % of patients on antihypertensive medications in long-term follow-up.

Stenting for relief of residual gradient for patients who have previously undergone surgical coarctation repair remains a good option with a low incidence of aortic injury and good gradient relief.

Patients who are not good candidates for stenting include those with aortic arch hypoplasia or tortuous anatomy.

Covered Stent

The two main drawbacks of bare metal stenting for native coarctation are the risk of aortic wall injury – dissection, rupture, and incomplete gradient relief as a result of stent underexpansion to avoid the risk of aortic wall injury. To address these issues, balloon-expandable stents with coverings have been developed. Although self-made expanded polytetrafluorethylene (ePTFE) membranes have been used to cover stents, the first widely accepted commercially available stent has been the Covered CP stent (NuMed, Hopkinton NY) (Fig. 140.23). This stent has been available outside the USA for several years. In the United States, this stent remains

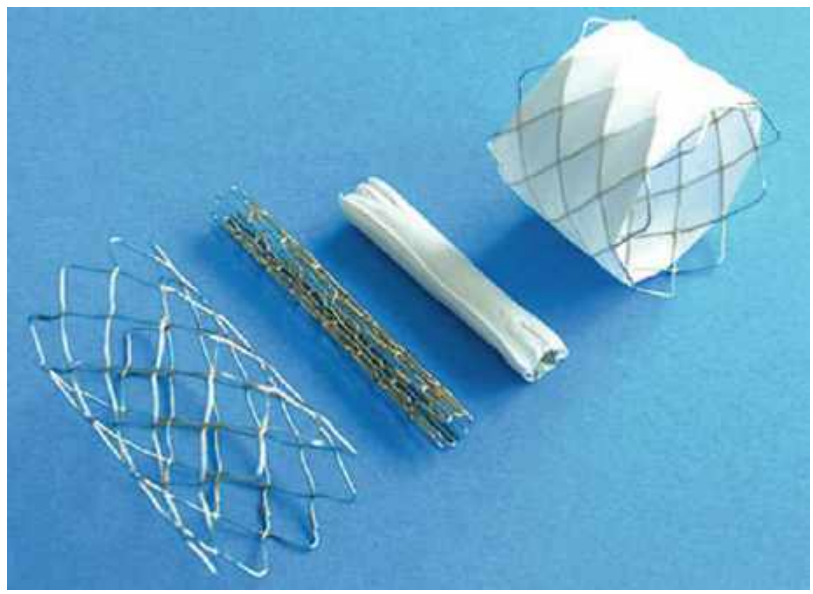

Fig. 140.23 NuMed CP covered stent. The stent is a balloon-expandable platinum-iridium scaffold with an expandable sleeve of ePTFE (expanded polytetrafluoroethylene) covering. The stent is not approved for sale in the United States

on an investigational protocol for treatment of aortic coarctation (COAST trial) [41]. Outside the USA, small trials have shown good results with the covered stent design [42, 43].

One disadvantage of a covered stent is that if the covered stent is landed such that the proximal end of the covered stent protrudes into the ascending aorta, the stent and covering may act like an umbrella in the wind and be "pushed" into the stent lumen causing acute, severe obstruction (L. Benson – personal communication).

Which Method Is Best to Treat Coarctation in the Adult?

There are no randomized trials comparing surgical with transcatheter treatment in the management of native coarctation. Consensus documents recommend either surgical or transcatheter therapy based on the experience and outcomes of the individual center [15, 16].

The Congenital Cardiovascular Interventional Study Consortium (CCISC) conducted a nonrandomized observational study of 350 patients from 36 institutions for children and adults treated for native coarctation [36]. Patients were treated with either surgical repair (variety of methods), stenting (bare metal), or balloon dilation alone. The findings of the study were that stent patients had the lowest overall incidence of complications (2.3 %) though they were most likely to require a planned or unplanned intervention (20 %). Patients in the surgical and stent groups were equally likely to have complete gradient resolution (81 and 85 %, respectively) compared with balloon dilation alone (68 %). Finally, balloon dilation patients were more likely to have aortic injury (dissection or aneurysm) (21 %) than surgery (11.5 %) or stent (3.1 %). This study though nonrandomized confirmed the growing trend away from balloon dilation alone to treat native coarctation in the adult.

At the current time, stenting for coarctation and surgical repair remain reasonable options for treatment of native coarctation.

For patients with recurrent coarctation after surgical repair, consensus documents [15, 16] recommend transcatheter intervention. While most patients are suitable candidates and do well with this approach, a recent review of the Mayo experience comparing their (nonrandomized) experience with transcatheter versus surgical intervention for recurrent coarctation showed low risks of both but a 96 % freedom from reintervention at 5 years in the surgical group and 72 % in the endovascular group. Both strategies however decreased the percentage of patients with hypertension (57 % compared with 74 % pre-intervention) and reduced the need for antihypertensive medication from a median of 2 prior to intervention to a median of 1 post-intervention [44].

Medical Therapy

Management of hypertension is particularly important in patients with repaired coarctation of the aorta to prevent late cardiovascular sequelae. Indeed a recent population-based study from Quebec found that coarctation was not a risk factor for coronary artery disease, independent of hypertension [45]. Once significant anatomic obstruction has been excluded or addressed, medical management for hypertension should be aggressive to achieve normal resting blood pressure (Table 140.3).

There are few data identifying the best antihypertensive medical therapy in patients with coarctation. One small study comparing metoprolol with candesartan in patients with hypertension following coarctation repair showed that metoprolol at high dose (163 +/− 50 mg/day) had more antihypertensive effect than a high-dose Candesartan protocol (13+/− 4 mg/day) [46].

Because many of the patients will also have a bicuspid aortic valve and dilated ascending aorta to some degree, beta-blocker and angiotensin receptor blockers are popular for management of hypertension in patients with repaired coarctation because of their possible benefit in decreasing

Table 140.3 Late sequelae in the adult with repaired coarctation

	Frequency	Treatment
Hypertension	Up to 25 % of adults especially if age of repair > 9 years	Evaluate for recurrent stenosis
		Medical therapy and coronary artery disease risk modification
Recurrent coarctation	7–10 %	Usually transcatheter with stent; however surgery may be preferred if anatomy not conducive to stenting
Aneurysm formation	2–10 %	Occurs in patients treated with surgery and also with balloon dilation or stenting
		May be treated with covered stent in certain circumstances; others will need surgery. If very small, may be followed with serial CT/MRI imaging
Coronary artery disease	Variable and multifactorial	Good blood pressure control and control of modifiable risk factors (cholesterol, smoking, HbA1C)
		Interventional treatment or bypass grafting may be needed
Ruptured cerebral aneurysm	Rare	Patients should be screened with cerebral imaging (CT or MRI) and if aneurysm present, should be managed in consultation with competent neurosurgeon
Endarteritis	Rare	Antibiotics and resection of mycotic aneurysm

the rate of ascending aortic dilation. In patients without a dilated ascending aorta, angiotensin-converting enzyme inhibitor and diuretics alone or in combination would also seem reasonable choices so long as the end point of maintaining good blood pressure control is realized.

Other coronary artery disease risk-factor modification seems all the more important for patients with coarctation and long-standing hypertension including lipid control, glucose control in patients with concomitant diabetes, and smoking cessation.

Endocarditis Prophylaxis

There are rare case reports of patients with repaired or unrepaired coarctation of the aorta developing endarteritis at the site of coarctation. More commonly, patients with aortic valve disease and coarctation are at risk for aortic valve endocarditis. Aortic endarteritis however usually leads to mycotic aneurysm formation with a high risk of fatal rupture if left untreated [47].

Nonetheless, endocarditis prophylaxis is not recommended by the American Heart Association or the American College of Cardiology for patients with coarctation of the aorta (repaired or unrepaired) unless surgical repair or stenting has been performed in the prior 6 months or unless the patient has had prior endocarditis [15].

Pregnancy

Patients with repaired coarctation of the aorta with minimal residual gradient, no aortic wall aneurysm, and good baseline blood pressure control generally tolerate pregnancy well [48]. Cesarean section is typically not indicated for maternal indications.

Patients contemplating pregnancy who have residual hypertension on medical therapy should not be on angiotensin-converting enzyme (ACE) inhibitors or angiotensin receptor blockers (ARBs) during pregnancy because of the potential teratogenic effect on the fetal kidney. While this recommendation holds, the risk of teratogenicity is not extreme [49] so if a woman discovers she is pregnant while on an ACE or ARB, stopping the medication is warranted with fetal follow-up.

Patients with unrepaired coarctation should not become pregnant; however the scenario does present where expectant mothers with unrepaired coarctation are only first diagnosed

during pregnancy. Depending on the severity of the coarctation, blood pressure, and the status of the left ventricular function and symptoms, consideration for termination versus continuing the pregnancy can be made.

In patients with repaired coarctation, similar considerations need to be undertaken prior to pregnancy with respect to residual coarctation gradient, blood pressure control, and left ventricular function.

Both repaired and unrepaired patients with coarctation should have imaging of the aorta to exclude aneurysm. If not performed prior to the pregnancy, then cardiac MRI would be test of choice in the expectant mother. Aneurysms of the aorta are particularly worrisome during pregnancy because of the risk of rupture. In addition to the increased cardiac output and increase in blood pressure with labor and delivery, pregnancy is known to weaken the arterial wall. If an aneurysm is found, then consideration should be given to termination, intervention during pregnancy, and consideration given to an epidural with an assisted second stage or primary Cesarean section delivery [48].

Patients with Turner's syndrome seem to be at even greater risk of aortic dilation and dissection [50]. These patients are often infertile, and patients who choose to conceive with egg donation and hormonal assistance appear to be at even greater risk.

Tetralogy of Fallot in the Adult

141

Massimo Chessa, Alessandro Giamberti, Sara Foresti, and Marco Ranucci

Abstract

Tetralogy of Fallot is the most common form of cyanotic congenital heart disease. In developed countries, almost all patients with this cardiac malformation are repaired in childhood. Innovations in the diagnosis and management of tetralogy of Fallot have led to dramatic improvements in early survival. As a result, the population of tetralogy of Fallot repair survivors is growing rapidly. Surgical management of tetralogy of Fallot leaves anatomic and functional abnormalities in the majority of patients. This chapter will discuss the different issues related to the most important problems (as chronic pulmonary-valve insufficiency and obstruction of the right ventricular outflow tract, right ventricular outflow tract aneurysm, pulmonary branch artery stenosis, dilated ascending aorta, aortic regurgitation, residual ventricular septal defect, arrhythmic problems) that physicians can face in managing these patients.

Introduction

Tetralogy of Fallot (TOF) is the most common form of cyanotic congenital heart disease. If left untreated, it carries 33 % mortality in the first year of life and 50 % mortality in the first 3 years of life [1].

Since the introduction of palliative systemic-to-pulmonary artery shunt by Blalock and Taussig in 1945, followed by the first open-heart repair by Lillehei and Varco in 1954, the surgical management of TOF has evolved to primary repair during infancy in the majority of patients. Innovations in the diagnosis and management of TOF have led to dramatic improvements in early survival. As a result, the population of TOF repair survivors is growing rapidly. Surgical management of TOF leaves anatomic and functional abnormalities in the majority of patients.

In this chapter, all the specific issues related to the unrepaired and repaired patients, the postsurgical sequelae, and the postoperative management of right ventricular (RV) dysfunction will be discussed.

Unrepaired Tetralogy of Fallot in Adults

Historically, approximately 2 % of untreated patients with TOF reached the fourth decade of life [2]; however, there are still a certain number of older patients with uncorrected TOF. The chronic hypoxemia results in exercise intolerance and excessive erythrocytosis with an increased risk of thrombosis. Cerebral abscesses are frequent since infectious agents can easily reach the brain via right-to-left shunting at ventricular level. The risk of thrombosis and brain abscess is increased in the presence of iron deficiency. Death occurs frequently secondary to right ventricular (RV) failure due to long-standing RV pressure load and secondary to endocarditis or to arrhythmias.

More recently, the number of operations for these adults' TOF has increased in Milan due to the growing influx of patients from underdeveloped countries. Indications for corrective surgery in this specific population remain controversial due to higher operative risks and doubtfully beneficial effects. These patients survive until adulthood because of favorable morphologic conditions such as systemic-to-pulmonary collaterals, or a palliative shunt procedure performed in childhood, or because of relatively mild stenosis of the right ventricular outflow tract (RVOT).

These adult patients represent a high-risk population. Chronic hypoxemia may stimulate the development of large systemic-to-pulmonary collaterals that increase the pulmonary blood flow, and together with myocardial hypertrophy and myocardial hypoxia, lead to reduced biventricular function. Impaired ventricular function, severe and chronic hypoxemia with high hematocrit due to cyanosis, and tricuspid regurgitation are associated with higher operative mortality [3, 4].

The surgical mortality for these adult patients in the literature [4–8] ranges between 2.5 % and 24 %. A complete preoperative evaluation including cardiac catheterization and MRI must be performed in all patients. Systemic-to-pulmonary collaterals can be closed preoperatively in cath lab.

The perioperative course management is difficult, but the long-term survival has been reported

to be excellent [4], comparable as great as 35 years after correction, with the life expectancy of the general population.

Not only the long-term survival but also the functional status has been reported [6–8] to be excellent with a significant improvement in NYHA functional class. At follow-up, 75 % of these patients have a normal life with full-time work, more than 65 % are married, and 70 % of women had delivered children.

Despite the higher perioperative mortality, uncorrected adult TOF may benefit from total correction because the functional status improves markedly.

Repaired Tetralogy of Fallot in Adults

The introduction of surgical repair of TOF has dramatically improved the survival and decreased the morbidity in these patients. However, there are several issues that must be taken into consideration years later (survival, chronic pulmonary-valve insufficiency, obstruction of the right ventricular outflow tract, pulmonary artery branch stenosis, residual ventricular septal defect leaks, dilated ascending aorta, aortic regurgitation, and arrhythmias), which are important to consider for the long-term care of adult patients surviving surgical repair.

Survival

It is obvious that the era in which a patient was operated would influence the outcome, as well as the age at which the patient underwent the repair.

A hospital mortality of 50 % in 1955 and 15 % in 1960 was reported in 1960 [9]. Currently the hospital mortality will be <5 % in patients after repair in most centers [10, 11].

The overall 32-year actuarial survival rate among 163 patients that underwent complete surgical repair of TOF at the Mayo Clinic (USA) between 1955 and 1960 and survived the immediate (30 days) postoperative period was 86 % as compared with an expected rate of 96 % in a control population matched for age and sex [12]. This study provides evidence that the rate of long-term survival – even in the earliest era of open-heart surgery – is excellent but remains lower than in the general population. The actuarial survival rate was 90 % of the expected survival rate. The late functional status was also excellent.

Similar good long-term results were reported in a large series of patients operated in Munich (Germany) from 1958 to 1977 and who survived the first year after surgical repair [13]. They found actuarial 10-, 20-, 30-, and 36-year survival rates of 97 %, 94 %, 89 %, and 85 %, respectively. The most common cause of death was sudden cardiac death followed by congestive heart failure.

It is important to realize that the mortality increased 25 years after surgery from 0.24 % to 0.94 % per year which emphasizes the need for close lifelong follow-up examinations.

Furthermore, it was shown that there was no difference in long-term survival between patient with and without a transannular patch [10, 11].

Chronic Pulmonary-Valve Insufficiency and Obstruction of the Right Ventricular Outflow Tract

The management of the possible surgical sequelae, such as chronic pulmonary-valve insufficiency (PVI) and/or obstruction of the right ventricular outflow tract (RVOT), and right ventricular (RV) dysfunction, has become a frequent problem. This is a timely topic of increasing clinical interest, as shown by the fact that pulmonary-valve replacement (PVR) for PVI is the reoperation most frequently performed today for these patients [3, 14].

Long-standing chronic PVI, in these patients, can result in RV dilatation and failure, increasing tricuspid regurgitation, impaired exercise performance, and supraventricular or ventricular arrhythmias.

The questions of when to perform a PVR, in whom and how, are becoming increasingly pressing [15]. Clear guidelines to assist in this decision have proven difficult to identify. The presence of symptoms is a clear indication for reoperation.

Indications for treatment include severe PVI (regurgitation fraction of ≥35 % on MRI), RV dilatation (RV end-diastolic volume/LV end-diastolic volume ≥1.4 with symptoms or ≥2.0 without symptoms), RV systolic pressure ≥2/3 of the systemic pressure with symptoms or ≥3/4 without symptoms, and impaired exercise capacity (peak oxygen consumption ≤65 % of predicted value). Consideration should also be given to the presence of peripheral pulmonary-arteries stenosis, severe tricuspid regurgitation, and supraventricular/ventricular arrhythmias.

The percutaneous approach now offers a less-invasive treatment that may potentially reduce the number of patients for surgery and shift the indications toward earlier intervention.

Unfortunately, not all the patients, like the patients here presented, are good candidates for transcatheter pulmonary-valve implantation because of RVOT morphology, associated cardiac anomalies, or both, and the number of surgical patients is still high.

Surgical Approach

The type of valve to be inserted into the RVOT is still debated.

Several different types of prostheses have been used for PVR, but all are prone to failure and will likely require reintervention. At present time, options include mechanical and several biological valves. Bioprosthetic valves (including homografts, xenografts, prosthetic valved conduits, and bioprosthetic valves) perform well hemodynamically but are prone to structural degeneration that may result in multiple reoperations. Mechanical valves lead to a persistent need for anticoagulation therapy and, despite some positive reports in the literature, have generally been associated with pulmonary thromboembolic complications [16, 17].

Consequently, none of these valves seems to be ideal, as they all present advantages and disadvantages at the same time.

Homograft valves have been widely considered the first choice for the reconstruction of the RVOT since their introduction into clinical practice in 1962 by Donald Ross [18]. In the largest published outcome series, the authors report freedom from reoperation at 10 years of 40 %–80 % [19–22] and the development of homograft regurgitation more than moderate at 5 years in 50 %–70 % [23–25]. Homograft valves have shown the best long-term results when they are used in conjunction with pulmonary autograft replacement of the aortic valve.

Technical problems implanting the homograft are an important topic to be discussed. Homograft implantation, as well as for xenograft valves, and prosthetic valved conduits require extensive dissection of the pulmonary arteries to avoid kinking or external compression. These pulmonary-valve substitutes have a length that needs a complete pulmonary arterial dissection to avoid technical complications. Dissection can be difficult and dangerous in patients who have had several previous surgical procedures.

A recent study [26] suggests that RVOT reconstruction with a homograft can be performed with low operative mortality. The freedom from valve-related reoperation was 83 % at 10 years and 70 % at 15 years. These results are more encouraging than those reported by other investigators. Zubairi et al. [27] retrospectively analyzed the outcome of 169 consecutive patients with repaired TOF or pulmonary stenosis undergoing a first PVR using homograft, stented porcine valve, stented porcine valve in Dacron conduit, and bovine pericardial valve. The freedom from reoperation for bioprosthetic valve failure during 10 years of follow-up was excellent in all the valves used, but younger age, TOF, and the use of homograft were identified as risk factors for early pulmonary-valve failure.

A more recent study by Fiore et al. [28] that directly compared three biological valve types (stented xenograft valve, bovine pericardial valve, and pulmonary homograft) concluded that the late dysfunction was more likely with homograft valves than either porcine or bovine pericardial valves. At 6 years, the freedom from explantation of the homograft was only 35 %.

All this data suggests that homografts have initially very good hemodynamic performance, but they calcify over time and become insufficient.

Considering all these limitations, many authors now agree that homograft valves are far from ideal.

For pulmonary-valve insertion, many surgeons now implant xenografts. Many different xenografts are available today, including porcine pulmonary-valve conduits, stentless porcine aortic-root bioprostheses, and bovine jugular valved vein conduits. The results for xenografts remain controversial at this time [29–33], and a longer follow-up is needed to determine the rate of structural valve deterioration and function. In any case, an extensive dissection of the pulmonary arteries, as with the homograft valves, is needed to avoid kinking due to the substantial length of the prosthesis. Extreme care must be taken during implantation as any twisting, kinking, or external compression [31] can easily lead to early prosthetic valve failure.

The same considerations can apply to the prosthetic valved conduits, such as Hancock or Edwards conduits.

Few papers are present in the literature regarding mechanical valves in the pulmonary position [33, 34]. Mechanical valves in the RVOT require long-term anticoagulation, subjecting the patient to the inherent risks of chronic anticoagulation therapy.

Kawachi and coworkers [35] compared St. Jude mechanical valves and bioprosthesis valves in the pulmonary position. Bioprostheses showed better performance in terms of freedom from thrombotic events, freedom from reoperation, and valve-related events.

Bioprosthetic valves are probably the most widely used for pulmonary-valve replacement because they are readily available and do not need permanent anticoagulation therapy.

Shinkawa and colleagues [36] analyzed the outcome and performance of bovine pericardial valves in the pulmonary position. Freedom from pulmonary-valve reoperation was 100 %, 97.7 %, and 97.7 % at 1, 3, and 5 years, respectively.

Fiore et al. [28] reported that late pulmonary-valve dysfunction was lower in bovine and pericardial valves when compared with homograft valves.

The current approach in these authors' institution, since 2005, is to reconstruct the RVOT with a bioprosthetic porcine valve. At the 1-year MRI control, pulmonary regurgitant fraction, right ventricular end-diastolic volume (RVEDV), and RV/LV EDV improved significantly. In a follow-up ranged from 6 to 132 months (mean 49 months), no reoperations or valve revisions were necessary. No episodes of structural valve deterioration or endocarditis or thromboembolic events were noted. These early results are encouraging. The bioprosthetic valves are very easy to implant and permit the avoidance of extensive dissection of the pulmonary arteries, which is particularly favorable in patients who have previously had multiple operations.

These excellent results with bioprosthetic valves in the RVOT may be due to the minimal hemodynamic load when placed in the pulmonary position. Orthotopic insertion of these valves with small-patch reconstruction of the RVOT permits the insertion of larger valves, reduces "peel" formation within the valved conduit, and eliminates external compression of the conduit [37, 38].

The bioprosthetic valves are available in all sizes and are very easy to implant. The implantation does not require dissection of the pulmonary arteries and can be performed, after a RVOT incision, with a running suture. Related to the RVOT size, the surgeon may need a small heterologous patch to close the RVOT incision on the anterior part of the valve. This small patch does not limit at all the possible RV-remodeling procedures that very often must be undertaken during RVOT reconstruction [39]. The bioprosthetic valve does not require anticoagulation therapy, and there is no risk of external compression.

Another criterion to take into consideration in the RVOT reconstruction should be the facilitation of future interventional procedures, such as percutaneous pulmonary-valve implantation. Until now, homograft valves or prosthetic valved conduits seemed to be the ideal candidates, but many recent reports appeared in the literature show the feasibility of the percutaneous approach even in bioprosthetic pulmonary valves. Percutaneous reimplantation of a pulmonary valved stent in a degenerated bioprosthetic valve has been successfully done [40, 41], and the new models

of percutaneous pulmonary valves presented [42] make possible and easier the transcatheter approach in the setting of bioprosthetic valves.

Percutaneous Approach

Many patients will have had multiple operations, and as the number of operations increases, so does the surgical risk. In order to reduce the number of operations, the first percutaneous valve was implanted in a human in Paris by Philipp Bonhoeffer [43]. This valve, with some modification, is now commercially available as the Melody valve by Medtronic and has provided the majority of data in this field. A detailed discussion about this alternative is provided in another chapter elsewhere in this textbook.

The Melody valve is a length of bovine jugular vein containing a venous valve, sutured into a 34-mm platinum iridium Cheatham Platinum (CP) stent, producing a covered stent with the valve leaflets near to its proximal end. The thin compliant leaflets of the venous valve pack more easily into a delivery catheter, and the geometric structure of the leaflets enables them to work at a wide range of diameters and shapes (as a venous valve has to in a vein), whereas pericardial tissue prosthetic valves function best at their designed size and shape. Failing conduits are rarely circular and have complex shapes and stenoses, but the Melody valve remains competent in different sizes and geometries [44]. The Edwards SAPIEN bovine pericardial valve is now available for use in the pulmonary position, having been developed for aortic valve replacement. This is a stent with a pericardial valve mounted within it, necessitating expansion to the designed size and shape. The Edwards Sapien valve finds its major indication in the treatment of larger conduits up to 26 mm, overcoming the size limitation of the Melody valve at 22 mm.

Initial experience demonstrated the Melody valve to be a safe and effective alternative to surgical conduit replacement in a range of congenital heart lesions [44]. Tetralogy of Fallot patients were well represented, but the experience also includes patients with a range of congenital heart malformations such as aortic stenosis patients treated with the Ross operation and transposition treated by the Rastelli operation. Clinical efficacy was shown in studies of many relevant parameters describing clinical end points such as exercise capacity and symptoms and catheter and imaging-based assessments of right ventricular performance and hemodynamics [45–47].

Homograft rupture and coronary compression (Figs. 141.1–141.3) are the most feared complications. In order to assess this risk, the conduit should be dilated with a balloon to the planned size with a simultaneous coronary angiogram performed with a pigtail catheter, prior to pre-stenting; if coronary compression is evident, PVI must be avoided [48]. Coronary stenting is unlikely to hold a coronary open against the force of a large stent, and if coronary compression occurs, urgent surgical removal of the stent is likely to be needed.

Homograft rupture may be treated by surgery or a covered stent and maybe by reversal of heparin. Fractures of the CP stent were also seen with a rate of 21 % [49], without clinical consequence if the fractures did not affect stent integrity. Risk factors for fracture were stent insertion in an outflow tract without a conduit, absence of calcification, and recoil of the stent when the balloon was deflated [50]. Reintervention with the second percutaneous valve is however a feasible treatment option for this complication [51]. Fractures have been improved by pre-stenting the "landing zone" (implanting one or more stents within the conduit) for the valve [52].

The recently published German results show a much improved stent fracture rate of only 5 %, which is likely due to pre-stenting [47]. Pre-stenting can also provide additional stability particularly if the conduit is near the maximum size of the Melody valve stent or if the circumference of the conduit contains potentially distensible areas.

Whatever the mechanisms, treating pulmonary-valve dysfunction not only improves right ventricular volumes, but it can also improve left ventricular performance [53].

Transcatheter treatments are generally more acceptable to patients and their parents than

surgery, which may lead to earlier treatment of valve dysfunction. A self-expanding valve to treat pulmonary regurgitation in large outflow tracts has already been reported [54], and the use of pre-stenting to allow treatment of some patients without conduits with balloon-expandable valved stents is gaining momentum. As a consequence of these advances, it is possible to envisage a time in the near future where percutaneous valve replacement may be available for a majority of patients with pulmonary-valve dysfunction, which will hopefully lead to the preservation of the right ventricular function in these patients.

Right Ventricular Outflow Tract Aneurysm

The correction of the inciting lesion of PVI may not be a sufficient treatment to allow RV recovery when PVR is performed at either an advanced stage of RV failure and/or when done in the presence of either aneurysm or akinesia of a portion of the right ventricular outflow tract (RVOT) [55–58].

The implications of these aneurysmal or akinetic lesions are that they disrupt RV structure and thereby produce functional alterations of the physiologic peristaltic RV contraction pattern that proceeds from RV inlet toward the outlet, a contractile sequence that is heavily dependent upon the RV geometric configuration. Recognition, today, of the deleterious functional consequences of the aneurysm or akinetic lesions of RVOT suggests to the surgeon to include surgical treatment of these ventricular wall defects at the time of PVR.

Several factors account for the aneurysm or akinesia of the RVOT after repair of TOF. The anatomic contributors include prior placement of a large transannular or infundibular patch, as well as aggressive myomectomy during infundibular resection. There may also be an ischemic insult resulting from conal arterial branch interruption during suture placement area around the patch.

The surgical treatment of the aneurysm or akinesia of the RVOT, the so-called RV remodeling, starts by removing the previous transannular or infundibular patch. All the aneurysmal tissue in the RVOT is removed, and the functioning edges of the adjacent RV muscle are identified. Related to the altered RV geometry, a more longitudinal [59] or circular [55] ventriculoplasty is done. The circular one [55] is preferred to reduce RV volume.

Tricuspid Valve Regurgitation

Tricuspid valve regurgitation (TR) is a well-known possible complication in adult TOF patients after complete repair and can be associated with different anatomical or functional mechanisms. Sometimes the tricuspid valve is damaged by previous operations. In some patients the septal leaflet of the tricuspid valve (TV) becomes distorted by the patch used to close the VSD or by a fibrotic reaction to this patch.

Functional TR is the consequence of right ventricular (RV) dilation and/or dysfunction. RV dilation/dysfunction is typically associated with chronic volume overloading related to long-standing PVI after a previous repair of tetralogy of Fallot. The physiologic consequences of chronic RV volume overloading in these patients can compromise tricuspid valve function.

In the absence of anatomical modification or damage, the TR is associated with a dilated tricuspid annulus and hence RV dilatation.

Very often, adults having repaired TOF with chronic PVI present associated moderate to severe TR via annulus dilatation and adverse leaflet tethering due to left-sided septal bulging, a secondary consequence of the RV dilation [60].

The number of patients with functional TR will increase in the near future as will the incidence of ACHD.

Moderate to severe TR is a clear indication for surgical treatment.

It was thought in the past that the severity of secondary or functional TR would decrease or even disappear after correction of the primary lesion. This concept, widely supported in the past, has influenced current practice regarding conservative management of secondary TR. As demonstrated in the functional TR secondary to mitral lesions, TR does not spontaneously disappear once the left heart lesion has been corrected. The data demonstrate that once the annulus is dilated and RV function is therefore at least mildly impaired, the process of TR is progressive. Once the RV is dilated, it is not enough to treat the cause of the RV volume overload (PVR) alone. Such an approach does not correct TV dilation. Once the TV annulus is dilated, its size cannot spontaneously return to normal and may continue to dilate further. TR may continue to

impact right ventricular function and may explain why some patients require a second operation for the TR years after the first lesion has been repaired surgically.

The hospital mortality is extremely high with regard to reoperation for isolated secondary severe TR [61], and medical treatment for these patients is rather limited and inefficient. It has therefore been recommended by some experts that a more aggressive approach should be taken in cardiac surgery patients with concomitant TR [60–62].

Obviously, tricuspid valve repair is preferable to tricuspid valve replacement. It remains unclear which technique is optimal for repair of the tricuspid valve. It has therefore been recommended that such patients undergo tricuspid valve repair with an annuloplasty ring [63, 64]. The annuloplasty ring remodels the annulus, decreases tension on suture lines, increases leaflet coaptation, and prevents recurrent annulus dilation.

Unfortunately, TV repair is not always possible, especially when the mechanism of TR is more anatomical than functional.

In cases of tricuspid valve replacement, a bioprosthesis is preferable. Previous reports [65, 66] show that bioprostheses in the tricuspid position are more satisfactory than mechanical valves, resulting in favorable long-term outcomes, a low incidence of structural valve deterioration and reoperation.

Pulmonary Artery Branch Stenosis

The pulmonary artery branch stenosis (PABS) may be discrete or associated with long-segment hypoplasia and may be congenital or secondary to a previous surgical procedure. Postsurgical stenosis is most commonly due to scar formation, especially at the site of a shunt, at the edges of a patch arterioplasty, or at the anastomotic sites of previous unifocalized vessels.

Obstruction within the pulmonary arterial tree can result in elevated right ventricular pressures and potentially worsen pulmonary insufficiency in patients with repaired TOF. This can lead to ventricular dysfunction, ultimately increasing the risk of ventricular arrhythmias and sudden death [67]. Ideally, interventions should take place prior to the development of signs or symptoms from chronic pulmonary obstruction. Universally accepted indications for intervention include symptoms, iso- or supra-systemic right ventricular pressure or dysfunction, and significant differential pulmonary perfusion. Noninvasive imaging, such as echocardiograms and MRI, is useful for monitoring patients with known or suspected disease and can be used to define the ideal timing for interventions in the absence of symptoms.

The relief of the stenosis and reduction of the pressure gradient can be obtained by surgery if the stenosis is proximal; however, if the stenosis is located in a peripheral area of the lungs, transcatheter balloon dilation is a therapeutic option.

Balloon angioplasty for pulmonary artery stenosis is not uniformly successful; it was clear from the beginning that stenotic lesions in pulmonary arteries were unpredictable and variable in their response to balloon dilation. The introduction of high-pressure balloons [68] has improved the results of simple angioplasty, but a subset of vessels remained resistant to therapy, with recoil of the stenotic artery after dilation [69]. In the late 1980s, therefore, Mullins et al. [70], using a canine model, assessed the potential role of stents in the relief of obstructed pulmonary arteries; since then different stents become available on the market, but the ideal stent for congenital and postoperative lesions is not yet available. If the angioplasty is not effective and the desired effect is not achieved, the next option is stent implantation. In adult patients stenting is preferable as the primary treatment of stenotic vessels because it prevents most of the vascular elastic recoil. The best stent used is the shortest that can be dilated to the largest diameter (eventually to the normal vessel diameter). PA stenting results in increasing PA size, reducing pressure gradients, decreasing right ventricular pressure, and improving PA blood flow [71–74].

Long-term follow-up (>15 years) for implanted PA stents in a cohort of patients undergoing this procedure between 1989 and 1992 was published in 2010 by Law et al. [75]; the authors described a cohort of 50 patients that had 71 stents implanted with a mean follow-up of 13.2 years. TOF was the diagnosis in 68 % of the patients. The gradient dropped from 43 to 8 mmHg, and the narrowest PA size increased from 4.7 to 13.4 mm. The percentage of stenosis changed from 62 % to 12 % (all $p < 0.001$) at final catheterization. Significant in-stent restenosis and neointimal proliferation was a rare finding. A 1-mm intimal peel was almost universally seen on follow-up catheterization. Patients experienced improvement in symptoms and baseline NYHA class at long-term follow-up. No surgical repair was needed in patients with TOF, confirming long-lasting favorable hemodynamic and clinical effects in these patients. Pressure gradients, PA size, and RV pressure remained significantly improved at follow-up. Complications, including stent migration, hemoptysis, pulmonary edema, partial or complete jailing of a side branch, thrombosis, and even death, have been reported [75, 76]; the incidence of complications is about 12 %; many of these occurred during initial stent implantation experience and are potentially avoidable in the current era [75]. Stents placed in the PA's fracture much less frequently than those placed in RV-PA conduits presumably because conduits are subject to extrinsic compression against the sternum [75]. Stents are amenable to further dilation to accommodate somatic growth and can be re-dilated to treat restenosis when necessary [76, 77]. Heavy body weight was reported as the single risk factor in restenosis [78].

A hybrid technique, when it is difficult to approach the pulmonary branch artery stenosis either percutaneously (vein access problems, difficult access owing to anatomic location, right ventricular hypertrophy, etc.) or surgically (owing to scarring and postoperative adhesions, excessive pulmonary blood flow from collaterals, and even sometimes the need to implement circulatory arrest or low-flow cardiopulmonary bypass), is a safe and effective alternative [79].

Dilated Ascending Aorta and Aortic Regurgitation

It is common for the ascending aorta and aortic root, in conotruncal anomalies, like TOF, to be dilated at birth and at initial repair.

Niwa and colleagues [80] examined aortic specimen from patients with congenital heart defects, and all the aortic specimens of the conotruncal defects had medial wall abnormalities of smooth muscle, elastic fiber, collagen, and ground substance. At the same time, progressive aortic-root dilatation has been reported in relation to patients' factors such as right aortic arch, male sex, palliative shunt before repair, and late repair [81, 82].

A recent series [83] from Mayo Clinic group analyzed the reoperations performed on the aortic root, ascending aorta, or aortic valve in adult patients with conotruncal anomaly over a long period (1973–2008). This chapter shows interesting results. Early mortality for these operations was very low. The majority of reoperations were required for aortic valve dysfunction and not for ascending aorta dilatation. The presence of ascending aorta dilatation is usually not the main indication for operation. The indications and timing for reoperation, in these patients, more often revolve around pathology of the RVOT especially PVI [83]. Most of these patients come to medical attention because of right-sided problems, and the aorta is incidentally found to be dilated.

The risk of ascending aorta dissection or progressive aortic dilatation requiring intervention is very low [83]. The moderately dilated aorta in adult TOF may be managed by observation alone.

Residual Ventricular Septal Defect

A residual interventricular shunt following repair of TOF (usually poorly tolerated) was more frequent in the past. Repeat surgery to correct residual shunting carries a higher surgical morbidity and mortality. It may also be more difficult to localize a residual shunt using the standard right

atrial approach [84]. The transcatheter approach is a safe alternative, if feasible, and is appreciated by patients and their parents because it has less psychological impact (given the absence of a skin scar), the time spent in hospital is shorter, the procedure causes less pain and discomfort, and there is usually no need for admission to an intensive care unit [85]. It certainly is less risky from the view of another cardiopulmonary bypass run, infection, bleeding, atriotomy, and a possible ventriculotomy. The procedure is similar to that of a simple congenital ventricular septal defect (VSD) closure. General anesthesia and transesophageal echocardiography (TEE) are used during the procedure. Standard right and left heart catheterization is performed as the first step of the procedure, and the residual shunt is profiled angiographically using the left-anterior-oblique view with cranial angulation. TEE is performed to assess the shunt size and the valvar function.

As an alternative, intracardiac echocardiography may be used to monitor the procedure. Device selection is 1–2 mm greater than the VSD size. The residual VSD is crossed retrograde from the left ventricle, and an arteriovenous circuit is then created. The steps are the same as similar to those used for closure of muscular or perimembranous defects [85, 86]. In cases of residual perimembranous defects due to the presence of the patch, it can be quite difficult to direct the tip of the long sheath toward the left ventricular apex. In these cases it is possible to leave the sheath in the ascending aorta, advance the device up to the tip of the sheath, slowly withdraw the entire unit from the aorta in the left ventricular outflow tract, and then deploy the distal disk in the left ventricle rather quickly, thus avoiding a falling back into the right ventricle of the delivery system. Otherwise, a retrograde transaortic approach can be used when it is possible to use an Amplatzer muscular occluder.

Dua et al. [87] reported a series of 170 patients that underwent percutaneous VSD closure; 22(16 M) of them had residual postsurgical VSD (9 post TOF – 41 %). All 22 patients had successful closure. The incidence of residual shunting was 4.5 % during the follow-up. One patient (post TOF correction) had recurrent VSD due to patch dehiscence and required two transcatheter closures 2 years after; after the second recurrence she needed redo surgery which was complicated by a prolonged postoperative course. Arrhythmic problems and especially complete atrioventricular block (cAVB) are the most serious concerns closing VSD, as previously reported [85, 86]. It has been reported that [87, 88] few adult patients experienced transient arrhythmic problems and none with a complete cAVB. The cAVB requires pacemaker implantation, but it seems more frequent in young patients [86]. Besides, one should note that cAVB block can occur after surgical closure of a VSD in about 1 % of subjects.

If the closure of a residual ventricular septal defect is expected to be difficult both by transcatheter and surgically, a hybrid approach may be indicated. The hybrid approach involves closing the defect through a midline sternotomy, without using cardiopulmonary bypass, by deploying a device through the right ventricle [89, 90].

Arrhythmias

The risk of developing arrhythmias after the repair of TOF is influenced by the surgical approach and by the age at corrective surgery. Knowledge of complete anatomical and surgical details in the patient is also useful to assess risk stratification and arrhythmia treatment late after TOF repair.

Sudden death represents one of the most frequent causes of mortality in adult patients with TOF. The long-term prevalence of sudden death has been reported to be 3.98 % [91], reaching 8.3 % at 35 years of follow-up [92] with an annual incidence of 0.15 % rising to 0.62 % after 25 years from surgery [37]. Several studies have shown that sudden death is more likely to occur in patients receiving surgical correction at an older age or in patients receiving multiple interventions [37, 91, 92]. Also, it has been proven that the risk

of sudden death increases with time, and it is larger if a transannular patch was needed [37, 91–93]. These clinical characteristics are not very helpful in stratifying the risk in older TOF patients because their prevalence in the overall TOF population is pretty large.

A correlation between sudden death and QRS prolongation (≥180 msec) has been documented in different studies [92]. This is not surprising because QRS prolongation is the electrical expression of an unfavorable evolution of the right ventricle mainly due to volume overload leading to dilatation and fibrosis (mechano-electrical interaction). QRS prolongation is a sensitive marker of an increased risk of arrhythmia, but its specificity is questionable. Recording of premature ventricular contractions (PVCs) on Holter monitoring is a very frequent finding in TOF patients. High-grade ectopy and nonsustained VT have been associated with a higher incidence of sudden death [38, 93].

The understanding of the mechanisms underlying ventricular arrhythmias after TOF repair led to the natural conclusion of trying to investigate such mechanisms during programmed ventricular stimulation (PES). In a recent multicenter study, the inducibility of monomorphic and polymorphic VT was a powerful predictor of future events with a sensitivity of 77.4 % and a specificity of 79.5 %; the predictive value of the test was larger in a subgroup of patients with clinical parameters indicative of a larger risk compared to the one of patients in whom PES was performed as a routine screening test [38].

At present, it appears unlikely that single risk predictors may be identified to select TOF patients who might most benefit from ICD implantation. In fact, the selection of just one predictor may be misleading in these patients. When evaluating a TOF patient, the profile of that single patient must be defined taking into account symptoms, surgical history, and anatomical and hemodynamic status. PES can help identify patients more susceptible to ventricular arrhythmia in the high-risk population. Young patients not presenting conventional risk factors and still experiencing spontaneous arrhythmias and unfavorable hemodynamic evolution should be followed very carefully.

The clinical characteristics of patients presenting with ventricular arrhythmias are very similar to those of patients with sudden death. This observation, together with the information obtained from TOF patients implanted with ICDs, led to the widely accepted speculation that most of sudden deaths are related to ventricular arrhythmias.

Arrhythmia Management

It is a general rule when dealing with patients with adult congenital heart disease and cardiac arrhythmias to first exclude a hemodynamically correctable cause of the index arrhythmia. If this turns out to be the case, then the first therapeutic measure has to be the correction, whenever possible, of the hemodynamic cause either by surgery or percutaneous approach. Unfortunately the correction of the hemodynamic defect is sometimes not possible, and often it is not sufficient to prevent further arrhythmic complications.

The use of antiarrhythmic drugs in patients with CHD is limited. Typically, class IC drugs are not administered because of their negative inotropic and proarrhythmic effects. Amiodarone is less proarrhythmic and has less negative inotropic effect, but its long-term toxicity limits its use in patients with a long life expectancy. Beta-blockers and Sotalol are often used to control arrhythmia in patients experiencing multiple ICD shocks or presenting with symptomatic PVCs. The role of Dronedarone, a newly introduced class III antiarrhythmic drug, in adults with CHD is still to be fully evaluated, but the recent evidence of significant hepatic toxicity makes its use less appealing for patients with a risk of hepatic dysfunction due to right ventricular failure.

ICDs represent a powerful tool for the termination of ventricular arrhythmias and prevention of sudden death. They have proven effective in adult patients with CHD including TOF [94]. Nevertheless, device implantation is associated

with a high incidence of early and late complications in these patients. ICD therapy implant is indicated for the secondary prevention in patients surviving a cardiac arrest or presenting with sustained ventricular tachycardia. The risk of limited vascular access and the possible presence of intracardiac shunts represent a limiting factor for chronic placement of an endocardial lead. When selected, ICD therapy for primary prevention is associated with a 7.7 %/year rate of appropriate therapy delivery [94]. This population may benefit from the recent availability of the fully subcutaneous ICD systems.

Results from transcatheter ablation of VT after repair of TOF are promising, but evidence of long-term efficacy in a large cohort is still lacking. Since VT has been correlated with the risk of sudden death in this population, at this time, the patients presenting with clinical sustained ventricular arrhythmias should be protected with an ICD. Transcatheter ablation should be performed in association or as an alternative to antiarrhythmic drug therapy in patients experiencing device-appropriate therapies.

An early experience reported by Therrien et al. [95] suggests that pulmonary-valve replacement may reduce progression of QRS prolongation and significantly decrease the incidence of ventricular arrhythmias (from 22 % to 9 %) during 4.7 years follow-up. The experience published from the Boston Children's Hospital group did not support a beneficial effect of pulmonary-valve replacement on arrhythmia incidence. In their series, surgical treatment had no effect on VT and sudden death nor did it influence QRS duration. Therrien et al. did not report any VT recurrence in 15 patients with TOF in whom ablation was performed at the time of surgery [95]. In the series from the Boston Children's Hospital, 5/7 patients receiving cryoablation during surgery experienced VT recurrence [15].

In patients undergoing redo surgery, the ability to reconstruct postsurgical anatomy and to identify areas of slow conduction that might sustain ventricular arrhythmias may significantly improve the efficacy of subsequent intraoperative ablation. Such strategies and the optimal timing for pulmonary-valve replacement to prevent VT and sudden death need to be addressed in large multicenter studies.

Postoperative Management of Right Ventricular Dysfunction

Adult patients receiving complete Fallot correction or additional procedures after a previous complete correction may experience *acute right ventricular failure* after the operation. This pattern may appear immediately after the completion of the operation in the operating room or in the first postoperative hours in the intensive care unit. The basic pathophysiological mechanisms recognize the preoperative diastolic and/or systolic dysfunction that may have deteriorated due to the ischemia-reperfusion insult during the operation. The hypertrophic right ventricle may be difficult to protect during the ischemic time of the aortic cross clamping, despite the use of adequate cardioplegic solutions. The hemodynamic marker of RV failure is the inability of the RV to *recruit* volume into the systemic circulation. Under these conditions, the clinical pattern is quite specific: the left ventricle appears unloaded, with all the dynamic fluid responsiveness indicators (pulse pressure variation, systolic pressure variation) suggestive of a hypovolemic condition. Actually, rather than being an absolute hypovolemia, this condition is a relative hypovolemia of the systemic circulation, with large amount of *unrecruitable* fluids placed in the venous bed.

As a result, the CVP is high (>15 mmHg) and the inferior vena cava and hepatic veins are overloaded. The right ventricle may appear dilated in case of systolic dysfunction with pulmonary regurgitation or hypertrophic with a reduced end-diastolic volume in the restrictive diastolic pattern.

The global cardiac output is inadequate, with reduced systemic arterial pressure, urine output, SvO_2 (<68 %), and increased arterial serum lactates (>3 mMol/L). The end-tidal CO_2 is

typically reduced, as an expression of a reduced pulmonary blood flow, and a large venous-arterial CO_2 gradient may appear.

Pharmacological Strategies for the Treatment of Acute Right Ventricular Failure

Different drugs may be used for the treatment of the failing RV, and many therapeutic algorithms greatly depend on physician's preference. However, there is a general agreement on the use of the phosphodiesterase inhibitor *milrinone* (dose 0.375–0.75 μg/kg/min). This drug may be particularly useful for the treatment of systolic dysfunction, without deteriorating diastolic function due to its action that is independent on adrenoreceptor activity. Milrinone seems to improve myocardial relaxation and induces a limited increase in myocardial oxygen demands. Its role in the treatment of acute heart failure following pediatric cardiac surgery is well established [96, 97]. It must be considered that milrinone induces a considerable systemic vasodilation, and its effects should be considered within a comprehensive strategy of RV preload preservation. In this respect, the patients with RV diastolic dysfunction and no left ventricular dysfunction may benefit from a mild to moderate systemic vasoconstriction (norepinephrine, 0.05–0.2 μg/kg/min). When milrinone alone is insufficient, direct adrenoreceptor agents may be added, like *dopamine* (3–8 mcg/kg/min) or *epinephrine* (0.02–0.2 mcg/kg/min). Both these agents increase the heart rate and may be responsible for arrhythmias. The use of new-generation inotropic agents (*levosimendan)* is anecdotal and not supported, at present, by the existing literature.

Non-pharmacological Strategies for the Treatment of Acute Right Ventricular Failure

The failing RV needs an appropriate preload to recruit blood from the venous system toward the systemic circulation. Therefore, CVP values in the range of 12–15 mmHg are not unusual and may be required. Diastolic filling should be facilitated by guaranteeing a correct atrioventricular conduction and a normal heart rate. Tachycardia decreases the diastolic filling time, and junctional rhythm or any pattern of atrioventricular block excludes the atrial contribution to the diastolic filling. Therefore, the use of atrioventricular pacing is mandatory in the absence of a spontaneous normal conduction and heart rate.

The heart-lung interaction under mechanical ventilation is of particular importance in the setting of an impaired blood transit through the pulmonary vessels. Positive pressure ventilation decreases venous return, RV preload, and cardiac output, especially when a positive end-expiratory pressure is applied. At the same time, pulmonary vessel compression during positive pressure ventilation increases the RV afterload. Mechanical ventilation should therefore be settled at the lowest possible positive pressure regimen, however avoiding the occurrence of hypoxia and/or hypercapnia which determines pulmonary vasoconstriction.

Inhaled nitric oxide (iNO) is a powerful pulmonary arterial vasodilator. Its role in congenital heart surgery is limited to the treatment of pulmonary hypertension. Some TOF patients who received a Blalock-Taussig palliation may have areas of inhomogeneous pulmonary blood flow after correction, and anecdotal reports of the use of iNO in the treatment of RV failure exist [98].

RV failure refractory to pharmacological treatment may require additional measures, ranging from the need for leaving an open sternum to mechanical circulatory support. Even if the primary culprit for the low cardiac output state is a RV failure, isolated RV assistance is difficult to perform due to the need for a pulmonary artery cannulation and the presence of different degrees of residual pulmonary regurgitation. Therefore, mechanical assistance of the failing RV in the adult tetralogy of Fallot is based on the placement of an extracorporeal membrane oxygenation (ECMO) system. This includes a venous and an arterial cannulation, a centrifugal pump, an oxygenator, and a heat exchanger. Depending on the situation, the cannulas can be directly inserted into the right atrium and the ascending aorta

when the chest is open or through the groin (femoral vein and artery) once it is closed. ECMO in refractory RV failure after cardiac operations in adult tetralogy of Fallot patients should be considered a bridge to recovery or a bridge to transplant depending on the clinical characteristics of the patient.

Univentricular Heart Physiology and Associated Anomalies in the Adult

142

Jamil Aboulhosn, Leigh Reardon, Reshma Biniwale, and Johanna Schwarzenberger

Abstract

This chapter details the long-term considerations and unique challenges faced in the care of the adult with single-ventricle physiology. This patient population is heterogeneous and the only unifying feature is the presence of only one effective ventricular pump. Numerous surgical interventions have been developed to palliate the condition; however, there is no truly "corrective" surgery. The care of the adult with single-ventricle physiology is challenging in that there are numerous long-term considerations and sequelae; although long-term survival is the norm, these patients face a myriad of issues related to their unique anatomy and physiology. A thorough understanding of the anatomic variations, expertise in imaging and interventions, surgical and medical teams experienced in the care of adults with congenital heart disease, and mechanisms for psychosocial support are all necessary for the adequate care of this complex population.

Introduction

The surgical and medical advancements of the past 50 years have altered the dismal natural history of patients with single-ventricle physiology and resulted in dramatic improvements in survival and quality of life. Long-term survival is now the norm and has resulted in a growing population of adults with unoperated, palliated, and corrected single-ventricle physiology. The management of the adult with single-ventricle physiology is challenging to say the least; the anatomic heterogeneity is dizzying and the number of surgical palliations varies widely. There is one unifying feature among all subtypes, the presence of only one adequately sized, effective ventricular pumping chamber for sustenance of adequate systemic blood flow. There is often a second hypoplastic chamber and "true single ventricles" are rare. The long-term survival following the latest versions of the Fontan operation is improved, yet patients face numerous challenges as they age. These are the first generations with single-ventricle physiology to survive to adulthood and represent a unique evolution of the human cardiovascular system. Our understanding of this population and the challenges they face grows as they age. The first generation of palliated patients has now reached their sixth decade, the Fontan patients are entering their fourth and fifth decades of life, many are having children, most live active and productive lives, yet they face a myriad of ongoing and future challenges. This chapter will address the various aspects that need to be considered in the care of the adult with single-ventricle physiology, from the medical and psychosocial to the surgical and interventional.

Medical Considerations

Patients with single-ventricle physiology encompass a wide array of anatomic subtypes, including but not limited to the following: tricuspid atresia, pulmonary atresia, hypoplastic left heart syndrome, and double-outlet or double-inlet ventricles. Patients with single-ventricle physiology are dependent on that functional ventricle to pump to the systemic circulation; there is no dedicated pump to the pulmonary circulation. Pulmonary blood flow in the unoperated patient is determined by the degree and severity of pulmonary stenosis, collateral arteries, and the presence and extent of arterial-to-pulmonary arterial communications; pulmonary blood flow may be increased, normal, or decreased. All patients with uncorrected single-ventricle physiology are cyanotic given the invariable mixing of oxygenated and deoxygenated blood in the single ventricle; however, the degree of cyanosis is correlated with the extent of pulmonary blood flow. Unoperated patients generally do not survive to reach adulthood, but those that do either have a protective degree of pulmonary stenosis limiting pulmonary blood flow and pressure elevation or have excessive pulmonary blood flow resulting in severe pulmonary hypertension and "Eisenmenger" syndrome [1].

Surgical Palliations

Early surgical interventions were designed to either increase pulmonary blood flow in those with pulmonary atresia or severe stenosis. The first of these was the Blalock-Taussig shunt,

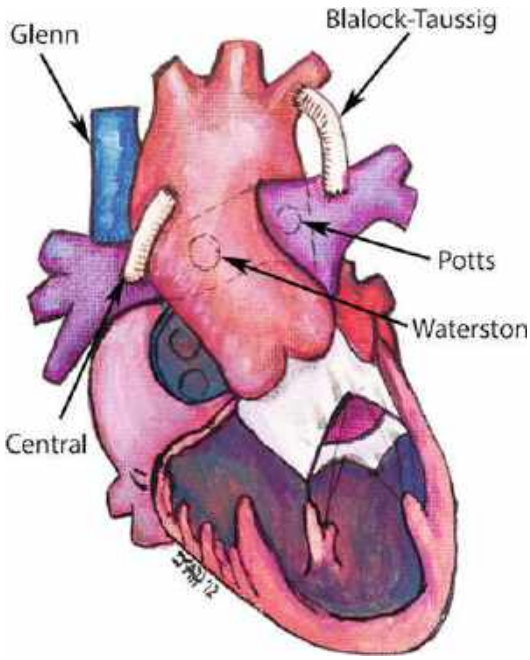

Fig. 142.1 Surgical shunts commonly employed in single-ventricle palliation. Blalock-Taussig shunt: cylindrical communication between the subclavian and pulmonary artery. Potts shunt: communication between the descending thoracic aorta and pulmonary artery. Waterston shunt: communication between the ascending aorta and the pulmonary artery. Central shunt: cylindrical communication between the ascending aorta and pulmonary artery. Glenn shunt: partial cavopulmonary connection between the superior vena cava and the pulmonary artery

originally designed in 1945; numerous other arterial-to-pulmonary communications have been developed since that time (Fig. 142.1) [2]. Pulmonary artery banding was used as a means of decreasing excessive pulmonary blood flow and preventing pulmonary hypertension and progression of pulmonary vascular disease [3]. These palliative procedures control the volume of pulmonary blood flow but leave the patient cyanotic. The long-term consequences of cyanosis include but are not limited to the following: hyperviscosity, limited exercise capacity, increased risk of thromboembolism, bleeding, infective endocarditis, stroke, hyperuricemia, heart failure, and arrhythmias [4–7]. The Waterston and Potts shunts have generally been abandoned given the propensity for patients to develop pulmonary hypertension. These arterial-to-pulmonary shunts are generally utilized in the infant as the first stage of surgical palliation and are often followed by successive operations to establish direct cavopulmonary communications eventually eliminating mixing of the systemic venous and pulmonary venous circulation. While most infants and children go on to have total cavopulmonary palliations, there continue to be a minority who do not undergo Fontan completion for a variety of potential reasons, including unacceptably elevated pulmonary arterial pressure and resistance, poor single-ventricle function, and inadequate access to early surgical intervention, among others. These patients remain cyanotic and many survive to reach adulthood; however, their clinical course and long-term hemodynamic consequences are not well studied as compared to the abundant literature on the long-term outcomes of Fontan patients.

The first surgical attempts to separate the pulmonary from the systemic circulation were aimed at partial separation and represented connections between systemic venous structures and the pulmonary arterial system. The "Glenn" shunt typifies this approach by connecting the superior vena cava directly to the pulmonary artery and thereby allowing nearly 1/3 of deoxygenated systemic venous return to passively flow to the lung and improve effective pulmonary blood flow (Fig. 142.2) [8, 9]. Patients continue to be cyanotic since systemic venous return from the lower body still mixes with pulmonary venous return at the atrial or ventricular level. The Glenn shunt can be unidirectional (the SVC is connected to a single pulmonary artery and the right/left pulmonary arteries are discontinuous; classic Glenn) or bidirectional (the SVC is connected to a pulmonary artery and the two pulmonary arteries are continuous). The Glenn shunt is typically used as an intermediate shunt, typically placed after 6 months of age, and often followed

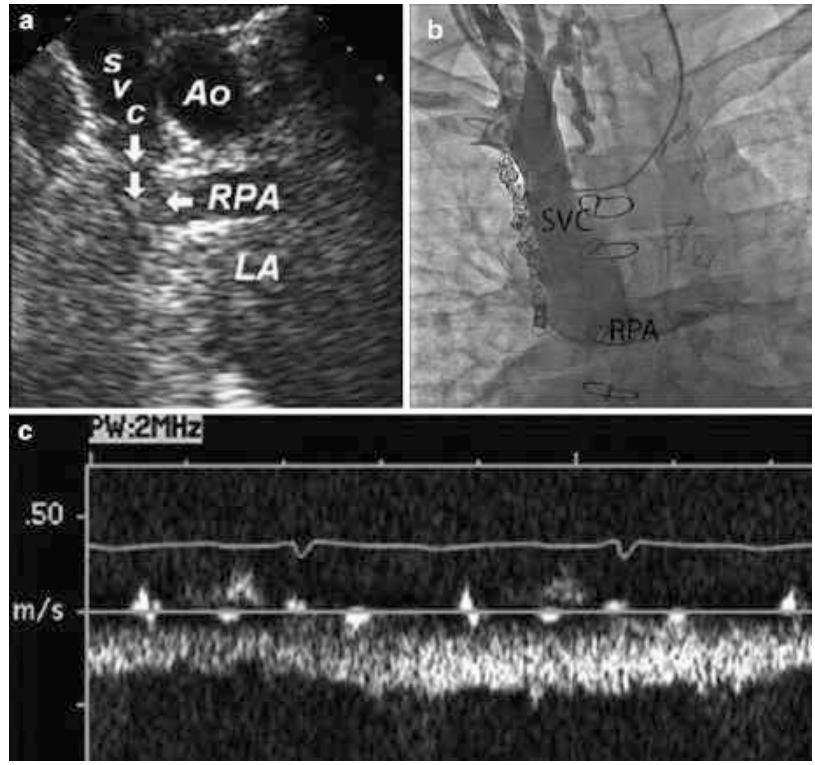

Fig. 142.2 (**a**) Transthoracic 2-D echo, suprasternal notch view of a Glenn shunt. Note the superior vena cava (SVC) running along the right side of the aorta (Ao) and entering the right pulmonary artery (RPA) which runs above the left atrium (LA). (**b**) Fluoroscopic anteroposterior frame of contrast injection in the SVC with unobstructed communication with the RPA (Glenn). Note the web of dilated venous collaterals coming from the right internal jugular vein and coursing inferiorly

Table 142.1 Morphologic and hemodynamic criteria for performing the Fontan operation at the Ahmanson/UCLA Adult Congenital Heart Disease Center

Morphologic criteria
Tricuspid atresia with pulmonary stenosis/atresia
Single ventricle with pulmonary stenosis/atresia
A hypoplastic ventricle that precludes biventricular repair
Hemodynamic criteria
Pulmonary arterial mean pressure <15 mmHg
Pulmonary arterial mean pressure up to 22 mmHg if Qp:Qs > 2:1, provided pulmonary vascular resistance index is <5 Wood units/m^2
Normal or mildly decreased ventricular systolic function (LV ejection fraction ≥45 %, RV ejection fraction ≥40 %)
No more than mild atrioventricular valve regurgitation (greater degrees of regurgitation considered amenable for Fontan operation if concomitant valve repair or replacement is thought to significantly improve ventricular function and filling pressures)
Ventricular end-diastolic pressure ≤12 mmHg

by Fontan completion by 3 years of age if anatomy and hemodynamics are deemed acceptable (Table 142.1) [10]. However, there are a subset of patients with Glenn shunts that are deemed to have unacceptably high pulmonary arterial or ventricular filling pressures and are not deemed candidates for Fontan completion. These patients often survive into adulthood and are invariably cyanotic. They suffer from the consequences of long-term cyanosis.

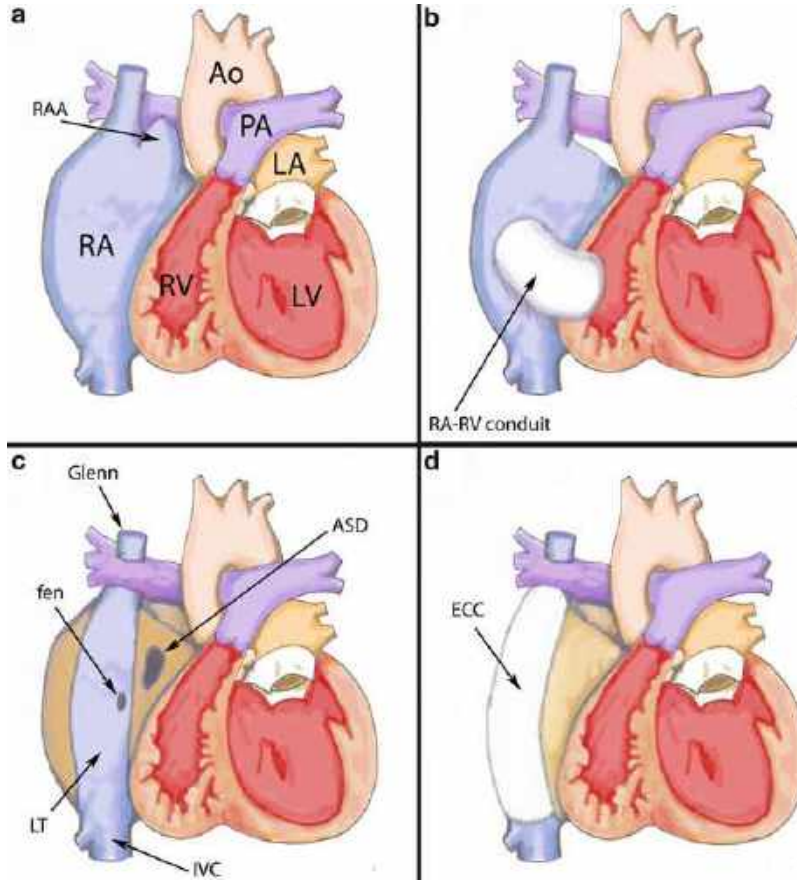

Fig. 142.3 (**a**) The modified right atrium (RA) to pulmonary artery (PA) Fontan, with a direct communication between the RA and PA, in this case consisting of the right atrial appendage (RAA). (**b**) The Bjork modification with an RA to right ventricle (RV) conduit (valved or nonvalved), previously used in patients with tricuspid atresia and a functional pulmonary valve. (**c**) The lateral tunnel (LT) Fontan modification with an intra-atrial tunnel from the inferior vena cava (IVC) to the PA. The superior vena cava is directly connected to the PA via a Glenn shunt. There is a fenestration (fen) in the lateral tunnel allowing shunting from the Fontan to the common atrium, made so by placement of an atrial septal defect (ASD). (**d**) The extracardiac conduit (ECC) Fontan modification excludes the right atrium altogether; the synthetic conduit is placed from the IVC to the PA, and the SVC is connected to the RPA to form a Glenn shunt. This is currently the most widely used Fontan modification for de novo Fontan and Fontan conversion

The cyanosis in these patients is often progressive as they tend to develop pulmonary arteriovenous malformations due to the absence of "hepatic factor" in the pulmonary blood [11]. Patients may benefit from surgical placement of a limited systemic arterial shunt to increase pulmonary blood flow and provide "hepatic factor." Cases have been reported that are not responsive to provision of hepatic venous effluent containing "hepatic factor" [12].

The Fontan Operation

In 1971, Fontan and Baudet described a novel surgical procedure for palliation of tricuspid atresia; they described an operation partitioning the oxygenated and deoxygenated circulations via a right atrium to pulmonary artery anastomosis (Fig. 142.3) [13]. They appropriately reasoned that this operation would not be applicable to patients with pulmonary hypertension, and that

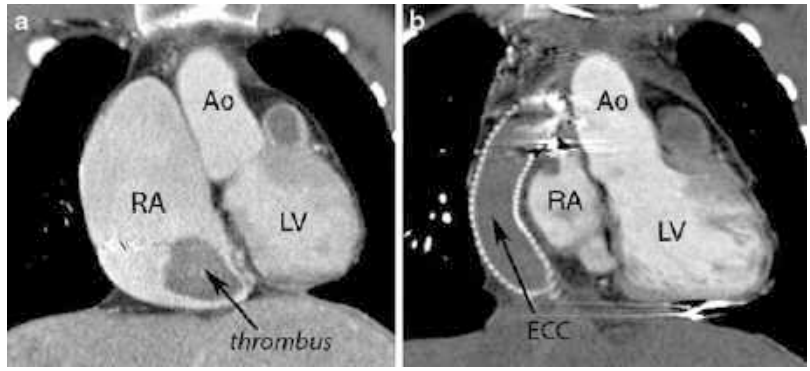

Fig. 142.4 (**a**) Cardiac CT angiogram, coronal view, demonstrating a large thrombus within a severely dilated right atrium (RA) in a patient with tricuspid atresia and an RA-PA Fontan and atrial arrhythmias. (**b**) The same patient 2 weeks following Fontan conversion to an extracardiac conduit (ECC), RA reduction, and arrhythmia surgery. The aorta (Ao) and left ventricle (LV) are labeled

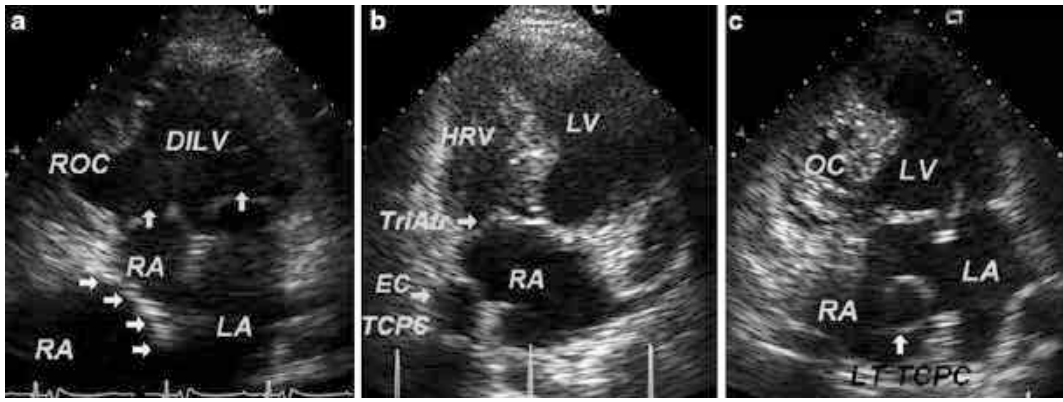

Fig. 142.5 (**a**) A patient with double-inlet left ventricle (DILV) with a right atrium (RA) to pulmonary artery Fontan, 2-D echocardiogram apical 4-chamber view. Note the dilated posterior portion of the RA is within the Fontan circuit and is divided from the more proximal portion of the RA by a pericardial patch (horizontal arrows). The hypoplastic right ventricle forms a right outlet chamber (ROC). The RA and left atrium (LA) communicate with the ventricle via well-formed atrioventricular valves (vertical arrows). (**b**) Apical 4-chamber view of a patient with tricuspid atresia (TriAtr) and a hypoplastic right ventricle (HRV) with a systemic left ventricle (LV) who has undergone Fontan conversion to an extracardiac Fontan (EC) total cavopulmonary shunt (TCPS). The right atrium (RA) has been surgically reduced but is still dilated. (**c**) Tricuspid atresia status post lateral tunnel Fontan (LT) total cavopulmonary connection (TCPC). The RV forms a hypoplastic outlet chamber (OC)

has generally remained true; however, there are some reports of the Fontan completion in patients with elevated pulmonary vascular resistance that improves with pulmonary vasodilators. The criteria for Fontan completion at the Ahmanson/UCLA Adult Congenital Heart Disease Center are outlined in Table 3 [10]. Inclusion of the right atrium in the Fontan circulation results in massive right atrial dilation, increased propensity for thrombus formation, sluggish and non-laminar flow within the dilated right atrium, and an increased propensity for developing atrial arrhythmias (Fig. 142.4) [14, 15]. Experimental evaluation of atrial function suggested that atrial contraction is not essential and is likely detrimental, prompting surgeons to develop Fontan modifications that to varying degrees exclude the right atrium (Figs. 142.3 and 142.5) [16]. The classic Fontan operation necessitated extensive intra-atrial surgery and resulted in

subsequent distention and elevation of right atrial pressure, often leading to sinus node dysfunction and atrial tachyarrhythmias. Late atrial arrhythmias occur in 69 % of patients with atriopulmonary-type Fontan as compared with 20 % in patients with total cavopulmonary connection excluding the right atrium [17]. Intra-atrial reentrant tachycardia, a term encompassing various macro-reentrant atrial arrhythmias, frequently involving an atriotomy scar, is the most commonly encountered arrhythmia.

Conversion of an atriopulmonary Fontan connection to a lateral tunnel or extracardiac cavopulmonary connection with concomitant arrhythmia surgery results in reduction in the frequency of atrial tachyarrhythmias [16, 18–20]. However, patients often require placement of epicardial pacemakers, and arrhythmias do recur in 15 % of patients within 3 years of conversion, occasionally necessitating additional electrophysiologic interventions [21]. The same hemodynamic criteria used for Fontan performance are used for Fontan conversion (Table 142.1).

Fontan patients face a myriad of long-term sequelae and potential complications, including but not limited to the following:

- Atrial arrhythmias – often necessitating use of antiarrhythmics and potentially requiring ablation and surgical conversion.
- Sinus node dysfunction and atrioventricular conduction abnormalities – may require pacemaker placement (usually epicardial).
- Ventricular dysfunction (systolic and diastolic).
- Pulmonary problems – restrictive or obstructive physiology, diaphragmatic paralysis.
- Chronic liver congestion even in patients with "desirable" Fontan pressure.
- Thromboembolic complications.
- Protein-losing enteropathy.
- Progressive cyanosis in those with fenestrations (Fig. 142.6), venous collaterals (Fig. 142.7), and pulmonary arteriovenous malformations.
- Poor systemic venous health with development of varicosities and ulcers [22].
- Obstructions to the Fontan circulation – should be corrected, typically with transcatheter stent deployment (Fig. 142.6).
- Obstructions to single-ventricle inflow (pulmonary vein compression) or outflow (subaortic stenosis, aortic stenosis, coarctation of the aorta) – should be corrected either via surgical or transcatheter means.
- Elevations in pulmonary vascular resistance, possibly at altitude – can be improved with use of pulmonary vasodilators.
- Pulmonary vasodilators may improve pulmonary blood flow and cardiac output [23–26].
- Pregnancy – considered high risk in all single-ventricle patients. Outcomes in non-cyanotic and functional females are good [27].
- Psychosocial issues [28].
- Addressing other comorbidities that can adversely affect Fontan pressure and single-ventricle function, including diabetes mellitus, dyslipidemia, obesity, and systemic hypertension.
- Potential need for heart transplantation or multiorgan transplantation (e.g., heart/liver or heart/kidney) for the failing Fontan.
- Emerging role for the use of assist devices in the failing Fontan [29].
- Diminished exercise capacity.

Protein-Losing Enteropathy (PLE)

PLE is an uncommon (3.7 %) but dreaded complication of the Fontan operation associated with a poor prognosis, with a 5-year mortality nearing 50 % [30, 31]. PLE is thought to result from bowel edema secondary to low cardiac output and elevated systemic venous and lymphatic pressures. Mesenteric vascular resistance increases in low cardiac output states and is generally elevated in patients with Fontan circulation. This may be due, in part, to the increased impedance to emptying of the portal venous system in patients after the Fontan operation. Patients with PLE have a further increase in mesenteric vascular resistance as compared with Fontan patients without PLE. Perioperative risk

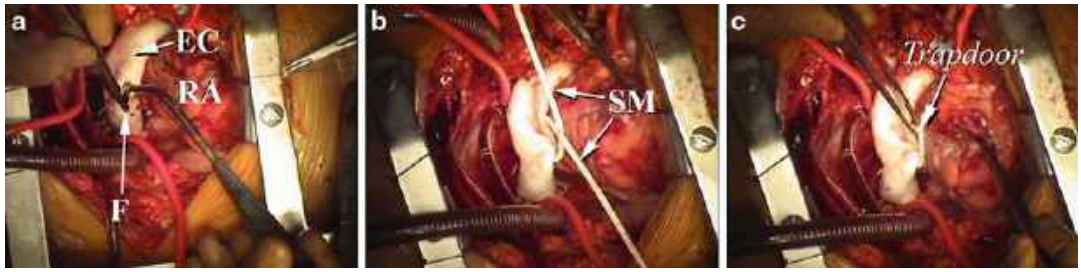

Fig. 142.6 (**a**) Fontan conversion to an extracardiac conduit (EC) placed along the lateral wall of the right atrium (RA) and fenestrated (F). (**b**) The fenestration is then sutured to the outside wall of the RA, and radiolucent silastic membrane is tied around the communication. (**c**) The trapdoor serves as a radiographically identifiable location for transseptal needle puncture should a fenestration be needed or access to the atria is necessary for electrophysiologic catheter ablation or intervention

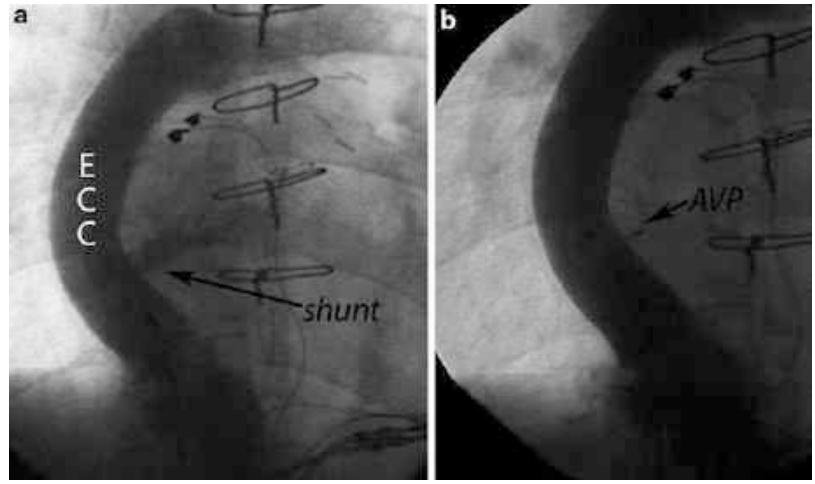

Fig. 142.7 (**a**) Extracardiac conduit (ECC) with a tubular shunt into the common atrium. (**b**) Amplatzer vascular plug (AVP) (St Jude Medical) occluding the shunt. The patient's resting systemic saturation rose from 88 % to 96 % immediately as a consequence of shunt closure. The Fontan pressure increased from 14 mmHg to 15 mmHg

factors for the development of PLE include longer cardiopulmonary bypass time and single right ventricle anatomy. Patients with PLE frequently develop peripheral edema and refractory ascites and pleural effusions. These patients often demonstrate evidence of liver congestion and cirrhosis. The serum albumin is low and random assessment of fecal 1-antitrypsin concentration is reliable in identifying enteric protein loss. Therapeutic options include symptomatic relief via drainage of pleural and ascitic fluid, afterload reduction, diuresis, intravenous albumin infusion, immunoglobulin infusion, and a high-protein/low-fat diet. It is imperative to treat any narrowing of the Fontan circuit or pulmonary arterial tree to relieve even mild obstruction [32]. Oral steroids and pulmonary vasodilators have also been demonstrated in small series to be effective in the treatment of PLE [33–35]. Other medical interventions purported in various case reports to decrease PLE via incompletely understood mechanisms include heparin, spironolactone, octreotide, and calcium infusion. Atrial pacing has been reported to improve PLE, likely as a result of augmented cardiac output in patients with sinus node dysfunction. Surgical or transcatheter fenestration of the atrial septum allows some right-to-left shunting and decreases systemic venous pressure, thus reducing the risk of PLE or unremitting pleural effusions, at the expense of arterial oxygen desaturation [36]. Heart transplantation is reserved for patients who have failed medical or surgical therapy [29].

Thromboembolism

The Fontan circulation represents a hypercoagulable state. The prevalence of intracardiac thrombosis is approximately 10 % in the RA-PA Fontan and 5 % in the extracardiac Fontan [37, 38] (Fig. 142.4). The thromboembolic risk appears to be the highest within the first year after the operation; however, strokes have been reported ≥9 years after the operation. The Fontan circulation represents a hypercoagulable state given the presence of prosthetic materials and passive blood flow. Given the poor outcome of thromboembolic complications (25 % mortality), prophylaxis is appropriate; warfarin or antithrombins are generally used in patients with a prior history of thromboembolism, atrial arrhythmias, or additional hypercoagulable state. Aspirin is used in lower-risk patients but the evidence for superior efficacy of anticoagulant vs. antiplatelet therapy is lacking [37]. Pulmonary thromboembolism is often inappropriately diagnosed in patients undergoing computed tomographic or magnetic resonance angiography with upper extremity injection of contrast preferentially opacifying one lung; in such cases, we recommend performance of angiography via an upper and near simultaneous lower extremity venous injection of contrast to fully opacity the cavopulmonary circuit.

Developmental Issues and Transition of Care

Single-ventricle patients are at high risk of adverse development during childhood that has implications well into adulthood. Patients with single ventricular physiology have long-term cyanosis, disturbances of cerebral flow in utero, high risk of additional genetic abnormalities, and exposure to prolonged cardiac bypass times [39, 40]. Neurocognitive testing, IQ testing, and other measures of neurodevelopment demonstrate diminished capacity in this patient population. Studies are limited to the pediatric population but the consequences have functional implications well into adulthood. Patients with single-ventricle physiology are at significant long-term risks, and gaps in care can have profound implications [40]. Early implementation of transitional care principles can decrease gaps in care and ultimately complications [41, 42]. We advocate for introducing of transition to the adult setting in the early teen years to help patients develop independence and the capacity to manage their chronic disease by the age of 18–21 or as developmentally appropriate. Early attention to the maintenance of adequate health insurance and vocational counseling is of the utmost importance.

Pregnancy

Pregnancy in single-ventricle patients requires prepregnancy consultation and risk stratification. The physiologic consequences of pregnancy include a doubling of cardiac output and stroke volume, increases in myocardial oxygen consumption by 20 %, and increases in heart rate by 15–20 %; these factors can have profound impact on the Fontan circulation [27, 43]. Maternal complications are low in a well-functioning Fontan patient [44] but can include atrial arrhythmias, worsening of congestive symptoms, thromboembolic events, increased liver stress, and protein-losing enteropathy. Fetal risks include preterm labor, intrauterine growth retardation, and increased risk of spontaneous abortion [45, 46]. Pregnancies carried beyond 14 weeks of gestation have a higher likelihood of carrying the pregnancy to term. Pregnant patients should be followed closely and should be offered fetal echocardiographic screening. Warfarin therapy should be avoided during pregnancy.

Liver Injury

While indolent, long-term liver congestion in growing number of adult patients with the Fontan circulation will have important clinical consequences for single-ventricle patients. Chronically elevated venous pressure, decreased cardiac output, and hepatic hypoperfusion result

in fibrosis, metabolic derangements, and in some cases cirrhosis and hepatocellular carcinoma [47]. Many factors ranging from medication toxicity to genetic abnormalities to hepatitis C infection contribute to hepatic disturbances. Radiological evaluation of the liver with dual-phase computed tomography is abnormal in all adults with the Fontan circulation, consisting of heterogeneous enhancement in the majority of patients; other findings may include varices, sinusoidal dilation, portal vein thrombosis, and hepatic adenocarcinoma [48]. The FibroSURE panel (LabCorp), a test that analyzes the results of serum biomarkers to provide a quantitative surrogate marker for liver fibrosis, can be utilized to predict the degree of liver fibrosis and the presence of cirrhosis in this population. A recent study demonstrated that the majority of Fontan patients had abnormal Fibrosure scores, with 50 % demonstrating either advanced fibrosis or less commonly cirrhosis [48, 49]. Adult congenital specialists are additionally observing cases of adenocarcinoma of the liver in Fontan patients [50, 51]. Patients with evidence of advanced liver cirrhosis are considered for heart and liver transplantation [52].

Surgical Considerations

Arteriovenous Shunts to Increase Pulmonary Blood Flow

Occasionally, patients with Glenn shunts and hemodynamics that are not ideal for Fontan completion may benefit from increasing pulmonary blood flow. This is especially true in those with pulmonary arteriovenous malformations secondary to the absence of hepatic factor. An off-pump central shunt, modified Blalock-Taussig shunt (Fig. 142.1), or axillary arteriovenous fistula can be performed to increase blood flow and provide "hepatic factor" to the pulmonary circulation. The improved oxygenation and increased pulmonary blood flow must be weighed against the inevitable increase in pulmonary artery pressure and ventricular filling pressure.

Fontan Completion in Adulthood

A considerable number of single-ventricle patients palliated with Blalock-Taussig shunts do not proceed to bidirectional Glenn and Fontan creation due to elevated pulmonary artery pressure and resistance or if they have poorly functioning systemic ventricles. A minority of patients may have acceptable hemodynamics or develop acceptable hemodynamics on pulmonary vasodilator therapy and go on to have "late Fontan completion" [53].

As these single-ventricle patients have had prolonged exposure to hypoxia, they are cyanotic and may have multiple aortopulmonary collaterals. These make for a difficult reentry sternotomy and contribute to considerable intraoperative blood loss. Diversion of the systemic venous return to the Fontan circuit may also be poorly tolerated requiring Fontan fenestration.

Fontan Conversion and Arrhythmia Surgery

In the last two decades, total cavopulmonary connection has become standard practice for Fontan completion. The extracardiac Fontan has become the most commonly employed modification with concomitant arrhythmia surgery. Candidates for Fontan conversion typically present with atrial arrhythmias in the presence of an RA-PA or RA-RV modified Fontan, typically placed in the 1970s, 1980s, or early 1990s [16, 19, 20, 54]. The lateral tunnel Fontan is technically more challenging than the extracardiac Fontan or the intracardiac tunnel Fontan and is associated with higher arrhythmia risk [55]; however, controversy continues as to the optimal technique.

Indications for Fontan conversion include enlarged right atrium containing thrombus, refractory atrial arrhythmias, and pulmonary venous obstruction by the enlarged right atrium. The risk of mortality with Fontan conversion is 5–10 % and is highest in those with cirrhosis of the liver [20]. Progressive systemic ventricular dysfunction and intractable atrial arrhythmias

along with the passive Fontan circulation are associated with a chronically decreased cardiac output. The presence of collaterals and diminished liver function may result in excessive bleeding. Bleeding can be encountered either on reentry or following heparinization for cardiopulmonary bypass. Occasionally, femoral cannulation may be necessary if chest imaging reveals immobile cardiac structures in close proximity to the sternum.

The surgical technique consists of direct bicaval cannulation following careful dissection of adhesions. In the presence of intra-atrial shunts, the rest of the operation is performed after aortic cross-clamping and administration of cardioplegia. A vent is placed in the right superior pulmonary vein to collect the increased pulmonary venous effluent from the aortopulmonary collateral flow. The caval snares are tightened. A right atriotomy is made and complete atrial septectomy is performed. The inferior vena cava is divided from the right atrium. The connection between the right atrial appendage and the inferior margin of the right pulmonary artery is taken down. This area of the pulmonary artery may be patched or used for the distal anastomosis of the extracardiac conduit. An 18–24 mm synthetic conduit (depending on the weight of the patient) is used to create the extracardiac conduit Fontan between the inferior vena caval orifice and the inferior aspect of the right pulmonary artery. The bidirectional superior cavopulmonary anastomosis is performed. Right atrial reduction at the time of Fontan conversion can be accompanied by a right-sided MAZE procedure. A curvilinear cryoablation lesion can be placed from the IVC orifice to the annulus of the tricuspid valve and then extending to the orifice of the coronary sinus and then on to the inferior margin of the fossa ovalis. A second lesion is placed between the fossa ovalis and the base of the cut right atrial appendage. An additional lesion from the fossa ovalis to the crista terminalis completes the right-sided MAZE. Left-sided ablation (MAZE-COX) is performed if there is underlying atrial fibrillation. This includes cryolesions encircling the pulmonary veins, ligation of the left atrial appendage, lesions connecting the base of the left atrial appendage, and the mitral valve annulus to the box lesion around the pulmonary veins. Epicardial pacing leads are often placed given the high likelihood of sinus node dysfunction and bradyarrhythmias [18, 54]. An external defibrillation coil may have to be placed in the pericardium surgically in those with documented ventricular tachycardia or fibrillation. Electrical resynchronization and improved cardiac output may also be obtained by biventricular placement of bipolar pacing electrodes [56]. A "trapdoor" modification is used for Fontan conversions in adults at UCLA as a means of retaining and of easily establishing Fontan and RA communication should it be necessary [20] (Fig. 142.6).

Atrioventricular Valve Regurgitation

There are a variety of potential atrioventricular (AV) valve subtypes encompassed in patients with single-ventricle physiology, including but not limited to systemic tricuspid valve in transposed great arteries, cleft mitral valve or bridging atrioventricular valve in those with endocardial cushion defects, and myxomatous and prolapsing mitral leaflets. Systemic tricuspid valve function deteriorates over time, especially if it is anatomically dysplastic, in which case valve replacement is a prudent option. Clefts and prolapsing segments can be surgically repaired and additional annuloplasty is often performed [53]. Despite advances in surgical repair techniques, AV valve regurgitation remains a poor prognostic indicator in the adult with single-ventricle physiology.

Transplant Considerations

Application of traditional heart transplantation criteria to the failing single-ventricle patient is problematic given the absence of traditional transplantation criteria for isolated low-pressure right-sided heart failure as is the case with the failing Fontan. Indications for transplantation in Fontan patients are not well established and are

considered on a case-by-case basis [57–59]. Indications include ventricular failure, progressive systemic atrioventricular valve regurgitation in the presence of poor ventricular function, plastic bronchitis, and protein-losing enteropathy not responding to management as detailed earlier in this chapter.

Elevated Fontan pressures can cause chronic passive venous congestion in the liver, which can progress to bridging fibrosis and eventually cirrhosis. In the event that the liver is more than moderately affected, a combined heart/liver transplant may have to be performed. Similarly decreased renal function due to elevated central venous pressures can lead to end-stage renal disease warranting combined heart/kidney transplantation.

Multiple prior cardiac surgeries and exposure to blood products result in elevated panel-reactive antibodies. The transplant must be both prospectively and retrospectively cross-matched in order to prevent hyperacute rejection. Transplantation in patients with heterotaxy and prior Kawashima procedures require reconstruction of the systemic venous pathways with the use of conduits. Some may require a baffle of the pulmonary venous pathway to the left side to anastomose with the donor atrium.

Assist Devices

Experimental animal models have shown that mechanical circulatory support of the failing total cavopulmonary connection is feasible and reproducible. Several devices have been used in this setting including the HeartMate II (Thoratec) device and the Berlin heart device [60]. These have been used to support the systemic ventricle and thus indirectly improve the pulmonary blood flow. Computational studies have shown benefit in using a right heart substitute either of pulsatile or continuous flow types directly in the failed Fontan circulation [61]. Preliminary animal studies are promising; however, clinical series are still pending [62, 63].

Anesthesia and ICU Considerations

Adult patients with palliated univentricular hearts undergo percutaneous or open procedures requiring anesthesia on a regular basis. With the publication of the 2008 AHA guidelines for the management of adults with congenital heart disease (ACHD), a standard for the perioperative support of these patients has been set [64]. Specifically, the guidelines recommend that patients with univentricular hearts undergo all their operative care in CHD specialized tertiary medical centers irrespective of the type of procedure. Twenty-four hour availability of a cardiac anesthesiologist familiar with CHD lesions is recommended.

The cardiac anesthesiologist plays an integral part in safekeeping the patient throughout his procedure. While percutaneous, laparoscopic, and minimally invasive approaches have reduced surgical stress and postoperative pain to a major degree, the need for general anesthesia and all its caveats in the altered cardiopulmonary status of hypoplastic heart syndrome has remained the same. Thus, the anesthesiologist should be an integral part of pre-procedure work-up, procedural planning, and post-procedural care.

Preoperative Considerations and Work-Up

Cardiovascular Status

The most important perioperative consideration is the presence and/or the potential to develop or exacerbate low systemic cardiac output in a palliated univentricular heart. Specifically, the Fontan heart has reduced cardiac output due the absence of a pre-pulmonary ventricle that pumps blood to the pulmonary circulation, making a potentially necessary increase in stroke volume during surgery dependent on intravascular volume status and pulmonary vascular resistance alone. In addition, the systemic ventricle, particularly in hypoplastic left heart disease, is prone to diastolic dysfunction and high systemic vascular resistance. Sinus rhythm,

atrioventricular valve patency and competence, and low pulmonary vascular resistance are all prerequisites for optimal performance of the Fontan circulation during noncardiac intervention. While these factors might be stable at rest, surgical stress and/or anesthesia may uncover the propensity for atrial tachyarrhythmias, worsening AV valve regurgitation or variable pulmonary vascular resistance.

Preoperative exercise testing should be entertained depending on the type of surgical intervention planned. Exercise testing is of prognostic significance in patients with single-ventricle physiology [65]. In the preoperative history, signs and symptoms of the failing heart should be carefully sought, as many of such symptoms may be nonspecific: fatigue, weight gain, or decreased activity. The anesthesiologist must recognize that self-reported activity level may not reflect true exercise capacity. While no formal recommendations exist regarding the presurgical risk stratification of Fontan patients, elective surgery should be postponed in patients with signs or symptoms of heart failure, uncontrolled arrhythmias, or protein-losing enteropathy until these conditions have been appropriately treated.

Intraoperative adaptation of the Fontan heart to the anticipated hemodynamic challenges such as surgical manipulation of abdominal organs resulting in altered inferior vena cava filling, sudden blood loss, and sympathetic stimulation due to pain can be estimated by preoperative exercise testing. If the patient demonstrates severely reduced exercise capacity, decreased heart rate response, and delayed recovery from peak exercise, preoperative cardiac catheterization and intervention should be considered. Interventions may be medical (diuretics, pulmonary vasodilators, etc.), mechanical (occlusion of collaterals, occlusion/creation of fenestration, stenting, etc.), or electrophysiologic (pacing, ablation, etc.) [66, 67]. In the adult Fontan patient, cardiac catheterization seldom requires the use of general anesthesia. Minimal sedation is preferable if the procedure is purely diagnostic and the patient is agreeable. Central venous pressure, pulmonary artery pressure and resistance, common atrial pressure, and ventricular end-diastolic pressure provide crucial information for the anesthesiologist. Unfortunately, our experience has been that the majority of adult Fontan patients referred for catheterization prefer to be under deep sedation for procedures lasting >1 h, which these procedures typically do. Additionally, the performance of transesophageal echocardiography concomitantly can result in significant discomfort. During cardiac catheterization, formal pulmonary vasodilation testing is typically performed with inhaled nitric oxide to ascertain the reactivity of the pulmonary vascular bed and its effect on cardiac output [68]. As a result of such testing the beneficial effects of inhaled and oral pulmonary vasodilators to decrease PVR variability perioperatively should be entertained. The use of these agents to improve filling and performance of the systemic ventricle was recently demonstrated [26, 68, 69]. Other benefits from preoperative catheterization are the delineation of the sources of hypoxemia in the Fontan patient: baffle leaks, persistent fenestration, or veno-veno/veno-atrial decompressing collaterals (Figs. 142.7 and 142.8) may all become more prominent during general anesthesia where variability in pulmonary vascular resistance cannot always be avoided. Preoperative percutaneous closure of such communication may be beneficial. Cardiac catheterization is also helpful in delineating patency of vessels and interventional ballooning and stenting can be performed to optimize hemodynamics (Fig. 142.9).

Electrophysiological study (EPS) and radio-frequency ablation should be considered prior to major elective noncardiac surgery in patients with uncontrolled tachyarrhythmias [70]. The presence of sinoatrial dysfunction or bradyarrhythmias may require the placement of a dual chamber pacemaker with or without resynchronization abilities. Placement of an epicardial implantable cardioverter-defibrillator (ICD) may be necessary if ventricular tachyarrhythmias that are present cannot be treated successfully with radio-frequency ablation or medication. Perioperative reprogramming of ICDs and pacemakers will be required and should

(**b**) Widely patent ECC noted with 3-D TEE. (**c**) Rotational angiography with cone beam CT surface-rendered 3-D reconstruction in the catheterization laboratory provides superb imaging of the Fontan circuit. (**d**) 3-D *maximum intensity projection* of rotational angiogram demonstrating a mild kink of the ECC that was not appreciated by other imaging modalities (2- and 3-D TEE, rotational angiography, conventional angiography, or 3-D volume rendering as seen in (**c**). There was a 2 mmHg mean gradient across this narrowing

be done in close cooperation with the electrophysiology cardiologist.

Pulmonary Status

Intrathoracic abnormalities may also be responsible for chronic hypoxemia in the Fontan patient. Pleural effusions, intrinsic lung disease, pulmonary arteriovenous malformations (AVM), and plastic bronchitis should be considered if low pulmonary venous saturations are found on cardiac catheterization. Thoracocentesis and diuretics are the mainstay of therapy for pleural effusions. Pulmonary infections must be cleared before surgery and bronchial reactivity should be treated aggressively with beta-agonists and steroids. Preoperative occlusion of AVMs, fenestrations, and veno-venous collaterals may be beneficial in decreasing left to right and right to left shunts. Plastic bronchitis is a rare complication after the Fontan operation with bronchial casts forming in the airway potentially leading to obstruction and asphyxiation. While the etiology of this complication is unknown, therapy is aimed primarily at improving cardiac output. Fontan fenestration, pulmonary vasodilating agents, and inotropic therapy may resolve plastic bronchitis [71]. Treatment of plastic bronchitis using serial flexible bronchoscopy and aerosolized heparin has been described.

Neurological Status

Fontan patients are at risk for neurological and developmental deficits. Prior exposure to chronic hypoxemia, cardiopulmonary bypass, hypotension, and thromboembolic episodes places the adult Fontan patient at higher perioperative risk for cerebrovascular accidents. It is imperative that sources of thrombi are excluded prior to surgical intervention. A perioperative transesophageal echocardiogram (TEE) can exclude intracardiac and Fontan baffle thrombi. Sources of arterial occlusive disease should be screened for if clinically indicated.

Developmental delay, attention deficit disorder, high anxiety state, as well as depression may be present in Fontan patients. A preoperative screening interview by the anesthesiologist will alleviate many fears and can provide the Fontan patient with a feeling of emotional security throughout the perioperative process.

Hepatic/Gastrointestinal Issues

As discussed earlier in this chapter, hepatic function decreases steadily with increasing venous congestion of the liver due to low cardiac output. Thus, time since Fontan palliation is a predictor of liver dysfunction. Many centers (including ours) now attempt to perform routine surveillance transvenous liver biopsy concomitantly with a hemodynamic or interventional catheterization in Fontan patients given the high risk of fibrosis and possible cirrhosis. Preoperatively, liver enzyme and liver synthetic function tests should be performed. Anesthetic considerations include altered drug metabolism, the presence of esophageal varices, and perioperative risk of bleeding (and thrombosis) due to abnormal synthetic function of the liver.

Protein-losing enteropathy poses another perioperative challenge. Hypoalbuminemia, poor nutritional status, pleural effusions, and generalized edema all increase perioperative risk for infection, renal, and respiratory failure.

Renal Considerations

Renal dysfunction is present in nearly 50 % of adult Fontan patients [72], manifested by the presence of microalbuminuria, the presence and degree of which is correlated with pulmonary vascular resistance. The use of angiotensin inhibitors appears to ameliorate microalbuminuria. Perioperative renal dysfunction increases the risk of in-hospital morbidity and mortality in all patients [73]. Preoperative hydration and renal dosing of all medications according to the GFR are imperative.

Hematologic Considerations

Thromboembolic events due to hypercoagulability and atrial arrhythmias are common in the adult Fontan patient. Numerous anticoagulation protocols are currently used, yet thromboembolic events continue to occur due to the abnormal clotting factor profile in the Fontan patient: protein S and C as well as antithrombin

III are decreased, while factor VIII, X, prothrombin, and P-selectin are increased. If the patient has hepatic dysfunction, the coagulation profile can be further disturbed. Given the complexity and variability of clotting abnormalities in the Fontan patient, a hematology consult may be warranted in anticipation of major surgery (spine fusion, large abdominal resection, etc.), especially in those with prior thrombotic or bleeding events. Recommendations for or against the use of antifibrinolytic agents should also be sought.

Anesthetic Management

Anesthetic management is guided by preoperative findings and the invasiveness of the planned procedure. If a procedure must be done on an urgent basis in a Fontan patient with signs of a failing heart without cardiac catheterization results available, the preoperative use of either milrinone or dobutamine to support cardiac function should be considered. Premedication of the patient with an anxiolytics such as midazolam is possible as long as it is provided in the presence of a physician who will monitor the patient for potential hypoventilation and hypercarbia. All lines should also meticulously de-bubbled and fitted with a particle filter to decrease the risk of paradoxical embolization.

Monitoring in addition to standard intraoperative monitors should be guided by patient status and procedure planned. Arterial line monitoring provides beat-to-beat blood pressure and access to frequent arterial blood gases. Blood pressure differences in the extremities (e.g., due to a history of BT shunt or coarctation) should be assessed and factored in prior to arterial line cannulation. A continuous cardiac output (FloTrac ^{TM}) module can be mounted on the arterial line. Although this technology has not been validated in patients with complex shunt lesions, the calculated cardiac output, stroke volume, and SVR can be monitored for trends. Central venous pressure monitoring is recommended for surgeries with potentially large volume shifts. Transesophageal echocardiography is an invaluable tool for online monitoring of ventricular and valvar function during a procedure in the intubated Fontan patient.

The anesthetic goal in a Fontan patient is the maintenance of an optimal transpulmonary gradient (TPG). A TPG $<$ 10 mmHg will assure adequate pulmonary blood flow and cardiac output. The induction of anesthesia may depress cardiac output acutely due to low preload state in addition to the negative inotropic effects of almost all induction agents. Even in an urgent case, the anesthesiologist should aim for hemodynamic stabilization (augmentation of preload, use of inotropes) prior to the induction of anesthesia. Inhaled nitric oxide to treat acute pulmonary hypertensive episodes should be considered. Patients with pleural effusion and or low respiratory reserve should be induced in the semi-sitting position to avoid sudden redistribution of pulmonary blood flow while lying supine. Succinct control of the airway is necessary to avoid alterations in pulmonary vascular resistance.

Fontan patients generally benefit from negative pressure ventilation and its augmentation on venous return. However, the positive effects of a low-volume, low inspiratory positive-pressure ventilation on decreasing afterload of the systemic ventricle with subsequent increase of cardiac output outweigh the potential negative effect of a spontaneously breathing patient under general anesthesia. Airway pressure release ventilation with its positive impact on pulmonary blood flow may be considered [74].

The potential harmful hemodynamic effects of laparoscopic procedures should be discussed with the surgeon prior to the start of the procedure. The risk of a steep Trendelenburg position, intra-abdominal distention, reduced venous return, and systemic uptake of insufflated CO2 on the Fontan circulation should be weighed against the benefit of faster recovery time and less pain following a laparoscopic procedure. In general, the laparoscopic approach has been successful as long as the intra-abdominal pressure has been less than 10 mmHg [75].

Postoperative Care

The postoperative care and disposition of the Fontan patient is dependent on the extent of the intervention, the encountered hemodynamic derangements during the procedure, and the anticipated need for pain management and overall care postoperatively. While many Fontan patients could be cared for in a regular unit instead of an ICU, one has to consider the need for familiarity of the nursing staff with complex cardiac anatomy and physiology as well. In general, postoperative objectives mirror the intraoperative goals: to maintain low PVR state, adequate preload, and good cardiac output. Postoperative fluid management should be guided by physical examination and CVP and transthoracic echocardiography monitoring particularly in the patients prone to acute kidney injury. Non-opioid perioperative pain management modalities (local and regional anesthesia, paracetamol if available) should be considered whenever possible to avoid narcotic-induced hypoventilation and nausea/vomiting. Supplemental oxygen is advised for all patients receiving patient-controlled analgesia and may be particularly helpful in the Fontan patient. Nonsedating antiemetics should be used to treat postoperative nausea and vomiting. Deep vein thrombosis prophylaxis with pneumatic compression stockings should be continued postoperatively until the patient ambulates fully. Anticoagulation should be reinstituted as soon as possible in consultation with the patient's cardiologist.

Constantine Mavroudis, Barbara J. Deal, and Carl L. Backer

Abstract

The sequelae of Fontan-type repairs for functionally univentricular hearts include hemodynamic changes related to atrial enlargement and underlying anatomy, arrhythmias, and multiorgan system effects. Therapeutic interventions addressing both hemodynamic sequelae and arrhythmia substrates have been effective in improving quality of life and markedly reducing arrhythmia recurrence during midterm follow-up. Successful arrhythmia intervention requires careful assessment of the arrhythmia mechanisms and application of the appropriate surgical ablation techniques. The surgical intervention is challenging owing to redo sternotomy in univentricular physiology and anatomic variations. This chapter outlines the authors' resternotomy and operative techniques for safe mediastinal reentry and the surgical and anatomic variants encountered in association with Fontan conversion.

Introduction

Principles of Fontan Conversion

The Fontan surgical repair was originally designed in 1968 for the anatomic single left ventricle, with modifications ensuing as the repair was extended to more complex anatomic variations and ultimately the single right ventricle. With a staged approach to repair, current modifications of Fontan surgery have achieved operative mortality of less than 5 %, with 20-year survival of at least 84 % [1]. Inherent to all Fontan surgical variations is the chronic elevation of right atrial and vena caval pressures, with the need for low pulmonary vascular resistance and adequate ventricular function [2]. Surviving adults with atriopulmonary or atrioventricular repairs now present with the sequelae of chronic systemic venous congestion, including atriomegaly and its consequences of impingement on pulmonary venous return, reduced exercise tolerance, atrial arrhythmias, hepatic dysfunction, cyanosis, and declining ventricular function. The final stages of this unchecked progression include elevation of pulmonary vascular resistance with progressive intrapulmonary shunting and cyanosis, manifestations of severely limited cardiac output with ascites, protein-losing enteropathy, plastic bronchitis, cardiac cachexia, and risk of hepatic carcinoma.

Reinterventions to optimize the Fontan circulation have been refined since the early 1990s and have included atrial reduction and relief of hemodynamic obstructions in either the pulmonary or systemic outflow pathways resulting in improved hemodynamics but persistence of atrial arrhythmias [3–10]. Catheter interventions for atrial tachycardia in the Fontan patient have success rates of approximately 50 % and over 85 % recurrence of arrhythmias within 4 years [11], without addressing the hemodynamic abnormalities. In 1994, the current authors began a strategy of conversion of the prior Fontan circulation to an extracardiac total cavopulmonary connection integrated with operative arrhythmia surgery to eliminate atrial tachycardia and pacemaker implantation to optimize atrial rhythm and rate [12–15]. An extensive learning curve included modifications to the arrhythmia surgery lesions, dictated by anatomic complexity and type of arrhythmia including atrial fibrillation, accessory connections, atrioventricular nodal reentry tachycardia, and rarely, ventricular tachycardia [16]. Concomitant repairs of atrioventricular valves, pulmonary arteries, and aortic valve/root abnormalities have been incorporated. Operative mortality of less than 3 % has been maintained, and a 10-year survival of over 85 % has been reported [17, 18]. Extensive and seamless collaboration between electrophysiologists, anesthesiologists, and perioperative intensivists with the surgical team is required to achieve successful results.

The operative principles of the Fontan conversion procedure include (1) patient selection, hemodynamic evaluation, and imaging; (2) careful assessment of arrhythmia substrates and planning appropriate ablative techniques; (3) planning and execution of safe resternotomy; (4) revision of the existing atrial or vena cava to pulmonary artery connections to extracardiac total cavopulmonary connections; (5) performing the indicated arrhythmia operation; (6) antitachycardia dual-chamber pacemaker therapy to insure atrially paced rhythm; and (7) careful hemostasis and maintenance of hemodynamic stability during the mediastinal closing process. Other important technical considerations for optimal results include careful dissection, appropriate cardiopulmonary bypass strategies, conscientious application of myocardial preservation principles, and management of associated lesions. Associated lesions include aneurysms, valvar regurgitation and stenosis, pulmonary artery stenoses, discontinuous pulmonary arteries, and obstructed intracavitary pathways or outflow tracts. The surgeon must be cognizant of all diagnostic and therapeutic options in order to perform a safe and indicated operation to achieve satisfactory outcomes.

Patient Selection, Hemodynamic, and Arrhythmia Evaluation

Fontan conversion with arrhythmia surgery begins with appropriate patient selection;

comprehensive hemodynamic, anatomic, and arrhythmia evaluation; and optimization of hemodynamic status before surgery. Clearly, the patient who is referred for surgery has abnormalities of circulation that are expected to improve with operative intervention and should have organ function sufficient to tolerate prolonged cardiopulmonary bypass. Almost uniquely among patients with repaired congenital heart disease, patients with single-ventricle physiology are unlikely to complain of symptoms other than arrhythmias until an advanced stage of decline has been reached. Early identification of patients whose single-ventricle circulation can be optimized requires routine monitoring of exercise capacity and serial assessment of multiple organ systems including renal, hematologic, pulmonary, and hepatic function [2]. Metabolic markers of cardiac output including albumin, alkaline phosphatase, and natriuretic peptides should be periodically assessed. The optimal timing of intervention should occur before the development of end-stage physiology. Patients with poor cardiac function not attributable to pathway obstruction, atriomegaly, or persistent arrhythmias are considered for transplantation. Patients with severely restrictive lung disease or cardiac function that has declined to the degree of protein-losing enteropathy, plastic bronchitis, or renal or hepatic dysfunction are unlikely to benefit from Fontan conversion. Appropriate patient selection and coordination of care among the surgical team should result in an expectation of significant improvements in functional status and quality of life for the patient with chronic single-ventricle physiology.

Preoperative electrophysiology study is performed in patients without atrial fibrillation to assess the arrhythmia mechanism and determine right or left atrial tachycardia origin. By 15 years postoperatively, the reported incidence of supraventricular tachycardia (SVT) in the atriopulmonary or Fontan repairs ranges from 38 % to 65 % [19–21] and from 13 % to 60 % in the lateral tunnel repairs [1, 22, 23]. The mechanism of SVT is atrial macro-reentry tachycardia in about 80 % of patients, but it is important to recognize the presence of other SVT mechanisms. The modified right atrial Maze procedure is specifically designed for right atrial macro-reentrant tachycardia circuits [18, 24]; techniques other than the right atrial Maze are needed to successfully treat the remaining 20 % of SVT mechanisms.

The atrial macro-reentrant circuits may exist in the partitioned left atrium following lateral tunnel-type repairs or surgery involving atrial baffles or patches over the right-sided atrioventricular valve, which will require left atrial Maze procedures. Focal atrial reentry is identified in 7–15 % of patients, often from an automatic focus in the low lateral right atrium [25], and is treated with focal resection or ablation. Atrioventricular nodal reentry tachycardia is present in about 5 % of patients, more commonly seen in patients with heterotaxy syndrome [26], and a small percentage of patients have SVT via accessory connections. Atrial fibrillation is becoming increasingly common, perhaps related to multiple recurrences of atrial reentry, transcatheter ablation procedures, or left-sided atrioventricular valve regurgitation, and is treated with both a modified right atrial Maze procedure and a left-sided Cox Maze III procedure [24]. Ventricular tachycardia is identified in less than 7 % of patients [1, 23, 27] and was successfully treated in one patient with a prior Bjork anastomosis in the Backer et al. series [24]. A detailed description of the mechanism-specific surgical techniques is reported separately [28, 29]. These surgical techniques need to be modified for the unique anatomic variants encountered and coordinated with for the performance of associated repairs, such as left-sided valve repair and the left atrial Maze procedure.

In general, indications for surgery include the need for both pathway conversions owing to residual hemodynamic abnormalities in addition to arrhythmia ablation, although some patients whose only indication was uncontrolled atrial arrhythmias have been converted. The goal of therapy is to repair any pathway obstruction, correct any important associated anatomic and hemodynamic lesions, ablate the identified arrhythmia(s), and institute paced atrial rhythm. The operation is long and complicated, and several important risk factors that are associated with poor outcome have been identified.

Major risk factors for early death or transplant are protein-losing enteropathy, severe ventricular dysfunction, right or indeterminate ventricular morphology, and plastic bronchitis [18, 30, 31]. One challenge to assessing these profound risk factors is the possibility that the ventricular dysfunction is caused by ongoing arrhythmias and therefore is treatable by an arrhythmia operation. In these settings, conversion of atrial tachycardia to sinus rhythm, inotropic support, and diuresis with subsequent reassessment of hemodynamic status may clarify which patients potentially retain hemodynamic reserves needed to successfully undergo operative intervention.

Fontan Conversion Surgery

The conduct of the Fontan conversion requires (1) anatomic revisions for venous to pulmonary artery pathway reconstruction by extracardiac connections; (2) repair of associated lesions for pulmonary artery stenoses, aortic aneurysms, pathway obstructions, etc.; and (3) arrhythmia surgery including pacemaker insertion. Resternotomy and cannulation are technically challenging in this population, and particular attention must be devoted to a description of this process. The following sections will highlight previously published operative techniques [16, 32].

Resternotomy, Cannulation Techniques, and Preoperative Imaging

The importance of safe resternotomy cannot be overstated in patients with existing Fontan physiology [33]. Unwanted cavitary entry during mediastinal dissection can cause marked hemodynamic instability as the giant right atrium is most often affected. Any precipitous decrease in right atrial pressure secondary to uncontrolled hemorrhage results in the obvious hypovolemic consequences and unfavorably impacts the driving force (elevated central venous pressure) that controls the pulmonary circulation and cardiac output. There are numerous methods of resternotomy; the technique to be discussed has been associated with excellent results and a minimal rate of unwanted cavitary reentry considering the size of the right atria in the majority of these patients.

Considering the profound consequences of unwanted atrial entry during dissection, preoperative variables may guide the decision for prophylactic cannulation before sternotomy. This team's presternotomy peripheral cannulation incidence is low. There are, however, important considerations that help the surgeon identify low-risk and high-risk patients for unwanted cavitary reentry. Patients with tricuspid atresia tend to have thick-walled right atria and are not as prone to cavitary reentry as patients with double-inlet left ventricle or pulmonary atresia and intact ventricular septum, who tend to have thin atrial walls. Thin atrial walls under high right atrial pressure are prone to injury with dissection. Antero-aortic atrial to pulmonary artery connections are at high risk for unwanted cavitary entry as the entire length of the connection may be adhered to the underside of the sternum. Patients with great vessel malposition/transposition tend to have large aortas that are located in the anterior mediastinum and are often adhered to the sternum. In addition, patients with aortic false aneurysms and those who require high aortic cannulation are excellent candidates for prophylactic cannulation. Advanced imaging techniques using magnetic resonance imaging or computed tomography scanning (Fig. 143.1) help to identify intracavitary structures which are at particular risk during resternotomy.

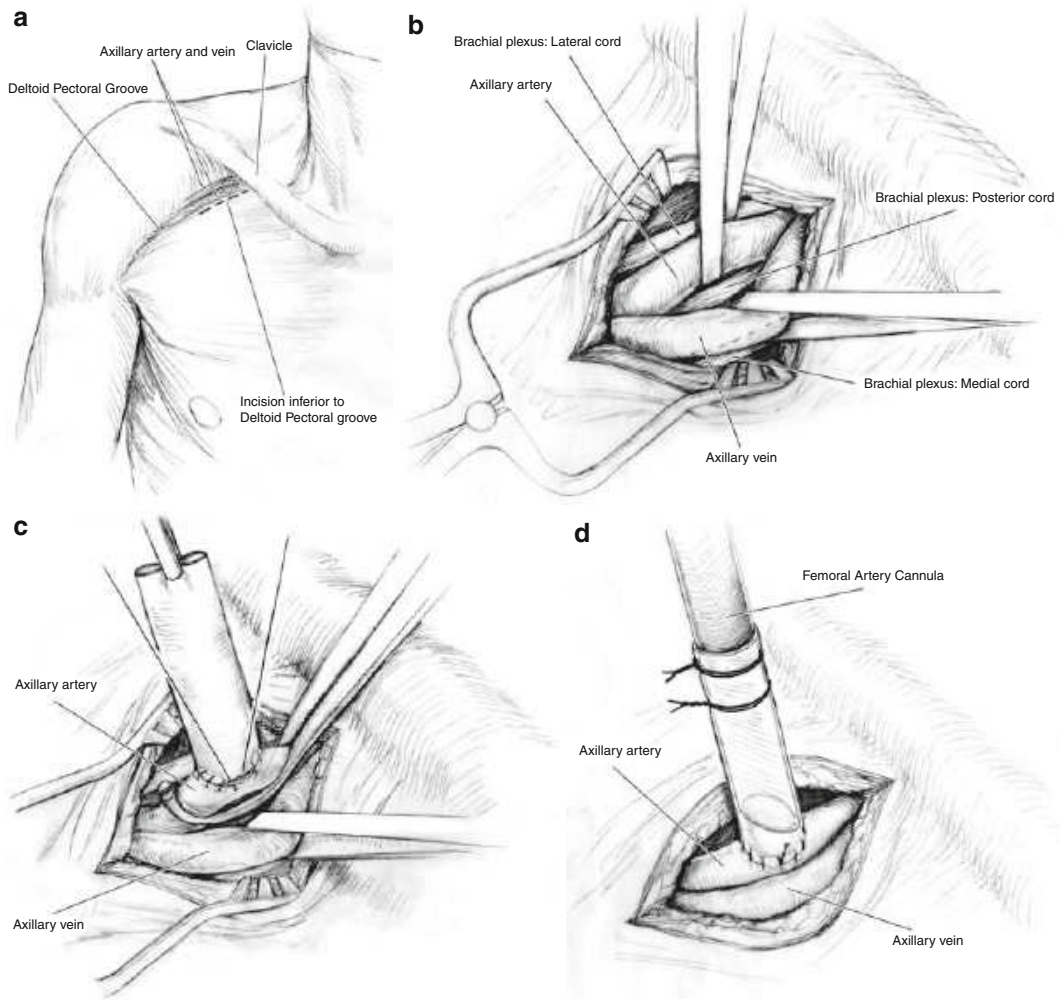

Fig. 143.2 (**a**) Surface anatomy for incision and dissection of axillary artery in preparation for arterial cannulation. (**b**) The axillary artery is dissected from the brachial plexus cords. (**c**) A polytetrafluoroethylene graft is anastomosed end to side to the axillary artery. (**d**) Arterial cannula being connected to the graft in preparation for cardiopulmonary bypass (Reproduced with permission from Mavroudis C et al. (2013). World J Pediatr Cong Heart Surg. 4: 85–97) [33]

Femoral cannulation has been the standard technique for emergency or prophylactic cannulation for cardiopulmonary bypass in the event of unwanted cavitary entry. However, recent publications [34, 35] have suggested axillary cannulation when complicated anatomic lesions endanger the safe conduct of resternotomy. The surface anatomy for incision and dissection of the axillary artery in preparation for arterial cannulation is shown in Fig. 143.2a [33]. The deltopectoral groove is identified, the incision is made, and the dissection is performed by identification of the axillary vessels (Fig. 143.2b) [33]. The brachial plexus is preserved; arterial proximal and distal control is secured. An appropriately sized polytetrafluoroethylene (PTFE) graft is anastomosed end to side to the axillary artery after systemic anticoagulation (heparin) (Fig. 143.2c) [33]. A femoral arterial cannula is connected to the graft in preparation for cardiopulmonary bypass (Fig. 143.2d) [33]. This cannulation technique can be employed during the

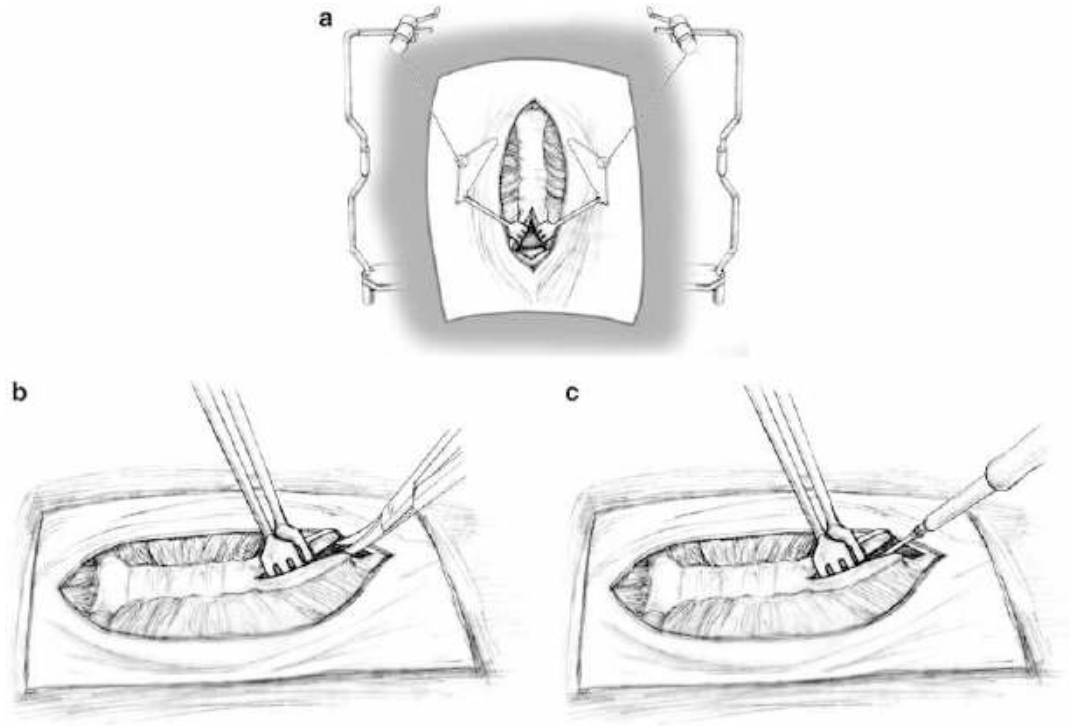

Fig. 143.3 (**a**) Using self-retaining internal mammary artery retractors to lift the sternum from the mediastinal structure. (**b**) Substernal scissors dissection. (**c**) Substernal Bovie dissection. (Reproduced with permission from Mavroudis C et al. (2013). World J Pediatr Cong Heart Surg. 4: 85–97) [33]

entire operation and does not require aortic recannulation after mediastinal dissection. Moreover, this technique can be used to perform regional cerebral perfusion if elected.

Safe sternotomy requires some form of retraction and often is accomplished by an assistant who is called on to exert considerable force. Self-retaining internal mammary artery retractors can be used to lift the sternum away from the undissected mediastinal structures, thereby facilitating the reentry under direct vision (Fig. 143.3a) [33]. A plane can be developed by scissor dissection at the inferior portion of the sternum where visual exposure is achieved (Fig. 143.3b) [33]. The heart is identified by its contractile motion, the sternum by its nonmobile osseous nature. The surgeon is challenged to find the appropriate dissection plane between them. Once this is accomplished, alternative blunt and electrocautery dissection are used to create fenestrated adhesive tissue bands that can be lysed, while constantly visualizing the extent of the dissection (Fig. 143.3c) [33]. An advancing delta dissection plane is created, and the resternotomy proceeds using scissors, electrocautery, and a standard sternal saw as elected for safe mediastinal reentry. Safety measures are mandatory. Presternotomy defibrillation pads are placed. Preference for scissor dissection is necessary in the event that electrocautery causes premature ventricular contractions or an episode of ventricular fibrillation and for aortic adherence to the sternum. After the dissection is completed, standard aortobicaval cannulation is performed as shown in Fig. 143.4 [36]. Sometimes aortouniatrial cardiopulmonary bypass may be necessary because of hemodynamic instability due to retraction of the large atrium and to facilitate the dissection. The operating team must be cognizant of the possible presence of a right atrial clot, which may be dislodged by atrial cannula insertion. Preoperative imaging studies and epicardial echocardiography can assist in clot

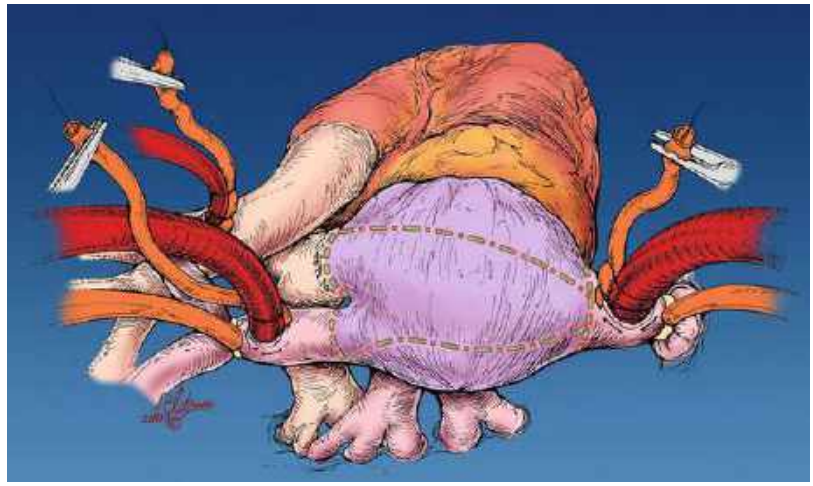

Fig. 143.4 Technique of cannulation for conversion. Note direct caval venous cannulation. Projected right atrial resection is shown (dotted lines) (Reproduced with permission from Backer CL et al. (2006) Cardiol Young. 16(suppl 1): 85–91) [36]

identification to avoid the possibility of embolic cannula obstruction resulting in poor venous return and ineffective cardiopulmonary bypass [16]. Figure 143.5 shows how the venous catheter can be placed away from the atrial clot [16].

Fig. 143.5 Global view of aortouniatrial cardiopulmonary bypass with the venous catheter placed away from the clot in the inferior portion of the right atrium where it was identified by epicardial echocardiography. Oftentimes, when the right atrium is large, single atrial cannulation for cardiopulmonary bypass can help with the completion of the dissection without causing hemodynamic instability. This can then be followed by conversion to bicaval cannulation (Reproduced with permission from Mavroudis C et al. (2007) Semin Thorac Cardiovasc Surg Pediatr Card Surg Ann. 10: 136–145) [16]

Arrhythmia Surgery

As noted above, the majority of Fontan patients have right atrial macro-reentrant tachycardia circuits, and this operating team performs an operative arrhythmia technique based on identification of the most critical areas of slow conduction and anatomic barriers in the right atrium, with modifications based on the variable anatomic features. Endocardial mapping of the right atrium was routinely performed in most early patients to confirm the findings from the preoperative electrophysiology study and to assess the anatomic barriers relevant to the tachycardia circuit. Subsequently, the majority of patients have presented with atrial fibrillation, and electrophysiology testing is not performed. In some situations, this omission may fail to identify a triggering tachycardia mechanism, such as atrioventricular nodal reentry or a concealed accessory connection, and may result in late arrhythmia recurrence. Careful review of electrocardiograms from episodes of tachycardia may identify patients with atrial fibrillation who are likely to have an additional "regular" mechanism of SVT and guide this assessment. Knowledge of details of prior surgical techniques, such as atrial septal realignment, will also guide modification of lesions. It has been a common practice to use cryoablation as the energy source, based on the continuity of the lesion and the avoidance of injury to coronary arteries as possible. The availability of a linear malleable cryoablation probe has significantly shortened the time required for arrhythmia surgery.

From an initial isthmus ablation, the right atrial arrhythmia surgery evolved to a modified right atrial Maze procedure [14, 16]. A large portion of anterior right atrial wall is resected. For the modified right atrial Maze procedure, cryoablation lesions are delivered from the coronary sinus os to the inferior vena cava and from the inferior vena cava to a right-sided atrioventricular annulus when present. From the atrial septal defect, lesions are delivered to the posterior edge of the transected atrial wall, to the posterior rim of the coronary sinus, and to the base of the resected right atrial appendage. The atrial septum is widely resected [17, 18]. For patients with left atrial tachycardia or atrial fibrillation, the Cox Maze III procedure for the left atrium is performed [13, 24]. Encircling lesions are delivered around the 4 pulmonary veins, with an extension to the os of the left atrial appendage, with the appendage either resected or a circular lesion delivered to the os. A cryoablation lesion extends from the encircling pulmonary vein lesion to the mitral valve P2 leaflet. An epicardial circular lesion is delivered on the coronary sinus in alignment with the endocardial lesion to the mitral valve. A dome lesion from the left atrial appendage to the base of the remaining right atrial tissue near the superior vena cava is delivered.

Anatomic variations of the various Fontan operations, each with its own venous to pulmonary artery connections, have proven to be a challenge for arrhythmia treatment. Unusual atrioventricular anatomy, discordant ventricle to great vessel connections, juxtaposed atrial appendages, pulmonary and systemic venous return anomalies, scar formation, and the anatomic characteristics of heterotaxy syndrome (e.g., absence of the coronary sinus, left superior vena cava, and separate hepatic entry to the atria) require modifications of the planned arrhythmia operation [15–18]. The presence of additional arrhythmia mechanisms, such as orthodromic reciprocating tachycardia using an accessory connection, atrioventricular nodal reentry tachycardia, or focal atrial tachycardia, requires performance of the specific ablation techniques. Whenever feasible, accessory connections are ablated preoperatively using a transcatheter approach, reserving operative ablation of accessory connections for unsuccessful catheter ablations [32]. The arrhythmia surgery techniques are reported in ▶ Chap. 164, "Surgical Therapy of Arrhythmias and Conductive Disorders," elsewhere in this textbook.

Takedown of Right Atrial to Right Ventricular Bjork Modification

Patients who have had a Bjork-Fontan modification for repair of tricuspid atresia and small right ventricle (right atrial to small right ventricle connection with a valved or nonvalved conduit) have experienced growth of the diminutive right ventricle commensurate with somatic growth (Fig. 143.6a, b) [16]. The hemodynamic problem is conduit stenosis secondary to sclerosis of the valved conduit or neointimal hyperplasia of the nonvalved conduit. Removing the conduit and establishing total cavopulmonary extracardiac connections are clear; what is not clear is the management of the right ventricle [16].

The general management of the pulmonary artery in most reconstructive cases is to detach and isolate it from the subtended ventricle allowing only nonpulsatile pulmonary flow from the venous connections. If the main pulmonary artery is disconnected, however, the right ventricle will not have an egress, a situation that can result in right ventricular distention and by extension deterioration of left ventricular function. Fourteen patients have been revised and required takedown of Bjork-Fontan connection, 13 with tricuspid atresia and 1 with unbalanced atrioventricular canal [16]. Takedown of these conduits (Fig. 143.7a) [32] is performed with careful dissection of the right atrioventricular grove which facilitates amputation of the right atrial appendage (Fig. 143.7b, c) [16], affects reduction of the right atrial wall, enhances epicardial pacemaker lead placement, and allows for right ventricular patch closure. The course of the right coronary artery is a landmark for this dissection and is at risk for injury. Great care is taken to avoid arterial injury (Fig. 143.7c) [16]. Artist's drawings

demonstrate the stages of cavity closure indicating the right ventricular outflow tract before the patch (Fig. 143.7d) [32] and the right ventricular patch and right atrial closure (Fig. 143.7e) [16] in association with the extracardiac total cavopulmonary connection.

Right Ventricular Hypertension and Tricuspid Regurgitation After Atriopulmonary Fontan for Pulmonary Atresia and Intact Ventricular Septum

Patients with pulmonary atresia and intact ventricular septum who were triaged to univentricular repair owing to a small right ventricle by a staged approach had various atriopulmonary connections depending on the institutional biases of the time. In most cases, the atretic or severely stenosed pulmonary valve had been disconnected. The tricuspid valve may have been made incompetent by intention or by natural deterioration to avoid the hemodynamic problem of a contractile cavity without an outlet. This surgical team had experience with two patients with this physiologic aberration. During somatic growth, the right ventricle enlarged, hypertrophied, and caused suprasystemic right ventricular pressure, which impacted negatively on the atriopulmonary connections causing elevated right atrial pressures and atriomegaly. Revising this pathophysiologic anatomy to an extracardiac Fontan connection would effectively transfer the considerable atrioventricular valve regurgitation to the common left atrium, resulting in left atrial hypertension. This problem has been mitigated against by attaching a fenestrated patch to the tricuspid valve orifice to limit right ventricular inflow and decrease developed right ventricular pressure. During diastole, therefore, accumulated right ventricular volume could ebb into the common atrium without causing right ventricular distention (Fig. 143.8) [16]. Postoperatively, the developed right ventricular pressure was significantly reduced and had no important hemodynamic effect on the left atrial pressure and Fontan circulation.

Takedown of Atrioventricular Valve Isolation Patch for Right-Sided Maze Procedure

The Fontan operation developed over time from its initial application to treat tricuspid atresia with

atriopulmonary connections to numerous other forms of functionally single ventricle with complex atrioventricular connections. Establishing Fontan physiology in these patients was attended by ingenious application of complex atrial patches to compartmentalize the atria into systemic and pulmonary venous circulations. These operations were highly effective; however, some

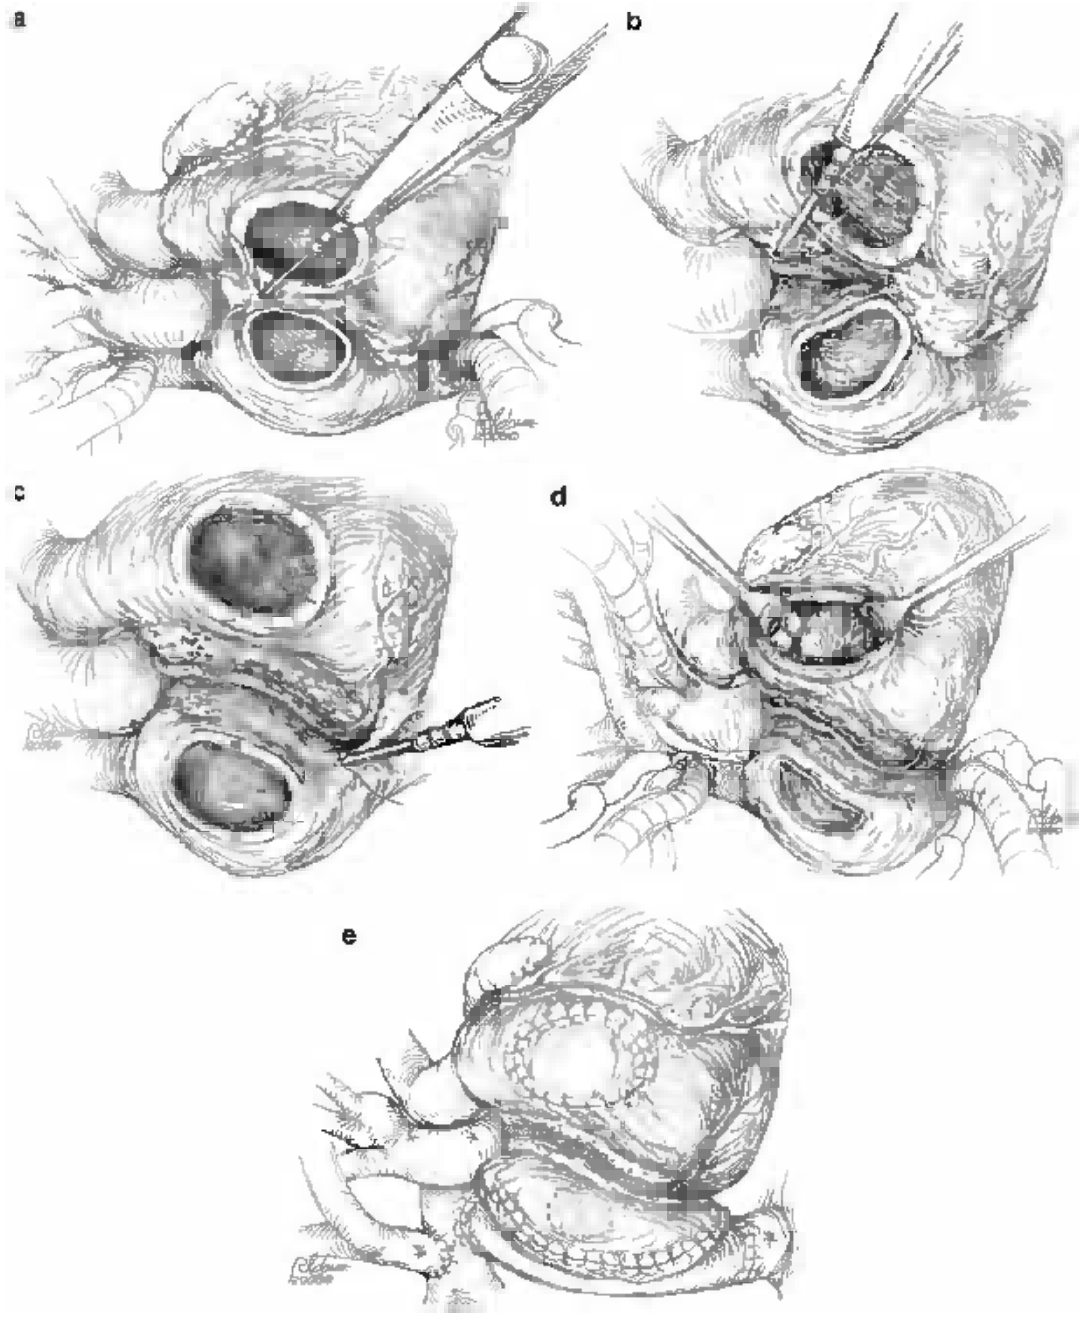

Fig. 143.7 (continued)

of the complex patches were placed to cover the right-sided atrioventricular valve, as well as the coronary sinus, to avoid heart block. This resultant reconstruction has the effect of concealing the coronary sinus from the landmarks (the coronary sinus and the tricuspid valve) that are needed to perform the modified Maze operation (Fig. 143.9a) [32]. Therefore, the patch must be removed to identify the landmarks (Fig. 143.9b, c) [16, 32] and perform the arrhythmia operation (cryoablation) (Fig. 143.9d) [16]. The newly exposed tricuspid valve can be assessed for competency by bulb syringe to determine whether the valve needs to be covered again. If the valve is competent, there is no need to cover it and exclude it from the circulation. If the valve is incompetent, then a patch can be configured and attached to the valve tissue to avoid injury to the conduction system (Fig. 143.9e) [16].

Surgical Translocation of Atrial Septal Alignment

In his recollection of the groundbreaking atriopulmonary anastomosis, Kreutzer [37] noted that optimal results would depend on a large and favorably placed atriopulmonary anastomosis. This idea urged some surgeons to translocate the interatrial septum posteriorly into the left atrium to favorably align the resultant connection between the systemic venous pathway and pulmonary artery. The circulations were separated by a synthetic patch that effectively dropped the atrial septum into the dome of the left atrium (Fig. 143.10a) [16]. This anatomic reconstruction, the *dropped atrial septum* technique, was found to have important electrophysiologic implications for arrhythmia treatment because of left atrial suture lines. Arrhythmia ablation under these circumstances is performed by additional localized left atrial resection, left atrial Maze procedure, and left atrial reconstruction (Fig. 143.10b) [16] to prevent pulmonary vein obstruction.

Distended Left Superior Vena Cava Causing Left Pulmonary Vein Stenosis

There are occasions when a left superior vena cava can become distended and result in significant left pulmonary vein stenosis and subsequently negatively impact the Fontan circulation [16]. Two patients were treated with this problem. In the first patient, a left superior vena cava was electively ligated in preparation for a future cavopulmonary artery Fontan operation. This patient had an undiagnosed congenital orifice atresia of the coronary sinus; ligation of the left superior vena cava prevented the only egress of coronary venous flow, resulting in a chronically enlarging cardiac chamber that eventually caused left-sided pulmonary venous obstruction

Fig. 143.7 (**a**) Artist's depiction of electrocautery dissection at the atrioventricular groove commencing at the base of the aorta with extension to the right ventricular free wall. Care is taken to perform this dissection with a low electrocautery setting to avoid unwanted injury to the right coronary artery. (**b**) Artist's depiction of electrocautery dissection at the atrioventricular groove commencing at the base of the aorta with extension to the right ventricular free wall. Care is taken to perform this dissection with a low electrocautery setting to avoid unwanted injury to the right coronary artery. (**c**) Artist's depiction of completed electrocautery dissection of the entire atrioventricular groove. The amount of atrium that is freed from this maneuver allows for a larger atrial reduction and provides unscarred atrial tissue for the atrial pacemaker leads that are placed at the end of the Fontan conversion. (**d**) The right ventricle to pulmonary artery connection is prescribed to prevent the unwanted condition of a myocardial chamber without an outflow. The figure shows the intact pulmonary valve in continuity with the diminutive right ventricle and the downsized right atrial wall before atrial closure. (**e**) The completed extracardiac connections are shown. Right atrial wall reduction and closure is noted by the long atrial suture line. Right ventricular to main pulmonary artery continuity is maintained by a right ventricular patch thus insuring outflow of Thebesian venous flow and avoidance of right ventricular dilatation. (**a** and **d** are reproduced with permission from Mavroudis C, et al. (2013) Surgical therapy of cardiac arrhythmias. In Pediatric Cardiac Surgery 4th edition. Oxford: Wiley Blackwell [32]. **b, c**, and **e** are reproduced with permission from Mavroudis C et al. (2007) Semin Thorac Cardiovasc Surg Pediatr Card Surg Ann. 10: 136–145 [16])

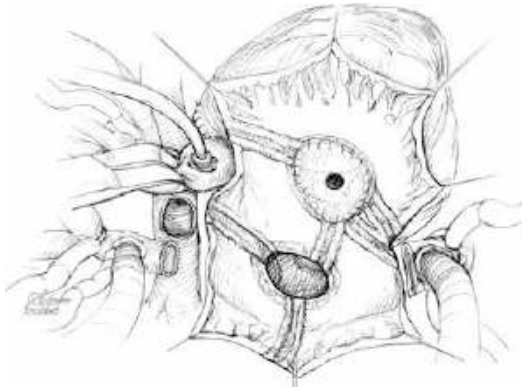

Fig. 143.8 Right atrial view of a patient with pulmonary atresia and intact ventricular septum who had a prior atriopulmonary Fontan and presents now with arrhythmias and suprasystemic right ventricular pressure. The cryoablation lines are noted for the modified right-sided Maze procedure as well as the fenestrated tricuspid valve isolation patch. The idea of the fenestration is to limit the inflow to the right ventricle in diastole which will decrease the developed pressure of the right ventricle in systole (Reproduced with permission from Mavroudis C et al. (2007) Semin Thorac Cardiovasc Surg Pediatr Card Surg Ann. 10: 136–145) [16]

(Fig. 143.11a) [16]. The second patient developed coronary sinus occlusion because of transvenous radiofrequency catheter ablation, which also caused an enlarging obstructive cardiac chamber resulting in pulmonary venous stenosis. At the time of Fontan conversion, the coronary sinus was unroofed (Fig. 143.11b) [16] in the first patient and relieved of stenosis by fibrous tissue resection in the second patient.

Discontinuous Pulmonary Arteries

In the past, some surgeons staged the Fontan operation by performing a classic right Glenn operation, which was followed by completion of the right atrium to left pulmonary artery connection. This resulted in discontinuous pulmonary arteries [17]. In time, these patients developed cyanosis causing right pulmonary arteriovenous malformations, thought to be related to the absence of hepatic factor to the right pulmonary venous pathway. It was quickly discovered that revision of the systemic venous pathway to include inferior vena cava flow to the right pulmonary artery reversed these pulmonary arteriovenous malformations. Pulmonary artery reconnection is recommended in any patient undergoing Fontan conversion regardless of the presence of cyanosis and pulmonary arteriovenous malformations. Initially, aortic homografts were used to reconnect the pulmonary arteries because of the natural and favorable curve beneficial to performing an end-to-end anastomosis between the distal homograft and left pulmonary artery, a side-to-side anastomosis between the homograft and the classic Glenn, and an end-to-end anastomosis between the proximal homograft and the inferior vena cava. It was recognized, however, that some patients may require subsequent cardiac transplantation; implanting a homograft could complicate future cardiac transplantation because of increased panel reactive antibody levels that could interfere with optimal immunosuppression. In order to avoid these future complications, PTFE grafts are now preferred for reconnection of discontinuous pulmonary arteries (Fig. 143.12) [16, 17, 32].

Right Atrial Reduction in the Setting of a Systemic Right Ventricle Leading to Pulmonary Vein Stenosis

Right atrial wall reduction is performed in the majority of patients undergoing Fontan conversion. It can be accomplished without difficulty in patients with tricuspid atresia as long as the resultant atrial suture line can be performed without tension or distortion [16]. Pulmonary venous return is rarely compromised under these conditions as it is the right atrium that is being reduced and not the left atrium.

However, in the case of a dominant right ventricle, intracardiac obstructive flow restriction can occur from an excessive right atrial wall reduction. This condition can severely limit pulmonary venous flow from the left atrium through the atrial septal defect into the now restrictive right atrium and thence to the tricuspid valve. This has the physiologic effect of systemic atrioventricular valve stenosis and bodes poorly for Fontan

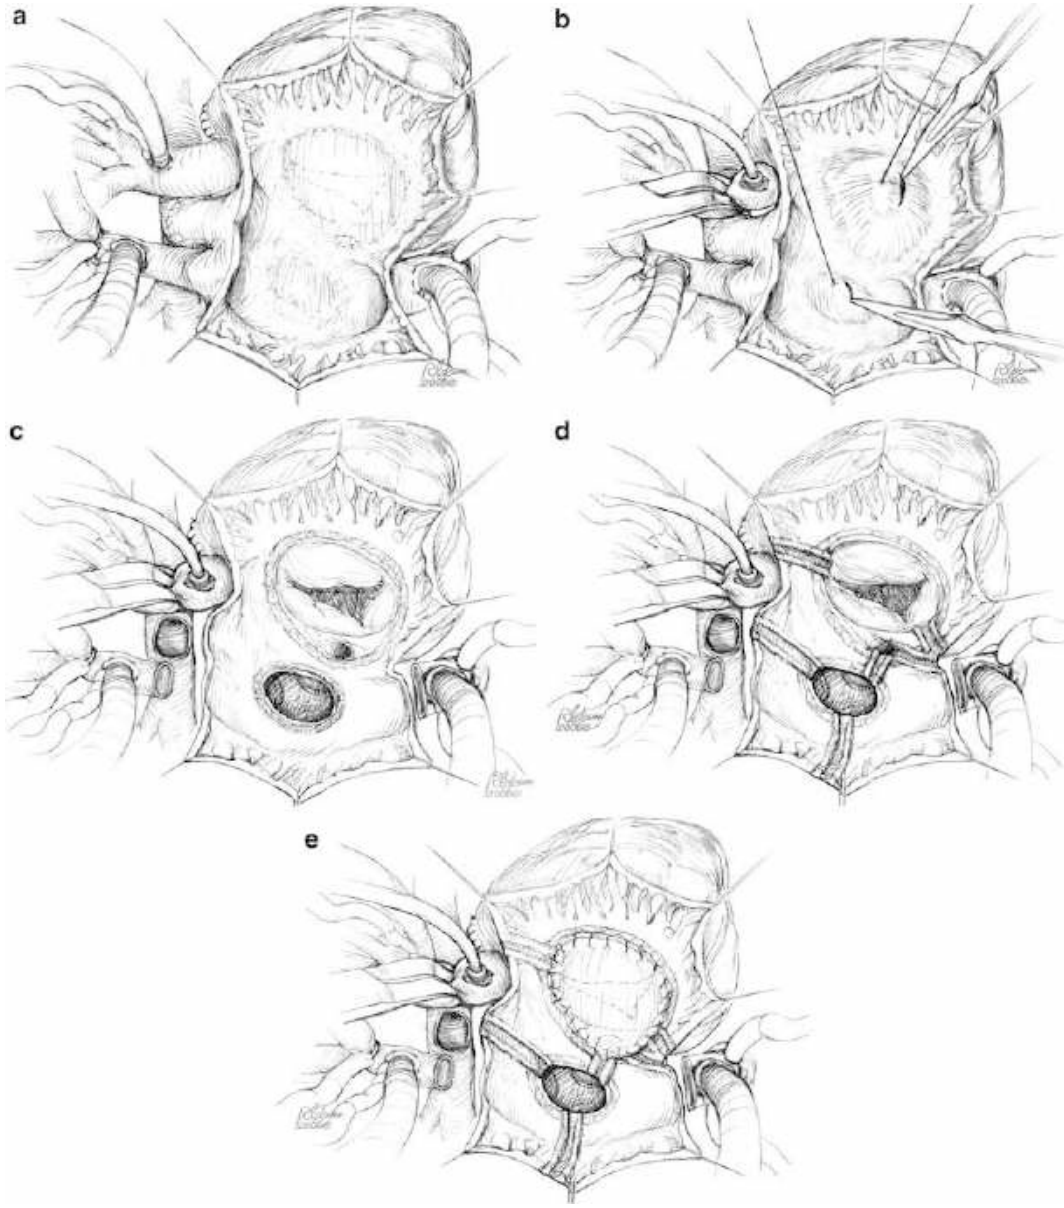

Fig. 143.9 (**a**) Right atrial view of a patient with double-inlet ventricle who had an atriopulmonary Fontan with tricuspid valve isolation and atrial septal defect closure. (**b**) Right atrial view of a patient with double-inlet ventricle who had an atriopulmonary Fontan with tricuspid valve isolation and atrial septal defect closure. The isolation patch is sharply removed to uncover the tricuspid valve and the coronary sinus in order to perform the right-sided Maze procedure. (**c**) Right atrial view showing the results of isolation patch removal and atrial septal defect creation. The anatomic landmarks for application of the cryoablation lesions are now manifest. (**d**) Right atrial view showing the results of isolation patch removal and atrial septal defect creation. The cryoablation lesions are shown after proper identification of the tricuspid valve annulus and coronary sinus. The cryoablation lesion from the base of the right atrial appendage to the anterior tricuspid annulus is optional. (**e**) Right atrial view of Gore-Tex tricuspid valve isolation after cryoablation. The suture line for attachment is placed in the valve tissue near the annulus in order to avoid injury to the atrioventricular node. (Reproduced with permission from Mavroudis C et al. (2007) Semin Thorac Cardiovasc Surg Pediatr Card Surg Ann. 10: 136–145 [16])

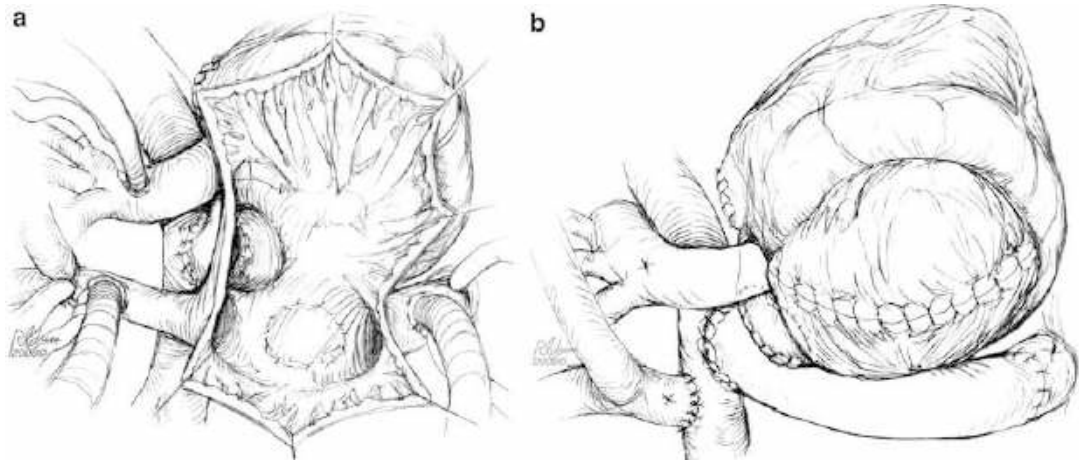

Fig. 143.10 (**a**) Right atrial view of a patient who underwent atriopulmonary Fontan by moving the atrial septum posteriorly which realigned the outflow of the right atrium to conform to the more posterior main pulmonary artery. This "dropped atrial septum" required a suture line in the left atrium which caused scarring and an area of slow conduction leading to atrial reentry tachycardia. In addition, when this anastomosis was taken down, a significant moiety was created which required attention lest pulmonary venous obstruction be created. (**b**) Global view of the corrected patient in Fig. 143.10a. A Gore-Tex patch was inserted in the dome of the left, now common, atrium in order to prevent pulmonary vein obstruction (Reproduced with permission from Mavroudis C et al. (2007) Semin Thorac Cardiovasc Surg Pediatr Card Surg Ann. 10: 136–145) [16]

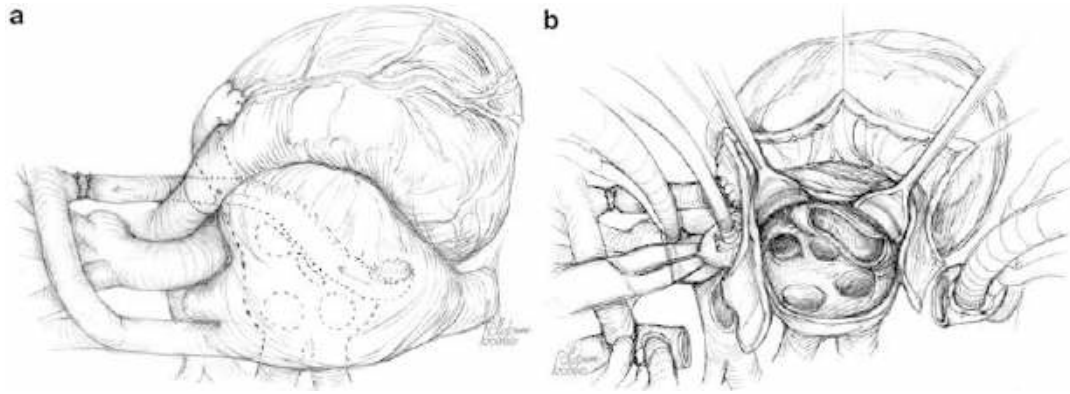

Fig. 143.11 (**a**) Drawing of a patient with double-inlet left ventricle, bulboventricular foramen, and l-transposition of the great arteries with bilateral superior venae cavae. The patient underwent ligation of the left superior vena cava in preparation for an eventual atriopulmonary Fontan without prior knowledge of orifice atresia of the coronary sinus. Lack of ebb flow from the coronary sinus caused sinus dilatation and obstruction of the left pulmonary veins as noted. (**b**) Left atrial view of a patient described in Fig. 143.11a. The large coronary sinus was unroofed thereby establishing proper coronary sinus drainage and relief of the left pulmonary vein stenosis (Reproduced with permission from Mavroudis C et al. (2007) Semin Thorac Cardiovasc Surg Pediatr Card Surg Ann. 10: 136–145) [16]

physiology. The authors have experience with one patient in whom an extensive right atrial wall resection (Fig. 143.13a) [32] resulted in atrial pathway compression and turbulence of pulmonary venous flow into the right ventricle (Fig. 143.13b) [16] documented by transesophageal echocardiography [16]. The complication was corrected without delay with a large Gore-Tex patch that relieved the localized obstruction (Fig. 143.13c) [16]. A similar second case with functionally single

Fig. 143.12 Artist's representation of a patient who previously had a classic Glenn shunt to the right pulmonary artery connection who had reconnection of the pulmonary arteries using a Gore-Tex interposition graft and an extracardial inferior vena cava to pulmonary artery connection. Homografts are not used to avoid stimulation of preformed antibodies which could complicate cardiac transplantation should it become necessary (Reproduced with permission from Mavroudis C, et al. (2013) Surgical therapy of cardiac arrhythmias. In Pediatric Cardiac Surgery 4th edition. Oxford: Wiley Blackwell) [32]

right ventricle required a large atrial wall reduction owing to a preexisting right atrial wall patch that was causing an area of slow conduction and resultant atrial tachycardia. Because the right atrial wall resection was extensive, it was reasoned that pulmonary flow would be compromised and a large Gore-Tex patch was placed to augment the atrial closure, resulting in laminar flow from the pulmonary venous to right ventricular circulation.

Unwanted Inferior Vena Cava Retraction During the Extracardiac Connection

On occasion, the transected inferior vena cava can retract caudad through the surrounding tourniquet making the end-to-end vena cava to Gore-Tex anastomosis impossible to perform (Fig. 143.14a) [16]. This dilemma can be easily solved by releasing the tourniquet, establishing sucker bypass or vacuum assisted venous drainage, and accomplishing an open anastomosis (Fig. 143.14b) [16]. The caval catheter can then be replaced, and gravity drainage can be resumed (Fig. 143.14c) [16]. This complication can be largely avoided by segmented vena cava transection and strategically placed traction sutures, which can help to avoid vena cava retraction beyond the confines of the caval tourniquet.

Management of Associated Lesions

Associated lesions are managed according to the principles of shortening the cardiopulmonary bypass and aortic cross-clamp (myocardial ischemia) times, which takes into consideration a planned operation using optimal myocardial preservation techniques (intermittent doses of antegrade and retrograde cold blood cardioplegia, topical iced saline, and avoidance of coronary air embolism). Oftentimes, right atrial, pulmonary artery (pulmonary artery reconnection, pulmonary artery arterioplasty), and vena caval procedures can be performed without the use of an aortic cross-clamp as long as the operating team can be assured that no atrial or ventricular shunting is present that might cause cerebral air embolism. When the systemic circulation is approached for atrioventricular valve procedures, neoaortic valve operations, aneurysm resections, Cox Maze III procedures, or relief of obstructed outflow tract stenoses, the aortic cross-clamp time is considerable, and plans are made to perform segments of the operation to take advantage of local anatomic exposure. For instance, left atrial exposure is required and maintained to perform atrioventricular valve repairs and Cox Maze III procedures; a transaortic exposure is required and maintained to perform ventricular outflow tract resections and replacement or repair of the aortic valves. The surgical team must make intraoperative decisions to determine whether valve repair or valve replacement is required. Difficult valve anatomy may require longer and repeated cross-clamp times, which can be ameliorated if a prosthetic

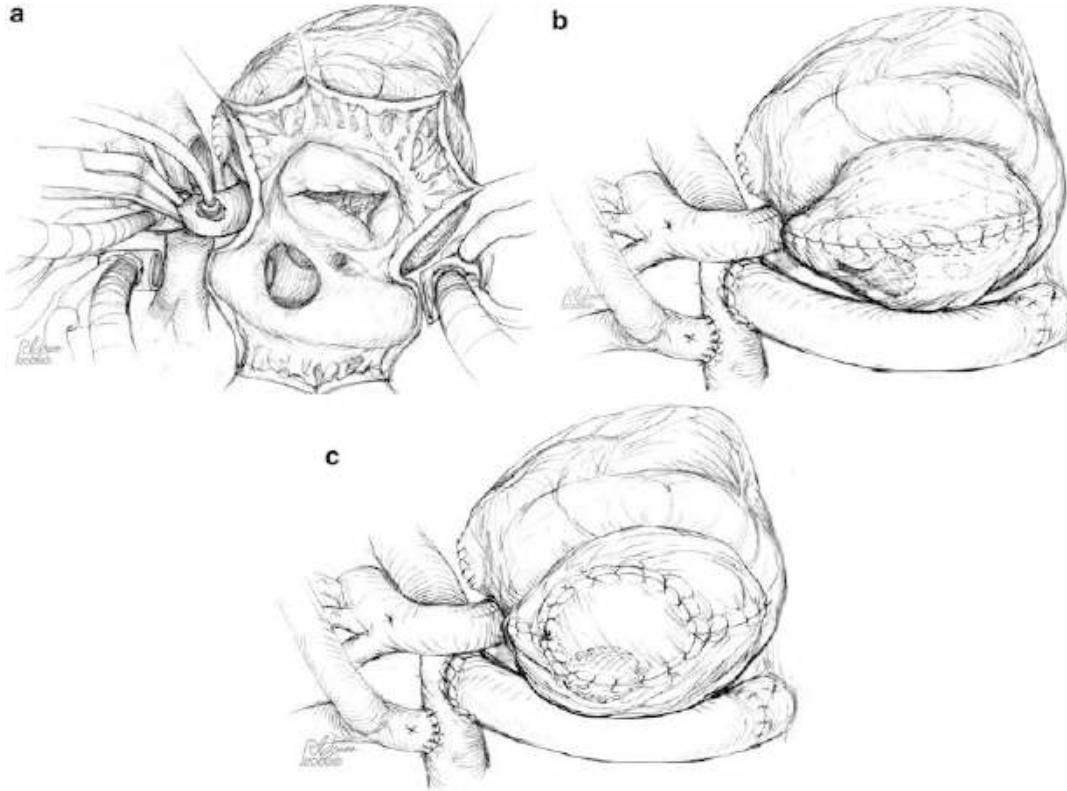

Fig. 143.13 (**a**) Global view of the right atrium and single right ventricle after an overzealous right atrial wall reduction was performed. (**b**) Global view of a completed extracardiac Fontan in a patient with a dominant right ventricle and tricuspid valve. An overzealous right atrial wall resection was performed and the reconstruction resulted in atrial septal compression and pulmonary venous obstruction to the right ventricle which was noted on transesophageal echocardiography. The compression of the atrial septum is noted within the right atrium. (**c**) Global view of a Gore-Tex augmentation patch that was used to enlarge the right atrium which eliminated the atrial septal defect compression as noted within the right atrium. (**a** is reproduced with permission from Mavroudis C, et al. (2013) Surgical therapy of cardiac arrhythmias. In Pediatric Cardiac Surgery 4th edition. Oxford: Wiley Blackwell [32]. **b** and **c** are reproduced with permission from Mavroudis C et al. (2007) Semin Thorac Cardiovasc Surg Pediatr Card Surg Ann. 10: 136–145 [16])

valve is placed during initial cross-clamp time. Preoperative consideration of these principles serves to effect conscientious myocardial preservation, limit cross-clamp time, and result in better myocardial systolic and diastolic function.

Hemostasis, Sternal Closure, Device Implantation, and Hemodynamic Stability

After separation from cardiopulmonary bypass, the operating team is faced with achieving hemostasis and close hemodynamic monitoring during a time of evolving physiologic conditions that include pacemaker lead(s) placement, sternal closure, antiarrhythmic medication administration, and adjustments in ventilation. Hemostasis is an important element in the post-cardiopulmonary bypass perioperative course as excessive bleeding and hemodynamic compromise in a Fontan patient can result in severe life-threatening conditions. Control of mediastinal bleeding is only a part of the overall hemostasis strategy. Thoracic wall bleeding due to lysis of arteriopulmonary collateral arteries is inevitably present and will not stop unless surgically treated by the use of electrocautery, suturing, and clips. Excessive and

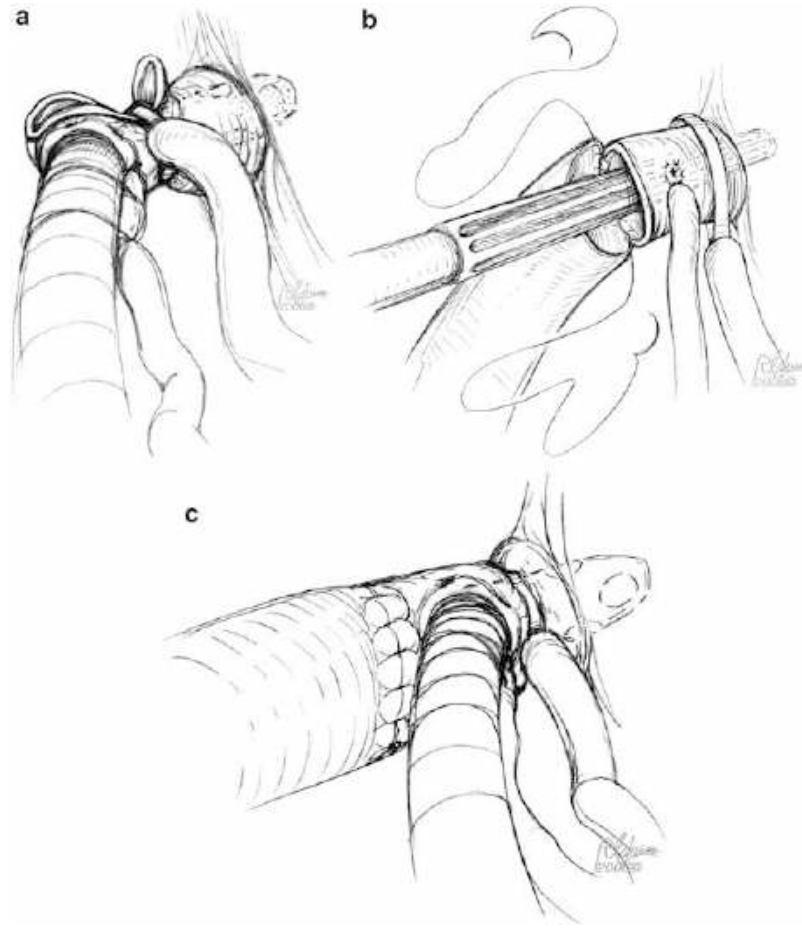

Fig. 143.14 (**a**) Artist's representation of a partially retracted transected cannulated inferior vena cava below the Rummel tourniquet. The end-to-end anastomosis between the extracardiac Gore-Tex tube and the inferior vena cava cannot be performed under these circumstances. (**b**) Artist's depiction of tourniquet removal, establishing of sucker bypass and the end-to-end anastomosis in progress. (**c**) Artist's view of the completed inferior vena cava to Gore-Tex graft anastomosis, recannulation and tourniquet application (Reproduced with permission from Mavroudis C. et al. (2007) Semin Thorac Cardiovasc Surg Pediatr Card Surg Ann. 10: 136–145) [16]

uncontrolled intrathoracic bleeding will cause hemodynamic compromise and cyanosis resulting from blood replacement (inflammatory response), pulmonary compression, and poor gas exchange. Careful titration of the amiodarone infusion will avoid the problem associated with hypotension and increased need for pressor agents. Recently, the use of milrinone has been avoided because of the vasoactive characteristics that result in excessive vasodilatation and subsequent need for excessive volume resuscitation and increased pressor support.

Pacemaker Lead Placement

Presently, all patients undergoing Fontan conversion and arrhythmia surgery undergo atrial and ventricular lead placement, with multisite resynchronization and/or defibrillator implantation in a select group of patients. Use of pacing strategies has evolved over the last 18 years concurrent with technology and device changes, recognition of the advantages of ventricular leads for improved sensing, and the occasional development of late second-degree atrioventricular block necessitating dual-chamber pacing [38]. Despite the placement of dual-chamber leads, the vast majority of patients managed by this team have pacemakers programmed long term in an atrial rate-responsive mode, limiting the potential deleterious effects of ventricular dyssynchrony from ventricular pacing whenever possible.

Pacemaker leads and pulse generators are placed at the end of the Fontan conversion

operation when hemodynamics are stable, bleeding is controlled, and the operating team is tired – usually after a 7–12 h operation. There have been many adages ascribed to fatigue in the worlds of competitive sport, mortal combat, and professional judgment. In the first two, injury is likely to occur to the tired protagonist; in the third, injury is likely to occur to the patient/client because of the tired protagonist. A two-team approach to these procedures is warranted and recommended for just these reasons. Finding a suitable place for lead placement may be time consuming, frustrating, and challenging. Rested surgeons, even for a short period of time, often do better under these circumstances. Because of the amount of atrial tissue resected, identifying atrial tissue with acceptable pacing thresholds and limited ventricular oversensing presents limited options. Freshly dissected areas of atrial tissue without epicardial fat may be found in the dissected right atrioventricular groove. Bipolar steroid eluting epicardial leads are used. The base of the left atrial appendage is also a favorable location for lead placement. The dome of the left atrium may also be an acceptable site. Placement of ventricular leads can be more challenging, requiring repeated lead placement and testing. The best locations for these leads are on visible ventricular muscle tissue devoid of epicardial fat. The most common ventricular location is on the inferior ventricular surface just adjacent to the diaphragm. Sometimes, epicardial locations cannot be found, and coiled "screw-in" type leads are used. The pacemaker generator is implanted underneath the left rectus muscle [38].

The intrinsic rhythm during rewarming is generally junctional with minimal atrial activity. With inotropic administration, accelerated junctional rhythm at 90–110 beats per minute is frequently present. The goal of pacemaker programming acutely is to achieve a consistent atrial rhythm above the junctional rate to obtain the hemodynamic benefit of atrioventricular synchrony. The pacing rate acutely is commonly 120 bpm, and this rate is gradually decreased on each postoperative day following pacer interrogation to assess the underlying rhythm and rate. Patients who have undergone a left-sided Maze procedure receive intravenous infusion of amiodarone after final lead placement. The intravenous route is continued for at least the first 3 postoperative days at gradually decreasing dosages. Once the patient is tolerating oral intake for at least 24–48 h, amiodarone is administered orally. By the time of hospital discharge, the atrial pacing rate is generally 80–90 bpm, and rate responsiveness is programmed on after 10–14 days. For patients receiving amiodarone, this medication is discontinued 3 months postoperatively. Patients who did not undergo a left-sided Maze procedure undergo an atrial stimulation pacing study using the implanted pacing system before hospital discharge, when diuresis is complete and hemodynamics are favorable. Based on the results of this study, antitachycardia pacing detection and determination may be needed, although this is quite uncommon. These patients receive prophylactic beta-blocker therapy for a period of 3 months.

The performance of the modified right atrial Maze procedure has essentially eliminated the recurrence of right atrial macro-reentry tachycardia late postoperatively [14, 18]. Patients undergoing a left-sided Maze procedure have not experienced recurrent atrial fibrillation, but the recurrence of organized atrial reentry tachycardia in approximately 15 % of such patients has been reported, similar to reported recurrences following transcatheter ablation of atrial fibrillation [13, 18, 24]. Adjustments have been made by the authors to the left atrial Maze procedure to reduce such recurrences, with the routine performance of an atrial dome lesion and attention to eliminating the potential for electrical conduction via fibers in the coronary sinus by aligning the endocardial lesion to the mitral (or left-sided atrioventricular valve) annulus with the epicardial coronary sinus lesion. A markedly distended coronary sinus may require more than one circular or linear lesion. In patients with recurrent tachycardia, the antitachycardia pacemaker can be used to detect and terminate tachycardia based on electrophysiologic testing using the device. Recurrences have tended to be infrequent and may respond to beta-blocker therapy and device reprogramming as noted.

Table 143.1 Fontan conversion-arrhythmia surgery results

	n ($N = 135$, 136 procedures)
Reoperation for bleeding	2 (1.5 %)
Sternal infection	4 (3 %)
Acute renal failure	9 (6.7 %)
Mean postoperative length of stay	13.8 ± 11.6 (median 11 days)
Early mortality	3 (2.2 %)
Late mortality[a]	19 (14 %)
Transplant	9 (6.7 %)
Arrhythmia	17(12.6 %)

[a]Four posttransplant

Conclusions

It cannot be emphasized enough that the Fontan conversion is highly dependent on a well-informed, conscientious, and cooperative diagnostic and therapeutic team. Careful follow-up and retrospective analysis result in constant reassessment of protocols to mitigate complications in good candidates and avoid operations in high-risk patients who may fare better with cardiac transplantation. Updated results are noted in Table 143.1. Operative mortality is low, reoperation for bleeding is low, and the resultant quality of life is dramatically improved in the majority of patients. The Fontan conversion is warranted in patients who have uncontrolled arrhythmias, hemodynamic pathway obstructions, and important associated lesions. Those who have associated protein-losing enteropathy, ventricular dysfunction not attributable to arrhythmias or antiarrhythmic medications, and plastic bronchitis are better treated by cardiac transplantation. The role of ventricular assist devices as a bridge to cardiac transplantation or destination therapy is being evaluated.

Late Sequelae in the Adult Patient with Congenital Heart Disease

144

Joseph D. Kay and Amber Khanna

Abstract

Adults with congenital heart disease frequently have comorbid conditions of all organ systems. Neurocognitive, pulmonary, vascular, renal, and liver abnormalities are common. Adults with congenital heart disease, and in particular those with syndromes such as Down and Noonan syndrome, are at increased risk for malignancy. In particular, adults with cyanotic congenital heart disease represent some of the most complex and challenging patients in an adult congenital heart disease clinic. To maximize quality of life and survival, meticulous care of the total patient is necessary for optimal outcome.

Introduction

Within the last two decades, there has been a rapid growth of multidisciplinary adult congenital cardiac programs. With the significant improvement in survival for even the most complex congenital cardiac lesions, many residual cardiac and non-cardiac problems are becoming more prevalent, and many may progress over time. Other chapters within this section deal with late cardiac sequelae which develop later after "repair" or, more appropriate in most, palliation. More recently, a number of non-cardiac sequelae unique to adult congenital survivors are being identified, which require the providers to follow over time and, if needed, reach out to other specialists. Hence, training for providers of adult congenital heart disease (ACHD) survivors should not focus solely on cardiac problems, but include broad exposure of the multiple non-cardiac problems that develop over the life span, and develop plans to address these problems as they arise.

It has only been since the 1980s that the pediatric cardiac community has routinely performed complex neonatal cardiac surgery, and recent evidence has shown this leads to neurocognitive deficits in many, which can be subtle, but frequently impact the individual's ability to independently

direct their own care. In countries without universal health coverage, finding meaningful employment allowing for ongoing health care has become more challenging. Multiple studies involving ionizing radiation throughout childhood and early adulthood may place these patients at higher risk for early malignancies, particularly in sensitive organs near the fields of interest such as the thyroid and breast. Little is currently known about the risks for these patients, and what if any additional surveillance is needed? Finally, the chronic alterations of physiology in some ACHD lesions have been shown to have an impact on other organ functions, such as renal dysfunction in those with chronic cyanosis, pulmonary mechanics after multiple surgeries, and liver fibrosis with elevated hepatic venous pressure as seen after staged single-ventricle palliation.

Behavioral and Neurologic Issues

It is difficult to completely separate behavioral problems from neurologic issues in this population since small neurologic events in infancy or early childhood may lead to significant behavioral problems in later childhood and beyond. Although gross intelligence may be normal for the majority of survivors with CHD, studies have shown many children with previously treated congenital cardiac defects show neurodevelopmental abnormalities and perform below the average population [1–8]. Genetic defects such as 22q11 deletion, only recently routinely screened in most cono-truncal defects, have been shown to predict worse developmental outcomes [9]. Many have suggested that a large percentage of these impaired developmental out-comes occur more as result of pre-surgery developmental abnormalities in the brain [10–14], while others who have shown mild brain injury during cardiac surgery (frequently unrecognized clinically in the perioperative period) have been shown to also have an impact on worse developmental outcomes [15–17]. One study showed new brain lesions or progression of previously identified lesions in 67 % of infants studied with serial magnetic resonance scans before and after cardiac surgery [11].

Early identification of these seemingly minor abnormalities may have important longer-term impact for these children, as some investigators have shown that early focused therapy for these children and families may decrease the degree of these later neurologic problems [18]. Such treatment strategies have yet to be proven in larger-scale studies, and widespread use of this approach to screening has yet to be instituted in many centers. Hence, by adolescence and early adulthood, many of these seemingly minor neurologic insults can become more pronounced with poor academic performance, problems with social interactions, and self-esteem [19]. One study has shown the combination of many factors leads to an increased incidence of suicide in ACHD populations compared to age-matched controls [20]. Many investigators are studying ways to try to minimize this late neurocognitive impairment from cardiac surgery in children [21–24], but pediatric and adult cardiologists need to be more vigilant in screening and treating late behavioral and developmental problems to maximize this population's overall health and well-being. It has become important for pediatric and ACHD providers to alert our patient's primary providers regarding the importance of these issues within this population to allow them to provide appropriate screening and treatment.

Access to Care/Insurability

With the early childhood challenges many of these survivors face, obstacles for overall social independence tend be amplified in the ACHD patient compared to peers when reaching adulthood. Obtaining employment has been shown to be difficult for many adult congenital heart disease (ACHD) survivors, particularly those with more complex lesions [25, 26]. Even when gainful employment is obtained, other important aspects of adult fiscal stability such as life insurance, home mortgages, and disability insurance are frequently very difficult if not impossible to obtain [26–30]. Many cardiologists do not think to question patients about such social issues during a busy clinic, but these aspects of life may

have a big impact on an individual's psychological stress and health. ACHD providers quickly learn the importance of this in many patient's lives. Such examples include the time-consuming job of filling out a large number of forms on the patient's behalf in order to advocate for them. In developing ACHD programs, providers and administrators need to be aware that this can be a time-consuming part of the program's function and plan accordingly to help address these issues. In addition, for providers caring for teens with moderate and complex congenital lesions, educating the patients and their families about these challenges is an important part of the transition process, with the goal of allowing them to be better prepared to deal with these challenges that many of their friends and peers will not have to face. Becoming aware of local, regional, and national resources to help these young adults deal with these challenges at times becomes more important than which medical therapy is best suited to treat hypertension. Hence, access to clinical psychologists and social workers is an important component in ACHD programs, although to date lacking in many.

Late Vascular Problems

Late vascular problems remain a significant issue for many ACHD survivors, occurring secondary to either previous interventions or inherent to associated congenital vascular abnormalities within the venous or arterial system. An easy way to frame this issue would be to break the discussion into venous and arterial circulation.

Arterial Abnormalities/Complications

Although coarctation of the aorta was one of the earliest surgical therapies developed for congenital heart disease [31], late complications leading to persistently lower life expectancy than age-matched controls remain a problem [32]. Some of this early mortality occurs from cardiac maladaptation from long-term hypertension, such as congestive heart failure and perhaps early coronary artery disease. This is particularly important for those who were older at repair. Vascular complications have been shown in some series to have prevalence of up to 11 %, such as intracranial bleeding or embolic events. Asymptomatic late aortic complications at the repair site have been reported to occur anywhere between 5 % and 20 %, depending upon the repair strategy [33, 34]. Some of these late changes may be due to the diffuse arteriopathy that is seen in individuals with isolated coarctation, or with bicuspid aortic valve, or both. Recent prospective screening protocols have identified intracranial berry aneurysms to be five times more prevalent in the patients with bicuspid aortic valves and in adult survivors with coarctation of the aorta [35, 36]. Of the more recent European, North American, and Canadian guidelines for the management of adults with congenital heart disease, only the Canadian guidelines recommend routine radiographic imaging of the brain to screen for intracranial aneurysms [37–39]. Despite this lack of uniform consensus pertaining to routine screening, in view of a high incidence of abnormalities, the clinician must maintain a higher index of suspicion for their presence and consider vascular imaging of the brain for those with symptoms or for those with resting or exertional hypertension, as those are theoretically at higher risk. To date though, routine screening and treatment of asymptomatic small or moderate intracranial aneurysms in this population has not been shown to improve outcome and may even lead to adverse outcomes from iatrogenic complications. More investigation in this area is needed before stronger guideline strategies can be issued.

The presence of a bicuspid aortic valve has also been shown to correlate with a high incidence of ascending aortic dilation and aneurysm formation [40–44]. Bicuspid aortic valve disease is believed to occur in an autosomal dominant pattern of inheritance with variable penetrance, as it clusters in families, with linkages believed to occur on chromosomes 15q, 13q, and 18q [45–48]. It is postulated that abnormal flow and shear stress on the ascending aorta, even in the absence of valve stenosis or regurgitation, cause differential cell signaling in the aortic wall

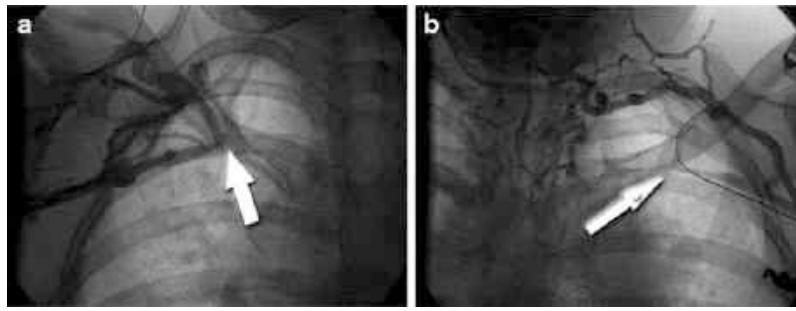

Fig. 144.1 Thirty-year-old female with history of pulmonary atresia/VSD now with severe left ventricular systolic dysfunction, and non-sustained VT, requiring biventricular pacemaker/defibrillator insertion. Panel (**a**) & (**b**) *arrows* showing complete occlusion of the right and left subclavian veins, respectively. The electrophysiologist did not perform these venograms before a left pocket was created, requiring closure of the pocket, and planned balloon venoplasty to allow access of the system at a later date

compared to patients with trileaflet aortic valves. It has been demonstrated that a combination of increased matrix metalloproteinases (MMP) 2 & 9, decreased levels of MMP inhibitor 1, and decreased endothelial nitric oxide synthase contributes to the aortopathy. It remains to be defined which of these pathways play the largest role, but retrospective studies have shown that aortic aneurysm formation is seen in up to 50 % of patients with combined lesions of previously repaired coarctation of the aorta and a bicuspid aortic valve [40, 44, 49–52]. The combination of the relatively decreased aortic compliance after coarctation repair, with the abovementioned ascending aortic changes when a bicuspid aortic valve is present, increases the risk of ascending aortic aneurysm formation, hence requiring regular careful assessment of the ascending aorta above the aortic root for these patients. Hence, regular scheduled tomographic imaging of the aorta is recommended in those with repaired coarctation in the AHA, Canadian, and European guidelines [37–39].

In addition to the inherent problems with the arterial tree in many ACHD survivors, late vascular abnormalities commonly exist secondary to surgeries and invasive procedures performed during childhood. Classic Blalock-Taussig shunts and subclavian flap repair involved sacrificing the subclavian artery, allowing it to be used as a native vascular shunt or patch, respectively, which would grow with the patient. Problems rarely occurred with the ipsilateral arm, as collaterals provided blood flow through the vertebral artery, rarely causing a subclavian steal phenomenon. However, significant arm length discrepancies have been described. Knowledge of these historical surgeries is important for the accurate care of these patients, as blood pressure tracking from that arm does not reflect central aortic pressure accurately, and failure to communicate this with all providers may lead to inappropriate treatments and/or testing. In rare patients, subclavian flap repair or sacrifice of the subclavian artery at the coarctation site may have occurred, along with an aberrant contralateral subclavian artery origin below the level of the coarctation. This would prevent *either* upper extremity blood pressure monitoring from accurately measuring ascending aortic and carotid artery pressure, which must be understood and taken into account at follow-up, particularly during scheduled and emergent surgical or interventional procedures.

In addition, arterial catheterization as a young child can lead to femoral and iliac artery stenosis or occlusion long term (Fig. 144.1). In many instances, secondary to extensive collateral blood flow formed at a young age; this does not lead to symptoms such as claudication, but can lead to difficulty in achieving arterial access for future surgeries or catheterizations. The true incidence of this problem is not clearly defined in the medical literature. Finally, although early reports have shown that carotid artery cutdown

Fig. 144.2 Panel (**a**) shows complete inferior vena caval occlusion in a 19-year-old with previous lateral tunnel Fontan palliation, with a deep collateral seen at the left side of her spine. Panel (**b**) shows complete iliac, inferior vena cava reconstruction after stenting. Panel (**c**) shows complete left femoral and common iliac vein occlusion in a 40-year-old woman with previous Mustard palliation for D-TGA. Ultrasound imaging of the right femoral vein confirmed right-sided occlusion as well

for trans-catheter procedures such as aortic balloon valvuloplasty is a safe and effective alternative to risking lower extremity ischemia in neonates [53, 54], only short midterm results have been reported on sequelae; while clinically these patients seem to be doing well, careful vascular assessments reveal these arteries are not normal, and the late complication rate remains unknown [55].

Venous Abnormalities/Complications

Congenital venous abnormalities can occur with both simple and complex congenital cardiac defects as discussed elsewhere in the textbook. Adult congenital providers need to remain vigilant in documenting previously identified abnormalities as well as in searching for additional abnormalities previously not identified that may impact future care. The most common congenital abnormality of the systemic veins includes the persistent left-sided superior vena cava. While usually physiologically inconsequential, its presence can lead to challenges for future pacemaker and defibrillator placement and become a cause for late cyanosis in patients treated with various forms of the Fontan palliation. A less common but also important systemic venous abnormality is congenital interruption of the inferior vena cava (frequently seen with heterotaxy syndromes), with azygous or hemi-azygous continuation. Again, while not physiologically important in most cases, this abnormality poses challenges for future invasive cardiac assessment and treatments. As in the arterial system, previous surgeries and catheterization procedures frequently lead to venous occlusion or stenosis. This may occur secondary to prolonged central venous cannulation from these sites, with prolonged and repeat infusions of sclerosing agents such as calcium and central intravenous nutrition. There is an increasingly recognized problem of chronic venous insufficiency in adult survivors with single-ventricle physiology and chronically elevated venous pressure, in addition to the previous frequent catheterizations performed [56]. Even when asymptomatic, single or bilateral venous occlusion can exist, leading to challenges with later procedures (Figs. 144.2 and 144.3).

Lung Disease

The lungs are intimately related to the heart, in terms of both anatomy and function. Disease processes that affect one can lead to dysfunction of the other. Surprisingly little is known about the prevalence of pulmonary disease in adults with congenital heart disease. Likewise, little is known if pulmonary disease is secondary to previous surgeries and what impact it has on mortality and functional status. It is difficult to separate the pulmonary effects from months or years of

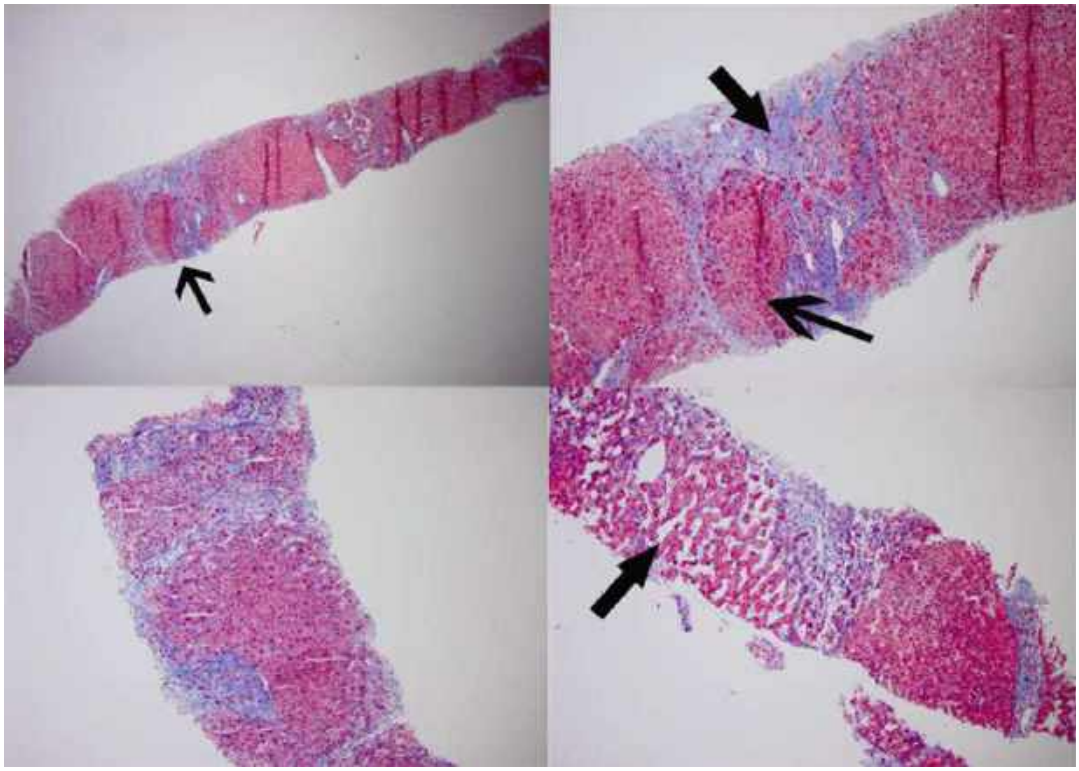

Fig. 144.3 *Upper left panel* showing a liver biopsy specimen of a patient with an atrial to pulmonary Fontan with standard H&E staining showing a section with regenerative nodule (*arrow*). The *upper right panel* shows the same specimen magnified, showing the dense fibrosis surrounding relatively normal liver tissue. The *bottom left panel* demonstrates more extensive but patchy fibrosis that can bridge the central veins to portal triads. The *right bottom panel* shows sinusoidal dilation characteristic of increased central venous pressure

chronic pulmonary overcirculation or pressure from the effects from surgery on late pulmonary function. In a simple study by Zaqout et al., the midterm pulmonary function test results of a group of patients with atrial septal defects (ASD) closed percutaneously versus those closed with a mini-sternotomy and cardiopulmonary bypass (CBP) were compared. At an average of 5 years from intervention, there was significantly lower expiratory reserve volume and forced vital capacity in the surgical cohort, showing that even simple cardiac surgery has at least a mild detrimental outcome on midterm pulmonary function [57]. In a single-center study with a large adult congenital heart disease population, respiratory muscle (as measured by maximal inspiratory and expiratory pressure) and skeletal muscle (as measured by hand grip strength) were significantly reduced in a large percentage of ACHD survivors compared to controls [38]. In a separate, large single-center study by Dimopoulos et al., abnormal ventilatory efficiency, as expressed by the ventilation per unit of carbon dioxide production (VE/VCO2 slope), was the strongest predictor of mortality in non-cyanotic ACHD survivors [58]. In a smaller but still informative study, Rigolin et al. showed that functional capacity of ACHD survivors, as measured by maximal exertional oxygen consumption, correlated independently with forced expiratory volume (FEV) regardless of right ventricular function. In patients with an exertional decrease in RV function, that variable was the best predictor of exercise capacity, but in those with no change in RV function, there was a positive correlation with FVC [59]. Hence, ACHD providers need to pay attention

to residual pulmonary function abnormalities in their patients with more than mild exercise limitations, as they may be responsible for a significant component of these limitations, of which additional surgical intervention may be of little help in improving.

Anatomic Abnormalities of the Cardiovascular System Affect the Lungs

Anatomically, abnormal vascular structures or pathologic enlargement of cardiac chambers can cause obstruction of the bronchi and compression of the lung parenchyma. Vascular rings, including double aortic arch, can cause compression of the trachea, leading to respiratory distress. Most are diagnosed in childhood, but some cases are present in adults [60–62]. Aortic changes with aging, including enlargement and increased tortuosity, can worsen tracheal compression. Presenting symptoms include dyspnea on exertion, recurrent pneumonia, bronchitis, difficulty swallowing, or stridor. Surgical correction improves symptoms in most patients with vascular compression of the airways [63]. Aneurysms of the thoracic aorta can also cause airway compression of either the right or the left main bronchi [64, 65]. Aneurysms of the pulmonary arteries are less common but can also lead to compression of the airways [66]. Symptoms include dyspnea on exertion, hemoptysis, cough, and chest pain. Airway collapse from severe pulmonary aneurysms has been reported [67].

Airway compression can also occur from cardiac structures, particularly a giant left atrium, frequently secondary to mitral valve disease. The atrium can compress the main bronchus and the lung parenchyma, leading to severe respiratory dysfunction [68–70]. It is associated with a poor prognosis in patients undergoing surgery. Surgical plication at the time of mitral valve surgery is associated with an increase in vital capacity [71]. An enlarged left heart can also compress the lung parenchyma, particularly the left lower lobe [72]. This compression varies depending on the patient position. Patients have improved systemic oxygenation in the right lateral position [73]. Treatment is difficult if the underlying cardiac abnormality cannot be treated.

Cardiac Impairment Can Lead to Pulmonary Edema

In addition to external compression of lung structures, cardiac abnormalities can cause intrinsic pulmonary dysfunction. Pulmonary edema is abnormal fluid accumulation in the interstitium and alveoli [74]. It can be cardiogenic or noncardiogenic. The latter is related to increased permeability and can be due to acute respiratory distress syndrome (ARDS), reexpansion of a collapsed lung, medication side effects, toxins, transfusions, neurologic events, or high-altitude exposure and will not be discussed further. Cardiac pulmonary edema is due to increased filling pressure of the systemic atrium and/or ventricle [75]. This increased filling pressure can be due to systemic ventricular diastolic dysfunction or abnormalities more proximal to the ventricle, including mitral stenosis, cor triatriatum, supramitral ring, or pulmonary veno-occlusive disease. As the pulmonary capillary hydrostatic pressure increases, the fluid initially fills the peribronchovascular interstitial spaces, forming the "cuffs" that can frequently be seen on chest X-rays. When the volume of the interstitial space is exceeded, fluid accumulates in the alveolar spaces. Eventually, the fluid can leak into the pleural space and cause pleural effusions [76]. Even the early phases of pulmonary edema are associated with decreased lung compliance [77]. With progressive edema, the lungs become restrictive with decreased total lung capacity. Diffusion capacity of carbon monoxide (DLCO) is also decreased [78].

Patients with Fontan Circulation Have Specific Pulmonary Complications

Patients with Fontan circulation do not enjoy a normal life span. Although children and adults

with the Fontan circulation have reduced exercise capacity compared to normal controls, many develop more severe impairment, frequently associated with disorders such as protein-losing enteropathy (PLE) or right heart failure without PLE. Reasons for why some adult Fontan patients do more poorly than others are not always clear but may at times be related, at least partially, to changes in pulmonary function, particularly pulmonary vascular resistance [79]. In the immediate postoperative period, the systemic venous pressure is very sensitive to changes in pulmonary vascular resistance [80]. Increases in pulmonary vascular resistance are associated with congestion and low cardiac output. Chronically, pulmonary vascular resistance can become elevated in patients with Fontan circulation, with an unclear underlying mechanism. Potential causes include the lack of pulsatile flow recruitment [81, 82] and endothelial dysfunction [83]. Evidence-based guidelines for the management of a failing Fontan are lacking. Therapies targeting pulmonary vascular resistance have had mixed but overall favorable results [84–86]. Further studies are needed.

Plastic bronchitis is a rare complication from Fontan circulation in which there is formation of rubbery "casts" in the airway which are usually spontaneously expectorated. Plastic bronchitis is more frequently noted in children but has been seen in adults [87, 88]. There are no clinical trials of effective treatment; however, ex vivo studies have shown tPA to reduce the weight of the cast [89] and it has been used clinically in case reports [90–94]. Aerosolized heparin has also been used as treatment.

With time, many patients with classic unilateral cavopulmonary (Glenn) anastomoses develop pulmonary arteriovenous malformations (AVMs). These AVMs lead to right-to-left shunting of deoxygenated blood and increased cyanosis. They are present and clinically significant in up to 25 % of patients several years after such a cavopulmonary anastomosis [95]. Contrast echocardiography can detect subclinical AVMs with much greater sensitivity than angiography [96, 97]. There is evidence that hepatic-derived elements play a critical role in preventing the development of AVMS. Patients with unilateral anastomosis of the superior vena cava to the pulmonary artery (a classic Glenn shunt) generally develop AVMs in the ipsilateral lung [98, 99]. Surgically redirecting hepatic venous flow to the pulmonary circulation via completion of the Fontan circulation is associated with regression of AVMs [100, 101]. In some patients, inclusion of hepatic venous flow is difficult, if not impossible. Augmentation of pulmonary blood flow with systemic blood has been described. Future studies on the use of angiogenesis inhibitors are needed [102]. Studies on other potential causes of AVMs are also needed as some patients with a Fontan circulation occasionally have this complication despite the inclusion of the hepatic circulation [103].

Lung Infections

Although children with congenital heart disease are at increased risk of infections, particularly pneumonia, the risk does not seem to be increased in adults. Pulmonary involvement is a frequent complication of right-sided infective endocarditis. It frequently presents with cough, pleuritic chest pain, and occasionally hemoptysis and dyspnea [104, 105]. Risk factors for tricuspid valve endocarditis include intravenous drug use, pacemakers, central lines, and congenital heart disease [106]. Chest X-ray is abnormal in 75 % of cases, including single or multiple rounded pulmonary infiltrates, pleural effusions, and/or empyema [104]. Not only can endocarditis lead to pulmonary involvement but the converse is also possible with pneumonia, leading to endocarditis [107]. Influenza is another important pulmonary pathogen in adults with congenital heart disease. Prior to 2010, influenza vaccine was recommended for patients with risk factors for influenza-related complications, specifically including congenital heart disease [108]. It is now recommended that all persons aged $\geq$6 months receive annual influenza vaccine. Guidelines for the 23-valent pneumococcal polysaccharide vaccine (PPSV23) are less specific regarding congenital heart disease [109]. The vaccine is recommended for adults aged $\geq$19 years with

chronic medical conditions including chronic heart disease. Congestive heart failure and cardiomyopathies are specifically included, while hypertension is specifically excluded. If the vaccine is received before age 65 years, a repeat dose is recommended at age 65 years or later if at least 5 years have passed since the first dose. The European guidelines for the management of adult congenital heart disease recommend annual influenza vaccinations and pneumococcal vaccinations every 5 years.

Renal Impairment

Adults with congenital heart disease have a relatively high burden of renal disease. In the general population, the prevalence of significant renal dysfunction in patients 35–44 years of age is less than 1 % [110, 111]. In similarly aged, non-cyanotic adults with congenital heart disease, 8 % have similar degree of renal dysfunction [112]. In cyanotic adults, 16 % are affected. Evidence of mild renal dysfunction is present in an additional 50 % of adults with cyanosis. Moderate to severe renal dysfunction is highly correlated with mortality in both a propensity score weight-adjusted model (hazard ratio 3.25, 95 % confidence interval 1.54–6.86, $p = 0.002$) and in multivariable models which includes NYHA class, systemic ventricular dysfunction, age, and cyanosis (hazard ratio 2.31, 95 % confidence intervals 1.17–4.56, $p = 0.015$). Screening for renal dysfunction is generally recommended for adults with congenital heart disease.

Cyanotic Nephropathy

Patients with cyanosis represent some of the most complex and challenging patients in an adult congenital heart disease clinic. They have multisystem involvement and the kidneys are not spared. Pathologic changes include larger glomerular size, more glomerular capillaries, global glomerular sclerosis, and interstitial fibrosis [113]. One of the first signs of renal dysfunction is proteinuria which can progress to nephrotic syndrome. Over 50–70 % of patients with cyanotic heart disease have microalbuminuria/proteinuria [114, 115]. The incidence of significant proteinuria (>1.0 g/24 h) is approximately 20–30 % [114, 116]. The etiology is thought to be hyperviscosity due to erythrocytosis [113]. Small studies have suggested ACE inhibitors can reduce the urine protein excretion but do not have a consistent effect on glomerular filtration rate (GFR), renal plasma flow, or filtration fraction [116]. If ACE inhibitors are not tolerated, phlebotomy was successful in one case report [117].

Contrast-Induced Nephropathy

Cardiac catheterization is crucial to the diagnosis and management of patients with congenital heart disease but relies on iodinated contrast for adequate visualization of chambers and vessels. Contrast material can lead to acute kidney injury and contrast-induced nephropathy. Contrast-induced nephropathy is an acute decline in renal function that typically occurs 48–72 h after intravascular use of contrast [118]. Contrast-induced nephropathy is associated with significant adverse events, including increased in-hospital death rates and median survival [119]. Risk factors for contrast-induced nephropathy include solitary kidney, acute hypotension, dehydration or volume contraction, and nephrotoxic drugs [118]. Although not widely studied, cyanosis is also considered a risk factor [120]. Many of the risk factors are prevalent at increased rates compared to the general population. The most important risk factor is baseline glomerular filtration rate (GFR). Patients with estimated GFR ≥60 mL/min are at very low risk, GFR 45–59 mL/min are associated with low risk, and GFR <45 mL/min are at moderate risk [118, 121]. Current recommendations for prevention include fluid administration. Although bicarbonate solution was initially very promising [122], subsequent studies have not supported its superiority [123]. The results of N-acetyl cysteine have been mixed, with one randomized trial showing a benefit [124] and several studies showing no

difference [125–129]. Increasing doses of contrast material are related to increased rates of nephropathy, as are subsequent studies within 48 h [130–132]. Dialysis has not been shown to prevent nephropathy [133]. Although the use of contrast is necessary for appropriate care of adults with congenital heart disease, caution should be used, especially in those at highest risk of contrast-induced nephropathy.

Renal Infarction

The kidneys receive approximately 20–25 % of total cardiac output [134]. It is not surprising that embolic material can lead to renal infarctions. Adults with CHD have many predisposing factors associated with renal infarction. First, atrial fibrillation is the most common cause of acute renal embolic infarction [135]. Adults with CHD are predisposed to the development of atrial arrhythmias [136]. Mechanical aortic and mitral valves are a frequent cause of embolic stroke [137] and have been implicated in renal infarctions as well [138]. Pregnancy increases the risk of embolic events for several reasons. Not only is atrial fibrillation/flutter the most common adverse cardiovascular event during pregnancy but [139] pregnancy is also a high-estrogen state. Embolic events are much more common in women with congenital heart disease than those without (odds ratio 8.2, 95 % confidence interval 4.7–14.3) [139]. Finally, patients with secondary erythrocytosis from chronic cyanosis may also be pro-thrombotic, particularly during periods of relative volume depletion [140]. Adults may also have traditional risk factors for cardioembolic events, including advanced age and history of diabetes or hypertension. Overall, adults with CHD frequently have several risk factors for embolic events.

Symptoms of renal infarction are nonspecific and include nausea, vomiting, abdominal pain, and flank pain [135]. Leukocytosis and elevated lactate dehydrogenase levels are the most notable laboratory findings. Diagnosis is confirmed by computed tomography, which typically demonstrates a wedge-shaped hypodensity. Acute kidney injury is common at the time of acute renal infarction occurring in approximately 40 % of affected patients. Long-term renal outcomes are relatively good, with resolution of kidney injury within a month [141]. Treatment includes avoiding nephrotoxic medications and appropriate anticoagulation.

Renal Tract Anomalies

Patients with congenital heart disease have a high incidence of renal tract anomalies [142–144], including hydronephrosis, duplication, ectopia, agenesis, and dysplasia of kidneys. There are many specific syndromes associated with both renal tract anomalies and congenital heart abnormalities. The 22q11 microdeletion is associated with renal dysplasia, hydronephrosis, and unilateral renal agenesis [145, 146]. Smith-Lemli-Opitz syndrome is a rare autosomal recessive disorder of cholesterol metabolism with a very broad phenotypic spectrum [147]. It is associated with atrial and ventricular septal defects, patent ductus arteriosus, atrioventricular canal, as well as renal malformations, hypospadias, and cryptorchidism. Kabuki syndrome is characterized by dysmorphic face, growth retardation, mental retardation, skeletal abnormalities, and unusual dermatoglyphic patterns. Both cardiovascular anomalies (42 % of cases, including ventricular septal defects, atrial septal defects, coarctation of the aorta, patent ductus arteriosus, and transposition of the great vessels) and renal tract anomalies occur frequently (28 % of cases) [148]. Turner syndrome, due to partial or total loss of the second sex chromosome, is associated with approximately 20–30 % prevalence of cardiovascular abnormalities, particularly bicuspid aortic valve and coarctation. Renal tract abnormalities occur in 30–40 % of cases, including horseshoe kidney, renal malrotation, and collecting system malformations [149, 150]. Renal tract anomalies are important for adult cardiologists to be aware of as they increase the risk of chronic kidney disease.

Cancer/Malignancy

Radiation and Risk of Malignancy

The link between radiation exposure and malignancy is difficult to prove. Nonetheless, medically used low-dose ionizing radiation is likely a risk factor for cancer, a claim supported by the International Commission of Radiological Protection [151] and the National Council on Radiation Protection [152]. Carcinogenesis is a stochastic effect, which means the *probability* of the outcome (i.e., cancer) is determined by the dose but the severity of the outcome is not. These effects do not have an apparent threshold dose. Radiation exposure is documented in millisieverts (mSv). Fifty chest X-rays are equivalent to approximately 1 mSv. There is an excess incidence of cancer at even low doses of radiation, such as 50 mSv [153]. There is no direct epidemiologic evidence of increased risk for doses of radiation less than 50 mSv; however, the current belief is that even small doses can increase the risk of future malignancy [154].

Patients with congenital heart disease may have undergone many cardiac catheterizations as children, and therefore, have been exposed to radiation. Diagnostic cardiac catheterization is reported to deliver a mean 4.6 mSv, whereas therapeutic procedures are associated with 6.0 mSv [155]. Although these doses are relatively small, there are several factors that increase the risk of future malignancy, including younger age, sometimes as young as a few days old, and repeated procedures as some patients require multiple procedures over the course of their lifetime.

Epidemiologic studies on the risk of malignancy have had mixed results. A retrospective cohort study on 4,891 children with congenital heart disease did not document an increased risk of leukemia after a mean of 13 years [156, 157]. A subsequent study of 674 children observed a 2.3 times excess cancer risk, primarily lymphoma and melanoma, in children exposed to radiation [158]. To document the risk of cancer from one cardiac catheterization, that is, 10 mSv or less, a study would require five million people [153]. A valid surrogate endpoint would overcome the limitations of epidemiologic studies. Andreassi et al. studied chromosomal aberrations and micronuclei in peripheral blood lymphocytes [154]. These cytogenetic biomarkers have been associated with an increased risk of cancer [159–161] and are a reliable "biological dosimeter" for estimating radiation exposure. Patients who had undergone at least one cardiac catheterization at less than 1 year of age were compared to age- and gender-matched controls who did not have radiation exposure. Patients with radiation exposure were found to have long-term chromosomal damage. Based on similar studies, the lifetime attributable risk for a 1-year-old child with complex congenital heart disease requiring a cardiac catheterization, exposed to a median lifetime cumulative effective dose of 7.7 mSv, is 1 in 382 for a boy and 1 in 156 for a girl [162].

The risk of radiation is not limited to infancy. Even as adults, radiation exposure is associated with a theoretic increased risk of malignancy, with the risk being higher in women and younger age. One computed tomography (CT) coronary angiogram is associated with an organ dose of 42–91 mSv and has a lifetime attributable risk of 1 in 143 for a 20-year-old woman to 1 in 3,261 for an 80-year-old man [163]. A CT scan that images the heart and aorta has a calculated lifetime attributable risk of 1 in 114 for a 20-year-old woman. For patients that require frequent imaging, such as Marfan patients, the risk of malignancy is serious.

Cardiac catheterization, and the use of radiation, is of vital importance to children with congenital heart disease. Pediatric interventionalists must be aware of the risk of radiation to the patient and do everything reasonable to reduce the effective dose. Radiologists must consider methods of reducing radiation exposure from CT imaging. Adult cardiologists must not only minimize radiation exposure by ensuring all tests are necessary but also ensure that our patients are offered routine cancer screening as recommended by current guidelines. Providers are at times wishful that because their patient has "been through so much," there is no way their current complaint could be from cancer, when in fact the

converse is true, that is, because our patients have been through so much, their risk of cancer is increased.

Syndromes Associated with Heart Disease and Altered Risk of Malignancy

Down syndrome (DS) is the most common chromosome abnormality among live-born infants. The estimate congenital heart disease in children born with Down syndrome is between 33 % and 48 % [164]. Because of the prevalence of Down syndrome and of congenital heart disease, patients with Down syndrome are frequently encountered in adult congenital heart disease clinics. There are many studies documenting the increased risk of leukemia in children and adolescents with Down syndrome [165, 166]. The risk of malignancy in adults is mixed [165, 166]. Although there are many case reports of testicular tumors [167], the standardized incidence ratio is elevated at 3.7 (confidence interval 1.0–9.4) in one study and 1.86 (confidence interval 0.50–4.77) in another study [168]. An increased rate may be due to high frequency of undescended testes [167]. Breast cancer is the most common malignant disease in women but is remarkably rare in women with Down syndrome. In one study, there were no cases of breast cancer among 1,278 women with DS. Based on population studies of women without Down syndrome, 7.3 cases would have been expected [168]. Patients with Down syndrome have about a 50 % decreased risk of all solid tumors [168].

Other syndromes that are frequently associated with cardiac disease also have a link to malignancy. Noonan syndrome is characterized by short stature, distinct facial features, and developmental delay. Cardiovascular abnormalities are common, occurring in more than 80 % of patients with Noonan syndrome [169]. Pulmonary valve stenosis is the most common abnormality, with secundum atrial septal defects, hypertrophic cardiomyopathy, and partial atrioventricular canal defects also frequently found [170, 171]. The most common cancers in Noonan syndrome are neuroblastoma, low-grade glioma, rhabdomyosarcoma, and acute leukemia. Mutations of the renin-angiotensin system pathway are related to Noonan syndrome and these four malignancies, so the link is biologically plausible [172]. Costello syndrome, cardiofaciocutaneous syndrome, and Noonan syndrome with multiple lentigines (formerly Leopard syndrome) overlap clinically with Noonan syndrome in terms of cardiac defects and malignancy risk.

Liver Disease

Although previously not a significant concern for pediatric or adult cardiologists, it has been known for decades that chronic cyanosis in early childhood leads to increased fibrosis in the liver [173]. Only recently has more attention been paid to this phenomenon as interventions such as Fontan palliation have evolved. These children have chronic cyanosis for at least the first couple years of their lives, followed by a chronically elevated inferior vena cava and hepatic vein pressures following the Fontan procedure (12–20 mmHg depending upon their status and type of Fontan palliation). Some of these patients develop mild recurrent cyanosis from fenestrations or venous collaterals, combined with the elevated venous pressure. This group of survivors can be very heterogeneous. The original Fontan procedure first described in 1971 for palliation for tricuspid atresia [91] utilizing an atrial to pulmonary artery connection led to elevated right atrial and IVC pressures, with frequent late right heart failure (IVC pressures 16–25 mmHg) and recurrent atrial arrhythmias. This procedure has hence undergone many evolutionary steps, to the total cavopulmonary connection such as the lateral tunnel Fontan and later the extracardiac Fontan. Since the 1990s, these latter two Fontan palliations have replaced the older atrial to pulmonary Fontan, resulting in more laminar IVC flow believed lower hepatic vein pressures. Many adult Fontan survivors have undergone conversion from the older atrial to pulmonary artery Fontan to extracardiac total cavopulmonary connection [174–179], with resultant improved but still elevated IVC pressures. Hence, from

a hepatic standpoint, practitioners can classify Fontan survivors into three groups: those with persistent atrial to pulmonary artery connection, those with a prior atrial to pulmonary artery Fontan now status post conversion to an extracardiac Fontan, and those with total cavopulmonary artery connection from a young age. It remains unclear whether these groups will have similar hepatic changes.

Small series of patients with histologic analysis of the liver in patients with the Fontan palliation have shown 100 % of patients had at least mild hepatic fibrosis, with 11–58 % showing cardiac cirrhosis [180–182]. Histologic changes are similar to that seen with chronic heart failure with sinusoidal dilation and centrilobular fibrosis (Fig. 144.3). There tends to be little to no inflammation. The inflammation that is present tends to be patchy, with some areas showing limited to no fibrosis and other extensive bridging fibrosis [181]. A few recent case reports have suggested that this hepatic change can lead to malignant changes, which in some cases had remained asymptomatic until development of fatal complications [180, 183]. Hence, many ACHD centers are developing screening protocols for liver disease in adults with previous Fontan palliation, particularly for those needing additional interventions such as Fontan conversion or cardiac transplantation. The most cost-effective approach remains to be identified, with future data hopefully helping the community to develop more evidence-based guidelines.

Endocrine

Patients with congenital heart disease are at increased risk of thyroid disease. Certain syndromes are highly associated with both congenital heart disease and thyroid dysfunction. Patients with Turner syndrome have an 11 % prevalence of hypothyroidism and a 27 % prevalence of subclinical hypothyroidism [184]. Patients with 22q11.2 deletion syndrome have a high prevalence of hypothyroidism [185]. In patients with tetralogy of Fallot with syndromic features, such as dysmorphic facial features, cognitive impairment, and/or speech problems, but without a confirmed diagnosis of 22q11 deletion syndrome, thyroid dysfunction remains more prevalent than in patients with tetralogy of Fallot without syndromic features (20 % versus 4 %, $p = 0.001$) [186]. Down syndrome is also associated with abnormalities in thyroid hormone secretion with hypothyroidism being much more common than hyperthyroidism [187]. Hypothyroidism in Down syndrome patients is either congenital and present at birth [188] or acquired later in life [187]. Hyperthyroidism is less common but still more prevalent than the general population [187, 189].

Atrial and ventricular arrhythmias are very common in adults with congenital heart disease and are frequently treated with amiodarone [190, 191]. Amiodarone use is associated with a high incidence of thyroid dysfunction in adults with congenital heart disease, with 21 % of patients experiencing hyperthyroidism and 15 % becoming hypothyroid within 2–3 years [192]. Independent risk factors for thyroid dysfunction include female sex and cyanotic heart disease. Patients with a Fontan circulation are at particular risk of thyrotoxicosis. Despite lower doses of amiodarone, thyroid dysfunction occurs more often in adults with congenital heart disease than in older patients with acquired heart disease. Amiodarone-induced thyrotoxicosis is particularly associated with morbidity and mortality [193]. Specific risk factors for amiodarone-induced thyrotoxicosis include age, cyanosis, and decreased BMI [194].

As noted, patients with congenital heart disease are at increased risk of thyroid problems. These issues can, in turn, have effects on the heart and cardiovascular systems [195]. Hyperthyroidism enhances systolic and diastolic function, cardiac output, and resting heart rate [196]. It also leads to increase in blood volume and venous return [197]. With time, cardiac mass increases [198]. Pulmonary artery pressure increases, which can lead to right heart failure [199, 200]. Left heart failure can occur, particularly in the setting atrial fibrillation and rapid ventricular response [201]. Hypothyroidism is associated with a narrowed pulse pressure, low

cardiac output, decreased ejection fraction, impaired diastolic filling, and bradycardia [196]. It is also associated with hyperlipidemia, hypertension, atherosclerosis, and coronary artery disease [202, 203].

Bone Density and Vitamin D Deficiency

Normal bone development is dependent on physical activity, balanced nutrition, and normal hormonal status [204–206]. In adults with chronic heart failure, there is an increased incidence of osteoporosis [207, 208]. Based on this evidence, adults with congenital heart disease are at increased risk of abnormal bone mineral density, osteopenia, and osteoporosis. Studying bone density is complicated by the typical use of age- and gender-matched controls [209]. Many patients with congenital heart disease have short stature and, therefore, smaller bones which can appear artificially as decreased bone mass. When compared to gender- and height-matched controls, most young adults with congenital heart disease have normal bone parameters. The exception is patients with Fontan circulation and with advanced heart failure (NYHA class III). These patients have abnormal bone mass even when compared to height- and gender-matched controls. These patients also had lower oxygen saturation, higher number of operations, and longer duration of hypoxemia. Patients with Turner syndrome have high rates of osteoporosis and osteopenia, which is likely related to intrinsic structural bone defects and estrogen deficiency [184]. Again, estimates of prevalence may overestimate the true prevalence due to decreased stature. Down syndrome is highly associated with vitamin D deficiency and decreased bone mineral density [210–212]. The effects of treatment of decreased bone mass on quality of life or other outcomes are unknown.

Vitamin D has a well-defined role in bone and calcium metabolism but increasingly seems related to cardiovascular health. Deficiency has been related to hypertension, stroke, coronary artery disease, and heart failure [213–215]. The prevalence of vitamin D deficiency is 25–57 % in the general population [216]. In cardiac patients, vitamin D supplementation is associated with improved survival. Vitamin D deficiency is also associated with pediatric heart failure [217–219]. Studies on adults with congenital heart disease are needed.

Diabetes and Glucose Metabolism

Little is known about diabetes in adults with congenital heart disease. There is an increased risk of abnormal glucose metabolism in adults with complex congenital heart disease including unrepaired disease (44 %), Fontan circulation (43 %), and biventricular repaired disease (47 %) compared to healthy controls (4 %) [220]. Risk factors for abnormal glucose metabolism in this patient population include central obesity, liver and kidney dysfunction, diuretic use, and increased renin activity. Patients with Turner syndrome and Down syndrome are also more likely to have glucose intolerance [184, 221].

Quality of Life

Patients with congenital heart disease have many potential threats to their quality of life, including need for multiple surgeries, lifelong medical care, activity restrictions, and difficulties obtaining employment and health insurance. Defining quality of life is difficult but more likely related to life satisfaction than to subjective health status. Heart disease severity has little influence on perceived quality of life, whereas functional status has a much stronger influence. Compared to the general population, adults with congenital heart disease have lower physical functioning and appraisal of physical dysfunction but no significant difference in nonphysical domains such as social functioning, role functioning, emotional, daily activities, and mood [25] [222]. In patients with Fontan circulation, despite an increased prevalence of depression, overall quality of life does not differ from healthy, matched controls [223].

Mental Health

Adults with congenital heart disease face specific challenges that may be associated with increased risk of psychosocial difficulties including heart-focused anxiety, concerns about mortality, treatment decision-making, surgical preparation, adjustment to implanted cardiac devices, difficult pediatric-adult transitions, and adherence concerns [224]. Current guidelines recommend screening for a variety of psychosocial issues including cognitive, mood, and psychiatric disorders [39]. There is a high prevalence for a lifetime mood disorder (33 %) or lifetime anxiety disorder (26 %) [225]. At the time of one study, 33 % of patients met diagnostic criteria for current mood or anxiety disorder [225]. Depressive symptoms were significantly associated with loneliness, fear of negative evaluation, and perceived physical health status. Compared to the general population, rates of depression appeared similar while anxiety is more common in adults with congenital heart disease. A large proportion of affected individuals had never had psychotherapy or psychotropic medications (40 %). Among the patients that met criteria for current anxiety or depression, 70 % were not under treatment. Despite the high proportion of untreated patients, a majority of adults with congenital heart disease are interested in treatment of managing mood and/or anxiety, coping with a cardiac condition, stress management, anger management, relationship management, substance use, and/or smoking cessation [226]. There are also a significant number of patients interested in peer support.

Sexual Health

Sexuality is an important component of overall quality of life. Patients with acquired heart disease have loss in sexual interest, decreased sexual frequency, decreased satisfaction, and increased sexual dysfunction [227, 228]. When compared to age- and gender-matched controls, adults with congenital heart disease perceive lower body esteem, decreased sexual esteem, and more distress during sex, but there is no difference in overall sexual satisfaction [229]. Adolescents and young adults are less likely to be sexually active compared to normative samples [230]. Having a surgical scar is not related to being sexually active, but patients with scars are less likely to have multiple sexual partners. Among sexually active adolescents, 72 % engage in risky sexual behavior including two or more partners in the past 3 months, questionable birth control, and/or using drugs or alcohol before sex. It is important to discuss these issues with patients starting at a young age, as one survey-based study found 15 % of women engaged in sexual activity prior to 16 years of age [231].

Employment

Another aspect of quality of life is occupational success. Guidelines recommend vocational planning to begin early in adolescence [39]. The American with Disabilities Act prohibits discrimination, and patients are not required to disclose their congenital heart disease; however, some patients have physical restrictions which make disclosure necessary. Compared to controls, rates of full-time employment decreased as disease severity increased. In particular, men were more likely to be employed part time than healthy men [232]. A significant proportion (55 %) of adults with complex congenital heart disease have had at least one problem with their career as a result of their heart disease, including feeling restricted in the choice of a job, being excluded from a job, having given up on a job, being excluded from a job after a medical examination, and not being promoted [25].

End of Life

Although there is general agreement among patients and providers that advanced care planning is important, the vast majority of adults with congenital heart disease have not completed an advance directive and a significant number are not aware formal documents exist [233]. Documentation of end-of-life discussions with patients

is rare, particularly in the outpatient setting [234]. Many patients with congenital heart disease die in the hospital under full resuscitative efforts. There are many possible reasons for continued aggressive care including a relatively younger age, and difficulty in defining prognosis and recognizing the dying phase. Despite barriers to both discussion of end-of-life care and improvements in palliative care, it is clear the dying process can and should be improved for adults with congenital heart disease.

Conclusion

As described throughout this chapter, the care of the adult with palliated congenital heart disease involves more than understanding the cardiac lesion and the common late cardiac complications that occur. It also involves an understanding of how the various treatments impact other organs and their function, as well as psychosocial impacts for the patients and their families. Currently, the ACHD community is only beginning to understand these long-term impacts. With the evolution of newer surgical techniques, often at younger ages, we will need to continue to study and learn how these changes impact new generations of ACHD survivors. Fortunately, the adult congenital community is becoming more connected, with multicenter research initiatives blossoming throughout the world. Hopefully this will provide a better understanding of the late sequelae that may not be clearly seen in single-center studies. This ongoing new knowledge will need to be integrated into best practices for our trainees and programs. Only through that continued learning and integration of new knowledge will ACHD providers be able to best adapt our approach and thus provide the best care for this ever evolving and growing population of adults with congenital heart disease.

Transfer and Transition in Congenital Heart Disease

145

Eva Goossens, Adrienne H. Kovacs, Andrew S. Mackie, and Philip Moons

Abstract

Over the past decades, survival of children born with congenital heart disease has increased significantly. This has resulted in an exponential growth in the number of adult patients, which brings challenges to the organization of adult congenital heart disease care. Since patients with congenital heart disease are prone to develop late complications, lifelong specialized follow-up is recommended. International guidelines stress the importance of providing uninterrupted, age, and developmentally appropriate health care to patients with congenital heart disease throughout their life-span. During childhood, care is provided by pediatric-focused providers. This care should ideally be transferred to adult-focused providers or programs when the patient reaches adulthood. Transfer of care should,

however, be preceded by a transition process in which patients learn about their condition and develop self-management and self-advocacy skills to manage their health.

This chapter provides an overview of the literature regarding transfer and transition in patients with congenital heart disease. The evidence highlighting the importance of transfer and transition is described, and recommendations to improve transitional care are summarized. An overview of developmental milestones, skills, and educational topics is offered, in order to provide hands-on information for professionals caring for adolescents and young adults with congenital heart disease.

Introduction

Congenital heart disease (CHD) is a condition present at birth that continues to affect most patients throughout their lives. Indeed, irrespective of the initial treatment, most patients with CHD cannot be considered being cured and therefore require lifelong follow-up and care. Since 90 % of patients born with CHD currently survive into adulthood [1], specific programs for adults with CHD have been established. International guidelines for the management of CHD state that health-care provision for these patients should continue without interruption as an individual transitions from adolescence to adulthood [2–4]. Therefore, timely transfer from pediatric to adult-centered care is essential. Over the past decade, the issues of transfer and transition have received increasing attention [2–4]. The aims of this chapter are to provide an in-depth review of transfer and transition in CHD and to provide pathways to improving transitional care.

Definitions

Although numerous definitions of transfer and transition can be found in the literature, to date, there is no standard definition of these concepts. Neither is there a clear distinction with or between other related constructs, such as transition process, transition planning, and transition readiness [5]. These concepts are frequently, although incorrectly, used interchangeably. Therefore, it is important to clearly define these terms.

Transfer has been defined as "*an event or series of events through which adolescents and young adults with chronic physical and medical conditions move their care from a pediatric to an adult health care environment*" [6]. The goal of this transfer is to maximize a patient's functioning and potential through the provision of high-quality, developmentally appropriate health-care services [7]. In late adolescence, the pediatric setting may be less suitable to provide appropriate care. Therefore, it is recommended to transfer patients from a pediatric to an adult-focused health-care setting where one is available [8]. More specifically, patients with CHD ought to be transferred from pediatric cardiology to an Adult Congenital Heart Disease (ACHD) program, understanding that this may not be feasible in jurisdictions not having an ACHD center.

Transitions, in general, are passages from one life phase, physical condition, or social role to another [9]. Four types of transition have been described [10]. First, "*health/illness transitions*" refer to changes in health status of patients and

range from adapting to a chronic illness, returning home from hospitalization, or recovering from surgery. Second, "*developmental transitions*" occur with standard changes in the developmental stages of life such as adolescence, parenthood, or aging. Third, "*situational transitions*" pertain to environmental, contextual, and social changes, such as changing educational or professional roles or altered family situations. Fourth, "*organizational transitions*" reflect changes in leadership, policies, or organizational structures, affecting both personnel and clients of an organization [10].

With respect to adolescent health care, developmental transitions are the most relevant type of transition. From this perspective, transition can be viewed as *the evolution of an individual with a chronic condition from a dependent child to an independent adult*. It corresponds with "*the process by which adolescents and young adults with chronic childhood illnesses are prepared to take charge of their lives and their health in adulthood*" [6]. Transition as a health-care intervention is frequently defined "as *a purposeful, multifaceted, planned process that addresses the medical, psychosocial, and educational/vocational needs of adolescents and young adults with chronic physical and medical conditions*" [11]. All too often, it is added that this process is undertaken "*as they move from child-centered to adult oriented health care systems*." However, this additional statement may confuse the distinction from the concept of transfer. Furthermore, it is frequently argued that the transition process is needed to prepare patients for the transfer from pediatric to adult care [4;6]. However, transition should not end at the time of transfer, because the individual continues to evolve toward adulthood [6]. Indeed, transitional care remains important to further coach and guide individuals with CHD toward adulthood, even beyond the transfer to adult care.

Among young adults who remain with a pediatric cardiologist into adulthood (i.e., do not undergo transfer of care), transition remains an important and necessary process. Indeed, transition is normal and something that *all* adolescents and young adults with CHD need to go through.

Transfer

Why Is Transfer of Care from a Pediatric Focus to an ACHD Program Important?

Transfer of care from a pediatric to an ACHD-focused program allows patients be to be cared for in an environment suited to their medical and psychosocial needs. For example, adult survivors of CHD may develop comorbid conditions with which pediatricians are not familiar. Health-care transfer overlaps with other significant life events, including independent living, employment, relationships, and family planning, which adult providers are better suited to address. From a practical perspective, pediatric hospitals in many countries have an upper age limit (typically 16–18 years) for inpatient care. In the United States, this is not required in most institutions, allowing for different care models to be designed. For these reasons, the involvement of adult specialists, where available, is ideal for the well-being of young adults with CHD, as is true for young adults living with other chronic health conditions.

Transfer of care to an ACHD team need not preclude the ongoing involvement of a pediatric cardiologist in a young adult's care. Many ACHD programs include one or more pediatric cardiologists as part of the patient care team. The relative paucity of adult cardiologists trained in ACHD care and the expertise that pediatric cardiologists have with respect to the anatomy, physiology, and management of CHD means that the involvement of pediatric cardiologists in ACHD teams may be very appropriate. The interaction between pediatric cardiology and adult congenital cardiology remains crucial for optimal care of the patient in most institutions. Should a pediatric cardiologist continue to follow his/her patients into adulthood, this should happen in conjunction with allied health-care providers (e.g., nursing, pharmacy, social work, psychology) experienced in working with adult patients and in a setting that provides easy access to internal medicine specialties (e.g., adult nephrology).

Not only is transfer important from the perspective of providing quality patient care, it is

also important to many adolescents and young adults. Although data are mixed, with many young adults reluctant to leave the comfort of the familiar pediatric health-care setting [12], others indicate a lack of enthusiasm for continuing to share a waiting room with infants and toddlers [13], feeling that the experience of attending the pediatric cardiology clinic is something that they have "outgrown."

What Is Known from Empirical Data About Transfer?

Despite the rationale for transfer to ACHD programs, only ¾ of pediatric cardiology programs in Europe and North America transfer their patients to adult-focused care, and only ½ transfer their patients to formalized ACHD programs [14]. These data were published in 2009 and the situation may have improved in the interim. Nonetheless, it is clear that ACHD guidelines and review articles published before this 2009 study had not led many pediatric cardiology programs to adopt transfer of care [6, 15, 16].

A prerequisite of transferring adolescents to ACHD programs is that they are not lost to follow-up *before* reaching the age of transfer. Likewise, the process of transfer needs to be seamless from the patient's perspective in order to not discourage young adults from attending their first ACHD appointment. Unfortunately, loss to follow-up is a common problem in CHD and occurs both within the pediatric age range and during the transfer process. Reid and colleagues were the first to report on the scope of the problem of lost to follow-up [17]. Among 360 19–21-year-olds with moderate or complex CHD, only 47 % had attended an ACHD clinic [17]. This occurred in the context of a universal health-care system free of financial barriers to care. Mackie and colleagues demonstrated how increasing age within the pediatric age range is associated with a steady decline in attendance at pediatric cardiology clinics, with >20 % of youth with complex lesions lost to follow-up before age 18 [18]. Loss to follow-up was even more prevalent among subjects having less severe CHD but requiring periodic cardiology reassessment [18]. As a result, less than half of adults in Canada who require ACHD care are actually followed in an ACHD center, despite an ACHD network across the country [19]. This is likely to be an even greater problem in countries having 3rd-party payers (e.g., out-of-pocket payments), in which unemployed persons experience financial barriers to care. Risk factors for loss to follow-up include male gender [18], lower socioeconomic status, absence of chart documentation regarding the need for follow-up [17, 20], and fewer surgical interventions [17]. Interview data has identified several other factors that contribute to loss to follow-up, including a lack of awareness of the importance of follow-up and lack of an organized approach within some families to remembering appointments [20]. The presence of comorbid conditions, avoidance of risk-taking behaviors, and a history of attending pediatric cardiology appointments without a parent or sibling were however found to be associated with a successful transfer [17].

In order to bring about a change in practice among pediatric programs, outcome data among young adults for whom transfer of care has not gone well is needed. Among 52 adults in Denmark with CHD who sought and obtained cardiology care in response to an article in the lay press about loss to follow-up, 62 % had significant residual lesions and over 1/3 had symptoms [21]. Yeung and colleagues reported on 158 adults with moderate or complex CHD referred to an ACHD program in Colorado, of whom 99 (63 %) had a lapse in care >2 years since being seen in a pediatric cardiology clinic [22]. One third had been told there was no need for follow-up [22], despite guidelines to the contrary [23]. This lapse in care was associated with an increased risk of cardiac symptoms at presentation and with a threefold greater likelihood of needing a catheter or surgical intervention within 6 months of being seen at the adult care facility [22]. As important as these experiences are, more outcome data are needed with respect to transfer from pediatric to adult care and in particular to identify which clinical practices best promote successful transfer of care.

How to Transfer Patients with CHD?

Numerous guidelines, predominantly based on explorative and descriptive studies, emphasize the need to develop structured and flexible plans for the transfer of care from pediatric cardiology to an adult-focused care setting [2–4, 24]. These recommendations indicate that transfer of care, or the actual handing-off of the responsibility of care to the patient and a team of ACHD providers, should be part of a comprehensive transition program [2, 4]. The following key components for transfer of care have been recommended:

- The concept, objectives, and components of transfer to ACHD care should be introduced to the patient, the family, and other caregivers starting when the patient is about 12 years of age [3, 4, 25].
- There should be a flexible institutional policy on the timing of transfer of care [4]. This timing could be based on the chronological age of the patient (e.g., 16–18 years) [2, 3], the patient's level of developmental maturity [4], or an assessment of the patient's readiness to transfer [26]. The establishment of an institutional policy ensures that transfer does occur in the care process for the adolescent patient with CHD when needed [4].
- An obstacle to successful transfer is a lack of knowledge regarding the principles of transfer (and transition) in physicians [6]. In order to optimize the success rate of transfer, physicians should be informed about the need, objectives, and key elements of transfer [24, 27].
- The transfer of care should be organized as a coordinated process, creating a link between pediatric cardiology and a regional ACHD center [2, 3]. This process should include the development of a written transfer plan tailored to the needs of the patient with CHD [2–4]. Furthermore, this process can include an actual or virtual pre-transfer visit to the adult clinic giving the patient an opportunity to be introduced to the ACHD environment. Transfer should be managed by a coordinator, ideally located within both pediatric and adult cardiology. This role could be fulfilled by a clinic nurse, advanced practice nurse, or clinical nurse specialist [2]. Such a transfer coordinator assumes responsibility for guiding youth and their families through the transfer process, is readily contactable when problems arise, and serves as a liaison between pediatric and adult programs.
- The transfer should be made toward the recommended level of ACHD care based on an established algorithm for the initial evaluation and ongoing follow-up of adults with CHD [24]. It is recommended that every patient, irrespective of the level of complexity, should be seen by an ACHD specialist at least once after transfer of care from pediatric cardiology. During this initial post-transfer evaluation, a thorough clinical assessment of the patient is performed in order to undertake a risk stratification and decide on the advised setting, level, and frequency of future follow-up visits [24]. Hence, this initial visit to a regional ACHD center serves as a good opportunity to review patient's understanding about the heart lesion(s), anticipated prognosis including the possible need for interventions in the future, the risk of developing complications, and strategies to access adult health care, especially in urgent situations [3, 24].

The recommended levels of follow-up are as follows:

1. *Level 1 – Specialist care*: Care exclusively performed by specialized CHD cardiologists in regional ACHD clinics [3, 24] or at satellite centers. Satellite centers are regional hospitals in which a CHD cardiologist performs outpatient visits [28]. This level of care is indispensable for patients with complex cardiac conditions [3].
2. *Level 2 – Shared care*: Shared care is defined as care performed by a general cardiologist who sees patients with CHD in collaboration with and by sending reports to specialist centers [3, 28]. Patients with mild to moderate complexity lesions can be seen in shared care [3].
3. *Level 3 – Nonspecialist care*: Nonspecialist cardiac follow-up refers to care provided by a general adult cardiologist without any collaboration with an ACHD program, or care provided by a general practitioner or family

physician [3, 24, 28]. This level of care is appropriate for patients who are at low risk for developing new problems [3, 24]. These are typically mild heart defects. Access to specialized ACHD care must be possible if needed.

In terms of health policy-making, a balanced geographical distribution of the different levels of care is ideal. Indeed, long distances and the accompanying travel expenses may be an obstacle for some patients seeking appropriate follow-up care. Arrangement for satellite clinic visits to smaller communities by a CHD cardiologist is one way to bring care closer to patients.

- Beginning in childhood and adolescence, strategies should be explored to help patients with CHD obtain or maintain health insurance. The lack of adequate health insurance has been reported to be a barrier for patients to transfer to a specialized ACHD program [27].
- Transfer of care should only be performed during a period of medical stability [2] and after addressing any current medical or surgical issues [4]. For example, transfer should be avoided prior to planned surgical interventions.
- It is advised that transfer is preceded by an educational process in the clinical setting that prepares adolescents to assume increasing self-responsibility for their health care and allows adolescents to demonstrate that they have met these maturational milestones (see section on "Transition" below) [4].
- When the patient is transferred to an ACHD care center, the medical file of the patient, or at least a complete summary, should be transferred as well. This medical summary should include detailed information regarding the adolescent's previous cardiac diagnoses and interventions, including findings of most recent investigations (e.g., echocardiogram, Holter, exercise test), recent laboratory values, all operative and catheter reports, medications, and comorbidities. Ideally, the summary would also include any challenges related to adherence, education/vocation, or other psychosocial issues, patient knowledge of the anticipated prognosis of the condition, and any history of end-of-life discussions [4, 24]. This information should be provided to the patient and the ACHD team [2–4]. Furthermore, an accompanying letter of transfer should be sent to the ACHD team [4], including an explicit recommendation to the ACHD team about the appropriate follow-up (e.g., timing of first ACHD appointment, diagnostic tests to occur at this appointment).
- After the transfer of care to an adult-focused facility, an ongoing consultation with the referring pediatric cardiologist(s) should be maintained as needed [2].
- Regular reevaluation should be made of the successes and ongoing challenges encountered locally as they relate to transfer of care, in conjunction with members of the pediatric and adult CHD teams.

How to Measure the Success of Transfer?

Continuation of cardiac follow-up is a major endpoint for successful transfer. For patients with complex CHD, this follow-up ideally takes place in a specialized ACHD center [3]. Patients with moderate complexity lesions should be followed either in specialized ACHD centers or in shared care [3]. On the other hand, for patients with mild CHD, follow-up in a nonspecialized setting would be sufficient [3]. Hence, an evaluation of the appropriate level of care, or at least the minimal level of care, would provide critical information on the success of transfer. Previous studies have used this strategy to define successful transfer. For instance, Reid and coworkers defined successful transfer as at least one appointment at a specialized ACHD center for whatever reason, in patients with moderate or complex heart defects [17]. Goossens and colleagues noted patients as being in appropriate follow-up if they received follow-up in a setting that met at least the minimum level of care [28].

Assessing post-transfer retention in appropriate cardiology care is another indicator of successful transfer. Indeed, adult patients can be

considered to have a lapse of care if they are absent from appropriate cardiology care for a specified period of time (e.g., >2 years for moderate complexity lesions, >1 year for complex defects) at any age [20, 22, 23]. For example, transfer may be considered to be unsuccessful for patients with moderate complexity defects who attend their first ACHD clinic appointment 3 years after discharge from pediatric care (perhaps attending only after experiencing a medical crisis) or who attend their initial visit but are then absent from care for several years [17].

What Is Not Yet Known?

Irrespective of the current insights, there remain blind spots in the body of knowledge regarding transfer of individuals with CHD. These issues should be put on the research agenda. First, although it is recommended to assess the patient's readiness to transfer, limited evidence exists on how to appropriately assess readiness [26]. Evaluation of developmental maturity, self-management skills, and self-efficacy is essential [26]. Furthermore, predictors of transfer readiness should be identified. This could aid transition coordinators with individualizing the preparation and timing for transfer of care [26].

Second, studies on loss to follow-up have only investigated clinical patient characteristics and provider factors, but all these predictors were measured at the level of the individual patient [17, 18, 20, 28, 29]. However, factors related to care providers, the organization of care within an institution, and the health-care system have an important impact on continuity of care [20, 28]. Health-care system and organizational factors have yet to be systematically evaluated and addressed.

Third, studies on the prevalence and correlates of discontinuation of cardiac care in adolescents with CHD have only been undertaken among patients without developmental or cognitive disorders. Future research should expand the study populations to include patients with neurodevelopmental disorders.

Transition

Why Is Transition Important?

When working with "adolescents with CHD," it is likely more natural for health-care providers to focus on the "with CHD" qualifier and pay minimal attention to the "adolescent" role. From developmental and psychological perspectives, however, adolescents are quite different from children and adults and represent a distinct group that warrants one's attention and respect. Regardless of the presence of a chronic medical condition, a number of changes occur in adolescence, including those related to cognition, emotions, sexuality, and identity [30, 31]. As individuals progress through early, mid-, and late adolescence, they move from concrete thinking to more complex abstract thinking and transition toward social autonomy [31]. Significant social development occurs in adolescence [32, 33].

Health-care transition does not occur in isolation and should be considered within the broader context of other transitions common to adolescence and young adulthood, including education, employment, and romantic relationships. There are distinct life-span developmental tasks that occur during adolescence and others that take place during young adulthood [2]. For example, adolescent tasks include setting educational and vocational goals, whereas typical tasks during adulthood include obtaining and maintaining employment. With regard to social and family relations, peers play a prominent role for adolescents, while the selection of life partners and reproductive issues become more prominent in adulthood. These patterns are present for most individuals, irrespective of the presence of CHD. Transitioning adolescents and young adults with CHD, however, might benefit from additional supports because individuals with pediatric-onset chronic medical conditions, as a group, are known to achieve fewer developmental milestones (e.g., autonomy, psychosexual development, social development) or achieve them at a later age than healthy peers [34, 35].

Identity formation is another important developmental process during adolescence. A longitudinal study of adolescents revealed that, over time, they generally undertake more in-depth exploration and develop more stable identities [36]. Luyckx and colleagues compared 429 adolescents (aged 14–18 years) with CHD with 403 matched controls in order to investigate the extent to which adolescents with CHD succeed in forming a personal identity [37]. These researchers concluded that adolescents with CHD were, in general, quite similar to healthy peers in terms of identity formation. Among adolescents with CHD, identity issues were largely unrelated to demographic or medical variables but varied according to symptoms of depression, loneliness, quality of life, and perceived health status. Thus, the educational and counseling focus of transition must not be limited to physical health issues and should also target psychosocial variables (e.g., mood, social functioning) in order to promote individual well-being and successful identity formation. In addition, given that approximately 10 % of the adolescents in the aforementioned study had a problematic identity status, it was recommended that health providers be sensitive to a patient's difficulty considering future plans [37].

Mid-adolescence is the stage in which people are typically most likely to challenge authority and take risks [31, 38]. Risk-taking increases between childhood and adolescence and subsequently decreases between adolescence and adulthood [38]. Adolescents take risks partially to establish peer acceptance and autonomy [39]. Egocentric thinking and the sense of invincibility ("it won't happen to me") are strongest during adolescence [40]. Although understandable from a developmental perspective, risk-taking clearly poses additional risks for adolescents with chronic health conditions. Risky health behaviors are certainly not uncommon among adolescents with CHD, with over one-quarter reporting cigarette smoking, binge drinking, or marijuana or illicit drug use in a 30-day recall period [41]. Further, many adolescents and young adults with CHD have overly optimistic expectations regarding their life expectancy [42]. Although risk-taking is understandable from a developmental perspective, during the transition process, parents and health-care providers can support adolescents with CHD to help them mature and develop effective long-term health behaviors. Positive personal relationships and having personal goals might also serve as protective factors to lessen involvement in risky behaviors [40].

Communication with adolescents during the time of transition can be challenging for many health-care professionals [31, 43]. For example, it has been observed that they are often late for appointments, are reluctant to talk, and may even be rude and/or defiant [43]. Such behaviors, as frustrating as may be, are certainly not atypical for teenagers. It is therefore important that health-care providers avoid an exclusive focus on disease management and address developmental concerns (e.g., social acceptance, autonomy) and risk behaviors [39]. Adolescent patients can be supported as they learn to answer and ask questions with their health-care providers and are therefore encouraged to meet with their providers independently for at least a portion of their clinic visit [44]. It is important for providers to communicate in a developmentally appropriate manner (e.g., by using more concrete language with younger adolescents). Given that individuals mature and develop at varying rates, however, the timing of transition initiatives should be guided by emotional maturity and developmental level rather than an individual's chronological age [4].

The needs of transitioning patients do not end at the time of transfer (around the age of 18). "Emerging adults" is a term used to describe individuals between the ages of 18 and 25 years who sense that they have left adolescence but have not yet reached complete adulthood [45]. For emerging adults, it is not the achievement of demographic milestones (e.g., school graduation, marriage) that confers becoming an adult. Rather, they associate the process of reaching full adulthood with accepting responsibility for themselves and making independent decisions [45]. Brain imaging techniques reveal that the brain continues to mature through the early twenties [46, 47]. One of the last regions of the brain to mature is the dorsal lateral prefrontal cortex,

which is responsible for controlling impulses and weighing consequences [47]. Therefore, health professionals working in the ACHD setting should be mindful that patients who have transferred to adult care are undergoing a continued process of brain maturation and might benefit from extended education and support regarding making independent decisions.

What Is Known from Empirical Data About Transition?

Despite consistent recommendations for comprehensive transition programs [4, 6, 27, 48], currently there are minimal empirical data regarding the transition of adolescents and young adults with CHD. As pointed out above, ¾ of American and European pediatric cardiology programs reported that they transfer patients from pediatric to adult care at an average age of 18 years [14]. Of those that transfer patients to adult care providers, less than 1/3 reported that they provide structured preparation for patients and family [14]. Therefore, there is clear discordance between recommendations for a structured approach to transition and what is currently being provided in CHD programs.

Two qualitative studies shed light on the perspectives of patients and parents regarding transition. Moons and colleagues conducted semi-structured, in-depth interviews with 14 Belgian adolescents with CHD between the ages of 15 and 17 years [12]. Although the focus was the adolescents' perspectives on transferring from pediatric to adult cardiac programs, the themes that emerged are relevant to the overall concept of transition. Adolescents considered the departure from pediatric cardiology to be a normal experience, such that they were ready to leave the pediatric setting, but also acknowledged the challenge with leaving familiar surroundings. They generally held a calm and positive wait-and-see attitude toward the ACHD program and recognized that it might take time to adjust to the new environment. Adolescents who had already had a visit in the ACHD clinic indicated that better information about the adult clinic, such as whether parents could be present during medical appointments, would have been helpful. Finally, and most relevant to the transition process, adolescents recognized the important shift in roles between adolescents and parents, such that it was time for adolescents to become more knowledgeable about their heart condition.

Clarizia and colleagues conducted semi-structured interviews with 23 Canadian patients with CHD (aged 9–18) and 22 of their parents regarding attitudes and opinions about transition and its preparation [49]. Eight patients (36 %) and 19 parents (86 %) had an accurate understanding about who would be responsible for the patients' care following their 18th birthday (which is the mandatory age of transfer to adult hospitals in Ontario, Canada). Nine parents (41 %) reported general concerns regarding their children leaving the pediatric hospital, and 11/20 parents (55 %) thought that their children would be ready to take complete responsibility for their health care at the age of 18. As part of this study, a 6-item survey was also administered to 45 health-care providers. Thirty-two providers (72 %) thought that adolescents were ready to begin learning about the transition process between the ages of 13 and 16, 7 (17 %) thought it should occur sooner, and 6 (14 %) thought it should occur later. The most common provider-endorsed barriers to successful transition to adult care were lack of self-advocacy, adolescents having limited understanding of their conditions, lack of structure in the local transition program, parental reluctance to transition, and lack of time during clinic appointments to address all issues.

How to Transition Patients with CHD?

The objective of a transition program is to give the adolescent with a chronic disease the time and possibility to develop a set of skills, attitudes, and behaviors needed to prepare for, more specifically, transfer of care to an adult-focused program, and, more generally, for adult life [4, 8]. A transition program should support patients in accomplishing skills related to decision-making,

self-advocacy, and self-efficacy [26]. Transitional care should result in uninterrupted, patient-centered, age, and developmentally appropriate and flexible though comprehensive care. Ultimately, the implementation of a transition program should result in the optimization of the everyday functioning of the adolescent, satisfaction with life, and future productivity in adult life [4, 11].

In 2011, recommendations about managing the transition to adulthood of adolescents with CHD were published by the American Heart Association [4]. This comprehensive document recommends a formal transition process to prepare teenagers and young adults with CHD to become responsible for their health care in order to achieve optimal quantity and quality of life. This process can be subdivided into three consecutive phases: pre-transition, transition, and transfer [4].

Pre-transition

The pre-transition phase should be seen as an introduction phase established in pediatric cardiology. The purpose of this first phase is to introduce and explain the objectives and key elements of transition and transfer early in childhood. At a young age, it is appropriate to raise the awareness of the patient and his/her family about the implications of the heart lesion(s), the need for lifelong specialized follow-up, and the importance of maintaining a heart-healthy lifestyle. Additional attention should be given to the role of the parent or other caregivers. This introductory phase provides parents the opportunity to gradually adapt to the growing independence of their children [4]. It also helps parents to expect that patients will eventually be transferred to adult-focused cardiology care.

An early introduction on transfer and transition, combined with a repeated discussion of these issues, is a tool to increase the patients' readiness to take responsibility for health in adult life [26].

Transition

Although empirical data identifying effective components of a transition program are scarce [50, 51], some aspects are generally accepted as key elements:

- A transition program should be flexible with respect to timing and should be adapted to the medical, developmental, cognitive, and psychosocial status of the patient [3, 4, 52].
- In order to support the development of a trusted relationship between the patient, the family, and the ACHD team, it is recommended to include both pediatric and adult CHD cardiologists in the development and implementation of a transition program [3].
- The identification of a transition "coordinator" or "champion" is also recommended [15, 53]. This transition coordinator is an expert in educating, counseling, assessing, and coaching the patient with CHD and is the primary contact for patients, families, and providers regarding the transition process. This key role could be assigned to a nurse specialist, advanced practice nurse, or nurse practitioner who is able to function with both the pediatric and adult care program [2, 3, 54]. In reality, however, transition requires commitment and support from all providers who come into contact with patients and families.
- In order to guarantee age- and developmentally appropriate lifelong continuity of care, close collaboration and involvement of a primary care provider is mandatory in transitioning adolescents with CHD [2, 3].
- The provision of a transition program can be facilitated through the development of transition clinics. These clinics can be organized in two different ways. First, joint clinics could be organized in which outpatient visits are performed by the pediatric and adult congenital cardiologist simultaneously. Second, in case of limited availability of staff, clinic time, and space, the formal transition clinic can be provided in either pediatric or adult cardiology [53].
- In order to ascertain that the transition process is coordinated, systematic, and well organized, the development of a written transition plan is recommended. This plan should be based on the input of the patient, his/her parents, and the interdisciplinary team of healthcare providers [15]. Such a transition plan

should be established in early adolescence, preferably before the patient reaches the age of 14 years [48].

- Comprehensive transition programs require administrative support. Furthermore, management links between all health services included in the transition process should be established, and a detailed plan concerning financial and logistical issues should be developed with sufficient institutional support [2, 3, 48, 53]. The development and implementation of a formal policy on transfer and transition could improve the success of a transition program. By establishing such an institutional policy, the chance that every adolescent with CHD can participate in a transition process is increased [6, 27].

A transition program can be developed around three components: (i) education and skills development, (ii) counseling, and (iii) assessment of readiness.

(i) *Education and skills development*: Most recommendations for formal transition programs include a set of developmental tasks to be achieved by adolescents approaching adulthood [4]. An important component of this program is a comprehensive educational curriculum for patients and parents regarding the condition, treatment, preventive measures, and lifestyle matters [4] (see Table 145.1).

A second component of the educational curriculum is the development of self-management skills to enable patients to gradually assume responsibility for their health and health care (see Table 145.2).

(ii) *Counseling*: Patient education often implies a one-directional input, from health-care worker to patient. Counseling, on the other hand, involves a reciprocal relationship. Counseling is defined by the American Counseling Association as "a professional relationship that empowers diverse individuals, families and groups to accomplish mental health, wellness, education and career goals." Shared decision-making is a critical element in this respect. It is the process in which decisions are made by both the patient and his or her health-care providers, informed by the best evidence available, and weighted according to the specific characteristics and values of the patient.

Examples of issues appropriate for counseling include education and employment; disclosing the heart defect to any future

Table 145.1 Educational topics to be included in a transition curriculum [12–14, 16]

Name, description, and anatomy of the heart defect(s)
Diagnostic and therapeutic interventions performed in the past or potentially needed in the future
Medication regimen including the rationale for medications, importance of adherence, potential side effects, and interactions with other drugs, alcohol, illicit drugs, and tobacco
Risk for development of complications (e.g., arrhythmias) and possible preventive measures (if any)
Sign and symptoms of complications or deterioration which would need medical assessment
Definition, signs, symptoms, recurrence rate, prophylaxis, and primary prevention strategies of endocarditis [55]
The potential impact of the heart condition on daily functioning, educational and vocational choices, life expectancy, etc.
The need for follow-up, the advised frequency of visits, and the type of setting and provider most appropriate to perform this follow-up
Healthy lifestyle issues, including nutrition, physical activity, and the importance of avoiding tobacco, illicit drugs, and excessive alcohol
Heart-healthy sexual behaviors, including safe and effective contraception and the prevention of sexually transmitted diseases
Maternal and fetal risk of pregnancy, recurrence rates of heart defect(s), importance of prepregnancy counseling, family planning
Precautions when travelling; how to seek medical care when travelling abroad

Table 145.2 Self-management skills to be included in the transition curriculum [2–4, 6]

Schedule own medical appointments
Coordinate prescription renewals
Be actively engaged in open communication with health providers during outpatient visits; be able to discuss topics of concerns with providers independently from parents
Know how to obtain and maintain health-care and life insurance

employer and colleagues; and sexuality, pregnancy, and family planning [4]. Counseling, however, should take potential neurodevelopmental disorders into account. Indeed, some patients may have attention deficits or learning difficulties, which hampers the retention of information and decision-making skills [4]. For these patients, repeated information and the provision of portable, written medical information can be especially important.

As many patients with CHD experience challenges living with a lifelong cardiac condition, special attention should be given to the psychosocial well-being of the patient. Previously reported studies showed that adult patients with CHD have an elevated risk of anxiety and mood disorders, which are often neglected by health providers and rarely receive specialized mental treatment [56, 57]. In order to provide holistic transitional care to patients, it is mandatory to assess the psychosocial well-being of the patient in a systematic way. Kovacs and colleagues found that 50 % of adults with CHD are interested in receiving supportive psychological treatment which can help them learn to cope with their condition, to deal with stress, anxiety, and mood disorders [58].

(iii) *Assessment of readiness*: At the end of the transition phase, patients' readiness to function as an emerging adult should be assessed. This includes evaluating whether an adolescent can meet the expectations of society and the adult health system before formally transferring care to an ACHD program [4]. It is generally assumed that patients should be capable of planning their own checkups; be responsible for adhering to the prescribed medication regimen and health behaviors; be able to recognize signs and symptoms; and understand the nature, prognosis, and implications of their condition [4]. Assessing the level of self-management and self-efficacy of adolescents with regard to their care is mandatory in order to evaluate the patient's readiness to transfer care [8, 26, 59]. If the assessment of readiness reveals that an adolescent has not achieved crucial developmental tasks, the option, if available, to delay transfer should be considered. If this option is not available, this information should be conveyed to the adult team in order to facilitate ongoing education and self-management skills development [26].

Transfer

The issue of transferring patients from pediatric care to ACHD programs has been extensively described earlier in this chapter. Transfer to adult care is recommended only if the patient is medically stable and well prepared for transfer [2, 25].

Patient education and counseling should not end following transfer to adult care. In fact, this can be a useful time to reassess knowledge and areas in need of improvement. Comprehensive educational curricula will include contraception and family planning considerations [6, 48], and while these issues should be introduced in adolescence, such concerns might become more prominent for patients in the adult setting. The importance of lifelong cardiac surveillance should also be continually reviewed.

How to Measure the Success of Transition?

The success of transition can be assessed by evaluating specific patient outcomes. Four broad categories of outcomes that reflect successful transition can be measured: behavioral/self-management, cognitive, developmental, and emotional/psychosocial. Examples of behavioral/self-management outcomes include adopting a heart-healthy lifestyle (refraining from smoking, binge drinking, and illicit drug use), adherence with prescribed pharmacological and non-pharmacological regimens, and demonstrating shared decision-making skills (e.g., self-advocacy and self-efficacy). Long-term self-management outcomes include vocational choices, insurance coverage, and productivity in adult life. One example of a self-report measure for behavioral

issues is the Health Behavior Scale – Congenital Heart Disease (HBS-CHD) [60].

The cognitive outcomes of transition include the knowledge and understanding that patients have about their condition, treatment, and preventive measures. Patients' knowledge can be measured using the Leuven Knowledge Questionnaire for Congenital Heart Disease (LKQCHD) [61] or the Knowledge Scale for Adults with Congenitally Malformed Hearts (KnoCoMH) [62].

Developmental outcomes pertain to an adequate identity formation, a growing independence from their parents, and good peer relationships. Identity can be assessed using the Dimensions of Identity Development Scale (DIDS) [63], and relations with peers may be evaluated using the Inventory of Parent and Peer Attachment (IPPA) [64].

Emotional outcomes can be measured in terms of specific psychosocial issues, such as anxiety and depression, but also in terms of more general aspects, like satisfaction with life or general well-being. The Hospital Anxiety and Depression Scale [65] and the Satisfaction with Life Scale [66] are useful instruments in this respect.

What Is Not Yet Known About Transitional Care in Patients with CHD?

Although there is a general consensus regarding the importance of transitional care in patients with a chronic condition such as CHD, empirical studies investigating the effectiveness of transition interventions and programs are currently lacking. Hence, there is an urgent need for controlled (quasi-) experimental studies in this field. Such studies are needed to scientifically underpin existing recommendations and guidelines [67]. It comes as no surprise that transfer and transition were rated among the top five nursing research priorities in ACHD [67]. More specifically, the priority is research that identifies core elements, outcomes, and benefits for patients, parents, and providers of a transition program. Furthermore, Deanfield and colleagues recommended studies examining the interplay between the type of heart lesions, the level and type of follow-up, the emotional status of the patient, and the psychosocial health and performance of adults with CHD [3].

Education and counseling are critical elements of transition. Previous studies have shown that patients with CHD, irrespective of their age, have significant gaps in their knowledge of their heart defect, treatment, lifestyle, and expected prognosis [68, 69]. It is, however, not yet known to what extent an improvement in knowledge and understanding will impact clinical outcomes. Therefore, the effectiveness of different educational and counseling strategies and their impact on patient outcomes should be further evaluated.

Lessons Learned from Other Conditions

Over the past few decades, the number of publications on transfer and transition in adolescents with chronic health conditions has increased significantly [70]. The majority of these articles support the need for systematic development, implementation, and evaluation of the key elements of transfer and transition. Unfortunately, the methodological rigor of these publications is very limited. More than 60 % of the papers found in Medline were expert opinions, consensus statements, and case studies, which ought to be categorized as nonempirical work [70]. The remaining 40 % of articles represent empirical studies, the majority of which were descriptive, observational studies in patients with disabilities and special health-care needs, endocrine disorders, asthma, or cystic fibrosis.

To date, the number of publications with a high level of evidence, such as meta-analyses, systematic reviews, and experimental designs, is very scarce. To date, four systematic and ten narrative reviews were indexed in Medline (in 2011) about transfer and transition in adolescents with chronic disease [71–84]. These reviews, however, were not able to clearly identify best practices on transfer and transition due to the lack of primary empirical studies [27, 85]. However, common themes in these reviews were found, predominantly regarding the timing of transfer,

the transition readiness, and the importance of structured education of adolescents regarding their condition and lifestyle choices [27].

A systematic review by Crowley and colleagues revealed that three types of interventions have been described in the literature [85]. First, most studies focused on interventions targeting the patient, such as educational programs and the improvement of self-management skills. Second, some studies implemented interventions targeting staff; these interventions primarily focused on transition coordinators. Third, some studies have addressed service delivery (e.g., joint clinics, telephone support) and access to health care [85]. This review also concluded that the implementation of patient education programs, joint clinics, or specific young adult clinics could be supported based on preliminary promising test results. Enhanced follow-up, the availability of out-of-office-hours telephone support, and the appointment of a transition coordinator were components of "successful" transition. However, one has to bear in mind that the level of evidence supporting these components is fairly low [85]. Moreover, most of the published studies were conducted in patients with type 1 diabetes, limiting transferability of study findings.

Conclusion

The majority of patients with CHD require lifelong specialized care, and, as such, transitional care has received increasing attention over the past decade. As adolescents mature, their care should be transferred from pediatric care to programs that are adapted to care for adults, where available. Transfer and transition are concepts that are often used interchangeably. However, they represent distinct entities. Transfer refers to the move of care from pediatric to an adult healthcare environment. Transition, on the other hand, can be seen as "*the process by which adolescents and young adults with chronic childhood illnesses are prepared to take charge of their lives and their health in adulthood*."

The transfer of patients to adult-focused programs facilitates the provision of care in an environment that is developmentally appropriate and by providers familiar with adult-onset comorbid conditions. Strategies to implement or improve the transfer of patients include the development of institutional policies on transferring patients, making written transfer plans, formally transferring information from pediatric cardiologists to adult CHD providers, employing transfer coordinators, and transferring patients to the recommended level of care.

As transition is linked with the shift from a dependent child toward an independent adult, transitional care must acknowledge the developmental milestones associated with adolescence and young adulthood. In this phase of life, patients are learning how to integrate their medical condition with their identity and lifestyle. Three phases in this process are recognized: pretransition, transition, and transfer. Transition should be adapted to the medical, developmental, cognitive, and psychosocial situation of the patient. Transition as a health-care intervention ought to start in pediatric cardiology, but continue once in adult CHD care. While outcome data are lacking, transition clinics, transition coordinators, and written transition plans are recommended components of transition programs. Administrative support and a formal transition policy are also indispensable. It is anticipated that a comprehensive and collaborative approach to transfer and transition will help young people with CHD live the longest and most fulfilling lives possible.

Aortopathy in Adults with Congenital Heart Disease

146

Ali N. Zaidi, W. Aaron Kay, and Curt J. Daniels

Abstract

Over the past two decades, there has been an increasing body of data that has acknowledged the progressive nature of aortic dilation in adult patients with congenital heart disease. Aortic disease can have overwhelming effects on affected individuals, resulting in severe morbidities including aneurysms, tears, dissections, and aortic valve regurgitation secondary to annular dilation. Several explanations have been provided for this rising paradigm of aortic disease including the incremental number of adult survivors with moderate and complex forms of congenital heart defects, along with an associated improvement in diagnostic cardiovascular imaging modalities like cardiac magnetic resonance and computed tomographic angiography. Although the natural history of aortic root dilation in patients with connective tissue disorders like Marfan syndrome has previously been described, the natural history of the aorta in adult congenital heart disease remains poorly assessed. This review describes the presence of "aortopathies" in adults with the more common congenital heart defects including bicuspid aortic valve, repaired Tetralogy of Fallot, conotruncal lesions, and patients with single ventricular physiology after Fontan palliation.

Introduction

The aorta is the main trunk of a series of vessels which convey oxygenated blood to the tissues of the body. It commences at the superior part of the left ventricle, where in adults it measures about 3 cm in diameter. It then continues to ascend for a short distance, arches backward and to the left, over the root of the left lung, then descends within the thoracic cavity on the left side of the vertebral column, and continues into the abdominal cavity through the aortic hiatus in the diaphragm. Hence, it is described in several portions, namely, the ascending aorta, the arch of the aorta, and the descending aorta, which last is again divided into the (a) thoracic (above the diaphragm) and (b) abdominal aorta (below the diaphragm).

As with all other arteries, the aorta is made up of three layers: the *tunica intima* (composed mainly of endothelial cells), the *tunica media* (a muscular middle layer containing smooth muscle cells and elastic fibers), and the *tunica adventitia* (an outer layer of connective tissue). The aortic *tunica media* consists of smooth muscle and an extracellular matrix that is composed of ground substance, in which elastic fibers and collagen are embedded in a hydrated gel, allowing it to be a large elastic artery with inherent distensible properties.

Although the main function of the aorta is transporting oxygenated blood from the heart to the rest of the body, of equal importance is its capacity to distend and recoil in response to pulsatile flow, thereby reducing left ventricular afterload and facilitating diastolic perfusion of the coronary arteries [1]. The combination of smooth muscle cells (determining vasodilation and vasoconstriction), collagen (key for strength of the aortic wall), and elastin (permitting distension and recoil) within the walls of the aorta allows the aorta to maintain pulsatility and pressure across the entire circulation [2]. With advancing age, the aortic wall structure undergoes unfavorable changes, exacerbated by secondary effects due to adverse cardiovascular risk factors like systemic arterial hypertension, atherosclerosis, smoking, hypercholesterolemia, and diabetes, resulting in a decline in aortic elasticity and an increase in aortic circumference leading to aortic aneurysmal formation [2].

There is a growing body of data documenting progressive aortic dilation in patients with both repaired and unrepaired congenital cardiac defects [3, 4]. Several explanations might account for the increased incidence of aortopathy in adult congenital heart disease (ACHD), including a growing number of patients with congenital cardiac defects surviving into adulthood, along with improvements in cardiac imaging modalities, which provide unlimited and accurate assessment of aortic caliber, cardiac anatomy, and function in patients with congenital heart disease (CHD) [5].

As the life expectancy of CHD patients continues to improve, cardiologists will continue to be tested with the challenge of associated aortic sequelae like aneurysmal dilation, risk for aortic dissection, deteriorating aortic valvular disease, or progressive ventricular dysfunction. Although the natural history of aortic dilation (AD) has

been very well documented in certain genetic disorders, namely, Marfan syndrome [6], the expected course and functional significance of aortopathy in patients with structural forms of CHD remains less well defined [7].

A growing number of ACHD patients will go on to develop progressive AD and may be prone to associated complications including aortic valve insufficiency and aortic dissection or rupture; however, the risk of these complications in any individual patient with underlying CHD remains unknown. This chapter will review several congenital heart defects that are associated with aortopathies and will be divided into the following categories: (1) aortopathy associated with congenital BAV and coarctation of the aorta (CoA), (2) conotruncal lesions (TOF), transposition of the great arteries (TGA), double outlet right ventricle (DORV), interruption of the aorta, and truncus arteriosus (TA), and (3) patients with single-ventricle lesions after the Fontan palliation.

Bicuspid Aortic Valve

The congenitally bicuspid aortic valve (BAV) is the most common congenital malformation, occurring in approximately 2 % of the general population [8]. It is the most common cause of isolated valvular aortic stenosis in adults, with a male to female ratio of 3:1 [9]. Although the majority of cardiac events in BAV are due to valve dysfunction, there is a recognized increased prevalence of AD and aortic dissection (Fig. 146.1a–c). It is still unclear why patients with BAV may have a related aortopathy, aside from having specific associations with structural forms of CHD like CoA and an interrupted aortic arch, which has given rise to consideration of a common underlying aortopathy that may exist in patent with a BAV [10]. There is a five to tenfold increase in the incidence of aortic dissection in patients with BAV (when compared to patients with trileaflet aortic valves) without concomitant aortic stenosis, aortic coarctation, or systemic hypertension [11]. Warren et al. in children and Hahn et al. in adults showed that the aortic root was enlarged in patients with a BAV without aortic stenosis as compared to age- and sex-matched controls [12, 13].

It is also postulated that increased risk of aortic disease in patients with BAV (including normally functioning aortic valves) is mediated by coexisting defects in the aortic media by fragmentation of elastin, loss of smooth muscle cells, and increase in collagen [14, 15]. In acute aortic dissection, the underlying cause in approximately 15 % of patients was BAV, which is a higher proportion than those described with Marfan disease. In a study of 2,000 patients undergoing aortic valve surgery for BAV, 20 % required surgery for an ascending aortic aneurysm [16, 17]. These associations have led to the theory that congenital abnormalities of the aortic valve and the aorta may reflect a common developmental defect. The current understanding of the genetic basis of BAV has been improving and may be useful at preventing thoracic aortic complications in relatives of patients with known BAV. Patients with BAV can also have relatives with similar findings, thought to be transmitted as an autosomal dominant condition, with some affected relatives developing a thoracic aortic aneurysm despite the absence of a BAV [18]. With the current knowledge of the genetic basis of BAV, current guidelines recommend screening first-degree relatives of patients with BAV, or those with premature thoracic aortic disease (without significant known risk factors) to evaluate for the presence of a BAV [19]. It is also recommended that patients with BAV have both the aortic root and the ascending thoracic aorta evaluated for evidence of AD [16, 17, 20]. The ascending aorta should be imaged annually once the maximum diameter reaches 4.0 cm or more often depending on the progression of the aortic root [19]. Although the incidence of aortic dissection in BAV is nearly ninefold that of the general population, the overall incidence of aortic dissection in BAV is still low, given the large population with BAV.

Though still a subject of debate, surgery has been recommended to repair the aortic root or replace the ascending aorta in patients with BAV if the (a) diameter of the aortic root or

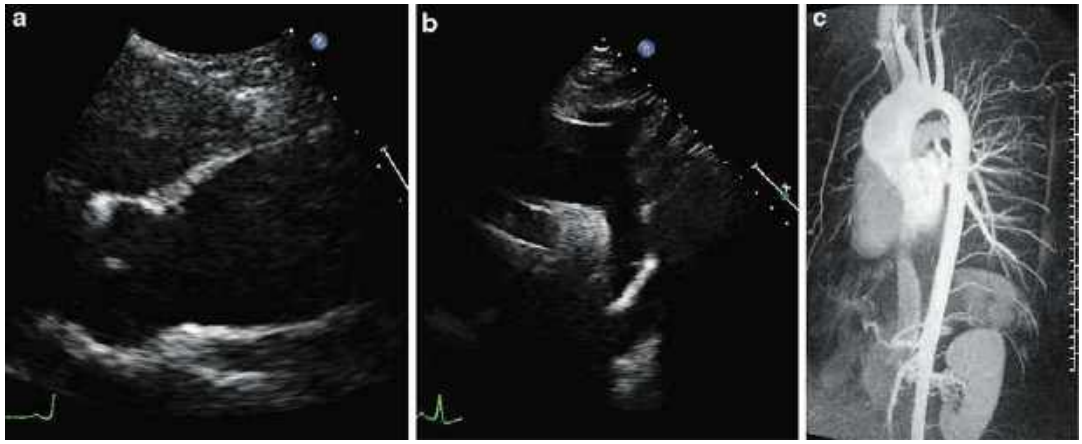

Fig. 146.1 A 20-year-old asymptomatic man with a BAV and an aneurysmal aortic root. (**a**) TTE PSLA view with aneurysmal dilation distal to the ST junction. (**b**) TTE suprasternal view with a dilated proximal transverse arch. (**c**) Cardiac magnetic resonance angiogram (MRA) showing the entire aorta. The maximum dimension of the ascending aorta was 5.1 cm

ascending aorta is greater than 5.0 cm, (b) if the rate of increase in diameter is 0.5 cm per year or more, or (c) if patients are undergoing aortic valve replacement (AVR) due to severe aortic stenosis or aortic regurgitation, with the diameter of the aortic root or ascending aorta being greater than 4.5 cm [21–23]. More recent studies have shown an acceptably low mortality rate for AVR when combined with ascending aorta repair in patients with BAV. Borger et al. found the 15-year freedom from aortic root complications (replacement, dissection) following AVR was 86 %, 81 %, and 43 % for aortic diameters of <40 mm, 41–44 mm, and >45 mm, respectively, at the time of AVR [23]. The decision of when to intervene with an elective surgery in an asymptomatic patient with a BAV and AD to prevent a potentially devastating dissection also depends on the patient's age, sex, and size, as well as other comorbidities and likelihood of surviving surgery. There is now a growing proportion of women reaching reproductive age with a BAV and associated AD. Such women with an aorta reaching 4.5 cm should be clearly counseled about the risks associated with pregnancy in the presence of AD [19].

With meticulous attention to best practice guidelines and close long-term follow-up with appropriate usage of imaging modalities to screen for aortic dilation and its complications, the long-term prognosis for patients with BAV is excellent and approaches an average life expectancy of 70 years [22].

Coarctation of the Aorta

Coarctation of the aorta (CoA) accounts for 5–10 % of all CHD and is associated with significant morbidity and mortality even after surgical repair. The prognosis of untreated coarctation is dismal, with 80 % dying prematurely from complications, including mortality from aortic dissection or rupture, heart failure, and intracranial hemorrhage [22]. Fortunately, most are treated in childhood and native CoA rarely presents in adulthood. Typically, the adult patient presents for routine follow-up after surgical palliation. Unfortunately, despite adequate surgical repairs, patients are at risk for several concerning long-term complications including systemic hypertension, re-coarctation (Fig. 146.2), aortic aneurysms (Figs. 146.3 and 146.4) and pseudoaneurysms, aortic dissection, sudden cardiac death, and patient-graft discrepancy from prior repairs [22]. A long-term follow-up study of patients repaired in childhood or adolescence demonstrated a significantly reduced

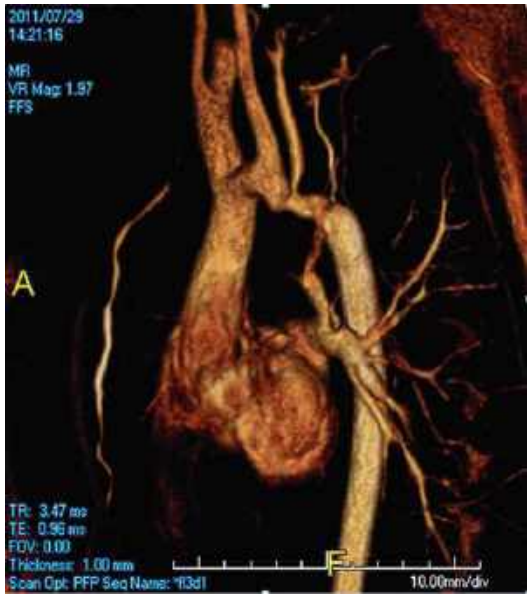

Fig. 146.2 A 50-year-old woman with CoA after surgical repair with a 12 mm Dacron tube graft at the level of the left subclavian artery. Three-dimensional volume-rendered MRA with evidence of re-coarctation just distal to left subclavian artery at the site of prior surgical repair

Fig. 146.3 A three-dimensional volume-rendered magnetic resonance angiogram (MRA) showing a large descending aortic aneurysm at the site of prior surgical repair in a 36-year-old woman with CoA. Maximum dimension was 4.8 cm with no evidence of aortic dissection noted

long-term survival with a mean age of death of approximately 38 years of age [24].

A variety of surgical options have been used over the past few decades and have continued to change over time. Treatments have included subclavian artery patch aortoplasty, patch aortoplasty, bypass of the coarctation segment with a graft, and tube-graft replacement. Endovascular techniques, such as balloon dilation and stent placement, including covered stent placement, have been used successfully and have become a less invasive alternative to open surgical procedures [25]. The type of palliation determines in large part the risks of re-coarctation and other complications.

An understanding of the underlying aortopathy in CoA will hopefully improve the long-term treatment and prognosis of patients with this pathology. Histologic abnormalities in the aortic wall with reduced elastic properties proximal and distal to the site of coarctation are evidence that CoA is a systemic vascular disease and not simply a narrowing of a discrete segment of the aorta. The presence of concomitant BAV in up to 85 % of coarctation patients and the strong histological similarity of aortic wall abnormalities between both entities are also suggestive of an inherited origin of aortic wall pathology [2].

Despite successful re-anastomosis of the aortic segments proximal and distal to the coarcted segment, long-term complications include persistent hypertension, re-coarctation, aortic dilation, aortic aneurysm, and aortic dissection or rupture [26]. Several factors have been identified as contributing to the development of hypertension, including the loss of aortic distensibility leading to a "functional" re-coarctation [27]. Patients with long-standing

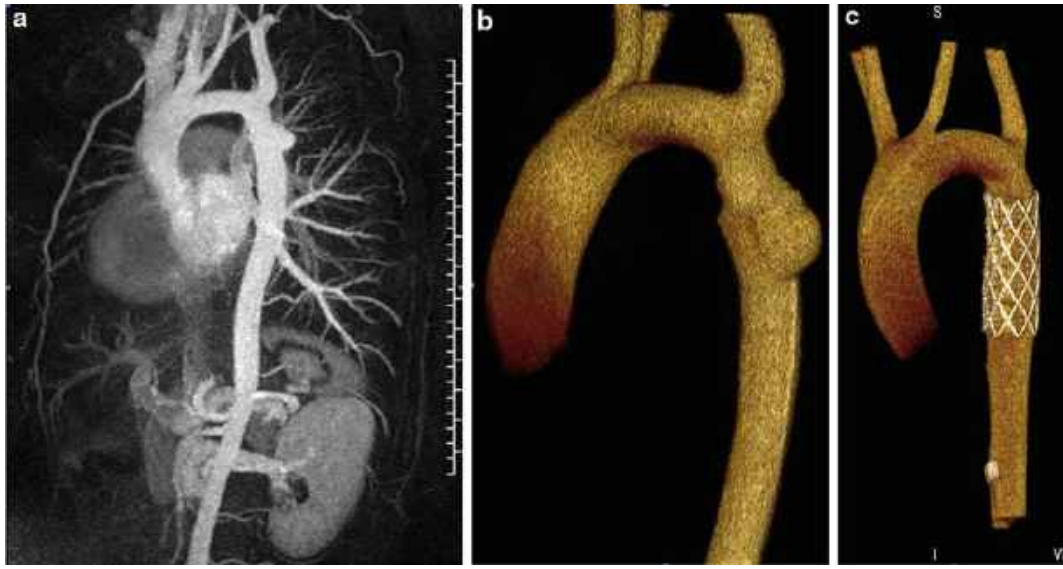

Fig. 146.4 A 26-year-old asymptomatic man with prior surgical repair of CoA during infancy. Routine screening three-dimensional reconstruction of a cardiac computed tomographic angiogram revealed a large saccular aneurysm at the site of prior repair with no evidence of aortic dissection

hypertension have been shown to have increased collagen in the aortic media and a decrease in smooth muscle [2]. The shape of the aortic arch may also predict adverse late events. A "Gothic" or triangular-shaped arch has been linked with increased vascular thickening, reduced aortic distensibility, and late-onset hypertension when compared to a "Romanesque" or more rounded arch [28]. In some patients, impaired LV function and increased LV mass have been found despite having coarctation repair and acceptable control of systemic hypertension, leading to the hypothesis that reduced elastic properties after coarctation repair can increase left ventricular afterload [29].

The appropriate type of treatment for native coarctation of the aorta in adults remains somewhat controversial. In particular, for women who are or will be of childbearing age after repair, there is a concern about the tissue integrity of the para-coarctation region, particularly during pregnancy. As such, caregivers may select direct surgical repair with excision of the para-coarctation tissue. For recurrent CoA (coarctation after surgical repair), catheter-based interventions (balloon or stent) are generally safe and the preferred alternative to surgery in the absence of confounding features (e.g., aneurysm or pseudoaneurysm formation, or significant coarctation that affects the adjoining arch arterial branches). For localized discrete narrowing, balloon angioplasty is an acceptable primary intervention but is still considered less suitable for long-segment or tortuous forms of coarctation. In many ACHD centers, surgery is reserved for patients who are unsuitable for or who have already failed percutaneous intervention [19].

Aortic aneurysms and rupture may occur years after successful repair of CoA [30]. This adverse late-term event appears to occur without recurrent coarctation and despite relief of systemic hypertension. For the majority of patients, aneurysm repair requires surgical intervention with resection of the aneurysm and graft placement. Unfortunately, there are no criteria to guide the timing of aortic aneurysm repair in this population. Pseudoaneurysms can also occur at the CoA repair site. They demonstrate an area of weakening with outpouching of the adventitial layer, usually along the suture lines, and are at a higher risk for rupture. Pseudoaneurysms should be considered for repair at the time of

initial diagnosis. Either surgical repair of the pseudoaneurysm or, in select cases, excluding the aneurysm with a covered stent percutaneously should be considered to remove the risk of rupture.

Though there is no apparent etiology for the higher incidence of hypertension and aortic dissection following coarctation repair, there is evidence of an intrinsic abnormality of the aorta that persists despite adequate repair [30, 31]. This "stiff" or less distensible aorta has also been described with essential hypertension, coronary artery disease, and Marfan syndrome and may be the underlying mechanism contributing to the late abnormalities associated with repaired coarctation of the aorta.

Adults with a history of successful coarctation repair should be meticulously followed for the presence of adverse sequelae such as re-coarctation, progressive AD, and dissection [26]. Routine screening with appropriate diagnostic modalities including echocardiography and at least one complete cardiac Magnetic Resonance Imaging (cMRI) or cardiac CT has been proposed to allow for early detection of these complications [32, 33].

Conotruncal Lesions

Conotruncal anomalies are a group of congenital heart defects that involve the outflow tracts of the heart and the great vessels. The outflow tract of the embryonic univentricular heart, also known as the conotruncus, begins as a common outlet but undergoes a highly choreographed sequence of events that results in the creation of separate left and right ventricular outflow tracts as well as the aorta and main pulmonary artery [34]. Of non-syndromic CHD, approximately 25–30 % are conotruncal cardiac defects [35]. Conotruncal cardiac defects include Tetralogy of Fallot (TOF), truncus arteriosus (TA), transposition of the great arteries (TGA), and double outlet right ventricle (DORV), and the very rare interruption of the aorta [36].

Although AD is commonly seen in conotruncal defects, such as TOF, d-TGA, and DORV, with some histological evidence of intrinsic aortopathy, there are at present no guidelines specific to conotruncal lesions regarding how to manage AD in these patients. Currently, aortopathies in patients with conotruncal lesions are managed similarly to patients with underlying connective tissue disease or a hereditary aortopathy.

Tetralogy of Fallot (TOF)

TOF is the most common form of cyanotic CHD and comprises 3.5–9 % of patients with CHD. The four components of TOF include the following: (1) malalignment ventricular septal defect (VSD), (2) overriding of the aorta, (3) right ventricular (RV) outflow tract obstruction/multilevel pulmonary stenosis, and (4) concomitant RV hypertrophy. The aortic arch is right-sided rather than left-sided in approximately 25 % of patients. Although TOF is the most commonly encountered cyanotic congenital heart defect in infancy, insidious development of progressive AD has been seen in adult survivors who have undergone surgical repair [37]. The underlying pathophysiology of ascending AD is unknown. In addition to previous long-standing volume overload, intrinsic histologic abnormalities in the aortic root and ascending aortic wall have been observed in several studies. Abnormalities of smooth muscles, elastic fibers, collagen, and ground substance in the tunica media of the ascending aorta were found to be prevalent in these patients, predisposing to aortic dilation, aneurysm, and/or aortic rupture [4, 37].

Single case reports of progressive AD first began appearing in the early 1970s [38]. It was not until the 1990s that the frequency of AD was described as occurring in up to 48 % of patients [39]. Since then, progressive aortic root dilation has frequently been described after TOF repair (15–88 %) [4, 40] (Fig. 146.5). Aortic dissections were first described in patients with repaired TOF in 2005 [41, 42].

It has been postulated that increased blood volume to the overriding aorta due to the additional volume through the VSD from the RV

Fig. 146.5 A 52-year-old man with repaired TOF. Three-dimensional volume-rendered reconstruction of a cardiac MRA showing aneurysmal dilation of the ascending aorta with a maximum diameter of 5.2 cm

before surgical repair may result in increased stress on the aortic wall [4, 37]. Another hypothesis suggests that TOF itself may be a genetic aortopathy. Evidence supporting this hypothesis includes visualization of a dilated aorta on fetal echocardiography in TOF patients and multiple histologic studies using either pathologic specimens or surgical biopsies in infants with unrepaired TOF [2, 37]. Some studies have shown strong histological similarities of the aortic media as in Marfan syndrome in patients with repaired TOF with dilated aortas although a direct linkage to gene mutation(s) encoding for fibrillin-1 has not been clearly defined [2, 37]. Whether aortic wall pathology results from an intrinsic medial abnormality inherent to TOF itself or is secondary to the antecedent volume load through the aorta before repair (or perhaps a combination of the two) remains difficult to determine. Niwa et al. had investigated the ultrastructure of the great arteries in a series of patients who were already scheduled to undergo heart surgery. Of the 15 TOF patients in the series, all patients had at least grade 2 or 3 elastin fragmentation of the aorta [2]. Tan and colleagues found similar histologic evidence of an intrinsic aortopathy (including cystic medial necrosis, elastic fragmentation, and elastic lamellae disruption) in pathologic specimens of TOF which was present as early as a few days after birth, naïve to any surgical intervention [37]. Rutz et al. showed the incidence of AD and reduced aortic distensibility in patients with repaired TOF compared to age- and sex-matched controls [43]. The aortic diameters from the sinus to the level of the pulmonary artery bifurcation were larger, and the aortic distensibility was significantly reduced in patients with repaired TOF when compared to normal controls [43].

The ascending aorta should be imaged on a yearly basis in all patients with TOF if a progressive increase in aortic diameter, defined as an increase in aortic *z*-score, has been noted [4]. The risk of dissection in this patient cohort is being increasingly recognized; however, there remains no consensus guidelines in regards to surgical repair of a dilated aorta in these patients. In the only three cases reported in the literature, the absolute diameter of the aorta was $\geq$7 cm at the time of dissection, and the patients were much younger (18, 30, and 36 years, respectively) [41, 42]. Since all dissections occurred in patients with aortic diameters >5.5 cm, this raises the question as to whether ascending aortic replacement should be undertaken in those patients with an aortic diameter of $\geq$5.5 cm. Measurement of aortic stiffness, aortic curvature, and consideration of patient body size might enable us to further risk-stratify such patients [44, 45]. Prior studies have also reported the progressive nature of AD in TOF, which increased at a rate of 1.7 mm/year, in contrast to 0.03 mm/year in healthy controls [4]. Aortic dissection late after TOF repair in adults whose aortic roots exceeded 6 cm in diameter indicates that close monitoring of aortic dimensions is mandatory, especially when a dilated ascending aorta is present [37]. Elective surgical repair for the dilated aorta in

patients with repaired TOF has been actively debated with no current consensus guidelines. Aortic root surgery has also been considered in the case of progressive aortic valvular regurgitation and aortic root dilation exceeding 5.5 cm [7].

Given that TOF is the most common cyanotic congenital heart disease, and therefore one of the most common groups of ACHD patients, the need for more data to help determine ways to prevent aortic complications is growing daily. The potential for complications of AD that may necessitate surgical intervention is now increasingly recognized [37]. Despite overall excellent hemodynamic outcomes after surgery for TOF, there remains a concerning incidence of long term sequelae including aortic dilation. It is recommended that all ACHD patients with repaired TOF should have scheduled close and long-term follow-up with either echocardiographic and/or CMR evaluations as part of their routine follow-up to screen for early-onset complications [19].

Double Outlet Right Ventricle (DORV)

DORV is said to be present when both great arteries arise predominantly from the right ventricle with an incidence estimated at 127 per million live births [46]. DORV is not a single cardiac anomaly, but often used to describe an aberrant position of the great arteries in association with various cardiac anomalies in which the physiology is similar to that in VSD, TOF, TGA, or single ventricle (SV). DORV is defined as a form of ventriculo-arterial connection in which both great arteries arise completely or predominantly from the morphologic right ventricle. A VSD is almost always present; its location in relation to the semilunar valves may be subaortic (50 %), subpulmonary (30 %), uncommitted, or remote [47]. The relationship between the VSD and the great arteries, the relative outflow obstruction, and the anatomy of the atrioventricular valves determine the physiologic function, clinical course, surgical management, and long-term outcomes in DORV.

The ultimate goal of surgical management of DORV is to align the left ventricle with the systemic outflow and the right ventricle (RV) with the pulmonary outflow to achieve biventricular repair. Late complications after surgical repair of DORV vary with the individual anatomy and physiologic function, as well as the type of surgical procedure. The complications after repair of DORV with pulmonary outflow tract obstruction are similar to those seen after TOF repair, including chronic pulmonary regurgitation, dilation, and dysfunction of the RV, and arrhythmia. Aortic arch obstruction can be found in patients after coarctation or interrupted aortic arch repair. Those who undergo an arterial switch operation (ASO) may have the same problems described above for this procedure [48].

AD has been reported in adult patients with underlying DORV, but the data has been scarce (Fig. 146.6a, b). At the Mayo Clinic, from December 1973 through January 2008, 81 consecutive adults (median age, 34 years; range, 18–59 years) with conotruncal anomalies underwent operation on the aortic root, ascending aorta, or aortic valve. Primary cardiac diagnoses included TOF with or without pulmonary atresia in 60 patients, TA in 12, DORV in 6, and others in 3. Median ascending aortic size was 45 mm (23–80 mm). Operations included isolated aortic valve repair/replacement in 63 patients, combined AVR and reduction aortoplasty in 9, aortic root replacement in 7, and isolated ascending aortic replacement in 2. Median follow-up was 3.8 years (maximum 31 years). There were no ascending aortic reoperations after previous reduction aortoplasties or supracoronary ascending aortic grafts, and there were no late aortic dissections [49].

There is very limited data in regards to the incidence and rate of AD in patients with surgically repaired DORV. The true risk of either aortic dissection or rupture is currently unknown in this cohort of patients. Those who undergo an ASO may have similar complications, as described in the section on d-TGA s/p ASO including RVOT obstruction, coronary artery obstruction, and aortic root dilation [50, 51]. Currently there are no consensus guidelines to manage the aortic root

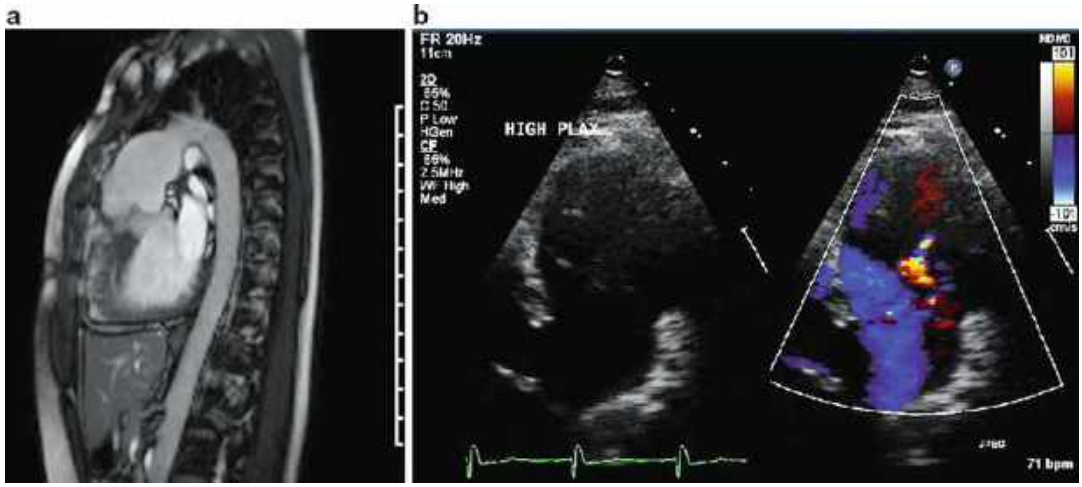

Fig. 146.6 A 22-year-old old woman with a history of DORV with a complex surgical history. (**a**) Cardiac MRI revealed a 5.1 cm ascending aortic aneurysm with no dissection. (**b**) TTE color Doppler images showing an eccentric jet of mild-to-moderate neo-aortic valvular insufficiency

in such patients with surgical repair. However, lifelong, systematic follow-up of their aortas to assess for AD, dissection, aneurysm, or pseudoaneurysm formation is strongly suggested.

Truncus Arteriosus

runcus arteriosus (TA) is an uncommon conotruncal anomaly with a reported incidence of 94 per million live births [46]. It is defined by the presence of a single artery arising from the heart with a single semilunar valve, giving rise to the coronary arteries, aorta, and at least one branch pulmonary artery. In the majority of cases, there is a sub-truncal VSD over which the truncal valve sits, similar to TOF. Associated cardiovascular and noncardiac anomalies are frequent [48]. Surgical repair usually follows the diagnosis. Typically, the VSD is closed with a patch so that the truncal valve is aligned with the LV (becoming the neo-aortic valve), and the pulmonary arteries are detached from the arterial trunk and connected to the RV with a valved homograft. Surgical repair of the truncal valve for stenosis or regurgitation is uncommon during the initial repair. The use of a nongrowing homograft in infancy makes additional operations inevitable as patients grow. Aortic arch interruption or coarctation is repaired at the same time.

The main complications after truncal repair are right ventricle–pulmonary artery conduit stenosis or regurgitation, branch pulmonary artery stenosis, neo-aortic valve (truncal) insufficiency or stenosis, VSD patch leak, and aortic arch obstruction. Most commonly, patients eventually require replacement of the right ventricle–pulmonary artery homograft because of increasing obstruction over time [52]. Long-term follow-up after TA repair performed in infancy has rarely been reported. A large retrospective review of surgeries since 1975 performed by Rajasinghe et al. assessed long-term outcomes among 165 patients who survived the initial hospital stay after complete repair of truncus arteriosus [53]. During the follow-up period, 107 patients underwent 133 conduit reoperations with a median time to conduit reoperation of 5.5 years. In addition, 26 patients underwent 30 truncal valve replacements. No patients had aortic root dilation or complications that needed surgical repair [53]. Large vessel (aortic and pulmonary arterial) dilation or dissection has rarely been reported in such patients, including young adults with unrepaired TA, highlighting the importance of the histological

abnormalities identified in the pulmonic trunk if placed under systemic pressure [54].

Overall, the 20-year survival and functional status appears to be satisfactory among patients who underwent complete repair of TA as infants, with conduit replacement or revision almost inevitably being the most common reason for repeat surgery in this group of patients.

Interruption of the Aorta

An interrupted aortic arch is defined by luminal discontinuity between the ascending and descending portions of the thoracic aorta. The discontinuity may be complete, or it may be spanned by an atretic fibrous band. Interrupted aortic arch is a rare condition; it is found in approximately 1 % of infants with a critical congenital heart defect [55]. An underlying genetic cause is thought to be responsible for many cases: A chromosome 22q11.2 deletion is identifiable in approximately 50 % of patients with an interrupted aortic arch, and 42 % of patients with DiGeorge syndrome have an interrupted aortic arch [55]. Surgical repair should be undertaken as soon as possible. In most institutions, the preferred surgical approach is direct anastomosis of the interrupted (or atretic) aortic segments. When the distance between the interrupted aortic arch segments is large, homograft augmentation may be added to the arch reconstruction. The use of a tubular conduit to bridge between the arch segments is usually reserved for unusually long-segment interruptions or for reoperations [48]. Long-term complications that require follow-up include residual or recurrent arch obstruction, aneurysm formation at the surgical site, residual obstruction of the LVOT, VSD patch leak, and left ventricular hypertrophy [47].

D-Transposition of the Great Arteries

D-TGA is defined by discordant connections between the ventricles and the great arteries. The aorta arises from the right ventricle, and the pulmonary artery arises from the left ventricle. The most common type of TGA is a d-loop (malposition) [47]. D-TGA is the second most common cyanotic congenital heart condition, with an incidence of 315 per million live births [46]. Associated defects with this lesion commonly include VSD, left ventricular outflow tract obstruction, and rarely CoA. Palliation of d-TGA became possible in 1950 with the development of the Blalock-Hanlon atrial septectomy, which improved inter-circulatory mixing. A physiologic repair using native atrial tissue was first reported by Senning in 1957, followed by Mustard's success with an atrial switch using a pericardial baffle in 1963. In 1975, Jatene [56] reported the first successful arterial switch operation (ASO), ushering in a new era of surgery for d-TGA. The ASO had become the predominant surgical strategy at most institutions by the late 1980s [57]. Patients with a large subaortic VSD and pulmonary stenosis may require a Rastelli procedure (valve conduit from right ventricle to pulmonary artery and patch created to tunnel blood from left ventricle to aorta) [58]. Today, the survival rate for infants with d-TGA is greater than 90 % with many patients surviving to adulthood with long-term outcomes often determined by the type of repair performed.

Transposition of the Great Arteries: Atrial Switch Palliation (Mustard/Senning)

Little has been written about the aorta in patients with d-TGA who have undergone a Mustard or Senning procedure. Given that morbidity and mortality is largely secondary to atrial or ventricular arrhythmias and congestive heart failure, evaluation of the aorta itself has not been an active area of investigation for most centers. Some of the research done so far has focused mainly on ventricular-arterial coupling as a mechanism of heart failure, exploring aortic distensibility and other measurements of aortic function rather than focusing exclusively on aortic diameter. Ladouceur and colleagues presented

results from 29 patients with d-TGA and intact ventricular septum, who had previously undergone atrial switch procedures [59]. Compared with age- and sex-matched controls, the patients had larger aortas at both the annulus (21.0 ± 3.6 vs. 17.6 ± 4.1 mm) and the sinus of Valsalva (30.0 ± 4.0 vs. 26.8 ± 4.2 mm) and also had lower aortic distensibility than controls (3.5 ± 1.6 vs. 5.3 ± 2.4 × 10^{-3} mmHg^{-1}). Rutz et al. showed that the incidence of aortic diameters from the sinus to the level of the pulmonary artery bifurcation was significantly larger in patients with d-TGA s/p atrial switch repair and the aortic distensibility was significantly reduced compared to age-matched controls [43].

There continues to be scarce data in regards to the incidence of AD in patients with d-TGA with atrial switch repairs. Although the follow-up studies of d-TGA after atrial repairs are important to the ACHD community, they are of less relevance to the d-TGA patient born in the current era now that d-TGA patients usually undergo the ASO. There are no consensus guidelines in regards to the imaging and management of the dilated aorta in patients with d-TGA after atrial baffle procedures. Echocardiographic imaging is recommended to evaluate the anatomy and hemodynamics with additional imaging with transesophageal echocardiography (TEE), cardiac CT, or cMRI used as appropriate, to evaluate the great arteries and veins [19].

Transposition of the Great Arteries: Arterial Switch Palliation

The transition from the atrial switch to the ASO spanned the decade of the 1980s. By 1985, patients with d-TGA were managed chiefly by ASO. Neo-aortic root dilation is common and may have significant implications in adulthood as afterload increases (Fig. 146.7a, b). In a report from Boston, freedom from aortic root dilation (z-score ≤3) was only 51 % at 10 years, and patients operated on more recently seem to be dilating earlier. However, dilation does not seem to be progressive once a z-score ≥3 is reached [60]. Thus, the functional fate of the neo-aortic root is unclear and may prove to be the most significant long-term issue in early adulthood [57].

Intrinsic aortic wall pathology in d-TGA has been postulated to be due to abnormal aortico-pulmonary septation or damage to the vasa vasorum and surgical manipulations during the ASO, thus predisposing the aorta to dilation, aneurysm formation, and even dissection [1]. Aortic distensibility may be reduced by impaired aortic elastogenesis and by scar formation at the site of anastomosis. High-grade medial abnormalities in the ascending aorta have already been observed during the neonatal period, suggesting that they are inherited analogously to Marfan syndrome. Aortic wall abnormalities may also develop due to structural wall differences between the two great arteries, as the former pulmonary arterial wall is exposed to higher systemic pressures after ASO, posing increased stress on the neo-aortic wall [2].

A high incidence of AR has been reported after ASO (30 % at 6 years after ASO) and is probably the result of a multifactorial process for which aortic root geometry, surgical techniques, and preoperative size discrepancy between the two great arteries are involved. In addition, AR appears to be functionally correlated with aortic root dilation and reduced elasticity of the proximal aorta, while the concomitant LV volume overload, increased LV dimensions and subsequent decreased LV ejection fraction [61]. Other authors have also reported that long-term follow-up has shown that some patients with ASO develop complications of the neo-aorta or neo-aortic valve requiring root or valve surgery [60, 62].

In order to help determine the natural history of neo-aortic dilation after ASO, Schwartz and colleagues evaluated a cohort of 335 patients who had undergone ASO for d-TGA either with or without a VSD, also including DORV with subpulmonary VSD [60]. Patients were followed for a median of 5.0 years. Overall, 33 % of the cohort had aortic dilation (defined as a neo-aortic root z-score ≥3.0 during at least one time point). When analyzing only the

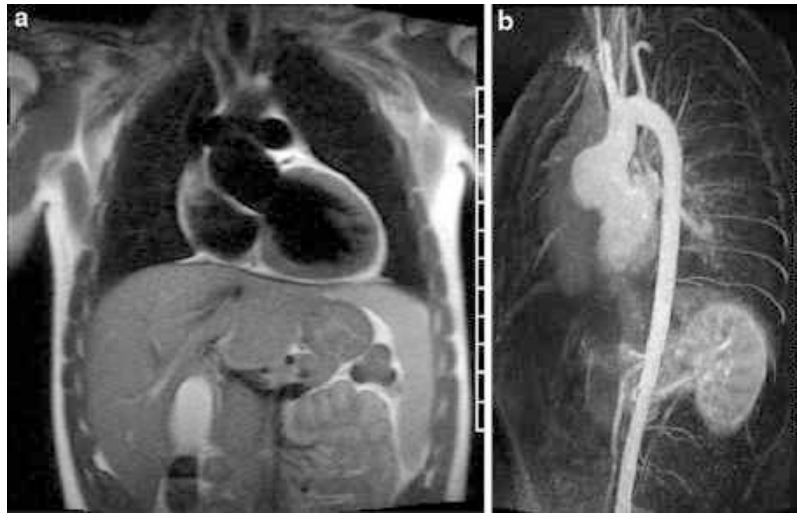

Fig. 146.7 A 16-year-old male with d-TGA after arterial switch operation presented with fatigue and exercise intolerance with a dilated ascending aorta measuring 5.0 cm. (**a**) Dark blood coronal image showing aneurysmal dilation of the sinuses of Valsalva and effacement of the sinotubular junction. (**b**) Maximum intensity projection of a cardiac MRA showing dilation at the level of the aortic sinuses and ascending aorta, with normal dimensions of the remainder of the aorta

patients with significant dilation, the mean z-score change was only minimal (increase of 0.05 per year), with a mean z-score of 4.6. Six patients had massive neo-aortic dilation with neo-aortic *z*-score $\geq$8.0, with three undergoing a neo-aortic root replacement. Although 49 % had AD at 10-year follow-up, only 5 % of the entire cohort required surgery on the neo-aortic root or valve. It should be highlighted that among those whose aortic root was dilated, the dilation tended to plateau rather than progress [60]. Though older patients with atrial baffle repair for d-TGA are at risk for arrhythmia, ventricular failure, and sudden death, it is thought that these sequelae are not likely to affect younger children with the newer arterial switch operation to the same degree. However, emerging complications, such as progressive coronary disease or progressive AD, have been described, and these may continue to arise as a result of this surgical approach [57].

Currently there are no agreement guidelines for ACHD patients with d-TGA after ASO in regards to management of the dilated aorta. Comprehensive echocardiographic imaging to evaluate the anatomy and hemodynamics in patients with d-TGA and prior ASO repair should be performed at least every 2 years. cMRI and CT angiography are recommended only periodically to evaluate the anatomy and hemodynamics in greater detail [19].

Congenitally Corrected Transposition (cc-TGA)

The second most common type of transposition of the great arteries is congenitally corrected TGA (cc-TGA), or l-loop transposition of the great arteries. cc-TGA is rare and is characterized by atrioventricular and ventriculo-arterial discordance. The condition is not cyanotic and may be discovered incidentally in asymptomatic patients. However, associated cardiac lesion such as a VSD, tricuspid valve abnormality (e.g., Ebstein anomaly), or pulmonary stenosis can coexist.

The minority of patients may be relatively normal from a functional standpoint, and survival to the seventh and eighth decades has been reported when no associated anomalies exist [63]. Complications include a progressive

incidence of complete AV block occurring at approximately 2 % per year, abnormalities of the systemic AV valve in up to 90 % of patients, and failure of the systemic ventricle. Systemic AV valve replacement is relatively common in the adult age group [64].

Very little has been written regarding dilation of the thoracic aorta in cc-TGA. A multicenter cross-sectional study done in 2000 showed an unexpectedly high prevalence of moderate or worse aortic regurgitation in 33 % of a population of 182 patients (mean age 32 ± 13 years, range 18–70 years) [65]. Unfortunately, no data on aortic root size was recorded in this study, so it is uncertain if this unexpectedly high prevalence of aortic regurgitation could be due to aortic dilation. It is difficult to gather comprehensive data on cc-TGA outcomes given how rare this diagnosis is in ACHD and how commonly there are other associated congenital anomalies [65]. Echocardiography-Doppler study and/or MRI should be performed yearly or at least every other year along with close clinical follow-up in adult patients with cc-TGA [19].

Single-Ventricle Physiology After Fontan Palliation

Many complex cardiac malformations are characterized by the existence of only one functional ventricle which has to maintain both systemic and the pulmonary circulations. The Fontan operation places the systemic and pulmonary circulation in series and is the treatment of choice for patients with a univentricular heart, resulting in near normalization of arterial saturation and removal of the chronic volume overload. As the oldest survivors of the Fontan palliation now enter their fourth decade of life, both the benefits and long-term sequelae associated with this palliation are increasingly being recognized. Several late complications including arrhythmias, heart failure, exercise intolerance, ventricular dysfunction, thromboembolic complications, hepatic dysfunction, protein-losing enteropathy, and worsening cyanosis have been described [66].

Fig. 146.8 A 38-year-old woman with DILV and malposed great arteries after Fontan palliation. Routine imaging revealed severe dilation of her ascending aorta extending to the mid-transverse aortic arch. Axial images from a CTA with maximum ascending aortic dimension of 5.2 cm with no evidence of aortic dissection

However, the role of aortopathy in older patients with SV physiology has not been well reported in the literature (Fig. 146.8). It is likely that aortic dilation will be encountered, since single-ventricle lesions often require reconstruction of the aortic arch in order to provide an adequate egress from the systemic ventricle to the systemic circulation.

The elastic properties of the reconstructed aorta are especially important in order to ensure efficient cardiac output in single-ventricle patients, especially in those with a single right ventricle, given that a morphologic right ventricle is more sensitive to increases in afterload than a morphologic left ventricle [67]. Hypoplastic left heart syndrome (HLHS) was the last common type of complex CHD to become amenable to csurgical therapy. It was not until 1983 that Norwood et al. reported successful palliation of a patient with HLHS to the Fontan circulation [68]. Thus, the longest possible follow-up for any patient with HLHS is just over 25 years, although additional predictions can be

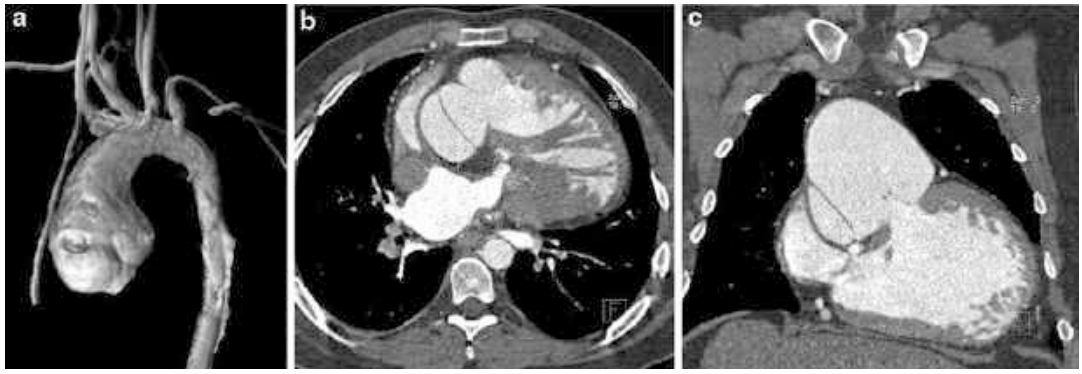

Fig. 146.9 A 27-year-old man with HLHS after Fontan palliation with a massive ascending aortic aneurysm. (**a**) Magnetic resonance angiography with three-dimensional volume-rendered reconstruction showing severe dilation of the aortic root. Maximum dimension was 8.2 cm. (**b**) Axial slices from a CTA 1 year later showed an acute aortic dissection, beginning distal to the neo-aortic valve. (**c**) Coronal CTA imaging showing the dilated ascending aorta and the dissection plane. There is a single systemic right ventricle that gives rise to the dilated aorta

extrapolated from data on late outcomes of the Fontan palliation for other forms of CHD [57]. The "neo-aorta" is often dilated especially after the Norwood palliation for several reasons (Fig. 146.9a–c). First, the pulmonary root, which is reconstructed into the neo-aortic root, is larger than the aortic root of healthy subjects [69]. Second, the ascending aorta and transverse aortic arch diameters are dependent on how much aortic patch material is used during the neo-aortic reconstruction. Prior studies have shown that patients with HLHS after Fontan palliation have a lower aortic distensibility index with elevated aortic stiffness [70].

Ultimately, the Fontan operation is a palliative procedure resulting in a unique single-ventricle physiology with a high incidence of long-term complications. The management of patients with SV physiology (especially HLHS) continues to evolve in the current era, including variations to the Stage I reconstruction using a right ventricle to pulmonary artery conduit (Sano operation), the choice between a lateral tunnel and extracardiac Fontan, aside from proposed interventional catheter techniques to replace one or more stages of the Fontan. These innovations promise that assessing long-term outcomes in adult patients with single ventricles will continue to require systematic long-term follow-up, with close analysis of the eventual neo-aorta with periodic echocardiography, cMRI, or CT evaluation [19, 57].

Conclusions

Aortopathy is common in several forms of CHD. Although AD and dissection are the most worrying complications, abnormal aortic elasticity has been reported and can result in impaired ventricular function. Multiple congenital heart defects including BAV, conotruncal defects, or patients with Fontan palliations have been associated with dilated aortas, dissection, aneurysm, or pseudoaneurysm formation in the past. Several of these defects are now considered part of a more generalized aortopathy with multiple prior studies documenting histologic evidence of elastin fragmentation, tying in to the hypothesis of an underlying tissue abnormality as a possible cause for the AD.

Patients with underlying BAV, CoA, repaired TOF, d-TGA, and Fontan physiology have been found to have AD. Long-term complications like aneurysmal dilation and dissections have also

been reported in such patients. Fifteen percent of all thoracic aortic dissections are associated with BAV. Rarely, aortic dissection has been reported in patients with repaired TOF, prompting increased awareness in regards to the dilated aorta in adults with CHD. However, there continues to be lack of data to determine when to intervene on a dilated aorta in conotruncal defects, such as TOF and d-TGA.

At this time, there are no exclusive guidelines for the management of thoracic aortic disease specific to patients with conotruncal defects or single ventricle physiology. Care should be individualized to each patient, with detailed assessment of the patient's underlying CHD, associated comorbidities, and the risk of surgery. Further research is necessary to determine adequate intervals for following progression of growth in aortic diameter and to determine the usefulness of novel imaging indices to further assess the dilated aorta in ACHD.

Pregnancy and Contraception in ACHD Patients

147

Rachel M. Wald, Jack M. Colman, Mathew Sermer, Jose C. A. Carvalho, Eric M. Horlick, Nadine Shehata, and Candice K. Silversides

Abstract

As a consequence of advances in diagnosis and treatment of congenital heart disease in childhood, most women with heart disease can expect to reach reproductive years (Perloff, J Am Coll Cardiol 18:340–342, 1991). A large portion of these survivors are women of childbearing age (Marelli et al., Circulation 115:163–172, 2007). Many of these women will contemplate pregnancy and may seek counseling regarding outcomes of pregnancy in the context of heart disease. In the majority of women with congenital heart disease, pregnancy results in favorable outcomes, but there are important exceptions which can pose significant risk to the mother and/or the child. There may also be long-term effects of pregnancy on the heart. In this chapter, cardiovascular adaptations to pregnancy, general outcomes, and

Congenital heart disease • Contraception • Outcome • Pregnancy

Introduction

The majority of pregnant women with heart disease seen at referral centers in developed countries have known congenital heart disease (CHD), although acquired heart disease, primarily rheumatic heart disease, predominates in the developing world [1–4]. In general, maternal death during pregnancy in women with heart disease is rare, but there are conditions which pose increased risk, including pulmonary vascular obstructive disease, Marfan syndrome with aortopathy, peripartum cardiomyopathy, severe symptomatic aortic stenosis, and mechanical heart valves [1, 2, 4–8]. Notwithstanding that death is rare, pregnant women with heart disease remain at risk for adverse events during pregnancy which may be cardiac (most commonly related to heart failure and/or arrhythmia), obstetric, and/or fetal-neonatal [1, 2, 9–12]. In women with CHD, there is evidence to suggest that cardiac events in pregnancy may confer increased risk of late adverse cardiac outcomes [13].

A preconceptual cardiac evaluation is often of benefit to a woman with CHD contemplating pregnancy. At such a visit, baseline testing can be arranged and pregnancy-related risk established. In some instances, cardiac interventions may be needed to reduce the risk of complications during pregnancy. Medications are reviewed and, depending on teratogenic potential and maternal need, can be discontinued, altered, or if safe, continued. Discussion regarding the impact of pregnancy on and long-term outcome of specific forms of CHD should take place before pregnancy; cardiac-related morbidity and mortality may profoundly impact a woman's ability to care for her child. In select circumstances, as will be detailed below, pregnancy imposes substantial risk to the mother with CHD and/or her child, such that the most relevant aspect of counseling and the most important therapeutic intervention is to ensure consistent and optimally effective contraception. In a very high-risk patient, termination of pregnancy itself may carry important risks to the mother, so in these situations pregnancy is best avoided altogether. Cardiologists need to ensure that age and circumstance-appropriate counseling regarding contraception and family planning takes place in all females of childbearing age and that it begins during pediatric care. If such counseling is not provided by the cardiologist, it often does not occur [14].

A management plan can be specifically tailored for the individual patient embarking on pregnancy by coupling knowledge of the physiologic changes relating to normal pregnancy with an understanding of the pathophysiology of the underlying CHD. This chapter provides a framework for the cardiology practitioner aiming to care for women with CHD before, during, and after pregnancy.

Cardiovascular Physiology and Pregnancy

Increases in blood volume, red cell mass, and heart rate result in a 30–50 % antepartum increase in cardiac output [15]. Increases in left ventricular (LV) volume are present by

14 weeks of gestation and reach maximum levels early in the third trimester. Contractility remains in the normal range. Gestational hormones, circulating prostaglandins, and the low-resistance vascular bed in the placenta result in decreased peripheral vascular resistance and blood pressure. During labor and delivery, there are additional increases in cardiac output and oxygen consumption. Immediately following delivery, relief of caval compression and autotransfusion from the emptied uterus synergistically result in a transient increase in cardiac output. This may be offset by the blood loss that occurs at the time of delivery. Most of the hemodynamic changes of pregnancy have resolved by the second postpartum week, but complete return to baseline may not occur until 6 months after delivery.

Global Risk Assessment

Maternal Risk

Evaluation of the woman with CHD contemplating pregnancy should be as comprehensive as possible. In addition to a thorough history, a critical review of prior catheterization and operative reports is often necessary to clarify the diagnosis and define the nature of the clinically important residua and sequelae, such as ventricular dysfunction, elevation of pulmonary pressures, severity of obstructive lesions, persistence of shunts, and presence of hypoxemia. A detailed physical examination will include blood pressure (in both arms and a leg in the patient with a diagnosis of coarctation of the aorta), measurement of oxygen saturation at rest (and with exercise when appropriate), as well as assessment of dysmorphology which may suggest the presence of a syndromic or genetic anomaly. Routine testing includes a 12-lead electrocardiogram and a detailed transthoracic echocardiogram. Exercise stress testing, to specifically examine maximal O_2 consumption and chronotropic response, can be considered prior to pregnancy [16]. In some instances, such as in women with Marfan syndrome, a cardiac magnetic resonance scan before pregnancy may be appropriate, to visualize the aorta in order to refine risk stratification related to the possible aortopathy.

The use of various cardiovascular drugs during pregnancy has been recently and comprehensively reviewed (Table 147.1) [17–19]. With the exception of heparin, almost all cardiovascular medications can be expected to cross the placental barrier. Whenever possible, medications with the lowest risk profile should be used for the management of cardiac disease during pregnancy. Commonly used cardiac medications which can have detrimental effects on the fetus or neonate include warfarin, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers. Timing of exposure may be important and risks and benefits of the medications for the mother need to be considered.

A meta-analysis of published studies of pregnant women with CHD included 2,491 pregnancies and found that important pregnancy-related adverse cardiac events were seen in 11 % of pregnancies. The most frequent events were heart failure (prevalence 4.9 %) and arrhythmia (predominantly supraventricular, prevalence 4.5 %); event rates varied according to lesion (Fig. 147.1) [11]. The overall likelihood of developing an adverse cardiac event during pregnancy can be estimated by calculation of a maternal risk score. Such a risk score was proposed by Siu and colleagues following a large, prospective, multicenter, Canadian study of maternal and fetal outcomes in women with acquired and congenital heart disease (the CARPREG Study) (Fig. 147.2) [1]. Independent predictors for maternal cardiac complications during pregnancy included (a) poor functional status (NYHA $>$ II) or cyanosis, (b) left ventricular systolic dysfunction, (c) left heart obstruction, and (d) history of cardiac events prior to pregnancy (arrhythmia, stroke, or pulmonary edema) (Table 147.2). The overall risk of developing an adverse maternal cardiac event during pregnancy was found to be low ($<$5 %) if no predictors were present,

Table 147.1 Common cardiovascular drugs and their use in pregnancy

Drug name	Description	FDA category[a]	Placenta permeable	Adverse effects
Acetylsalicylic acid (low dose)	Antiplatelet	B	Yes	No teratogenic effects known
Adenosine	Antiarrhythmic	C	No	No fetal adverse effects reported
Amiodarone	Antiarrhythmic (Vaughan Williams class III)	D	Yes	Thyroid insufficiency, hyperthyroidism, goiter, bradycardia, growth retardation, and/or premature birth
Atenolol	Beta-blocker (Vaughan Williams class II)	D	Yes	Hypospadias (first trimester); birth defects, low birth weight, bradycardia, and hypoglycemia in fetus (second and third trimester)
Bisoprolol	Beta-blocker (Vaughan Williams class II)	C	Yes	Bradycardia and hypoglycemia in fetus
Candesartan	Angiotensin II receptor blocker	D	Unknown	Renal or tubular dysplasia, oligohydramnios, growth retardation, skull abnormalities, lung hypoplasia, contractures, anemia, intrauterine fetal death
Captopril	ACE inhibitor	D	Yes	Renal or tubular dysplasia, oligohydramnios, growth retardation, skull abnormalities, lung hypoplasia, contractures, anemia, intrauterine fetal death
Clopidogrel	Antiplatelet	C	Unknown	No information during pregnancy available
Digoxin	Cardiac glycoside	C	Yes	Maternal serum levels unreliable, safe in pregnancy
Diltiazem	Calcium channel blocker (Vaughan Williams class IV)	C	No	Possible teratogenic effects
Disopyramide	Antiarrhythmic (Vaughan Williams class IA)	C	Yes	Uterus contraction
Enalapril	ACE inhibitor	D	Yes	Renal or tubular dysplasia, oligohydramnios, growth retardation, skull abnormalities, lung hypoplasia, contractures, anemia, intrauterine fetal death
Flecainide	Antiarrhythmic (Vaughan Williams class IC)	C	Yes	Unknown (limited experience)
Furosemide	Diuretic	C	Yes	Oligohydramnios
Glyceryl trinitrate	Nitrate	B	Unknown	Bradycardia, tocolytic
Heparin (low molecular weight)	Anticoagulant	B	No	Long-term application: seldom osteoporosis and less thrombocytopenia than unfractionated heparin
Heparin (unfractionated)	Anticoagulant	B	No	Long-term application: osteoporosis and thrombocytopenia
Hydralazine	Vasodilator	C	Yes	Maternal side effect: lupus-like symptoms, fetal tachyarrhythmias
Hydrochlorothiazide	Diuretic	B	Yes	Oligohydramnios
Irbesartan	Angiotensin II receptor blocker	D	Unknown	Renal or tubular dysplasia, oligohydramnios, growth retardation, skull abnormalities, lung hypoplasia, contractures, anemia, intrauterine fetal death

(*continued*)

Table 147.1 (continued)

Drug name	Description	FDA category[a]	Placenta permeable	Adverse effects
Isosorbide dinitrate	Nitrate	B	Unknown	Bradycardia
Labetalol	Alpha-/beta-blocker	C	Yes	Intrauterine growth retardation (second and third trimester), neonatal bradycardia and hypotension (used near term)
Lidocaine	Antiarrhythmic (Vaughan Williams class IB)	C	Yes	Fetal bradycardia, acidosis, central nervous system toxicity
Methyldopa	Central alpha-agonist	B	Yes	Mild neonatal hypotension
Metoprolol	Beta-blocker (Vaughan Williams class II)	C	Yes	Bradycardia and hypoglycemia in fetus
Nifedipine	Calcium channel blocker	C	Yes	Tocolytic; potential synergism with magnesium sulfate may induce maternal hypotension (mother) or fetal hypoxia
Procainamide	Antiarrhythmic (Vaughan Williams class IA)	C	Yes	Unknown (limited experience)
Propafenone	Antiarrhythmic (Vaughan Williams Class IC)	C	Yes	Unknown (limited experience)
Propranolol	Beta-blocker (Vaughan Williams class II)	C	Yes	Bradycardia and hypoglycemia in fetus
Ramipril	ACE inhibitor	D	Yes	Renal or tubular dysplasia, oligohydramnios, growth retardation, skull abnormalities, lung hypoplasia, contractures, anemia, intrauterine fetal death
Sotalol	Antiarrhythmic (Vaughan Williams class III)	B	Yes	Bradycardia and hypoglycemia in fetus (limited experience)
Spironolactone	Aldosterone antagonist	D	Yes	Antiandrogenic effects, oral clefts (first trimester)
Statins	Lipid lowering drugs	X	Yes	Congenital anomalies
Ticlopidine	Antiplatelet	C	Unknown	Unknown (limited experience)
Valsartan	Angiotensin II receptor blocker	D	Unknown	Renal or tubular dysplasia, oligohydramnios, growth retardation, skull abnormalities, lung hypoplasia, contractures, anemia, intrauterine fetal death
Verapamil	Calcium channel blocker (Vaughan Williams class IV)	C	Yes	Oral well tolerated (although limited experience during pregnancy): intravenous preparation may be associated with greater risk of bleeding and subsequent fetal hypotension
Warfarin and other coumarins	Vitamin K antagonist	D	Yes	Coumarin embryopathy and bleeding

Table adapted from the 2011 European Society of Cardiology Guidelines for the Management of Cardiovascular Diseases in Pregnancy (reference [19]), with permission

[a]FDA (US Food and Drug administration classification): category A (safest) to category X (known danger therefore do not use)

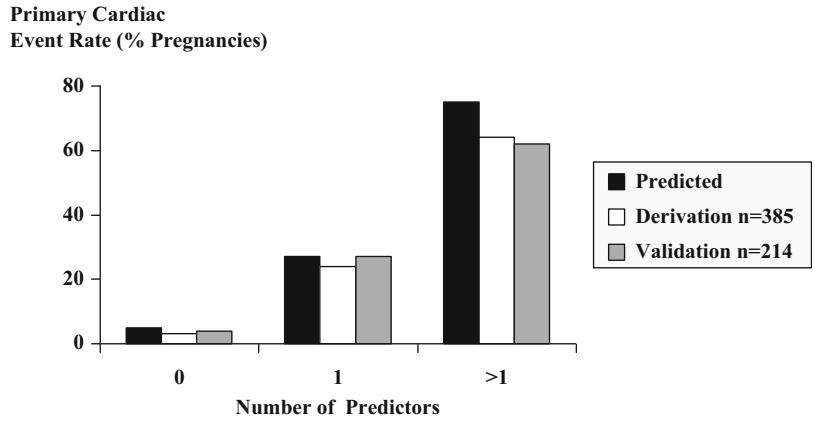

Fig. 147.1 The frequency of maternal cardiac complications (pulmonary edema, cardiac arrhythmia, stroke, or cardiac death), as predicted by the number of risk factors, observed in the derivation and validation groups (n = number of pregnancies) (Reproduced with permission from reference [1])

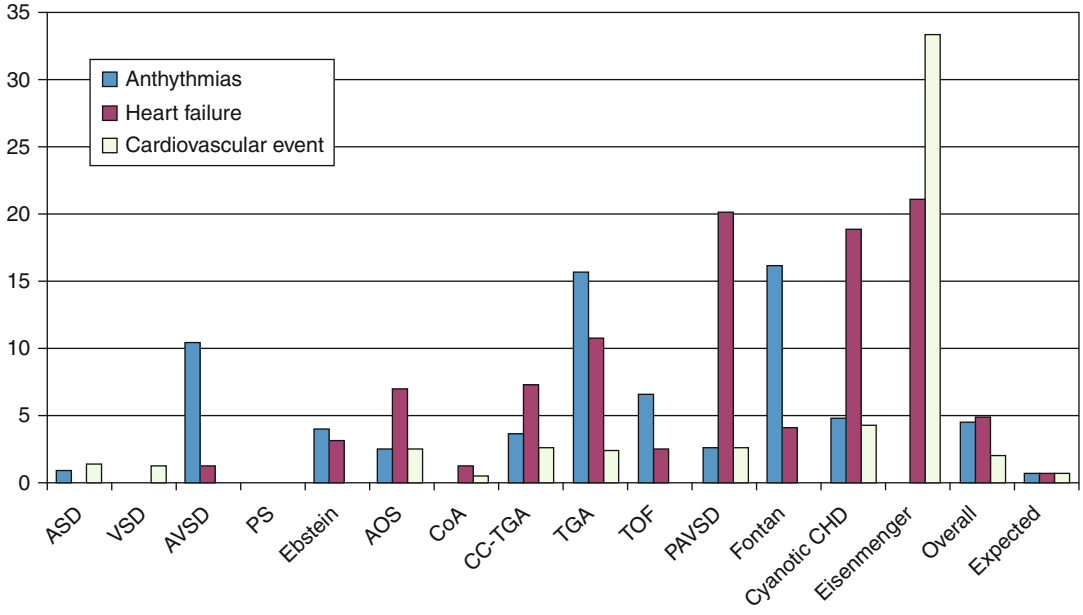

Fig. 147.2 Prevalence of adverse cardiovascular outcomes in women with congenital heart disease undergoing pregnancy. Event rate (%, y axis) is classified according to diagnosis (x axis). *AOS* aortic stenosis, *ASD* atrial septal defect, *ASVD* atrioventricular septal defect, *cc-TGA* congenitally corrected transposition of the great arteries, *CHD* congenital heart disease, *CoA* aortic coarctation, *PAVSD* pulmonary atresia with ventricular septal defect, *PS* pulmonary stenosis, *VSD* ventricular septal defect (Reproduced with permission from reference [11])

intermediate (27 %) if one predictor was identified, and high (75 %) if more than one predictor was found. Because some high-risk populations were underrepresented in this study (e.g., Marfan syndrome, Eisenmenger syndrome, Fontan circulation, mechanical valves), it remains important to use this risk estimate in conjunction with lesion-specific estimates. The highest risk estimate should be used to guide management.

Further studies by other groups have validated the CARPREG score and have offered additional dimensions for further refinement of risk

Table 147.2 Risk factors for maternal cardiac adverse events during pregnancy (Adapted from reference [1])

Adverse maternal cardiac event	Maternal risk factors
• Pulmonary edema • Arrhythmia • Stroke • Death	*General*[a]: • New York Heart Association functional classification III or IV or cyanosis • Systemic ventricular ejection fraction <40 % • Left heart obstruction (mitral valve area <2 cm^2, aortic valve area <1.5 cm^2, peak left ventricular outflow gradient >30 mmHg) • Cardiac event (arrhythmia, stroke, pulmonary edema) prior to pregnancy *Lesion specific*: As discussed in the text

[a]The general risk factors can be used to create a maternal risk index (CARPREG Index) for adverse cardiac events related to pregnancy: 0 risk factors <5 % risk, 1 risk factor ~27 % risk, ≥2 risk factors 75 % risk

stratification. In a single-center retrospective study from Boston, Khairy, and his colleagues validated the global risk factors described in CARPREG and found in addition that subpulmonary ventricular dysfunction and/or severe pulmonary regurgitation were predictors of adverse maternal cardiac outcomes [12]. A large study of 1,302 pregnancies in women with CHD (the ZAHARA study) identified additional factors associated with maternal cardiac complications (use of cardiac medications prior to pregnancy, presence of a mechanical valve, and at least moderate atrioventricular valve regurgitation); the authors of this study have proposed an alternative risk prediction score [20].

Notwithstanding the difficulty of the topic, maternal life expectancy and ability to care for her child should be addressed. If a woman has limited physical capacity or a condition that may result in premature maternal death, this should be explained in a sensitive way that nevertheless explores the implications of her potential inability to look after her child over an extended period. As well, women whose condition imparts a high likelihood of fetal complications, such as those with cyanosis, must be made aware of important associated risks to fetal well-being.

High-Risk Lesions Which May Preclude Pregnancy

A small number of maternal cardiac conditions are associated with high maternal morbidity and mortality. In such circumstances pregnancy should be discouraged until corrective surgery can be performed, if feasible. Otherwise risks must be emphasized, and the patient guided to an appropriate understanding that for most this will result in pregnancy not being attempted at all. These high-risk conditions are severe pulmonary hypertension, Marfan syndrome with an aortic diameter >44 mm [21, 22], systemic ventricular dysfunction (NYHA functional classes III–IV or ejection fraction <40 %), peripartum cardiomyopathy with residual ventricular dysfunction, and severe left heart obstructive lesions including aortic stenosis [1, 12, 17, 19, 23–25] Some experts suggest that pregnancy need not be discouraged in the setting of *asymptomatic* severe aortic stenosis; however, prepregnancy testing should be applied to gain assurance that LV function and exercise capacity are normal [19].

Fetal-Neonatal Risk

Women with CHD and compromised cardiovascular status are at increased risk of adverse fetal and/or neonatal events. Suboptimal fetal-neonatal outcomes may be driven, at least in part, by insufficient uteroplacental perfusion. In a meta-analysis of outcomes of 2,491 pregnancies in women with CHD, premature delivery occurred in 16 % of pregnancies overall, but the prematurity rate was higher in those with complex CHD (including cyanotic lesions) with premature deliveries seen in 22 % of this high-risk population. The overall mortality in offspring in this cohort was 4 % and was related to an increased risk of prematurity as well as a higher frequency of CHD in offspring [11].

Table 147.3 Maternal risk factors for fetal/neonatal adverse events during pregnancy (Adapted from reference [9])

Adverse neonatal events	Maternal risk factors
• Premature birth • Small-for-gestational-age birth weight • Respiratory distress syndrome • Intraventricular hemorrhage • Death (fetal or neonatal)	*Cardiac* • New York Heart Association Functional classification III or IV or cyanosis • Left heart obstruction (mitral valve area <2 cm^2, aortic valve area <1.5 cm^2, peak left ventricular outflow gradient >30 mmHg) *General* • Maternal age <20 or >35 years • Anticoagulant therapy • Smoking during pregnancy • Multiple gestation pregnancy *Obstetric* • Premature delivery/premature membrane rupture • Incompetent cervix • Cesarean section • Intrauterine growth retardation • Bleeding >12 weeks gestation • Febrile illness • Uterine/placental abnormalities

In a prospective controlled study of pregnant women with heart disease reported by Siu and colleagues, adverse fetal-neonatal events (prematurity, low birth weight, respiratory distress syndrome, intraventricular hemorrhage, fetal demise, and neonatal death) were associated with identified maternal cardiovascular risk factors, namely, poor maternal functional class, cyanosis, and left heart obstruction (Table 147.3). The risk of neonatal complications was further increased in women with heart disease (27 % in those without cardiac risk factors for a neonatal event and 33 % in those with at least one risk factor) who had established obstetric risk factors or multiple gestation, who smoked, or who received anticoagulant therapy [9].

There is also the risk of transmission of heart disease to the offspring. A genetic anomaly with autosomal dominant inheritance in a parent (such as 22q11 deletion or Holt-Oram syndrome) confers up to 50 % risk of recurrence in the offspring. In the absence of an identifiable syndrome in a parent with CHD, the risk of recurrence of CHD in the fetus is approximately 6 %, contrasted to a background population risk of about 0.8 % [26, 27]. The type of CHD seen in offspring can differ from the lesion seen in the parent [28]. Recurrence risk of CHD in offspring varies by lesion and in some reports is as low as 0.6 % in association with maternal transposition of the great arteries (TGA) [11] and as high as 18 % in the presence of maternal left ventricular outflow tract obstruction (LVOTO) [29].

The performance of transabdominal fetal echocardiography is accepted clinical practice for women with structural CHD. The study is best performed between 18 and 22 weeks gestation when visualization of the fetal heart is optimal [30]. Fetal echocardiography not only allows for early counseling and decision-making for the expectant parents but, in some forms of congenital heart disease, the outcome of a fetus with an antenatal diagnosis of congenital heart disease is improved relative to an infant with the same cardiac lesion diagnosed postnatally [31, 32]. Although most major structural and functional cardiac disease can be reliably excluded with fetal echocardiography [33, 34], some forms of CHD cannot be definitively diagnosed. The limitations of fetal echocardiography may be explained by features inherent in the fetal circulation (i.e., obligatory presence of an atrial level shunt and patent ductus arteriosus), cardiac morphogenesis (i.e., normal presence of muscular ventricular septal defects during cardiac development), and the resolution of current ultrasound technology (i.e., difficulties with visualization of some lesions such as minor valvular abnormalities or anomalies of pulmonary or systemic venous return). Postnatal pediatric cardiac assessment in offspring is important and offers additional diagnostic utility even when the fetal echocardiogram is normal [35].

Outcomes Associated with Specific Cardiac Lesions

A rational approach to the management of a pregnant woman with heart disease can be developed when the expected physiologic changes of pregnancy are placed in the context of a specific congenital heart lesion. For instance, pregnancy is generally better tolerated in women with volume overload lesions as compared with pressure overload lesions, and close surveillance during pregnancy is warranted for the latter, if pregnancy goes forward after careful evaluation of risk. Patients with CHD often defy simple classification, as multiple lesions in various stages of palliation may exist in the individual patient. Nevertheless, for the purpose of this chapter, each congenital lesion is considered as an independently occurring condition.

Volume Overload Lesions

Left-to-Right Shunts

The increase in work required of a volume-loaded right ventricle (RV) in the presence of an atrial septal defect (ASD) or LV in the context of a ventricular septal defect (VSD) or patent ductus arteriosus (PDA) is offset by a decrease in peripheral vascular resistance during pregnancy. As a consequence, and in the absence of pulmonary hypertension, pregnancy and delivery are generally well-tolerated [1, 36–39]. In a recent overview, significant arrhythmia requiring therapy was reported in 1/123 pregnancies with ASD (0.8 %) and in none of the 83 pregnancies with VSD; there were no reports of CHF [11]. Paradoxical embolization may infrequently be encountered (particularly in the setting of an ASD).

An atrioventricular septal defect (AVSD) may be less well tolerated in pregnancy as compared with the simpler defects described above due to its relative complexity. A retrospective review of 48 pregnancies (92 % of women postsurgical repair) reported postpartum persistence of deterioration in NYHA class, arrhythmias, and worsening of preexisting left atrioventricular valvular regurgitation in 23 %, 19 %, and 17 % of women, respectively [40].

Valvular Regurgitation

Significant pulmonary regurgitation (PR) is common after repair of tetralogy of Fallot (TOF) particularly if a trans-annular patch was applied. Sequelae of severe PR include RV dilation, RV dysfunction, and a propensity for arrhythmias. A retrospective review of 82 successful pregnancies (including 20 pregnancies in women with unrepaired TOF) reported cardiovascular events in six women (14 %), including supraventricular arrhythmia, CHF, pulmonary hypertension, and pulmonary embolus. The majority of women with cardiovascular complications had a significant abnormality of structure or function, including severe PR with RV dilation, RV hypertension, or peripartum LV dysfunction [41]. Another study of 50 pregnancies in women with corrected TOF reported cardiac complications in 12 % of pregnancies, either CHF or arrhythmia or both [42]. Most recently, a study demonstrated that women at highest risk of heart failure are those with at least moderate PR *and* one of the following: residual RV outflow obstruction or RV systolic dysfunction or RV hypertrophy [43].

Important congenital tricuspid valve insufficiency is commonly found in women with unrepaired Ebstein anomaly. Apical displacement of the tricuspid valve leaflets results in atrialization of the RV which can reduce the size of the inlet portion of the functional RV. A compromised functional RV may not be able to accommodate the increased stroke volume of pregnancy, leading to worsening tricuspid insufficiency, raised right atrial pressure, and in those women with atrial shunts, right-to-left shunting across the atrial septum. In some, chronic tricuspid regurgitation can result in RV volume overload, RV dysfunction, and similar inability to adapt to the hemodynamic changes of pregnancy. Nonetheless, women with Ebstein anomaly typically do well during pregnancy. In a study of 111 pregnancies in 44 women with Ebstein anomaly (10 postsurgical repair), no serious maternal cardiac complications

were reported (e.g., no deaths, life-threatening arrhythmias, heart failure, or stroke), but there was an increased risk of prematurity and fetal loss; birth weight was significantly lower in the newborns of cyanotic women [44].

Both mitral and aortic regurgitation (even if severe) are generally well tolerated during pregnancy (in the setting of preserved ventricular function) because reduced maternal systemic vascular resistance attenuates the impact of the increased volume load on the subaortic ventricle. If decompensation does occur, response to medical therapy is generally seen [17, 45].

Pressure Overload Lesions: Left Heart

Aortic Stenosis

When aortic stenosis (AS) complicates pregnancy, it is usually due to a bicuspid aortic valve (BAV), which may also be associated with aortic coarctation and/or ascending aortopathy. Subvalvular and supravalvular AS have similar hemodynamic consequences to valvular AS. Women with symptomatic AS should delay pregnancy until after percutaneous catheter intervention or surgical correction [17, 19]. Women with moderate or severe AS are at increased risk for heart failure or arrhythmia during pregnancy even if they are asymptomatic prior to conception [1, 36, 46, 47]. In the asymptomatic woman with severe AS, prepregnancy evaluation should establish that LV wall thickness and function are normal and that exercise testing is reassuring [19]. Contemporary studies report low maternal mortality in asymptomatic women with AS [46–49]. Symptomatic AS during pregnancy is better managed by palliative percutaneous balloon valvuloplasty when feasible because cardiac surgery carries a substantial risk of fetal mortality [46, 50–53]. In the absence of prosthetic valve dysfunction, women with a tissue prosthesis usually tolerate pregnancy well. Pregnancy has not been clearly shown to accelerate degeneration of bioprosthetic or homograft valves [54, 55]. In two reports of women post-Ross operation (pulmonary autograft aortic valve replacement), no cardiac complications were reported during 24 completed pregnancies; one woman developed a dilated cardiomyopathy 6 months after delivery unrelated to aortic valve dysfunction [56, 57].

Pregnancy in a woman with a mechanical valve prosthesis carries increased risk of valve thrombosis as a result of the prothrombotic state of pregnancy and the competing need to modify anticoagulation regimes for fetal reasons. Thrombosis risk during pregnancy is also influenced by valve type (the risk is higher in older-generation valves), position (the risk is greater in the mitral as compared with the aortic position), prenatal valve function, and type of anticoagulant used [58].

Mitral Stenosis

Although congenital mitral stenosis (MS) is relatively rare, acquired MS due to rheumatic heart disease is not uncommonly seen in the parturient from developing countries. The hypervolemia and tachycardia associated with pregnancy exacerbate the impact of mitral valve obstruction. The resultant elevation in left atrial pressure increases the likelihood of atrial fibrillation and/or heart failure [45]. Thus, even women with mild to moderate MS who are asymptomatic prior to pregnancy may develop substantial cardiovascular morbidity during the antepartum and peripartum periods [1, 13, 49, 59]. In a study of 80 pregnancies (moderate or severe MS in 47 %), maternal complications were seen in 28 pregnancies or 35 % (specifically, pulmonary edema in 25 and arrhythmias in 9 of the pregnancies) [59]. Maternal morbidity is generally seen in the setting of moderate or severe left-sided valvular disease [49].

In pregnant women in persistent NYHA functional class III or IV despite optimal medical therapy, percutaneous mitral valvuloplasty should be considered during pregnancy, if feasible [60–62].

Coarctation of the Aorta

In women with repaired coarctation of the aorta, the risk of mortality related to pregnancy is

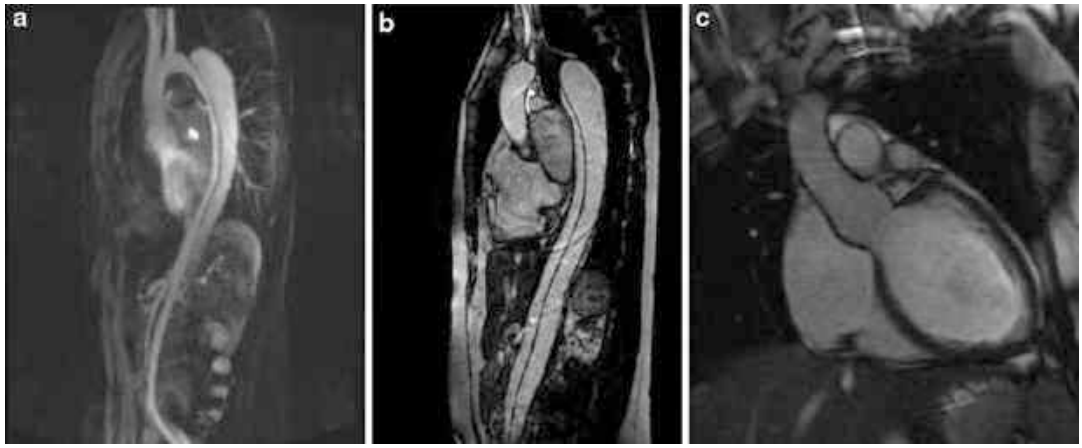

Fig. 147.3 An extensive type B dissection was diagnosed by cardiac magnetic resonance imaging 6 days postpartum in this 35-year-old with a known diagnosis of Marfan syndrome (sagittal view demonstrating dissection originating distal to the left subclavian artery with extension to the iliac vessels as demonstrated using time-resolved and conventional magnetic resonance angiography, *panels a* and *b*). Aortic root dimensions were normal and unchanged throughout the pregnancy (monitored echocardiographically) and postpartum (steady-state free-precession cine image of the aortic root measuring 33 mm in the coronal view, *panel c*)

generally low, except in those with Turner syndrome. In 308 pregnancies reported in four contemporary studies, the only maternal death occurred as a result of aortic dissection in a woman with Turner syndrome who had previously undergone coarctation repair [1, 36, 63, 64]. The primary pregnancy risk relates to hypertension (with or without associated proteinuria) and, based on administrative data from the United States, occurs in approximately 24 % of pregnancies in women who had a coarctation repair [65]. The risk of aortic dissection and rupture is reduced following coarctation repair, but not eliminated [63, 66]. In women with uncorrected coarctation, satisfactory control of upper body hypertension may lead to excessive hypotension below the coarctation site, compromising the fetus. Intrauterine growth restriction and premature labor are more common [63, 66].

Aortopathies

The life-threatening aortic complication of Marfan syndrome is aortic dissection resulting from medial aortopathy, which most commonly occurs in the last trimester of pregnancy or in the early postpartum period (Fig. 147.3) [19]. Risk is increased in pregnancy due to hemodynamic stress and perhaps hormonal effects. A prospective study of 45 pregnancies in 21 patients reported no increase in cardiac complications or significant change in aortic root size in women with normal aortic roots. However, in the eight women with a dilated aortic root (>40 mm) or prior aortic root surgery, 3/9 pregnancies were complicated by either aortic dissection (2) or rapid aortic dilatation. Beta-blocker pharmacotherapy was not used during pregnancy in the majority of women in this study [24]. In another prospective study of 33 pregnancies in 23 women with Marfan syndrome, favorable outcomes were found with aortic root diameter <45 mm and no previous history of dissection. There was a small but statistically significant increase in aortic root diameter during pregnancy in women with an initial aortic root diameter ≥40 mm as compared with those whose root diameter was <40 mm (Fig. 147.4) [25]. In a review of published studies between 1995 and 2006 describing more than 350 pregnancies in women with Marfan syndrome, the overall dissection risk was 3 % (1 % if the root diameter was <40 mm and 10 % if the root diameter was ≥40 mm) [67].

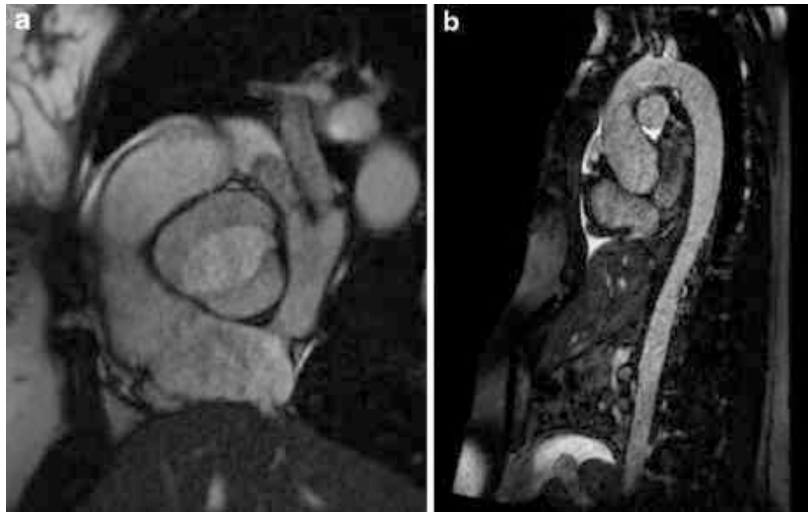

Fig. 147.4 A new diagnosis of Marfan syndrome was made during pregnancy in this 31-year-old woman. Cardiac magnetic resonance imaging was performed at 32 weeks gestation to confirm aortic root measurements after progressive root dilation was diagnosed on echocardiography. Steady-state free-precession (SSFP) imaging cine imaging of the aortic root in cross-section reveals a bicuspid aortic valve with a maximum dimension of 50 mm (*panel a*). 3D SSFP imaging excludes an aortic dissection (*panel b*) (Note the presence of the fetus in the *bottom left* of the figure)

Surgical repair should be offered to women prior to conception if the aortic root diameter is >40–45 mm depending on individual characteristics [17, 19], although root replacement does not fully eliminate the risk of dissection thereafter [68]. Thus, women with aortic root enlargement should receive preconception counseling emphasizing their risk, and in early pregnancy should be counseled regarding the risks of proceeding. In contrast, women with normal aortic root diameter may tolerate pregnancy well, though there remains a possibility of dissection even with normal aortic dimensions (Fig. 147.3). Serial echocardiography (every 6–8 weeks) should be used to identify progressive aortic root dilatation during pregnancy, and women should be closely followed for the first 6 months postpartum [69]. Medical therapy with beta-blockade may reduce aortic wall stress in women with aortopathy, but its clinical efficacy has not been formally studied in pregnancy. Despite the absence of trials specifically evaluating beta-blocker therapy in pregnancy, the potential benefit likely outweighs the relatively small risk, and beta-blockers should be prescribed [19].

In ascending aortopathy associated with BAV, the risks are much less than in women with Marfan aortopathy, but dissection has been reported [70, 71]. The histological features of aortopathy related to a BAV are similar to what has been described in Marfan syndrome [72]. Management guidelines differ. Some have suggested that criteria as described for Marfan syndrome be applied to aortopathy related to a BAV; [17, 71] others have stated that prepregnancy surgery be offered only if the ascending aortic diameter exceeds 50 mm [19].

With assisted reproductive technology, women with Turner syndrome (in whom fertility is compromised) can now become pregnant. These women are at particular risk of dissection relatively early in life [45], even in the absence of recognized aortic root pathology or hypertension [73]. Dissection risk in this population has been identified when the indexed aortic size exceeds 2.5 cm/m^2 [74]. Pregnancy appears to increase the risk of cardiovascular mortality in Turner syndrome when associated with structural heart disease (such as BAV, aortic dilation, aortic coarctation unrepaired or repaired) and is therefore not advised [63, 75].

Pressure Overload Lesions: Right Heart

Pulmonary Stenosis

Unlike aortic stenosis, pulmonary valve stenosis (PS) is not associated with significant risk during pregnancy [1, 36, 49]. Two recent studies examining 68 women have reported no major cardiac complications [76, 77] (although hypertension and thromboembolism were noted in 15 % and 4 %, of pregnancies, respectively) [76]. Although rarely required, balloon valvuloplasty during pregnancy is feasible if symptoms of PS progress.

Pulmonary Vascular Obstructive Disease

In women with Eisenmenger physiology (i.e., pulmonary hypertension related to an intracardiac shunt), the reduced systemic vascular resistance associated with pregnancy facilitates an increase in right-to-left shunting, exacerbating maternal cyanosis with adverse effects on fetal outcome. Consequently, such women are particularly sensitive to volume depletion and hypotension, situations which augment right-to-left shunting resulting in worsening cyanosis, hypoxemia, and pulmonary vasoconstriction.

Women with pulmonary hypertension often have less reserve to adapt to the increased plasma volume of pregnancy. Right-sided heart failure can develop, particularly postpartum, given volume shift and fluid administration at the time of labor and delivery. Thromboembolic complications are well described [78]. Mortality in pregnant women with Eisenmenger syndrome continues to be prohibitively high, approximately 30 % in each pregnancy [7, 78]. In a contemporary review of pregnancy outcomes in women with pulmonary hypertension related to CHD, maternal mortality remains high despite the use of pulmonary vasodilator therapy in more than half of the women, with little improvement in mortality compared to the previous era (28 % maternal mortality in 1997–2007 compared with 36 % in 1978–1996) [78]. Most complications occur at term and during the first week postpartum. Current consensus is to advise against conception and to offer termination in the event of a pregnancy [19, 79]. In the event of pregnancy, spontaneous abortion is common, intrauterine growth restriction is seen in 30 % of pregnancies, and preterm labor is frequent. The high perinatal mortality rate of 28 % is largely due to prematurity-related deaths [7].

Cyanotic Heart Disease: Unrepaired and Repaired

In the absence of pulmonary hypertension, mortality associated with pregnancy is rare in women with uncorrected cyanotic CHD although morbidity may be substantial [80]. The usual pregnancy-associated fall in systemic vascular resistance and rise in cardiac output can exacerbate right-to-left shunting and lead to increased maternal hypoxemia and cyanosis. A study examining the outcomes of 96 pregnancies in 44 women with a variety of cyanotic congenital heart defects reported a high rate of maternal cardiac events (32 %) and prematurity (37 %), as well as a low live birth rate (43 %) [80]. The lowest live birth rate (12 %) was observed in mothers with arterial oxygen saturation $\leq$85 %.

Complete Transposition of the Great Arteries

Complete Transposition of the Great Arteries After an Atrial Redirection Procedure

Most published data regarding pregnancy outcomes in women with transposition of the great arteries (TGA) are derived from women after atrial redirection (Mustard or Senning procedure). After such surgery, the morphologic RV supports the systemic circulation. Tricuspid regurgitation, RV dilation, and RV dysfunction are common. Additional sequelae include sinus node dysfunction, tachyarrhythmia, and baffle leak/obstruction. Two retrospective studies of pregnancy after atrial redirection were published in 2005 and 2008, describing 68 women who had 139 pregnancies. The most commonly reported complications were arrhythmias (13 % and 22 %) and CHF (7 % and 15 %) [81, 82]. Maternal death and/or transplant after pregnancy (8 %) have been

reported (cardiac transplant shortly after delivery in one woman, heart failure-related death 1 month after delivery in one woman, and sudden death 4 years after delivery in one woman) [81, 82]. One study suggested that pregnancy may adversely impact the subaortic RV in this population [83]. With serial echocardiographic studies of the subaortic right ventricle during and after pregnancy, progressive RV dilation occurred during pregnancy in 5/18 women (21 %) and worsening RV function was noted in 4/21 (25 %) women [83]. Although these data suggest that pregnancy may affect subsequent systemic RV function, these observations require confirmation using more objective and reproducible methods of RV quantification.

Complete Transposition of the Great Arteries After an Arterial Switch Procedure

Women managed with an arterial switch operation have only recently reached childbearing age. In the absence of ventricular dysfunction, coronary obstruction, or other important residua or sequelae, a good outcome may be anticipated. In a recent, multicenter, retrospective review of 17 pregnancies in 9 women, there were no maternal deaths. There were two notable complications of pregnancy: non-sustained ventricular tachycardia in one woman with impaired LV function and postpartum valve thrombosis in one woman with a mechanical valve [84].

Congenitally Corrected Transposition of the Great Arteries

In congenitally corrected transposition (atrioventricular and ventriculo-arterial discordance or "double discordance"), the morphologic RV supports the systemic circulation. Tricuspid regurgitation and RV dilation and dysfunction are frequently seen. In two large studies of 105 pregnancies in 41 women, the most common complication was CHF (9 % and 16 %). No maternal deaths were reported [85, 86]. The impact of pregnancy on the subaortic RV in this population is not known.

Functional Single Ventricle Post-Fontan Palliation

The Fontan palliation surgically redirects systemic venous return to the pulmonary arteries in patients with single ventricle physiology. However, an inherent limitation in the heart's ability to augment cardiac output remains. Long-term sequelae may include arrhythmia, ventricular dysfunction, protein-losing enteropathy, and thromboembolic events. As freedom from death or cardiac transplantation is only 54 % in adults 25 years after Fontan surgery [87], it is important that long-term maternal prognosis be discussed during preconception counseling.

In the largest series of pregnant women with Fontan palliation published to date, 33 pregnancies were reviewed in 14 mothers. The single cardiac complication reported in this study was supraventricular tachycardia in one woman [88]. In two subsequent studies examining eight completed pregnancies in six women, maternal cardiac complications included atrial tachyarrhythmias (three pregnancies, 38 %) and decline in functional capacity (three pregnancies, 38 %); the rate of premature birth was remarkably high (six pregnancies, 75 %) [89, 90]. There have been no reported maternal deaths [91].

Antepartum Management

General Principles

Women with heart disease who are at intermediate or high risk for complications should be managed in a high-risk pregnancy unit by a multidisciplinary team from cardiology, high-risk obstetrics, obstetric anesthesia, and neonatology. When dealing with a complex problem, the medical team should meet early in the pregnancy to develop and then distribute a written management plan. For women who are believed to be at low risk, initial consultation at a regional referral center may still be helpful, although consideration can be given to ongoing management in a community hospital setting.

Normal hemodynamic adaptations to pregnancy may result in symptoms and signs which

mimic those of cardiac decompensation. Women with structurally and functionally normal hearts may experience presyncope, syncope, palpitations, dyspnea, and exercise intolerance during a normal pregnancy. Furthermore, normal physical examination findings in pregnancy can mimic heart disease, such as prominence of the jugular venous pulsation, displacement of the apical impulse, presence of a murmur, development of a gallop sound, and/or peripheral edema. Differentiation between expected physiologic changes of pregnancy and worsening cardiac disease in a woman with known CHD can sometimes be difficult based on history and physical examination alone. ECG and echocardiogram help to clarify the significance of symptoms and signs when abnormalities are noted on physical examination. In addition, serum B-type natriuretic peptide (BNP) may be a useful adjunct; a normal BNP level is particularly helpful and has a high negative predictive value [92].

In some women with structural cardiac lesions and NYHA III or IV symptoms, activity limitation and occasionally hospital admission may be advisable. Gestational hypertension, hyperthyroidism, infection, and anemia should be identified early and treated vigorously.

For women with significant mitral stenosis (MS), beta-adrenergic blockers should be used to control heart rate and lengthen the diastolic filling period. Diuretics should be used for the treatment of pulmonary congestion or right heart failure; however, overly aggressive diuresis may lead to decreased uteroplacental perfusion. Women with MS and atrial arrhythmias should receive anti-coagulant therapy. Some experts have advocated for the use of anti-coagulation prophylaxis in the presence of severe MS and an enlarged left atrium, even in the absence of an established atrial tachyarrhythmia, due to the hypercoagulability inherent in pregnancy and the possibility that an atrial tachyarrhythmia, especially atrial fibrillation, may develop [93]. Penicillin prophylaxis to protect against recurrent rheumatic fever should continue as in the nonpregnant state [17]. Guidelines recommend beta-blockade in all patients with Marfan syndrome [19]. If such therapy has not been initiated prior to pregnancy, it should be begun when the pregnant woman is first assessed. Some offer empiric therapy with beta-adrenergic blockers to those with a dilated aorta in the presence of a BAV.

Special Circumstances

Arrhythmias

The pregnant state may increase arrhythmia propensity because of cardiac chamber dilation, altered hormonal milieu, and enhanced sympathetic tone [94]. Premature atrial or ventricular beats are common in normal pregnancy. The most common arrhythmias encountered during pregnancy are atrial arrhythmias; ventricular arrhythmias are much less frequent, even in women with structural heart disease. Women with a previous history of arrhythmia are at increased risk of recurrence during pregnancy. Adverse fetal and neonatal outcomes have been related to recurrent arrhythmia during pregnancy [95]. Women with CHD at highest risk of arrhythmia are those with atrial redirection surgery for transposition, those after Fontan repair, and those with a history of AVSD [11].

Pharmacological treatment is usually reserved for patients with frequent or sustained arrhythmias, particularly if poorly tolerated and/or in the presence of structural cardiac abnormalities. Sustained tachyarrhythmias such as atrial flutter or atrial fibrillation should be treated promptly, avoiding teratogenic antiarrhythmic drugs (Table 147.1). Electrical cardioversion is thought to be safe in pregnancy [19]. The use of antiarrhythmic agents should be carefully considered due to the potential impact on the fetus. Beta-adrenergic blockers are the antiarrhythmic drugs of choice in view of their attractive safety profile. Digoxin is also safe but less commonly used [17–19]. Quinidine, sotalol, adenosine, and lidocaine can be used, but published data on their use during pregnancy are more limited. Amiodarone is not recommended as it may interfere with neonatal thyroid function [96, 97]. Because of limited experience in pregnancy, dronedarone, a newer antiarrhythmic agent with properties similar to amiodarone, is not recommended in

pregnancy [19]. Pregnancies in women with implantable cardioverter-defibrillators are associated with favorable maternal and fetal outcomes [98].

Anticoagulation for Mechanical Heart Valves

In a systematic overview of pregnancy outcomes in women with prosthetic heart valves, the overall pooled maternal mortality was 2.9 % and was mostly related to valve thrombosis [5]. Thus, prevention of thrombosis is of utmost importance. The choices of anticoagulants include oral warfarin, unfractionated heparin, and low molecular weight heparin (LMWH). Warfarin is effective (with a 3.9 % risk of thromboembolism) [5] but carries a risk of embryopathy during organogenesis, and fetal intracranial bleeding can occur throughout pregnancy. Although the incidence of embryopathy is lowest when a daily warfarin dose of $\leq$5 mg was utilized [99], there are ongoing concerns about neurodevelopmental abnormalities as a consequence of fetal intracranial bleeding. Fetal intracranial hemorrhage during vaginal delivery is a risk with warfarin and substitution with heparin has been suggested 2–3 weeks prior to planned delivery or at 36 weeks gestation [19]. Newer oral anticoagulants, such as direct thrombin (e.g., dabigatran) and anti-Xa (rivaroxaban, apixaban) inhibitors, are not recommended for use during pregnancy [100].

Adjusted dose subcutaneous unfractionated heparin has no teratogenic effects, as the drug does not cross the placenta, but there is increased risk of valve thrombosis (25 % risk of thromboembolism [5]), maternal thrombocytopenia, and osteoporosis. Claims of inadequate effectiveness of unfractionated heparin in patients with mechanical heart valves have been countered by arguments that inadequate doses were used; however, dosing unfractionated heparin remains challenging during pregnancy. Weight-adjusted therapeutic LMWH has better bioavailability than unfractionated heparin and has been suggested as an alternative to adjusted dose unfractionated heparin. There is growing experience with use of LMWH during pregnancy in women with mechanical valves [101–104].

In the absence of persuasive data establishing optimal anticoagulation regimens in pregnant women with mechanical heart valves, current practice guidelines are all based on expert opinion and recommendations differ [17, 19, 100, 105]. The American College of Chest Physicians (ACCP) recommends that either LMWH or unfractionated heparin be used throughout pregnancy with dose adjustments based on careful monitoring of plasma anti-Xa levels; the European Society of Cardiology suggests that oral anticoagulants are preferred during pregnancy and that LMWH is controversial but may be considered if anti-Xa levels are carefully monitored. Some have proposed alternate strategies for patients deemed at "higher risk" as compared to those deemed to be at "lower risk" for of thromboembolism [58]. When LMWH is chosen, weight-adjusted therapeutic LMWH doses should be used to maintain levels of anti-Xa between 0.8 and 1.2 U/ml 4 h after administration, based on the ACCP guidelines. Women at high risk for valve thrombosis may be switched to warfarin after the first trimester. Adjunctive use of low-dose aspirin should also be considered [17, 105]. Low-dose aspirin is safe for the fetus, even at term, unlike higher doses which may promote premature closure of the fetal ductus arteriosus if used prior to delivery.

Advanced Cardiac Imaging During Pregnancy

On occasion, more refined cardiac imaging is required during pregnancy than that afforded by transthoracic echocardiography. Transesophageal echocardiography is considered to be relatively safe during pregnancy, although the operator should be aware of the increased risk of aspiration related to pregnancy, and fetal monitoring should occur if sedation is given [19]. Cardiac computed tomography (CT) can offer an alternative imaging modality for assessment of the coronary arteries; however, it is generally not recommended in pregnancy because radiation doses exceed those of conventional angiography [19]. Cardiovascular magnetic resonance (CMR) may provide useful information during pregnancy, particularly regarding arterial and/or venous structures which

are suboptimally seen on echocardiography. Current recommendations suggest that CMR be avoided during the first trimester of pregnancy due to limited information on impact of magnetic field gradients on organogenesis and that gadolinium not be used because effects on the developing fetus are currently unknown [106, 107].

In the event of a suspected acute coronary syndrome, coronary angiography should be performed expeditiously to confirm the diagnosis, since causes other than atherosclerosis, especially coronary artery dissection or coronary thromboembolism, may be found, and so that percutaneous angioplasty and stenting can be achieved without delay when indicated. The main concern pertaining to angiography during pregnancy relates to fetal radiation exposure. Estimated radiation exposure to the mother after conventional coronary angiography is ~7 mGy (7 mSv, equivalent to 70 chest X-rays) and after percutaneous coronary intervention is ~15 mGy (15 mSv, equivalent to 150 chest X-rays); however, with tissue attenuation ~20 % of this radiation exposure is expected to reach the fetus [19]. Evidence suggests that there is no increase in fetal congenital malformations if the maternal dose is less than 50 mGy [108, 109]. Radiation exposure of the fetus in the catheterization laboratory can be further minimized by using a radial artery approach, adequate shielding of the maternal abdomen, shortening of fluoroscopic time, and if possible, delay of a procedure until major organogenesis is complete (i.e., after 14 weeks of gestation).

Interventional Cardiac Procedures During Pregnancy

Interventions for structural and acquired heart disease during pregnancy are uncommon. First and foremost there must be reasonable certainty that medical alternatives have been exhausted and that the safest and most prudent approach for the patient is to intervene. The involvement of a multidisciplinary team to aid in decision-making and planning has been universally helpful. Team members should include those from cardiology, high-risk obstetrics, neonatology, obstetric anesthesiology, interventional cardiology, cardiac surgery, and cardiac imaging. These disciplines should formulate a plan not only for the intervention but for contingencies in case of procedural complication or failure. A patient who is sufficiently ill to require an intervention while pregnant may also have a significant risk of an adverse event related to the procedure. Decisions about obstetric management should be made in advance of the procedure and appropriate personnel and resources should be available and "standing by" depending on the risk of the procedure being proposed. The consent process for the patient should address risks to the mother and fetus or neonate, as well as risks of continued medical management and cardiac surgery, where applicable.

The most common invasive cardiac interventions in the pregnant patient involve the treatment of severe left-sided obstructive valvular lesions. Balloon aortic and mitral valvuloplasty can usually be carried out quickly and efficiently by experienced operators and can have a significant impact on symptoms. Both of these interventions can theoretically involve dramatic complications including bleeding and severe valvular regurgitation, and thus, a plan should be in place to deal with these possibilities, in advance of the procedure. Right-sided obstructive lesions are generally well-tolerated in pregnancy without intervention but are also candidates for valvuloplasty. Closure of atrial level shunts for relief of cyanosis caused by Ebstein anomaly or platypnea orthodeoxia can be contemplated during pregnancy with device closure, a procedure requiring only several minutes of fluoroscopy time with the possibility of almost no fluoroscopy with adjunctive intracardiac echocardiographic imaging. Closure of a shunt lesion for volume overload is almost never required. A role for transcatheter valve replacement in the symptomatic patient will likely emerge as these technologies mature.

Hypertension in Pregnancy

Some women with CHD are at risk for hypertensive disorders of pregnancy. In women without heart disease, mild preexisting hypertension may not require pharmacotherapy in pregnancy, as fetal outcomes are unaffected, maternal blood pressure generally falls below baseline during

the first 20 weeks of gestation, and excessive lowering of maternal blood pressure may compromise placental perfusion. Therapy is often initiated or reinstituted if moderate-severe hypertension develops (systolic BP $\geq$150–160; diastolic BP $\geq$100–110; or both) or there is target organ damage. For women with heart disease, blood pressure targets need to be individualized, and therapy is often initiated at lower thresholds than for women without structural heart disease [19, 110].

If treatment is indicated, recommended drug therapy options include labetalol or other beta-blockers, methyldopa, hydralazine, and/or nifedipine [111, 112]. Choice of an antihypertensive should be based on the potential for side effects and should factor in the underlying heart disease of the mother [113]. Diuretics are indicated for the management of volume overload in renal failure or CHF, and may be used as adjuncts in the management of preexisting (chronic) hypertension, but should be avoided in gestational hypertension (preeclampsia), which is a volume-contracted state [114]. Due to increased risk to the fetus, angiotensin-converting enzyme inhibitors and by extension angiotensin receptor blocking agents are not considered safe during the second and third trimesters of pregnancy; the first trimester risk of fetal malformations is likely due to the underlying hypertension, rather than the use of medications [115].

Gestational hypertension with proteinuria (preeclampsia) is treated definitively only by delivery of the fetus and placenta. Delay in delivery to allow maturation of the fetus can often be accomplished if the syndrome is mild, the patient is under very close surveillance in a hospital or obstetrical day unit, and pregnancy is terminated as soon as further benefit to the fetus is unlikely or maternal safety is compromised [110].

Management During Labor and Delivery

Vaginal delivery is generally recommended in women with CHD [19]. Cesarean delivery for cardiac indications should be considered in women with aortic dissection, Marfan syndrome with dilated aortic root, or failure to switch from warfarin to heparin within 2 weeks prior to labor. Preterm induction for cardiac indications is rarely indicated. At term (after 37 weeks gestation), a planned induction for logistic reasons is reasonable in high-risk situations particularly if the patient lives far away from the hospital or if appropriate resources are not readily available in a timely fashion.

Invasive hemodynamic peripartum monitoring, apart from intra-arterial monitoring, is seldom required. Our approach is to utilize intra-arterial monitoring if there is concern about the interpretation and deleterious effects of a sudden drop in systemic blood pressure (i.e., in the setting of severe AS, pulmonary hypertension, or important systemic ventricular systolic dysfunction). The introduction of minimally invasive and noninvasive cardiac output monitoring in recent years offers an exciting opportunity to monitor changes in cardiac output and systemic vascular resistance at the bedside, allowing for optimization of fluid balance for the patient.

Prophylactic and therapeutic LMWH are discontinued at least 12–24 h prior to induction and can be resumed 6–12 h postpartum in the absence of hemorrhage [19, 100]. Unfractionated heparin is discontinued 6–12 h prior to induction and it can be reversed with protamine if spontaneous labor develops. Minimizing the period of no anticoagulation in patients with mechanical valves is crucial to prevent valve thrombosis. According to current cardiology guidelines, routine prophylactic antibiotic therapy is not indicated during labor and delivery [116]. In the presence of a shunt, air and particulate filters should be placed on all intravenous lines.

For a vaginal delivery in women with intermediate or complex CHD, epidural or combined spinal-epidural analgesia with adequate volume preloading is the technique of choice and can be offered to most patients. Women in whom a sympathetic blockade may pose special risk to hemodynamic stability may have a limitation on the concentration of local anesthetic used in the epidural mixture. A mixture of local anesthetics and narcotics (either fentanyl or sufentanil)

provides very effective analgesia while using relatively low concentration of the former. If operative vaginal delivery is indicated and there is contraindication to higher concentrations of local anesthetic in the epidural space, analgesia may be supplemented by perineal infiltration of local anesthetic or alternatively a pudendal block.

If a cesarean section is indicated, most patients will tolerate a slowly titrated epidural or combined spinal-epidural anesthesia. However, the use of regional anesthesia is controversial in patients with severe aortic stenosis, pulmonary hypertension, cyanotic cardiac disease, and hypertrophic and dilated cardiomyopathy. In some of these cases, general anesthesia is indicated. Induction agents suitable for these patients include etomidate and ketamine, depending on the case; propofol should be used with caution, due to its cardio-depressant effects. An opiate-based anesthetic is preferred in all cases. Although some cases will be most suitable for total intravenous anesthesia, inhalational agents such as sevoflurane in low concentration are usually well tolerated. Overall complication rates related to anesthetic management in women with heart disease are not significantly different from the general obstetric population [117].

Labor is conducted in the left lateral decubitus position, when possible, to attenuate hemodynamic fluctuations associated with contractions in the supine position. A facilitated second stage of labor will reduce need for maternal expulsive efforts. Because of the potential for postpartum complications, those patients at intermediate or high risk may require additional monitoring postpartum. The duration of monitoring needs to be individualized. For instance, women with Eisenmenger syndrome require longer postpartum observation, since mortality risk persists for weeks after delivery. We routinely monitor these women for at least 7 days postpartum.

Contraception

Discussions regarding family planning should begin when a young woman approaches childbearing age (during early adolescence). Contraceptive methods should be individually tailored to the patient, keeping in mind, for each contraceptive method, personal preference, efficacy, and safety. Factors to be considered which relate directly to a woman's cardiac condition include the risk of thromboembolism with estrogen-containing products, risk of endocarditis and vagal response with insertion of an intrauterine device, and maternal risk in the event of contraceptive failure. All barrier methods have a significant failure rate and are therefore not an optimal strategy for a population of women in whom pregnancy is a high risk or best avoided [118].

Efficacy rates for oral contraceptive pills that combine estrogen and progesterone are extremely high, nearing 99.5 % if optimally administered [119]. Newer modes of delivery for combined hormonal contraception include a vaginal ring containing ethinyl estradiol and etonogestrel (NuvaRing®), a contraceptive patch containing ethinyl estradiol and norelgestromin (OrthoEvra®), and an injectable preparation consisting of medroxyprogesterone acetate and estradiol cypionate (Lunelle®), all with similarly high efficacy rates [120]. However, women with CHD who are at particular risk of thromboembolic events, such as women with cyanosis and an obligatory right-to-left intracardiac shunt, pulmonary hypertension, Fontan circulation, sustained arrhythmias, mechanical heart valves, and/or significant ventricular dysfunction, should avoid estrogen-containing contraceptive methods due to the increased risk of arterial and venous thrombosis. Anticoagulation with warfarin may not completely protect against the thrombogenic effects of estrogen [121]. Risk of estrogen-related thromboembolism is further increased by traditional cardiovascular risk factors such as smoking, hypertension, diabetes, and obesity [122].

The possible interaction between hormonal contraception and additional medications should be considered. Estrogen and progesterone can individually affect the metabolism of warfarin; heightened surveillance of anticoagulation efficacy is advised when hormonal contraception is initiated in these women [121]. Because of reports of combined oral contraceptive failure with concurrent antibiotic use (even when

short term) an additional method of contraception is recommended in such circumstances [122]. Bosentan, an endothelin antagonist used in the treatment of pulmonary hypertension, can decrease the efficacy of some hormonal preparations, and additional contraceptive precautions should be advised in women with pulmonary hypertension being treated with bosentan [123].

Progestin-only contraceptive methods, which include oral, injectable, and implantable formulations, do not increase the risk of thromboembolism and are therefore commonly used when estrogen-containing products are deemed unsafe. The older-generation progestin-only pills, or "mini-pills," have considerably lower efficacy as compared with combined oral contraceptive pills. A newer progestin-only pill containing desogestrel (Cerazette®) has reported lower failure rates than the "mini-pill"; its efficacy is similar to combined oral contraceptive preparations [121, 124]. An intramuscular injection of medroxyprogesterone acetate (DepoProvera®) every 3 months is highly efficacious [125] although it may be accompanied by fluid retention which may pose difficulty for a patient in heart failure [19]. A low-dose progestin implant containing etonogestrel (Implanon®) or levonorgestrel (Norplant®) which is inserted in the subcutaneous tissue of the inner surface of the upper arm provides reliable contraceptive protection for 3–5 years [120, 122].

Intrauterine devices (IUDs) are highly effective [125] but may carry particular risk for some women with congenital heart disease. Bacteremia in the presence of pelvic inflammatory disease may result in endocarditis. The ideal candidate for IUD contraception is a woman in a monogamous relationship who desires long-term contraception. During instrumentation of the cervix, a vasovagal reaction occurs in up to 5 % of women. The drop in preload may have deleterious effects on a woman with a Fontan circulation or pulmonary vascular obstructive disease [121]. Intrauterine devices containing levonorgestrel (Mirena®) are reported to be highly efficacious [121]. Intrauterine devices generally must be replaced every 3–5 years.

Female sterilization is achieved through ligation of the Fallopian tubes or intratubal stent implantation (Essure®). This method of contraception may be the desired approach in situations where the risk of pregnancy is exceedingly high. Intratubal device insertion can be successfully achieved hysteroscopically without anesthesia [126] making such an approach attractive in women in whom the risk of general anesthesia may be high (e.g., Eisenmenger syndrome) or laparoscopy is poorly tolerated due to the need for abdominal insufflation with carbon dioxide (e.g., Fontan circulation) [120, 121].

Conclusion

With important exceptions, women with cardiac disease can be expected to do well during pregnancy if they receive appropriate management based on systematic risk stratification. A preconceptual cardiac evaluation is of great value as baseline testing can be arranged, medications can be reviewed and revised if need be, pregnancy-related risk stratification can be established and necessary interventions can be planned prior to pregnancy. Pregnancies deemed to be at intermediate or high risk should be managed and delivered by a team with expertise in pregnancy and heart disease, including cardiologists, high-risk obstetricians/maternal fetal medicine specialists, obstetric anesthetists, neonatologists, and obstetric nurses. Antepartum multidisciplinary case conferences should take place to coordinate management if complex care is anticipated. In very high-risk cardiac conditions, conception should be avoided.

Heart Failure in Adult Congenital Heart Disease

148

Joel McLarry and Craig S. Broberg

Abstract

As the adult congenital heart disease population expands and ages due to the success of early diagnosis and intervention, many of those individuals have or will develop myocardial dysfunction and the symptoms of heart failure. Given the incidence of myocardial dysfunction in this population today, expectations are that future numbers of individuals with heart failure over the coming decades may be overwhelming. The clinical characteristics of the adults with congenital heart disease population, in general, are similar to other heart failure populations, including biomarker elevation, exercise intolerance, arrhythmia, and mortality. The etiology of heart failure in adults with congenital heart disease is often multifactorial, resulting from chronic adverse loading conditions, fetal and neonatal events, abnormal ventricular architecture and geometry, and abnormal coronary perfusion, each leading to a final common pathway of myocardial fibrosis.

Abundant data demonstrate clear benefit of pharmacotherapy in heart failure from acquired heart disease, including ACE inhibitors, angiotensin receptor blockers, beta-blockers, and aldosterone antagonists. However, in adults with congenital heart disease, the benefit of these medicines has not been clearly shown. As heart failure progresses in this population, ventricular assist devices and cardiac transplantation are being increasingly used; however, experience in utilizing them in adults with congenital heart disease still remains limited.

Introduction

As the adult congenital heart disease (ACHD) population expands and ages due to the success of early diagnosis and intervention, many of those individuals have or will develop myocardial dysfunction and the symptoms of heart failure (HF). Based on prevalence estimates of congenital defects and survivorship, there are likely over one million adults at present in the United States and 1.2 million in Europe with congenital heart disease (CHD) [1–3]. Given the incidence of myocardial dysfunction in this population today, expectations are that future numbers of individuals with HF over the coming decades may be overwhelming.

While there is considerable heterogeneity in anatomy and, by extension, underlying etiology, there are many reasons to expect the myocardium to eventually become dysfunctional. These include pressure and volume loading, prenatal myocardial hypoxia, genetic predisposition, the effect of cardiopulmonary bypass in early life, as well as acquired myocardial insults throughout life. All are likely to contribute to the overall problem, which has justifiably been called "the original heart failure syndrome" [4]. Anatomical subgroups must all be considered individually, including patients with right-sided volume overload (such as tetralogy of Fallot (TOF), pulmonary regurgitation after congenital pulmonary stenosis repair, or Ebstein's anomaly), systemic right ventricle (RV) in transposition of the great arteries (TGA), or with a single ventricle and prior Fontan palliation.

HF can be defined in many ways. The AHA guidelines define HF as a clinical syndrome characterized by the symptoms of dyspnea and fatigue, as well as signs of congestion (edema, rales), resulting from any structural or functional cardiac disorder [5]. The term can encompass all clinical manifestations of cardiovascular dysfunction from many causes, including myocardial dysfunction (either systolic dysfunction or diastolic dysfunction), valve disease, arrhythmia, and cyanosis. The contribution of these issues to circulatory dysfunction and exercise intolerance is discussed in detail elsewhere. The purpose of this chapter is to explore the causes and treatments specifically of myocardial dysfunction in ACHD.

This chapter will explore the prevalence of HF, its known clinical characteristics, potential mechanisms in ACHD patients, and existing data on medical and surgical treatment options. There will be a discussion on what is known about the population in general, followed by considering each specific diagnostic subgroup.

Prevalence of Heart Failure in ACHD

HF in ACHD is unquestionably on the rise. Although absolute numbers of HF patients are not available, the denominator of ACHD patients is rising. Of individuals born with a congenital heart defect who survived the first year of life, 96 % remained alive at 16 years of age [6], significantly higher than prior decades. Current estimates are that now 1,000,000 adults in the United States have congenital heart disease [1]. The number of these patients affected by HF is less well known, partly due to an inherent referral bias in the literature and because of inconsistent definitions of HF.

The prevalence of HF in this population is a function of both the type of cardiac lesion, the patient's age, and the complexity of the defect. One large series reported that approximately 25 % of all

ACHD patients had HF, including up to 50 % of patients with TOF or single-ventricle physiology and up to 1/3 of TGA patients palliated with atrial switch having HF [7]. Another series found that the patients at greatest risk of heart failure are those with a systemic right ventricle, namely, those with a prior atrial switch palliation (Mustard and Senning) for TGA or congenitally corrected TGA (CCTGA). For example, by age 45, HF was found in 67 % of patients with CCTGA with associated lesions and 25 % of patients without associated lesions [8]. Similarly, the prevalence of HF has been reported in almost one third of the same patients elsewhere [9]. In TOF, where RV dysfunction is common, even left ventricular (LV) dysfunction is present in some 20 % of patients [10]. It should be noted that the majority of these studies suffer somewhat from referral bias; the healthier patients may not have been seen at centers reporting these estimates.

Patients who have had a Fontan procedure are also affected, though the definition of HF (diastolic or systolic dysfunction) vs. "Fontan failure" makes prevalence estimation problematic. By comparison, HF prevalence in purely aortic and pulmonic valvular lesions or aortic coarctation after catheter or surgical intervention remains low, about 6 % [7]. For patients with simple shunts, such as simple VSDs and ASDs, the prevalence is also very low. Although several series have shown an increase in HF as these patients age, it is unclear to what degree. Also uncertain is how current prevalence estimates will change in newer generations of survivors with earlier or more sophisticated palliations.

Characteristics and Clinical Manifestations of Heart Failure in ACHD

Much of the current literature on ACHD-related HF is descriptive. Collectively studies show abnormalities of biomarkers, exercise intolerance, arrhythmia, and mortality and how these are similar to other HF populations. On the whole, the features described provide a foundation for understanding the varying potential mechanisms involved and therefore offer rationales for treatment. They support the argument that congenital heart disease is the original HF syndrome [4]. Therefore, they are worth presenting in some detail here. A major recurring difference between ACHD and other HF settings is that ACHD patients are typically 20 years younger.

Biomarkers of Heart Failure in ACHD

Similar to HF from acquired heart disease, high neurohormone levels have been described in various types of ACHD [11]. Atrial natriuretic peptide (ANP), brain natriuretic peptide (BNP), aldosterone, endothelin, renin, and norepinephrine were all elevated in a series composed of four anatomic subgroups: TOF, single ventricle, systemic right ventricle, and cyanotic heart disease. ANP, BNP, endothelin, and norepinephrine levels increased with increasing NYHA class and worsening systemic ventricular function. Interestingly, even asymptomatic patients showed some degree of neurohormonal activation. Additionally, no difference was seen in neurohormone levels across the four anatomic subgroups.

Natriuretic peptides are known to be expressed in situations of atrial and ventricular pressure elevation and commonly used to identify patients at risk of heart failure or to document progression or response to treatment. Elevations in ANP and BNP have been shown in ACHD as well; however, the correlation between natriuretic peptides and ventricular function has been variable across several studies; there is close correlation in some studies and no correlation at all in others [12–16]. Some of this variability may be explained by the fact that ejection fraction is an imperfect metric of ventricular systolic function, especially when evaluating the complex geometric shape of the RV. On the other hand, BNP values have been shown to increase with worsening systemic atrioventricular valve regurgitation as well as higher NYHA class [12, 17]. Elevation in natriuretic peptides is also a marker of poor prognosis. In one study, ANP and BNP predicted mortality in a broad symptomatic ACHD population, indicating these biomarkers likely

have a prognostic role across the wider ACHD population [18].

Changes in BNP may vary over the course of a lifetime as physiology changes. For example, in a series of ventricular septal defect (VSD) patients, BNP was directly proportional to the severity of pulmonary hypertension [19]. The proposed mechanism is that elevation of pulmonary artery pressure leads to increased right ventricular strain, deterioration of right ventricular function, right ventricular enlargement, and ventricular/atrial stretch. Conversely, as the pulmonary hypertension becomes severe and right-to-left shunting becomes noted consistent with Eisenmenger physiology, the BNP levels may paradoxically decrease [20]. As the increased resistance limits left-to-right shunting and the RV is relatively unloaded, its volume decreases and BNP production decreases with it. As such, HF in Eisenmenger physiology is surprisingly low initially [7], despite having the most profound exercise intolerance of any ACHD subgroup [21]. Yet later, as ventricular dysfunction worsens, BNP elevation reemerges and predicts poor prognosis [22]. Although natriuretic peptides have been shown to correlate with multiple clinical parameters, interpreting the meaning of specific BNP values in an individual is difficult, secondary to the multiple factors that influence natriuretic peptides. Therefore, trends over time are often more clinically useful.

Another clinical marker of abnormal function is hyponatremia, which in ACHD reflects significant neurohormone activation similar to the acquired heart disease HF population and portends a worse prognosis. Hyponatremia is associated with higher NYHA functional class, cyanosis, elevated creatinine, and diuretic use. Hyponatremia carried an almost threefold risk of death independent of other variables [23].

Recent abstract series have confirmed general elevation of biomarkers indicative of myocardial fibrogenesis and inflammation [24], but not in every setting. For example, in a small cohort of TOF patients shown to have lower LV and RV ejection fraction, higher BNP, and lower 6-min walk distance than controls, markers of myocardial fibrosis, namely, collagen by-products, matrix metalloproteinase, or its tissue inhibitor, were not elevated even though this would be expected given the clinical abnormalities seen [25]. This raises questions of whether the mechanisms of myocardial dysfunction differ significantly from non-congenital etiologies of HF, as will be explored below.

Exercise Intolerance and Assessment

Exercise intolerance is central to the definition and diagnosis of HF [5]. It is also a major cause of morbidity and reduced quality of life in ACHD. Almost ½ of ACHD patients followed in tertiary centers complain of some degree of exercise intolerance, which is most common in patients with complex cardiac anatomy, unrepaired or palliated lesions, and those with significant pulmonary hypertension [26]. Yet it is also likely that ACHD patients underreport HF symptoms, making assessment of functional capacity difficult by history alone. Cardiopulmonary exercise testing to objectively measure function has a strong role in assessing exercise intolerance. Exercise capacity, quantified by peak oxygen consumption (VO_2) or heart rate reserve, is also prognostically associated with risk for hospitalization and mortality [21, 27].

Exercise intolerance in ACHD patients is multifactorial, not simply related to myocardial dysfunction alone. Pulmonary vascular disease, valvular dysfunction, cyanosis, chronotropic incompetence, skeletal abnormalities, restrictive lung disease, anemia, and deconditioning may all contribute. This partly explains the significant difference in exercise capacity between various types of ACHD diagnoses (Fig. 148.1) [21]. However, these other insults also potentially trigger neurohormonal activation that can in turn contribute to myocardial dysfunction and hence may also be part of the cascade of myocardial dysfunction.

Arrhythmia

There is a high incidence of atrial tachyarrhythmia in congenital heart disease [28–32]. The etiology is multifactorial, including surgical scars

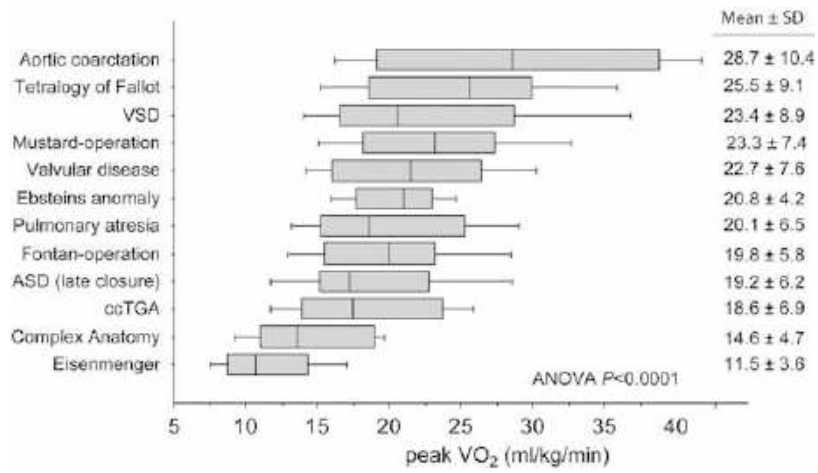

Fig. 148.1 Distribution of peak VO_2 values (mL/kg/min) in ACHD by defect type [21]

and atrioventricular valvular regurgitation leading to atrial enlargement. But there is also evidence that both ventricular and atrial tachyarrhythmia relate to ventricular dysfunction. Thus, arrhythmia may be considered another manifestation of HF. In a series of patients with TGA undergoing cardiac magnetic resonance, documented arrhythmia and/or syncope was higher in patients with fibrosis indicated by late gadolinium enhancement in the systemic RV [33]. In a similar study of TOF, clinical arrhythmia was more prevalent in those with late gadolinium enhancement as well (26 % vs. 10 %, $P = 0.03$)[34]. Similar to surgical scars, dense fibrosis can be a substrate for reentrant arrhythmia, but, as these chapters also show, fibrosis is also a marker of myocardial dysfunction, corroborating the idea of arrhythmia as a manifestation of underlying myocardial dysfunction.

As further evidence of the link between myocardial dysfunction and arrhythmia, in a retrospective review of patients with TOF and implanted cardioverter/defibrillators, the highest predictor of appropriate shock was LV end-diastolic pressure (LVEDP) greater than 12 mmHg [31]. LVEDP was more predictive than other markers that would be considered high risk for arrhythmia including RV size or function, prior syncope, or QRS duration. Stated differently, ventricular dysfunction is a very strong driver of ventricular tachyarrhythmia. Supporting this, in another series of 556 TOF patients, arrhythmia occurred in 43 %, including ventricular arrhythmia in 14 % [30]. A strong predictor of ventricular arrhythmia was the presence of diastolic dysfunction as determined by echo parameters (OR, 3.3; 95 % CI, 1.5–7.1). While the same burden of arrhythmia related to heart failure has not been demonstrated in all patient groups, the findings are important in demonstrating the relationship between ventricular function and arrhythmia.

Morbidity and Mortality of Heart Failure in ACHD

If the biomarker elevation, exercise dysfunction, and arrhythmia noted above are indeed indicative of HF, it follows then that HF should be a substantial cause of mortality as well. In fact, HF is one of the leading causes of death in adults with CHD. HF was reported as cause of death in 26 % of all deaths in a national registry of over 8,000 adults with CHD in the Netherlands [35], which is consistent with other reports [36–38]. In other studies, sudden cardiac death is also a frequent cause of cardiovascular death [39], which likely is higher in those with HF as discussed above. The other common cause is perioperative deaths, which could also reflect higher operative risk in patients with myocardial dysfunction.

However, in addition to decreased survival in ACHD, due in part to HF, ACHD faces

significant morbidity as well. Hospitalization rates for ACHD patients are two times that of the general population, most commonly for arrhythmia; however, heart failure remains a common reason for admission as well [40]. As the ACHD population increases in number, so too will ACHD hospitalizations, which have increased 101 % from 1998 to 2005 [41]. The proportion of these hospitalizations that are secondary to HF is not yet known.

Mechanisms of Heart Failure in ACHD

Chronic Adverse Loading Conditions

Unlike HF from acquired heart disease, HF in ACHD is caused by a diverse array of mechanisms that alter preload, afterload, and contractility. Some mechanisms are unique to each anatomical subtype, and others are present throughout the spectrum of ACHD [42]. The most obvious causes of myocardial dysfunction are chronic volume or pressure loading, which are ubiquitous in ACHD. Volume loading is seen in patients with simple shunts including septal defects, atrioventricular canal, and Ebstein's anomaly, as well as in some postoperative states such as severe pulmonary regurgitation after repair of congenital pulmonary stenosis or TOF. Pressure loading is likewise very common, seen in all forms of LVOT stenosis, aortic valve disease, coarctation, pulmonary stenosis, double-chamber right ventricle, and increased pulmonary vascular disease which sometimes develop late. These conditions are known to incite many of the neurohormonal reactions discussed above, likely leading to myocardial dysfunction [11].

Fetal and Neonatal Events

Other events in either fetal or early life may trigger changes that lead to detrimental effects on myocardial dysfunction later in life. In an in utero animal model, abnormal loading conditions influence embryonic morphogenesis and function by modulating the myofiber architecture in the developing myocardium, leading to changes in myocardial fiber orientation [43]. In another animal model of hypoplastic left heart syndrome (HLHS), changes in RV and LV myocardial fiber orientation were noted in utero as well, reflecting altered cardiovascular function and/or morphogenesis very early in life [44]. Similar findings have been described in humans with alterations in the orientation and architecture of the muscle fibers in hearts with tricuspid atresia compared to normal hearts [45].

Cyanosis in the newborn period may similarly cause cellular and subcellular changes that later prove detrimental. For example, the RV in TOF shows increased density of endomysial collagen and remodeling of collagen matrix from birth [46]. Coronary ischemia plausibly also contributes to myocyte dysfunction in ACHD; however, data to support this is lacking.

Ventricular Architecture and Geometry

Another mechanism of HF is adverse ventricular geometry, which particularly affects those with a systemic RV or single ventricle. The RV is architecturally different from the normal LV not only in geometry but also in arrangement of myocardial fibers [47]. It lacks the middle layer of circumferential fibers, which occupies over half of the ventricular wall thickness of a normal LV [45]. Also, as the RV enlarges, concurrent with systolic dysfunction, the heart is subject to ventricular–ventricular or interventricular interaction by several mechanisms inducing left ventricular dysfunction (Fig. 148.2a, b). Firstly, the Torrent-Guasp model of the helical heart suggests that wall tension in one area translates to adverse tension throughout the heart via these inherently meshed tissue layers [48]. Secondly, as pressure increases in the RV, less volume is delivered to the LV, which may eventually change the contour of the interventricular septum and the natural ellipsoid geometry of the LV [49] (Fig. 148.3). This decreases LV compliance and function. Thirdly, neurohormonal activation initiated by RV loading conditions through the

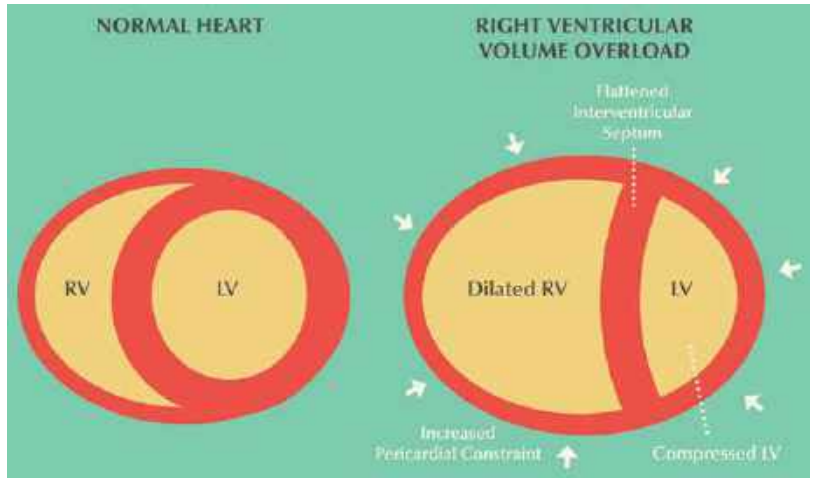

Fig. 148.2 *Panel A* shows a patient with tetralogy of Fallot and RV enlargement and dysfunction after long-standing pulmonary valve regurgitation. *Panel B* shows a patient with transposition of the great arteries after atrial switch palliation (baffles indicated by *arrow*). The systemic right ventricle has severely reduced systolic function. There is systemic tricuspid valve regurgitation. *RV* right ventricle, *LV* left ventricle, *RA* right atrium

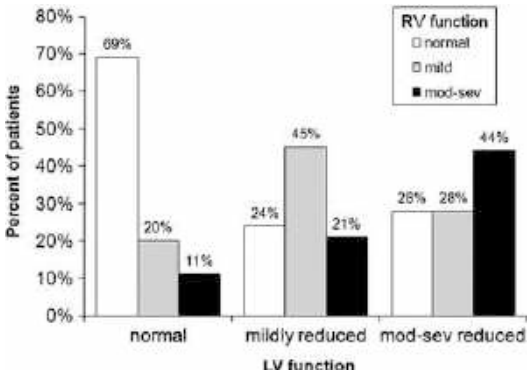

Fig. 148.3 Interventricular interaction in RV failure [51]. RV dysfunction leads to RV dilatation, shifting the interventricular septum toward the LV, altering the LV geometry. These changes can reduce cardiac output by decreasing LV preload, distensibility, and elastance. More acute RV dilatation can lead to pericardial constraint (arrows)

renin–angiotensin–aldosterone system has systemic effects including myofibroblast activity which affects both ventricles. As described previously, the global nature of ventricular remodeling has been shown in decreased LV systolic function in TOF, despite the fact that the anatomic defects are isolated to the right heart. RV systolic dysfunction is associated with LV systolic dysfunction in this group (Fig. 148.4) [50].

Similarly, single-ventricle patients also have abnormal myocardial mechanics. Myocardial efficiency is reduced by 40 % in single-ventricle patients when compared to 2-ventricle controls [52], indicating that there is inherent circulatory failure even when all other factors are considered normal. After the Fontan operation, with the absence of a pre-pulmonary ventricle to propel blood through the pulmonary vasculature, cardiac output is reduced [53, 54]. Clinically this can be seen in the form of higher capillary oxygen uptake, higher hemoglobin, and lack of stroke volume increase during exercise. Animal data suggest Fontan patients have a contractility–afterload mismatch, that is, relatively normal resistance in the pulmonary bed without a forced-delivery system [53–56].

Abnormal Perfusion

Additionally, inadequate coronary perfusion has been implicated as a mechanism of myocardial dysfunction in ACHD, especially in systemic RV dysfunction [57]. The LV coronary supply is a two-vessel system, the left main which bifurcates typically into the left anterior descending and left circumflex arteries. The RV is exclusively supplied by the right coronary artery. For the systemic RV, this pattern is unchanged; it is largely supplied by only the right coronary artery. Because of the severe hypertrophy and enlargement, there is decreased coronary flow reserve and likely chronic recurrent ischemia [58]. Some such patients will complain of chest pain

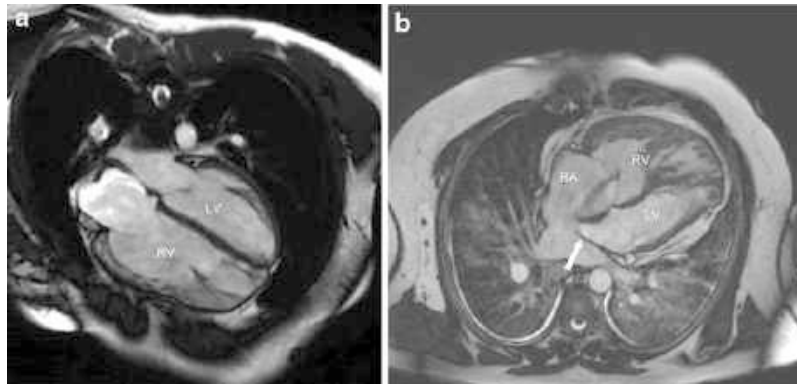

Fig. 148.4 The relationship of *LV* and *RV* function in adults with repaired tetralogy of Fallot [50]. Normal right ventricular function is associated with normal left ventricular function. Conversely, moderate-to-severe (mod-sev) LV dysfunction is more common in patients with moderate-to-severe RV dysfunction (p <0.001, chi-square test)

without coronary atherosclerosis. Single-ventricle patients, particularly hypoplastic left heart patients, may also be vulnerable from decreased coronary flow reserve [59].

Additionally, many patients have undergone several cardiothoracic operations. Although no one has demonstrated significant ill effects of cardiopulmonary bypass surgery, there is still concern that cardioplegia and cardiac arrest may leave the myocardium vulnerable to future deterioration long term, particularly from older methods of cardiopulmonary bypass. For example, bypass is known to incite a host of inflammatory mediators and cytokines [60], leading to vasodilatory shock [61], acute kidney injury, and platelet dysfunction [62], which may make the myocardium vulnerable in the future.

Myocardial Fibrosis

All of these mechanisms likely lead to a final common pathway of myocardial fibrosis. Fibrosis, or abnormal accumulation of extracellular material in the myocardium, is a process resulting from a number of cardiovascular stresses, such as myocardial infarction and congestive HF. Neurohormonal activation of the renin–angiotensin–aldosterone system in response to these stressors activates fibrogenesis [63]. Fibrosis leads to systolic dysfunction, diastolic dysfunction, arrhythmia, and increased mortality. Similar to HF from acquired heart disease, evidence of myocardial fibrosis has been seen in ACHD as well across a wide variety of anatomic subtypes. A few pathologic studies have demonstrated increased fibrosis in the myocardium of ACHD patients [64, 65]; however, recent investigation has focused on noninvasive methods to detect myocardial fibrosis in ACHD patients. MRI with late gadolinium enhancement has been shown to detect macroscopic myocardial fibrosis in many subgroups. This includes TOF [34], TGA [33], Fontan circulation [66], and Eisenmenger physiology [67], the same groups in which ventricular dysfunction is most prominent. From these studies, late gadolinium enhancement generally correlates with ventricular enlargement and dysfunction, NYHA class, the presence of arrhythmia, measured exercise capacity, and BNP levels. Furthermore, extracellular volume fraction as a marker of extracellular matrix remodeling, measured by T1 differences after gadolinium, has been used to detect microscopic myocardial fibrosis as well. This was present across the ACHD spectrum and also correlated with ventricular size and function [67]. These findings all support the theory that the neurohormonal activation incites fibrogenesis and dysfunction. This is an important notation because pharmacotherapy of HF has been shown to reduce fibrosis in HF from acquired heart disease.

Therapeutic Considerations

Medical Therapy

An abundance of research demonstrates clear benefits of pharmacotherapy in HF from acquired heart disease, including ACE inhibitors, angiotensin receptor blockers, beta-blockers, and aldosterone antagonists. Because the characteristics of HF in ACHD described above are very similar to acquired HF, the data should be seen as strong evidence for these same pharmacotherapeutic strategies to be effective in ACHD. However, the data have not shown the promising effects expected. The majority of relevant studies are discussed and summarized by anatomical subtype. There are many reasons to speculate why the therapies in many of these studies have not produced positive results. These include studies that are limited in patient number with short follow-up, the possibility of measuring the wrong outcomes to show beneficial effects, as well as studying patients that are either too healthy or too ill to demonstrate appreciable benefit from therapy. Regardless of the reasons, the bulk of the literature available does not confirm the beneficial results expected. Exceptions to this are patients with systemic LV dysfunction, which are generally treated as other HF patients with more confidence in pharmacotherapy, and will not be explored here.

Systemic Right Ventricle

All studies to date of ACE inhibitor therapy in patients with TGA have been small, single center and most have been nonrandomized. A retrospective study in 14 d-TGA patients using lisinopril did not show improvement in systolic function or peak VO_2 [68], and a prospective study of lisinopril in eight patients with d-TGA also did not show improvement in peak VO_2 or cardiac index [69]. The only randomized trial to date used ramipril in 17 adult d-TGA patients and did not demonstrate a change in right ventricular systolic function or right ventricular end-diastolic volume after 1 year of treatment [70].

With ARBs the data has been mixed. A prospective crossover study using losartan in seven patients with d-TGA did demonstrate improved ejection fraction and exercise duration [71]. However, in the only multicenter, randomized trial to date using ARBs in 29 adults with TGA and CCTGA, no improvement was found in exercise duration, VO_2 max, or BNP levels. However, limitations to this study were a brief follow-up of only 4 months, and 93 % of patients were asymptomatic at baseline. Additionally, most patients had only mildly reduced RV function and no TR or only mild TR, making it difficult to show benefit or to generalize these findings to the symptomatic HF in ACHD population [72]. Currently ongoing is a multicenter, randomized, placebo-controlled trial to better evaluate the effect of ARBs on systemic right ventricles [73]. The study subjects are d-TGA and CCTGA. This study will certainly add to the limited literature currently available; however, the study is underpowered to detect benefit in mortality or major cardiac events.

A few small single-center studies have shown a benefit of beta-blockers in adult TGA patients, demonstrating an improvement in symptoms and improved systemic tricuspid regurgitation and NYHA class [74, 75]. A larger retrospective series of 60 adults with TGA showed an improvement in functional class after only 4 months of beta-blocker [76], but did not show an improvement in RVEF or systemic tricuspid regurgitation. In a multicenter observational study of 37 patients with d-TGA who also had implantable defibrillators for either primary or secondary prevention, treatment with beta-blockers decreased arrhythmic events [29]. An additional case report showed improved right ventricular systolic function with carvedilol therapy in a patient with congenitally corrected TGA [77] (Table 148.1).

Single-Ventricle Physiology

ACE inhibitors have been used in HF patients with single-ventricle physiology, but few studies have evaluated their use. Enalapril therapy was used in a randomized trial in 230 neonates with single-ventricle physiology with preservation of ventricular function and improvement in growth as the endpoints [78]. It showed no benefit in HF symptoms, growth, ventricular systolic function, or death at 12 months. In a randomized,

Table 148.1 Medical therapy in patients with transposition of the great arteries

Reference	Medication	Age (mean ± SD)[a]	N	Study type, follow-up	Outcome variable(s)	Results
Hechter SL (2001) [68]	Lisinopril	31, range 26–42 years	14 d-TGA with Mustard	Retrospective	Exercise tolerance	No improvement
Robinson B (2002) [69]	Lisinopril	12 ± 4 years	9 d-TGA with atrial switch	Prospective, 12 months	Peak VO_2 Cardiac index	No improvement
Therrien J (2008) [70]	Ramipril	26.4 ± 5.2 years	17 d-TGA with atrial switch	RCT, 1 year	RV systolic function or RVEDV	No improvement
Lester DB (2001) [71]	Losartan	≥ 13 years	7 d-TGA with atrial switch	Prospective, 8 weeks	RVEF by echo, exercise tolerance, AV valve regurgitation	Improvement in all
Dore (2005) [72]	Losartan	30.3 ± 10.9	21 d-TGA 8 CCTGA	RCT, 15 weeks	Exercise duration, peak VO_2, NT-proBNP	No improvement
Van der Bom (2010) [73]	Valsartan	35.7 ± 9.8 years	75 d-TGA And CCTGA	RCT, 3 years	RVEF	Trial is ongoing
Josephson CB (2006) [75]	Sotalol, metoprolol, or carvedilol	30.1 ± 4.2	8 d-TGA with atrial switch	Case series, retrospective	Functional capacity, ventricular function	Trend toward improvement

[a]Age presented in mean ± SD, unless otherwise noted

placebo-controlled trial in 18 adolescent patients, enalapril did not alter cardiac index or exercise capacity [79]. A small series studying a mixed group of 10 cyanotic adults, including single-ventricle patients, showed improvement in NYHA functional class with enalapril therapy [80]. Overall the data is limited and conflicting regarding the effect of ACEi in single-ventricle patients, making their role in treating HF in this population unclear.

There is only one study on the efficacy of beta-blocker therapy in single-ventricle physiology. In this retrospective study in a mixed group of 51 children and young adults with Fontan circulation, bidirectional Glenn circulation, and unoperated single ventricles, the addition of carvedilol to existing medical therapy, including diuretics, digoxin, and/or ACE inhibitors, improved NYHA functional class, diuretic requirements, and ventricular function in the Fontan patients only [81].

As noted above, the response to ACE inhibitors and ARBs in single ventricles has been mixed. This is at least partially because attempts

Table 148.2 Medical therapy in single-ventricle patients

Author	Medication	Age (mean ± SD)	N	Patient anatomy	Study type, follow-up	Outcome variable(s)	Results
Hsu DT (2010) [78]	Enalapril	20.4 ± 9 days	230	Single ventricle	RCT, 11 months	HF symptoms, growth, ventricular function, death	No improvement
Kouatli AA (1997) [79]	Enalapril	14.5 ± 6.2 years	18	Fontan	RCT, 10 weeks	Resting cardiac index, exercise capacity	No improvement
Hopkins WE (1996) [80]	Enalapril	32 ± 9 years	10	Cyanotic ACHD including single ventricle	Case series, retrospective	NYHA functional class	Improvement
Ishibashi (2011) [81]	Carvedilol	10 ± 12 years	51	Single ventricle	Prospective, 11 months	NYHA class, diuretic requirements, EF	Improvement
Goldberg DJ (2011) [82]	Sildenafil	14.9 ± 5.1 years	28	Fontan	RCT, 6 weeks	Ventilatory efficiency	Improvement

to decrease systemic vascular resistance with ACEi or ARB do not increase cardiac output because of the uncoupling of the pulmonary and systemic circulations in the Fontan circuit. Output remains impeded by lack of a pulmonic ventricle to propel blood beyond the inherent pulmonary vascular resistance. However, decreasing pulmonary vascular resistance could result in increased pulmonary blood flow, better cardiac filling, and increased cardiac output. In a randomized, placebo-controlled trial conducted in 28 children and adolescents with Fontan circulation, sildenafil significantly improved ventilatory efficiency during exercise, suggesting it may have a role in treating exercise tolerance [82]. Further study is needed to better understand the importance of these effects in single-ventricle patients (Table 148.2).

Tetralogy of Fallot

A randomized controlled trial in 33 asymptomatic or mildly symptomatic adults with repaired TOF patients who had reduced RV function, elevated BNP, and impaired peak VO_2 were randomized to receive bisoprolol or placebo. No improvement was seen in functional class, exercise tolerance, or systolic function of either ventricle. Surprisingly, the patients in the bisoprolol arm actually showed a statistically significant increase in BNP compared to the placebo group [83]. The reasons for this finding are unclear.

Another randomized controlled trial assessed the efficacy of ramipril in 72 adults with repaired TOF who also had pulmonary regurgitation and right ventricular dilation [84]. No improvement was seen in right or left ventricular function, exercise capacity, or pulmonary regurgitation. At baseline, the RVEF was only mildly reduced (mean 53 %), making it more difficult to show improvement with therapy. Although RVEF and LVEF did not show improvement with therapy, RV and LV long-axis shortenings were significantly improved in the ramipril group. Additionally, in a subgroup of patients with restrictive physiology, ramipril did show improvement in LV function and dilation. These findings are of interest considering the fibrosis discussed above; the beneficial effects of ramipril may be more measurable in those with fibrosis, including restrictive physiology (Table 148.3).

Surgical Therapy

Ventricular Assist Device

Experience with mechanical circulatory support is limited in ACHD-related HF compared to HF from acquired heart disease. Investigations from the UNOS database on heart transplantation show that there has been a dramatic increase in VAD use for non-congenital patients, but no change in utilization in ACHD patients [85]. In the last

Table 148.3 Medical therapy in tetralogy of Fallot

Author	Medication	Age (mean ± SD)	N	Patient anatomy	Study type, follow-up	Outcome variable(s)	Results
Norozi (2007) [83]	Bisoprolol	30.9 ± 9.5 years	33	TOF	RCT, 6 months	BNP, peak VO_2, systolic function	No improvement, BNP worsened
Babu-Narayan (2012) [84]	Ramipril	30.1 ± 10.3 years	72	TOF	RCT, 6 months	RVEF	No improvement, but LVEF improved in restrictive RV physiology

decade, VAD use was 18.2 % in HF from acquired heart disease versus 4.7 % in ACHD patients. The discrepancy has many potential causes. ACHD patients are more complex anatomically, with prior surgeries making further thoracotomy more complicated. Additionally, they often are not as sick when listed for transplantation, necessitating fewer VADs as a bridge to transplantation [86]. Still, the message is that familiarity with VAD use in ACHD is markedly less, with mostly anecdotal reports in the literature.

The most challenging group for VAD placement is the Fontan population, in whom decisions about VAD use present multiple difficulties. Initially, one must determine whether to support the systemic circulation or the pulmonic circulation. Then when supporting the pulmonic circulation, there is an absence of a single receiving or pumping chamber to place the intake cannula, which would normally be placed at the apex of a ventricle. Also, there is often not a single artery to place the outflow cannula. If the VAD supports the systemic circulation instead, the circulation still lacks a pulmonic ventricle to propel blood through the pulmonary vascular resistance. Successful VAD use has been reported in Fontan patients [87], but not yet described well enough to allow for any analysis in which to address the ideal solutions to these questions.

Transplant

Transplantation is becoming an important endpoint for an increasing number of patients when all other options have been exhausted. Studies have shown transplantation to largely be successful, though certain challenges are often present [85, 88]. These include anatomic issues, including the need to harvest more of the great arteries, for example, from a donor in whom the lungs will not be used. Also, panel-reactive antibodies may be present after multiple transfusions with multiple prior surgeries. These challenges may mean longer transplant wait times.

Higher 30-day mortality has been noted with heart transplant in ACHD. Surgical site scarring and adhesions as well as impaired kidney and/or liver function, particular in Fontan patients, likely at least partially account for this. However, beyond the initial perioperative period, the relatively younger ACHD population has better long-term survival than other groups. Thus the challenge for the future is to identify patients sooner and establish criteria for transplant listing that are perhaps unique from other heart failure populations.

Conclusions

It is becoming apparent that a final common pathway for the rising population of adults with congenital heart disease is myocardial dysfunction and clinical HF. The prevalence of dysfunction seen today is likely only the beginning of a steady onset of congenital patients reaching this end, where surgical repair of defects or interventional efforts to improve hemodynamics are no longer effective. The potential etiologies for HF are many and may begin even in fetal life. The clinical characteristics of the ACHD population, in general, are similar to other heart failure populations, including biomarker elevation, exercise intolerance, arrhythmia, and mortality.

Yet despite the similarities, favorable response to standard HF therapy has seemed elusive in existing literature, leaving one with questions about the nature of HF in ACHD and empiric guesses when treating the patients with medical therapy. Surgery in the form of mechanical circulatory support and/or heart transplantation is becoming more commonplace but presents new challenges and experience is limited. Thus, there is much to learn in order to be ready for the imminent wave of heart failure patients with congenital heart disease.

Section XX

Extracorporeal Life Support (ECLS) of the Cardiac Patient

Heidi Dalton and Paul Bakerman

New and Developing Technologies for Ventricular Assistance

149

David Michael McMullan and Jeffrey M. Pearl

Abstract

The use of mechanical cardiac support for children with heart failure has increased during the past decade. Ventricular assist devices are now more commonly used to provide perioperative cardiac support and as a bridge to transplantation in a wider range of infants and children with acute and chronic myocardial dysfunction. Although the number of FDA-approved ventricular devices for children remains limited, several novel pediatric devices are being developed as part of the NHLBI-sponsored PumpKIN program. This chapter describes the use of ventricular assist devices in children and reviews the devices that are currently available and additional devices that are currently being developed. The use of intra-aortic balloon pumps in pediatric patients is also reviewed.

Introduction

Mechanical circulatory support is widely used in the management of adults with acute or chronic heart failure. In North America, over 1,700 adult patients per year receive mechanical cardiac support beyond the perioperative period with an FDA-approved ventricular assist device (VAD). Despite the broad clinical experience gained with this growing population of patients, fewer than 450 adults receive mechanical cardiac support using extracorporeal membrane oxygenation (ECMO). In contrast, approximately 800 pediatric patients receive ECMO support for heart failure, whereas VADs are used in fewer than 100 pediatric patients annually in the United States. Multiple factors contribute to the observed age-related discrepancy in VAD utilization, including poor clinical outcomes for adults in early ECMO trials, a rapidly growing population of older heart failure patients, the role of market forces in the development of novel medical devices, and challenges related to miniaturization of devices and applicability of VAD technology across the entire spectrum of pediatric patients which ranges from neonates to young adults. Currently, the Berlin Heart EXCOR® VAD is the only FDA-approved pediatric VAD system that is commercially available in the United States. In 2004, the National Heart, Lung, and Blood Institute established the Pediatric Circulatory Support Program to provide $22.5 million in research funding to develop five novel circulatory assist devices for infants and children. The NHLBI subsequently provided an additional $23.6 million in funding in 2010 to support the Pumps for Kids, Infants, and Neonates (PumpKIN) program. The goal of the PumpKIN program is to complete preclinical testing and begin a clinical trial of four novel pediatric devices by 2013. These devices are currently in various stages of development and testing.

Mechanical cardiac support beyond the perioperative period may be used to facilitate myocardial recovery by unloading the heart, as bridge to heart transplantation or as destination therapy in adults. In contrast, the use of VADs in infants and children is limited primarily to providing circulatory support until heart transplantation. The use of VADs as destination therapy is currently not appropriate for children. The design of most adult VADs has shifted from extracorporeal or paracorporeal to intracorporeal implantation. However, numerous challenges have been encountered related to miniaturization of intracorporeal devices to accommodate the relatively small and variable size of infants and children. Advances in biomedical engineering and increased use of impeller-based systems have led to smaller and more efficient devices that appear to be more applicable to the pediatric population.

Bridge to Transplantation

The number of pediatric heart transplants performed annually has increased during the past decade, with 373 transplants performed in the United States and more than 500 performed internationally in 2011 [1]. During this period, the proportion of children who require mechanical cardiac support as a bridge to transplantation has also increased. Ventricular assist devices are now used to support approximately 16 % of pediatric patients at time of transplantation in North America [2]. Survival curves for patients on VAD support at time of transplantation are almost identical to those for patients who do not require mechanical cardiac support [3]. The use of VAD as a bridge to transplantation is associated with greater pre-transplant survival, when compared the use of ECMO [4]. Furthermore, the survival benefit of pre-transplant VAD versus ECMO appears to extend to the early post-transplant period, with over 90 % of VAD patients surviving 30 days compared with only approximately 75 % of ECMO patients [3]. The use of mechanical cardiac support as a bridge to transplantation is expensive. Hospital costs for pre-transplant VAD patients typically exceed $600,000. Improved survival in these patients is associated with an incremental cost-effectiveness ratio of nearly $120,000 per quality-adjusted life year gained [5].

Pump Design

Mechanically supported blood flow may be pulsatile (pneumatic membrane displacement pumps) or continuous (centrifugal and impeller/axial-flow pumps). Several studies designed to characterize the unique hemodynamic profiles of pulsatile and non-pulsatile pumps and their effects on end-organ function have failed to clearly establish the superiority of either type of blood pump. Pulsatile and non-pulsatile pumps have been used clinically to provide short- and long-term circulatory support in adults. An important benefit of non-pulsatile axial-flow pumps is the potential for miniaturization and development of fully implantable devices for young children. Potential advantages of implantable devices include reduced risk of device-related local infection and sepsis and improved mobility and rehabilitation potential. Historically, centrifugal pumps were associated with clinically significant hemolysis that limited their use to short-term, perioperative support of cardiac output. However, newer centrifugal and axial-flow pumps incorporate important design modifications, such as bearingless, magnetically levitating rotors that reduce friction-related thermal damage blood cells. Non-pulsatile VADs are capable of providing several liters per minute of blood flow utilizing low priming volume, low profile blood pumps.

FDA-Approved Pediatric Devices

Berlin Heart EXCOR® Pediatric VAD

The EXCOR® Pediatric VAD is currently the only mechanical circulatory support device that is approved by the FDA for use as a bridge to cardiac transplantation for neonates, infants, and small children. The EXCOR® system is based on paracorporeal pump technology that has been used successfully in adult patients for a number of years. The EXCOR® VAD is available in five sizes in the United States, with pump volumes ranging from 10 to 60 mL. Consequently, the EXCOR® system can be used to support patients ranging from 3 to 60 kg. The blood pump consists of a transparent, heparin-coated pumping chamber with integrated trileaflet polyurethane inflow and outflow valves. Blood is directionally propelled through the pumping chamber by pneumatic displacement of a flexible polyurethane membrane.

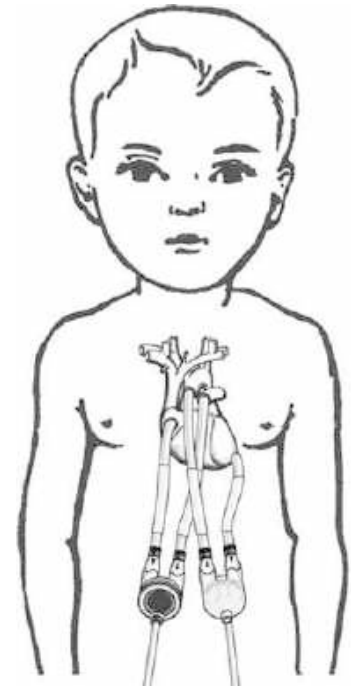

Fig. 149.1 The EXCOR® Pediatric extracorporeal VAD may be used to provide biventricular support, in addition to isolated left or right ventricular support

A major advantage of the EXCOR® system is that it may be used to provide biventricular support, in addition to isolated left or right ventricular support (Fig. 149.1). The system utilizes custom cannulae to provide flexibility in cannulation strategy that is particularly important in young children who have congenital (structural) heart disease. Support of the left ventricle is accomplished by placing the inflow cannula into the left atrium or left ventricular apex and the outflow cannula into the ascending aorta. Left ventricle cannulation appears to facilitate better left side unloading, which may obviate the need for biventricular support in some patients.

Aortic valve competence is necessary for all left ventricular assist devices. Right ventricular support is accomplished by right atrial or right ventricle and pulmonary artery cannulation. The cannulae exit the body through the upper abdominal wall, where they interface with the blood pump.

The Berlin Heart EXCOR® VAD has been implanted in over 900 patients worldwide since its introduction 20 years ago. The initial North American experience with the device from 2000 to 2007 was reported in 2011 [6]. During that period of time, 97 EXCOR® devices were implanted at 29 different institutions. The median age of patients receiving support was 2.1 years, and the most common diagnosis was dilated cardiomyopathy (58 %). The device was used to provide left ventricular support in 57 % of patients and biventricular support in the remaining 43 %. ECMO was used as a bridge to EXCOR® VAD implantation in 30 % of the patients. In this series, 70 % of patients were successfully bridged to transplantation, 7 % recovered ventricular function and the VAD was explanted, and 23 % died. Patients receiving biventricular support were over twice as likely to die as those receiving left ventricular support. Younger age was also identified as a significant risk factor for death. Although the EXCOR® VAD appears to improve overall survival of children with irreversible end-stage heart failure, many children experience device-related complications. This was highlighted by a recent prospective trial of the EXCOR® VAD in which a majority of children experienced serious adverse events such as major bleeding (46 %), infection (57 %), and stroke (29 %) [4]. Some centers have reported brain injury occurring in up to 38 % of patients supported with the EXCOR® VAD [7].

MicroMed HeartAssist 5® Pediatric VAD

The MicroMed HeartAssist 5® Pediatric VAD was approved under the Humanitarian Device Exception program in 2004, making it the first pediatric intracorporeal device to receive FDA approval. The device consists of small (92 g) continuous-axial-flow pump that can achieve >10 L/m flow. A ridged titanium inflow cannula removes blood from the left ventricular apex, and a flexible Dacron outflow graft delivers blood to the ascending aorta. A percutaneous cable that is connected to an external control system and energy source powers the system. The HeartAssist 5® Pediatric VAD is approved for use in patients as young as 5 years of age to 16 years of age (≥18 kg and 0.7 m^2 BSA), and an adult version of the device can be used to support larger patients. Major limitations of this VAD include a fixed inflow cannula position that limits its use to left ventricular support and the inability to support small children and infants. An early report on the initial clinical use of the HeartAssist 5® VAD in children described frequent bleeding and thrombotic complications and 50 % overall mortality [8]. The device has not been widely adopted and has been largely supplanted by the EXCOR® VAD.

Non-Pediatric Devices

Some VADs that are designed to provide mechanical cardiac support for adult patients have been used to successfully support older children and teenagers. The Thoratec HeartMate II® VAD is a small (375 g) implantable axial-flow pump that has been approved for use as a bridge to transplantation and for destination therapy. The inflow cannula configuration of this device allows only left ventricular support. A magnetic rotor that is rotated by the electromotive forces generates blood flow of up to 10 L/m. A transcutaneous driveline powers the device by either continuous current or a portable battery pack that provides tether-free activity for up to 3 h. The HeartMate II® features an automatic speed control mode that modulates pump speed in response to changes in cardiac activity. The HeartMate II® has been implanted in over 10,000 patients worldwide, in some as young as 10 years of age. In a prospective study of this device as a bridge to transplantation in adults, 75 % of patients were successfully transplanted,

recovered cardiac function, or were still on VAD support at 6 months [9]. During this time only 8 % of patients experienced a stroke.

The Thoratec PVAD™ is a paracorporeal device that relies on pneumatic displacement of a flexible membrane within the pumping chamber to displace blood. The blood pump consists of a transparent polyurethane chamber with integrated inflow and outflow valves. Like the Berlin Heart EXCOR® VAD, the Thoratec PVAD™ may be used for left, right, or biventricular support. However, the PVAD™ is available in only one size (65 mL), which limits its use to older children with BSA $\geq$0.73 m^2. The PVAD™ has undergone relatively few design modifications since its introduction over 30 years ago. Despite the fact that this system has been implanted in over 5,000 patients worldwide, its use in pediatric patients remains limited. Overall success with the PVAD system led to the development of the implantable Thoratec IVAD™ in 2004. The IVAD™ pump contains a polyurethane pumping chamber that is enclosed in a titanium housing. Like the PVAD™ system, the IVAD™ may be used for left, right, or biventricular support. The IVAD™ has been implanted in over 600 patients, including patients with BSA as low as 1.3 m^2.

The Thoratec CentriMag® is an extracorporeal centrifugal pump that provides up to 9.9 L/min flow to provide left, right, or biventricular support. The unique magnetically levitated pump impeller creates a contact-free environment that minimizes hemolysis. The device is approved to provide short-term ($\leq$6 h) support of the systemic circulation and right ventricular support for up to 30 days. The CentriMag® is currently being used as an ECMO pump in some centers. The CentriMag® is being used in an ongoing clinical trial to establish its effectiveness and safety for extended ($\leq$ 30 days) use as a bridge to decision. The Thoratec PediMag® is a smaller version of the magnetically levitated pump that is approved to provide up to 1.5 L/min flow to support children for up to 6 h. The PediMag® has been used to provide prolonged (17 days) biventricular support in patients as young as 5 months of age [10].

The Abiomed Impella® 2.5 is a miniaturized impeller VAD that may be used for short-term ($\leq$6 h) left ventricular support to facilitate ventricular recovery or transition to a long-term mechanical support device. The Impella® VAD consists of a 4 mm microaxial impeller pump that is incorporated into a 9 Fr catheter that is advance across the aortic valve into the left ventricular cavity. The device can be inserted percutaneously through the groin or directly through the ascending aorta. Although the Impella® VAD can generate up to 2.5 L/min of flow, its potential for use in the pediatric population is limited to children and young teenagers. The experience with a larger version of this device (Abiomed Impella® 5.0) has been almost exclusively limited to adults.

The CardiacAssist TandemHeart® is another percutaneous VAD that is designed for short-term (<6 h) left ventricular support. The TandemHeart® consists of a 7 mL extracorporeal centrifugal pump that is capable of delivering up to 5 L per minute of flow. Blood is removed from the left atrium and then pumped into a femoral artery. The left atrium is accessed by a trans-atrial septal puncture via a femoral vein. The device utilizes a localized anticoagulation system and a hydrodynamic fluid bearing to achieve thromboresistance with relatively low systemic anticoagulation. Although the TandemHeart® system has been used to provide short-term support for over 2,000 patients, its use in children has been extremely limited.

The HeartWare HVAD® is a miniaturized centrifugal pump that is implanted within the pericardial space to provide left ventricular support (Fig. 149.2). The HVADÒ is very small (50 cc) and utilizes a magnetically and hydrodynamically suspended impeller to pump up to 10 liters per minute from an integrated inflow cannula attached to the apex of the left ventricle to the ascending aorta. The HVADÒ is currently approved for use in Europe and Australia and the United States, with at least one 13-year old patient successfully supported by the device [15]. The FDA granted conditional approval for enrollment in a clinical study of the device for destination therapy in 2010.

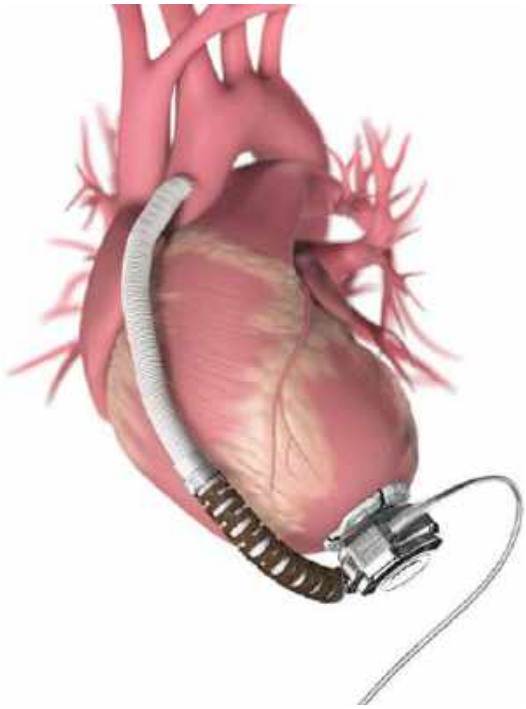

Fig. 149.2 The HeartWare HVAD®

PumpKIN Devices in Development

Ension Pediatric Cardiopulmonary Assist System (pCAS)

The pCAS is an extracorporeal pump-oxygenator system that is intended to provide circulatory support and gas exchange. Unlike current ECMO circuits, the pCAS features a pump impeller that is integrated with a blood oxygenator via a diffuser. The system utilizes a novel heparin-based bioactive surface that is permeable to oxygen and carbon dioxide. The pCAS is being designed to provide partial or complete cardiopulmonary support for patients ranging from 2 to 15 kg for periods of up to 2 weeks. The integrated pump-oxygenator can be exchanged to provide extended periods of support. The pCAS is currently undergoing in vitro and in vivo animal model testing [11]. The system has not been evaluated in humans.

Jarvik 2000 Infant and Child

The Jarvik 2000 Infant and Child VADs are implantable axial-flow pumps that are based on the widely used adult Jarvik 2000 FlowMaker VAD. The pumps are implanted into the apex of the left ventricle and deliver blood to the aorta via a Dacron conduit. The Infant Jarvik 2000 is the size of a AAA battery and capable of supporting infants as small as 3.5 kg. The Pediatric Jarvik 2000 is a slightly larger version of the pump that is capable of supporting children between 10 and 25 kg. Although pump thrombosis was initially a problem during early in vivo animal studies, the problems of hemolysis and thrombosis-related pump failure appear to have been eliminated since the development of a novel ceramic blood-immersed pump bearing. The Jarvik 2000 systems have undergone preclinical in vivo testing in animal models [12] in anticipation of a clinical trial.

PediaFlow Ventricular Assist Device

The PediaFlow® VAD is an implantable continuous-flow rotary blood pump that utilizes a magnetically levitated impeller housed in a titanium shell. The device attaches to separate inflow and outflow cannulae, potentially enabling it to provide ventricular support in a variety of configurations. About the size of a AA battery, the pump can deliver 0.3–1.5 L/min flow, which will allow it to support children weighing 3–15 kg. The device is designed to be fully implanted or used as an extracorporeal VAD in smaller patients and is intended for intermediate (up to 6 months) support. The PediaFlow® VAD has undergone several design changes and is currently undergoing in vitro and in vivo animal testing [13].

Levitronix PediPL System

The Levitronix PediPL is an extracorporeal integrated pump-oxygenator system that is intended to provide circulatory support and gas exchange. The PediPL incorporates a magnetically suspended continuous-flow, centrifugal rotary

pump with uniquely configured hollow fiber membranes. The PediPL system generates flows up to 3 L/min and is being developed to provide a "bridge-to-decision" or full cardiopulmonary support for patients ranging from 3.5 to 20 kg for periods of up to 30 days. The PediPL system is currently undergoing in vitro and in vivo animal model testing to evaluate the hemocompatibility of heparin surface bonding [14]. The system has not been evaluated in humans.

Intra-Aortic Balloon Pump (IABP)

The concept of counterpulsation to provide diastolic augmentation to support the failing left ventricle was first introduced in 1958. Following development of the prototype IABP and determining optimal timing of balloon inflation in relation to the cardiac cycle, the device was introduced into clinical practice in 1968. Its initial clinical use was to provide pre- or postoperative support of the failing left ventricle in the face of myocardial ischemia by reducing afterload while augmenting coronary perfusion during diastole. Although the IABP is now widely used in the adult arena, use of the device has decreased recently as a result of advances in medical and interventional modalities and increased utilization of VADs. Major advantages of the IABP are the fact that it is readily available and can be rapidly deployed. In addition, IABPs may be utilized in conjunction with axial-flow VADs in adults to provide pulsatile augmentation.

In contrast to its role in providing support in adults, the IABP is much less widely used in children. Until recently, IABPs were utilized in this population due to an absence of alternative mechanical support modalities, including ECMO, which has become a viable alternative only during the past 25 years. In some centers, the IABP may represent an intermediate step in cardiac support that is somewhat less invasive, potentially less risky, and certainly less expensive than ECMO and VADs.

Although the underlying physiologic principles used to provide left ventricular support and augment cardiac output in children are similar to those in adults, there are important differences. Most notably, the smaller size of pediatric patients makes vascular access and potential complications related to access more problematic. In addition, the higher heart rate in children makes appropriate inflation timing more challenging, often requiring the use of a 1:2 or 1:3 ratio. Echocardiographic triggering, rather than electrocardiographic triggering, may be useful in achieving optimal IABP timing in children [16]. Contraindications to the use of IABP include moderate-to-severe aortic insufficiency, aortic dissection, and inability to gain vascular access without vascular compromise.

Physiologic Effects of IABP Therapy

When properly inserted, the balloon of the IABP is located in the proximal descending thoracic aorta, just distal to the left subclavian artery. Inflation of the balloon at the onset of diastole displaces blood from the thoracic aorta, thereby augmenting diastolic blood pressure in the proximal aorta and facilitating coronary perfusion. Deflation of the balloon prior to the onset of systole reduced cardiac afterload and augments forward blood flow. Because myocardial wall tension is reduced during systole, overall myocardial oxygen demand is also reduced. This is a potentially important physiologic advantage over ECMO and some VADs, which may increase myocardial afterload by pumping blood into the aorta. For this reason, the IABP is believed to aid myocardial recovery in addition to augmenting cardiac output. Consequentially, there may be a role for concomitant IABP counterpulsation in patients supported by continuous-flow, non-pulsatile VADs.

Insertion of IABP in Children

Percutaneous insertion of the IABP through an 8.5 French sheath can be performed in older children in a manner that is similar to adults. Fluoroscopic guidance is preferable to facilitate optimal balloon location. Smaller patients may

require a femoral artery cutdown to allow either direct femoral artery arterial insertion or insertion through a Dacron or GORE-TEX graft that is sewn to the vessel. Direct trans-aortic insertion may be used in post-cardiotomy patients. Complications related to the use of IABPs are largely related to placement, irrespective of the technique used. Limb and/or visceral ischemia, vascular dissection, and bleeding can be very morbid and potentially lethal complications. Patients must be continuously evaluated for signs of regional ischemia, which is addressed by prompt removal of the device and repair of the arterial access site. Thromboembolism may also occur, which may necessitate removal of the device or additional anticoagulation. The device's balloon is filled with helium, which enables rapid inflation and deflation. Balloon rupture, therefore, can result in potentially clinically significant gas embolization. Like other indwelling catheters, IABPs are at risk for infection.

Extra-Corporeal Membrane Oxygenation

150

Warwick Butt and Shannon Buckvold

Abstract

Mechanical support of the failing myocardium is currently an integral part of modern cardiac intensive care. For children, extracorporeal membrane oxygenation is now and has been the primary mode of mechanical support over the last two decades. Extracorporeal membrane oxygenation was initially adapted from cardiopulmonary bypass developed for cardiac surgery. However, its earliest applications in the 1970s–1980s were for respiratory failure, and results were variable. During the 1990s, the use of extracorporeal membrane oxygenation increased dramatically and was predominantly applied to neonates with respiratory failure. Extracorporeal membrane oxygenation has been increasingly applied to patients with cardiac failure, since the standard veno-arterial extracorporeal membrane oxygenation circuit design offers support for the failing heart as well as the lungs. In the past decade, extracorporeal membrane oxygenation support for cardiac indications and for assistance during cardiopulmonary resuscitation has grown to account for nearly 50 % of reported annual extracorporeal membrane oxygenation cases. This chapter discusses the indications, relative contraindications, duration, and desired endpoint that should be evaluated by caregivers, when extracorporeal membrane oxygenation is considered for support of the failing myocardium.

Introduction

Mechanical support of the failing myocardium is currently an integral part of modern cardiac intensive care. For children, extracorporeal membrane oxygenation (ECMO) is now and has been the primary mode of mechanical support over the last two decades. ECMO was initially adapted from cardiopulmonary bypass developed for cardiac surgery. However, its earliest applications in the 1970s–1980s were for respiratory failure, and results were variable. During the 1990s, the use of ECMO increased dramatically and was predominantly applied to neonates with respiratory failure. ECMO has been increasingly applied to patients with cardiac failure, since the standard veno-arterial (VA) ECMO circuit design offers support for the failing heart as well as the lungs. In the past decade, ECMO support for cardiac indications and for assistance during cardiopulmonary resuscitation (CPR) has grown to account for nearly 50 % of reported annual ECMO cases (Fig. 150.1), with an overall survival between 53 % and 64 % [1].

During the same time, advances in polymer technology led to the development of newer generation low-resistance combined oxygenator-heat exchangers, incorporation of newer centrifugal pumps in ECMO circuits, and a move toward miniaturization and simplification of ECMO circuit design. For the last several years, centrifugal pumps have been increasingly replacing roller pumps in ECMO circuits. In 2011, the majority of ECMO circuits applied to patients for cardiac indications included a centrifugal pump with a newer generation oxygenator (Fig. 150.2) [2]. These technology advancements can lead to improvements in patient outcome [3].

ECMO is invasive, resource intensive, and potentially hazardous. Clinicians should define the indications, relative contraindications, duration, and desired endpoint, with an appreciation for current overall results when ECMO is considered for support of the failing myocardium.

Indications for ECMO Support in the Cardiac Patient

ECMO is indicated for the temporary provision of tissue oxygen delivery in cardiac patients with reversible cardiac, pulmonary, and/or circulatory failure when pharmacologic and mechanical ventilator supports are insufficient. Defining when pharmacologic and mechanical ventilator supports are insufficient for a cardiac patient can be challenging, controversial, and influenced by institutional perspective on the utility of ECMO. ECMO for cardiac or circulatory support is typically considered when escalating doses of vasoactive medications are required to treat or prevent hemodynamic instability, combined with persistent or increasing evidence of inadequate tissue oxygen delivery. Patients may demonstrate progressive acidosis, lactate accumulation, and clinical or biochemical organ dysfunction. Inadequate tissue oxygenation may be further evidenced by a large arteriovenous oxygen saturation difference or a cerebro-somatic regional saturation difference by near infrared spectroscopy (NIRS) suggesting redistribution of blood flow to preserve cerebral tissue oxygen delivery (Table 150.1). In cardiac patients, it is imperative to establish that the child has no surgically correctable cardiac or coronary lesion, which may require angiography or CT scan. A systematic, sequential evaluation of each of the factors that underlie the patient's inadequate oxygen delivery can identify correctible or treatable causes before mechanical support is necessary (Fig. 150.3).

Following a thorough evaluation for correctible causes, ECMO initiation should be considered before the critical point at which oxygen consumption becomes delivery dependent (Fig. 150.4). Cardiac failure and organ complications arising from low cardiac output are the most commonly reported cause of death in ECMO-supported cardiac patients. Initiation of ECMO prior to this critical point limits the damage caused by extended periods of myocardial and organ ischemia [4–8]. From a cardiac perspective, the definition of significant hemodynamic support is somewhat subjectively and variably defined

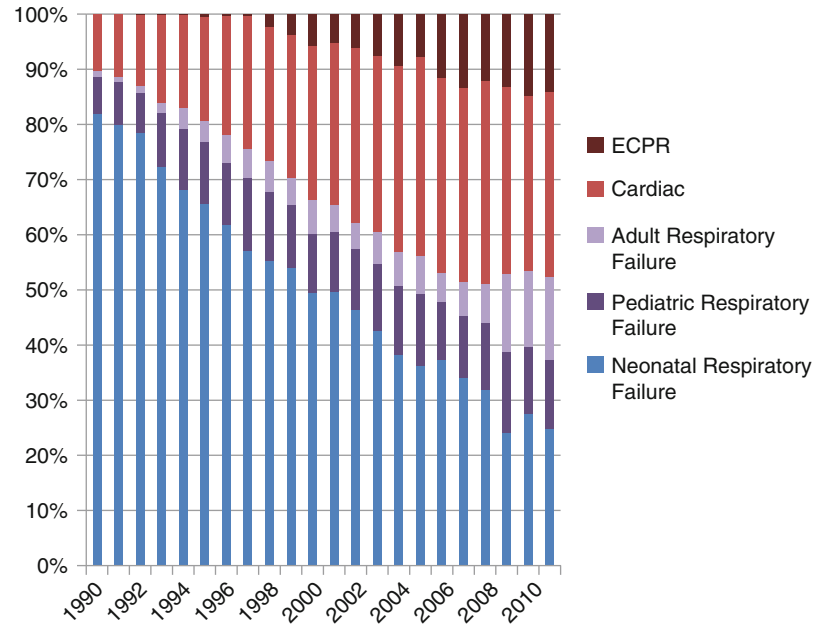

Fig. 150.1 Twenty-year trend in the demographics of extracorporeal life support

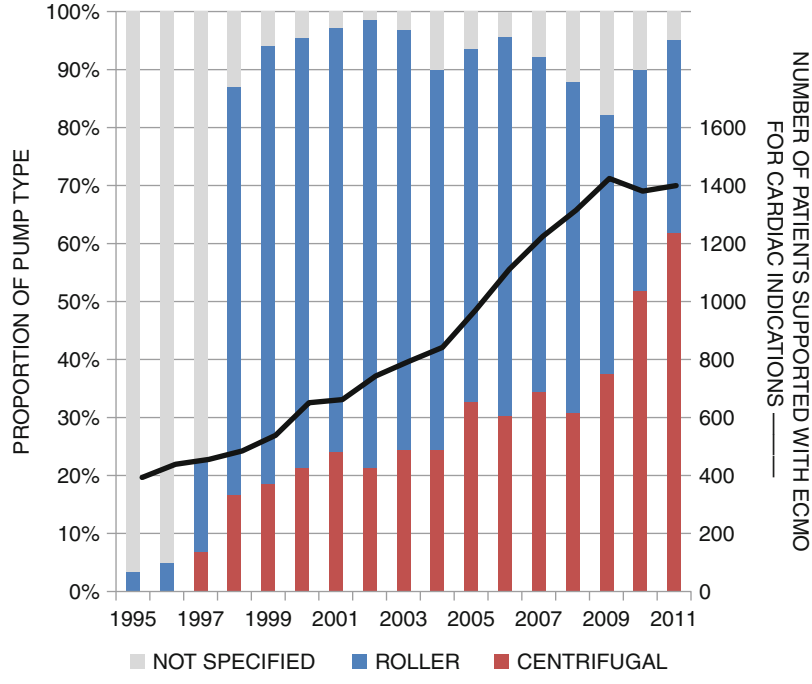

Fig. 150.2 Increasing use of centrifugal pumps in cardiac applications, including ECPR, commensurate with increasing number of cardiac ECMO patients

by the number and doses of vasoactive agents required to maintain adequate hemodynamics. For example, some cardiac centers designate a threshold epinephrine dose of 0.3 mcg/kg/min in biventricular hearts and 0.2 mcg/kg/min in uni-ventricular hearts as an indication for mechanical support of the myocardium [9]. At Children's Hospital Colorado, discussion of the potential need for mechanical support begins when there are persistent signs of inadequate tissue oxygen

delivery at epinephrine dose of 0.15 mcg/kg/min or sooner if recalcitrant arrhythmias preclude further up-titration of catecholamine support. At Royal Children's Hospital (RCH), Melbourne, mechanical support would be considered in patients with increasing lactate, progressive hypotension, or echocardiographic documentation of poor ventricular function despite two inotropes with no easily correctable factor (such as hypovolemia, anemia, or effusion). A summary of the kinds of situations for which ECMO has been applied in cardiac patients is provided (Table 150.2).

Table 150.1 Signs of inadequate tissue oxygen delivery

Hemodynamic instability AND a combination of:
Large arteriovenous oxygen difference
Large cerebrosomatic regional saturation difference
Progressive metabolic acidosis
Lactate accumulation
Clinical or biochemical organ dysfunction
Hepatic dysfunction
Renal dysfunction
Muscle breakdown
Gut ischemia
Central hyperthermia with cold extremities

Consideration of absolute and relative contraindications for ECMO is equally important. Extreme prematurity and aortic dissection are probably the only remaining absolute contraindications to transthoracic or central veno-arterial ECMO (Table 150.3). However, there are numerous relative contraindications which require patient-specific consideration (Table 150.4). The cardiac team must weigh the desired endpoint, risks, benefits, and timing of mechanical support in patients with these conditions.

Most children are placed on ECMO for acute or acute-on-chronic heart failure as a consequence of a variety of circumstances (Table 150.2). In many cases, there is an

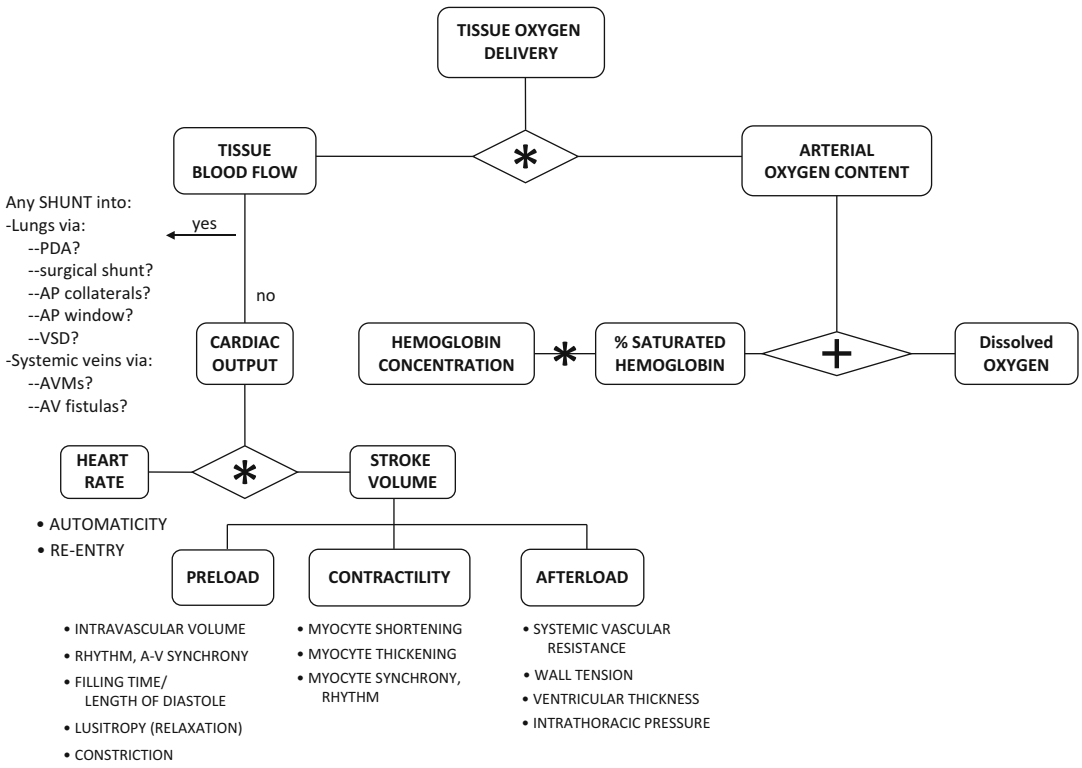

Fig. 150.3 A systematic sequential evaluation of factors underlying oxygen delivery

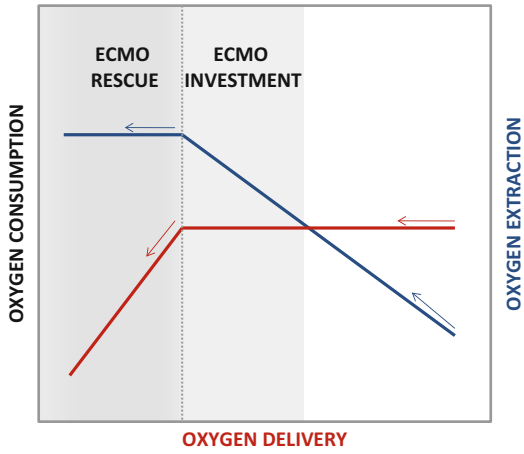

Fig. 150.4 The relationship between oxygen consumption, delivery, and extraction. Conceptually, oxygen consumption is relatively constant in a critically ill patient. As oxygen delivery falls (*red line*), increased oxygen extraction (*blue line*) at the tissue level maintains oxygen consumption. This increasing oxygen extraction is reflected by decreasing systemic venous oxygenation (*purple line*, SvO_2). At the critical point of maximal extraction (*dashed line*), oxygen consumption becomes delivery-dependent, and organ ischemia ensues. Initiation of mechanical support before this point can be described as an "investment strategy," whereas initiation of mechanical support after this point can be described as a "rescue strategy"

expectation that there will be recovery of enough cardiac function to allow separation from ECMO within a matter of days. If cardiac function has not recovered within a week, ECMO support may be extended as a bridge to ventricular assist device implantation and/or transplant. Occasionally, a patient can recover from extended periods of extracorporeal support, especially in conditions such as myocarditis- or arrhythmia-induced cardiomyopathy.

Circuits

All ECMO circuits include the same basic components: cannulas, a pump, an oxygenator, a heat exchanger, and tubing (Fig. 150.5). The pumps draw blood directly from the patient or from a venous reservoir placed between the patient and the pump. From there, the blood advances either through an oxygenator and then a heat exchanger, or through a combined oxygenator-heat exchanger, and then back to the patient. Roller and centrifugal pumps are both options for consideration in cardiac patients.

Table 150.2 Indications for ECMO in cardiac patients

Signs of persistent or progressive inadequate tissue oxygen delivery secondary to:	
Post-operative univentricular failure	
Post-operative biventricular failure	Low cardiac output
	Cardiac arrest
	Donor heart dysfunction after transplant
Isolated left ventricular failure	ALCAPA, ALCAO, TGA, left heart obstructive lesions, borderline left ventricle
Isolated right ventricular failure	Pulmonary hypertension, right heart obstructive lesions, borderline right ventricle with reduced pulmonary blood flow
Recalcitrant arrhythmias	Neonatal SVT, junctional ectopic tachycardia, ventricular tachycardia
Pulmonary dysfunction/ Pulmonary venous desaturation	Air space disease
	Systemic inflammation and pulmonary capillary leak
	Pulmonary edema
	Pneumonia/pneumonitis
	Meconium aspiration
	Hypoxic-ischemic reperfusion injury
	Interstitial lung disease
	Transient surfactant deficiency
	Pulmonary hemorrhage

Inability to accept blood products
Lack of vascular access

tubing, thereby positively displacing or propelling blood forward. In these pumps, blood flow is proportional to pump speed, tubing diameter, and track length. However, because these pumps operate by occlusion, they carry risk of malocclusion, spallation, over-pressurization, and air transport. Malocclusion includes both under- and over-occlusion. With under-occlusion or under-compression, less blood is displaced per revolution of the roller which results in lower flow than intended; with over-occlusion or over-compression, complications can include blood trauma, hemolysis, increased wear of the tubing, and spallation. Spallation is a process in which fragments of tubing (spall) are ejected from the tubing wall due to impact or stress. Excessive positive pressure, particularly in the setting of spallation and tubing wear, can lead to catastrophic tubing rupture. Alternatively, excessive negative pressure can lead to cavitation and formation of micro-air emboli. Since roller pumps propel whatever is in the tubing lumen, whether blood or air, they are also capable of large-volume air transport. To minimize these risks, roller pumps require a regulation system to control pump speed in response to air and extremes in pressure. Additionally, venous drainage to roller pumps is gravity dependent. Considerable bed height and tubing length is required in pediatric and adolescent patients, significantly limiting their portability.

Centrifugal pumps rely on roto-dynamic forces to propel the blood forward. These pumps use a rotating impeller or a conical rotor to create flow by adding motion energy to blood. They are more efficient than roller pumps, as much less mechanical energy is required to move an equal volume of blood. The earliest versions were associated with thrombosis and hemolysis, limiting their application to short-term ventricular assist devices, particularly in smaller patients. Furthermore, the use of high-resistance silicone oxygenators in ECMO circuits made these afterload-sensitive pumps difficult to use in ECMO. Over the last decade, low-resistance hollow fiber gas oxygenators have been increasingly incorporated into ECMO circuits, and centrifugal pumps have become more suitable for use in ECMO. In fact, the newer generation centrifugal pumps confer several distinct advantages for cardiac applications – gravity-independent venous inflow, small pump head size, and small circuit size – yet capable of a range of flows to suit a variety of patient sizes.

Physics of Centrifugal Pumps

Since centrifugal pumps now account for the majority of pumps in ECMO circuits utilized for cardiac indications, it is important to understand their design and function. The basic centrifugal pump consists of a disposable pump head secured within a drive, controlled by a console. The disposable pump head is comprised of a blood inlet at the top and an outlet along the side of a polymer housing that encases either an impeller arranged with blades or vanes, or a conical rotor connected to the bases of two smooth concentric cones. The impeller vanes or conical rotor have embedded magnets which are coupled to a rotating magnetic field within the drive. This magnetic coupling means that the speed of the driver magnet (the set RPM) equals the rotational speed of the pump. The spinning impeller or conical rotor transfers motion energy to the blood that is

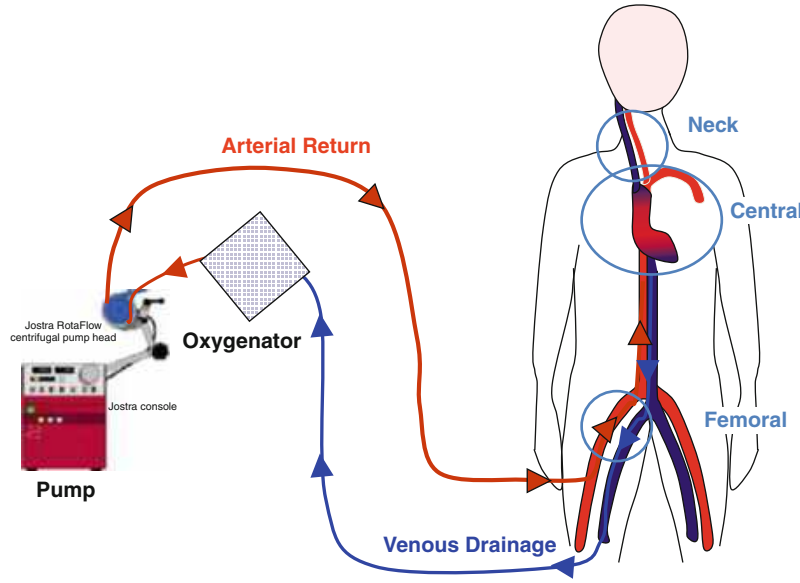

Fig. 150.5 Basic VA ECMO Circuit

then transformed to pressure energy at the pump outlet. When the pressure energy at the pump outlet exceeds the sum of all resistance to outflow, blood flows from the pump outlet.

The pump must impart enough motion energy to the blood to overcome the sum of all the resistances to blood flow for a given pump speed. Resistance increases with decreasing diameter of the tubing, increased length of tubing, increased viscosity of blood, number and type of connections, number and type of components, height to which the blood is pumped (pump head), and pressure at the end of the tubing, or systemic vascular resistance (in VA-ECMO applications). Mathematically, resistance is partially characterized by Poiseuille's equation:

$$R \propto \frac{\eta \cdot L}{r^4}$$

where R is resistance, η is viscosity, L is length, and r is radius.

Simplification and miniaturization of centrifugal pump-containing ECMO circuits, therefore, are vital to improving pump efficiency by reducing outflow resistance.

The Physiology of the Centrifugal Circuit-Patient Interaction

Flow generated by a centrifugal pump is determined by speed (revolutions per minute, or RPM), preload, and the sum of all pump outflow resistance often called "afterload" to maintain congruence with basic cardiology concepts (Fig. 150.6). Pump speed must be sufficient to overcome resistance in order to generate blood flow. For each patient-centrifugal circuit combination, there is a critical pump speed below which the potential energy generated at the pump outlet is insufficient to create flow. In this situation, reverse flow occurs from the patient's higher "driving pressure." However, once this resistance is overcome, further increases in pump speed result in a proportional increase in pump flow until flow reaches the maximum output for a given combined outflow resistance. At this point, further increases in speed at this point will only increase turbulence and resistance and reduce pump efficiency, resulting first in decrease and then a plateau in flow.

Preload augmentation results in proportionally increased flow for a given pump speed, until flow

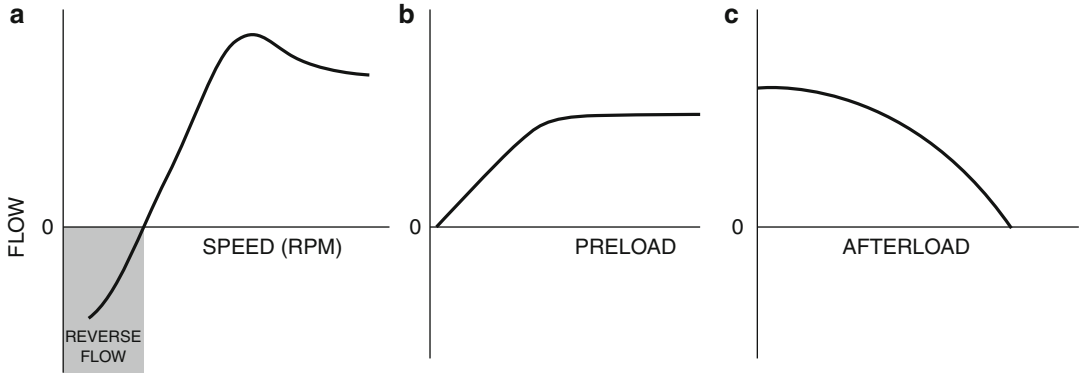

Fig. 150.6 Relationship between speed, preload, afterload, and flow with centrifugal pumps. (**a**) The speed at which flow is zero corresponds to the point where the potential energy (pressure) at the pump head outflow exactly equals the afterload to flow. From this point, increasing pump speed results in a proportional increase in pump flow, until the maximum flow for a given preload and afterload is achieved. Above this speed, blood becomes turbulent, and flow is compromised. (**b**) At any given pump speed, increases in preload result in proportional increases in flow until the maximum flow for a given preload is achieved. (**c**) For a given patient-centrifugal circuit relationship, as afterload (see text) increases, flow decreases. In this example, the Y axis corresponds to the afterload "value" which allows the most flow. Below this value, flow becomes limited by preload dependence

reaches the maximum output for a given preload. Above this level, further volume administration or preload augmentation will not produce more flow and results only in increased volume in the reservoir – the patient central venous system – with increased central venous pressure. For the additional preload to further augment flow, either pump speed must be increased or pump outflow resistance must be decreased.

Finally, for a given pump speed, increasing outflow resistance ("afterload"), such as by increasing systemic vascular resistance, results in an exponential reduction in pump blood flow, until the point at which total obstruction to pump outflow exists, and flow ceases. In this situation, the rotational mechanical energy of the pump continues to be transformed via motion energy of the blood in the impeller into potential energy at the pump outlet, but the potential energy is insufficient to overcome the outflow resistance. The pump outflow is pressurized, but unlike the roller pump system, excessive positive pressure will not result in tubing rupture. Only when outflow resistance decreases will flow resume at this pump speed. In this system, progressive decreases in afterload will augment pump flow provided that adequate preload is maintained in the venous reservoir (right atrium) to support the increased flow.

The hydraulic version of Ohm's law, $\Delta P = QR$, describes flow through the centrifugal circuit-patient connection when flow is laminar. In this description, ΔP is the measure of resistance to flow (Q) and flow varies inversely with resistance (R). As total outflow resistance falls, flow increases; as total outflow resistance increases, flow decreases. Because flow is variable with changes in the patient's systemic vascular resistance (afterload), centrifugal circuits must incorporate either ultrasound or electromagnetic flow monitors to measure circuit and patient flow.

Centrifugal circuits can be designed and operated with no circuit monitoring other than flow monitoring. However, these pumps are capable of generating significant negative pressure on their inlet side, creating a potential risk of cavitation, micro-gaseous emboli, or hemolysis. There is a lack of published clinical data about the clinical occurrence of these events and the level of negative pressure at which they occur. At Children's Hospital Colorado, the goal is to maintain

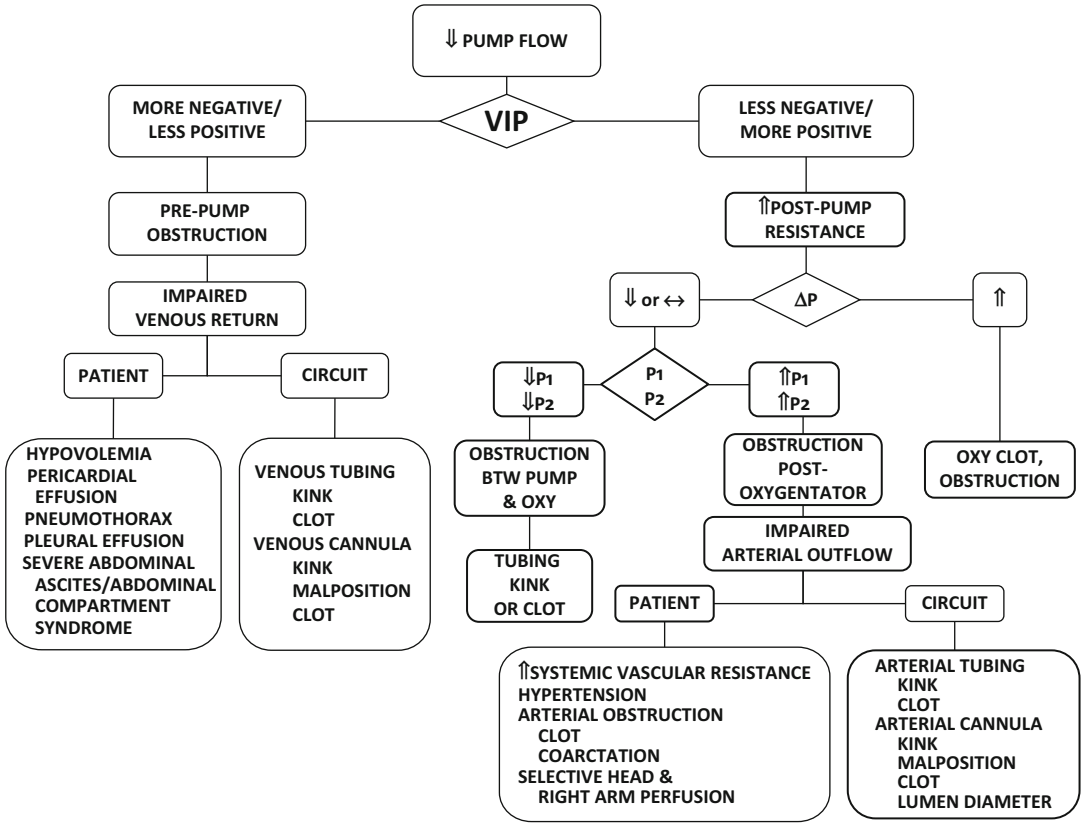

Fig. 150.7 An algorithm for trouble-shooting disturbances in VA ECMO flow in a centrifugal circuit. VIP, venous inlet pressure, or pre-pump pressure. P1, P2 are pre- & post-oxygenator pressures, respectively. While monitoring these pressures is not necessary for safe pump operation, it is convenient for quick localization of disturbances in flow, with identification of a discrete differential diagnosis

minimal negative venous pressure. However, we have not observed a relationship between venous inlet pressure, hemolysis, and cavitation despite negative pressures of −100 mmHg or more (albeit in veno-venous applications).

The practice at RCH, Melbourne, is to measure the venous pressure at the venous cannula and with a goal to maintain this pressure between 0 and −20 mmHg. A variety of cannula and circuit pressures can be monitored and regulated, depending on the capabilities of the selected pump console [10]. Variably incorporated into the circuit are measures of venous cannula pressure, pre-pump pressure, reservoir ("bladder") pressure, pre- and post-oxygenator pressure, and arterial return cannula pressure. Roller pumps require servo-regulation of excessive negative and positive pressures, which has led to a convention of monitoring pre-pump and pre- and post-oxygenator pressures. Monitoring the "conventional" pressures in a centrifugal circuit allows for quick localization of centrifugal ECMO pump flow disturbances and allows for a more discrete differential diagnosis in VA ECMO (Fig. 150.7). Additionally, monitoring of conventional pressures can be helpful in training and understanding the physiology of centrifugal pump-patient interaction. A similar differential can be systematically derived from evaluation of patient vital signs and patient-ECMO flow alone (Figs. 150.8 and 150.9). Following the transition from roller to centrifugal pump ECMO, the conventional

monitoring can be whittled away as the program becomes established in understanding the physics of the patient-centrifugal circuit interaction. Figure 150.10a is a schematic of the most recent centrifugal ECMO circuit at Children's Hospital Colorado, and Fig. 150.10b is a schematic of the centrifugal circuit at RCH, Melbourne.

The Physiology of the Patient-ECMO Support Interaction

When mechanical support with ECMO is required for any of the indications elaborated in Table 150.2, the primary goal is to achieve and maintain acceptable tissue oxygen delivery while allowing for myocardial recovery. Tissue oxygen delivery in ECMO-supported patients is determined by the sum of the patient and ECMO

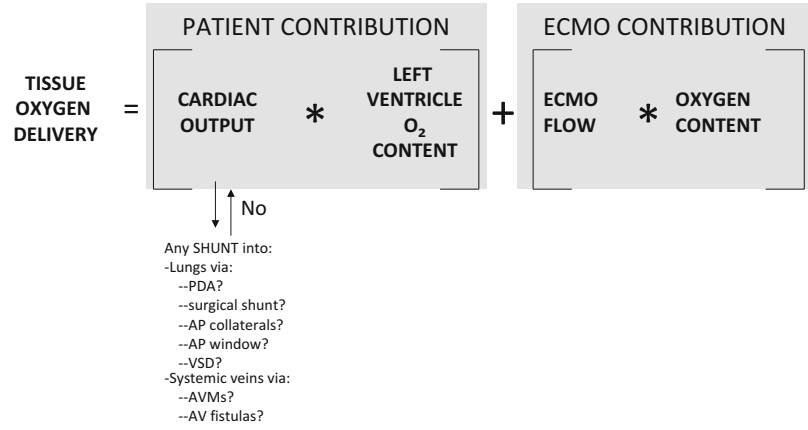

Fig. 150.11 Determinants of tissue oxygen delivery in ECMO-supported patients

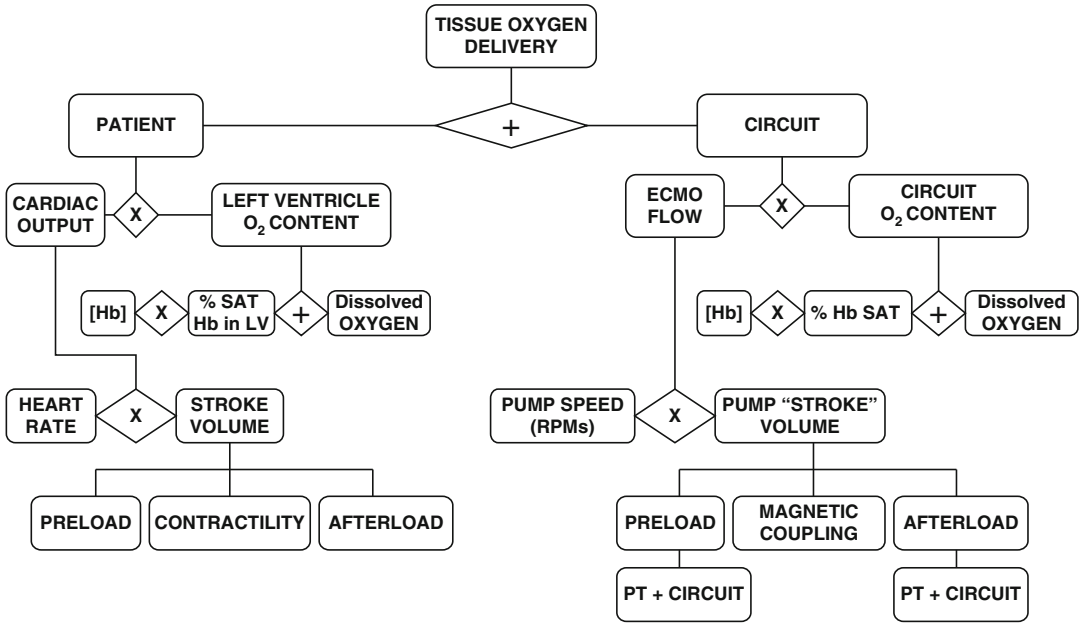

Fig. 150.12 Summary of systemic oxygen delivery in ECMO-supported patients with biventricular circulations

variables which independently contribute to oxygen delivery (Figs. 150.11, 150.12, and 150.13).

During a failing circulation, prior to initiation of ECMO, systemic oxygen delivery is compromised and is derived entirely from the patient and is often associated with reduced systemic arterial blood pressure and an attenuated pulse wave contour. Following initiation of ECMO, systemic oxygen delivery is increased and is predominantly, if not entirely, comprised of the ECMO contribution. Clinically, there may be non-pulsatile arterial wave form and echocardiographic evidence of absent aortic valve opening. As ventricular function improves, the patient's contribution to total systemic oxygen delivery increases; upon tapering and separating from ECMO support, the patient's contribution accounts for the majority, then the entirety, of total systemic oxygen delivery. A pictorial view of this relationship, including consideration of the influence of effective alveolar ventilation to systemic oxygen delivery, is provided in Fig. 150.12.

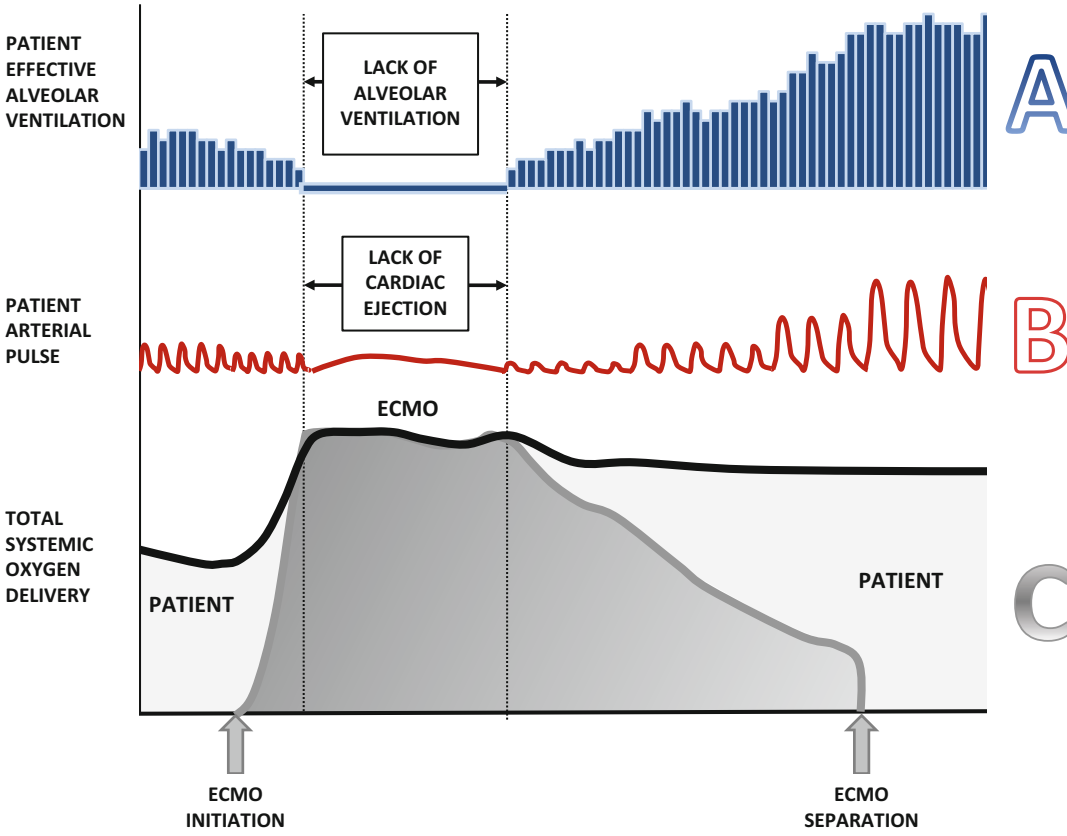

Fig. 150.13 A pictorial of patient versus ECMO contribution to systemic oxygen delivery during a theoretic ECMO course (see text) (Adapted from Annich et al.)

In the ECMO-supported patient, total systemic oxygen delivery (black line) is the sum of patient and ECMO contributions. Patient effective alveolar ventilation (a) corresponds to the translocation of oxygen from the air spaces to the pulmonary capillary and into the systemic arterial vasculature for oxygen delivery to the tissues. Patient arterial pulse (b) corresponds to systemic blood flow and oxygen delivery supplied by the patient. Prior to ECMO initiation, the cardiac patient supplies the entire, albeit declining, systemic oxygen delivery (c), either from reduced effective alveolar ventilation (a), reduced systemic blood flow (b), or a combination thereof. Upon initiation of ECMO, the total systemic oxygen delivery is comprised of the patient's contribution (light shaded gray) added to the ECMO contribution (dark shaded gray). If effective alveolar ventilation ceases for a period [between the dotted lines in (a)] or if cardiac ejection ceases for a period [between the dotted lines in (b)], then during this time, ECMO supplies the entire systemic oxygen delivery. With lung recovery (a), effective alveolar ventilation improves, and patient contribution to total systemic oxygen delivery increases. With myocardial recovery (b), ejection returns, and patient contribution to total systemic blood flow and total systemic oxygen delivery increases. Patient contribution continues to increase while ECMO flow is tapered. Upon separation from ECMO, total systemic oxygen delivery is again provided solely from the patient.

ECMO is initiated with the primary goal of providing normal or near-normal systemic oxygen delivery during a period of reversible cardiac and/or pulmonary dysfunction. The patient's PaO_2 and in-line circuit SvO_2 are useful monitoring parameters. In patients with biventricular

circulation, systemic arterial PaO_2 is maintained ~100 mmHg. Since oxygen delivery is comprised primarily of ECMO flow, addition and titration of air with oxygen in the sweep gas is required. In-line SvO_2 monitoring on the venous side of the circuit is important to assure acceptable tissue oxygen delivery in the biventricular circulation. However, this parameter is variably affected by a left-to-right atrial level shunt, depending on the pulmonary venous saturation. Interpretation of alterations in patient systemic arterial PaO_2 and circuit SvO_2 in the ECMO-supported patient requires consideration of relative proportion of patient and ECMO circuit contributions to systemic oxygen delivery (Fig. 150.13) and careful consideration of each of the variables comprising the patient and ECMO circuit contributions (Fig. 150.12). Systemic arterial PaO_2 and SvO_2 can reflect changes in systemic oxygen delivery from the patient or the circuit, patient oxygen consumption, alterations in the direction and magnitude of intracardiac and extra-cardiac shunts, and the degree of cardiac or pulmonary dysfunction. Accurate interpretation of systemic arterial PaO_2 and circuit SvO_2 depends on a thorough evaluation all of these potential contributing factors, as well as consideration of the sources of blood flow being sampled from a particular site. Alterations in systemic arterial PaO_2 and circuit SvO_2 in patients with biventricular circulation are summarized in Tables 150.5 and 150.6.

Cannulation Strategies

The ECMO cannulation strategy for patients in the cardiac intensive care unit requires consideration of the patient's anatomy, indication for ECMO, goals of support, and vascular patency. In general, central (transthoracic) cannulation of the right atrial appendage and the ascending aorta is performed in patients who are unable to separate from cardiopulmonary bypass or in whom mechanical support is required in the early postoperative period. The advantages to transthoracic cannulation in post-cardiotomy patients include expeditious initiation of support with larger cannula sizes, greater flow, less negative venous pressure, optimal left heart venting with placement of an additional venous cannula to drain the left atrium, and simultaneous

cardiac massage, as indicated. The disadvantages include increased bleeding and infection risk; these risks are significant enough that that cervical or femoral vascular cannulation is preferred for most other VA ECMO applications.

Cervical cannulation offers the advantage of good exposure and easier insertion with larger, shorter cannulas when compared with the femoral site However, this approach carries increased stroke risk. Permanent ligation of the carotid artery distal to the arterial cannula is unnecessary, and the vessel can often be repaired at the time of decannulation with reasonable patency at 5 years [11, 12]. Neurodevelopmental and cognitive outcomes during childhood, adolescence, and adulthood have not been fully investigated. Femoral cannulation for larger children, on the other hand, offers the advantage of lessened stroke risk. However, with this approach, centrifugal pump efficiency is decreased due to the requirement for smaller, longer cannulas. This results in less optimal flow characteristics with more negative venous pressure. There is potential for leg ischemia from arterial insufficiency or venous obstruction, which often necessitates additional cannulas for perfusion and drainage of the leg [13]. In addition, this approach may lead to suboptimal oxygen delivery to the coronary and cerebral circulations. In adults, major vascular complications occur in 10 % of patients [14]. Nevertheless, with appropriate prevention and surveillance for complications, femoral cannulation has been successfully used to support adolescent and adult patients with cardiac failure. When required, additional arterial and venous access can be achieved by placement of supplementary cannulas. Potential sites include most commonly the contralateral femoral vessels or internal jugular vein. If access sites are particularly limited, the axillary vessels or cutdown to the subclavian or iliac vessels may be considered.

Critical Care Management of the ECMO-Supported Cardiac Patient

In addition to maintaining acceptable systemic oxygen delivery and left ventricular decompression, several medical strategies may be required to facilitate myocardial recovery and optimize potential for recovery. Cardiac support with low-dose inotrope and aggressive inodilator or vasodilator infusions are sometimes maintained to improve myocardial contractility and reduce left ventricular afterload with the goal of improving ventricular ejection and emptying. Periodic echocardiogram surveillance should be performed to evaluate cardiac contractility, valve function, direction and gradient of shunts, effusion, and intracardiac or vascular thrombosis. Pulmonary support should include a ventilation strategy that is aimed at maintaining both an open lung and normal pulmonary venous oxyhemoglobin saturation, since coronary perfusion is derived principally from left ventricular ejection [15]. Pulmonary biotrauma, volutrauma, and barotrauma should be limited to prevent potential for delayed ECMO separation caused by progressive lung injury. In most cardiac patients, these goals can be achieved with an inspired oxygen fraction of <0.4 and volume control ventilation using a moderate positive end-expiratory pressure (PEEP) of 8–10 cm H_20 and a tidal volume (V_t) of 8–10 ml/kg while still maintaining peak inspiratory pressure (PIP) less than 25–30 cm H_20, at a rate of 10–15 breaths/min, depending on the patient's age and size.

The goals for fluid balance should be to utilize diuretics and hemofiltration to remove systemic volume overload, reduce left ventricular distention and wall tension, promote ejection and emptying, and resolve cardiogenic pulmonary edema. Nutritional support should be initiated promptly based on estimated energy expenditure. The enteral route is preferred when pre-ECMO bowel ischemia has resolved. Any excess volume from nutritional support should be managed by diuretics and hemofiltration, rather than fluid restriction. Hematologic management involves anticoagulation, but should also include plasma free hemoglobin measurement at least daily to assess the degree of hemolysis. Significant hemolysis induced by the circuit has been associated with hemoglobinuria nephropathy as well as impaired tissue perfusion due to its nitric oxide scavenging properties [16, 17]. Abrupt elevation in plasma hemoglobin can be managed in

Table 150.7 Percentage incidence of complications in patients on ECMO

a centrifugal circuit by changing the pump head [18], or when utilizing a roller pump, by adjusting the occlusion or changing the circuit. Renal management includes maintaining urine flow with diuretic infusion to avoid oliguria and tubular nephropathy. However, if oliguria and renal insufficiency do occur, systemic volume overload must be managed with hemofiltration or dialysis. Infection surveillance must be compulsive, with constant assessment of changing clinical status and periodic assessment of white blood cell count, inflammatory markers, and blood cultures. Antibiotic prophylaxis should be considered; at Children's Hospital Colorado, antibiotic prophylaxis is provided for patients receiving transthoracic ECMO, but not for patients with cervical or femoral cannulation sites. Neurologic management includes sedative and analgesic infusions as standard, and these infusions can be periodically interrupted safely, in order to achieve the benefits of reduced cumulative doses [19]. Neuromuscular blockade should be limited or avoided if at all possible, to allow for repeated neurologic assessment.

Anticoagulation

Anticoagulation is a requirement for the routine use of extracorporeal circuits in clinical practice. However, bleeding (both local and systemic) as well as circuit thrombosis with thromboembolism to the patient remains problematic. Indeed, the ELSO registry records hemorrhagic complications as occurring in at least 30 % of patients and thrombosis in at least 5 %, and at least 15 % of circuits have clots [1]. In cardiac ECMO, the incidence of cannulation and surgical site bleeding is increased compared to respiratory ECMO, but the incidence of major organ bleeding is similar except for CNS and the incidence of circuit clots is less (Table 150.7). Hemorrhagic and thrombotic complications appear to be a major issue in non-survivors. In a recent series of 29 consecutive autopsies from a single center, 86 % had thrombosis and/or hemorrhage; 69 % had thrombosis and 52 % hemorrhage after ECMO initiation [20].

Following cardiac surgery, children already have disordered coagulation due to a number of factors [21]. These factors include residual effects of anticoagulants administered during cardiopulmonary bypass (CPB), dilution coagulopathy, platelet dysfunction due to platelet injury during CPB, systemic inflammatory response causing circulating procoagulants, and activation of thrombolysis. Severity of coagulopathy is increased with complexity of the surgery and the length of time on CPB [22]. Treatment for coagulopathy typically includes transfusion with plasma, cryoprecipitate, and platelets and administration of drugs such as protamine, calcium, and vasopressin. Despite therapeutic attempts to correct the coagulopathy, the risk of surgical bleeding remains. The use of ECMO in this situation exacerbates the risk of the patient bleeding and thromboembolism, as well as the additional risk of circuit thrombosis [23].

Cannulation strategy impacts the likelihood of bleeding and therefore the anticoagulation

Fig. 150.14 Open chest ECMO with a clear membrane

strategy. The use of peripheral cannulation involves new surgical incisions, and local bleeding is common. This local bleeding may be controlled with meticulous hemostasis, the use of tissue glue and directly applied pressure. Percutaneous rather than "cutdown" technique is associated with less bleeding, but this approach is more difficult in small infants as compared to adults. Central (transthoracic) cannulation may be associated with sternal bleeding. A clear membrane over an open chest allows this technique to be safely employed as bleeding and clots can be directly visualized (Fig. 150.14); the size of the clot and the intrathoracic pressure can be evaluated, and the clot may be evacuated in the ICU.

Continuous intravenous infusion of heparin is mainstay for anticoagulation of the ECMO circuit, and there is much debate about the most appropriate monitoring strategy. There is no consensus, and experts continue to debate fundamental questions. Should bedside tests of clotting such as the activated clotting time (ACT) or the thromboelastogram (TEG) be used? What is the role of standard laboratory tests that reflect the likelihood of clotting, such as activated partial thromboplastin time (aPPT) or prothrombin time (or international normalized ratio)? Once a monitoring protocol is determined, what is the target for that test? What clotting factor levels should be targeted? What is the role for more sophisticated tests of heparin activity, such as anti-Xa or heparin levels or antithrombin III (ATIII) levels (Table 150.8)? While the answers to these questions are not fully determined, approach to anticoagulation management is critically important because outcome may depend on appropriate heparin therapy [24, 25].

The ACT is a measure of how long a sample of patient's blood takes to form a clot in the presence of an activator; it is the most common test used to monitor anticoagulation on ECMO. This test measures the end result of both intrinsic and common coagulation pathways, as well as platelet number and function. The ACT is sensitive to other coagulopathies and is not specific for heparin effect alone. Different ACT machines have different normal values, and caution should be used in deciding on the desired level of ACT. The aPTT is also frequently used to monitor patients on ECMO; in adults, this test is utilized more commonly than ACT. Although the effects of heparin influence the aPTT, it is also sensitive to other coagulopathies including clotting factor deficiencies, DIC, and coagulation inhibitors. Therefore, the aPTT does not give a "pure" guide to the amount of heparin (or heparin effect) in the sample. The anti-Xa assay is currently the most specific method for measuring heparin

Table 150.8 Heparin monitoring

Measures	Whole blood clotting	Whole blood clotting	Intrinsic & common pathways	Heparin activity (indirect)

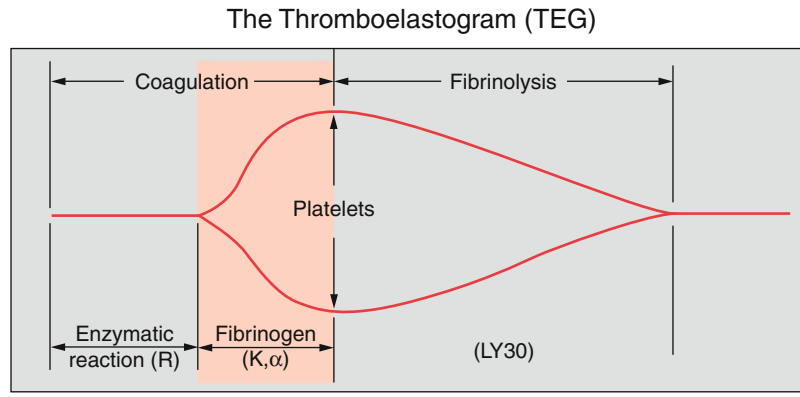

Fig. 150.15 The Thromboelastogram (TEG)

effect. The therapeutic level is 0.25–0.5 μm/ml when low molecular weight heparin is used, and it is the only way to monitor therapy (goal, 0.4–1 μm/ml). The thromboelastogram (TEG) is a more complicated version of an ACT and reflects clot initiation, rate of formation, strength, stability, as well as clot lysis. TEG also utilizes a second sample that has "heparinase" in the cuvette which eliminates the effect of heparin (Figs. 150.15 and 150.16), and the patterns generated may suggest different problems within the clotting mechanism (Fig. 150.17). TEG gives additional details about the nature of clotting abnormalities which is very useful in complex patients on ECMO following cardiac surgery or those with sepsis.

Platelet count and function has long been appreciated as a significant factor affecting the incidence of bleeding while on ECMO. Monitoring and targeting of specific platelet levels and more recent interest in platelet function have led to a dramatically lower incidence of major bleeding. However, this focused attention may have increased the incidence of circuit clot formation, which can lead to hemolysis and thromboemboli. Clot formation can be particularly problematic at lower circuit flow rates. Neonates on ECMO may have blood flow rates of less than 400 ml/min; this relatively low flow also increases the risk of clots in the extracorporeal circuit. Some ECMO programs utilize a bridge to allow increased circuit flow, while others do not, and argue that a bridge allows areas of stasis. Each approach has advantages and disadvantages that require consideration and recognition of risk versus benefit. Antiplatelet drugs such as prostacyclin or tyrofiban are increasingly being used to treat circuit clots. A TEG or other methods to measure platelet function such as the PFA 100 (Siemens) may be used to monitor the effects of these drugs on platelet function.

Activation of fibrinolysis sometimes occurs during and after CPB. The use of antifibrinolytic agents such as tranexamic acid, aprotinin, or aminocaproic acid has been associated with decreased postoperative bleeding. These drugs are also potentially useful when there is evidence of increased fibrinolysis in children on ECMO after cardiac surgery. Increased fibrin

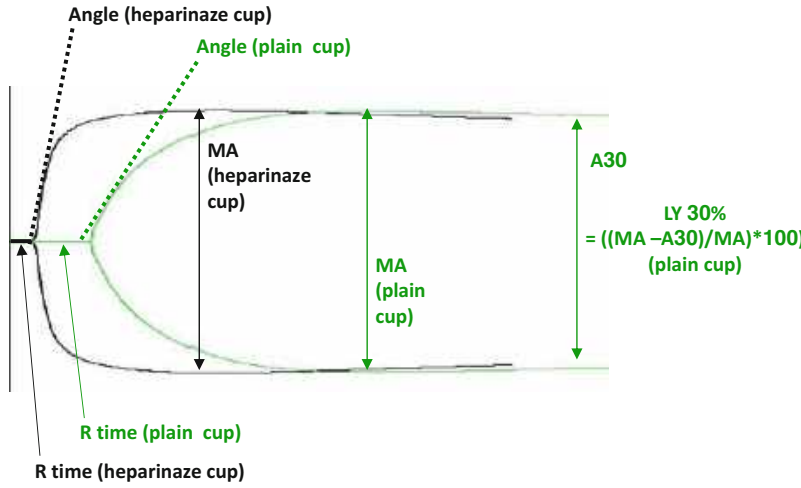

Fig. 150.16 Thromboelastogram normal and heparinase traces

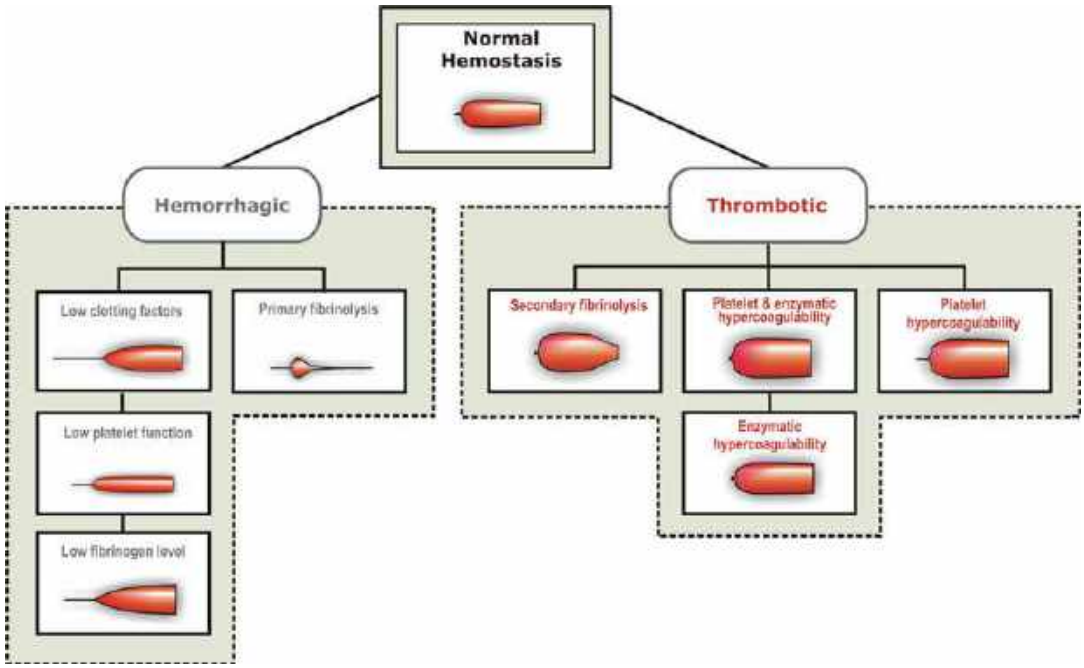

Fig. 150.17 Thromboelastogram in different clinical situations

degradation ("split") products (FDP or FSP) or d-dimer will document this increase in fibrinolysis, which may clinically present as bleeding. The TEG may also be useful for evaluating this situation. When central ECMO is performed via a sternotomy and the chest is left open (with a clear, sealed membrane covering the "open chest"), a large collection of blood or an outwardly bulging membrane with visible clot may develop. Fibrinolysis may develop in this clinical setting and will often resolve with evacuation of the clot.

It is important to differentiate local bleeding from systemic coagulopathy. Local bleeding related to cannulation or surgical site requires local measures, whereas generalized bleeding is more ominous and difficult to control. A clear diagnosis as to the cause of bleeding is essential to successful management. Similarly, the type of clotting issue must be defined. Fibrin strands or clots are easily seen in the circuit and can be managed with antiplatelet agents or increased anticoagulation; eventually, a new circuit may be required. These issues are more easily managed than cannula or intravascular clots, which are a formidable problem. In these situations, surgical removal may be required. Clot lysis with tissue plasminogen activator (t-PA) has occasionally been performed, but is very hazardous and has been associated with intracerebral bleeding.

Heparin-induced thrombocytopenia (HIT) does occur, but is uncommon in patients on ECMO; this complication occurs more commonly in adults than children [26]. The diagnosis is suggested by thrombocytopenia, but there are usually other more likely causes. Intravascular clots suggest that HIT may be present. If heparin cannot be utilized, other anticoagulants have been successfully used, such as bivalirudin or loperidan [27–29].

Age of the child and clinical situation will substantially impact the goals of anticoagulation and the therapies employed. The complexities of anticoagulation can only be managed by carefully devised and detailed protocols. While major center-to-center differences are often seen and many of the anticoagulation goals are arbitrarily established, somehow as long as the local protocols are followed, bleeding, clot formation, and hemolysis are generally manageable. Examples are provided of protocols for anticoagulation currently in use for ECMO at RCH, Melbourne, for newborn infants/small children and for children between 5 and 18 years of age (Figs. 150.18–150.21). There are separate protocols for the standard patient and also a different one for patients with bleeding; thus, 4 protocols are required. The anticoagulation protocol utilized at Children's Hospital Colorado is also provided (Fig. 150.22).

Clinical Scenarios

Postoperative

ECMO may be initiated after surgery for one of three primary reasons: (1) inability to wean from CPB, (2) sudden unexpected cardiac arrest, and (3) inadequate systemic oxygen delivery. Inadequate systemic oxygen delivery is usually due to ventricular failure or residual anatomic defect, and children with single-ventricle physiology may have an unbalanced circulation.

Postoperative mechanical support has become standard management option in many centers throughout the world [8, 30–34]. The January 2012 ELSO registry records 10,287 cases of cardiac ECMO in children less than 16 years of age. Analysis of these cases reveals that 62.4 % survived ECMO and 44.3 % survived to hospital discharge. Approximately 75 % of these children were on ECMO for perioperative management of congenital heart disease; most cases were initiated following surgery. Of these patients, 41 % survived to hospital discharge. There are numerous single-center reports that document and provide some insight into the factors that affect survival and outcome of these children. Single-ventricle circulation is not a contraindication to mechanical support. The reason for ECMO is important: if the problem is one of residual shunt or obstruction to blood flow, then ECMO will provide ongoing support until an accurate diagnosis can be determined and an effective plan is developed to resolve the problem. If the problem is poor ventricular function, then ECMO will allow time for ventricular recovery. However, if ventricular function does not begin to improve by 3–5 days, then the long-term outlook is poor. As expected, complications such as neurological injury or multi-organ failure due to low cardiac output or cardiac arrest have a major impact on outcome.

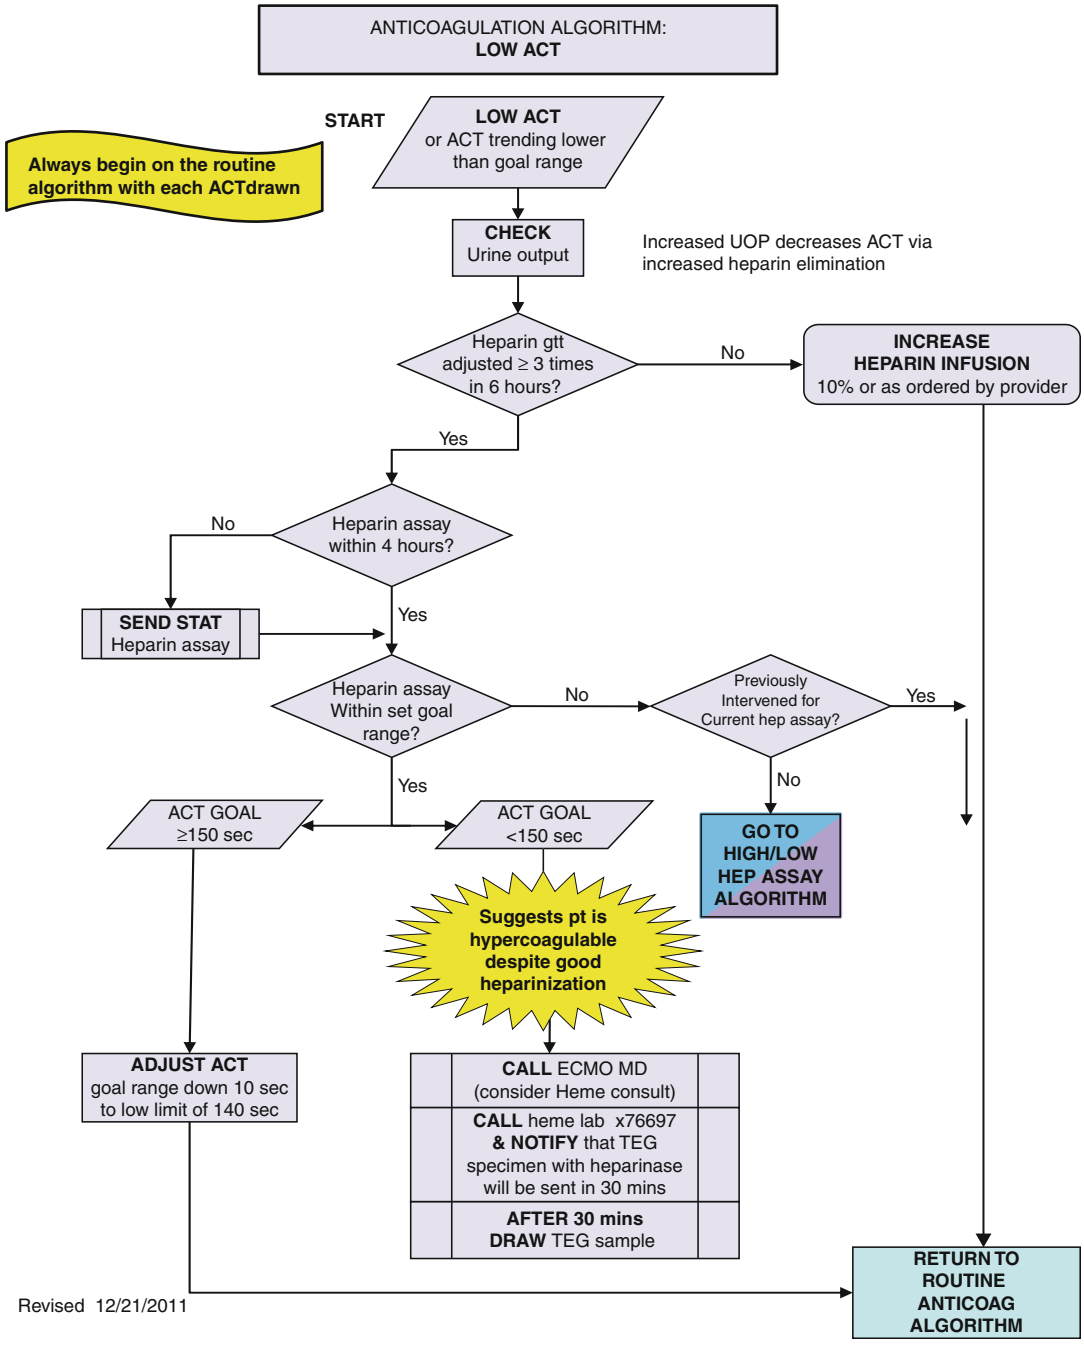

Fig. 150.22 Routine anticoagulation algorithm at Children's Hospital Colorado

ECPR

In many centers, ECPR has become the standard management for children with unexpected, refractory cardiac arrest. Individual centers are increasingly reporting encouraging survival and neurological outcome in this situation [6, 35–37], but similar to non-ECPR patients, prolonged CPR

and multi-organ failure are associated with a worse outcome. The ELSO registry has recorded the details of 2,226 newborns and children who have received ECPR with a recorded survival rate of 39.3 %. In this cohort, the majority have cardiac disease and are in the ICU. Early initiation of ECMO is likely to lead to improved patient outcomes. Underlying diagnosis of complex single-ventricle disease should not preclude the use of ECMO. While ECPR is a viable option, ECMO should ideally be deployed in postoperative cardiac patients, with deteriorating clinical status, before cardiac arrest occurs.

Cardiogenic Shock (Nonoperative)

Irrespective of etiology, ECMO has become a standard resuscitative therapy for acute cardiogenic shock. ECMO provides rapid stabilization of the circulation with improved oxygen delivery to tissues. ECMO will allow for a decrease in high-dose inotropes/vasoconstrictors and ensure adequate ventilation and oxygenation. Once adequate vital organ blood flow is reestablished, multi-organ failure can often be improved or even reversed, potentially leading to an improved patient outcome. The longer-term plan depends on the underlying cause of the shock. ECMO resuscitation followed by conversion to long-term mechanical support is a viable option and common clinical practice [38–41].

Bridging

Pediatric cardiac transplantation has been performed for over 20 years. Unlike adolescents and adults, mechanical support for the small young patient listed for transplantation has been problematic, with fewer options available to this population. Many centers have used ECMO as a bridge to transplant. In the USA from 1987 to 2009, 773 children received ECMO with a view to bridging for transplantation. Diagnoses were as follows: 218 cardiomyopathy, 61 myocarditis, 263 congenital heart disease (2 ventricles), and 231 congenital heart disease (single ventricle). Survival to hospital discharge was accomplished in 63 %, 59 %, 44 %, and 33 %, respectively [42]. In a single transplant center from the UK [43], 189 transplants were performed in 182 children from 1987 to 2009. Mechanical support for children on the waiting list was introduced as an option in 1998 and was utilized in 32 (17.6 %) of children. The overall mortality rate for the group was 22.5 % (41/182) with a median survival time of 2.7 years (range 0–15 years) after transplantation; the mortality before 1998 was 32 % and 16 % after 1998. The 30-day survival was 97 % for cardiomyopathy and 86 % for congenital heart disease. ECMO is not an ideal option for "long-term bridging" to transplantation but can provide an intermediary support until longer-term devices can be implemented.

Special Considerations

Single Ventricle

ECMO has been used for cardiopulmonary support in patients with all types of single-ventricle circulation including those with systemic-pulmonary artery shunts, cavo-pulmonary shunts, pulmonary artery bands, and after other types of surgery involving "Fontan"-type circulation. The indications for ECMO in these patients are similar to the indications for ECMO in patients with other cardiac diagnoses: persistent hypoxemia, refractory low cardiac output or low systemic blood flow, recalcitrant arrhythmias, cardiac arrest, or failure to wean from CPB. The cannulation strategy for single-ventricle patients requires special consideration of the patient's cardiac anatomy, stage of palliation, and vascular patency. Patients with systemic to pulmonary artery shunts require increased ECMO flow to maintain circulation to both the systemic and pulmonary vasculature. Occasionally, flow through the shunt must be restricted to reduce pulmonary blood flow and pulmonary edema, but is usually not required. The outcomes for ECMO support of single-ventricle circulations are not quite as good as for two-ventricle circulations but are reasonably close. In patients with

single-ventricle physiology, it is the indication for ECMO and the degree of end-organ injury that determine the outcome, just as it is for patients with two ventricles. The best outcomes are reported for patients with parallel circulations who require ECMO for shunt thrombosis, with a survival of 83 % [44].

Differential Ventricular Failure

Patients on peripheral or central VA ECMO can develop differential ventricular failure. In this situation, there is some preservation of right heart function with minimal or no function of the left ventricle. If the right heart continues to eject blood, then progressive dilatation of the left heart will occur; left ventricular end-diastolic pressure will rise, leading to pulmonary edema if the condition is left untreated. Progressive distension of the left ventricle may impair coronary perfusion, exacerbate myocardial ischemia, and prolong or prevent ventricular recovery. Initial treatment options include increasing the ventilator PEEP setting, and the use of inotropic drugs to improve left ventricular ejection. Increasing ECMO flow with a goal of more effective emptying the right heart may also reduce this problem.

If conservative management options fail, then decompression via percutaneous, transseptal, or open surgical procedures will be necessary. If the patient is on central ECMO, a left atrial catheter inserted via the left atrial appendage will resolve the problem. For patients cannulated in the cervical or femoral areas, an additional percutaneous cannula can be advanced under echocardiographic or fluoroscopic guidance from an available femoral vein, positioned across the atrial septum, and left in place to facilitate biventricular decompression [45, 46]. Alternatively, the tip of right atrial ECMO cannula may be placed in the left atrium via a transseptal approach. If the patient is on peripheral ECMO, then a blade and balloon atrial septostomy can be performed in the catheter laboratory or the ICU. This procedure relieves left atrial hypertension and reduces left ventricular volume overload, though at the expense of increased volume load to the right heart and pulmonary circulation [47–49]. Early and serial echocardiography and serial plasma BNP [50] levels may be used to monitor for early LV distension to try and avoid the occurrence of excessive ventricular distension.

At RCH, Melbourne, 49 children required ventricular decompression on VA ECMO from January 1990 to December 2011. The median age was 0.9 years (range 0–16 years) and the weight was 8.7 kg (range 2.2–80 kg); 44 were cannulated via an open chest and 5 were cannulated peripherally. Diagnoses included the following: post congenital heart surgery ($n = 25$), cardiomyopathy [8], myocarditis [6], septic shock [5], post heart transplantation [4], and cardiac tumor [1]. The reasons for ECMO were ECPR [20], low cardiac output [16], failure to wean CPB [9], and conversion from VAD [6]. Decompressions were performed at the time of initial cannulation in 27, with the remaining 22 procedures performed at a median of 23 h later (range 4–99 h). Systemic ventricular decompression was achieved by the left atrium in 37 children and via the left ventricle in 12. Median ECMO support time was 113 h (range 17–1,032 h); 31 survived ECMO and 20 survived to ICU discharge.

Repeat ECMO

In newborns with respiratory failure, repeated use of ECMO is associated with substantial technical and cannulation problems, increased complication rates, and poorer outcomes when compared to patients with single ECMO runs [51]. Children with recurrent cardiac failure who required a second ECMO run following surgery for congenital heart disease has been evaluated in two small series. In these series, the frequency of a repeat ECMO run was approximately 5 % of patients. In the first series from Boston, 25 % (5/20) of children survived to ICU discharge following a second ECMO run [52]. In this series, 25 % of the patients had single-ventricle circulation. The ECMO duration was a median of 191 h (range 171–485 h), and hospital stay was a median of 41 days (range

6–297 days). In a second series from RCH, Melbourne, 25 % (5/20) of children survived to hospital discharge [53]. After a median follow-up of 42.5 months (range 16–66 months), 4 were still alive, three of which had substantial neurological problems.

Table 150.9 Blood product usage on mechanical support RCH 2005–2011

~ml/kg/day	Respiratory ECMO	Cardiac ECMO	VAD
Packed cells	23	44	25
FFP	14	22	9
Platelets	18	20	9

Type of Mechanical Support

At RCH, Melbourne, two types of short-term mechanical support for inadequate cardiac function are available: ECMO and centrifugal ventricular assist (cVAD). Centrifugal ventricular assist offers uni-ventricular support without pulmonary support. It may be considered as ECMO minus an oxygenator. The circuit diagrams of ECMO and cVAD are shown in Figs. 150.5 and 150.22a, b.

There are clear advantages to ECMO, in that it offers biventricular support and ensures adequate gas exchange. However, the ECMO circuit is more complicated than cVAD, and the presence of the oxygenator increases the likelihood of clots and hemolysis. Central or transthoracic approach is required for cVAD, so patients must have an open chest. The results of both approaches are presented in Tables 150.9–150.13. ECMO is used much more commonly than cVAD (163 vs. 51), but either option can be used in single-ventricle and two-ventricle circulations. Both can be used in patients who fail to wean from CPB and for low oxygen delivery after surgery. Fewer blood products are given to children who receive cVAD compared to those who receive cardiac ECMO. Overall survival is slightly better with ECMO: 58 % versus 52 %. Conversion from ECMO to cVAD was accomplished in 18 patients whose lung or partial ventricular function improved, whereas 11 patients converted from cVAD to ECMO as ventricular failure or hypoxemia worsened. Survival was about 50 % in either scenario.

Table 150.10 Cardiac ECLS: Outcome by weight

Weight	ECMO	Survive ICU	VAD	Survive ICU
Less than 4 kg	90	52	25	9
≥4–≤10 kg	46	25	17	14
>10 kg	27	18	9	4

Table 150.11 Cardiac ECLS outcome by indication

Indication	ECMO	Survive ICU	VAD	Survive ICU
Failure to wean CPB	23	7	11	8
Low Cardiac output	101	55	37	19
Arrest	39	33	3	0

Rapid Deployment

Rapid deployment of ECMO in critical situations appears to improve patient survival and long-term neurological outcome [54]. When children are admitted to the intensive care unit, a decision is often made about whether ECMO/ECPR will be offered, and if so, what cannula sizes and circuits will be used. Also, most units have a pre-primed circuit on standby for immediate use. This helps to minimize the time delay between deterioration, decision to implement, and the actual starting time of ECMO augmented oxygen delivery.

Weaning

Tapering from ECMO support is considered when signs of ventricular recovery become apparent. Typically, the arterial tracing demonstrates improved pulsatility, and the patient's arterial blood gas demonstrates a decreasing

Table 150.12 Cardiac ECLS: outcome by timing

Timing of ECMO/VAD	Total ECMO	Survived ICU	% Survival	Total VAD	Survived ICU	% Survival
Pre-op ECMO	14	10	71	1	0	0
Intra-op ECMO	21	14	66	28	16	57
Post-op ECMO	128	71	55	22	11	50

Table 150.13 Cardiac ECLS: outcome by type of circulation

	Total ECMO	Survive ICU	% Survive ICU	Total VAD	Survive ICU	% Survive ICU
Single ventricle	76	34	45	22	10	45
Two ventricle	87	61	70	29	17	59

PaO_2, consistent with increasing patient contribution (with less PaO_2 than pump PaO_2) to systemic arterial oxygen delivery. Additionally, in patients with a left atrial venting cannula or an atrial septostomy, the circuit SvO_2 may decline slightly, reflecting reduced left-to-right shunt of oxygenated blood due to improving left ventricular end-diastolic pressure in the recovering myocardium. Following signs of ventricular recovery, a complete assessment of hemodynamic and pulmonary functions must be made. Echocardiography is essential for demonstrating cardiac contractile function and valve function and assessing for pericardial effusion. In addition, the direction, magnitude, and gradient of remaining shunts can be assessed, particularly at the atrial level. Each of the factors which may affect the patient's ability to contribute to systemic oxygen delivery (Fig. 150.3) is evaluated and optimized. Mechanical ventilation is increased to accommodate progressively increased pulmonary blood flow, and blood gases are monitored to assure normal pulmonary venous blood pH, oxygen, and carbon dioxide content. Temporary pacing may be required in postoperative patients with cardiac failure during taper and trial separation. Inotropic and vasodilator infusions are reintroduced or increased, and circuit blood flow is tapered by decreasing pump speed and/or opening a shunt in the circuit. If there is no bridge in the circuit, anticoagulation targets should be increased to prevent clotting in the circuit with progressively lower flow rates. Continuous echocardiographic monitoring with repeated hemodynamic measurements by spectral Doppler often facilitates weaning and trial separation from ECMO. Adequacy of systemic oxygen delivery is evaluated at regular intervals using a combination of the criteria itemized in Table 150.1. The patient's pulmonary mechanics are monitored on the ventilator to obtain an understanding of the degree of pulmonary impairment. Parameters that are assessed include lung compliance and effective alveolar ventilation, with serial determination of the ratio of dead space ventilation to tidal ventilation (V_D/V_T).

When ventricular function, hemodynamics, and pulmonary mechanics are all acceptable at low flow, the patient undergoes a trial separation from ECMO. Weaning is often first attempted by rapid taper over several minutes to an hour while optimizing ventilator and inodilator support. If hemodynamics and other parameters appear favorable, this is followed by a brief trial separation from ECMO of 20–30 min. If rapid taper is unsuccessful, then ECMO support is gradually tapered over several hours to a flow of ~30 ml/kg/min. Patients who require a slow taper may require an extended trial separation of 1–2 h with intermittent flashing of the cannulas, though the increased risk of thrombotic complications during this extended trial separation should be recognized. During the trial separation, the ECMO circuit is clamped and cannulas remain in place. Cannulas are flashed periodically (every 10 min, at Children's Hospital Colorado) to minimize thrombosis formation, while ECMO flow and full anticoagulation are maintained in the circuit

through an arterial to venous shunt (bridge). When decannulation is indicated, it often occurs at the bedside, and sometimes in the cardiovascular operating room, and may be accomplished with or without sternal closure.

Conclusion

ECMO support of cardiac dysfunction with VA ECMO is increasingly utilized successfully in pediatric cardiac critical care. Results are continuing to improve because of greater understanding of pathophysiology and patient circuit interactions, improved technology and equipment, and improved protocols of care that lead to earlier and more effective utilization with fewer adverse events. Most (90 %) of the children who survive to hospital discharge are alive at 1 year. However, these children are at substantial risk for poor functional outcome and a poor quality of life. Many factors may contribute to poor outcomes, including primary cardiac condition, other congenital abnormalities, severity of illness, and complications related to their care. These children often have complex medical needs that require multidisciplinary care. Major neurological problems occur in approximately 10 %, and up to 30 % have a moderately poor quality of life [3, 55].

Despite these challenges, each year's results show improvement. At RCH, Melbourne, a 58 % survival was noted for the 7-year period from 2005 to 2011; in 2011, the survival rate was 73 %. Additionally, these children may show further improvements in function and quality of life. Future advances in knowledge and technology will undoubtedly lead to even better results.

Brigitte Stiller and Holger Buchholz

Abstract

Mechanical circulatory support with ventricular assist devices has evolved in the pediatric population as an accepted modality for the failing heart refractory to maximal medical and surgical management. A ventricular assist device is a pump that is attached between the heart and the aorta or pulmonary artery and helps to circulate a patient's blood. Refinement of preimplantation planning and post-implantation management has resulted in survival rates to transplantation comparable to those without preceding ventricular assist device support. The pediatric population has been limited to fewer devices with the Berlin Heart *EXCOR® Pediatric* garnering the most experience to date. Within the past decade improvements have been made in pediatric device outcomes, and currently this is leading to growing interest in long- and short-term continuous-flow pumps like the CentriMag, HeartMate II, or HeartWare. The Levitronix CentriMag® and PediVAS® systems are continuous-flow devices that can be used for left, right, and biventricular support in adults and children. The device is generally used for short- to intermediate-term support as a bridge to decision or bridge to bridge with the exchange to a longer-term ventricular assist device. The HeartMate II is a continuous-flow left ventricular assist device that has gained widespread acceptance due to its small size and ease of implantation. The HeartWare is one of the newest mechanical circulatory support systems with the purported advantages of being smaller than previous left ventricular assist devices. With a pump weight

Introduction

A ventricular assist device (VAD) is a pump that is attached between the heart and the aorta or pulmonary artery and helps to circulate a patient's blood when the heart can no longer adequately support the circulation. The aim of such a device is to unload the heart and to provide peripheral circulation sufficient to ensure adequate functioning of the organs. By reducing cardiac work and oxygen consumption, the device liberates the energy required for repair processes, and synchronized heart performance can thus lead to recovery of the myocardium, or it can increase the chances of the patient undergoing heart transplantation [1, 2]. In the adult age group, clear therapeutic strategies in the treatment of heart failure have become increasingly established and include mechanical circulatory life support at the end of the cascade of possible treatment modalities, which continues until recovery of the myocardium occurs or as a bridge to transplantation [3].

Congenital heart disease (CHD) is the most frequent birth defect, and many of the children affected have to be operated early in life. When weaning from bypass in these small children fails, non-pulsatile devices such as centrifugal pumps and extracorporeal membrane oxygenation (ECMO) can be used for very limited periods of time [4–6]. Especially in infants with cardiomyopathy or fulminant myocarditis awaiting recovery or heart transplantation, these systems do not always offer enough time to save the child's life. Therefore, mechanical circulatory support (MCS) with ventricular assist devices (VADs) has evolved in the pediatric population as an accepted modality for the failing heart refractory to maximal medical and surgical management [7–9].

Within the past decade improvements have been made in pediatric devices, and currently this is leading to growing interest in long-term pediatric VAD support. Funding for development of pediatric assist devices by the NHLBI has resulted in the pumpKIN trial, which awarded contracts over $23 million dollars for development of such devices. Now, in an extension of the original funding period, several of these devices are close to clinical trial (pumpKIN, 2004). European developmental improvements are axial-flow pumps that can be totally implanted in young school-age children. Currently, the most frequently used ventricular assist device in children is the Berlin Heart EXCOR (Berlin Heart AG, Berlin, Germany).

Brief History of VAD Application in Children

Centrifugal pumps and extracorporeal circuits have been applied in infants and children since the development of a pediatric centrifugal pump head by Medtronic Bio-Medicus (Eden Prairie, MN, USA) in the late 1980s. The Thoratec ventricular assist devices (Thoratec Laboratories Corporation, Pleasanton, CA, USA) have been available since the early 1980s for adult use,

Supported by DFG: STI 613/1-1

but they can also be implanted in older children and adolescents. Several adult-size VADs, such as the Novacor, have been applied in adolescents, and the MicroMed DeBakey axial-flow VAD has been modified to form a "child" version which has been implanted in a small number of children. The first pneumatically driven extracorporeal assist device designed specifically for infants and small children, the Berlin Heart EXCOR VAD, was introduced into clinical routine in 1992. The development of such miniaturized pump systems followed the first reported case of an 8-year-old boy with end-stage heart failure being supported with an adult-size VAD until later transplantation at the Berlin Heart Center [10]. The Berlin Heart was approved for use in children in the United States in November of 2011.

Different Ventricular Assist Devices

Table 151.1 shows the comparison of different MCS systems (ECMO; centrifugal; VAD, pneumatic pulsatile VAD; axial-flow pump) in terms of feasibility and efficiency in children.

Centrifugal Pumps

Centrifugal pumps are available to support children of all ages with postoperative cardiac failure and competent lung function. Originally these devices have been mostly applied for temporary assistance of stunned myocardium of the left ventricle. While early versions of centrifugal pumps were associated with hemolysis when used at low flow rates in small children, technological advancements have diminished this complication, and they have been successfully used for weeks to months in small children. These new short-term VADs are based on vortex technology and seem to generate less hemolysis than older versions. While the usual operating rotations per minute (rpm) are usually within 1,000–3,000 for small infants in whom flow may be less than 1 l, they can operate at much higher rates as well, up to 10,000–20,000 rpm, and easily create a flow of up to 5–6 l/min. Being designed for isolated left or right ventricular support, biventricular support is possible with two pumps connected in series.

Advantages of this system are as follows: no need of an oxygenator, low priming volume,

Table 151.1 Comparison of different MCS systems (ECMO; centrifugal; VAD, pneumatic pulsatile; VAD, axial-flow pump) in terms of feasibility and efficiency in children with heart disease

	ECMO	Centrifugal pump	Pulsatile VAD Berlin Heart	Axial-flow pump
Patients size Newborn/toddler/school-age	Yes/yes/yes	Yes/yes/yes	Yes/yes/yes	No/no/yes School-age only!
Membrane oxygenator	Yes	No	No	No
Peripheral cannulation in the ICU	Yes	No	No	No
Thoracotomy necessary	No/optional	Yes	Yes	Yes
Support time	1–2 weeks	1–3 weeks	Some months	Some months
Support of	The heart and lung	Right or left ventricle	Right and/or left ventricle	Left ventricle
Anticoagulation	Extensive	Less than ECMO	Lesser than ECMO	Less than ECMO
Complications	Moderate	Few	Few	Experience lacking
Transport under ongoing support to a transplant center	Yes	Yes	Yes	Yes
Mobility of the child	Maybe	Maybe	Moderate	Best mobility
Discharge from ICU under ongoing support	No	No	Yes	Yes

adequate left ventricular (LV) decompression, low-heparin requirements, little hemolysis, ease of transport, and lower costs than longer-term devices. Available products from Maquet, Sorin, Thoratec, and others exist on the market, although pricing between pump systems and associated disposable elements varies considerably.

In case of impaired pulmonary function and the need for ECMO, these centrifugal pumps can serve as driving units for ECMO if an oxygenator is added to the system.

Duncan et al. reported 29 pediatric patients supported with an early-generation VAD. In the patients with anomalous left coronary artery from the pulmonary artery (ALCAPA) or cardiomyopathy, the survival rate was 71 %. In those who underwent heart transplantation after support, survival was 50 % with fewer instances of neurological complications and blood trauma than in the ECMO group reported in the same paper [11, 12].

Thuys et al. reported on the Melbourne experience of 34 children with congenital heart defects and weighing 6 kg or less who were supported with a centrifugal pump. This team was able to wean 64 % of the patients from the VAD, and overall survival to discharge was 31 % [13].

Levitronix PediVAS (Thoratec Corporation, Pleasanton, CA, USA)

The Levitronix CentriMag® and PediVAS® systems are continuous-flow devices that can be used for left, right, and biventricular support in adults and children [12, 14] (Fig. 151.1). This device is a bearingless magnetically levitated centrifugal pump. There are two magnetic forces in play: a passive magnetic force raises the impeller so that there is no direct contact with a bearing, and an active magnetic force created by an electrical current in the motor spins the impeller, resulting in forward flow of blood. The blood enters the pump from the 3/8 in. inlet on the top of the pump and is propelled by the impeller, creating a circular motion with centrifugal force so that blood exits the pump from the outer wall of the pump head. A low priming volume of 33 mL is required. The PediVAS® is a smaller version of the original CentriMag which can provide flows as low as 0.4 L/min up to 1.7 L/min and requires only a 14 mL priming volume. It also accommodates a 1.4-in. tubing in the circuit. The device is generally used for short- to intermediate-term support as a bridge to decision or as a bridge to a longer-term device if transplantation is sought. Furthermore, the Levitronix can function as a complete ECMO system by addition of an oxygenator to the circuit. The small footprint of this device makes it amenable for patient transport, and it can be used in a wide variety of patient sizes. The small priming volume and efficiency of the device have made it a popular choice, but the high cost of the disposable pump head and circuit limits its selection in some programs.

Fig. 151.1 A 2-year-old child with the Levitronix PediVAS system for left ventricular support

Deltastream DP3 (Medos Medizintechnik AG, Stolberg, Germany)

This device is a rotational pump with a diagonally streamed impeller. It has a low priming volume of only 16 mL and can be used for children of all ages, with optional pulsatile operating modes that can produce pulsatility between 40 and 90 bpm (flow 0–8 L/min, speed 100–10,000 rpm, weight 38 g). It is not available in the USA.

Pulsatile Devices

There are two pulsatile systems having proved successful support in children of all ages, from the newborn to the adolescent. These are the most

frequently used Berlin Heart EXCOR (Berlin Heart AG, Berlin, Germany) and the rarely used Medos HIA (Medos Medizintechnik AG, Stolberg, Germany).

Both devices have extracorporeal chambers which are housed outside the body, and flow is provided by a pneumatic pulsatile compressor-operated diaphragm pump with valves which pumps inflow blood to the body based on filling time and rate of compression. Both devices have a transparent polyurethane pump housing that allows early thrombus detection and fast and safe pump changes if required. For the Medos HIA only a small series of children have been reported.

Fig. 151.2 Neonate on the 10 mL Berlin Heart EXCOR device, currently the smallest long-term pump suitable for this age group

Berlin Heart EXCOR®

This extracorporeal VAD is mounted with trileaflet polyurethane valves and is available in pump sizes which deliver 10, 25, 30, 50, 60, and 80 mL of ejection. The smallest pumps are suitable for neonates and infants with body weight of up to 8 kg and the 25 and 30 mL pumps for children up to 20–25 kg (Fig. 151.2).

Special long-term silicone cannulas connect the blood pumps to the body. For left heart support (LVAD), cannulation is preferred in the apex of the left ventricle, because this provides better ventricular unloading compared to the alternative left atrial cannulation site. Aortic cannulation with the special Berlin Heart end-to-side cannula allows additional blood flow from the recovering ventricle to provide additional cardiac output. In some patients, ventricular recovery and weaning allow removal of the device without need for cardiac transplant.

For right heart support (RVAD), the cannulas are anastomosed to the right atrium or the right ventricular apex (depending on the size and trabecularization of the myocardium) and to the pulmonary artery.

Cannulas are designed to exit the body through the upper abdominal wall. A Dacron velvet cover in the middle portion of the cannula promotes rapid in growth of tissue as a biological barrier against ascending infections.

The pumps are driven by a pulsatile pneumatic system, and all blood-contacting surfaces are heparin-coated (Carmeda®, Upplands Väsby, Sweden), providing early protection against thrombosis. The inhospital driving unit (Ikus, Berlin Heart, Germany) operates pumps of any size in either univentricular or biventricular configuration. For larger pumps (>50 mL) a mobile system allows the children a higher mobility.

The Berlin Heart EXCOR enables prolonged circulatory support; offers time to restore renal, hepatic, and gastrointestinal organ function; allows extubation, mobilization, and neurological examination; and increases the chances for transplantation. Compared to ECMO, use of the Berlin Heart in children results in less blood loss and lower consumption of red blood cells, platelets, and fresh frozen plasma [15, 16].

Table 151.2 shows the worldwide results with the Berlin Heart. Despite its acceptance, the recently completed Berlin Heart trial in the USA noted that 78 % of patients required at least 1 pump change due to thrombus, and stroke occurred in 29 % of patients. Despite much investigation into the "best" anticoagulation regimen during long-term use, thrombotic problems continue to be a major source of concern.

Continuous-Flow Pumps

HeartMate II

The HeartMate II (HM II) is a continuous-axial-flow pump which is used as an LVAD only. Because of its small size, it can be used in patients

Table 151.2 Results with the Berlin Heart (until November 30, 2011) (Data provided from the Company Berlin Heart, Berlin, Germany)

1,009 pediatric patients	Number of pediatric patients (worldwide) N = 1,009
Sex (male/female)	519 male/475 female/15 missing data
Age at implantation (mean and range)	4.9 years (2 days to 17 years)
Body weight (mean and range)	18.5 kg (2.2 kg to 93.6 kg)
Support time (mean and range)	78.6 days (0 days to 902 days)
Diagnosis (patients) Myocarditis	950 patients (59 missing data)
	124
Cardiomyopathy	557
End-stage congenital heart defect	222
Post-CPB, weaning failed	45
Outcome (patients (percentage)) Weaned	12.3 %
Heart transplantation	71.2 %
Died on VAD	6.1 %
	10.4 % currently on device
Survival until transplant or discharge	**83.5 %**

> 30 kg body weight. The inflow cannula is placed in the left ventricle, and the outflow cannula is situated in the ascending aorta. The pump is located distal to the heart in an intra-corporeal position and is connected through a driveline with the controller and two batteries, which are located outside the body. Initial clinical results from the pivotal adult HeartMate II multicenter clinical trial for bridge to transplant (conducted from 2005 to 2008) noted survival rates of 75 % at 6 months and 68 % at 1 year [17]. These results led to approval from the US Food and Drug Administration (FDA) of the HM II LVAD for bridge to transplantation (BTT). A post-approval study was required by the US Food and Drug Administration to determine whether results with the device in a commercial setting are comparable to other available devices for the same indication. Adverse event rates were similar or lower for HM II versus the comparison group for all events. Bleeding was the most frequent adverse event for both groups (1.44 vs. 1.79 events/patient-year). Operative 30-day mortality for HM II was 4 % versus 11 % for the controls. The percentage of patients reaching transplant, cardiac recovery, or ongoing LVAD support by 6 months was 91 % for HM II and 80 % for the comparison group [18].

HeartWare

The HeartWare (HeartWare Inc, Miami Lakes, FL) is one of the newest devices with the purported advantages of being smaller and more durable than previous LVADs. The pump (weight of only 140 g) is implanted in the left ventricle and connected to the ascending aorta. It is a centrifugal continuous-flow pump with a hybrid magnetic bearing. It is implanted within the pericardial space and connected to the external power and control panel via the driveline that is externalized through the abdominal wall [19]. Recently, centers have also reported the use of the HeartWare device as a biventricular assist device in adults [20]. The group from Berlin reported their experience with this new continuous-flow, ventricular assist system in the pediatric population. 7 children (aged 6–16 years) received it as a bridge to cardiac transplantation. 6 patients were successfully bridged to transplantation, and 1 remained on support at the time of this writing. Median support time was 75 days. None of the patients suffered a clinically evident thromboembolic event or an infection [21].

Decision Making

In Cardiomyopathy

Children in whom all intensive pharmacological treatment fails and return of adequate cardiac function is deemed unlikely should be supported with a long-term assist device, since heart transplantation is the primary goal. The waiting time to heart transplantation is unpredictable and

varies by size of the patient and demographics, and many children die while on the waiting list. Although infrequent (<10 %), myocardial recovery may occur which allows explantation of the device without need for cardiac transplant [22].

In Fulminant Myocarditis

Children with acute viral myocarditis are the most promising group for successful recovery of cardiac function. These patients were healthy until the onset of fulminant myocarditis, and prolonged circulatory support with a pulsatile pneumatic device is an effective method for bridging until cardiac recovery. Early decompensation of such patients often results in emergent extracorporeal support with ECMO, which has also been associated with 70 % survival, with cardiac recovery occurring after multiple days to weeks. In patients for whom cardiac support is not emergent, then use of VAD may be preferred, as these devices may allow longer-term support to ventricular recovery or transplantation if needed [23]. Duncan et al. reported ECMO or centrifugal pump treatment of 15 children with fulminant myocarditis [6]. They achieved excellent results with 80 % survival, but survival without transplantation was only 47 %. In this study the median support time was only 6 days, and 5 children underwent early heart transplantation.

After Cardiac Surgery

Despite improvements in surgical techniques and in the management of cardiopulmonary bypass and myocardial protection, myocardial dysfunction can occur after operation for complex congenital heart disease, resulting in left and/or right ventricular failure. Approximately 2–3 % of children undergoing open heart surgery need mechanical circulatory assistance. After cardiac surgery, the decision in favor of mechanical support should be made early in the process. While exact criteria for need for mechanical support do not exist, poor hemodynamic profile combined with metabolic acidosis, oliguria, rising lactate level or failure to clear lactate over time, or poor perfusion despite high-dose inotrope treatment are often noted in the pre-support period. Failure to wean from cardiopulmonary bypass is also an indication for mechanical support if a reversible cause of cardiac failure is expected. While all efforts to rule out any residual cardiac defects which may be amenable to operative or interventional cardiology repair should be taken, there are times when placing the patient on mechanical support to allow stabilization prior to cardiac catheterization or a return to the OR is appropriate. A period of time between cardiopulmonary bypass to allow hemostasis to develop is preferred. If full recovery within 2 weeks can be expected and the patient's lung function is not compromised, a centrifugal pump circuit without an oxygenator may be the best choice. Alternatively, in cases of concomitant respiratory failure, ECMO should be considered. For cases in which ventricular recovery is thought to be unlikely, then bridging to decision for transplant with a longer-term VAD may be the best option [2, 4, 24].

In Chronic Stages of Congenital Heart Disease

Children in chronic stages of congenital heart disease may develop ventricular failure within some years after cardiac surgery and be listed for transplantation when all other surgical and medical options have been exhausted. As in children with cardiomyopathy, pneumatic pulsatile devices for long-term support should be implanted when transplantation is the only realistic goal. Since children in this group have complex anatomic disorders and have often had several previous operations, surgical placement of the cannulas may be more demanding than in the cardiomyopathy group [22].

Unsolved Problems

Patient Selection Remains a Major Factor Influencing Outcome and Survival

Implantation under ongoing long-term resuscitation with unclear cerebral outcome is a difficult ethical problem. Every attempt to assess neurologic function should be taken. While placement of patients in cardiac arrest on extracorporeal support makes neurologic assessment at the time of arrest often impossible, serial monitoring of neurologic status by eliminating sedation to allow spontaneous awakening and use of near-infrared spectroscopy, electroencephalograph, computed tomography, cerebral ultrasound, or transcranial Doppler assessment may be helpful. Evidence of significant neurologic injury should preclude the child from transplantation, and withdrawal of mechanical support should be implemented following discussion with the family.

Infrastructure of a VAD Center

Pediatric mechanical cardiac support with longer-term devices can only be successful in a well-structured VAD center with excellent communication and teamwork. There is need for an advanced surgical infrastructure including a well-equipped neonatal and pediatric intensive care unit, a cardiothoracic surgery department with comprehensive experience and the personnel and technical equipment necessary to treat congenital heart disease of all ages, a highly experienced pump technician team with shifts 24 h/7 days per week, and a laboratory permanently available to monitor sophisticated coagulation status. If a center does not meet these requirements, the preferred approach should be the use of emergency ECMO to transport the child to a VAD and transplant center unless myocardial recovery occurs within a short time.

Decision Making: Implantation of BVAD or LVAD Only

How to decide whether to implant a biventricular assist device (BVAD) or just an LVAD remains challenging. Having only one external device (LVAD) is not only favorable from the financial aspect of view, but it improves the chance for survival and reduces the complication rate [15]. Within the last years the majority of the VAD centers were able to reduce the BVAD frequency in favor of only LVAD support, as improved understanding and medical management of right ventricular compromise occurred.

Implantation strategy may be optimized by stabilizing a resuscitated or critically circulatory depressed child by going on cardiopulmonary bypass first or using ECMO. Once hemodynamics are optimized, evaluation of cardiac function may determine if the patient is best served by a LVAD, RVAD, or BIVAD device. Excellent unloading of the LV is the precondition for good circulatory success with single LVAD, as a high left end-diastolic pressure (LVEDP) will result in elevated left atrial pressures (LAPs) and thus increase the afterload with which the right ventricle has to function as well. Often, following successful LVAD implantation and unloading of the LV, rapid improvement in presumed right ventricular failure occurs as the afterload on the right side decreases.

As patients are being assessed for response to device implantation (or even before), transesophageal echo may be useful to monitor any atrial and/or ventricular septum shift and RV improvement. It is of utmost importance that in the first hours of implantation, the LVAD does not "over-pump" the circulation. There is no need for a very high cardiac index in this early phase, as long as there is no metabolic acidosis, no lactate, and no proof for sufficient end-organ perfusion. The central venous pressure should be maintained in the low to normal range; to improve limited RV function and medical right heart support with diuretics, milrinone, catecholamines, nitric oxide, Ilomedin, and/or sildenafil may also be needed. Systemic blood pressure

support is supplied by the LVAD output. If pharmacological right heart support, and optimization of gas exchange, combined with LV unloading from the LVAD device, does not result in adequate RV function within several hours, then addition of RVAD support may be required. Such decisions are often made only after prolonged periods of observation and assessment in the operating room [15].

Special Aspects with VAD in the Univentricular Heart: The Pulmonary Vascular Resistance (PVR) Makes the Difference

Mechanical circulatory support in the univentricular heart with modified Glenn anastomosis or total cavopulmonary connection (TCPC) was for many years only limited to ECMO. Rare case reports describe that with improved devices and ICU experience, actually univentricular hearts and TCPCs are one of the actual challenges for LVAD or BVAD [25].

To be successful in these cases caregivers should exactly be aware of the hemodynamic situation. Careful measurement of pressures within the cardiopulmonary circuits in the catheterization laboratory is essential. A single LVAD might be successful in the case of severe isolated myocardial failure with high left ventricular end-diastolic pressure (LVEDP) and very low transpulmonary gradient. In case of "pre-pulmonary-failure," where there is good myocardial function and a low LVEDP, but a high transpulmonary gradient and high pressure in the systemic veins are noted, the LVAD will bring no benefit to the patient. In this case, need for takedown of the total cavopulmonary connection, combined with cannulation of the newly created right atrium (or conduit) and the pulmonary artery, may be considered. Many failing Fontan patients present with a mixture of both cardiac and pulmonary pathology and may require a BVAD following Fontan takedown. Bridging to heart transplant in such patients should be considered.

As more patients with Fontan physiology are reaching older ages and cardiopulmonary function may deteriorate, the need for assist devices may continue to grow. Implantation of devices in these patients, who have received multiple sternotomies and cardiac operations, is often difficult and fraught with excessive bleeding. Occluded vessels may also present cannulation difficulties. Another problem in patients with univentricular heart is the selection of the pump size to be implanted. Because of collateral vessels and shunting, there is often a need for an oversized pump to maintain adequate cardiac support. Slower pump rates to allow adequate filling of the chamber may predispose the patient to thrombi from stasis within the device. Use of a device with a small pump chamber may result in hemolysis from elevated shear forces as the pump is required to work at a high rate of speed to maintain adequate circulatory support. TCPCs following hypoplastic left heart syndrome repair often have abnormal patch material in the aorta or other aortic vascular pathology which makes aortic cannulation difficult. The systemic RV in these patients may be trabecularized, making apical cannulation for the device difficult as well.

Patients with protein losing enteropathy or ascites may have resolution of these complications following successful heart transplantation, but care of such patients on VAD devices may be more complicated than in other groups. Patients with additional organ dysfunction such as renal or hepatic failure should be assessed carefully as to whether they are appropriate for VAD support as a bridge to transplantation as their outcomes may be poor.

ICU Management After BVAD or LVAD Implantation

When a BVAD has been implanted, usually *no inotropic medication* is needed. Changes in blood pressure are performed by the pump. There must be a harmonic and complete filling and emptying to guarantee the full stroke volume of the pump. Blood pressure can be manipulated mainly by the

change of pump parameters (interval of systole or diastole, pump rate) or by increasing or decreasing the preload with fluid loading (to increase volume, if there is no complete filling of the device chamber) or fluid removal by diuretics (if there is not complete emptying of the pump). Direct visual monitoring of the membrane in the device gives immediate information of the volume status of the child. In rare cases, such as with septic shock, loss of peripheral vasomotor tone may require vasoconstrictors such as norepinephrine or vasopressin. For the intensivist caring for the patient after LVAD implantation, the need for intricate care to prevent or help reverse right ventricular failure makes management often difficult. The weaning from cardiopulmonary bypass after surgical implantation of the LVAD device is to be performed with caution to prevent right heart failure. Prophylactic IV medical support with phosphodiesterase inhibitors (milrinone), diuretics, low-dose catecholamines, inhaled nitric oxide (NO), iloprost or other medications, and mild hyperventilation/alkalosis to reduce pulmonary vascular resistance may be advantageous. Adequate hemoglobin to optimize oxygen carrying capacity while preventing sludging from increased viscosity of blood is also important. Patients should be able to wean from mechanical ventilation within a few days (or less) of LVAD support. If right ventricular dysfunction prevents extubation, then need for a right heart device should be considered [15].

Anticoagulation Protocols

Anticoagulation for VAD

Bleeding and thromboembolic events continue to be a devastating complication during short-term or long-term, pulsatile or non-pulsatile VAD support. Varying anticoagulation protocols across centers and lack of reporting to multicenter registries also make it difficult to characterize the true incidence of thromboembolic or hemorrhagic events. The majority of anticoagulation protocols were developed for the adult population, without consideration for the differences in the coagulation system that occur in infants and children, in whom maturation may have significant effects. The so-called Edmonton Anticoagulation Protocol (Table 151.3) is the primary pediatric protocol which is currently followed. Preexisting coagulation abnormalities, renal failure, liver dysfunction, or sepsis will increase the risk for thromboembolic and or hemorrhagic complication during VAD support. In addition to serial monitoring of the patients' anticoagulation profile, it is also necessary to perform strict monitoring of the pump performance [26–28]. The most common anticoagulation drugs which are used in pediatric VAD patients are unfractionated (UNF) heparin, low molecular weight (LMW) heparin, warfarin, aspirin, and dipyridamole.

Table 151.3 Edmonton anticoagulation protocol Berlin Heart

Unfractionated heparin (UFH) dosing at 24–48 h post-VAD surgery			
	≤12 months	≥12 months	
Initial dose*	15 IU/kg/h	10 IU/kg/h	
After 6 h*	28 IU/kg/h	20 IU/kg/h	
Low molecular weight heparin (LMWH) at 48 h post-VAD surgery			
	≤3 months	≥3 months	>1 year
LMWH dosing	1.8 mg/kg s	1.5 mg/kg s	1.3 mg/kg s
Antiplatelet therapy post-VAD surgery			
	Acetylsalicylic acid	Dipyridamole	
	>48 h	>4 days	
Starting dose	1 mg/kg/day	4 mg/kg/day	

*We Start with 15/resp 10 IU/kg/h 24 h after surgery and increase the dose after 6 hours later

Anticoagulation in Berlin Heart EXCOR® Pediatric

The Edmonton Anticoagulation and Platelet Inhibition Guidelines for Pediatric VADs© was applied to the North American FDA Berlin Heart EXCOR® Pediatric trial. The guideline suggests to start unfractionated heparin after 24 h. The dose should be age appropriate. If stable in hemostasis and hemodynamics, with normal renal function, the patient may be transitioned from unfractionated heparin to low molecular

weight heparin (Enoxaparin™). In patients older than 12 months of age, oral anticoagulation therapy with a vitamin K antagonist can be initiated (target INR 2.7–3.5). Based on results of TEG® and Platelet Mapping™, acetylsalicylic acid and dipyridamole are started [29].

Anticoagulation for the Levitronix

The guidelines recommend to start unfractionated heparin infusion 6–12 h post-cardiopulmonary bypass. The target is to maintain an active clotting time (ACT) of 160–180 s, a PTT 1.3–1.6 times baseline. An antiplatelet agent can be initiated after 4 days, depending on the hemostatic conditions of the patient and the pump.

The Weaning Procedure: How to Make the Decision

EXCOR Weaning Protocol

Children on a Berlin Heart device who were enrolled in the FDA study and demonstrated signs of ventricular recovery may be weaned according to a standardized weaning protocol. Weaning is an uncommon event; the goal of the weaning protocol is to outline for centers the safest possible and consistent weaning strategy while reducing extraneous variation in practice. The weaning sequence differs according to pump size given that, in theory, the minimally acceptable beat rate (vis-à-vis thrombosis risk) may vary according to pump size [29].

Conclusions and Outlook

Children with advanced heart failure and profound cardiogenic shock who would not otherwise survive can be kept alive using ventricular assist devices and may either completely recover or qualify for heart transplantation. This has to be considered before irreversible end-organ damage occurs.

Ventricular assist devices, especially the Berlin Heart EXCOR, have demonstrated their efficiency, reliability, and superiority in small infants, who were previously only able to be supported with ECMO. The advantages of long-term mechanical circulatory assistance – less anticoagulation, extubation, enteral nutrition, and full mobilization of the patient – combined with low complication rates and good survival rates should make these VAD systems an appropriate treatment of choice for young infants with myocardial dysfunction. All mechanical circulatory assist systems are associated with a wide range of possible complications, of which bleeding and thromboembolic complications are the most frequent and most serious. Infections, hemolysis, pulmonary edema, and multi-organ failure have also been reported. The choice of pulsatile VAD systems, instead of ECMO, seems to significantly lessen the complication rate if the expected duration of circulatory assistance is likely to exceed 1–2 weeks.

Challenges for the future remain the clinical application of implantable intra-corporeal devices which are appropriate for even smaller infants. Optimizing or even avoiding anticoagulation while preventing thrombotic or bleeding complication would be major advance in the field. Finally, following the economic impact of these expensive devices and the short- and long-term quality of life obtained by their use is needed to insure adequate health-care resource use.

Drugs and ECMO

152

Julia Stegger, Anne Susen, Christoph Haun, and Hans-Joerg Hertfelder

Abstract

Pharmacokinetics of drugs administered during extracorporeal membrane oxygenation therapy are complicated by many factors. The volume of distribution is larger due to addition of the ECMO circuit, and drug elimination is modified in most patients. Moreover, the circuit components may alter the pharmacokinetics due to drug adsorption, sequestration, and inactivation of [1]. Very few agents have been thoroughly investigated in neonatal and pediatric patients on extracorporeal membrane oxygenation. Reports are generally limited to case studies and small pharmacokinetic trials. In this chapter, the ways in which extracorporeal membrane oxygenation may affect the pharmacokinetics of drugs are reviewed, and specific drugs that are important for the treatment of pediatric cardiac patients are outlined.

Introduction

Critically ill cardiac patients require the administration of multiple drugs to support their circulation, sedation and analgesia, multiorgan function, and eventual complications (i.e., sepsis), even prior to the initiation of extracorporeal membrane oxygenation (ECMO). One of the main objectives of ECMO is to reduce pharmacologic support and minimize the often deleterious effects of these drugs. Nevertheless, even with ECMO support, several drug categories are needed, including anticoagulants, analgesics, sedatives, and antibiotics. Additional drugs are required in patients with pulmonary hypertension, arrhythmias, and severe bacterial or viral infections or in patients with bleeding complications.

There are currently no standardized recommendations for drug dosing in pediatric patients on ECMO. As such, drug dosing is based on personal experience, data from case reports or small studies, or simply dose titration of drugs in individual patients. In the following section, the potential pharmacokinetic effects of critical illness in combination with ECMO are reviewed. Drugs that are important in the treatment of cardiac patients supported with ECMO are discussed.

Overview and Definitions

Pharmacokinetics are influenced by the volume of distribution and clearance [43]. The *volume of distribution* is clinically used to determine the loading dose needed to achieve a desired blood concentration of a drug. It is defined as the volume of plasma that would be needed to account for the total amount of drug in the body if that drug was present throughout the body with the same concentration as found in the plasma. This value is usually divided by the patient's weight and expressed in liters/kg. For example, the volume of distribution of cefotaxime is 0.3 L/kg and of fentanyl is 4 L/kg [44].

The *clearance* is clinically used to determine the maintenance dose of a drug. It is defined as the volume of blood cleared of drug per unit time, either by excretion or by metabolism [43]. The effectiveness of clearance depends on the amount of drug presented to organs, which in turn depends on the blood flow to these organs, and the volume of distribution of the drug. It is usually expressed mL/min/kg or as L/h. For example, the clearance of midazolam is 9.3 mL/min/kg and the clearance of fentanyl is 27–75 L/h [46].

Both of these pharmacokinetic parameters, volume of distribution and clearance, determine the *half-life* of a drug. If volume of distribution is increased and/or clearance is decreased, the half-life of a drug increases [43].

In ECMO patients, unique properties of the system affect drug volume of distribution and the clearance. These factors include the octanol-water partition coefficient of the drug as a measure of lipo-/hydrophilicity, the absorption to surfaces of extracorporeal components, the altered flow pattern during ECMO (continuous vs. pulsatile), the extracorporeal circuit volume, and the critical illness of the patient:

1. The octanol-water partition coefficient is the ratio of concentrations of a drug in the two-phase system of 1-octanol and water. It is a measure for relative lipophilicity (high concentration in octanol) and hydrophilicity (high concentration in water). It allows estimation of drug distribution among various compartments in the body. This is also of importance when determining the amount of drug lost to the ECMO circuit [4]. Drugs with a high octanol-water partition coefficient such as midazolam (log P 3.9) and fentanyl (log P 4.1) [46] are highly soluble in organic materials such as plasticizers and can exhibit considerable sequestration in an ECMO circuit [6]. Conversely, drugs with a low octanol-water partition coefficient such as antibiotics (e.g., cefotaxime log P 0.14, vancomycin log P 1.1) [46] show much lower loss [45].
2. Specific chemical compounds used in the pump, tubing, and oxygenator may lead to drug loss due to inactivation, adsorption, or sequestration [1]. An in vitro study conducted by Wildschut et al. examined drug recovery (i.e., the proportion of drug still present in the fluid inside an ECMO circuit without patient)

of midazolam and fentanyl in silicone membrane roller pump circuits. This study showed nearly complete loss of these drugs to the circuit. In contrast, drug recovery was significantly higher in centrifugal pump circuits with a hollow-fiber membrane oxygenator (midazolam 0.62 % vs. 63.4 %, fentanyl 0.35 % vs. 33.8 % after 180 min) [45]. Preston and coworkers examined the amount of drug loss caused by the oxygenator. The authors compared the polypropylene Jostra Quadrox D (Maquet Cardiopulmonary, AB Hirrlingen, Germany) to the Terumo Baby Rx (Terumo Cardiovascular Systems Corp., Ann Arbor, MI) membrane oxygenator. Although the surface of the oxygenators is quite large (e.g., 1.8 m^2), most of the drug loss occurred in the uncoated tubing, not in the oxygenator. There was also a difference between morphine and fentanyl drug loss. Morphine loss was not influenced by the oxygenator, whereas fentanyl loss was significantly affected, probably due to the lipophilicity of fentanyl [53].

The volume of distribution and drug loss to the circuit can change over time as binding sites become saturated. An in vitro study conducted by Dagan et al. measured pre- and post-oxygenator concentrations of several drugs in both new and used circuits. Drug levels fell to a much smaller extent in used circuits compared to new circuits for multiple drugs including vancomycin (11 % vs. 36 %), gentamicin (0 % vs. 10 %), phenobarbital (6 % vs. 17 %), phenytoin (0 % vs. 43 %), and morphine (16 % vs. 36 %). The surface coating of the tubing may be a factor in the sequestration of drugs. A study conducted by Preston et al. has shown that newer surface-coated tubings sequester as much as 30–40 % of fentanyl and 35–58 % of morphine. Site of drug administration may also be of considerable importance because inactivation, absorption, and sequestration of drugs in the circuit can significantly alter the pharmacokinetics of drugs. Highly absorbable lipophilic drugs like fentanyl should be given directly to the patient, whereas more hydrophilic drugs like morphine can be administered to the circuit. The use of venous reservoirs may also affect drug pharmacokinetics. Hoie and coworkers examined the impact of the site of injection (pre- vs. post-reservoir) and blood flow rates [51]. The authors found that was incomplete mixing if the drug was administered pre-reservoir, or into the reservoir at slower blood flow rates (<250 L/min).

3. In critically ill patients, the volume of distribution is usually increased due to an expansion of the extracellular fluid volume and total body water. Accompanying multiorgan failure may alter the blood flow to important organs like liver, kidneys, lung, and brain. This may result in a reduced drug metabolism. Drug clearance may be significantly reduced, resulting in an increased half-life. Conversely, if renal function is augmented by improved hemodynamics, the clearance of drugs can be temporary elevated during critical illness [43]. If the underlying critical illness is treated and oxygen delivery improves, organ function should improve during ECMO. These factors can lead to significant intra-patient differences in volume of distribution and clearance from one day to the next [50].
4. The choice of type of ECMO support and consequently the flow pattern can significantly affect drug pharmacokinetics. Venoarterial ECMO provides a continuous blood flow pattern. Arterial flow may be non-pulsatile, particularly when the patient is on full flow ECMO support (e.g., 200 mL/kg/min). There is ongoing discussion about the potential effects that this lack of pulsatility might have organ perfusion [48, 49] and therefore alter drug clearance. Additionally, pulmonary blood flow is significantly reduced during venoarterial ECMO, leading to altered elimination of drugs that are metabolized by the lungs [47]. In venovenous ECMO, recirculation can reduce the clearance of drugs as there is an incomplete distribution of drugs to the body [17]. Many patients require hemofiltration to support renal function and improve fluid balance. In these patients, drug clearance can be influenced by blood flow rate, ultrafiltration rate, membrane, and pore size [44].

Table 152.1 Drugs and ECMO: pharmacokinetics, recommendations

Drug	Altered pharmacokinetics	Usual dosage (Frank Shann, drug doses, 15th edition [76])	Dosing recommendation during ECMO	Literature
Anticoagulation and coagulation				
Heparin	Adsorption by circuit or by blood components in circuit	LD 75 µg/kg IV	LD cannulation, 50–100 µg/kg	[1, 2, 14]
		MD 20–40 µg/kg/h IV (<12 months), 20–30 µg/kg/h IV (child)	MD, 25–35 µg/kg/h	
			Monitoring of coagulation values necessary	
Argatroban	*U*nknown	2 µg/kg/min IV, monitoring of APTT	Case report (2 neonates): 0.5–10 µg/kg/min was effective	[15, 18, 31, 32]
			Study (9 adults): 0.15–0.2 µg/kg/min was effective. Usual dosage of 2 µg/kg/min resulted in excessive bleeding	
			Case report (1 adult): 0.35 µg/kg/min starting dose, continuous infusion 0.25–1.6 µg/kg/min	
			Case report (1 child): 2 µg/kg/min starting dose, continuous infusion 1–2 µg/kg/min	
Aminocaproic acid	Unknown	LD, 3 g/m^2 over 1 h IV; MD, 1 g/m^2/h	Retrospective study (25 neonates): bolus 100 mg/kg, 30 mg/kg/h for 5 days, risk for clot formation in circuit not increased	[25, 26]
			Retrospective study (298 patients, 60 % neonates): bolus 100 mg/kg, infusion 30 mg/kg/h for 72 h reduced surgical site bleeding	
Tranexamic acid	Unknown	LD, 10–15 mg/kg 8 H IV; MD 10 mg/kg/h IV; surgery for congenital heart disease 100 mg/kg load, then 10 mg/kg/h	Study [10 neonates, CHD]: 4 mg/kg bolus 30 min before surgery on ECMO, 1 mg/kg/h for 24 h after surgery	[24]
Antithrombin	Unknown	LD, 50 µg/kg/h for 3 h IV; MD, 6 µg/kg/h IV monitoring of antithrombin activity after 6 h, then 8–12 h	*Bolus*: *100* [*target value*] − [*AT value on lab test*] × *body weight* [*kg*]	[27]
			Study [*6 pediatric patients*]: *no bolus*, *target antithrombin concentration* > *100 % with continuous antithrombin infusion in 4 h*	

(*continued*)

Table 152.1 (continued)

Drug	Altered pharmacokinetics	Usual dosage (Frank Shann, drug doses, 15th edition [76])	Dosing recommendation during ECMO	Literature
Novo7 (rVIIa)	Unknown	LD, 90 µg/kg 2 H IV until bleeding stops	Study [6 pediatric patients]: median dose 94 µg/kg, median dosing interval 2 h, mean of 2.6 administrations/patient was successful	[20–23]
			Study [7 pediatric patients]: 90 µg/kg, up to 4 administrations/patient, no effect	
			Study [4 pediatric patients]: first dose 90–120 µg/kg, second identical dose 4 h later, good effect	
			WARNING: no co-administration of PPSB (enriched human plasma fraction) since risk of fatal thrombosis; caution with spontaneous ventricular contrast on ECMO	
Bivalirudin	Unknown	LD, 0.75–1 mg/kg stat IV, then 1.75–2.5 mg/kg/h for 4 h, then stop or give MD	Case report [1 adult]: bolus 0.5 mg/kg, Infusion of 0.5 mg/kg/h was successful	[28–30]
		for 14–20 h	Case report (1 adult): bolus 0.5 mg/kg, initial infusion after bolus 0.5 mg/kg/h, continuous infusion during ECMO 0.05–0.15 mg/kg/h	
			Study (13 patients, pediatric and adult): no bolus, continuous infusion of 0.03–0.05 mg/kg/during ECMO (used bolus of heparin for cannulation)	
Catecholamines				
Epinephrine (adrenaline)	No change	0.05–1 µg/kg/min IV	Ex vivo study: no extraction in the blood-primed circuit, no change necessary	[2]
Norepinephrine (noradrenaline)	Unknown	0.02–0.2 µg/kg/min IV	–	No studies
Dopamine	No change	5–20 µg/kg/min IV	Ex vivo study: no extraction in the blood-primed circuit, no change necessary	[2]

(*continued*)

Table 152.1 (continued)

Drug	Altered pharmacokinetics	Usual dosage (Frank Shann, drug doses, 15th edition [76])	Dosing recommendation during ECMO	Literature
Dobutamine	Unknown	5–20 μg/kg/min IV	–	No studies
Isoproterenol	Unknown	0.05–1 μg/kg/min IV	–	No studies
Vasopressin	Unknown	0.02–0.06 units/kg/h IV	–	No studies
Antihypertensives				
Phentolamine	unknown	5–50 μg/kg/min IV	–	No study
Hydralazine	Unknown	0.1–0.2 mg/kg stat IV, then 4–6 μg/kg/min IV	0.15 mg/kg bolus, repeated	[55, 56]
Nesiritide	Unknown	LD, 2 μg/kg IV; MD 0.005–0.03 μg/kg IV	Case report [2 neonates]: higher infusion dosage necessary, 0.01–0.09 μg/kg/min Case report: 2 neonates, 0.09 μg/kg/min for pressure control, 0.01–0.03 μg/kg/min for diuresis	[5, 8, 64]
Nitroglycerin	Yes	0.5–5 μg/kg/min IV	In vitro CPB: after 60 min only 18 % of initial concentration	[57, 58]
Sodium nitroprusside	Unknown	0.5–4 μg/kg/min IV	0.25–1 μg/kg/min	[59]
Nicardipine	Vd increased	1–3 μg/kg/min	Case report [1 neonate, 1 infant] no change necessary	[5, 9, 10]
Antiarrhythmics				
Amiodarone	Adherence to circuit (lipophilicity)	LD, 5 mg/kg IV; MD, 5–15 μg/kg/min IV	1 case report [newborn]: multiple loading boluses; infusion, up to 20 μg/kg/min	[5, 6]
Esmolol	Unknown	LD, 500 μg/kg IV; MD 25–300 μg/kg/min IV	1 case report [newborn]: LD, 700 μg/kg/min; MD, up to 700 μg/kg/min, 3 adults: dosage ranged between 50 and 80 μg/kg/min	[5, 7, 60]
Metoprolol	Unknown	LD, 0.1 mg/kg, repeat to max 3 doses; MD, 1–5 μg/kg/min	–	No studies
Propafenone	Unknown	LD, 2 mg/kg (over 2 h); MD, 4–8 μg/kg/min	–	No studies
Flecainide	Unknown	0.5 mg/kg 12H IV over 30 min	–	No studies
Sotalol	Unknown	0.5–2 mg/kg IV over 10 min 6 H	–	No studies
Diuretics				
Furosemide	Vd increased, half-life increased	Bolus, 0.5–1 mg/kg 6–24H IV (max 0.05 mg/kg/min IV); IV Infsn, 0.1–1 mg/kg/h	Study [7 neonates]: bolus, 1 mg/kg Infusion, 0.2 mg/kg/h Recommendation [in vitro study]: administration of furosemide directly to the patient	[5, 11, 16]

(*continued*)

Table 152.1 (continued)

Drug	Altered pharmacokinetics	Usual dosage (Frank Shann, drug doses, 15th edition [76])	Dosing recommendation during ECMO	Literature
Ethacrynic acid	Unknown	0.5–1 mg/kg 12–24 H	–	No studies
Aminophylline	Vd increased, CL decreased	LD, 5 mg/kg; MD, 5–15 mg/kg/min 3 mg/kg IV [77]	Study [24 neonates]: bolus of theophylline 2 mg/kg, then furosemide 1 mg/kg increased diuresis	[13, 17]
			Study [75 neonates]: bolus increased [long half-life], maintenance infusion should be decreased [Cl decreased] table with dosing recommendation [17]	
Bumetanide	Vd increased, CL decreased	25 µg/kg daily oral, may increase to 50 µg/kg 8–12H	Study [11 neonates]: bolus 0.1 mg/kg increased diuresis for 3 h	[5, 11]
Antibiotics, *antiviral*, *antifungal*				
Ampicillin	Unknown	15–25 mg/kg 6H IV, severe infection: 50 mg/kg 12H IV (1st week of life), 6H (2–4 weeks), 3–6 H or constant infsn (4+ weeks)	No recommendations	[2]
Gentamicin	Higher Vd, lower clearance, longer half-life	1 week–10 years: LD, 8 mg/kg day 1; MD, 6 mg/kg daily	Study (ex vivo): 4.3 mg/kg interval 18–24 h, TDM	[1, 33–35, 70]
		>10 years: LD, 7 mg/kg day 1; MD, 5 mg/kg daily	Study (10 infants): 2.5 mg/kg, TDM	
			Study (29 neonates): 2.5 mg/kg q 18 h, TDM	
			Study (18 infants): dose rate 25 % lower and longer intervals (see exact dosing recommendation in paper)	
			Recommendation [1]: 2.5–3 mg/kg every 18–24 h, TDM	
Vancomycin	Vd increased, lower clearance	LD, 25 mg/kg IV; MD, 15–20 mg/kg 8 H	Study (12 neonates) MD: 20 mg/kg every 24 h	[1, 67–69]
		Severe infection: LD 30 mg/kg IV, MD 15–20 mg/kg 8 H	Population model (45 patients, neonate to adult): see detailed dosing guidelines in reference [68]	
			Study (6 neonates) MD: 20 mg/kg every 18 h	
			Recommendation [1] MD, 15–20 mg/kg every 18–24 h, TDM	

(*continued*)

Table 152.1 (continued)

Drug	Altered pharmacokinetics	Usual dosage (Frank Shann, drug doses, 15th edition [76])	Dosing recommendation during ECMO	Literature
Cefazolin	Unknown	10–15 mg/kg 6 H IV	No recommendations	[2]
		Severe infection: 50 mg/kg IV 4–6 H		
Cefotaxime	Vd increased, clearance unchanged	25 mg/kg 12 H (<4 weeks), 8 H (4 + weeks) IV	Study (37 neonates): 50 mg/kg b.i.d (PNA < 1 week)	[36]
		Severe infection: 50 mg/kg IV 12 H (preterm), 8 H (1st week life), 6 H (2–4 weeks), 4–6 H (4+ weeks)	50 mg/kg t.i.d. (PNA 1–4 weeks)	
			37.5 mg/kg q.i.d. (PNA > 4 weeks)	
Ribavirin	No change	5–15 mg/kg 8–12 H oral	Case report (1 neonate): 5 mg/kg q.i.d., no dose adjustment for ECMO patients	[1, 40]
Acyclovir	Unknown	500 mg/m^2 IV over 1 h every 8 H (birth–12 years), 10 mg/kg 8 H IV (> 12 years) over 1 h	No recommendations	No studies
Oseltamivir	No, water-soluble drug	2 mg/kg 12 H for 5 days oral	Study (7 adult patients): no dose adjustment during ECMO, but in renal failure dose reduction is necessary	[41, 42]
			Study (3 pediatric patients): no dose adjustment during ECMO necessary, but reduced gastric motility impairs absorption of oseltamivir	
Tobramycin	Vd increased, elimination half-life prolonged, Cl unaffected	5 mg/kg 24 H IV (neonate 1st week), 8 mg/kg day 1, then 6 mg/kg daily (1 week–10years), 7 mg/kg day 1, then 5 mg/kg daily (>10 years)	Animal study (ten lambs): dose should be increased, no change in interval	[1, 71]
			Recommendation [1]: extension of administration interval to 18–24 h	
Voriconazole	Drug adsorption to the circuit, highly lipophilic drug	7 mg/kg 12 H IV, then 4 mg/kg 12 H	Study (ex vivo): 71 % of voriconazole was lost in the circuit	[2, 37–39]
			Case report (1 adult): TDM	
			Case report (2 adults): TDM	
			Case report (1 child): 10 mg/kg twice daily, TDM	
Caspofungin	No sequestration in the circuit, freely water-soluble [38]	70 mg/m^2 day 1, MD 25 mg/m^2 (neonate), 50 mg/m^2 (child), daily IV over 1 h	Case report (2 adults): no change necessary [38]	[38, 39]
	no detectable blood concentration [39]		Case report (1 adult): TDM [39]	
Amphotericin B liposomal	No	3–6 mg/kg daily over 1–2 h IV (severe infection up to 15 mg/kg)	Case report (1 adult): no change necessary, adequate blood levels	[39]

(*continued*)

Table 152.1 (continued)

Drug	Altered pharmacokinetics	Usual dosage (Frank Shann, drug doses, 15th edition [76])	Dosing recommendation during ECMO	Literature
Analgesics/sedatives				
Fentanyl	Adhesion to circuit, highly lipophilic drug	5–10 μg/kg stat, Infsn 5–10 μg/kg/h IV	In vitro study: drug loss in circuit was negligible at 3 h, but drug was completely lost after 24 h	[2, 72]
			Recommendation: fentanyl for short-term analgesia [procedures] but unsuitable for long-term analgesia, due to extensive ex vivo binding higher doses recommended	
			Study (12 infants): LD 5–10 mcg/kg, MD 1–5 mcg/kg/h was effective	
Morphine	Vd increased, clearance decreased after start of ECMO but normal after 10–14 days of ECMO	0.1 mg/kg stat IV, or 10–30 mcg/kg/h IV	In vitro study: extraction of drug by circuit (up to 40 %).	[2, 73, 74]
			Recommendation: higher doses required, can be used for long-term analgesia	
			Observation study (14 neonates): clinical monitoring of morphine therapy necessary	
Clonidine	Unknown	0.5–2 μg/kg/h	–	No studies
Propofol	Highly lipophilic drug, adsorption to circuit	Propofol Sedation in ICU 1–3 mg/kg/h for no longer than 48 h	In vitro study: 76–98 % was bound by circuit	[1, 4]
			Recommendation [1]: use of propofol is not recommended	
Midazolam	Vd is higher, clearance is higher, adsorptive drug loss in circuit, lipophilic drug	0.1–0.2 mg/kg IV stat, Infsn 1–4 μg/kg/min IV	Study (20 neonates): 300 μg/kg/h for 6 h, 150 μg/kg/h thereafter provide adequate serum	[50, 75]
			Concentrations for sedation, dose must be increased after 5–7 days	
Lorazepam	Lipophilic drug, adsorptive drug loss in circuit	0.05–0.2 mg/kg IV over 2 min, Infsn 0.01–0.1 mg/kg/h	In vitro study: 40 % was bound by circuit, increased dose necessary	[73]
Paralytics				
Pancuronium	Unknown	0.1–0.15 mg/kg IV prn	–	No studies
Vecuronium	Unknown	0.1 mg/kg IV prn	–	No studies
Gastrointestinal prophylaxis				
Ranitidine	Larger volume of distribution, elimination half-life prolonged	1 mg/kg slowly IV 6–8 H	Study (13 neonates): 1 mg/kg/day IV twice daily or 2 mg/kg/day continuous infusion	[1, 65]

(*continued*)

Table 152.1 (continued)

Drug	Altered pharmacokinetics	Usual dosage (Frank Shann, drug doses, 15th edition [76])	Dosing recommendation during ECMO	Literature
Anticonvulsants				
Phenobarbital	Vd is larger, half-life similar, adsorption to circuit	LD 20–30 mg/kg IV over 30 min stat, MD 5 mg/kg daily IV	TDM to maintain concentrations in therapeutic range	[1]
Phenytoin	Adhesion to circuit	LD (emergency) 15–20 mg/kg IV over 1 h, MD 2 mg/kg 12 H (preterm), 3 mg/kg 12 H (1st week of life), 8 H (2 weeks to 4 yr), 12 H (5–12yr), 2 mg/kg 8 H (>12 yr, usual max 100 mg)	In vitro study: 2 ECMO circuits in a freshly primed, loss of 43 % of concentration; in a 5 days old one, no loss	[19]
Other drugs				
Hydrocortisone (sodium succinate)	Adhesion to circuit	2–4 mg/kg IV 12–48 H	Ex vivo study: Loss of more than 20 % in crystalloid-primed circuit, no recommendation	[2]
Milrinone	Unknown	0.5–0.75 µg/kg/min IV	–	No studies
Amrinone	Adhesion to circuit	<4 weeks: 4 mg/kg over 1 h, then 3–5 µg/kg/min,	In vitro: blood-primed cardiopulmonary bypass, 20 % of drug becomes unavailable	[54]
		>4 weeks: 1–3 mg/kg over 1 h, then 5–15 µg/kg/min	Study: loading dose of 4.5–5.0 mg/kg in cardiopulmonary bypass	
Levosimendan	Unknown	12.5 µg/kg/ over 10 min, then 0.2 µg/kg/min for 24 h IV	–	No studies
Epoprostenol (prostacyclin, PGI2)	Unknown	5–15 ng/kg/min IV	In vitro study : reduction of platelet activation and consumption 5 ng/kg/min IV	[61, 76]
Sildenafil	Vd increased, clearance increased	0.3 mg/kg 3–6 H increase until effective or systemic hypotension occurs (usually 2–3 mg/kg/dose)	Study (11 neonates): 5–7 mg/kg/day; decreased to 3–5 mg/kg/day after decannulation	[50]
Bosentan	Unknown	1 mg/kg 12 H oral for 1–4 wk, then 2 mg/kg 12 H. IV: half oral dose	–	No studies
Digoxin	Unknown	15 µg/kg stat, and 5 µg/kg after 6 h, then 3–5 µg/kg 12 H slow IV or oral	–	No studies
Prostaglandin E_1 (alprostadil)	Vd increased, decrease of pulmonary metabolism	maintain PDA: 10–60 ng/kg/min	Case report [1 neonate]: effective 0.8 µg/kg/min	[62]
Liothyronine sodium (T3)	Unknown	0.1–0.4 µg/kg 8–12 H, septic shock: 0.1–0.2 µg/kg/h IV infsn	–	No studies

Abbreviations: *LD* loading dose, *MD* maintenance dose, *Vd* volume of distribution, *TDM* therapeutic drug monitoring b.i.d. twice daily, t.i.d. three times daily, q.i.d. four times daily; stat: at once, prn when necessary; PDA: patent ductus arteriosus, H hourly

5. The volume of the extracorporeal circuit affects the volume of distribution. The most apparent change in volume of distribution happens during the start of ECMO or during ECMO circuit changes. In small infants, the circuit priming volume of 200–400 mL may actually double their blood volume. Additionally, contact of blood cells with the extracorporeal surface generally causes a systemic inflammatory response with vasodilation, capillary leak, and increased fluid requirements. This increase in extracellular volume may influence the pharmacokinetics of drugs, particularly those with a small volume of distribution (e.g., cefotaxime), whereas drugs with a greater volume of distribution (e.g., fentanyl) are less affected [52]. Acute hemodilution occurs with ECMO initiation; plasma proteins are diluted, which in turn reduces protein binding and increases the free concentration of drugs. This effect is only transient, as blood and blood product transfusions will normalize the effects of hemodilution [1].

Conclusion

The pharmacokinetics of drugs administered during ECMO involve a complex interplay of multiple factors. While some studies have examined drug pharmacokinetics of patients on ECMO, many drugs have not been investigated. Further studies are needed to optimize the care of pediatric patients on ECMO and improve the prospects of recovery. Until then, therapeutic drug monitoring should be performed whenever possible to improve therapeutic outcome and avoid toxicity. Drugs that are important in the treatment of cardiac patients supported with ECMO are provided in Table 152.1, with literature citations as available.

Abstract

Pediatric clinical immunosuppression has been modeled after adult protocols which are virtually unchanged since the induction of cyclosporine. Ironically, the perception and goals of what is "success" in adults and children are dramatically different. The nature of the immune response to solid organ transplants is still incompletely understood. There is continued reliance on nonspecific maintenance immunosuppressive therapy, and many late deaths are the result of direct or indirect effects of this immunosuppression. Caregivers are entering an era of improved understanding of immunobiology, where the strategy of immunosuppression will give way to that of immunoregulation. Strategies that are steroid-free and calcineurin-free are a reality. New agents are available that may promote the induction of graft-specific tolerance. These strategies are particularly important in pediatrics because long-term survival must be the goal. This chapter attempts to familiarize the non-transplant physician with basic allograft immunobiology and a rational approach to current immunosuppressive strategies. Understanding immunosuppression requires a basic understanding of transplant immunobiology.

Introduction

Pediatric clinical immunosuppression has been modeled after adult protocols which are virtually unchanged since the induction of cyclosporine. Ironically, the perception and goals of what is "success" in adults and children are dramatically different. The nature of the immune response to solid organ transplants is still incompletely understood. There is continued reliance on nonspecific maintenance immunosuppressive therapy, and many late deaths are the result of direct (i.e., nephrotoxicity) or indirect (cancer or infections) effects of this immunosuppression. Caregivers are entering an era of improved understanding of immunobiology, where the strategy of immunosuppression will give way to that of immunoregulation. Strategies that are steroid-free and calcineurin-free are a reality. New agents are available that may promote the induction of graft-specific tolerance. These strategies are particularly important in pediatrics because decades-long survival must be our goal. This chapter attempts to familiarize the non-transplant physician with basic allograft immunobiology and a rational approach to current immunosuppressive strategies. It is not meant to be a specific "how-to" guide. Understanding immunosuppression requires a basic understanding of transplant immunobiology.

Goals of Immunosuppression in Solid Organ Transplantation

Complete immunosuppression is lethal and is not the goal in solid organ transplantation. Children must grow, be able to experience the world which includes experiencing and surviving common illnesses and the threats from within-cancer or autoimmunity. Children's immunity to self and to the world is constantly shaped from these internal and external threats. Each individual is unique based on proper genetics and immune history. Human beings augment (with vaccines) and inhibit (anti-inflammatory medications like ibuprofen) their immunity on a daily basis. The donor-recipient mismatch is completely random for heart transplantation. In infants, ABO compatibility can safely be ignored, and most recipients of incompatible blood group subsequently demonstrate tolerance to mismatched blood group antigens [1, 2].

Immunosuppression for transplant recipients is lifelong. Thus, immunosuppressive strategies that are standard for adults in their fourth, fifth, or sixth decade of life may not be as relevant in pediatrics. Immunosuppressive protocols used to manage children are center-specific and vary significantly even within an organ type, and they appear considerably different between different organ types (e.g., heart and liver). These differences make mastering immunosuppression by the primary care physician seem difficult.

The practical approach presented in this chapter is an attempt to organize immunosuppression in the context of known immunobiology. From the primary clinician's perspective, these two disparate topics are related. One way to organize immunosuppression is to divide drugs into those which primarily effect early antigen recognition events (pre-mRNA transcriptional) versus later cell proliferative (post-mRNA transcriptional) events. Some immunosuppressive drugs have both early and late effects (pan). With this basic framework almost all maintenance immunosuppressive regimens consist of one drug with early effects and one drug with late effects. In three-drug regimens, a drug with pan effects is included. In addition to maintenance immunosuppression, many new biologic agents are being introduced for special situations, such as induction, treatment of rejection, or complete avoidance of calcineurin inhibitors (CNIs). Typically, these biologic agents either delete a lymphoid cell population or interfere with cell-cell communication. A brief overview of the classes of immunosuppressive agents used in clinical transplantation is provided. Detailed discussion of these agents is found elsewhere. In general, modern immunosuppression for solid organ transplant has the goal of deleting, blocking, or regulating allospecific T-cells, which either harm the graft directly or play a critical role in the orchestration of the alloresponse.

Basic Allograft Immunobiology

There has been significant progress in unraveling the secrets of allograft immunobiology since the work of Medowar, but still it remains incompletely understood [3]. The mechanisms of allograft rejection and acceptance are multiple and redundant and occur simultaneously in an organ-specific manner. Caution is required so that generalizations are not made across all organ (tissue) types. For example, lung, skin, and bowel transplantations require more immunosuppression and have worse survival compared to kidney and heart transplantation. One difference is that exposure to the external world correlates with more antigen-presenting cells (APC) in lungs than hearts. The APCs in the lungs are sentinels to foreign invaders external environment. However, in transplantation, these APCs make the organ more immunogenic. Regulation of the allograft response and tolerance (graft acceptance without ongoing immunosuppression) is the elusive "Holy Grail."

The pediatric transplant physician must also realize that there are developmental considerations to the immune system. This is important not only from the perspective of preventing rejection but also from the perspective that the child's immune system must respond and develop to protect the individual in the real world. The following sections are not designed to be an exhaustive outline but rather a framework on which the rational use of immunosuppressive agents will make sense to the clinician.

Potential Outcomes After Antigen-Specific Encounter: Destructive Versus Nondestructive Immunity

The immune system is constantly sampling the extra and intracellular environment for evidence of injury, infection, or neoplastic transformation. How the immune system responds to these threats often predicts survival for the individual. A bacterial pathogen could be cleared, or a life-threatening tumor could be ignored. An immune response is an active process. The result of encounter of antigen from a heart transplant is usually either destructive immunity or nondestructive immunity (Fig. 153.1). Rarely does this encounter result in no response.

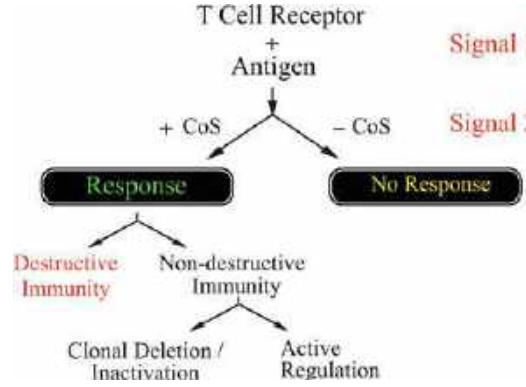

Fig. 153.1 Potential outcomes after antigen presentation and costimulation (CoS): a model of T-cell alloimmunity. CoS is considered the fundamental rate-limiting step of the immune system. In the absence of appropriate CoS signal (CoS−), T-cells do not respond. Activating CoS+ signal immune responses may be either "destructive" or "nondestructive," depending on the environment surrounding activation (see text Fate of Activated T-cells). Nondestructive immunity (tolerance) may be caused by the elimination or inactivation of antigen-responsive cells, or active regulatory T-cells (Treg), or both

Some general transplant terms are worth defining. Tissues that are antigenically identical are *isografts* and are said to be *histocompatible*. These tissues do not elicit an immune response if transplanted. Tissues that display significant antigenic differences are histoincompatible. *Allografts* are tissue or organ transplants between individuals of the same species. Most transplants performed in humans are histoincompatible allografts.

Mechanism(s) of Rejection

Three major types of acute rejection have been recognized: *hyperacute rejection*, *acute rejection*, and *antibody-mediated rejection* (*AMR*). Hyperacute rejection was the most feared type of rejection seen frequently in early cardiac transplantation but now occurs extremely rarely. It is

the result of preformed anti-donor antibodies and subsequent antibody-dependent cellular cytotoxicity (ADCC) which causes immediate (minutes) devastating graft dysfunction. Patients with these preformed antibodies are defined as "sensitized" recipients. They are now screened pre-transplant (see section on "Matching of HLA Antigens in Solid Organ Transplantation," below) most commonly with sensitive solid phase assays. Special precautions are taken in candidates who are highly sensitized. This may include desensitization, avoidance of unacceptable antigens (through prospective or virtual cross-match), or both. Acute rejection and antibody-mediated rejection will be discussed in some detail below. Care is required that acute rejection should not be thought of as a single mechanism nor the same in each recipient-donor combination. The mechanism of antibody mediated resection can be acute or chronic and tie back to acute cellular rejection. Transplant vasculopathy (previously termed chronic rejection) is a pathologic finding which is not completely understood but has associations to acute and antibody-mediated rejection but also to innate immunity and metabolic and drug toxicities. In this chapter, vasculopathy will be discussed only in the context of adaptive and innate immunity.

Antigen Presentation

Allograft rejection is T-cell dependent. Animals that lack T-cells ($rag^{-/-}$ mice lack all T- and B-cells) will not reject allografts indefinitely. Humans that have been depleted of T-cells will usually not reject allografts until the T-cell population returns (although infiltration of the graft with macrophages has been observed). T-cells recognize small donor peptides (antigen) displayed in association with HLA receptors (MHC in animals) on the surface of special antigen-presenting cells (APCs). The HLA loci are tightly linked and are typically inherited as a complete set from each parent, called a haplotype. Because of the high degree of polymorphism (variability) at most HLA loci, inheritance is likely to yield a high degree of heterozygosity at most loci. In out-bred animals (or humans), there is only a 25 % chance that any two siblings will inherit identical MHC (HLA) haplotypes. With parent-to-child allografts, there will always be matching of one haplotype but mismatching of the other.

The transplanted solid organ is an artificial situation for the recipient because the "passenger leukocytes" (*donor* APCs) within the graft can, like soldiers in the Trojan Horse, leave the graft and engage the host immune system. These donor APCs or HLA antigens can be recognized directly or indirectly by host T-cells (see section on "Direct Versus Indirect Antigen Presentation," below). This is the basis of the vigorous immune response, called alloreactivity. Direct presentation of donor APC only occurs in transplantation (as later discussed). The number of recipient lymphocytes which can recognize an allograft is on the order of a 100–1,000-fold greater than can recognize any other environmental pathogen. Acute allograft rejection is initiated by the large number of recipient T-cells that recognize donor alloantigens (most encoded by the highly polymorphic HLA region in the human) [4]. There are also antigenic differences between individuals outside of HLA loci (e.g., ABO blood group antigens). These antigens are termed "minor histocompatibility loci." These minor antigens are only recognized when they are presented in the context of (self) host HLA molecules.

Matching of HLA Antigens in Solid Organ Transplantation

Although in the current era it is common to check recipient and donor HLA status, this information is normally only part of the decision-making process when determining donor suitability for some organs, such as the kidney, or in the case of presensitized recipients. For most solid organs, retrospective studies have suggested that HLA compatibility is rare but may lessen rejection and improve graft survival in heart transplantation [5]. In part, because of the constraints of cold ischemic time (usually approximately 4 h) and the ongoing organ donor shortage, prospective HLA matching

is not routinely used in heart transplantation, the exception being the sensitized recipient.

The sensitized recipient has preformed antibody (Ab) to foreign HLA antigens because of previous blood transfusions, pregnancy, implantation of foreign tissue (homografts), or the use of mechanical assist prior to transplant (see section on "Memory T-cells and Heterologous Immunity"). The group requiring mechanical assist prior to transplant is a rapidly growing cohort. There are emerging strategies to avoid transplant antigens to which the recipient has preformed Ab or to decrease their titer and further production [6, 7]. The discussion of how to transplant a sensitized patient is complex and far from standard, as such is beyond the scope of this text.

Most T-cells in the body can present intracellular antigens in the context of class I HLA. Specialized (professional) APCs, dendritic cells, macrophages, and lymphocytes also can process and present extracellular antigens in the context of HLA class II. The T-cell, through its signature T-cell receptor (TCR), recognizes foreign antigens only as a complex with HLA molecules or foreign allo-HLA and can directly engage host T-cells [8]. This complex (HLA + antigen) is restricted in that antigen that is presented via HLA class I is presented to CD8 T-cells, whereas antigen presented via HLA class II is presented to CD4 T-cells. Class I HLA antigens on the surface of APCs generally present endogenously acquired antigens, whereas class II HLA antigens on the surface of APCs present exogenously acquired peptide antigens. Both CD4 and CD8 T-cells can participate in acute cellular rejection, but the rejection response in most tissues (the heart) is mediated by CD4 T-cells. Despite the importance of CD4 T-cells, CD8 (cytotoxic) T-cells, B-cells, and NK cells also infiltrate the allograft and participate in allograft rejection and in allograft tolerance.

Direct Versus Indirect Antigen Presentation

The concept of donor HLA-restricted (*direct*) and host HLA-restricted (*indirect*) pathways of graft antigen presentation has important implications for the nature of T-cell-dependent immune responses to the allograft. These two pathways of antigen presentation can fulfill the three-signal (see below) requirement for T-cell activation in the transplantation. The first is a (*direct*) donor APC-dependent process in which host T-cells recognize graft antigens directly on the surface of donor APCs capable of providing Ag + HLA *and* costimulation (CoS). The second is a (*indirect*) host HLA-restricted response, in which host T-cells indirectly recognize graft antigens that are processed and presented by host APC [9]. In the indirect pathway, host APCs process and present allograft antigens primarily in association with host HLA class II antigens. Such presentation would be expected to activate predominantly CD4 T-cells. This is the typical form of antigen presentation during an infection. The direct pathway of antigen presentation could activate host CD4 or CD8 T-cells specific for peptides presented by donor APC HLA class II and class I molecules, respectively [10].

The direct (donor HLA-restricted) pathway is responsible for the high precursor frequency of alloreactive T-cells (1:100–1:1,000). In contrast, the frequency of alloreactive indirect T-cells is one to two orders of magnitude lower. This author's laboratory demonstrated that "direct" presentation is essential for CD4-mediated rejection of cardiac allografts and that this rejection depends on donor HLA class II antigens and not on host HLA class II [11]. The indirect pathway is thought to be important for alloantibody production, chronic rejection (vasculopathy), and allograft tolerance. Thus, both pathways are operational in solid organ transplantation, although which is more clinically important for graft pathology is debatable.

T-Cell Activation: The Three-Signal Hypothesis

The original two-signal model of lymphocyte activation proposed by Lafferty and Cunningham [12] has recently been modified to include a third signal. A three-signal model of T-cell activation

is the favored model for the initiation of a T-cell-dependent alloresponse, whether destructive (rejection) or nondestructive (tolerance) in nature.

T-cell activation is initiated by signal 1, which is delivered by the interaction between the T-cell receptor (TCR) and the HLA-antigen complex present by the APC (HLA (MHC) + antigen + T-cell receptor). Importantly, signal 1 alone is not capable of initiating immune responses. However, in combination with signal 2, the costimulatory signal (CoS), signal 1 triggers several intracellular pathways such as the calcium-calcineurin pathway, mitogen-activated protein (MAP) kinase pathway, and the protein kinase C/nuclear factor kβ (NK-kβ) pathway. Together, these pathways promote transcription factors that mediate cell survival and expression of pro-inflammatory cytokines. Signal 3, an expansion step, is mediated through several cytokines (e.g., IL-2, IL-15, IL-4, IL-7, and IL-21 among others) to induce proliferation through the phosphoinositide 3-kinase (PI3-K) and mammalian target of rapamycin (mTOR) pathways.

Costimulatory Pathways

Costimulation is actually a complex array of receptor-ligand interactions rather than any single molecule. One way T-cells mediate help is through cognate costimulatory molecules on the cell surface that interact with other cells. One molecule, CD40L (CD154), is predominately expressed by CD4 T-cells, not by CD8 T-cells. The CD154/CD40 interaction between CD4 T-cells and APC leads to the upregulation of CD80/86 on APC. Activated APC can interact with naive CD8 T-cells, which leads to their activation. Under special conditions that directly activate CD80/86 on APCs, this signal can bypass the requirement for T-cell help (agonistic antibodies to CD40, infection with viruses, and inflammation) [13]. This latter point may be important clinically (e.g., cytomegalovirus infection and its association with acute rejection).

Costimulatory molecules can provide either positive or negative signals. For example, in the CD28-CD80/86 pathway, ligation of CD28 with CD80/86 is a *positive* signal for T-cell activation. CTLA4 is a competitive ligand for CD80/86 with much stronger avidity for CD80/86 and is a strong *negative* signal for T-cell activation.

Costimulatory events are important to mention because there is much enthusiasm that they may be an important target for immune manipulation in transplantation. In animals, long-term allograft tolerance can be achieved by blockade of CD28-CD80/86 *and* CD40/CD40L costimulatory pathways [14]. Blockade of either pathway alone does not result in tolerance, however, but it can result in prolonged allograft survival. The system is quite complex. For example, CD28 KO mice as recipients are able to reject cardiac allografts, whereas CD80/86$^{-/-}$ mice are not able to reject cardiac allografts. The ability of CD80/86$^{-/-}$ recipients to reject cardiac allografts is restored by antiCD28 Ab or exogenous IL-2. CD80/86$^{-/-}$ donor hearts are rejected with equal or slightly accelerated kinetics compared with wild-type controls [15, 16].

One therapy that has made it to human clinical trial in this pathway is CTLA4-Ig [17]. CTLA4-Ig is a fusion protein (a soluble CD28 receptor analog) that binds CD80/86 and inhibits CD28 activation. CTLA4-Ig has been shown to block the CD28-mediated costimulatory signal and inhibit immune responses in vitro and in vivo. CTLA4-Ig can induce transplantation tolerance in the murine cardiac allograft model [18]. CTLA4-Ig was found most effective 48 h after antigen presentation in a murine cardiac allograft model, which perhaps reflects induction of tolerance at a time of maximal CTLA4-Ig/CD80 blockade. CTLA4-Ig given later, at a time when the recognition/rejection process already began, was not effective [19]. Success with costimulatory blockade for transplantation has also been achieved in primates [20, 21]. Blockade of the CD40/CD154 pathway while promising, when transitioned to human trials with humanized anti-CD154, resulted in thromboembolic complications, and the trials were stopped. However, blockade of this pathway still has great promise. A fully humanized monoclonal antibody (4D11) directed against CD40 (ligand of

CD154) is still in development [22]. Thus, the manipulation of these pathways could have important implications for human solid organ transplantation. Second signal or costimulatory blockade has potential clinical use in solid organ transplantation (see *belatacept* in section "Biologic Agents") [17].

APCs can modify the immune response depending on their environment (e.g., pro-inflammatory vs. regulatory). By positive signals through CD80/86 or CD40, APC can deliver signals that amplify T-cell activation and prevent T-cell anergy. Other APCs may deliver inhibitory signals via CD80/86 interaction via CTLA4 or PD1-PDL1/PDL2 pathway. Both signals 1 and 2 are typically provided simultaneously on a metabolically active APC. Although, through a mechanism called costimulation *in trans*, signal 1 and signal 2 may be separated in time and even present on different APC. This phenomenon implies that "bystander" cells can have a profound effect on the outcome of T-cell activation.

Fate of Activated T-Cells

An important point is that immunity is an active process, and in most cases for an allograft either results in destructive immunity (rejection) or nondestructive immunity (tolerance or regulation) as in Fig. 153.1 depending on the context of antigen presentation.

In the 1980s, Mosmann made an observation that T-cells could be categorized as making pro-inflammatory cytokines that drive cellular responses (Th1 type T-cells) and other T-cells (Th2 T-cells) that produced cytokines that were viewed as tolerogenic and were important in allergy [23]. An early interpretation predicted that Th1 T-cells drove rejection of allografts, while Th2 T-cells were responsible for graft acceptance and tolerance.

When CD4 T-cells are activated in the presence of the pro-inflammatory cytokine IL-12 (produced by activated, mature dendritic cells), they become tissue-destructive, interferon gamma-producing T-helper (Th)1 cells. In contrast, CD4 T-cells are activated in the presence of IL-4 and differentiate into less destructive Th2 cells, which produce IL-4 and IL-5. In contrast, a true regulatory environment (the absence of pro-inflammatory cytokines) and in the presence of transforming growth factor (TGF)-β Foxp3 expression is induced in the T-cell. Foxp3 expression (the regulatory T-cell gene) causes differentiation of CD4 T-cells in to allograft-protective regulatory T-cells (Tregs). However, coexpression of TGF-β with pro-inflammatory cytokines IL-6 or IL-21 prevents development of the transplant-protective Tregs [24]. Instead, in this pro-inflammatory environment, the antigen-reactive CD4 T-cells become IL-17-producing T-cells (Th17), which are highly allograft cytopathic [25–27]. This leads us to a more modern view of T-cells with at least 4 distinct populations of differentiated T-cells: Th1, Th2, Treg, and Th17.

The important point is that the environment in which a T-cell encounters antigen has profound impact on the immune response. This has strong implications for the clinic. Allografts transplanted in the setting of failed surgeries or high-stress mechanical support states (ECMO) may have acceptable short-term outcomes because of over-immunosuppression but are unlikely to achieve allograft regulation (tolerance) and excellent long-term outcome – which is the goal in pediatrics.

Further, the cellular immune environment changes the fate of T-cells even after they have committed to a differentiated phenotype. It was thought that antigen-activated helper T-cells became *terminally* differentiated into Th1 or Th2 cells that had opposite effects (Th1-dependent cytopathic rejection or Th2 dependency with protective effects) [23]. This early Th1 versus Th2 paradigm is incorrect because Th1 and Th2 can both mediate graft rejection [28]. Regulatory T-cells, rather than Th2 cells, are the key inhibitors of cytopathic, allospecific immune responses [29, 30]. Recent discoveries also revealed that, instead of being terminally differentiated, Th17 and Tregs have remarkable plasticity and are closely interlinked [31]. Thus, Tregs can differentiate into IL-17-producing cells in the presence of IL-2 and IL-1β [32], whereas in the presence of IL-27, Th17-producing cells also produce IL-10,

an immunosuppressive cytokine that prevents them from functioning as destructive effector cells [33].

The current paradigm is that the outcome of transplant recipients, rejection or graft acceptance, is determined by the relative balance between cytopathic Th1 and Th17 CD4 T-cells versus rejection-blocking, cytoprotective regulatory T-cells. This balance depends on the level of inflammation in the microenvironment in which T-cell activation takes place. Although the specific role of Th17 cells in allograft rejection is under investigation, events that block T-cell commitment to the allograft-protective Treg phenotype prevent the development of transplant tolerance [34]. Further, the presence of Th17 cells in the allograft might be a biomarker of detrimental tissue inflammation rather than true allograft rejection that mediated initial graft destruction.

Memory T-Cells and Heterologous Immunity

In this era, when mechanical assist and LVAD in pediatrics are finding an increased role as a bridge to transplantation [35, 36], the immunologic consequences of these strategies are not trivial. Following T-cell activation and proliferation, after the pathogen has been destroyed, the level of immune activity must return to baseline. Homeostasis of the adaptive immune system is restored by cell death, apoptosis, via "neglect," of most antigen-specific T-cells. A small number of T-cells, however, survive and become long lasting *memory* cells that ensure protective immunity against pathogens [37]. Most resting memory T-cells are characterized by high expression levels of CD45RO (CD44 in mice), CD2, and CD11α [38, 39].

Based on their homing properties, memory T-cells can be separated into "central" and "effector" cells [40]. Central memory T-cells recirculate through the spleen and lymph nodes by means of their expression of the homing receptors CD62L and CCR7. In contrast, effector memory T-cells downregulate CD62L and CCR7 and are excluded from lymphoid tissues, migrating to peripheral tissues where they exert rapid and potent effector functions upon antigen rechallenge [40]. Therefore, whereas central memory T-cells are responsible for recall antigen-specific responses, effector memory T-cells survey peripheral tissues and immediately respond to invading pathogens. Because of continuous exposure to foreign antigen, memory T-cells accumulate with age and increase to approximately 50 % of the total T-cells in adults.

Potential recipients prior to transplant can generate memory T-cells which will be donor-reactive after transplant. This occurs through direct exposure to alloantigens via pregnancy or blood transfusion [41]. Donor-reactive memory T-cells can even be generated in the absence of alloantigen exposure, through heterologous immunity, wherein an antigen-specific immune response, which is typically directed against environmental pathogens, affects the response to an unrelated antigen through cross-reactivity of the T-cell receptor [42]. Heterologous immunity for human cardiac transplant patients correlates with prior surgery, sepsis, mechanical ventilation, and mechanical circulatory support. Heterologous immunity is easily demonstrable in rodent transplant models where all variables are more easily controlled [43]. The effects of heterologous immunity are not as apparent in human transplantation, particularly at short-term 1 month and 1 year survival endpoints. Some memory T-cells are therefore primed by an antigenic pathogen-derived peptide and cross-reactive with allogenic (often HLA-derived) peptides presented by self or donor HLA molecules. Following transplantation, alloreactive naïve T-cells can acquire a memory phenotype and generate a substantial pool of donor-reactive memory T-cells, even with recipient immunosuppressive therapy. Furthermore, the use of antibodies that deplete host T-cells can amplify this phenomenon by inducing homeostatic T-cell proliferation in response to lymphopenia [44]. Because of their capacity to rapidly generate effector immune responses upon rechallenge, memory T-cells are efficient at mediating allograft rejection [45, 46]. Memory T-cells are also less sensitive than naïve T-cells to many immunosuppressive strategies, such as

T-cell-depleting antibodies like ATG [47], or to therapeutics that block CD28 and CD154 costimulatory signals [43, 48] or inhibit mTOR [49]. The effects of memory T-cells in the allograft response have been well delineated in animal models of allograft tolerance wherein generation of memory T-cells by presensitization, heterologous immunity, or homeostatic proliferation prevents most tolerizing strategies [43, 44, 50]. In contrast to human recipients, inbred mice that live in the protected environments of transplantation laboratories do not usually contain many memory T-cells. This is one of the reasons that explains why animal results do not always translate to the clinic (or why results from nonhuman primates, who resemble humans in terms of the size of their memory T-cell pool, are more likely to). Given the lower efficacy of conventional immunosuppressive drugs in the control of previously activated or memory lymphocytes, it is not surprising that memory T-cells exert harmful effects in clinical transplantation. In kidney transplantation, for instance, the proportion of circulating donor-reactive memory T-cells, either before [51] or after [52] transplantation, correlates with the incidence of rejection and graft dysfunction.

Cellular Effector Mechanisms

Activated T-cells can acquire cytotoxic properties that allow them to damage or kill their targets. Potential effector mechanisms of T-cell-mediated rejection may involve either cytokine/DTH-type mechanisms or cytotoxic mechanisms. Which mechanisms are actually used, their relative importance and their molecular targets in allograft rejection are an active area of research. What is clear is that all these mechanisms occur simultaneously. Experimentally, mice that are deficient for one mechanism still reject allografts. For example, in mice heart transplants with CD95 (Fas) deficiency on the donor, hearts were readily rejected [53, 54]. In contrast, in our laboratory, we found that CD4 T-cell-mediated cytotoxic mechanisms require FasL (CD95L) *and* perforin pathway for effector function in acute cardiac allograft rejection [55]. As in cytokine knockout studies, these models do not address the contribution of overlapping pathways of immune-mediated destruction, which may explain the negative findings. The mechanism(s) that predominates in one individual with a solid organ allograft may differ significantly from the response in another individual with the same type of transplant. This occurs because of the influence of genetics, immunologic history, and the relatively random mismatched donor organ.

Chemokines in Allograft Rejection

Chemoattractant agents released from an area of inflammation or trauma (in this case the donor heart) – called chemokines – facilitate leukocyte (effector cell) infiltration. A more complete review of chemokines in transplantation is presented elsewhere [56]. Chemokines are released by various cell types, including endothelial, epithelial, and stromal cells. Chemokines start the inflammatory response in the brain dead heart donor. Chemokines regulate leukocyte traffic at the cellular level. T-cells, which typically encounter antigens in the spleen or lymph nodes, must be guided to the allograft. Circulating leukocytes, such as monocytes and eosinophils, also must be drawn to the allograft. Chemokines represent a family of more than 45 members. They are classified according to their terminal configuration of amino acids in relation to cystine. By this nomenclature, there are four major groups: CC-, CXC-, C-, and CX3-C. The chemokines also seem to play an important role in regulating this infiltration of leukocytes and the subsequent allograft response [57]. Among the chemokine pathways, two major pathways seem to play an important role in allograft rejection. The first role seems to be mediated through the chemokine receptor D6 and the second pathway is mediated through the chemokine receptor DARC (Duffy receptor) [56]. These pathways represent new targets for immune intervention, which only recently have been approached at the experimental level [56, 58].

Innate Immunity: Role in Allograft Rejection, Tolerance, and Vasculopathy

The acute allograft response is largely T-cell-dependent. The innate immune response (eosinophils, NK cells, among others) has historically been thought only to be important for inflammation. While it is true that the innate immune responses are insufficient to initiate allograft rejection, it is now appreciated that innate immunity plays a significant role in the damage of an organ under the siege of rejection. Further, the "yin and yang" of establishing a regulatory, allograft-specific tolerant state on the one hand and the pro-inflammatory chronic rejection state of cardiac allograft vasculopathy both appear to require NK cells, a key player in the innate response.

In transplantation, the innate immune response along with chemokine activation is significant during organ procurement. During rejection, when inflammation is raging, they are also clearly involved. Under these conditions, macrophages and neutrophils are recruited by activated T-cells. These cells engage the target allograft by the cytokine/DTH mechanisms. Eosinophils are attracted to the allograft by cytokines such as IL-4, IL-5, and IL-13 produced by alloreactive T-cells. Activated eosinophils release granules with toxic substances such as major basic protein, eosinophil-derived neurotoxin, eosinophil cation protein, and eosinophil peroxidase. Major basic protein is known to cause smooth muscle hyperreactivity and may be partly responsible for increased blood flow into the graft. Eosinophilcation protein can create toxic pores in the target cell's membrane causing tissue damage [59]. What specific roles any of these eosinophil effector mechanisms may play in allograft rejection are unclear. Once the process has begun, however, they are one of the many molecular mechanisms of damage.

NK Cells Can Promote Graft Rejection

Few studies have provided definitive evidence for the role(s) of NK cells in allograft rejection or acceptance. Acute T-cell-dependent allograft rejection dominates the response, such that inhibition or elimination of NK cells rarely results in significantly prolonged allograft survival. Given the emerging interest in the role of NK cells in allograft tolerance (see below), it might be tempting to underestimate the contribution of NK cells to graft injury. However, a number of studies over the past few years continue to highlight the ability of NK cells to promote several types of graft injury or rejection.

NK cells can play an essential role in solid organ allograft rejection. NK cells can be required for cardiac allograft rejection when the costimulatory molecule CD28 is either inhibited or genetically absent [60, 61]. In another model, IL-15-driven NK reactivity can result in skin allograft rejection independent of T- and B-cell adaptive immunity [62]. NK cells can also enhance skin allograft rejection by promoting CD4 T-cell-dependent "indirect" (host APC-dependent) alloantigen presentation [63]. The important point here is that "indirect" alloantigen presentation is not intrinsically positive or negative for allograft outcome but rather depends on the consequence of this response [64]. An important recent study connects the concept that NK cells can kill donor-type APCs and in turn "seed" antigen for indirect (host APC-dependent) alloreactivity. This latter result may well be related to the ability of NK cells to kill MHC-mismatched donor dendritic cells (DC) [65, 66] and so "seed" antigen to self-APCs.

NK Cells Can Promote Cardiac Allograft Vasculopathy

NK cells are also associated with chronic allograft injury. In a "hybrid resistance" mouse model, NK cells were shown to be required for chronic cardiac allograft vascular injury [67, 68]. The NK cells could be triggered by virus (LCMV) or antibody. Though there are varied means by which NK cells could contribute to such injury, an obvious role for NK cells in

antibody-dependent responses could be through antibody-dependent cellular cytotoxicity (ADCC) triggered by antibody Fc receptor binding and activation of host NK cells [69]. However, in a recent study complement fixing antibody does not appear to be required for the vasculopathy lesions [68]. Taken together, NK cells clearly have the capacity to exacerbate multiple forms of allograft injury.

NK Cells Can Promote Allograft Tolerance

While NK cells can promote allograft rejection, probably the more unexpected finding is that NK cells play in a role regulating the immune response, including a pronounced role in allograft tolerance. NK cells appear to kill *donor*-derived APCs in a pathway where NK cells can modify allograft reactivity and actually promote allograft tolerance rather than rejection. Our group found that NK cells and perforin were surprisingly necessary for some forms of induced allograft tolerance [70]. Soon thereafter, Yu et al. made the important observation that host NK cells rapidly killed MHC-disparate allogenic DCs [65]. This DC killing appeared to be the direct result of a "missing self" event since donor DCs expressing self-MHC class I (i.e., host × donor F1 cells) were protected from such elimination. A more recent report connected these two studies by demonstrating the NK cells could mediate perforin-dependent killing of donor APC [66]. Inhibition of NK cell responses can prevent donor DC elimination and actually enhance CD4 T-cell alloreactivity [71].

It is likely that NK cells do not primarily promote allograft tolerance through the direct induction of Tregs. Rather, by blunting APC and effector T-cell activity as described above, other regulatory mechanisms may contribute to tolerance. NK cells may not so much "induce" tolerance but simply inhibit destructive allograft immunity and so provide a more tolerance-permissive environment for other regulatory pathways to occur.

Cardiac Allograft Vasculopathy (Chronic Rejection)

Chronic rejection is a poor term because it has been used to mean chronic acute rejection and transplant vasculopathy. Transplant vasculopathy or coronary artery vasculopathy (CAV) is a major limiting factor for long-term survival after pediatric heart transplantation. A detailed more complete review can be found elsewhere [72, 73]. The exact cause(s) of CAV remains obscure, but most investigators agree that the mechanisms are primarily immune-mediated [73, 74]. Immunologic events interact with non-immunologic risk factors. In the donor, age and hypertension, graft ischemia, and reperfusion injury have been associated. In the recipient, hypertension, hyperlipidemia, obesity, diabetes, smoking, race, and gender have been associated [75].

A discussion of all potential mechanisms of graft vasculopathy and chronic rejection are beyond the scope of this chapter. An interesting finding is that CD4 D17 T-cells may play an important role in the development of transplantation vasculopathy [76]. The development of vasculopathy in this model occurred in the absence of a Th1 response, the original pro-inflammatory, pro-rejection T-cell phenotype. Recent data also suggests a role for innate immunity (NK cells) and antibody [68]. For a brief discussion of the role of NK cells and vasculopathy, see the section on "Innate Immunity: Role in Allograft Rejection, Tolerance, and Vasculopathy," previously. Both of these findings demonstrate the complex nature of the immune system and how incomplete our present understanding is.

Antibody-Mediated Rejection (AMR): The Humoral and Complement Response Pre- and Post-Transplant

Allograft antigens and tissue generate a strong antibody response. On the other hand, is alloantibody an associated finding and not the lynch pin for acute and chronic allograft destruction or the

development of vasculopathy? Further, B-cells are known to be important players in the regulation of an immune response, so elimination of B-cells with drugs like rituximab may be detrimental to the establishment of a graft-specific regulatory (tolerant) state. Thus, the complete role of antibody and B-cells in allograft rejection also remains unclear and is an area of intense investigation.

Preformed antibody to HLA antigens occurs in children who received blood transfusion, previous surgery (heart valves or conduits), or previous transplants or in adolescents or adults who have been pregnant. These preformed antibodies can coat the cells of an incompatible organ and either activate complement or opsonize the graft to attack by natural killer cells or by macrophage. Complement is a cascade of serum proteins that, when activated, can form a membrane attack complex that creates a pore in the target cell's membrane. This results in cell (target) death. Complement can be activated by two pathways, one of which is through activation by antibody fixed to the surface of a target cell. The nonantigen binding end (Fc portion) of certain classes of antibody (IgM and IgG, in the human) can bind key components of complement and begin the cascade. Antibody bound to a target cell (allograft) also can bind natural killer cells by cross-linking their Fc receptors. This is a process called antibody-dependent cell cytotoxicity. The T-cells and natural killer cells are believed to kill the cell by a pore-forming granzyme/perforin mechanism.

In acute cardiac allograft rejection, anti-allograft antibodies can be detected. Anti-allograft antibody alone does not seem to be sufficient to induce acute cardiac allograft rejection, however. Nude and athymic animals have a normal complement of B-cells that is able to mount a strong T-cell-dependent response. In passive transfer experiments in the absence of T-cells, neither immune nor hyperimmune serum was detrimental to kidney allograft survival [77]. Despite this evidence that antibody is not required for initiation of rejection, antibody-mediated responses play an important and ever growing role as an effector mechanism of rejection. Typically, the evidence for AMR is indirect with perivascular infiltration of lymphocytes, particularly macrophage and/or the deposition of a complement split product C4d. The pathologic findings of AMR are beyond the scope of this text but are reviewed elsewhere [78].

A primary role for alloantibody generally is believed to be hyperacute rejection [79, 80]. Hyperacute rejection was a major problem for allotransplantation but now remains an obstacle for the future in xenografting [81]. In ABO-matched human (allo) cardiac transplantation, it is a relatively rare occurrence. Sensitive assays are now conducted to detect preformed anti-HLA alloantibody. Because of the concern that circulating donor-specific HLA alloantibodies may decrease graft survival, patients with significant anti-HLA antibody before transplantation often undergo a prospective cross-match between donor and recipient before acceptance of a donor organ [82].

This process can limit severely the donor pool available to a recipient. Evidence exists that patients with elevated panel reactive antibody may have a higher degree of allograft loss and a higher mortality after transplantation despite a compatible cross-match [83]. Another strategy is a virtual cross-match to avoid potential high titer Ab [84]. A virtual cross-match is a flow cytometry test that uses latex beads coated with class I and II HLA antigen peptides. Thus, the presence of potential anti-donor antibody can be determined without the recipient serum being in the same laboratory as the donor cells. The cross-match is "virtual," on paper. Typically, this strategy is used to screen donor hearts that would have unacceptable antigens for the recipient.

Because of the significant difficulties associated with finding a compatible cross-match in patients with anti-HLA antibodies, some programs choose to try to desensitize the potential recipient. Multiple treatment modalities have been employed as desensitization protocols including intravenous immunoglobulin, plasmapheresis, azathioprine, cyclophosphamide, mycophenolate mofetil, and rituximab [7, 85–87]. Bortezomib, a proteasome inhibitor (see below), has recently been added to the regimen to halt Ab production by plasma cells [88].

Clinical Immunosuppression

Immunosuppression Strategies

There are really three basic types of immunosuppression strategies for solid organ transplantation: *induction*, *maintenance immunosuppression*, and the *treatment of rejection*. This is a gross over simplification but will provide a good framework for this text. *Induction* therapy is a perioperative regimen that is intended to change immunity to the allograft with only a short (days to weeks) period of treatment. *Maintenance* immunosuppression is lifelong, but it too changes, typically with a reduction in the level of immunosuppression over the first year in most centers. Maintenance immunosuppression may also change with the recipient's response to the allograft with a focus more toward AMR or vasculopathy in some recipients. *Rejection therapy* is acute and focused but also typically leads to a change or heightening of maintenance immunosuppression.

Induction therapy is typically a short course of a biologic agent coupled with the introduction of maintenance immunosuppression. Induction therapy can have several goals. First is the concept that it can change immunity to allograft such that low dose immunosuppression could be used for the long term [133]. In animals, induction is used as part of a tolerizing protocol. This has been achieved with limited success in humans [89]. Induction therapy on a practical level often achieves less lofty goals such as providing a period of time in which the risk of acute rejection is very low. In pediatrics in particular, this avoids peri-transplant biopsies. It also allows for delay in the introduction of calcineurin inhibitors, which aids renal recovery in the early post-bypass period. Currently, the most commonly used induction agent is the T-cell depleting antibody Thymoglobulin (rabbit antithymocyte globulin). More recently, there has been early experience (principally in adults) of the powerful agent alemtuzumab (Campath H1, anti-CD52) with success [90]. Other centers use induction with IL-2R inhibitors. IL-ZR inhibitors are well tolerated clinically with relatively few side effects.

Some have argued that induction therapy increases the risk for infection and malignancy. Judicious use of powerful induction agents warrants the decrease in other immunosuppression for weeks to months after induction to avoid this know pitfall [90]. Maintenance immunosuppression may be a lager risk factor for malignancy than whether induction was used [90, 91].

Maintenance immunosuppression is continually evolving. Protocols are very individualized to program and patient. This text will try to generalize and apply a logic to the use of these drugs in any protocol. In general, maintenance regimens are more intensive in the early transplant period and become more individualized with time post-transplant. Drugs used in most protocols are discussed in some detail below.

Treatment for acute rejection is also very program-specific but generally falls into three types. Low-level rejection might be treated with only a change in immunosuppression. Steroids either oral or IV in a high-dose burst are typically the next level of treatment. Finally, biologic agents ATG and ATGAM, for cellular rejection; rituximab for AMR; and alemtuzumab for severe resistant rejection might be used in addition to a change in immunosuppression. Treatment of rejection may be different in early post-transplant versus years later. Protocols may be different for re-transplant versus naïve first transplant. Clearly, treatment will be directed at mechanism(s), cellular, humoral, or some combination. The diagnosis of rejection is also beyond the scope of this text, but for cardiac rejection, this has been reviewed elsewhere [92–97].

Sites of Action of Small-Molecule Immunosuppressive Drugs

The intracellular events that result in T-cell activation can be conceptualized as either *early* (pre-mRNA transcription) or *late* (cell proliferation) events (Tables 153.1 and 153.2). Details of efficacy, pharmacokinetics, and complications are found elsewhere [6, 92, 93, 98, 99].

Although many points still require clarification, T-cell activation requires an integrated

Table 153.1 Definitions: solid organ transplants

Autograft: Tissue from the same individual transferred from one anatomic site to another.
Homograft: Tissue transferred from one individual to another within the same species, similar to an allograft, but typically with additional processing such as cryopreservation or denaturing the tissue. These grafts are typically vascular structures such as heart valves or the entire valve root.
Isograft: Tissue from a genetically identical individual. Typical between inbred animals for experimental purposes. In humans, this transplant can be performed only between identical (monozygotic) twins.
Allograft: Tissue transplanted between genetically different members of the same species. In humans, almost all transplants are allografts.
Xenograft: Tissue transplanted between different species.

intracellular signal 1 *and* 2 (details discussed in "T-Cell Activation: The Three-Signal Hypothesis" section above). Signal 1 then is an *early* event required for transcription of immune response genes, while signal 3 is a much *later* cellular event. This early versus late event will be the framework in which these drugs will be discussed.

Intracellular Mechanisms and Immunophilin-Binding Drugs

Drugs in maintenance immunosuppressive protocols are either (1) immunophilin-binding drugs that inhibit signal transduction (*early*) *or* (2) (*late*) antimetabolites or inhibitors of de novo synthesis of nucleotides (purines or pyrimidines) or (3) mTOR inhibitors. Steroids are included in a maintenance regimen (*or not*) in combination with any of the 3 mentioned groups of immunosuppressive drugs. A schematic of these intracellular mechanisms and the site of action of these drugs are presented in Fig. 153.2.

Calcineurin Inhibitors

TCR-antigen-specific recognition event (signal 1) is followed by the transmission of this signal to the interior of the T-cell by the activation complex. The activation complex is comprised of TCR in non-covalent association with the CD3 complex and CD4 or CD8 co-receptors. The CD4 and CD8 co-receptors engage conserved regions of MHC classes II and I, respectively. This TCR-mediated signal is chiefly responsible for two intracellular signals: (1) activation of the MAP kinase pathway and (2) activation of the calcium-calcineurin pathway leading to increased intracellular Ca^{+2} flux and subsequent activation of the Ca^{+2}-regulated protein phosphatase, calcineurin.

Calcineurin is the target of cyclosporine and tacrolimus. Of the immunophilin-binding drugs, cyclosporine was the first drug of this class to reach clinical use in the early 1980s and began the modern era of solid organ transplantation. Significant improvements in short- and medium-term survival (1 and 5 years) occurred as a result of cyclosporine. This class of immunophilin-binding drugs is the mainstay of immunosuppressive therapy and inhibits early events in T-cell activation [134].

Tacrolimus, like sirolimus (rapamycin), also acts at a distal site in the IL-2 activation pathway of lymphocytes, while cyclosporine does not [100]. Tacrolimus thus binds to mTOR (also previously FK-binding protein-12). Tacrolimus is approximately 100 times more potent than cyclosporine in the inhibition of secretion of activating cytokines in vitro [101]. Even with a therapeutic trough concentration, activity of the target enzyme is only reduced by 50 %; however, there is considerable individual patient variability. Cyclosporine and tacrolimus affect early events which are upstream from activation of the protein kinase C/ nuclear factor kβ (NK-kβ) pathway. Tacrolimus appears to be more efficacious (immunosuppressive) than cyclosporine [102]. However, some programs, including ours, continue to use cyclosporine as the preferred immunosuppressant with the goal of moving favorable patients to a regimen of low dose calcineurin monotherapy as long-term maintenance therapy [103, 104].

Table 153.2 Effect of small-molecule immunosuppressive drugs: early versus late

Class	Drug	Early	Late	Pan (both)
Steroids	Steroids			XX
CNIs	Cyclosporine	XXX		
	Tacrolimus	XXX	X	
Antimetabolites	Azathioprine		XXX	
	Cyclophosphamide		XXX	
	Methotrexate		XXX	
	Mycophenolate		XX	
mTOR inhibitors	Sirolimus		XX	
	Everolimus		XX	

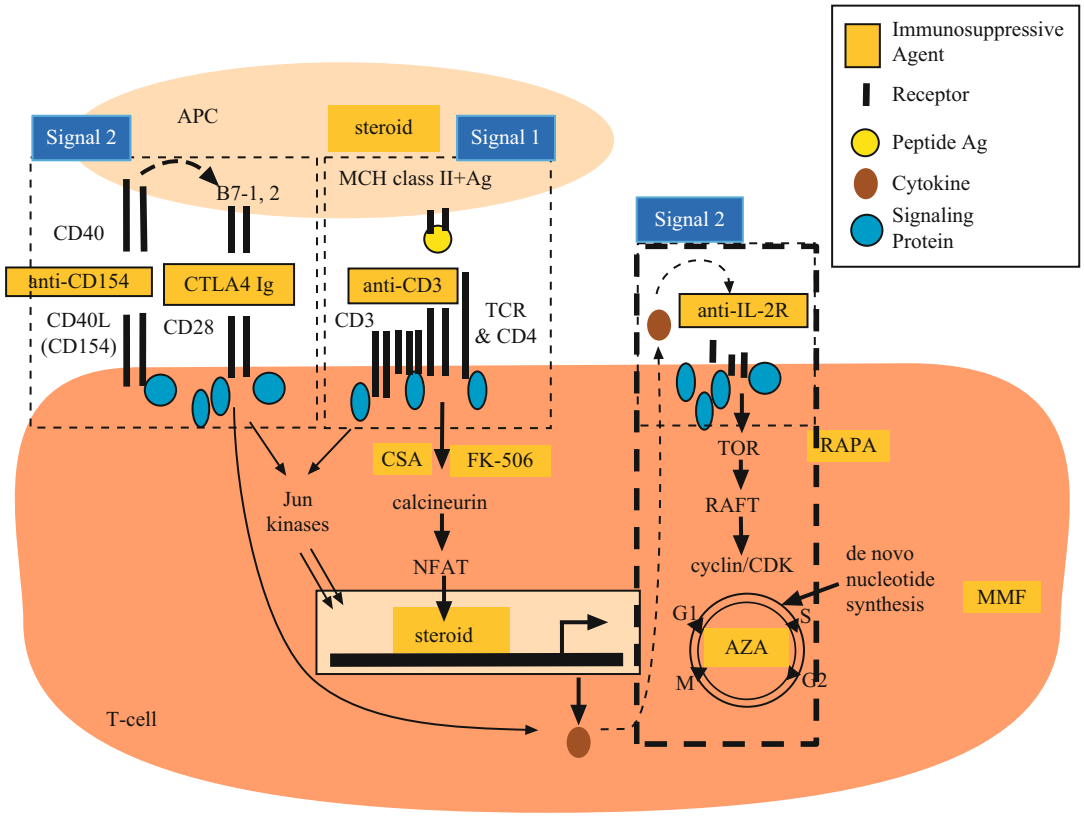

Fig. 153.2 Overview of the major intracellular molecular events that lead to T-cell activation: *signal 1*, *signal 2*, (transcription and production of IL-2), and *signal 3* (response to cytokines (IL-2) followed by cell proliferation). The sites of action of various immunosuppressive agents are also shown. *AZA* azathioprine, *CsA* cyclosporine, *TOR and RAFT* target of rapamycin and FK 506 target, *MMF* mycophenolate mofetil, *RAPA* rapamycin (same site for everolimus), *FK 506* tacrolimus, *TCR* T-cell receptor; anti-CD154 (out of development); CTLA4-Ig, belatacept; anti-CD3, OKT3; anti-IL2R, basiliximab and daclizumab; not shown: anti-CD52 (on all lymphocytes), alemtuzumab; and anti-CD20 (on B-cells), rituximab

mTOR Inhibitors

Sirolimus (rapamycin) and everolimus (Certican) are both prototypic mTOR inhibitors. Sirolimus has been available longer in North America, and subsequently, there is more experience in children. Both drugs appear to have very similar efficacy and safety profiles. Sirolimus acts at a more distal site (late) in the lymphocyte activation cascade. Sirolimus inhibits Ca^{+2}-dependent proliferation of T-cells. Sirolimus also inhibits IL-2-dependent and IL-2-independent proliferation of T-cells. Sirolimus inhibits signaling from growth factor receptors, such as IL-2R. Sirolimus binds to FKBP to create a complex that engages a protein called "molecular target of rapamycin" (*mTOR*, or "rapamycin and FKBP target"). The result is a block in the ability of cytokine receptors to activate cell cycling, which interferes with clonal expansion (proliferation) [105].

The MAP kinase pathway is also activated by "signal 1" via the T-cell receptor. This pathway also activates key cytokine transcription factors (such as AP-1). This pathway seems to intersect with the CD28 pathway (signal 2) at the level of the Jun kinases. CD28 signaling does not seem to contribute to calcineurin-mediated signals and does not seem to be cyclosporine sensitive. CD28 signaling also seems to lead to the translocation of nuclear factor kappa B (NF-κβ) into the nucleus, whereas TCR-mediated signals do not [101].

These two pathways (the calcium-calcineurin pathway and the MAP kinase pathway) lead to the translocation or induction of nuclear-binding proteins involved in cytokine gene expression and other T-cell activation molecules. IL-2 expression has been considered to be a hallmark of activated T-cells. Multiple transcription factors regulate the IL-2 gene, including AP-1, NFκB, Oct-1, and NFAT (nuclear factor of activated T-cells). Importantly, the IL-2 gene expression cannot be induced by a single signaling pathway but rather requires the action of several pathways that integrate at the level of these transcription factors. IL-2 signaling was believed to be critical for allograft rejection, and clinical IL-2R blockade was developed to abrogate this step (see later discussion of *basiliximab* and *daclizumab*). IL-2 signaling is not absolutely required, however, because of redundancy built into the immune system (e.g., IL-2 KO mice subsequently have been found to reject cardiac allografts, with IL-15 having many of the functions of IL-2).

Of interest is a new small-molecule drug in development, tofacitinib, which inhibits the JAK1/JAK3 activation pathway which also would inhibit signal 3. This drug appears promising in clinical trials, with improved renal side effects over CNIs [106].

Antimetabolites (Antiproliferative Agents)

As part of the immune response, activated T-cells divide rapidly. As T-cells move from G_0-G_S, these rapidly dividing cells become targets for antiproliferative (chemotherapy) agents. *Azathioprine* (*AZA*), along with steroids, was the original regimen used for immunosuppression in solid organ transplantation [107, 108]. *Cyclophosphamide* and *methotrexate* are other commonly used agents in this category. We have discussed the proteasome inhibitor *bortezomib* in the AMR section, above.

Azathioprine is a pro-drug that is converted by plasma esterases and glutathione to 6-mercaptopurine. Six-mercaptopurine is further converted to thio-inosine monophosphate, the active metabolite, which is incorporated into DNA inhibiting further DNA synthesis [109]. This is a nonselective inhibitor that causes generalized bone marrow suppression and also affects all rapidly dividing cells. Mycophenolate mofetil in comparison is more lymphocyte selective and has a better safety profile (see below).

The newer antiproliferative agents are *inhibitors of de novo nucleotide synthesis*. *Mycophenolate mofetil* (MMF) is the major member of this category for clinical use. Other members of this family, including mizoribine, brequinar, and *leflunomide*, are not used frequently. *Leflunomide* has a niche in the treatment

of rheumatic disease but may have a role in the maintenance regimen of the transplant patient with active CMV [110, 111].

MMF is a morpholinoethyl ester of mycophenolic acid. Mycophenolic acid is a potent noncompetitive inhibitor of inosine monophosphate dehydrogenase, a key enzyme in the de novo pathway for purine synthesis. Purine synthesis occurs either by the de novo pathway or the salvage pathway in most cells. Lymphocytes are dependent on the de novo pathway. MMF is then a selective inhibitor of lymphocyte proliferation with less nonspecific bone marrow suppression than AZA. The number of specific effector T and B lymphocytes is reduced by limiting clonal expansion. MMF blocks the late events in lymphocyte activation. The improved selectivity compared with azathioprine may provide more effective immunosuppression [112]. MMF is used in place of azathioprine in combination with cyclosporine or tacrolimus, coupling drugs that inhibit late and early events, respectively [113]. MMF has proven to be superior to AZA in almost any immunosuppression regimen when combined with either CSA or tacrolimus [99]. The combination of MMF and tacrolimus is now generally considered to be superior to CSA and MMF in terms of immunosuppression [99]. The long-term side effects of one regimen over the other are not clear.

A recent addition to the treatment options for either the desensitization of a potential recipient or the treatment of donor-specific antibody (DSA) in a transplanted patient is the antimetabolite, proteasome inhibitor *bortezomib* [88]. There is little experience in pediatric transplantation with this drug. Protocols are changing, but in general, bortezomib is used in repeated cycles with IVGG, rituximab (Rituxan, see section "Biologic Agents"), and plasmapheresis [114]. Typically, mycophenolate mofetil is used as maintenance therapy in such a regimen. Although desensitization therapy may improve the chances of being transplanted, there is little data on how desensitization affects long-term outcome, in this group where long-term outcome is clearly worse than the unsensitized recipient.

Corticosteroids: Nonspecific Immunosuppression

Corticosteroids are potent but not specific immunosuppressive and anti-inflammatory drugs. Unlike the mechanisms and drugs discussed thus far, corticosteroids diffuse across the cell membrane. There they associate with the glucocorticoid receptor and translocate into the nucleus and bind to a glucocorticoid response element in DNA. Thus, corticosteroids inhibit transcription of genes involved in the immune and inflammatory response. These generalized effects of corticosteroids are both early and late in our scheme of transplantation immunobiology. Steroids block T-cell activation (early) at the nuclear level and prevent upregulation of cytokine genes (late) required for proliferation in alloimmune and inflammatory responses, including IL-1, IL-2, IL-3, IL-6, FasL, tumor necrosis factor (TNF)-α, and INF-γ.

Steroid therapy is a standard component of induction, maintenance, and anti-rejection therapy. When in a maintenance regimen, steroids are used in combination with an *early* (calcineurin inhibitor) and a *late* (antimetabolite) drug as part of a three-drug regimen [115, 116]. Neonatal and infant lymphocytes may be more sensitive to the effect of steroids [117].

Biologic Agents

Biologic agents are typically reserved either as induction agents or for treatment of cardiac allograft rejection mainly because of the powerful immunosuppressive effects (and side effects, malignancy and infection) of sustained or repeated use of these drugs. One notable exception is the use of belatacept (discussed below) for renal transplantation without the use of CNIs [17].

Biologic agents (antibodies and receptor-specific fusion proteins) are used clinically to target T-cells and B-cells in an effort to modulate the immune response. The biologic agents currently available bind to extracellular antigens (receptors) and either lyse the target cell by fixing

complement or alter signaling via the receptor they bind. This section discusses agents that are targeted at the T-cell activation complex (T-cell receptor, CD3, CD4, or CD8 molecules) first. It then discusses agents that alter the receptors, which mediate signal 2 or 3.

Biologic drugs that are antibodies fall into two main categories: monoclonal antibodies and polyclonal antibodies. Polyclonal antibodies are conceptually easier to understand and have a wide range of cellular targets, not all of which are characterized. They are made by injecting human T-cells into animals (rabbits or horses, typically). Immune sera then is collected from these animals, processed, and quantified. Many different antibodies are generated, all of which bind to various parts of the original injected antigen. Two antithymocyte globulins, commercially available ATGAM (equine) and ATG (rabbit), are polyclonal anti-T-cell antibody preparations made by immunizing animals with human T-cells or thymocytes. These agents deplete human T-cells and abrogate the allograft rejection response. Because they are "polyclonal," however, they have "poly" cellular targets. This contrasts with monoclonal antibodies.

The most widely used monoclonal was Orthoclone-OKT3 (OKT3, muromonab-CD3) which is no longer available. A historical mention of OKT3 as a prototypic cytolytic monoclonal antibody with powerful immunosuppressive properties is warranted. OKT3 had been used extensively in solid organ transplantation. It is a murine monoclonal antibody made via hybridoma technology. The target for this drug is the CD3 molecule, which is universal on T-cells. This agent was used as induction or as antirejection therapy and was typically held in reserve as a second- or third-line agent for resistant rejection or hemodynamically significant rejection. OKT3 was removed from the market because of lack of superiority compared with other biologic agent yet worse rates of associated infection and malignancy. A humanized version of an anti-CD3 antibody (HuOKT3) which would be a chimera has been considered as a replacement but has not made it to market. Chimeric antibodies are monoclonal antibodies that have been altered such that the Fab portion is mouse, but the Fc portion is human.

Alemtuzumab (Campath H1) is an example of a chimeric antibody which is currently in use in transplantation (off-label) as either an induction agent or for the treatment of rejection [118]. Alemtuzumab is directed against the CD52 molecule which is found on virtually all lymphocytes including T-cells, B-cells, and cells of the innate immune system including NK. It is a lytic agent which leaves the patient extremely lymphopenic for an extended period, months to a year or more. It has been used as an induction agent for heart transplantation. We have also had significant success using it as salvage therapy for patients with severe rejection resistant to steroids and other T-cell therapies (ATG, OKT3, etc.).

For the treatment of AMR or some post-transplant lymphoproliferative disease (PTLD), a monoclonal Ab rituximab (Rituxan) is being used. Rituximab is directed against CD20 which is expressed on B-cells. It is a lytic agent which causes B-cell depletion. For the presensitized recipient or the patient with AMR, it is typically coupled with IVIG and plasmapheresis to remove preformed antibody [7, 96, 114]. Unfortunately, CD20 is present on B-cells but is downregulated on plasma cells which actually make antibody [119]. New strategies and drugs which target regulator molecules on plasma cells are in development [106]. Some promising targets to control humoral immunity include the B-cell-activating factors (BAFF). Belimumab is a humanized Ab that targets BAFF on plasma cells. It has been effective in the treatment of SLE [120] but may have a role in sensitized transplant patients and AMR. It is currently in early clinical trials.

Biologic agents directed at various targets on lymphocytes and APCs represent the greatest promise in transplantation. They represent the beginning of an era when the paradigm of immunosuppression turns toward immune regulation and graft tolerance. Although biologic agents such as OKT3 had been a mainstay in cardiac transplantation for years, there is currently a shift in the design of these agents away from lytic agents that affect all lymphocytes, to agents which are more precise in their effect. The agents that are available in this

category are expanding rapidly. Many agents are being developed for autoimmune diseases like rheumatoid arthritis, SLE, or dermatologic conditions. The agents that bind (inhibit) the IL-2 receptor (IL-2R) are examples of this trend. Newer agents are intended to be less cytolytic but rather block key signals required for immune activation.

Costimulation as a Therapeutic Target

Costimulation (signal 2 or signal 3) is a critical event for T-cell activation as noted above. They have great potential as targets for immune intervention in solid organ transplantation. Targeted mechanisms have included IL-2 receptor and CD28-CD80/86 pathway as well as the CD40-CD154 pathway, which we will discuss briefly below.

Interleukin-2 Receptor Inhibition

IL-2 is believed to be one of the critical cytokines required for the activation and proliferation of the immune response. At least part of the mechanism of action of cyclosporine and tacrolimus is the inhibition of IL-2 production. Blockade of the IL-2 receptor (IL-2R) pathway is a successful, currently used strategy for solid organ transplantation [121, 122]. Two commercially available products have been used. Daclizumab (Zenapax) is a humanized IgG1 monoclonal antibody against the alpha-chain of the IL-2 receptor (IL-2R, CD25). It appeared to be an effective induction agent but has recently been removed from the market and is no longer available for clinical use. Basiliximab (Simulect) is a chimeric monoclonal antibody. Both drugs specifically bind to the IL-2R and block signaling through this receptor. IL-2R is expressed by T-cells that participate in allograft rejection but not by resting T-cells.

Cognate Costimulatory Targets

The CD28-CD80/86 and CD40-CD154 pathways of CoS have been used as key targets of therapeutic intervention to prevent allograft [20, 123] and even xenograft rejection [124] in animal models. Blockade of the CD40-CD154 pathway in human trials was halted because of thromboembolic complications; newer agents are in development which may avoid this complication (discussed below). However, blockade of the CD28-CD80/86 pathway has reached human clinical trials. *Belatacept* is a fusion protein of CTLA4-Ig with high affinity to CD80/86, thus inhibiting a major costimulatory pathway. Equivalent patient and graft survival were seen with belatacept compared with cyclosporine and superior renal function in the belatacept group [17]. This drug may herald in a new way in which biologic agents are used in transplantation.

T-Cell Activation, Self-Tolerance, and Clinical (Prope) Tolerance

As discussed above, a fundamental property for T-cell activation is that antigen alone is not sufficient for efficiently triggering the response [12, 125]. For antigen to activate a T-cell, a "second signal" or costimulation (CoS) is required. Most antigens are encountered in the absence of a CoS+ signal. APCs from an inflammatory environment, such as the site of infection or trauma, might be more likely to provide a second signal (CoS). Under most normal conditions, self-antigens result in *nondestructive* immunity or no response (Fig. 153.1). Most cells that have self-reactive (autoreactive) potential have been deleted during lymphocyte development in the thymus in the process of *central tolerance*. An important caveat is that autoreactive cells are known to exist in non-autoimmune individuals, an example of *peripheral tolerance*. In patients who develop autoimmunity, however, these autoreactive cells are able to mount a destructive response. Likewise, in allograft immunity, alloantigens can result in no response (anergy), destructive immunity (rejection), or nondestructive immunity (tolerance). Lack of a response (anergy) is believed to occur when antigen is present in the absence of a costimulatory signal. Nondestructive immunity requires that the alloreactive T-cells are either regulated or deleted.

Calcineurin Inhibitors and Allograft Tolerance

Allograft tolerance has been the "Holy Grail" of transplantation research for more than 40 years. Experimental tolerance can be achieved in rodent models, but it has been difficult to translate into primates or humans. In part, the inability to translate tolerance into humans is the result of the calcineurin inhibitor (cyclosporine, tacrolimus)-based protocols that have made allograft transplantation so successful. This is related to the concept introduced in Fig. 153.1. Allograft rejection (destructive immunity) and allograft tolerance (nondestructive immunity) are active processes. In many models of tolerance induction, the presence of these drugs (calcineurin inhibitors) at the time of induction prevents tolerance. This may have great impact on the design of protocols for transplantation in humans in the future.

Special Considerations: The Neonate as a Recipient

The immune system changes dramatically during postnatal development, not only in the first years of life but also through adolescence and even into adult life. These age-dependent changes in the immune system complicate any attempt to assess the requirements for immunosuppression in children. For example, cord blood T-cells seem to be more sensitive to inhibition of proliferation by steroids. This sensitivity to steroids still can be observed in the first 2 weeks after birth, but it subsequently decreases till 1 year of age, when the adult response pattern has been acquired [117]. Further, the acquired immune experience of heterologous immunity and memory T-cells makes transplantation immunologically more challenging with time from birth, particularly in an ill child with congestive heart failure.

Maturation of the adaptive immune system occurs early in development, and by 14 weeks' gestation, the developing fetus has circulating differentiated T-cells and B-cells capable of responding to antigen. Many components of the neonatal immune system appear to be programmed to respond less in an inflammatory fashion compared with adults (see section on "Fate of Activated T-cells"). This has given rise to the concept of an "immunodeficiency of immaturity," which clearly has an inflammatory bias. The significance of this neonatal and infant immunodeficiency for solid organ transplantation remains to be fully explored.

Interestingly, there appears to be a decreased percentage of natural killer cells. There is also a decreased number and percentage of B-cells, ability to produce antibodies against nonprotein antigens, and reduction in complement activity [126, 127]. However, murine neonatal dendritic cells (DC) demonstrated enhanced TLR responses in comparison to adult cells [128]. Neonatal B-cells were found to have unique immunoregulatory functions that impaired DC responses to TLR activation in an IL-10-dependent fashion. This skewed T-cell responses impairing Th1, but not Th2, T-cell alloimmune responses in vitro and in vivo, in models of alloimmune priming and allotransplantation [128].

Neonatal T-cells are believed to have a Th2 bias. Neonatal T-cells can be driven toward a Th1 phenotype under strong CD28 costimulation conditions (IL-2, IFN-γ, and TNF-β), whereas in the context of low CD28, costimulation yields a Th2 response (IL-4 and IL-13) [129]. Neonates and infants have increased numbers (10–20 % of lymphocytes) of CD4 T-cells as "naive" cells ($CD45RO^{-}/RA^{+}CD31^{-/-}$), which are rare in adults, while low numbers of CD4 "memory" T-cells ($CD45RO^{+}/RA^{+}$).

Healthy children differ markedly compared with adults in their ability to produce cytokines (IL-2, IFN-γ, IL-4, and IL-6) [127]. Analysis of cytokine production demonstrates that all cytokines increase gradually and steadily after birth. IFN-γ and IL-10 production is low at birth, whereas IL-2 and IL-4 production are not. In vitro stimulation of neonatal cells demonstrates impaired cytokine production with markedly lower levels of all four cytokines produced compared with adult levels. When stimulated with antigen, IL-2 and IL-4 remained lower than adult values; IL-6 production was increased, as was IFN-γ albeit not significantly [130].

The effect of thymectomy, a common practice among neonatal cardiac surgeons at the time of congenital cardiac surgery or transplantation, is unknown. At 12 months after thymectomy, the percent of CD3+ and CD4+ T-cells but not CD8+ T-cells was found to be significantly less than in controls. Lymphocyte proliferation to a mitogen, phytohemagglutinin, and antibody response to tetanus toxoid were normal at 12 months. No increased incidence of infection has been reported after thymectomy. Neonatal thymectomy results in a modest decrease in T lymphocyte levels but no detectable decrease in immune function [131]. Its effect in the face of solid organ transplantation and immunosuppression is unknown; however, the thymus is necessary for the induction of acquired tolerance in some model systems [132].

Taken together, the neonate or infant is much more likely to achieve clinical tolerance than the adult. As new agents emerge with tolerizing potential, this group of patients is likely to benefit the most.

Summary

Transplantation has been performed clinically for five decades and has become the standard of care for end-stage organ failure. Understanding of the immunobiology of transplantation has made tremendous advances, but knowledge still lags, and as a result, nonspecific immunosuppression remains the standard therapy in 2013. This chapter has presented an overview of current knowledge of the immunobiology of solid organ transplantation, with emphasis on T-cell activation (antigen presentation, CoS) and cellular allograft (transplantation) immunity. The molecular events of T-cell activation, with some emphasis on the sites of action of modern immunosuppression, are reviewed. A simplified approach to understanding the immunobiology and strategy of maintenance immunosuppression is discussed. Key early and late steps in T-cell activation and the sites of action of immunosuppressive agents are reviewed. The required cellular interactions for alloimmunity and the relevant biologic targets are also reviewed. Special considerations for the immunology in neonates, infants, and children as recipients are provided. Understanding the immunobiology of transplantation is essential to making decisions about children with transplants, developing better protocols, and creating clinical tolerance in the future.

Immunosuppressive Medications 154

Donald Berry and Brian Feingold

Abstract

Immunosuppression following pediatric thoracic transplantation is typically centered on the use of calcineurin inhibitors, either cyclosporine or tacrolimus. While there is general agreement on the use of immunosuppressive medications for induction therapy, maintenance immunosuppression, and treatment of acute rejection, there is center-to-center variability with respect to target trough levels, changes in targets over time following transplantation, and selection and use of adjunctive immunosuppressive agents. In this chapter, the medications and therapies used to care for pediatric heart and lung transplant recipients are reviewed and discussed.

Keywords

Alemtuzumab • Antithymocyte globulin • Azathioprine • Basiliximab • Bortezomib • Calcineurin inhibitor • Corticosteroids • Cyclosporine • Everolimus • Heart transplantation • Intravenous immunoglobulin (IVIG) • Lung transplantation • Methylprednisolone • mTOR • Mycophenolic acid • Mycophenolate mofetil • Tacrolimus • Pediatric • Prednisone • Rituximab • Sirolimus

Introduction

Various immunosuppressive medication regimens exist for patients after thoracic organ transplantation. Essentially, all have in common the use of a calcineurin inhibitor (i.e., cyclosporine, tacrolimus) as the primary immunosuppressant. Most regimens in children also utilize an adjunctive immunosuppressant agent, such as mycophenolate mofetil, azathioprine, or sirolimus. Corticosteroids are also commonly used after thoracic organ transplantation, with a dual role as a chronic immunosuppressant in many recipients but also as a treatment for acute rejection. Other therapies, such as pooled gamma globulin (IVIG) or other targeted antibody preparations, proteasome inhibitors, and plasmapheresis, play specialized roles in the management of the thoracic organ recipient.

In this chapter, the medications and therapies used to care for pediatric heart and lung transplant recipients are reviewed. Agents are discussed by class, rather than by timing of introduction to the posttransplant care regimen; however, details about typical use and relative differences in use according to common clinical scenarios are discussed. This chapter is not intended to be a comprehensive guide to transplant-related immunosuppressive medications, but rather a clinically relevant discussion of drugs, principles of usage, doses, drug interactions, and side effects. Also, because the pediatric thoracic organ experience is much smaller than experience in adults and because thoracic organ transplantation is less common than renal and liver transplantation, much of the evidence for how these medications are used is derived from outside of the pediatric and thoracic organ recipient populations.

Calcineurin Inhibitors

The success of modern-day solid organ transplantation stems directly from the introduction of the calcineurin inhibitors (CNIs) cyclosporine and tacrolimus [1, 2]. Whereas prior to the use of CNIs, the standard end points of clinical trials in organ transplantation were 1-year recipient and allograft survival, in the current era median heart transplant recipient survival is between 12 and 18 years [3]. These drugs are the cornerstone of nearly all posttransplant immunosuppressive regimens; the exception being late posttransplant regimens in which the toxicities of chronic CNI exposure, mainly renal insufficiency, are thought to pose a greater risk than acute allograft rejection. In these instances, low-dose CNI regimens or complete CNI-withdrawal regimens may be implemented [4–6].

CNIs block intracellular T-lymphocyte signaling, resulting in decreased T-lymphocyte activation [7]. It is important to note that in any one patient, either cyclosporine *or* tacrolimus is used, never both. Since late posttransplant graft survival rates are equivalent, the decision on whether to use one or the other is usually driven by transplant center preference. Occasionally, patients are switched from cyclosporine to tacrolimus because of its association with lower rates of hypertension and hyperlipidemia [8]. Cyclosporine is also associated with gingival hyperplasia, hirsutism, and coarsening of facial features, effects not seen with tacrolimus. Patients may be switched from tacrolimus to cyclosporine because of side effects such as posttransplant diabetes or neurological symptoms which are probably more common with tacrolimus [9].

CNIs are initiated early after transplantation, usually hours to days following transplant surgery, though the use of intravenous formulations is uncommon because of the high risk of acute renal failure. Dosing is monitored and adjusted according to trough blood plasma levels obtained at the end of the dosing interval (i.e., just before the next scheduled dose is taken). Targeted plasma levels are highest early after transplantation and are decreased over time, in the absence of acute rejection and in accordance with institutional protocol. Late posttransplant drug levels are often 30–40 % of the early posttransplant targets.

Cyclosporine

Dosing

If cyclosporine therapy is initially begun with IV dosing, 3–5 mg/kg/day is given either as a continuous infusion over 24 h or in two divided doses. The dose should be adjusted based on serum levels, and enteral dosing should be initiated as soon as feasible. Note that the oral dosage for cyclosporine is approximately three times the IV dosage.

For oral initiation of cyclosporine, 10–15 mg/kg daily divided in two daily doses is often used. Again, dosing should be based on serum levels. Oral dosage forms are available as both modified and non-modified formulations, which cannot be used interchangeably. The modified cyclosporine has increased bioavailability over the non-modified form. If the dosage forms are changed, close monitoring of cyclosporine levels must be performed. Liquid formulations have dosage form and brand specific administration directions (diluents, mixing, glass containers only), so the manufacturers recommendations should be reviewed and followed.

Pharmacokinetics

Cyclosporine is incompletely and erratically absorbed when given orally and undergoes a large first-pass metabolism. The bioavailability of Sandimmune® capsules and the oral solution (non-modified) is approximately 28 % in children. Currently, almost all children receive microemulsion (modified) formulations, such as Neoral® capsules and oral solution, which have a bioavailability averaging 43 % in children, ranging from 30 % to 68 %. Cyclosporine is extensively metabolized in the liver by CYP3A4 enzymes. Clearance is affected by age, with pediatric patients clearing cyclosporine more rapidly than adults. The half-life of cyclosporine is 7–19 h in children and 19–40 h in adults. Metabolites are excreted primarily through the bile into feces [10].

Early posttransplant, heart transplant recipient serum levels are often targeted around 300 ng/mL. After 4–6 months this may be decreased to 250 ng/mL and weaned thereafter to a target of 50–100 ng/mL years after transplantation in the setting of a benign rejection history. Lung and heart-lung transplant recipients are often maintained at target levels that are 50 ng/mL higher than heart transplant recipients.

Drug-Drug Interactions

Cyclosporine is involved in many drug interactions. Perhaps most significant is the interaction with "azole" antifungals that inhibit metabolism of cyclosporine, requiring a dose reduction of at least 50 % with fluconazole and 75 % with voriconazole. Grapefruit juice may also increase cyclosporine blood concentrations and should be avoided. Other commonly used drugs that can increase cyclosporine concentrations include acyclovir, aminoglycosides, amphotericin B, erythromycin, metoclopramide, ketoconazole, diltiazem, verapamil, methylprednisolone, lovastatin, simvastatin, and cimetidine. St. John's Wort should also be avoided as it may significantly decrease cyclosporine concentrations. Phenytoin, phenobarbital, carbamazepine, rifampin, trimethoprim, and nafcillin decrease cyclosporine concentration by increasing hepatic metabolism. There is an increased risk of hyperkalemia when potassium-sparing diuretics are used concomitantly. Nonsteroidal antiinflammatory drugs (NSAIDs) increase the risk of nephrotoxicity when administered with cyclosporine, and sirolimus used in combination with cyclosporine has been associated with hemolytic uremic syndrome. Digoxin may undergo reduced clearance when used with cyclosporine and should be monitored closely. Lovastatin, simvastatin, and atorvastatin should be avoided due to reduced metabolism when used with cyclosporine. Pravastatin or rosuvastatin may be used in low doses with close monitoring.

Adverse Effects

The principal adverse reactions to cyclosporine therapy include renal dysfunction, hypertension, hyperkalemia, tremor, hyperlipidemia, and gingival hyperplasia. Nephrotoxicity occurs in the majority of patients on long-term therapy.

Hypertension, tachycardia, flushing, headaches, seizure, tremor, paresthesias, and insomnia may occur. Patients may also develop, hypomagnesemia, hyperuricemia, abdominal discomfort, nausea, diarrhea, hepatotoxicity, and hirsutism. Blood/serum drug concentration (trough), renal and hepatic function, serum electrolytes, lipid profile, blood pressure, and heart rate should be monitored periodically while the patient is taking cyclosporine. As with all potent immunosuppressants, opportunistic infections and posttransplant lymphoproliferative disorders may occur.

Tacrolimus

Dosing

Nearly all patients are maintained on twice daily tacrolimus. The starting oral dose is 0.1–0.2 mg/kg/day in divided doses every 12 h. An extended release formulation, which is not approved by the US FDA, has been evaluated in a few small studies in liver and kidney transplant recipients. In these limited assessments, no increase in rejection events has been reported [11, 12]. One potential benefit of this formulation would be enhanced adherence.

Initially, if oral intake is not tolerated, an IV continuous infusion of 0.02–0.05 mg/kg/day may be used in children [13]. When switching to oral therapy, it is important to remember the oral dose should be 3–4 times the IV dose. However, since IV use may lead to decreased urine output after cardiopulmonary bypass, IV tacrolimus is rarely used. More commonly, induction therapy with T-cell-depleting antibodies is used, allowing for delayed introduction of tacrolimus orally.

Pharmacokinetics

The oral bioavailability of tacrolimus has a large range of 5–67 %, with an average of 30 %. Administration with food reduces absorption by an average of 33 %. Tacrolimus is hepatically metabolized by CYP3A4 enzymes. Plasma protein binding ranges from 75 % to 99 %. Tacrolimus has an average half-life of 8.7 h, ranging from 4 to 40 h. Pediatric patients clear the drug twice as rapidly as adults and require higher doses on a milligram per kilogram basis to achieve similar blood concentrations. Tacrolimus is primarily eliminated in bile, with less than 1 % excreted as unchanged drug in urine [10].

Early posttransplant, heart transplant recipients are often targeted around 10–12 ng/mL. After 4–6 months this may be decreased to 8 ng/mL and weaned thereafter to a target of 5–7 ng/mL years after transplantation in the setting of a benign rejection history. Lung and heart-lung transplant recipients are often maintained at target levels that are 2–3 ng/mL higher than heart transplant recipients.

Drug-Drug Interactions

Diltiazem, verapamil, nifedipine, fluconazole, itraconazole, ketoconazole, cimetidine, clarithromycin, erythromycin, methylprednisolone, protease inhibitors, and oral clotrimazole increase tacrolimus serum concentrations. Drugs that decrease tacrolimus serum concentrations include antacids, cholestyramine, sodium polystyrene sulfonate, carbamazepine, phenobarbital, primidone, phenytoin, rifabutin, rifampin, and St. John's Wort. NSAIDS, nephrotoxic antibiotics, and amphotericin B may cause additive nephrotoxicity when administered with tacrolimus. Tacrolimus should not be used in combination with cyclosporine.

Adverse Effects

Common adverse effects from tacrolimus therapy are neurotoxicity (tremor, headache, paresthesias), hyperglycemia (more common when used with corticosteroids), and hypomagnesemia. Patients may also experience GI symptoms such as diarrhea, nausea, vomiting, and constipation or less common neurological symptoms of insomnia, dizziness and seizures. Other potential side effects include hypertension, QT interval prolongation, hyperkalemia, alopecia, pruritus, and rash. Serious adverse effects of tacrolimus that can be seen are opportunistic infections, posttransplant lymphoproliferative disorder, and diabetes mellitus.

Though blood tacrolimus concentrations should guide dosage adjustments, liver enzymes, blood urea nitrogen (BUN), serum creatinine, glucose, potassium, magnesium, phosphorus, complete blood cell count (CBC) with differential, blood pressure, neurological status, and electrocardiography should be monitored regularly to detect adverse effects of tacrolimus therapy.

Corticosteroids

Corticosteroids (steroids) exert their immunosuppressive effect by interrupting multiple steps in immune system activation, inhibiting antigen presentation, cytokine production, and lymphocyte proliferation [14]. Because of these broad immunosuppressive effects, steroids play a significant and multifaceted role in the management of thoracic transplant recipients. Perioperatively, a high dose of intravenous (IV) methylprednisolone (15–20 mg/kg) is typically used prior to allograft reperfusion, with continued dosing in the immediate postoperative phase. After heart transplantation, some centers choose to wean off completely within a few days (steroid avoidance), while others maintain patients on steroids for varying durations, ranging from 6 to 12 months (steroid withdrawal) to indefinitely. Data from the few randomized prospective studies of chronic steroid use among adult renal transplant recipients suggest that both steroid avoidance and withdrawal protocols are associated with increased rejection [15, 16], and most immunosuppressive regimens in adult heart transplantation include chronic, low-dose steroids in combination with a CNI and an adjunctive agent (e.g., MMF or sirolimus) [17]. The data are less clear following pediatric heart transplantation, and steroid avoidance and withdrawal protocols are more common than among adult recipients. Of note, because the requirements for immunosuppression are greater after lung or heart-lung transplantation, most of these patients are maintained on chronic steroids (triple-drug immunosuppression) indefinitely.

Steroids also serve a role as the first-line response to significant acute rejection episodes. In this setting, bolus intravenous dosing for 3–5 days is common, though oral prednisone or prednisolone may sometimes be substituted, dependent on the clinical situation. Patients with severe, recurrent, or refractory rejection events are also commonly placed onto chronic steroids as part of their maintenance regimen.

Methylprednisolone and Prednisolone/Prednisone

Dosing

Perioperatively, a 15–20 mg/kg dose of methylprednisolone IV is given. Then a gradual tapering dose beginning with 2 mg/kg/day may be given as a premedication to antilymphocyte antibodies.

High-dose intravenous (IV) methylprednisolone is the standard for episodes of acute rejection; typical dosing is 10 mg/kg once daily for 3 days or more. Some transplantation centers use moderate-dose oral prednisone for less severe episodes of acute rejection (e.g., 2 mg/kg for 5 days, sometimes followed by a taper).

Those centers that use long-term maintenance therapy typically use prednisone in doses of 0.5–1 mg/kg/day, with a maximum daily dose of 40–60 mg, given orally in single daily doses for the first 2 weeks after transplantation. Subsequently, the prednisone is weaned to long-term maintenance doses of 0.05–0.15 mg/kg/day. Some centers continue low-dose prednisone indefinitely, whereas others wean to discontinuation in the first few months if the rejection history is benign. Increasing evidence suggests that complete steroid avoidance beyond the intraoperative period is possible in many children, especially infants [18].

Pharmacokinetics

The peak effect is dependent on the route of administration of the corticosteroid. Onset of action after IV injection is almost immediate, while peak effect occurs within 1–2 h after oral

administration. The duration of activity of an oral dose is 30–36 h. Corticosteroids are metabolized in the liver by several CYP-450 enzymes. The half-life is 3–3.5 h, and elimination is via the kidneys [10].

Drug-Drug Interactions

Corticosteroid clearance will be increased if given with phenytoin, phenobarbital, or rifampin. Potassium-depleting diuretics such as furosemide enhance potassium depletion caused by corticosteroids. While glucose levels may be increased by corticosteroids, persistent diabetes mellitus may develop when corticosteroids are used in combination with cyclosporine or tacrolimus. Finally, tacrolimus levels may be increased by IV bolus doses of methylprednisolone.

Side Effects

Acute adrenal insufficiency may occur with abrupt withdrawal after long-term use, so withdrawal or discontinuation of corticosteroids should be done gradually.

Corticosteroids can have adverse effects on the endocrine and metabolic systems including Cushing's syndrome, pituitary-adrenal axis suppression, growth retardation, glucose intolerance, hypokalemia, alkalosis, weight gain, hyperlipidemia, and salt and water retention. Edema and hypertension may develop. Blood pressure, weight, height, serum electrolytes, and glucose should be monitored regularly. Other adverse effects include acne, skin atrophy, impaired wound healing, hirsutism, transient leukocytosis, muscle weakness, osteoporosis, and fractures. Patients should be monitored for onset of vertigo, seizures, psychoses, pseudotumor cerebri, cataracts, glaucoma, or peptic ulcer. Oral dosage forms may cause nausea or vomiting.

Antimetabolites

Medications in this class inhibit DNA synthesis by blocking the production of adenine and guanine (purines) and thereby preventing proliferation of both T- and B-lymphocytes [19]. In the 1960s, azathioprine (AZA) was used alone, and later in combination with corticosteroids, for immunosuppression after renal transplantation [20, 21]. After the introduction of CNIs, maintenance immunosuppression commonly consisted of cyclosporine/tacrolimus, azathioprine, and corticosteroids. Mycophenolate mofetil (MMF) replaced azathioprine in the mid-to-late 1990s after studies in renal transplantation showed enhanced patient and allograft survival with decreased allograft rejection [22, 23]. In a randomized, blinded study of MMF vs. AZA in adult heart transplant recipients, MMF showed improved 1-year survival and decreased treated rejection events, with a small increase in opportunistic infections [24]. In contrast to sirolimus, which also may be used as an adjunctive immunosuppressive medication, MMF lacks nephrotoxicity and does not alter the lipid profile. Its main side effects are gastrointestinal (diarrhea, abdominal pain, anorexia) and hematologic (leukopenia, anemia). The availability of an enteric-coated formulation of the active agent, mycophenolic acid (Myfortic®), can ameliorate the gastrointestinal side effects for some patients.

Azathioprine

Dosing

Azathioprine dosage must be carefully individualized according to patient response. The usual initial dose is 2–5 mg/kg/dose once daily given IV or orally, with maintenance dose range of 1–2 mg/kg/day. The dosage of azathioprine must be adjusted for renal dysfunction and should be reduced if significant bone marrow suppression develops.

Pharmacokinetics

Azathioprine is a prodrug that undergoes extensive hepatic metabolism to 6-mercaptopurine (6-MP), the active metabolite. 6-MP has a bioavailability of 50 % and is 30 % protein bound. The half-life of AZA is 12 min and of 6-MP is 0.7–3 h. In anuric patients, the half-life of 6-MP increases to 50 h. Metabolites and

a small amount of unchanged AZA are eliminated eventually in the urine [10].

Drug-Drug Interactions

Concomitant azathioprine therapy with angiotensin-converting enzyme (ACE) inhibitors such as captopril and enalapril may induce severe anemia and leukopenia and should be avoided. Xanthine oxidase is important in the conversion of 6-MP to its inactive metabolites. Because allopurinol inhibits this enzyme, dosage reduction of AZA to 25–33 % of the normal dose is necessary when this drug combination cannot be avoided. Olsalazine, mesalamine, and sulfasalazine may inhibit thiopurine methyltransferase (TPMT) metabolism of 6-MP, increasing the risk of myelosuppression by AZA; therefore, careful monitoring is required. Decreased anticoagulant effectiveness by warfarin may be seen with AZA use.

Adverse Effects

Azathioprine can cause bone marrow suppression, leukopenia, macrocytic anemia, and thrombocytopenia. Hematological effects are dose-related and usually respond to dosage reduction. During severe toxicity, the white blood cell (WBC) count and hemoglobin levels drop first, followed by a decreasing platelet count. Gastrointestinal adverse effects such as nausea, vomiting, anorexia, and diarrhea may occur in patients who are receiving large doses of AZA. These GI effects may be avoided by giving AZA in divided doses and/or with meals. As with all immunosuppressants, there is an increased risk of infection. Fungal, protozoal, viral, and uncommon bacterial infections may occur, with the highest risk during significant leukopenia. If infection occurs, the dosage of AZA (and other immunosuppressive agents) should be reduced as much as possible and appropriate antiinfective therapy instituted. Hepatotoxicity may occur as well as hepatic sinusoidal obstruction syndrome.

CBC with differential, platelet count, creatinine, total bilirubin, alkaline phosphatase, and liver function should be monitored in all patients taking azathioprine.

Mycophenolate Mofetil (Cellcept®)/ Mycophenolic Acid (Myfortic®)

Dosing

The initial oral or IV dose of mycophenolate mofetil (MMF) in children is 600 mg/m^2/dose twice daily, with a maximum initial dose of 2 g/day. An alternative dosing of 30–45 mg/kg/day divided every 12 h can be used. However, some pediatric patients require every 8 h dosing because of rapid clearance. Gastrointestinal side effects are common and may be reduced if dosing is started lower (i.e., 20 mg/kg/day divided every 12 h) and dosing is gradually increased to target dose and/or levels.

If mycophenolic acid (MPA) delayed release tablets are used, the initial maximum target dose is 1,080 mg given twice daily. It is important to note that mycophenolate mofetil and mycophenolic acid delayed release tablets cannot be used interchangeably. Mycophenolate mofetil doses as high as 3–3.5 g/day were used in clinical trials, but with no greater efficacy than lower doses, and side effects were more common.

Pharmacokinetics

MMF has rapid and extensive absorption, and the bioavailability is 81–94 %. Mycophenolate mofetil is metabolized to MPA after oral or intravenous administration, and MPA, in turn, is glucuronidated to the inactive MPA glucuronide (MPAG). The half-life of MPA is approximately 18 h. Most of the drug (87 %) is excreted in the urine as MPAG [18].

Use of therapeutic drug monitoring remains controversial. Many centers choose to dose based on weight and utilize a fixed-dose regimen. Because fairly good associations of MPA concentration and its pharmacologic effects have been demonstrated, monitoring of trough MPA levels may be utilized though target levels have not been well established.

Drug-Drug Interactions

Magnesium supplements or antacids containing aluminum or magnesium hydroxide decrease the absorption of mycophenolate unless separated by 2 h or more. Cholestyramine decreases plasma MPA concentrations via binding mycophenolate metabolites in the intestines and should be avoided.

Acyclovir/valacyclovir and ganciclovir/valganciclovir compete with MPAG for tubular secretion, possibly resulting in increased concentrations of the antiviral agents and increasing the risk of toxicities.

Probenecid inhibits tubular secretion MPA and MPAG resulting in increased concentrations of both. Rifampin, on the other hand, significantly reduces MPA blood concentrations requiring increased mycophenolate dosage if used together.

Adverse Effects

Common adverse effects are gastrointestinal and include diarrhea or constipation, nausea, and vomiting. A delayed release tablet (Myfortic®) was designed to reduce adverse GI events by slowly delivering drug to the small intestines and may be helpful in patients intolerant to standard release formulations. Heart transplant patients may also experience hypertension, edema, hypercholesterolemia, hyperglycemia, hypokalemia, anxiety, insomnia, headache, elevated BUN and creatinine, fever, and pain. Serious hematological abnormalities may occur including leukopenia, anemia, and thrombocytopenia. CBC with differential and platelet count should be monitored. As with other immunosuppressive agents, there is an increased risk of infection with mycophenolate therapy.

Proliferation Signal Inhibitors (Mammalian Target of Rapamycin (mTOR) Inhibitors)

Until recently, sirolimus was the only proliferation signal inhibitor approved for systemic use in the USA. Both sirolimus and everolimus bind FKBP12, the same target as tacrolimus, but do not inhibit calcineurin. Rather, the complex binds target of rapamycin and prevents cell cycle activation, thereby preventing lymphocyte proliferation. Sirolimus, also known as rapamycin, is most commonly used as an adjunctive immunosuppressive agent. However, in some patients in whom CNI have been fully withdrawn for toxicities, sirolimus may be supplemented by MMF and/or steroids for immunosuppression. Sirolimus use in solid organ transplantation has been limited by its side effect profile, primarily the additive nephrotoxicity which may occur when used in combination with either cyclosporine or tacrolimus [25]. Sirolimus use is also associated with impaired wound healing, limiting its utility early after transplantation for fear of sternal wound dehiscence [26]. While animal and limited human data suggest that sirolimus and everolimus slow the progression of coronary allograft vasculopathy (i.e., chronic rejection) [27, 28], further research is needed before superiority over MMF in this domain can be established.

Sirolimus

Dosing

The usual dosing for children begins with an oral loading dose of 3 mg/m^2 on day 1, followed by 1 mg/m^2/day administered daily or as twice daily dosing. In one study of sirolimus dosing in pediatric heart transplants, an average dose of 0.25 mg/kg/day (or 7 mg/m^2/day) was required to maintain target sirolimus levels of 5–15 mcg/mL [29]. Adults $\geq$40 kg can be loaded with 6 mg orally for 1 day and then given a maintenance dose of 2 mg/day. Doses should be taken consistently either with or without food. Subsequent dosing is adjusted to maintain sirolimus trough levels between 3 and 7 ng/mL. Higher target sirolimus levels may be used if there is a clinical indication to maintain CNI levels very low because of side effects or toxicities. Data from clinical trials suggest that creatinine levels will be higher when cyclosporine is used with sirolimus than when used with mycophenolate mofetil or

azathioprine, necessitating careful monitoring of renal function. Since sirolimus can impair wound healing, it should probably be avoided until surgical sites are healed.

Pharmacokinetics

Sirolimus is absorbed rapidly and reaches a peak concentration within 1–3 h for the oral solution and 1–6 h for tablets. Bioavailability is approximately 14–18 %, with extensive distribution to red blood cells and tissues. Sirolimus is hepatically metabolized by the CYP3A4 enzyme. The half-life averages 14 h in children and 62 h in adults. The majority (91 %) of sirolimus is eliminated in the feces [10].

Drug-Drug Interactions

Concurrent therapy with sirolimus and cyclosporine can result in increased sirolimus toxicity manifested by anemia, leukopenia, thrombocytopenia, hypokalemia, and diarrhea. Administration of sirolimus 4 h after the cyclosporine dose reduces this effect. Tacrolimus levels are reduced when combined with sirolimus therapy, and adverse effects of both drugs can occur. Care should be used when these drugs are used in combination.

Sirolimus is metabolized by CYP3A4. Inhibitors of CYP3A4 (calcium channel blockers, azole antifungal agents, macrolide antibiotics, and protease inhibitors) can increase sirolimus concentrations.

CYP3A4 inducers (rifampin, phenobarbital, carbamazepine, fosphenytoin, and phenytoin) decrease serum concentrations of sirolimus. Grapefruit juice may reduce the metabolism of sirolimus and should be avoided during therapy with sirolimus.

Adverse Effects

Some of the more common adverse effects of sirolimus therapy include hypertension, peripheral edema, fever, headaches, pain, acne, rash, impaired wound healing, nausea, diarrhea, constipation, abdominal pain, increased serum creatinine, and arthralgias. The more serious complications involve hematologic abnormalities including anemia, neutropenia, and thrombocytopenia. Hyperlipidemia is common and may include severe hypercholesterolemia and hypertriglyceridemia. Hepatotoxicity and interstitial pneumonia are also reported.

Whole blood sirolimus trough concentration, serum cholesterol and triglycerides, serum creatinine, CBC with differential, platelet count, blood pressure, liver function, and healing of surgical wounds should be monitored.

Everolimus

Doses

There is limited dosing information for everolimus in pediatric transplantation. In renal transplants, children $\geq$1-year-old and adolescents have been given initial doses of 0.8 mg/m^2/dose twice daily with a maximum single dose of 1.5 mg, targeting a serum concentration of 3–6 ng/ml. In a study looking at renal function benefits of switching from a CNI to everolimus in pediatric heart transplants, an average initial dose of 0.07 mg/kg/day divided twice daily was used, with an average maintenance dose of 0.15 mg/kg/day needed to achieve the target trough level of 5–8 ng/mL [30].

Adult initial dosing of everolimus is 0.75 mg give twice daily, with adjustments every 4–5 days if needed based on target serum concentrations.

Pharmacokinetics

Oral absorption of everolimus is rapid, with a bioavailability of 30 % and reaching a peak concentration at 1–2 h. It is hepatically metabolized by CYP3A4, with a half-life of approximately 30 h, and is eliminated primarily in feces (80 %).

Drug-Drug Interactions

Everolimus is metabolized by CYP3A4. Inhibitors of CYP3A4 (calcium channel blockers, azole antifungal agents, macrolide antibiotics, and protease inhibitors) can increase everolimus concentrations.

CYP3A4 inducers (rifampin, phenobarbital, carbamazepine, fosphenytoin, and phenytoin) decrease serum concentrations of everolimus.

Grapefruit juice may reduce the metabolism of everolimus and St. John's Wort may increase metabolism of everolimus. Both should be avoided during therapy with everolimus. Cyclosporine doses and target levels should be reduced when given in combination with everolimus.

Adverse Effects

Some of the more common adverse effects of everolimus therapy include hypercholesterolemia and hypertriglyceridemia, hypertension, peripheral edema, fever, acne, rash, impaired wound healing, nausea, diarrhea, constipation, abdominal pain, increased serum creatinine, cough, and upper respiratory infections. The more serious complications involve hematologic abnormalities including anemia, neutropenia, and thrombosis; hepatotoxicity; pneumonitis; infectious diseases; and malignancies.

Whole blood everolimus trough concentration, serum cholesterol and triglycerides, serum creatinine, CBC with differential, platelet count, blood pressure, liver function, and healing of surgical wounds should be monitored.

Antibody Therapies and Fusion Proteins

The medications in this section can be subdivided into lymphocyte-depleting and non-depleting agents. Depleting drugs destroy lymphocytes whereas non-depleting agents are monoclonal antibodies or fusion proteins that reduce lymphocyte responsiveness without decreasing lymphocyte numbers [19]. Most of these medications are used for induction therapy after transplantation or less commonly as rescue therapy for refractory rejection. One exception is belatacept, a recombinant fusion protein that is currently being investigated in renal and liver transplant recipients as a chronic immunosuppressive therapy in the context of CNI avoidance. While the monoclonal anti-CD20 antibody rituximab is technically a depleting antibody, its use in transplantation is in the treatment of posttransplant lymphoproliferative disorders (PTLD) and the avoidance/treatment of antibody-mediated rejection. For this reason, rituximab will not be discussed here but rather in the next section of drugs used in the management of antibody-mediated rejection.

Of note, muromonab CD3 (OKT3), a monoclonal murine anti-CD3 antibody, and daclizumab (Zenapax®), a therapeutic humanized monoclonal antibody to the alpha subunit of the IL-2 receptor on T-lymphocytes, are no longer produced and will not be discussed in this chapter.

Depleting Antibodies

The currently available T-lymphocyte-depleting agents are polyclonal antilymphocyte antibody preparations produced by immunizing horses (Atgam®) or rabbits (Thymoglobulin®) with human lymphoid cells [19]. These preparations result in profound T-lymphocyte depletion by way of complement-dependent opsonization and cell lysis [17] and are used for induction therapy in the perioperative phase and for treatment of steroid-resistant rejection in both heart and lung transplant recipients. In practice, these potent agents often allow for a 2–4-day CNI-free window immediately after transplantation to enable recovery of renal function, which sometimes may be depressed from a peri-transplant low cardiac output state combined with the insult of cardiopulmonary bypass. Also, because of the manner by which these preparations are made, there may be antibodies which bind platelets and/or erythrocytes, resulting in thrombocytopenia and/or anemia. Also, allergic reactions up to and including anaphylaxis can occur particularly with first use due to marked cytokine release with cell lysis [31]. In addition to these side effects, when multiple courses are used (e.g., for treatment of refractory rejection after previous use as induction therapy), serum sickness may occur [32].

Equine Antithymocyte Globulin (Atgam®)

Dosing

An intradermal skin test for sensitivity is recommended before administration of the initial Atgam® dose.

For cardiac allograft rejection prevention, 15 mg/kg/day for 7 days is one of several different protocols used. The initial dose should be administered within 24 h of transplantation. For treatment of rejection 10–15 mg/kg/day for 7–14 days has been used. Atgam® is currently less frequently used than Thymoglobulin®.

Premedications of acetaminophen (10 mg/kg, orally), diphenhydramine (1 mg/kg, IV), and methylprednisolone (1–2 mg/kg, IV) should be given 30 min before each dose, and each dose should be administered over at least 4 h. With administration times greater than 6 h, acetaminophen and diphenhydramine should be repeated. Atgam® should be administered through a central line to reduce phlebitis.

Pharmacokinetics

Atgam® binds to circulating lymphocytes, granulocytes, platelets, and bone marrow cells. The plasma half-life is 1.5–12 days, with only 1 % of a dose excreted in urine.

Drug-Drug Interactions

Though live virus vaccines are typically contraindicated after pediatric thoracic organ transplantation, avoidance of the use of live vaccines in the first 6 months after Atgam® therapy is recommended as the desired immune response may be reduced and increased risk of infection with the live vaccinal organism may develop.

Adverse Effects

The most common adverse effects are infusion-related reactions, such as fever, shivering, headache, and rash. This can be minimized using the premedications mentioned above. The patient may also experience diarrhea, nausea, vomiting, abnormal BUN/Cr, or dyspnea. Leukopenia and thrombocytopenia may be severe, as well as hemolysis. Anaphylaxis (symptoms can include hypotension, respiratory distress, chest pain, rash, and tachycardia) may occur at any time during therapy. Epinephrine and oxygen should be readily available. Serum sickness reactions or pulmonary edema may also occur. Atgam® may cause primary or reactivation of cytomegalovirus (CMV) infection.

Monitoring parameters while on Atgam® therapy include CBC with differential and platelet count, lymphocyte profile (T-cell levels), vital signs during administration, and renal function.

Rabbit Antithymocyte Globulin (Thymoglobulin®)

Dosing

Thymoglobulin® induction dosing for children varies from center to center, with many centers using 1.5 mg/kg/day IV once daily for 5 days. For treatment of severe or refractory acute rejection, a dose of 1.5 mg/kg/day once daily for 7–14 days has been used.

Premedications of acetaminophen (10 mg/kg, orally), diphenhydramine (1 mg/kg, IV), and methylprednisolone (1–2 mg/kg, IV) should be given 30 min before each dose, and each dose should be administered over at least 4 h. With administration times greater than 6 h, acetaminophen and diphenhydramine may be repeated.

Pharmacokinetics

Thymoglobulin® serum half-life after the first dose is approximately 44 h and increases with subsequent doses up to 13 days. The onset of T-cell depletion usually occurs within 1 day. Lymphopenia may persist for $\geq$1 year.

Drug-Drug Interactions

Though live virus vaccines are typically contraindicated after pediatric thoracic organ transplantation, avoidance of the use of live vaccines in the first 6 months after Thymoglobulin® therapy is recommended as the desired immune response may be reduced and increased risk of infection with the live vaccinal organism may develop.

Adverse Effects

The most common adverse effects are infusion-related reactions, such as fever, shivering, and headache. This can be minimized using the premedications mentioned above. The patient may also experience diarrhea, nausea, abdominal pain, myalgia, or dyspnea. Leukopenia and thrombocytopenia may be severe. Anaphylaxis may occur at any time during therapy. Epinephrine and oxygen should be readily available. Serum sickness reactions and peripheral edema may also occur. Thymoglobulin® therapy may result in severe viral, bacterial, fungal, or protozoal infections or malignancies including posttransplant lymphoproliferative disease.

Monitoring parameters while on Thymoglobulin® therapy include CBC with differential and platelet count, lymphocyte profile (T-cell levels), vital signs during administration, and signs of infection.

Alemtuzumab (Campath(R))

Alemtuzumab targets CD52 which is expressed on mature mononuclear cells, including T- and B-lymphocytes. In addition to its role as an induction agent, alemtuzumab has been used as treatment for refractory rejection [33, 34] after renal and heart transplantation. Though limited, data on the use of alemtuzumab induction therapy after lung transplantation suggested fewer acute rejection events in the first 6 months after transplant [35].

In late 2012, alemtuzumab was withdrawn for commercial purchase in the US by the manufacturer for its FDA approved indication of treatment of B-cell chronic lymphocytic leukemia. At present it is being evaluated by the FDA and European Medicines Agency (EMEA) for approval (as brand name Lemtrada(R)) for treatment of multiple sclerosis. Its availability for off-label use in transplantation is uncertain.

Dosing

IV infusions of 30 mg/dose for one to two doses have been used in adult solid organ transplantation. Limited dosing information is available for pediatric transplantation. In renal transplants in children, an induction dose of 0.4–0.5 mg/kg/dose IV with a maximum dose of 30 mg has been used. In a case report of one 16-year-old heart transplant, the dose used was 30 mg IV on day 1 and day 4 posttransplant [34]. Pretreatment with diphenhydramine, acetaminophen, and corticosteroids should be considered to prevent or ameliorate infusion-related reactions.

Pharmacokinetics

Alemtuzumab clearance decreases with repeated dosing because of loss of CD52 receptors in the periphery. The elimination half-life is initially 11 h and increases to 6 days after repeat doses [36].

Drug-Drug Interactions

Administration of live vaccines should be avoided in immunosuppressive therapy with alemtuzumab.

Adverse Effects

Alemtuzumab can cause serious hematological toxicities, including autoimmune idiopathic thrombocytopenic purpura (ITP), bone marrow hypoplasia, and autoimmune hemolytic anemia. Single doses >30 mg or cumulative doses greater than 90 mg/week have been associated with pancytopenia.

Infusion-related adverse events are common and can include rigors, hypotension, drug-related fever, nausea, vomiting, rash, fatigue, urticaria, dyspnea, pruritus, headache, and diarrhea. Other adverse effects that can occur include peripheral edema and skeletal muscle pain. Alemtuzumab therapy may result in severe viral, bacterial, fungal, or protozoal infections, and appropriate drug prophylaxis should be considered.

Carefully monitor blood pressure and other vital signs during alemtuzumab infusions. CBC and platelets should be monitored weekly, signs and symptoms of infection should be monitored regularly, and T-lymphocyte counts should be monitored after treatment until recovery.

Non-depleting Antibodies and Fusion Proteins

The principle non-depleting induction agent that is currently available commercially is basiliximab (Simulect®). Basiliximab binds the alpha subunit of the IL-2 receptor expressed on activated T-lymphocytes [17, 37]. Belatacept (Nulojix®) is a novel agent that is a recombinant fusion protein consisting of the extracellular domain of human CTLA4 linked to the crystallizable fragment portion of human immunoglobulin G1 [38]. Its mechanism of action is via binding of CD80 and CD86 on antigen presenting cells, thereby blocking a key co-stimulatory signal required for T-lymphocyte activation [39]. Unlike basiliximab, belatacept is not used for induction but has been shown to be effective as maintenance immunosuppression (i.e., rejection prophylaxis) in conjunction with MMF and steroids after de novo renal transplantation [40]. The obvious advantage here is the complete avoidance of CNIs and their associated toxicities. Also, in contrast to depleting antibody therapies, the non-depleting agents are associated with fewer serious adverse effects, such as cytokine release [41].

Basiliximab

Basiliximab has been described in a handful of studies in heart transplantation, which collectively suggest that when given as induction therapy with standard maintenance immunosuppression, basiliximab is well tolerated and not inferior to depleting antibody preparations in terms of acute rejection events [42–44].

Dosing

In pediatric patients weighing less than 35 kg, the recommended basiliximab regimen is two IV doses of 10 mg each. In pediatric patients weighing at least 35 kg, the recommended regimen is two IV doses of 20 mg each. The first dose is administered just before starting cardiopulmonary bypass or within 6 h of organ perfusion. The second dose should be administered 4 days after transplantation.

Pharmacokinetics

Basiliximab has a mean duration of activity of 36 days. The elimination half-life in children 1–11 years old is 9.5 days, in adolescents 12–16 years it is 9.1 days, and in adults it is 7.2 days.

Drug-Drug Interactions

Basiliximab may decrease the therapeutic effect of vaccines. There is an increased risk of vaccinal infection when live vaccines are given during and up to 3 months after basiliximab therapy.

Adverse Effects

Severe acute hypersensitivity reactions including anaphylaxis have been observed with initial doses and reexposure to basiliximab. If a severe hypersensitivity reaction occurs, therapy with basiliximab should be permanently discontinued. Basiliximab therapy results in an increased susceptibility to infection and increased risk of lymphoproliferative disorders. Adverse effects that occur with basiliximab treatment include abdominal pain, vomiting, hypertension, edema, insomnia, pain, fever, dizziness, asthenia, anemia, dysuria, dyspnea, candidiasis, cough, and CMV infections.

Belatacept

Though belatacept has shown promise as a possible CNI avoidance therapy in renal transplantation, there is no published data on the use of this agent after thoracic organ transplantation.

Drugs Used in the Management of Antibody-Mediated Rejection

With the exception of corticosteroids, which are somewhat broadly immunosuppressive, all of the drugs described thus far in this chapter are directed against T-lymphocyte-mediated (cellular) acute rejection. In stark contrast to this impressive armamentarium, there are very few medications that are known to be useful in the treatment of antibody-mediated rejection (AMR). Until relatively recently, AMR was poorly

understood and often not diagnosed. Though currently a topic of intense research, optimal diagnostic and management schemes remain uncertain [45]. Risk factors for AMR include the presence of alloantibodies (allosensitization) directed against the donor prior to transplantation (donor-specific antibodies, DSA) as well as the development of posttransplant, de novo DSA [46]. These antibodies fix and activate complement, resulting in tissue injury and coagulation [47].

It is not surprising that therapies employed in the treatment and prevention of AMR are focused primarily on removal and cessation of production of the offending alloantibodies. To that end there are currently three medications that are utilized in conjunction with plasmapheresis either prior to transplantation (desensitization) or for treatment of AMR: intravenous immunoglobulin (IVIG), rituximab (Rituxan®), and bortezomib (Velcade®).

There are also emerging reports in the renal and lung literature on AMR salvage therapy with eculizumab (Soliris(R)), a humanized monoclonal antibody directed against complement component C5 that blocks downstream formation of membrane attack complexes [54, 55].

Immunoglobulin (IVIG)

IVIG is a potent immunomodulator and has been widely used as an effective treatment for various autoimmune disorders [48]. It has also been used for desensitization and for treatment of AMR after solid organ transplantation. The mechanism of action has not been elucidated but has been postulated to occur as a result of anti-idiotypic antibodies in IVIG that bind to the B-lymphocyte receptor and crosslink the Fcγ receptor IIB, abolishing B-lymphocyte proliferation and resulting in B-lymphocyte apoptosis [49, 50]. IVIG may also modulate T-cell function.

Dosing

Various doses are used for desensitization and as part of a regimen for treatment of antibody-mediated rejection, ranging from 0.5 to 2.0 g/kg monthly for 4–6 months after transplantation across a positive cytotoxicity cross-match or diagnosis of antibody-mediated rejection. Because IVIG is removed by plasmapheresis, it should be given following the conclusion of planned plasmapheresis treatments.

Pharmacokinetics

Intravenous dosing of immune globulin provides immediate antibody levels. The half-life is variable at 14–40 days. Fever and infection may contribute to a shorter half-life.

Drug-Drug Interactions

The effect of live vaccines will be decreased by immune globulins. Vaccination with live organisms should be withheld for up to 6 months post-immune globulin therapy.

Adverse Effects

Acute renal dysfunction may occur with IV immune globulin administration, usually occurring within 7 days. Infusion-related reactions may occur and manifest as fever, chills, nausea, and vomiting and may be helped by decreasing the rate of infusion. Non-cardiogenic pulmonary edema, thrombotic events, and aseptic meningitis have been reported with IVIG use.

Rituximab

Rituximab (Rituxan®) is a mouse-human chimeric monoclonal antibody that binds CD20, expressed on the surface of B-lymphocytes. Use for desensitization and treatment of AMR is off-label and is based on the premise that while antibody-producing plasma cells are CD20 negative, most are relatively short-lived and require replacement from CD20 positive precursors [19]. Other mechanisms of action beyond B-cell depletion may also be important.

Dosing

Usual dosing of rituximab in children and adults is 375 mg/m^2 by slow IV infusion given

weekly for 3–4 doses. Premedication with acetaminophen and diphenhydramine may attenuate infusion reactions.

Pharmacokinetics

B-cell recovery begins in 6 months following treatment, with normal levels obtained by 12 months. The elimination half-life is variable within the range of 5–78 days.

Drug-Drug Interactions

Rituximab may decrease the therapeutic effect of vaccines. There is an increased risk of vaccinal infection when live vaccines are given during and up to 3 months after rituximab therapy.

Adverse Effects

Severe infusion reactions have occurred within 24 h of rituximab administration, with most occurring within 30–120 min of the first infusion. Progressive multifocal leukoencephalopathy (PML) and severe mucocutaneous reactions have been reported with rituximab use. There is a risk of developing serious bacterial, viral, and fungal infections up to 1 year after rituximab therapy. Other adverse effects associated with rituximab therapy include hypertension, cardiac dysrhythmias, peripheral edema, night sweats, fever, pain, pruritus, rash, diarrhea, nausea, vomiting, anemia, leukopenia, thrombocytopenia, neuropathy, arthralgia, and cough.

Bortezomib

Unlike IVIG or rituximab, bortezomib (Velcade®) is not an antibody-based therapy. It is a proteasome inhibitor that is approved for use in the USA for the treatment of multiple myeloma [51]. Though experience is limited, to date its use for desensitization and treatment of antibody-mediated rejection after heart transplantation has been described in small case series [52, 53].

Dosing

Bortezomib is given in a dose of 1.3 mg/m^2 intravenously by rapid injection as a series of four doses distributed over 2 weeks (1 cycle).

Pharmacokinetics

Bortezomib distributes widely to peripheral tissues. It is metabolized by hepatic CYP3A4 and CYP2C19 enzymes and has a half-life of 76–108 h with multiple dosing.

Drug-Drug Interactions

Azole antifungals (fluconazole, voriconazole) are CYP3A4 inhibitors and may increase the concentration of bortezomib. Clopidogrel active metabolites may be reduced due to CYP2C19 inhibition by bortezomib. St. John's Wort, ascorbic acid, and green tea may decrease the effectiveness of bortezomib and should be avoided. Rifampin, phenytoin, phenobarbital, and carbamazepine may reduce bortezomib plasma concentrations.

Adverse Effects

Reported adverse effects include peripheral neuropathy, gastrointestinal symptoms (diarrhea, nausea, emesis), leukopenia, anemia, and thrombocytopenia. Hypotension, new-onset heart failure, rash, myalgia, headache, and fever have also been reported. Whether increased infection may also be a concern for use in patients receiving other immunosuppressive agents remains to be seen.

Heart Transplantation

155

Shelley D. Miyamoto, David N. Campbell, and Scott R. Auerbach

Abstract

In the current era, cardiac transplantation is considered a very good treatment option for infants and children with end-stage heart failure and some forms of complex congenital heart disease. In 2009, there were 537 pediatric heart transplant recipients, increased from 387 in 1999. The overall outcome for heart transplantation continues to improve with a graft half-life of nearly 16 years in pediatric recipients. However, these results are not adequate when considered from the perspective of the life of a child. Therefore, further advancements in treatment options for acute and chronic rejection as well as ongoing efforts to attain donor-specific tolerance are necessary to achieve significant improvements in the long-term outcome of pediatric heart transplant recipients. This chapter will provide a comprehensive overview of heart transplant, indications and contraindications, pre- and post-transplant management, and outcomes.

Introduction

The first pediatric heart transplant was performed in 1967 by Kantrowitz et al., who transplanted a 3-week-old infant with tricuspid atresia using an anencephalic donor [1]. This infant only survived a few hours after surgery but served as evidence for the technical feasibility of cardiac transplantation in babies and children. Advancements in many aspects of heart transplantation continued through the mid-1970s and included improvements in donor heart preservation, selection criteria of donors and recipients, and increased donor awareness [2, 3]. However, until the discovery of cyclosporine in 1976, survival remained very poor primarily due to inadequate ability to control acute allograft rejection [4].

Secondary to improved outcomes related to the use of cyclosporine, a renewed enthusiasm in the potential of pediatric heart transplantation was realized in 1984 with the world's first successful pediatric heart transplant performed at Columbia University on a 4-year-old boy, followed shortly thereafter by the development of the infant transplant program at Loma Linda, California [5]. Beginning with the successful transplant of a 4-day-old infant with hypoplastic left heart syndrome (HLHS) in 1985, transplantation for this and other previously lethal congenital heart defects quickly evolved and persisted throughout the 1990s [6]. Due to limited infant donor availability and improvements in neonatal cardiac surgeries such as the Norwood procedure for HLHS, cardiac transplantation for infants with congenital heart disease has decreased over the past decade. In the present day, cardiac transplantation is considered a very good treatment option for infants and children with end-stage heart failure and some forms of complex congenital heart disease. In 2009, there were 537 pediatric heart transplant recipients, increased from 387 in 1999 [7]. The overall outcome for heart transplantation continues to improve with a graft half-life of nearly 16 years in pediatric recipients [7]. However, even these results are not adequate when considered from the perspective of the life of a child. Therefore, further advancements in treatment options for acute and chronic rejection as well as ongoing efforts to attain donor-specific tolerance are necessary to achieve significant improvements in the long-term outcome of pediatric heart transplant recipients.

Indications and Contraindications to Transplantation

Indications for Transplant

The most common diagnosis leading to transplant in the infant age-group is congenital heart disease, while in those children older than 1 year of age, cardiomyopathy is the most common indication for heart transplant [7]. Dilated cardiomyopathy (DCM) is the most common form of cardiomyopathy in children with a 5-year rate of freedom from death or transplant of only 58 % [8]. In the multicenter Pediatric Heart Transplant Study group registry, 76 % of children transplanted for cardiomyopathy had dilated cardiomyopathy [9]. Hypertrophic cardiomyopathy (HCM) is the second most common form of cardiomyopathy in children but rarely leads to the need for transplant in childhood. For those with HCM, age less than 1 year, lower ejection fraction, and higher posterior wall thickness on presenting echocardiogram have been associated with risk factors of death or transplant [10]. In a more recent study of children with isolated HCM, a drop in blood pressure during exercise

Table 155.1 Class I indications for heart transplantation in pediatric patients with past or present heart failure symptoms and abnormal cardiac structure and/or function

Heart disease requiring continuous infusion of inotropic support or prostaglandin E_1 to maintain ductal patency, mechanical ventilation, and/or mechanical circulatory support
Heart disease associated with severe exercise limitations (peak maximum oxygen consumption [VO_2 max] <50 % predicted in those patients old enough to perform exercise testing)
Significant growth failure that is attributable to heart disease
Heart disease associated with near sudden death and/or life-threatening arrhythmias not treatable with medications or an implantable cardioverter defibrillator (ICD)
Restrictive cardiomyopathy with reactive pulmonary hypertension

and severe left ventricular hypertrophy were associated with an increased risk for non-sudden cardiac death [11]. Restrictive cardiomyopathy is a myocardial disease of diastolic dysfunction that is associated with an increased risk of pulmonary hypertension, thromboembolic events, and sudden death [12]. Due to the risk of developing fixed and irreversible elevations in pulmonary vascular resistance, some groups advocate early transplant for children with restrictive cardiomyopathy. Arrhythmogenic right ventricular dysplasia is a rare disease of the right ventricle where myocardium is replaced by fat and is associated with an increased risk of life-threatening arrhythmias and development of heart failure.

In 2007, the American Heart Association published a scientific statement regarding the indications for heart transplantation in children [13]. Conditions for which there is general agreement and/or evidence that heart transplant is useful and effective are outlined in Table 155.1. In addition to these *class I indications* for heart transplant, there are other indications where agreement is not as strong (*class II indications*). Class II indications for heart transplant include (1) children with heart disease associated with reactive pulmonary hypertension but are considered at risk for developing fixed, irreversible elevations in pulmonary vascular resistance in the future; (2) infants with single ventricle physiology and associated severe stenosis or atresia in the proximal coronary arteries, significant stenosis or insufficiency of the atrioventricular or semilunar valves, and severe ventricular dysfunction and (3) in palliated congenital heart disease, risk of developing fixed, irreversible elevations in pulmonary vascular resistance, severe valve insufficiency not amenable to surgical repair, severe cyanosis not amenable to surgical correction, and persistent protein-losing enteropathy despite maximal medical management.

Contraindications

There are very few *absolute* contraindications to heart transplantation in pediatric patients. However, there are some and these must be considered given the limitation in the number of pediatric donors. Absolute contraindications for heart transplant (or re-transplant) that are generally agreed upon by the pediatric transplant community include (1) the presence of severe, irreversible end-organ or systemic disease; (2) the presence of severe, irreversible, and fixed elevation in pulmonary vascular resistance; (3) severe hypoplasia of the proximal branch pulmonary arteries or pulmonary veins; (4) presence of ongoing acute rejection in a heart transplant recipient; and (5) active neoplasm [13]. Although uncommon in children, insulin-dependent diabetes mellitus with end-organ damage, active peptic ulcer disease, and diverticulosis have also been considered absolute contraindications in adults [14]. A history of drug or alcohol abuse, history of medication noncompliance, and active infection can be considered a contraindication to transplant, but these decisions are often center dependent.

Candidate Evaluation and Pre-transplant Management

A comprehensive, multidisciplinary evaluation is required for all patients being considered for cardiac transplantation. The components of this evaluation process are outlined in the following section.

History and Physical Examination

The first step in evaluating a potential transplant recipient is to ensure that the cardiac diagnosis and history are consistent with end-stage heart disease. Children are considered candidates for cardiac transplantation if they have severe heart disease that has failed surgical or maximal medical management or if the outcome of palliative surgery compared to transplantation is comparable.

Cardiac Catheterization

A cardiac catheterization is a necessary part of the evaluation for the vast majority of potential transplant recipients. Assessment of anatomy in children with complex cardiac disease is useful for transplant surgical planning. In some instances, cardiac magnetic resonance imaging (cMRI) or magnetic resonance angiography (MRA) may also be necessary to delineate complex anatomical issues. Evaluation of the child's hemodynamics can play a critical role in determining the urgency for transplantation. Those with severely elevated ventricular filling pressures or extremely low cardiac output are at higher risk for wait list mortality, and urgent listing could be indicated and lifesaving. However, one of the most important indications for cardiac catheterization in the evaluation process is documentation of pulmonary vascular resistance. Evidence of elevated pulmonary vascular resistance that is fixed and does not respond to pulmonary vasodilator therapy (defined as nonreactive pulmonary hypertension) can be a contraindication to cardiac transplant. Although there have been variations across institutions, those considered reasonable candidates for cardiac transplantation historically had a pulmonary vascular resistance less than six wood units·m^2 or at least a 50 % decrease in baseline resistance in response to pulmonary vasodilator therapy (with an absolute resistance still less than six wood units·m^2), a mean pulmonary artery pressure less than 25 mmHg, and/or a transpulmonary gradient (the difference between the mean pulmonary artery pressure and the pulmonary capillary wedge pressure) less than 15 mmHg [13]. However, recent studies have shown that the PVRI threshold of six wood units·m^2 may be too restrictive and have highlighted the key role of vasodilator testing prior to transplantation [15, 16]. In fact, a recent single-center study found that a PVRI threshold of $<$9.29 wood units·m^2 resulted in an area under the curve of 0.863 for predicting 30-day survival [16]. The pulmonary vasodilator therapies that are most commonly used in the catheterization laboratory to test pulmonary resistance reactivity in patients with heart failure include oxygen, inhaled nitric oxide, nitroprusside, and even the phosphodiesterase-3 inhibitor, milrinone. Bosentan (endothelin receptor antagonist) and sildenafil (phosphodiesterase-5 inhibitor) are also utilized by some groups [13]. Another unique challenge is presented by those patients with single ventricle physiology in whom pulmonary vascular resistance cannot be accurately estimated due to inability to access the pulmonary arteries, differential pulmonary arterial flow, or the presence of veno-venous or aortopulmonary collaterals. Patients with markedly elevated or nonreactive pulmonary vascular resistance have a risk of acute right ventricular graft failure that is considered prohibitively high, and a heart-lung transplant may be necessary instead.

Exercise Testing

Cardiopulmonary exercise testing can be useful in the evaluation process of children old enough to participate (typically at least 7 years of age). In adults, aerobic capacity as measured by VO_2 max (maximal oxygen consumption) has been demonstrated as useful in standardizing candidacy for cardiac transplantation. Adults with a VO_2 max of less than 14 ml/kg/min or less than 50 % predicted are at high risk for cardiac-related death within one year and are considered candidates for cardiac transplant [17, 18]. However, a recent single center study noted that a VO2 max of $<$50 % predicted in children with a biventricular circulation was associated with outcome, but this did not hold true for those with single ventricle physiology

(PMID: 23580746). Exercise testing remains a valuable noninvasive tool to assess cardiac reserve in children suffering from cardiac failure.

Extracardiac Evaluation

Another important aspect of the recipient evaluation process includes investigations of extracardiac diagnoses and organ function. Lung function testing via formal pulmonary function testing can be useful in evaluating the presence of intrinsic lung disease that could influence post-transplant outcomes. Because many of the immunosuppressive agents used post-transplant can impact liver and renal function, evaluation of these organ systems is critical. If there is a history of renal insufficiency or serum creatinine is significantly elevated, a more aggressive assessment of kidney function including a 24 h urine test for creatinine clearance and consultation with a nephrologist is warranted. Irreversible renal failure requiring dialysis can be considered a contraindication to heart transplant, although some centers are willing to perform combined heart-kidney transplants in children [20]. Liver dysfunction related to chronic heart failure, Fontan physiology, or a mitochondrial myopathy may require a biopsy to evaluate for degree and severity of fibrosis or cirrhosis. As the palliated single ventricle population ages, it is becoming increasingly apparent that long-standing Fontan physiology can lead to serious hepatic problems including hepatocellular carcinoma [21]. The presence of liver cancer or significant cirrhosis that is deemed irreversible is considered a contraindication to heart transplant. Thyroid evaluation should be performed in patients at risk for dysfunction due to chronic amiodarone administration. Patients with associated skeletal or mitochondrial myopathies, genetic syndromes, or chromosomal abnormalities can be eligible for heart transplant. However, if the natural history of the underlying disease results in expected death before the anticipated life of a potential graft, then heart transplant is usually contraindicated. Children with a history of cancer can develop heart failure as a result of exposure to cardiotoxic chemotherapy (anthracyclines). A thorough evaluation to rule out active cancer must be performed, and in general, heart transplant is not recommended until the patient has been cancer-free for at least 1 year and the risk of recurrence is considered low [22]. However, due to variations in malignancies, the decision regarding timing of listing for a heart transplant should be done in consultation with the patient's oncologist. A neurologic evaluation, including imaging, may be necessary in patients with a seizure disorder or who have suffered a stroke. Severe malnutrition due to long-standing heart failure must be addressed as this could complicate recovery from the heart transplant and increase the risk of post-transplant complications such as impaired wound healing, risk for infections, and prolonged hospitalization.

Sensitization

Assessment of the panel reactive antibody (PRA) profile of a potential recipient is an important part of the evaluation process. The presence of circulating preformed antibodies to human leukocyte antigens (HLA) is measured either by a lymphocytotoxicity assay, enzyme-linked immunosorbent assay (ELISA), or a Luminex bead assay. Patients who have been exposed to blood products, had cardiac surgery that utilized homograft tissue, are supported with mechanical circulatory support (ventricular assist device [VAD] or extracorporeal membrane oxygenator [ECMO]), or had a prior organ transplant are at highest risk for having an elevated PRA (>10 %). This humoral sensitization is considered a risk factor for early graft failure due to rejection and the development of transplant coronary artery vasculopathy (CAV) [23, 24]. In a study performed by the PHTS, post-transplant mortality has been shown to increase twofold in patients with an elevated PRA [25]. Protocols aimed at decreasing the PRA are employed at some centers and can include the use of plasmapheresis, infusion of intravenous immune globulin (IVIg), and initiation of immune suppression aimed at B-cells [26]. Specific immunosuppressive medications

that are commonly used include mycophenolate mofetil (MMF), cyclophosphamide, and more recently rituximab (an anti-CD20 monoclonal antibody). However, even if these methods are successful in decreasing circulating antibodies, in most sensitized patients, a prospective crossmatch is performed, or alternatively HLA typing of the donor allows avoidance of known unacceptable antigens (virtual crossmatch).

Infectious Disease Evaluation

Active infection at the time of transplant can be a contraindication to listing and should be completely treated prior to further consideration. Pre-transplant evaluation includes investigation for the presence of current or past viral infections by determining serologies (IgG and IgM) to cytomegalovirus (CMV); Epstein-Barr virus (EBV); hepatitis A, B, and C; and human immunodeficiency virus (HIV). Serologies to *Toxoplasma gondii*, herpes simplex virus, measles, and varicella and performing a purified protein derivative (PPD) test are also recommended in some centers. Serologies are less useful in young infants as the immune response measured is indicative of the mother's status rather than the baby's. Because previously dormant infections (especially CMV and EBV) can become reactivated post-transplant during initiation of immunosuppressive medications, and since CMV-negative recipients that receive an organ from a CMV-positive donor are at increased risk for clinical CMV disease, antiviral prophylaxis (ganciclovir or valganciclovir) is often planned for those recipients with positive pre-transplant viral serologies or seroconversion post-transplant [27]. Routine administration of live viral vaccines (measles-mumps-rubella, varicella) prior to transplant is recommended as these are contraindicated post-transplant.

Psychosocial Evaluation

Psychiatric and social assessment of the potential pediatric recipient and his/her family is indicated to ensure that there is an adequate understanding of the transplant process and to identify those families that are likely to benefit from extra support during the waiting and post-transplant period. Adjusting to life after transplantation for some families represents a significant challenge that can be eased if anticipated and appropriate interventions instituted [28]. In addition to determining that appropriate psychological support is provided in the peri-transplant period, a comprehensive assessment of the families' social situation is also warranted. This process includes evaluation of the support systems that are in place, ensuring adequacy of transportation and housing and assessing that financial resources, such as health insurance, are available so that medications and clinical evaluations can be attained as recommended. For adolescent recipients, the presence of illicit drug, tobacco, or alcohol abuse or a strong history of previous medication noncompliance are associated with poor transplant outcomes and can be considered a contraindication [29]. Early involvement of a pediatric social worker and pediatric heart transplant coordinator is instrumental in identifying areas of need and providing guidance and support throughout this difficult process for patients and families.

Pre-transplant Management

Once a candidate has been approved and listed for transplant, ongoing medical management is critical to optimize survival to the time of transplant. Wait list mortality for children awaiting heart transplant is the highest among all solid organ candidates. The factors that are associated with the highest risk of waiting list mortality include the need for ECMO, ventilator support, listing status 1A, congenital heart disease, need for dialysis, and nonwhite race/ethnicity [30]. Advancements in medical and surgical treatment options for heart failure in children are necessary if wait list mortality in this vulnerable group of patients is to improve.

- *Management of heart failure*: Maximal medical therapy of heart failure in children is difficult to define with certainty based on lack of clinical trial data in this population.

However, diuretics, afterload-reducing agents (angiotensin-converting enzyme inhibitors), digoxin, potassium-sparing diuretics (spironolactone), and β-blockers (metoprolol, carvedilol) are the most common medications used based on extrapolation of adult heart failure trials. Proper nutrition is an important consideration as many children with severe heart failure are malnourished and could compromise the post-transplant course. In children with elevated pulmonary vascular resistance, pulmonary vasodilators may be indicated. Arrhythmia control with either placement of an implantable cardioverter defibrillator (ICD) or antiarrhythmic medications is necessary in only a very small percentage of patients, as the risk for sudden death while awaiting transplant is low in pediatric patients listed for transplantation [31]. In some patients with signs and symptoms of heart failure despite maximal oral medical therapy, continuous inotropic support can be utilized with caution. Dopamine, milrinone, and dobutamine are the most common intravenous inotropes used in children as a bridge to transplant. Milrinone in particular seems to be well tolerated in children suffering from heart failure and can be administered safely even in the outpatient setting [32, 33]. The use of mechanical circulatory support (MCS) as a bridge to transplant in children with end-stage heart failure is increasing. The choice of ECMO or a VAD is often center and patient dependent. ECMO remains the most readily available form of MCS and can be rapidly initiated in patients of all sizes, but is not a viable long-term support option and is associated with worse post-transplant survival when compared to MCS with a VAD [29]. The Berlin Heart EXCOR is a long-term, pneumatic support device that was developed in Germany and has been used in infants and small children as a bridge to transplant with reasonable success [34]. Although 77 % (86 % in the more recent era) of pediatric patients in a pediatric VAD study performed by Blume et al. were successfully bridged to transplant, the complication rate associated with VAD use in children was extremely high and included infection and sepsis, bleeding, stroke, and multisystem organ failure.

- *Limiting infections*: Because active infections are at least a relative contraindication to transplant, controlling and limiting infections in listed patients is extremely important. The risks of developing an infection are highest for those patients who are hospitalized while waiting and patients who are intubated, on MCS or with other indwelling lines or catheters. Therefore, outpatient management when possible, removing all unnecessary lines and catheters, ensuring proper hand washing of caregivers and rapid recognition and targeted treatment of infections is of critical importance in this population.
- *Hematologic management*: Children with poor ventricular function are at risk for intracardiac and deep venous thrombosis. Due to lack of evidence, the ideal regimen to prevent thrombus formation in children with heart failure is not known and is largely center dependent. Practice can include the use of aspirin (3–5 mg/kg/day), warfarin (goal INR of 1.5–2.5), low molecular weight heparin, or unfractionated heparin. Anemia of chronic disease is also a common problem in children with heart failure and can be exacerbated by poor nutrition and frequent blood draws. The use of erythropoietin or iron (in the setting of iron deficiency) should be considered to limit blood transfusions, thereby avoiding additional HLA antigen exposure to listed patients. If a transfusion is necessary, leukocyte-poor blood products can decrease the sensitizing exposure. If the patient is known to be CMV negative, CMV-safe products are also recommended.

Donor Evaluation

The success of a cardiac transplant is largely dependent on the donor evaluation process. Donor history, age, size, blood type, mechanism of death, heart function, and comorbidities must be thoroughly researched as part of the evaluation process. Importantly, due to the shortage of infant heart donors and the plasticity of the neonatal

immune system, unique strategies have also been employed to increase the donor pool. ABO-incompatible heart transplant, fetal listing, donor after cardiocirculatory death (DCD), and aggressive procurement practices are some of the strategies employed to begin to address the disparity between organ demand and supply in the infant population. More details about the latter aspects can be found in a chapter dedicated to heart transplant in infants with HLHS, elsewhere in this textbook.

Donor Demographics

One of the most important first steps in the donor evaluation process for non-infant donors is to ensure ABO compatibility prior to accepting and procuring the donor heart. Confirmation of both donor and recipient ABO blood type is performed by the organ procurement agency involved as well as the surgical team involved in the procurement and transplant operation. Advanced donor age is mainly an issue only for adolescent recipients as they are of a size that could match with an adult donor. In fact, 25 % of pediatric recipients receive a heart from an adult donor ($\geq$18 years) [7]. Although some studies have described worse outcome for adolescents whose donor age is older than 40 years [35,36], other studies suggest that outcomes for pediatric recipients of adult age hearts (even up to 51 years) can be quite good [37]. Donor gender does not influence outcomes in pediatric recipients and is not currently considered an important factor in donor acceptance [7, 38].

Donor size is an important characteristic with most pediatric recipients receiving a size-matched donor. Children with cardiomyopathy can accept larger donor hearts due to thoracic cavity changes associated with long-standing cardiomegaly. In the most recent International Society for Heart and Lung Transplantation registry report, a small number of patients received an undersized heart ($<$0.75 donor/recipient weight ratio), while 34 % received an oversized heart ($>$1.5 weight ratio) [7]. Although transient lung collapse and delayed chest closure can occur in those patients with a significantly oversized heart ($>$2.5 donor/recipient weight ratio) [39], a recent single-center study demonstrated good outcomes even with donor weights up to three times greater than recipient weight [40]. On the other hand, a recent review of the United Network for Organ Sharing (UNOS) database demonstrated that recipients with a low donor/recipient weight ratio of 0.6–0.8 had comparable short- and long-term outcomes to those with an ideal ratio of 0.8–2.0 [41]. This data suggests that a wide range of donor sizes is acceptable for pediatric recipients.

Trauma and asphyxia are the most common causes of death for pediatric donors. However, brain death is a complicated issue in pediatrics as the current methodology makes it impossible to declare most neonates and even infants with anencephaly brain dead. This fact further limits donor availability in the infant population. In addition, brain death itself is associated with hemodynamic, neuroendocrine, and metabolic derangements whose impact on post-transplant outcomes is incompletely understood in the pediatric population. In a single-center study, there was no correlation between outcome and graft ischemia, length of time between brain injury and declaration of brain death, or length of time from declaration of brain death to organ procurement [42]. However, in a study of the UNOS database, ischemic times of $>$3.5 hours were associated with a 30 % increased risk of graft loss within 6 months for pediatric recipients [43]. In pediatric recipients, the length of cardiopulmonary resuscitation required for the donor also has not been related to outcome [44]. A recent study by Bailey et al. investigated outcomes for 29 pediatric recipients of hearts from donors that were originally declined due to "poor donor quality" [45]. Despite the fact that there were longer recovery distance and cold ischemic time, the outcome of these 29 recipients (74 $\pm$ 10.5 % 7-year actuarial survival) was comparable to recipients receiving primarily offered organs over the same time period.

Donor infections can be transmitted to the recipient, and therefore, careful screening must be performed. Investigation for evidence of

CMV, EBV, HIV, human T-cell lymphotropic virus (HTLV), and hepatitis B and C infection is standard. Antibodies to syphilis, *Toxoplasma gondii*, and West Nile virus are sometimes obtained as well. Although antibodies to CMV and *T. gondii* are not contraindications to transplant, their presence can influence post-transplant antimicrobial management. Donor HIV and HTLV infection and the detection of hepatitis B surface antigen are considered contraindications to donation. The use of hepatitis C-positive donors is controversial and in general is reserved for critically ill patients or hepatitis C recipients. Due to increased risk of blood-borne infections, a history of intravenous drug abuse in the donor is considered a risk factor, and this information is also considered in the evaluation process. Current UNOS regulations require centers to inform a family if the potential donor is considered high risk (IV drug use, history of hepatitis B or C infection, donor behaviors that are high risk for HIV infection, and others) and obtain the consent of the family for the patient to receive an organ from a high-risk donor.

Donor heart structure and function are carefully evaluated prior to acceptance. An electrocardiogram (ECG), chest radiograph (CXR), echocardiogram, and cardiac enzymes are the most common tests performed. In adult donors, coronary angiography is often performed to rule out underlying coronary artery disease. Nonspecific ST and T wave changes and a prolonged QTc on ECG as well as elevated troponin levels are frequently seen in a potential donor and do not lead to increased risk of post-transplant mortality [46, 47]. Determination of normal cardiac structure, cardiac function, degree of atrioventricular valve regurgitation, and evidence of focal wall motion abnormalities can be assessed with a complete two-dimensional echocardiogram. Donors with more than mild cardiac dysfunction (ejection fraction <50 %) on inotropic support, donors requiring high doses of inotropic support, donors with significant valve regurgitation, or those with a pericardial effusion indicative of myocardial contusion are often declined. However, there are no prospective studies to define the true limitations of donor heart function on post-transplant outcome, so there is very little standardization to this process.

Transplant Surgical Procedure of Donor and Recipient

The operative method of performing a heart transplant in an infant or child is dependent on the size of the recipient as well as the underlying diagnosis leading to transplant. The transplant procedure is more complicated in those children with complex forms of congenital heart disease as additional reconstruction may be necessary and in those patients who have had multiple prior surgeries. For example, in infants with unrepaired HLHS, arch reconstruction is necessary at the time of transplant, while in those with palliated single ventricle physiology, with a Glenn or Fontan, reconstitution of the vena cava must be performed. Anomalous pulmonary or systemic venous drainage, pulmonary artery dilation or stenosis, aortic arch abnormalities, and dextrocardia can all add to the complexity of the operative procedure and must be taken into consideration.

Donor Organ Procurement

In most situations, there is a separate donor and recipient surgical team and communication between these teams is critical to the success of the procedure. The use of separate teams allows for optimization of surgical timing for both the donor and recipient and minimizes organ ischemic time. The procuring team should closely evaluate the contractility of the heart by direct inspection and perform a quick assessment for unexpected anatomic abnormalities. The first step in organ procurement is to cross-clamp the aorta, next an incision is made in the inferior vena cava to drain the heart of blood, and cold cardioplegia is infused. The exact type of cardioplegia used varies across institutions but is a critical component in ensuring good early graft function. At this point, the heart can be removed, placed in additional cardioplegia solution, and put on ice

(indirectly to avoid freezing of the tissue) for transport to the recipient location.

In some situations, extra donor superior and inferior vena cava (and even innominate vein), pulmonary artery, and/or aortic tissue is necessary for reconstruction of the recipient's anatomy. This must be communicated clearly to the procuring team and taken into consideration at the time of organ harvest.

Recipient Transplant Surgery

Transfer of the recipient to the operating room, placement of monitoring lines, and induction of anesthesia are not without risk in transplant recipients. These patients are suffering from heart failure and low cardiac output and have minimal physiologic reserve. Therefore, a comprehensive team experienced in transplant surgery is a key component to the success of the operation. Central cannulation is performed in a standard manner, while the aorta is cross-clamped to exclude the heart from circulation. The recipient's heart can then be removed.

In some institutions, a biatrial anastomosis is preferred in infants and small children as described by Lower and Shumway in 1960 [48]. This method minimizes the risk of stenoses of the vena cava, which is more likely to occur in the smallest patients. For this procedure, when the recipient heart is removed, the posterior wall of the right and left atria is left in place. The donor heart is implanted by completing the anastomosis of the donor to recipient left then right atrial walls. Care must be taken when preparing the donor right atrium for implant to avoid the sinoatrial node which lies at the base of the superior vena cava. Usually, the aortic anastomosis is performed next so that the aortic cross-clamp can be removed and rewarming of the patient can begin while the pulmonary artery anastomosis is completed.

In older children and adolescents, a bicaval anastomosis is usually preferred. Advantages of the bicaval method over the biatrial method include smaller atrial size, lower risk of sinoatrial node dysfunction and atrial arrhythmias, and improved atrial function [49–51]. The left atria of the recipient and donor anastomosis is performed first, followed by anastomoses of the superior and inferior vena cava of the recipient to the donor heart, and finally the great vessels. Care must be taken to ensure free and unobstructed drainage of the coronary sinus as well as positioning of the heart to avoid torsion or twisting of the atria.

In more complicated transplant operations, circulatory arrest is sometimes necessary to perform the complex reconstructions necessary for those with congenital heart disease. The transplant surgery is further complicated in patients with a prior history of surgeries requiring a sternotomy as scar tissue and adhesions can obscure landmarks and increase the risk of bleeding and cardiac perforation. In some situations where these risks are anticipated, patients are cannulated through their groin so that rapid cardiopulmonary bypass can be initiated if necessary.

Intraoperative Medical Management

The use of induction therapy (discussed in more detail in the next section) is center dependent and often begins in the perioperative period with administration of immune suppression to the recipient prior to going to the operating room. Irrespective of the use of induction therapy, it is common for the recipient to receive a dose of intravenous methylprednisolone in the operating room prior to going onto cardiopulmonary bypass and again during rewarming.

Sinus bradycardia and sinus node dysfunction are common post-transplant, and atrial and ventricular pacing wires should be placed prior to sternal closure [52]. In most cases, sinus node function normalizes within 2–3 days of transplant, but in some cases, permanent pacemaker implantation is necessary [53]. The use of inotropic agents post-transplant is routine and can include low doses of epinephrine, dobutamine, or dopamine. Milrinone is particularly useful in those patients with elevated systemic vascular resistance and low cardiac output. Isoproterenol is a favored drug by some groups given its combined chronotropic, inotropic, and pulmonary

vasodilatory effects. Inhaled nitric oxide is employed in those patients with pre-transplant elevations in pulmonary vascular resistance to limit donor right ventricular workload and early graft failure (e.g., unrepaired infants with single ventricle physiology, children with restrictive cardiomyopathy).

Although primary graft failure is uncommon, the outcome can be devastating. Primary graft failure and inability to successfully wean from cardiopulmonary bypass are usually attributed to donor factors, with poor donor heart preservation, prolonged ischemic time, and high-dose donor inotropic support considered as risk factors [54]. Beyond primary graft failure, early right (or left) ventricular failure can occur as a result of elevated pulmonary vascular resistance or rarely hyperacute rejection. Temporary support of failing grafts with ECMO is used as a bridge to graft recovery in these instances. If weaning from ECMO is unsuccessful and listing for re-transplantation is necessary, a ventricular assist device can serve as a bridge to re-transplantation. However, outcomes following re-transplantation for primary graft failure are poor [55].

Early Post-transplant Care

Although postoperative care of the transplant recipient is similar in many ways to that of children undergoing other types of cardiopulmonary bypass surgery, it is complicated by the addition of immunosuppression and graft-related alterations in physiology. Management issues specific to the transplant patient will be discussed in this section.

Cardiovascular Support

Although systolic function usually normalizes very early post-transplant, inotropic support is commonly required for at least the first 2–3 days post-transplant. The choice of inotropic agent and its duration of use is center and physician dependent, but low doses of dopamine, dobutamine, milrinone, and isoproterenol are the most common. Milrinone and isoproterenol have pulmonary vasodilatory effects that can be beneficial especially in those patients with elevated pulmonary pressures before transplant. Diastolic dysfunction post-transplant can be prolonged for days or weeks after transplant. The use of diuretics and maintaining ideal fluid balance can help manage the consequences of diastolic dysfunction. In cases of significant graft dysfunction, or when there is a large donor/recipient size mismatch, leaving the chest open for 1–2 days is necessary.

Sinus node dysfunction and sinus bradycardia are common post-transplant as previously discussed. Temporary pacing or chronotropic support with isoproterenol is often utilized in the early post-transplant period. The new cardiac graft has a relatively fixed stroke volume, so increasing the heart rate is critical in maintaining or improving cardiac output. Monitoring for cardiac arrhythmias is important and all patients are on constant telemetry. Arrhythmias can be related to ischemia-reperfusion injury of the graft, electrolyte imbalances, or rejection but are usually self-limited and rarely require chronic therapy.

Systemic hypertension is quite common in the early post-transplant period. This is most likely due to persistent elevation in systemic vascular resistance caused by low cardiac output prior to transplantation, the use of oversized donor organs, and corticosteroid treatment. In the presence of systemic hypertension, inotropes should be weaned, but this must be balanced with right ventricular graft function. The right ventricle may require ongoing inotropic support even when systemic hypertension is present, so pulmonary vasodilators in combination with low-dose dobutamine, dopamine, or even epinephrine may be needed. If despite the lowering or discontinuation of inotropes, systemic hypertension persists and systemic vascular resistance is high, systemic vasodilators may be employed.

As discussed previously, elevated pulmonary vascular resistance can be a major problem post-transplant and lead to acute donor right ventricular failure. Ideally, nitric oxide is started in the

operating room prior to weaning from cardiopulmonary bypass in high-risk patients and should be continued in the intensive care unit. Avoidance of acidosis, targeting a normal to low pCO_2, and adequate sedation can all assist in lowering pulmonary vascular resistance. Right ventricular inotropic support is often required in this setting with mechanical circulatory support, an option in those failing medical management.

End-Organ Function and Support

Renal function post-transplant is a very important consideration. There is increased risk of compromised kidney function in the transplant recipient at least in part due to the obligate use of medications such as cyclosporine or tacrolimus. Nephrotoxicity of these medications is exacerbated by the fact that these patients just underwent cardiopulmonary bypass and most lived with poor cardiac output with limited renal perfusion pre-transplant. Although oliguria and an increase in serum creatinine are common, anuria and renal failure necessitating dialysis is fortunately rare. The use of induction immunosuppression provides the added benefit of delaying the administration of calcineurin inhibitors until the recipient has shown stable renal function for the first 48–72 hours post-transplant. Avoidance of additional nephrotoxic drugs is recommended. However, certain circumstances make using drugs such as vancomycin and gentamicin unavoidable, and dosing of such nephrotoxic drugs should be based on serum levels when possible.

Infection is a major concern in the post-transplant patient and is exacerbated by the use of immune-suppressing medications. For this reason, removal of invasive tubes, central lines, catheters, and devices such as pacemaker wires should be done in an aggressive fashion in the transplant recipient. Prophylactic antibiotics (usually a first-generation cephalosporin) are employed for the first 48–72 hours post-transplant to limit mediastinal infections. Initiation of oral nystatin is common practice post-transplant and is continued for several weeks. Ganciclovir is indicated in situations where the donor or recipient has serology indicative of past CMV infection as active reinfection can occur in the immunosuppressed patient. This therapy is started in the intensive care unit after transplant and is continued after discharge. Prophylaxis for *Pneumocystis jiroveci* with oral Bactrim therapy is usually started at the time of discharge.

In some transplant recipients, muscular deconditioning can complicate the post-transplant course. For patients requiring mechanical ventilation pre-transplant, reconditioning of respiratory muscles may delay extubation post-transplant. For patients managed with mechanical circulatory support (ECMO or VAD), skeletal muscles may also require reconditioning, and aggressive physical therapy should be initiated early to avoid complications such as deep venous thrombosis, pneumonia, and skin breakdown.

Early Immunosuppression

The goal of early post-transplant immune suppression is to guide the immune system towards a path of nondestructive immunity with respect to the cardiac allograft while maintaining an intact response to other invading antigens. Early graft acceptance is critical to the ultimate success of the transplant and is essential for transition to an outpatient immune suppression regimen.

Although the use of induction therapy in pediatric recipients is institution dependent, its use has increased from 40 % in 2001 to nearly 70 % in 2010 [7]. The goal of induction therapy is to prevent T-cell activation in the early post-transplant period to encourage active immune regulation and graft acceptance. There are many options for induction agents, but the most commonly used are polyclonal antibodies such as equine or rabbit antithymocyte globulin (ATG) or monoclonal antibodies such as daclizumab and basiliximab that target the interleukin-2 (IL-2) receptor on activated T-cells. Advantages of induction therapy are the ability to use low doses of calcineurin inhibitor therapy postoperatively and a lower risk of early rejection. Although historically the use of induction therapy

was controversial, a recent multicenter registry study of induction therapy in pediatric heart transplant patients demonstrated no increased risk of infection or post-transplant lymphoproliferative disorder (PTLD) associated with this practice. In fact, patients that received induction had a lower incidence of PTLD and fungal infections [56].

Regardless of whether induction is employed, the use of high-dose intravenous corticosteroids (methylprednisolone) is common post-transplant with the first dose given in the operating room and then continuing for a variable period of time in the post-transplant period. Although the majority of centers continue to discharge patients on maintenance corticosteroids, the use of steroid-free immune suppression regimens in children is increasing [57].

IVIg is used by some centers in the post-transplant period with the goal of complementing the innate immune system's ability to control bacterial and viral infections. IVIg also has immune-regulatory functions as it can bind cytokines and other pro-inflammatory products limiting their destructive capabilities. The use of plasmapheresis in the post-transplant period followed by IVIg administration is an approach used for presensitized patients at some centers. IVIg contains anti-idiotypic antibodies which can inhibit and/or downregulate the production of HLA-specific alloantibodies in presensitized patients.

Maintenance immunosuppression is discussed in detail in a specific chapter in this textbook. In brief, calcineurin inhibitors remain the mainstay of pediatric heart transplant immune suppression regimens. The use of intravenous cyclosporine in the early post-transplant period is common with transition to an oral calcineurin inhibitor once the recipient is extubated and is able to tolerate enteral medications. Tacrolimus (FK506) is a more recently developed calcineurin inhibitor and is now more commonly used than cyclosporine in pediatric recipients [7]. Most centers use adjunctive therapy with an antimetabolite or antiproliferative medication in addition to the calcineurin inhibitor. Azathioprine, mycophenolate mofetil and sirolimus are the most commonly utilized. As mentioned above, the use of prednisone as part of the maintenance regimen remains common in the first year post-transplant in pediatric recipient, but weaning and transition to a corticosteroid-avoidance regimen is increasing in frequency.

Long-Term Management

The long-term management of the pediatric recipient is best done primarily or in close consultation with a pediatric heart transplant center. There is a paucity of evidence to support the medical management and graft surveillance of children, so this is usually extrapolated from the adult heart transplant experience, or based on the longitudinal experience of the pediatric center. Because immune suppression is covered comprehensively in a separate chapter, the focus of this section will be on the other management issues related to the pediatric heart transplant recipient.

Acute Cellular Rejection

Acute rejection is the leading cause of death in pediatric heart transplant recipients between 30 days and 1 year post-transplant. Rejection is most likely to occur in the first 1–2 months post-transplant, and by 1 year post-transplant, approximately 40 % of pediatric recipients have suffered an episode of rejection. Treated rejection in the first year post-transplant is associated with a 6 % reduction in 5-year survival [7]. Because moderate and even severe rejection can occur in the absence of clinical symptoms, an effective surveillance protocol is essential. Unfortunately, there is no true gold standard for rejection surveillance and institutions follow varied practices based on their bias and experience.

What is common across centers is an understanding that close serial evaluation is important for rejection surveillance. Signs and symptoms of rejection can be subtle and nonspecific, including fatigue, fever, cough, abdominal pain, vomiting, or diarrhea. Therefore, a high index of suspicion

is critical. Clinical assessment of a patient may reveal tachycardia, arrhythmias, tachypnea, pulmonary rales or crackles, hepatosplenomegaly, or a gallop rhythm in a patient with graft rejection. Infants and toddlers may present with poor appetite, vomiting, and irritability [58]. A chest radiograph may demonstrate pulmonary edema, an enlarged cardiac silhouette, or pleural effusions. The surface ECG may show arrhythmias, low QRS voltages, or change in QRS axis or duration. The intramyocardial electrogram has been studied by a group in Berlin who found that voltage changes had good specificity and sensitivity for moderate rejection [59].

Peripheral blood microarray expression profiling based on alterations in mRNA sequences in stimulated and resting leukocytes has been validated in adults [60]. There are commercially available assays that are now part of the routine surveillance process for adult programs. However, this methodology has not been validated in children under the age of 15.

The echocardiogram can be a very useful noninvasive rejection surveillance tool. Boucek et al. developed an echo scoring system for rejection that was prospectively compared to endomyocardial biopsy in infant recipients with excellent correlation [61]. Assessment for both systolic and diastolic dysfunction as well as alterations in left ventricular mass and volume, new or increasing valve insufficiency, and the development of a pericardial effusion represent echocardiographic evidence concerning for acute graft rejection.

Cardiac catheterization and endomyocardial biopsy continue to play a critical role in rejection surveillance. Hemodynamic assessment including filling pressures, cardiac output, and estimation of oxygen consumption provides useful information. Although the endomyocardial biopsy may clearly demonstrate a cellular infiltrate and myocyte destruction consistent with acute rejection (Table 155.2), not all episodes of symptomatic rejection are associated with a positive biopsy, so even this modality is not universally reliable. False-negative biopsies can result from sampling error and from the somewhat subjective nature and interobserver variability of pathologic interpretation. The necessity of treating acute rejection in the absence of clinical signs and symptoms has never been well demonstrated. In addition, as the time from transplant increases, the incidence of classic acute biopsy-proven rejection decreases underscoring the importance of a multifaceted approach to the diagnosis of acute rejection [62].

Table 155.2 2004 International Society for Heart and Lung Transplantation standardized cardiac biopsy grading for acute cellular rejection

Grade 0 R	No rejection
Grade 1 R, mild	Interstitial and/or perivascular infiltrate with no more than one focus of myocyte damage
Grade 2 R, moderate	Two or more foci of infiltrate with associated myocyte damage
Grade 3 R, severe	Diffuse infiltrate with multifocal myocyte damage ± edema ± hemorrhage ± vasculitis

Antibody-Mediated Rejection

Antibody-mediated rejection (AMR) is a form of rejection mediated by recipient antibody directed against the allograft. The pathologic diagnosis of AMR includes histologic findings within the endomyocardial biopsy of capillary changes and immunopathologic findings consistent with antibody-mediated injury [63]. Immunoglobulin or complement deposition (C3d, C4d, or C1q) noted by immunofluorescence or immunoperoxidase is present, and this methodology is increasingly used in the pediatric population [64]. The presence of donor-specific antibody on the PRA is also thought to play a role in AMR, although it is not part of the diagnostic criteria [24]. Historically, graft dysfunction has been required to make a diagnosis of AMR, but some make the case that asymptomatic AMR can lead to worse graft outcomes. While the ISHLT has recently published criteria for the biopsy diagnosis of AMR, it is unclear how to incorporate the new criteria into clinical practice in the absence of symptoms of graft dysfunction [54].

Rejection Treatment

Certainly not all episodes of biopsy-diagnosed rejection require treatment. Some forms of mild rejection and asymptomatic rejection can resolve without treatment. But in those patients that are believed to have a clinically significant form of rejection, corticosteroids remain first-line therapy. Steroids can be administered in intravenous (methylprednisolone) or oral (prednisone) forms depending on institutional preference and the severity of the episode of rejection. If the rejection episode is considered severe, if graft dysfunction progresses on steroid-only therapy, or if rejection recurs after the steroid course is completed, more aggressive treatment is indicated. Cytolytic anti-T-cell antibody therapy is commonly used, with the polyclonal antibody ATG being the most frequently employed agent. In addition to cytolytic therapy, increases or changes in maintenance immune suppression are also necessary. For example, a patient on cyclosporine may be transitioned to tacrolimus. Children on azathioprine may be placed on MMF or sirolimus as adjunctive therapy. Oral corticosteroids could be introduced or increased.

There are additional therapies used for rejection episodes that are steroid resistant or unresponsive to anti-T-cell antibody. Methotrexate is used on occasion but requires careful monitoring for neutropenia and thrombocytopenia. Total lymphoid irradiation has been utilized, although there is concern for increased risk of coronary artery vasculopathy (CAV) and PTLD in association with this therapy [65, 66]. With recent advances in equipment, photopheresis is increasingly and safely used in the heart transplant population for the treatment of resistant or severe rejection, but experience is still limited in the pediatric population [67].

There have been no large randomized therapies for AMR in the adult heart transplant population, and data specific to children is even less clear. Therefore, treatment approaches for children with AMR are variable. The goal of treatment of AMR is to remove circulating antibody and prevent ongoing antibody formation. Therefore, treatment regimens have included steroids, cyclophosphamide, anti-T-cell antibodies, plasmapheresis, photopheresis, and/or IVIg. Rituximab, an anti-CD20 monoclonal antibody, is increasingly used in the pediatric population and targets B-cells [68]. Bortezomib depletes plasma cells and therefore also has potential to be an effective therapy for AMR [69].

Coronary Allograft Vasculopathy

Coronary allograft vasculopathy (CAV) is the leading cause of late death and graft loss in pediatric heart recipients. Although the pathogenesis of CAV is unknown, older recipient and donor age, greater number of episodes of rejection in the first year post-transplant, late rejection, late rejection with hemodynamic compromise, CMV infection, and a history of AMR are risk factors for the development of CAV [70–72].

Many children with CAV are asymptomatic, although chest pain, syncope, palpitations, and sudden death can be presenting signs [73, 74]. While patients are unlikely to experience cardiac chest pain in the first few years post-transplant due to denervation, reinnervation can occur. The diagnosis in the current era is most commonly made by selective coronary angiography. The pathology of this disease results in myointimal proliferation that is usually concentric and involves the entire length of the vessel, thus resulting in a diffuse, distal disease. Intravascular ultrasound (IVUS) is a sensitive tool in the surveillance for CAV and has been used safely and effectively in the pediatric population. IVUS can identify evidence of intimal thickening within the coronary artery that is not visible on angiography [75]. Coronary flow reserve (CFR) can be useful in identifying patients with microvascular disease [76]. CFR is a Doppler-derived ratio of coronary flow before, and after, intracoronary infusion of a vasodilator (e.g., adenosine). A low CFR (<2.0) indicates the presence of distal microvascular disease that may not be visible on angiography or even IVUS exams. Dobutamine stress echocardiography has been proposed as a screening method for CAV in children [77]. However, limitations to this technique include experience of

the sonographer and the echocardiographer interpreting the data.

Treatment of CAV is particularly challenged by the lack of knowledge with respect to mechanism of disease development. Some centers routinely use statins (HMG-COA reductase inhibitors) in the early post-transplant period for not only their lipid lowering effect but also for their anti-inflammatory properties [23]. Other medications such as diltiazem, angiotensin-converting enzyme inhibitors, antioxidants (vitamin E), and antiplatelet drugs have been utilized with the goal of preventing CAV, but their efficacy has not been clearly proven [78]. Immune-modulating medications such as MMF, sirolimus, and everolimus have antiproliferative properties, and there is some adult and animal data to suggest that coronary intimal proliferation is reduced with these therapies [79–81]. Similar studies in children do not exist, so management is based entirely on extrapolation of this adult data and institutional preference.

Unfortunately, there is no definitive treatment for CAV after it has developed, although the rate of progression is variable across patients. Some children with CAV have maintained graft function and stable disease for long periods of time, while others have rapid progression of disease and require re-transplantation shortly after the diagnosis is made. Sirolimus and everolimus have been shown to slow disease progression in adults, so the addition of one of these medications to the maintenance immunosuppression regimen is one approach [79, 82]. Coronary artery bypass grafting and angioplasty with stent placement has limited utility due to the diffuse nature of CAV. However, treatment with coronary stent placement for severe, focal, proximal lesions has been used in pediatric recipients as either a palliation measure with the goal of improving wait list safety while awaiting re-transplantation or in those who are not considered re-transplantation candidates [83]. Re-transplantation is the only definitive treatment for patients with severe or progressive CAV. Once CAV is moderate or severe, prognosis is poor with a 4-year freedom from graft loss of 30 % [71]. However, due to the shortage of organ donors and the poorer outcomes noted with a second transplant, not all patients should be listed immediately [84]. Therefore, rather than based simply on the angiographic severity of CAV, other factors such as clinical symptoms, graft function, and rapidity of progression of CAV lesions should be taken into consideration when determining timing of listing a patient for re-transplantation.

Infectious Issues

Most infections in pediatric heart transplant recipients are caused by pathogens that are also common in immunocompetent children. However, symptomatic infections are more common and typically more severe in the immunocompromised patient. While rare, opportunistic infections (e.g., *Pneumocystis jiroveci*) are seen in pediatric heart transplant recipients on occasion. Although most infections are easily treated, infection is second only to graft failure as the leading cause of death in the first month after transplantation. A related concern with infections in a transplant recipient is the long-term effects resulting from the donor graft being seen by the recipient immune system in the context of a pathologic (infectious) agent. Persistence of viral genome, detected by polymerase chain reaction (PCR), in endomyocardial biopsies of heart transplant recipients is associated with increased risk of developing CAV and late graft loss in children [85, 86].

The most common bacterial infections in pediatric heart transplant recipients include *Staphylococcus* sp., *Pseudomonas* sp., and *Enterobacter cloacae* [87]. These organisms are considered nosocomial and are representative of the flora present early after transplantation. Invasive *Streptococcus pneumonia* is a more common infection later after transplant and may in part be due to the limited pneumococcal vaccine response by solid organ transplant recipients [88, 89].

CMV is an important pathogen which is responsible for a significant amount of morbidity and mortality in pediatric heart transplant

recipients. In the transplant recipient, infection can be primary, reactivation (secondary), or superinfection. Primary infection occurs in a host not previously exposed (seronegative). Reactivation occurs in an individual that was previously exposed (seropositive) and is most common in association with induction therapy in the early post-transplant period or when aggressive immunosuppression is used to treat acute rejection. Superinfection is typically the result of a new strain of CMV not previously seen by a seropositive host. The late risks of CMV infection include an increased risk of acute graft rejection and development of CAV [90,91]. Recommendations for prophylaxis in the early post-transplant period were discussed earlier in this chapter. Active infections (as determined by PCR) in the recipient are usually treated with intravenous ganciclovir or oral valganciclovir depending on the severity of the infection [92]. IVIg or CMV immunoglobulin is often used as adjunctive therapy.

EBV is another common viral infection in pediatric heart recipients. Seroconversion after exposure to EBV is common in the pediatric population as a significant number of recipients are seronegative at the time of transplant. Primary EBV infection is an important risk factor for the development of PTLD which is discussed in more detail later in this chapter [93].

Herpes simplex virus most typically manifests as skin or mucous membrane infection and is typically managed with oral acyclovir. Varicella zoster virus is a common childhood illness and can result in either primary or reactivation infections. For those transplant recipients with known varicella exposure, prevention therapy with varicella zoster immunoglobulin and acyclovir can be effective. For those with active disease, oral acyclovir treatment is recommended, and fortunately, most cases remain mild. Influenza, parainfluenza, adenovirus, respiratory syncytial virus, and parvovirus B19 are among other common viral infections in the community that can affect a transplant recipient. Nearly all viral infections are more likely to surface when the patient is being treated for rejection with increased immune suppression. Fungal infections are fortunately uncommon in the pediatric heart transplant population with *Candida* sp. being the most common. However, unlike many of the other infectious pathogens previously discussed, invasive fungal infections in the transplant recipient are life-threatening. In a recent multicenter study, mortality was nearly 50 % with all deaths occurring within 6 months of transplant [94].

As outlined earlier in this chapter, prophylaxis for many of these infections is available and should be considered in the immediate post-transplant period (e.g., during induction) and when escalation of immune suppression is required to treat acute graft rejection. In addition, immunizations play an important role in the pediatric recipient. Beginning approximately 6 months after transplant, immunizations should be administered at routine times, with the exception of live-attenuated vaccines which are contraindicated in the transplant recipient [95].

Outcomes and Their Risk Factors

Transplant Morbidity

Although heart transplant remains a good option for children with end-stage heart failure and severe forms of congenital heart disease, the immunosuppressive medications required and the psychosocial impact of being a transplant recipient can result in significant post-transplant morbidities. These morbidities can be difficult to manage and importantly can impact quality of life and outcomes for the pediatric heart transplant recipient. In addition to acute graft rejection, CAV, and post-transplant infections, which were previously discussed, renal dysfunction, hypertension, hyperlipidemia, and malignancy are important potential problems faced by this population, and each will be briefly reviewed.

Renal dysfunction is a common problem in pediatric heart transplant recipients. Nearly 10 % of patients develop severe renal dysfunction as defined by a serum creatinine of >2.5 mg/dl within 11 years post-transplant [7]. Renal replacement therapy consisting of dialysis or renal transplant is required in 50 % of those

with severe renal dysfunction. Late renal failure occurs primarily as a result of chronic exposure to nephrotoxic medications, such as calcineurin inhibitors, which are a mainstay of immune suppression. Other factors associated with late renal dysfunction include earlier era of transplantation, black race, rejection with hemodynamic compromise, and worse renal function 1 year post-transplant [96]. Renal tubular atrophy and interstitial fibrosis are present in these patients and lead to a progressive decline in renal function over time. There does not appear to be any difference between tacrolimus and cyclosporine with respect to renal injury. However, strategies aimed at lowering the dose or avoiding calcineurin inhibitor use altogether result in improvements in renal function. Single-center experiences have described the use of sirolimus in place of or with low-dose calcineurin inhibitors in pediatric recipients with renal dysfunction and demonstrated efficacy and safety for this approach [97, 98].

Hypertension in children is defined by systolic or diastolic blood pressures that are consistently greater than the 95 % ile for age, gender, and height. Systemic hypertension is very common in the pediatric heart transplant recipient, with nearly two-thirds of patients being hypertensive 5 years post-transplant [99]. Calcineurin inhibitors and steroids are the biggest offenders in the pediatric recipient. Lowering the calcineurin inhibitor dose and discontinuing steroids can be helpful, but in most patients, antihypertensive therapy is required. Angiotensin-converting enzyme inhibitors, calcium channel blockers, and vasodilators (e.g., hydralazine) are the most commonly utilized.

Hyperlipidemia is present in 25 % of patients by 5 years post-transplant [99]. This problem is a consequence of immunosuppressive medications (e.g., cyclosporine, steroids, and sirolimus), diabetes (e.g., steroids and tacrolimus), and obesity (e.g., steroids). Hyperlipidemia may contribute to the development of CAV, but its exact role is not entirely clear. Despite the fact that statin (HMG-CoA reductase inhibitor) use is standard in the adult heart transplant population, the use in pediatric recipients is less consistent. Although the safety and efficacy of atorvastatin and pravastatin have been described in single-center experiences, no controlled trial of these medications in pediatric recipients has been performed [100, 101]. There is some data that suggests statins have an immunomodulatory effect via an increase in regulatory T-cells (Tregs) in the circulation of treated patients [102]. However, whether increased circulating Tregs are beneficial in the treatment or prevention of CAV has not been determined. Therefore, practically speaking, various approaches are utilized and vary from initiation of statin therapy early after transplant to delaying statin therapy until there is documented hyperlipidemia or at the time of diagnosis of CAV regardless of the lipid profile. Concern for the side effects of chronic statin use in children and the descriptive nature of the current studies makes consensus on this subject challenging.

PTLD encompasses a wide range of malignancies varying from benign tonsillar hyperplasia to life-threatening monoclonal lymphoma. The risk of PTLD is highest in the first year post-transplant, but onset can occur at any time. PTLD is much more common in children than adults primarily due to increased likelihood of EBV-seronegative status at time of transplant. PTLD has an incidence of 4–10 % in the pediatric heart transplant population, and survival following a diagnosis of PTLD is approximately 68 % at 3 years, with the greatest hazard of death occurring within the first 2 years following diagnosis [93]. There is a clear association between EBV infection and PTLD which is supported by epidemiologic observations and identification of EBV genome within PTLD tumors [103, 104]. Immunosuppressive medications prevent a normal T-cell response to EBV infection which establishes an environment for development of the malignancy. Although there are cases of EBV-negative PTLD, given the rarity of this entity in the pediatric population, it will not be discussed separately. Other than young age and being seronegative at the time of transplant, described risk factors for the development of PTLD in children also include increased frequency of rejection (likely due to increased immune suppression

Table 155.3 World Health Organization classification of PTLD

Early lesions	Reactive plasmacytic hyperplasia
	Infectious mononucleosis like
Polymorphic PTLD	Polyclonal
	Monoclonal
Monomorphic PTLD	B-cell lymphomas (e.g., diffuse large B-cell lymphoma, Burkitt, myeloma)
	T-cell lymphomas
Hodgkin lymphoma and Hodgkin-like PTLD	

required) and higher overall amounts of immunosuppression [105, 106].

PTLD can manifest in a myriad of ways in children and depends to some degree on location of the tumor. Fever, lymphadenopathy, and splenomegaly are common. Patients with PTLD may have single-site (48 %) or multisite (52 %) disease. Abdominal disease can manifest with abdominal pain, weight loss, vomiting, and/or diarrhea. Lung involvement can resemble a lower respiratory infection that is not amenable to standard treatment with persistent cough, chest pain, or dyspnea. Central nervous system involvement and multiorgan disease can occur as well but are less common. The diagnosis of PTLD is based on obtaining tissue for histologic evaluation. The World Health Organization (WHO) has classified PTLD as outlined in Table 155.3. Additional staging could involve a bone marrow biopsy, lumbar puncture, CT scanning (sometimes combined with positron emission tomography [PET] scanning), and blood work including EBV viral load detected by PCR.

The treatment for PTLD is a significant challenge and no randomized trials have been performed. Reduction of immunosuppression is the first line of therapy and was initially described by Starzl et al., however, this is accompanied by an increased risk of rejection and close surveillance is essential [107]. This approach allows the host immune system to control EBV-infected B-cell proliferation and is most effective for patients with polymorphic disease. Treatment with antivirals (e.g., acyclovir, ganciclovir) is common, but its efficacy remains largely unproven in the absence of controlled trials [108]. Tumors that are CD20 positive have been successfully treated with rituximab [109]. Chemotherapy is reserved for those patients that do not respond to less toxic therapies. In general, chemotherapy is recommended for those with Burkitt lymphoma and Hodgkin's disease if they fail to respond to a decrease in immune suppression or if disease is widespread. Specifically, low-dose cyclophosphamide and steroids with or without rituximab have been used in combination successfully [110, 111]. Interferon-α, IVIg, and cytotoxic T-lymphocytes are other therapeutic options that have been used for PTLD, but data to support their use is very limited.

Survival and Outcomes

There are many factors that are currently known to influence survival of pediatric heart transplant recipients. Younger recipients survive longer and this could be related to the more naïve immune environment that exists at the time of transplant. To support this concept, infant recipients have a median survival of 18.4 years compared to 12.0 years for adolescent recipients [7]. Patients with a pre-transplant diagnosis of cardiomyopathy tend to do better than those transplanted for congenital heart disease. Re-transplantation has the worst outcome, with survival particularly poor for those children that require re-transplant within 1 year of their original transplant [7]. Center volume also plays a role in outcome, with centers performing more transplants per year having better infant transplant outcomes and better overall 15-year survival. From 2001 to 2010, according to the International Society for Heart and Lung Transplantation, 178 centers performed pediatric heart transplants. Of these centers, 145 (81 %) only did 1–4 transplants annually, while 16 centers (9 %) did 5–9 transplants annually and 17 centers (10 %) performed at least ten transplants per year [7].

Graft loss is highest in the first year post-transplant. Risk factors for 1-year mortality include requiring ECMO support, having a congenital diagnosis, renal failure, ventilator support at time of transplant, intravenous antimicrobials (within 2 weeks of transplant), previous sternotomy, and an elevated PRA (>10 %) [7]. The use of induction and the type of calcineurin inhibitor utilized do not influence survival.

The cause of death varies by time from transplant. The most common causes of death in the first year post-transplant are rejection (15 %), multiorgan failure (15 %), infection (14 %), and graft failure (13 %). For deaths occurring beyond 3 years post-transplant, death is usually a result of CAV or graft failure [7]. Graft failure is a somewhat nebulous term as it can occur as a consequence of CAV, chronic rejection, or recurrent episodes of acute rejection.

Pediatric heart transplantation outcomes have improved dramatically since the first heart transplant was successfully performed in a child in 1967. Graft half-life, which represents the time by which 50 % of recipients have died or required re-transplant, was 12 years for pediatric recipients in the era 1982–1989. For the era 1995–1999, graft half-life for pediatric recipients cannot yet be calculated but will exceed 15 years [7]. Despite these improvements in outcome, the expected survival times for pediatric recipients remain limited when considered in the anticipated lifetime of a child. Ongoing efforts to improve our understanding of CAV and research focused on how to attain graft tolerance are critical for significant future improvements in graft survival.

Lung and Heart Lung Transplantation

156

Stuart C. Sweet and Charles B. Huddleston

Abstract

Lung and heart-lung transplantation has become an accepted therapeutic option for children with end-stage pulmonary parenchymal and vascular disease. In the past 25 years, nearly 1,800 lung and 700 heart-lung procedures have been reported worldwide in children. As experience with bilateral lung transplantation has grown, indications for heart-lung transplant have diminished. The latter procedure now makes up less than 10 % of the combined total each year. In spite of steady improvements in survival, mostly related to better early outcomes, long-term survival rates for pediatric lung and heart-lung recipients remain worse than those in other solid organ transplants. As the lung is continually exposed to the environment through the airway, it is thought that exposure to infectious agents and toxins is responsible for higher rates of infection and immunologic complications such as bronchiolitis obliterans, which is the major cause of long-term morbidity and mortality. Ongoing research related to prevention and treatment of bronchiolitis obliterans and other posttransplant complications is needed to improve quality of life and survival in this population of patients.

Introduction

Although the first human lung transplant was performed in the early 1960s by Hardy [1] and the first human heart-lung transplant was performed in a 2-month-old infant later that decade by Cooley [2], it was not until the early 1980s when improvements in immunosuppression and surgical techniques allowed prolonged survival for these procedures [3, 4]. Success in adults led to early reports of lung transplantation in children [5–7] with a steady increase through the 1990s. From 1986 through June 2011, 1770 lung and 660 heart-lung transplants in children were reported to the Registry for the International Society for Heart and Lung Transplantation (ISHLT) [8]. Following a plateau in the early 2000s, there has been a steady increase in pediatric lung transplants, with 126 reported to the ISHLT registry in 2010 (Fig. 156.1) [8]. Although initially heart-lung transplant was considered the treatment of choice for children with end-stage lung disease (with the healthy native heart often used as a "domino" transplant) or severe pulmonary hypertension, in the current era heart-lung transplant is generally reserved for patients with left ventricular failure or congenital heart disease not amenable to repair. Thus, heart-lung transplant has become much less common (Fig. 156.1). In the recent past, the frequency of heart-lung transplant in children has dropped to less than 10 per year worldwide [8]. Although roughly 40 centers have reported pediatric lung transplants during the past few years (i.e., 2–3 transplants per center per year), nearly half of the transplants are performed in a small subset of centers. Nearly 90 % of centers perform less than 5 transplants per year [8]. Lung transplant continues to be performed less frequently than other pediatric heart, liver, and kidney transplants. This is likely due to several factors, including lower prevalence of end-stage pulmonary diseases in children, continued improvement in survival for children with cystic fibrosis and pulmonary hypertension, and a significantly lower procurement rate of donor lungs than other organs. In the United States, in spite of improvement in allocation to adolescents and adults, the mortality rate for pediatric candidates remains higher than for most adults [9]. Thus, efforts to expand the potential donor pool and increase access to lung transplant for children remain important [10].

Lung Transplantation

Indications and Contraindications to Transplantation

Lung transplantation is generally considered appropriate for children with end-stage lung disease or pulmonary vascular disease for which there is no other therapy. Although the early experience was predominantly for patients with cystic fibrosis (CF), indications for lung transplantation in children have become considerably broader as experience with this procedure has grown and expanded into infants [11, 12]. The most common diagnoses for which children are transplanted are listed in Fig. 156.2 according to the age in years at time of transplantation. The most common adult diagnoses, chronic obstructive pulmonary disease (COPD), emphysema, and idiopathic pulmonary fibrosis, are virtually absent in the pediatric age groups. For children younger than 1 year of age, the most common diagnoses include pulmonary hypertension (mostly associated with congenital heart disease) and other pulmonary vascular diseases (primarily pulmonary vein stenosis and rarely alveolar capillary dysplasia). Also common are disorders of surfactant metabolism such as surfactant protein B (SPB) and C (SPC) deficiencies, ATP binding cassette A3 (ABCA3) transporter, and NKX2.1 mutations [12–15]. Other indications

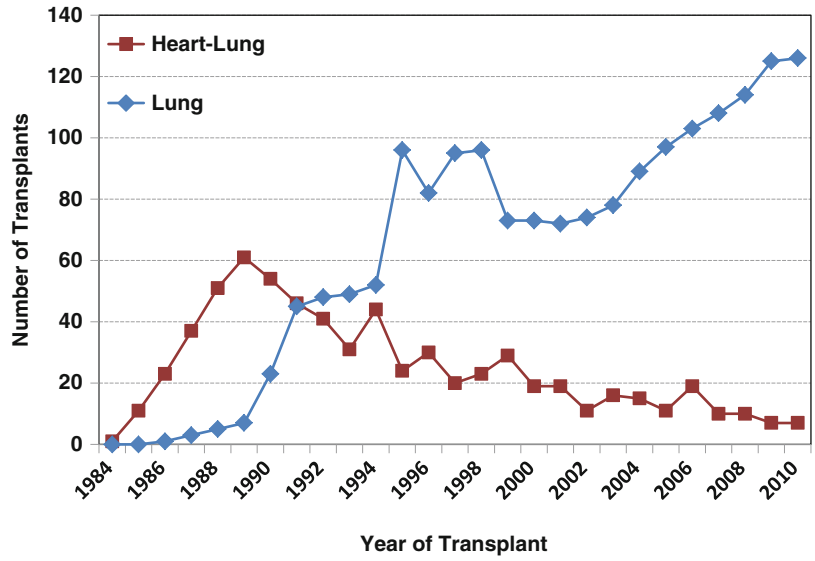

Fig. 156.1 Yearly number of pediatric lung and heart-lung transplants reported to the ISHLT registry 1984–2010 (Reprinted from, The Journal of Heart and Lung Transplantation, 31(10), Benden et al., The Registry of the International Society for Heart and Lung Transplantation: Fifteenth Pediatric Lung and Heart-Lung Transplantation Report—2012, 1087–1095, Copyright (2013), with permission from Elsevier [8])

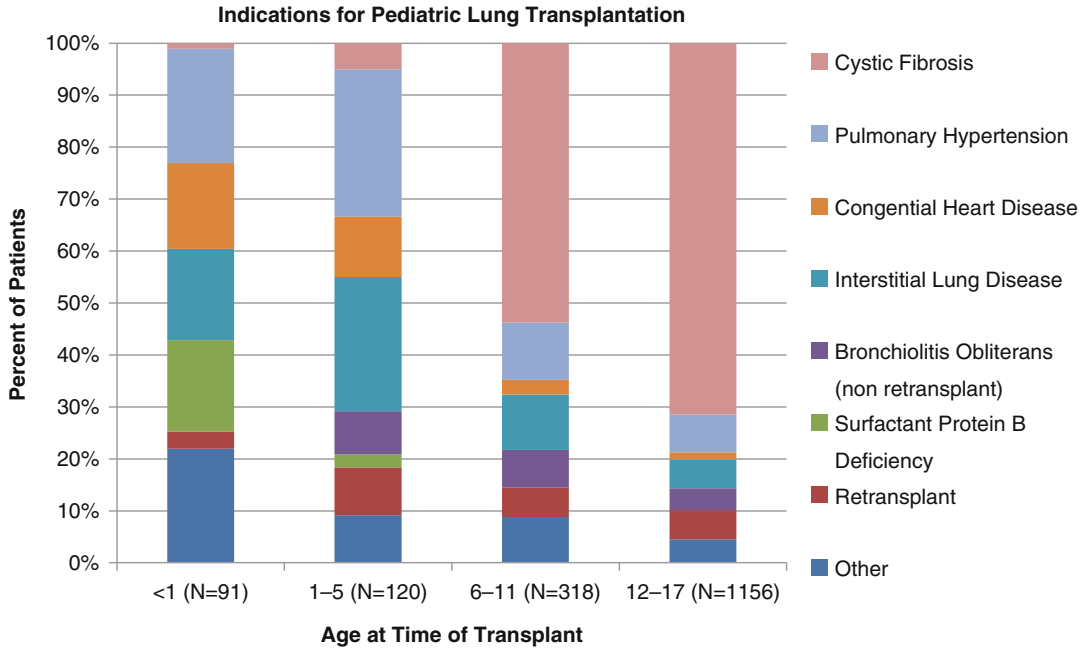

Fig. 156.2 Distribution of pediatric lung transplants by age and indication (Reprinted from, The Journal of Heart and Lung Transplantation, 31(10), Benden et al., The Registry of the International Society for Heart and Lung Transplantation: Fifteenth Pediatric Lung and Heart-Lung Transplantation Report—2012, 1087–1095, Copyright (2013), with permission from Elsevier [8])

for infants include interstitial lung disease, bronchopulmonary dysplasia, and pulmonary hypoplasia [10]. For children aged 1–5 years, disorders leading to pulmonary hypertension remain the most common indication. In patients 6–11 years of age, cystic fibrosis (CF) predominates. CF continues to be the most common indication in adolescents, accounting for nearly three quarters of that population. Overall, idiopathic pulmonary arterial hypertension as a lung

transplant diagnosis in children has diminished significantly during the past decade. The efficacy of medical therapies, including prostaglandins (epoprostenol), phosphodiesterase inhibitors (e.g., sildenafil), and endothelin-receptor antagonists (e.g., bosentan), is most likely responsible [8]. Surprisingly, the relative percentage of children with CF receiving lung transplants has declined only slightly in recent years in spite of a steady increase in the median survival for CF [8].

Absolute contraindications to pediatric lung transplant result from circumstances placing the child at clear risk for a poor posttransplant outcome (including multisystem organ failure and active malignancy) and are similar between pediatric and adult patients (Table 156.1). Other absolute contraindications include systemic infections such as HIV, active hepatitis C, or tuberculosis. Liver, renal, or left ventricular failure is an absolute contraindication to bilateral lung transplant though some transplant centers will consider multiorgan transplantation in such settings. Infectious contraindications are most common in patients with CF. Because lung transplant in patients with B. cenocepacia (formerly BCC, genomovar III) and a related organism, B. gladioli, is associated with significantly worse outcomes [16–18], B. cenocepacia colonization is an absolute contraindication in most pediatric centers. Based on case reports suggesting worse outcomes for patients colonized with Mycobacterium abscessus in some but not all settings [19, 20], colonization with atypical mycobacteria, particularly M. abscessus, may also be a contraindication. Although not an absolute contraindication, prior pleurodesis – either chemical or surgical – may lead to longer ischemic time related to bleeding. Some centers recommend avoiding talc pleurodesis. In patients with pulmonary vascular diseases, the presence of multiple aortopulmonary collaterals (often seen in congenital heart defects with absent central pulmonary arteries), coupled with multiple prior thoracotomies, has been associated with poor outcome [7, 21]. In addition, patients who have undergone multiple thoracic surgeries or who have had implantation of homograft valves or vessels have an increased likelihood of developing allosensitization and subsequent risk of hyperacute rejection or antibody-mediated allograft injury (see below). These risk factors are a relative contraindication in many centers.

Table 156.1 Contraindications to pediatric lung transplantation

Absolute	Relative
Active malignancy within 2 years[a]	Pleurodesis
Sepsis	Renal insufficiency
Active tuberculosis	Markedly abnormal body mass index
Severe neuromuscular disease	Mechanical ventilation or ECMO[c]
Documented, refractory nonadherence	Scoliosis
Multiple organ dysfunction[b]	Poorly controlled diabetes mellitus
Acquired immunodeficiency syndrome	Osteoporosis
Hepatitis C with histologic liver disease	Chronic airway infection with multiple resistant organisms[d]
Significant psychiatric illness in patient or primary caregiver	Fungal infection/ colonization
	Atypical mycobacteria infection/colonization (particularly smear positive)
	Hepatitis B surface antigen positive

[a]Some centers prefer a disease-free interval of 5 years
[b]Consider heart-lung transplant with concomitant left ventricular insufficiency or irreparable congenital heart disease, liver-lung transplant with concomitant hepatic failure
[c]Some transplant centers consider VA ECMO an absolute contraindication
[d]For some transplant centers, infection with *B. cepacia* complex organisms, particularly genomovar III (*B. cenocepacia*), is an absolute contraindication
Adapted from Faro et al. 2007 [41]

Finally, psychosocial issues particularly nonadherence can create a contraindication, especially when the child's parents share much of the responsibility for adherence. Managing such situations without creating the perception that the child is being punished for the parent's misbehavior is an individualized, shared responsibility between the referring and transplant

centers. For situations involving nonadherence to recommended treatment, prior to evaluation and listing for lung transplant, some transplant centers request that the referring center formulate a contract with the family that outlines the need for strict adherence and expect success with the contract for a 3–6-month period prior to proceeding. Adherence concerns may become an absolute contraindication in the presence of other medical risk factors or with failure on the part of the child and family to meet expectations in an agreed upon contract for care and follow-up. In addition to nonadherence, many centers consider significant psychiatric or mental health disorders in either the primary caregiver or the patient a strong contraindication to transplant.

Referral for lung transplant in pediatrics has typically been timed in order to match predicted mortality with the anticipated waiting time. In the United States, allocation of donor lungs is governed by the "Lung Allocation System" (LAS) implemented by the Organ Procurement and Transplantation Network (OPTN) in 2005 [22]. The LAS is based on models of waiting list mortality and posttransplant survival and prioritizes donor lung allocation to maximize the 1-year transplant survival benefit (LAS = posttransplant survival – 2* waiting list survival, normalized to a 0–100 scale). The survival models are based on diagnosis, age, height/weight, need for oxygen and ventilator support, pulmonary arterial pressures, 6-min walk distance, and lung function. Waiting time and waiting list mortality have decreased in the United States since the LAS was adopted [23]. However, due to the emphasis on waiting list mortality in the algorithm, sicker patients are receiving transplant and not surprisingly some (primarily those requiring mechanical ventilation) have worse overall survival than the norm in prior years [24]. The LAS does not govern allocation of lungs to children under 12. A modification of the allocation rules, creating two urgency tiers for this age group, was approved by the OPTN in 2009 in an effort to reduce waiting list mortality for younger children [25].

Timing of referral is quite disease-dependent. There are a few situations such as SPB deficiency, alveolar capillary dysplasia, and significant pulmonary vein stenosis where, once the family decides to pursue transplant, prompt referral and transport to the center is prudent. Such patients often progress quickly to refractory respiratory failure and require extracorporeal membrane circulatory support (ECMO). For most other diseases, the timing is less clear.

For cystic fibrosis, a series of studies over the years support a general recommendation to proceed with lung transplantation once the forced expired volume in 1 s (FEV_1) declines below 30 % predicted [26–28]. Nonetheless, even in the best model, the ability to accurately predict mortality in this case is less than 50 % [27]. Indeed, Liou et al. using proportional hazards models developed from the CF foundation and OPTN datasets concluded that lung transplantation did not provide a survival benefit to children with CF [29]. Their model was flawed – it was derived using data obtained at the time of listing and not at the time of transplant. Their study patients were listed prior the LAS implementation when patients were typically listed 2–3 years prior to their actual transplant to allow them to survive long enough to receive organs [10]. Nonetheless, prior and subsequent studies have demonstrated a survival benefit for children with CF [30, 31]. Lung transplantation remains the only treatment option available to extend life in patients with CF and end-stage lung disease [32].

For idiopathic pulmonary hypertension and pulmonary vascular disease, a cardiac index of less than 2 L/min/m^2, elevated pulmonary vascular resistance, right atrial pressures of greater than 7.4 mmHg, and right ventricular end diastolic pressure of more than 10.4 mmHg in spite of maximal vasodilator therapy portend poor survival and suggest the need to move to transplantation [33, 34]. Other factors that may correlate with survival include von Willebrand factor levels of more than 240 %, elevated uric acid levels, and plasma levels of brain natriuretic peptide (BNP) greater than 180 pg/mL [35–37].

Determining when to proceed with transplantation for patients with Eisenmenger's syndrome

continues to be challenging. Many of these patients can live for years, if not decades after diagnosis. For those with progressive disease, including severe hypoxia, syncope, or a limited functional status, lung (for patients with simple cardiac lesions amenable to repair at the time of transplant) or heart-lung transplantation should be considered [38, 39].

Patients with surfactant processing disorders other than SP B deficiency (i.e., SPC deficiency, ABCA3 transporter mutation, or NK2.1x mutation) can have variable presentations [40]. For these patients, referral should be made when it is clear that disease will lead to progressive respiratory insufficiency unresponsive to medical interventions.

In other diseases leading to lung transplant, criteria for timing of transplant are even less clear. Ultimately, in the absence of solid predictive models, most pediatric centers consider factors beyond cardiopulmonary function such as growth and nutritional status, frequency of hospitalizations, and potential for improvement in overall quality of life prior to committing a child to lung transplant. For this reason, most pediatric lung transplant centers recommend referral well before the patient reaches the tipping point between anticipated waiting list survival and estimated waiting time [41].

Candidate Evaluation and Pre-transplant Management

The transplant evaluation itself consists of a number of laboratory and radiographic studies as well as consultation with multiple services (Table 156.2). The evaluation is multidisciplinary in nature, involving both medical and psychosocial components.

Table 156.2 Recommended evaluation for pediatric lung and heart-lung candidates

Laboratory evaluation
Blood type (ABO)
Complete blood count
Coagulation studies (PT, INR, PTT)
Complete biochemistries including electrolytes and renal and liver function tests
Lipid profile
Serologies including CMV, EBV, HIV, hepatitis B and C, measles, varicella, herpes simplex, and Toxoplasma gondii
Anti-HLA antibody screen
Arterial blood gas
Autoimmune screen (ANA, ANCA, rheumatoid factor, quantitative immunoglobulins)
Thyroid profile
Microbiology
Sputum or deep throat culture and susceptibility testing
Tuberculin testing
Functional assessment
Pulmonary function testing
Six-minute walk test
Electrocardiogram
Cardiac catheterization (in select patients)
Imaging
Chest radiograph
Chest CT
Sinus CT (in patients with CF or immunodeficiency)
Echocardiogram
Bone densitometry
Consultations with
Cardiothoracic surgery
Cardiology (in select patients)
Infectious diseases
Social services
Psychology
Nutrition
Physical therapy
Child life

Most transplant centers partner with the referring center prior to transplant to maintain a state of health that will maximize the patient's chances of surviving the wait for organs and the opportunity for a successful posttransplant outcome. Many of the recommended interventions during this time period are independent of diagnosis: maximizing the nutritional status (including placement of a G-tube if needed), encouraging regular physical and occupational therapy to maximize muscle strength, minimizing infectious risks (including ensuring that vaccinations are up to date), and ensuring that the patient and family establish routines for adherence that will be of future benefit anticipating the complex posttransplant regimen.

Otherwise pre-transplant management will vary by disease state. For patients with CF, the focus will be on optimizing airway clearance, including the use of high-frequency chest wall oscillation devices (HFCWO) and intermittent percussive ventilation (IPV) and tailoring antimicrobial therapy to minimize the infectious burden and avoid the development of significant resistance. In patients with pulmonary hypertension and other pulmonary vascular disorders, maximizing pulmonary blood flow is key. Depending on the underlying etiology and severity of disease, pulmonary vasodilator therapy, diuretics, anticoagulation, and supplemental oxygen, may be of benefit. Atrial septostomy or Pott's shunt procedures may also be considered [42, 43]. In children with interstitial lung disease, steroids (either in high monthly dose pulses or daily regimens) and other immunosuppressive medications may be of some benefit [44].

Although mechanical ventilation is consistently shown to be a risk factor for mortality in ISHLT adult lung transplant registry reports [45], many pediatric centers will utilize mechanical ventilation for patients who develop respiratory failure after listing. Indeed, for infants and toddlers, patient and graft survival was similar for patients requiring mechanical ventilation at the time of transplant [29]. In addition to the use of veno-venous ECMO to bridge pediatric and adult patients to transplant [46–48], some centers are using the Interventional Lung Assist device (Novalung® iLA), a low-resistance membrane oxygenator that may be used in a pumpless configuration as a bridge to transplant [49]. The device has been used successfully in a child as young as 2 years of age [50]. The authors have also utilized the similar Maquet® Quadrox-iD membrane oxygenator in an attempt to provide adequate gas exchange while avoiding muscle relaxation. These devices carry similar risks for anticoagulant-related complications to ECMO; therefore, their role in long-term support remains to be clearly defined.

Donor Evaluation

The vast majority of pediatric lung transplant recipients receive organs from donors who have undergone brain death [9]. Potential donor lungs are evaluated using arterial blood gases, chest radiographs, airway cultures, and airway examination by bronchoscopy [51]. The donor history is reviewed for signs/symptoms of acute viral infection. In addition, the donor is routinely screened for hepatitis A, B, and C, HIV (as donor exclusions), as well as for varicella zoster, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and Herpes virus (to inform posttransplant management) [51]. More recently, techniques to allow ex vivo assessment of donor lungs have been developed that may effectively increase the donor pool, including the use of donation after circulatory death (DCD) donors [52]. This technology has yet to be widely adopted in the United States and current equipment has not been adapted for use with pediatric donors.

Transplant Surgical Procedure of Donor and Recipient

In contrast to adult lung transplantation, most procedures in children are performed while on cardiopulmonary bypass. Most commonly, the surgical approach is via a bilateral anterolateral transsternal incision at the 4th intercostal space (the "clamshell" incision) in order to optimize visualization and access to both pleural spaces. The recipient pneumonectomies are accomplished by first ligating and dividing the pulmonary and arterial and venous vessels. Then, the mainstem bronchus is dissected out and divided with a linear stapling device. The donor lungs are prepared by dividing and appropriately trimming the left atrial cuff, main pulmonary artery, and trachea. Each mainstem bronchus is trimmed to within two cartilaginous rings of the upper lobe takeoff. Most children receive bilateral sequential lung transplants with end-to-end rather than telescoping bronchial-to-bronchial anastomoses to minimize potential for stenosis [53, 54]. Generally, the membranous portion of the bronchus is anastomosed with a running suture and the cartilaginous portion with interrupted sutures. Absorbable monofilament material is preferred.

To improve the blood supply, pericardial or peribronchial lymphatic tissue from the donor and recipient is used to cover the anastomosis. This may also reduce the exposure of adjacent vascular structures to infection, in the event airway dehiscence [53, 55]. In patients with CF, vigorous washing of the recipient trachea and bronchial stumps with an antibiotic solution prior to implantation is used to reduce the likelihood of transmission of airway organisms to the donor allograft.

Living donor lung transplant, where a right lower lobe from one donor and a left lower lobe from another donor (generally family members) are implanted in the recipient, has virtually disappeared in the United States since the introduction of the LAS [56]. Nonetheless, living donor lung transplant is still used in Japan where access to donor organs suitable for children is more difficult. Other surgical strategies to increase the scope of organs available for transplant in infants and small children include downsizing the donor with a linear stapling device or lobectomy [57].

Early Posttranspant Care (ICU)

In general, immediate posttransplant management follows intensive care procedures for children having undergone a cardiothoracic surgical procedure. Fluid management deserves careful attention because the lungs may be prone to noncardiogenic pulmonary edema as a result of donor and ischemic injury. Therefore, inotropic and vasopressor support is preferable to aggressive fluid administration for maintenance of systolic blood pressure. Most recipients also receive liberal diuretic therapy. In addition to initiation of immunosuppression and appropriate antibiotic prophylaxis, postsurgical aspects unique to lung transplantation reflect the need for assessment and monitoring of the airway and vascular anastomoses and management of early graft dysfunction.

Immunosuppression

Virtually all pediatric lung transplant recipients receive triple drug immunosuppression in the immediate posttransplant period including a calcineurin inhibitor (CNI), an antimetabolite, and corticosteroids. In the current era, roughly 80 % of recipients receive tacrolimus and 65 % receive mycophenolate mofetil (MMF) [8]. Lung transplant recipients are felt to have a higher risk for rejection than other solid organ transplant recipients. This is likely due to external exposure of the graft through the airways and the fact that the graft receives the full cardiac output. Thus, most patients receive a more intense immunosuppression regimen: initial target trough levels for tacrolimus are 10–20 ng/ml, and initial dosing for prednisone is 0.5–1.0 mg/kg/day with most patients weaned to 0.25–0.5 mg/kg/day by 3–4 months after transplant. Based on the most recent ISHLT registry report, more than 60 % of recipients receive some form of induction. Most receive an IL-2 receptor antagonist (i.e., basiliximab); the majority of the remainder receive a polyclonal antilymphocyte or antithymocyte agent such as thymoglobulin [8].

Although data suggest that steroid avoidance strategies can lead to successful immunologic outcomes in other pediatric solid organ recipients [58], no systematic study of steroid withdrawal has been performed in pediatric lung transplantation. Thus, very few pediatric lung transplant recipients are on a steroid-free regimen at 5 years posttransplant [8]. Because of the long-term growth and other impacts of chronic steroid use, further study is needed in this area.

Antimicrobial Regimen

As a result of the ongoing exposure to the environment through the airways, plus the potential in CF and other patients for seeding of the graft from organisms colonizing the trachea, upper airway, and sinuses, pediatric lung transplant recipients typically receive prophylactic intravenous antibiotics before and for up to 2 weeks after lung transplantation. The antibiotic regimen is tailored to treat community-acquired pathogens, skin flora, and organisms colonizing the recipient and should be modified based on cultures obtained from the donor lungs prior to implantation. Patients without CF or methicillin-resistant Staphylococcus aureus (MRSA) generally receive a single

antibiotic with broad Gram-positive and Gram-negative coverage. Patients with CF receive antimicrobial therapy chosen to cover organisms in their sputum typically *Pseudomonas aeruginosa* and occasionally *Achromobacter spp., Stenotrophomonas maltophilia*, or other Gram negatives. Patients colonized with MRSA (which has recently become more prevalent in children with CF) receive vancomycin. Most centers use antifungal prophylaxis in patients colonized with Aspergillus fumigatus. Voriconazole or anidulafungin or in some cases aerosolized amphotericin or oral itraconazole are used [59]. *Pneumocystis jiroveci* prophylaxis with three times weekly trimethoprim/sulfamethoxazole (TMP/SMX) is begun once the patient is able to tolerate oral medications. Patients with allergy to TMP/SMX may be given atovaquone, dapsone, or nebulized pentamidine. Nystatin oral washes are used as prophylaxis for candidiasis.

Although the use of ganciclovir prophylaxis has significantly reduced the incidence of CMV pneumonitis, CMV continues to be a risk factor for mortality in pediatric lung transplant recipients [60, 61]. Strategies used for CMV prophylaxis vary considerably across transplant centers. Typically, no prophylaxis is given when both recipient and donor are CMV seronegative (although ganciclovir or acyclovir may be given for herpes simplex virus prophylaxis) [62]. When either the donor or recipient is seropositive for CMV, ganciclovir or valganciclovir is administered for 4–12 weeks. Based on recent studies, some centers extend prophylaxis (with IV ganciclovir or oral valganciclovir) for 6 months or longer [63, 64]. In addition, some pediatric centers augment ganciclovir prophylaxis with CMV hyperimmune globulin (CMVIg) [65]. However, the benefit of CMVIg as prophylaxis remains unclear [66].

Long-Term Management

As in adults, the key to effective graft assessment and management involves measurement of lung function. Yet, lung function testing in children is more challenging, particularly in young children. Spirometry is generally not feasible or reliable in children less than 6 years of age. Although spirometry is essential for the clinical diagnosis of bronchiolitis obliterans syndrome (BOS) (see below), increases in spirometry associated with lung growth in older children and adolescents may mask changes that would otherwise meet diagnostic criteria. Therefore, most pediatric centers use percent predicted values rather than absolute volumes when assessing for the development of BOS. Thoracoabdominal compression techniques are available for infants and can identify the presence of airflow obstruction. However, these techniques require sedation, specialized equipment, and experience and cannot be performed in children with height greater than 90 cm [67, 68]. Also, the requirement for sedation limits the frequency with which infant pulmonary function testing can be obtained. Moreover, the most recent BOS definition does not include criteria for using percent predicted FEV_1 or FEF_{25-75} or values obtained with infant pulmonary function in the diagnosis of BOS [69].

Because of these limitations, some pediatric transplant centers routinely include high-resolution inspiratory/expiratory chest CT scans and ventilation/perfusion scans to assess for bronchiectasis and air trapping suggesting of the presence of obliterative bronchiolitis (OB) [70–73].

A more recently developed technique that can be used in children as young as 2 years old to assess for airflow obstruction is impulse oscillometry (IOS) [74, 75]. In this technique, the patient briefly breathes normally into a mouthpiece or a special face mask. Active cooperation is not required. IOS may be particularly useful in preschool-aged children for whom both infant pulmonary function testing and conventional spirometry are not generally available.

Despite reports of comparable long-term outcomes when transbronchial biopsy (TBBx) is performed only in response to respiratory symptoms [76], surveillance is supported by reports that a single episode of minimal acute rejection may be a risk factor for chronic rejection [77, 78]. Thus, many pediatric centers perform TBBx in order to screen for asymptomatic acute rejection. A typical schedule would be TBBx at 2 weeks,

1, 2, and 3 months after transplant, at quarterly intervals for the first year and semiannually thereafter [41, 79]. Nonetheless, TBBx in infants and toddlers may be more challenging. Pediatric bronchoscopes suitable for infants and small children have a 1.2 mm suction channel requiring smaller transbronchial biopsy forceps that typically yield tiny pieces of tissue. Thus, with these small forceps, obtaining sufficient tissue for the reliable diagnosis of rejection in infants, particularly B and C grade rejection, is often quite challenging [80]. More recently, a hybrid bronchoscope has become available with a 2.0 mm suction channel. The authors have been successful using this bronchoscope in infants and toddlers.

In addition to diagnostic challenges unique to pediatric recipients, therapeutic challenges also exist. Younger children often require liquid forms of medication (for appropriate dosing or because they are unable to take pills). Yet, liquid forms are often not available for newer immunosuppressant and anti-infective agents. Medications may sometimes be compounded by local pharmacies, but dosing decisions must often be made in the absence of pediatric-specific absorption and pharmacokinetic data. Managing the use of liquid forms may also be challenging for patients and families due to refrigeration requirements or a short shelf life.

Outcomes and Their Risk Factors

Survival

According to the most recent ISHLT registry report (for patients transplanted between January 1990 and June 2010), survival after pediatric lung transplantation is comparable to that in adults with median survivals of 4.7 and 5.3 years, respectively ($P = 0.4368$) [8]. Five-year survival rates for pediatric recipients have improved significantly, from 41 % in the early era (1988–1994) to 46 % during 1995–2001 and 54 % in the recent era (2002–2010). However, when half-life conditional on survival to 1 year is examined, no significant difference is seen when comparing eras, suggesting that improvements in early mortality are primarily responsible for the era effect [8]. Survival in children transplanted between the ages of 1 and 11 years of age was also better when compared to patients transplanted between 12 and 17 years of age.

Lung re-transplantation has become a more frequent occurrence in the recent era [23, 81], likely as a result of shortened waiting times resulting from the LAS for children 12 and older and improved survival for selected recipients in the recent era [82]. This information must be tempered by data from a recent registry report which continues to show a poor – 36 % – 5-year survival [81]. Although patients transplanted more than 1 year beyond their primary transplant do better, appropriate selection of pediatric re-transplant candidates remains an important area for investigation.

Causes of Death

Causes of death vary by the time after transplant. Based on data in the most recent ISHLT report, graft failure is the most common cause of death in the first 30 days, followed by "cardiovascular" and "other." From 30 days to 1 year, infection is the primary culprit, followed by graft failure and multiple organ failure. Beyond 1 year, obliterative bronchiolitis accounts for roughly 40 % of deaths, followed by graft failure and infection [8]. It is important to note that this distribution has not changed substantially over the course of time, suggesting that effective therapies for obliterative bronchiolitis remain to be elucidated.

Risk Factors

Risk factors for 5-year mortality in the most recent ISHLT report include the era effect noted above, increased mortality in patients on the ventilator at the time of transplant, single-lung transplant recipients, patients >14 years old, and patients transplanted in less experienced transplant centers (<3 cases/year) [8]. The risk of mechanical ventilation is less clear when infants are considered: one report concluded that ventilator use is not a risk factor for posttransplant mortality in infants [83].

Adolescence

The finding that adolescents have worse long-term outcome than younger children is also consistent over time and across solid organs [84]. In the context of ongoing cognitive development and emerging autonomy, adolescents may embark on risk-taking behavior including nonadherence with medical therapy leading to an increased incidence of late acute rejection, graft failure, and mortality [85, 86]. Programs considering offering lung transplants to adolescents must take these issues into account and include on their team dedicated practitioners with sufficient experience dealing with the unique and special needs of adolescents. Moreover, these issues may be magnified during care transitions. It is not surprising that the addition of a new environment and often a new healthcare and insurance system onto the existing challenges of adolescence may lead to poor medical outcomes associated with transition [87]. Effective communication between the pediatric and adult centers, specifically between providers, is a key component for success [88, 89]. As success in long-term outcomes increases, adolescence, transition, and adherence will continue to be areas of active study in pediatric lung transplantation [90, 91].

Transplant Benefit, Functional Outcome, and Quality of Life

Quality of life (QOL) in adult lung transplant recipients is reported to be better than QOL in candidates on the waiting list [92–94]. Nonetheless, caution is recommended when extrapolating these findings to children and adolescents. Although ISHLT registry reports typically show that more than 80 % of lung transplant survivors have no limitations to activity at 1, 3, and 5 years posttransplant [8], there are only a few studies of QOL in pediatric lung transplant recipients. QOL in thoracic transplant recipients was 24 % better in one study [95]. A second study, involving a group of 47 thoracic organ recipients (6 lung transplant recipients), reported health status comparable to children with asthma, juvenile rheumatoid arthritis, and intractable epilepsy but lower than the normal population [96]. These studies may not take into account the child's baseline capabilities prior to transplant and their expectations after transplant [95]. Moreover, the child's development level must also be considered when constructing QOL instruments for children. Systematic assessment of quality of life and developmental impact of transplant remains a priority for longitudinal studies involving pediatric lung transplant recipients.

Development

Neurocognitive outcome following lung transplantation is of particular concern, especially in infants. In the critically ill infant faced with altered environmental interactions, impaired tissue oxygen delivery, recurrent infection, and poor nutrition, infants who receive solid organ transplants are at risk for the development of learning disabilities, visual and spatial deficits, and motor delays. Yet, the neurocognitive plasticity in infancy makes predication of outcome challenging. Although children with chronic renal failure who underwent transplant showed significant improvement in measurements of head circumference, motor skills, and cognitive functioning (most children were normal or near normal) [97], a report of infant lung transplant found 40–50 % of infants had severe motor and cognitive delays [83]. Thus, it is vital that transplant programs caring for infants consider the child's neurodevelopment status through all phases of transplant so that appropriate expectations can be set prior to transplant and interventions may be implemented early. Identification of the pertinent risk factors associated with developmental delay following lung transplantation is another priority area for research.

Lung Growth

One question raised in consideration of lung transplant for infants and young children is whether the lung allograft would grow [5]. Studies using animal models of allogeneic lung transplantation demonstrated an increase in lung volumes and airway size with age [98]. Serial CT scan data indicates growth of intrathoracic airways over time [99]. Spirometry and lung

volume measurements in human transplant recipients were reported to be normal in infants [100] and older children [7]. Yet, spirometry reflects alveolar volume rather than surface area for gas exchange. Measurement of the latter is important in growth assessment. Indeed, a small study showed that the diffusing capacity of carbon monoxide (DLCO) did not increase in pediatric recipients of cadaveric and living donor transplants suggesting that lung growth did not occur [101]. Further study is needed to clarify the extent of lung growth in lung transplant recipients, particularly in infant and toddlers for whom DLCO is not as easily measured.

Complications

Complications following lung transplant follow a predictable time course that can be broken down into three general phases. In the immediate posttransplant phase, complications related to the surgical procedure and the condition of the recipient and allograft at the time of implantation are paramount. In the early phase (1–3 months), immune complications and side effects of immunosuppression are most common. These issues continue during in the late phase (beyond 3 months), and chronic immunologic complications such as obliterative bronchiolitis and malignancy also appear.

The various forms of lung allograft rejection remain an important obstacle to achieving long-term lung transplant outcomes comparable to those of other solid organ transplant recipients. Mechanisms proposed to explain this discrepancy include abundance of antigen-presenting cells resident in the pulmonary vasculature and lymphatic system that arrive with the allograft; continued airway exposure to environmental irritants, toxins, and pathogens; and the fact that the lungs receive the entire cardiac output, increasing the efficiency of the adaptive immune response [102].

Immediate Posttransplant Phase

Most pediatric lung transplant procedures are performed on cardiopulmonary bypass. Thus, bleeding in the thoracic cavity or at the vascular anastomoses is a common immediate problem, particularly in patients who have had prior thoracotomy or pleurodesis [103]. Complications related to the vascular anastomoses may present with hypotension and radiographic abnormalities. For example, thrombus formation in the pulmonary veins or left atrium may occur [104]. Perfusion scintigraphy and echocardiography may be useful in evaluating the venous anastomoses.

Most pediatric lung transplant recipients undergo flexible bronchoscopy within 24–48 h of transplantation to assess the integrity of the airway anastomosis and obtain cultures. The finding of dehiscence at the bronchial anastomoses may require an early return to the operating room. Fortunately, dehiscence of the airway anastomosis has become rare since the development of techniques to cover the anastomosis with vascularized tissue [55, 105, 106].

Hyperacute rejection is a rare potentially catastrophic complication that can occur within hours of transplant. Hyperacute rejection is caused by preformed recipient antibodies binding to donor human leukocyte antigen (HLA) molecules on vascular endothelium. The resulting vascular damage may lead to obstruction and severe graft ischemia. Hyperacute rejection is treated with plasmapheresis and is preventable by performing a crossmatch with donor cells and recipient serum prior to transplant [107]. Because the logistics of organ allocation (including distance between donor and recipient) generally preclude prospective crossmatching, screening the recipient for anti-HLA antibodies and avoiding donors with related antigens is the most commonly used approach to prevent hyperacute rejection. In patients with a significant percentage of preformed antibodies, a crossmatch concurrent with transplant may be performed to allow patients with a positive crossmatch to have early initiation of plasmapheresis.

The most common complication seen during the first posttransplant week is primary graft dysfunction (PGD) [108, 109]. PGD, often equated to reimplantation lung injury, is affected by the duration of ischemia prior to implantation. Causative factors are thought to include generation of hydroxyl radicals and proinflammatory cytokines during graft

ischemia [110–112]. PGD encompasses a broad spectrum of symptoms ranging from mild, non-cardiogenic pulmonary edema to fulminant graft failure with diffuse alveolar damage on histologic assessment. PGD is graded based on the extent of hypoxemia and presence of diffuse infiltrates on chest imaging [109]. Treatment is supportive including meticulous fluid management and protective ventilation strategies [113]. ECMO may be beneficial in severe cases [114, 115]. Outcomes of re-transplantation for PGD are generally poor [116].

Early Phase

Surgical Complications

Complications related to the surgical procedure may persist beyond the immediate posttransplant period. The most important of these relates to the airway anastomosis. In addition to rare dehiscence, fibrotic strictures, excessive granulation tissue, and airway collapse at the site of the anastomosis may be seen at a frequency comparable to that seen in adults [117, 118]. Factors responsible for anastomotic narrowing are thought to include airway ischemia, impaired airway healing, and barotrauma related to prolonged ventilation after transplantation [117]. Clinically significant, airway stenosis is treated with balloon dilatation, typically through a rigid bronchoscope. The use of metallic expandable stents is problematic because of the formation of granulation tissue and their limited ability to expand to accommodate growth ultimately leading to a need for removal which may lead to fatal complications [119]. Silicone rubber stents are prone to dislodgement or obstruction [118]. Newer biodegradable stents have recently been developed with the potential to relieve stenosis but subsequently disappear to allow for growth of the airway [120].

Other complications of the surgical procedure include injury of the phrenic or recurrent laryngeal nerve, causing diaphragmatic or vocal cord dysfunction. In most cases, treatment is not indicated. However, plication of the affected diaphragm may be considered in situations where recurrent infection of the ipsilateral lung occurs.

Immune Complications: Acute Rejection

Most pediatric lung transplant recipients have at least one episode of acute rejection (AR). AR is most commonly seen from about 1 week after transplantation through the first few months (thought to be related to the window where donor-derived dendritic cells remain in the graft) but can be seen even 2–3 years later [102]. Signs and symptoms of acute rejection are similar to infection, including cough, fever, dyspnea, hypoxemia, and radiographic changes. Spirometry may show an obstructive pattern. Tachypnea and crackles may be evident on chest auscultation. Evaluation with bronchoscopy, bronchoalveolar lavage, and TBBx is generally indicated to distinguish between infection and AR, particularly during the first 3 months after transplant. AR is diagnosed by histology. Findings include perivascular lymphocytic infiltrates with or without airway inflammation and are graded A1 to A4 according to the ISHLT grading system [72, 121, 122]. As noted above, many transplant centers advocate surveillance bronchoscopy to identify asymptomatic AR. Support for screening biopsies during the first posttransplant year has been increased following publication of data suggesting that a single episode of minimal acute rejection (A1) is an independent risk factor for chronic rejection [77, 78]. However, this finding was not confirmed in a multicenter analysis of pediatric lung transplant recipients [123].

Most pediatric centers treat AR grade A2 and above with 10 mg/kg of intravenous methylprednisolone daily for 3 days and follow-up this therapy with repeat biopsies 2 weeks later. In cases of persistent or recurrent AR, augmented immunosuppression with antithymocyte globulin is a consideration, particularly if the underlying rejection is not improved. Although most patients have at least one AR episode, younger transplant recipients (<3 years of age) appear to have a lower risk for AR than older children or adults [7, 83, 124].

Immune Complications: Humoral Rejection

Antibody-mediated rejection (AMR) is a more recently recognized immunologic complication

of lung transplantation. Clinical manifestations of AMR are again similar to both infection and AR; patients present with dyspnea, pulmonary infiltrates, and decreased lung function. Although there has been ongoing debate regarding the specific criteria for diagnosis, identification of circulating donor-specific antibodies (identified using solid phase techniques), alveolar capillary complement (C4d) deposition, and capillaritis in the setting of allograft dysfunction has typically been considered sufficient evidence [125]. Recently, an ISHLT consensus statement was published that greatly broadens the histologic findings that should raise suspicion for AMR (including all other types of rejection) but also adds the constraint that C4d positivity must be present in greater than 50 % of interstitial capillaries [126].

Treatment of humoral rejection varies among pediatric centers. Most centers use some combination of steroids, plasmapheresis, intravenous immunoglobulin, and B-cell-directed therapy (Cytoxan or rituximab) [127]. Newer agents such as bortezomib, a proteosome inhibitor that targets plasma cells, or complement inhibitors such as eculizumab are increasingly being tried for treatment of AMR [128, 129].

Infection

Although lung transplant recipients are at increased risk for infection beginning immediately after transplant and continuing throughout the life of the graft, the incidence of infection is highest in the first weeks to months after transplant. Many factors contribute to this increased risk. In addition to the normal risk of nosocomial infection associated with surgery and ventilator support, risks specific to lung transplantation include immunosuppression (highest in the first few months posttransplant), organisms present in the donor at the time of procurement, impaired cough reflex resulting from the disruption of afferent and efferent nerves controlling the cough response, impairment of mucociliary transport associated with airway injury at the time of procurement, interruption of the normal mucociliary ladder at the level of the airway anastomoses, and altered trafficking of immune effector cells to regional lymph nodes [130]. In spite of prophylactic antibiotics given in the perioperative period (see above), recipient factors (particularly in patients with CF) and donor factors (e.g., active viral infection) may result in significant early infections. Early viral infection seems to be particularly common in infants and toddlers, perhaps because they are less likely to have developed immunity [11]. In recipients with CF, seeding of the blood or mediastinum with recipient airway flora may occur during explantation. Some centers, concerned that chronic sinus disease typical of CF is a potential source of infection to the allograft, advocate pretransplant sinus surgery coupled with antibiotic washing of the sinuses [131, 132]. However, pretransplant sinus surgery did not provide survival benefit in a retrospective analysis of sinus surgery in patients with CF undergoing transplant at a major transplant center [133].

Subsequently, infections may arise related to community and nosocomial bacteria as well as opportunistic pathogens (pneumocystis, Candida, CMV). Patients who are seronegative for CMV and receive lungs from a CMV-positive donor are at particular risk for CMV disease during this early phase though the prophylactic regimens against CMV (see above) are generally effective.

CMV infection may manifest as a viral syndrome associated with fever and leukopenia to full blown pneumonitis with viremia and GI tract involvement. Findings typical of CMV pneumonitis include cough, fever, chills, respiratory distress, crackles, and diffuse interstitial infiltrates. Diagnosis of CMV generally requires either evidence of CMV viremia (typically with PCR) or CMV pneumonitis on TBBx (typically with CMV immunohistochemistry) in the setting of the typical clinical picture. It is worth noting that BAL positive for CMV PCR in asymptomatic patients is suggestive of viral shedding. CMV infection is treated with IV ganciclovir for 2–6 weeks. Some centers add CMV hyperimmune globulin. Oral valganciclovir may be administered for 2–3 months after completion of the IV ganciclovir course. Although in the preganciclovir era, the incidence of CMV disease in mismatched recipients reached 75 % or higher in the first 6 months after transplant, [134] current

prophylaxis and treatment has decreased both the frequency of CMV pneumonitis and its importance as a risk factor for OB [135, 136].

As with CMV, effective prophylaxis with TMP/SMX beginning in the 1980s has significantly reduced the incidence of *Pneumocystis jirovecii (carinii)* pneumonia (PJP). Nonetheless, PJP should be considered in patients with acute onset of fever, respiratory distress, interstitial infiltrates, and hypoxemia, often out of proportion to radiographic disease. Diagnosis is made with silver or fluorescent staining of BAL specimens. IV TMP/SMX is the treatment of choice.

As noted above, children are at greater risk for respiratory viral infections. Causes include increased exposure (daycare, school, siblings) and lower immunity. Infections with adenovirus [137], paramyxoviruses including parainfluenza, and respiratory syncytial virus (RSV) can cause significant lung injury or mortality [138, 139]. Many centers treat these viruses aggressively with cidofovir and ribavirin as indicated [139–141]. Respiratory viral infections are also associated with the later development of BOS [142].

Finally, fungal infections and atypical mycobacterial infections also pose significant risk for adverse posttransplant outcomes [143, 144].

Gastrointestinal Complications

Gastrointestinal complications, most commonly gastrointestinal dysmotility and/or gastroparesis, occur with an incidence of up to 50 % [145]. Injury to the thoracic vagus nerve during the mediastinal dissection, neuropathy, infection, and effects of underlying disease may contribute [145]. GI dysmotility can lead to reflux, microaspiration, lung injury, and ultimately OB [146–148]. GI dysmotility may be particularly problematic in infants because of their predisposition for reflux [149].

Arrhythmias

Reentrant rhythms related to suture lines between the donor left atrium/pulmonary veins and the recipient left atrium may lead to supraventricular arrhythmias, including SVT, atrial flutter, and atrial fibrillation. In general, such arrhythmias do not cause hemodynamic compromise, respond to conventional therapy, and are self-limited [150].

Medication Side Effects

Although triple drug immunosuppression has allowed long-term success in solid organ transplantation, side effects of these medications can, in some patients, affect function and quality of life. CNI, including cyclosporine (CSA) and tacrolimus, may cause hypertension and nephropathy, perhaps less so with tacrolimus [151]. The renal impact of CNI is compounded by the need for use of nephrotoxic antibiotics including aminoglycosides, cidofovir, or amphotericin. These complications are significant. At 1 year posttransplant, 41.7 % of patients have hypertension and 10 % have renal dysfunction; at 5 years these numbers are 69.8 % and 32.8 %, respectively [8]. Hirsutism and gingival hyperplasia, most common with CSA, are much less frequent in the current era where most patients receive tacrolimus [8, 151]. CNI also cause neurologic toxicity. Seizures, often associated with posterior reversible encephalopathy syndrome (PRES), are the most concerning finding [152, 153]. But headache and sleep disturbance are also common problems felt to be related to CNI use that can develop in the first months after transplant [152].

Routine blood counts are recommended in patients receiving azathioprine or MMF because of their capacity to cause leukopenia. Patients should also receive periodic monitoring for the anticipated side effects of systemic and oral corticosteroids including hypertension, cataracts, osteoporosis, and insulin resistance. Diabetes, particularly in patients with CF and perhaps precipitated by the use of tacrolimus and corticosteroids, is present in more than 35 % of long survivors of lung transplantation [8, 154].

Late Phase

Complications seen in the early phase including infection, drug toxicity, acute cellular and humoral rejection, and airway anastomotic narrowing may still be seen during late phase. Complications that typically appear in this phase include posttransplant lymphoproliferative disease (PTLD)

and bronchiolitis obliterans (BO), two potentially life-threatening complications.

Posttransplant Lymphoproliferative Disease

Malignancy after lung transplantation occurs in 5.6 % of pediatric recipients by 1 year after transplant and reaches 11.2 % at 5 years. More than 90 % of these are PTLD [8]. In this setting, PTLD is typically an EBV-driven lymphoproliferation [155, 156]. The incidence of PTLD is higher in lung transplant recipients than other solid organ transplant recipients, higher in patients with CF, and higher in children compared to adults [157, 158]. Potential factors responsible for these observations include the intensity of immunosuppression in lung transplant recipients and the observation that a large percentage of children are EBV seronegative at the time of transplant [156].

PTLD may be difficult to diagnose as presenting symptoms are often vague and confusing. Although PTLD can be asymptomatic, symptoms of cough, fever, and dyspnea are not uncommon. Early diagnosis requires a high index of suspicion. This is important because early treatment improves the likelihood of effective cure. PTLD usually involves the allograft during the first year [159]. In this setting, the typical radiographic finding is single or multiple round or ovoid pulmonary nodules [160]. Involvement of lymph nodes draining the chest is not uncommon. After the first year, PTLD is often found in extrapulmonary locations, including the GI tract, the skin, and lymphatic tissue, including the nasopharynx [161, 162]. Quantitative measurement of EBV by PCR is a sensitive and somewhat specific marker for PTLD. Most centers obtain EBV PCR measurements routinely in children [163]. Although some adult centers respond to the presence of elevated EBV PCR by reducing immunosuppression [164], a recent study suggests caution with this approach in children [165]. Most pediatric centers respond to elevated EBV PCR with additional testing. For example, positron emission tomography can be a sensitive and specific test for PTLD [166]. Histologic diagnosis is a key component of the diagnostic and prognostic process. A monomorphous histologic pattern has a worse prognosis [167].

Although reduced immunosuppression can be successful in some patients, it carries a significant risk for the development of acute and chronic rejection. In most cases additional therapy is needed to induce remission. Many patients are now treated according to the Children's Oncology Group protocol ANHL 0221 (including rituximab, an anti-CD20 monoclonal antibody shown to be effective in non-Hodgkin's lymphoma, low-dose Cytoxan, and prednisone) which has shown promise as an approach to therapy for PTLD in pediatric solid organ transplant recipients [168, 169].

Obliterative Bronchiolitis and Bronchiolitis Obliterans Syndrome

Obliterative bronchiolitis (OB) is the primary reason long-term survival rates after lung transplantation are worse than other solid organ transplants. Six years after lung transplantation in children, only 40 % of survivors are free of OB. Moreover, OB is the leading cause of death after the first year posttransplant [8]. Although it was first described in the setting of lung transplantation nearly 30 years ago, the etiology of OB remains elusive and no uniformly effective treatment options exist [170].

OB is characterized by progressive, obstructive graft dysfunction associated with fibroproliferative obliteration of small airways. Minimal changes are seen on plain chest imaging. However, bronchiectasis and air trapping may be noted on high-resolution computed tomography [70]. In addition, xenon retention may be seen on ventilation/perfusion imaging [171]. Nonetheless, the gold standard for diagnosis of OB is lung biopsy. Histologic findings include dense eosinophilic submucosal fibrosis in the bronchioles associated with partial (concentric or eccentric) or complete luminal occlusion. Associated destruction of the smooth muscle and airway wall may also be present [72]. Although the original pathologic grading schemes made distinctions between subtotal and total [121] and active vs. inactive [122] forms, the most recent ISHLT grading scheme includes only C0 (no evidence

of OB) or C1 (OB present) [72]. Because OB may be focal, exclusion by TBBx is not possible. Diagnosis can occasionally be missed on open lung biopsy as well. Thus, a clinical correlate, BOS, was established [69, 172]. A BOS grade of 1 or greater (reflecting a decline in FEV_1 greater than 20 % from the posttransplant best) is felt to be highly suspicious for OB.

Because of the challenges noted above associated with establishing a diagnosis of OB/BOS in pediatrics, and limitations of TBBx in smaller children, evaluation for OB/BOS in pediatric lung transplant recipients often requires open lung biopsy (OLB). Because of the invasive nature of OLB, timing is often guided by other measures such as ventilation/perfusion scans and inspiratory/expiratory high-resolution CT [73].

A comprehensive review of single-center studies of OB/BOS confirmed only acute rejection and lymphocytic bronchiolitis as consistent risk factors. The most significant risk factor was acute rejection episodes occurring more than 3 months posttransplant [173]. Lymphocytic bronchitis/bronchiolitis, especially more than 6 months posttransplant, was also a consistent risk factor. CMV as a risk factor was deemed inconclusive [135, 136]. Recently, anti-HLA antibodies [174, 175] and autoantibodies to structural proteins (alpha tubulin and collagen V) have been shown to be risk factors in single-center analyses [176, 177]. Gastroesophageal reflux has also been implicated as a risk factor. One single-center study found that fundoplication reduced the incidence of OB/BOS [147, 148]. Community-acquired respiratory viruses such as paramyxoviruses, influenza, and adenovirus are associated with OB/BOS [178, 179]. Infants and toddlers [83] and children receiving living related lobar transplantation [180, 181] are at lower risk for developing OB/BOS. Finally, nonadherence with immunosuppression is associated with the development of OB/BOS [182].

Current hypotheses suggest that OB represents a response to airway injury induced by one or more of the identified risk factors, leading to chronic epithelial airway damage and subsequently fibrosis, perhaps driven by profibrotic cytokines such as transforming growth factor beta [183] or platelet-derived growth factor [184]. The resulting fibrosis causes severe airway obstruction [185]. Identification of acute rejection as a risk factor for OB/BOS reinforces the importance of routine surveillance bronchoscopy to detect and treat subclinical acute rejection.

Treatment of OB/BOS is difficult. Most patients receive augmented immunosuppression as an initial treatment. Changing from CSA to tacrolimus may be beneficial (though most pediatric centers no longer use CSA as the primary CNI) [186]. Azithromycin three times weekly appears to benefit the subset of patients with airway neutrophilia [187]. Agents such as antithymocyte globulin or OKT3 may be effective adjunctive therapy in some patients [188]. Cyclophosphamide [189], methotrexate [190], and total lymphoid irradiation [191] have been beneficial in some patients. Finally treatment with photopheresis may be beneficial [192–194]. Treatment is most likely to be effective when OB is identified early. However, disease progression may occur, often complicated by, or worsened by, infection. Most pediatric centers will offer re-transplantation as an option in patients with progressive decline in lung function and no other contraindications, particularly in the LAS era of reduced waiting time [23].

Heart-Lung Transplantation

Heart-lung transplantation in children was once the treatment of choice for end-stage respiratory failure due to chronic lung diseases such as cystic fibrosis and end-stage heart failure due to pulmonary hypertension. Isolated lung transplantation has supplanted heart-lung transplantation for these relatively common indications. Heart-lung transplantation is now primarily used for respiratory or pulmonary vascular diseases associated with significant heart disease particularly with poor left ventricular function. It is rarely performed in even the most active pediatric thoracic organ transplant centers.

Indications and Contraindications

Over the past 20 years, efforts to avoid heart-lung transplantation in favor of isolated heart or lung transplantation have reduced the number of heart-lung transplants performed (Fig. 156.1). These efforts include aggressive treatment of pulmonary hypertension with multiple medications and supporting the heart in an effort to have reasonable heart function after an isolated lung transplant. The primary indications for heart-lung transplant in the current era are listed in Table 156.3. Congenital heart disease is the most common indication for heart-lung transplantation according to the registry of the International Society of Heart and Lung Transplantation [8]. Eisenmenger's syndrome is listed separately, and combined, they account for approximately 35 % of all heart-lung transplants performed in children. An alternative to heart-lung transplantation is lung transplantation with repair of the associated heart defect [195]. This is appropriate only when the left ventricular function is good and the defect being repaired is not particularly complex. Patients with pulmonary hypertension and single ventricle anatomy may also be candidates for heart-lung transplantation, although many of these patients have had prior palliative operations via either thoracotomy or sternotomy.

Idiopathic pulmonary hypertension has been a common indication for heart-lung transplantation but is best treated with isolated lung transplantation. However, if the left ventricular function is poor or the left ventricular end diastolic pressure is very high, heart-lung transplantation may be a better option. Elevated left ventricular diastolic pressure in the setting of isolated lung transplantation puts the donor lungs at risk for pulmonary edema because there is loss of the lymphatic drainage. Consequently, pulmonary edema occurs at lower pulmonary venous pressures. Some concern is always raised about the suitability of the right ventricular function as nearly all these patients come to transplant with very poorly functional, dilated, and hypertrophied right ventricles. However, right ventricular recovery is seen in nearly all instances over a period of weeks [196]. Therefore, poor right ventricular function should not be an indication for heart-lung transplantation.

Table 156.3 Indications for heart-lung transplantation

Congenital heart disease with pulmonary hypertension (including Eisenmenger's syndrome)
Acquired heart disease with severe fixed pulmonary hypertension
Re-transplantation
Other end-stage pulmonary disease with left ventricular failure

Note: Idiopathic pulmonary hypertension and cystic fibrosis are no longer indications for heart-lung transplantation, though were common indications in early experience with this procedure

Patients with restrictive cardiomyopathy often have some element of pulmonary hypertension. This is usually the consequence of longstanding high left ventricular end diastolic pressures. The degree of elevation in pulmonary vascular resistance, and its reversibility, will determine whether these patients are suitable candidates for isolated heart transplantation or whether heart-lung transplantation should be considered.

Heart-lung transplantation has been employed in small infants with isolated lung disease, such as surfactant abnormalities. This is done to avoid the small bronchial anastomoses required for isolated lung transplantation in infants. Whereas this may seem reasonable, the authors do not believe the technical challenges of bronchial anastomosis in infants are significant enough to warrant this approach, given that the recipient has a normal heart. Nonetheless, this approach frees up a donor heart for an infant awaiting isolated heart transplantation. When heart-lung transplantation has been used for this, the heart from the recipient has occasionally been used in a "domino" arrangement as a donor for a patient awaiting heart transplantation [197, 198].

Finally, heart-lung transplantation as a re-transplant has been the strategy employed at some centers in the setting of end-stage bronchiolitis obliterans. It is clear from the literature that isolated lung transplantation is perfectly suitable for these patients when the cardiac function remains good and there is no evidence of posttransplant coronary artery disease.

Over the past 5 years, the average number of heart-lung transplants performed in children under the age of 18 is 10 per year with around eight centers reporting these transplants [81] (Fig. 156.2). In 1994, 28 heart-lung transplants were performed; this was the peak for number of such transplants worldwide. The reasons for the dramatic fall in number of transplants are likely reduction of this transplant strategy for cystic fibrosis and pulmonary hypertension (along with the dramatic improvement in medical therapy for pulmonary hypertension). This is certainly a more economical use of these thoracic organs to serve more patients. It is also possible that recognition of the serious risks involved with some potential transplant recipients has prompted reconsideration. The consequence of this is that fewer centers in general, and surgeons in particular, have any substantial experience with the procedure or management now compared with 15 years ago.

The same contraindications used for isolated heart or lung transplantation apply to heart-lung transplantation. In addition, one should tread cautiously in any patient who has had multiple prior sternotomies or thoracotomies. The adhesions in this setting are formidable and bleeding complications often severe. Bleeding is a leading cause of death in heart-lung transplantation and prior operations with the anticipated adhesions associated with this contribute.

Candidate Evaluation and Pre-transplant Management

Evaluation of the heart-lung candidate is driven by the underlying disease but essentially encompasses a combination of the evaluations used for isolated heart or lung transplant. Similarly, pre-transplant management of the heart-lung candidate is driven by the same priorities listed above for lung transplant coupled with management of the underlying causes of heart and lung failure.

Donor Evaluation

Obviously both the heart and lungs must be satisfactory for a donor to be acceptable. The evaluation of the donor is the same as for each individual organ. The echocardiogram should have relatively normal function on no more than moderate inotropic support. The chest radiograph should be clear with a pO2 on arterial blood gas of greater than 350 with an inspired FiO_2 of 1.0. The size of the donor is less flexible than with transplantation of either organ alone. A large donor is particularly difficult to fit into a smaller chest. An acceptable donor will have a weight range of 10 % above and below the recipient with a height range of similar proportions. The matching of donor to recipient size is complicated by poor nutrition of the recipient related to cardiac and/or pulmonary failure.

Transplant Surgical Procedure of Donor and Recipient

The incision is a midline sternotomy. Both pleural spaces are opened widely. The pericardium is opened well posterior to the phrenic nerves just anterior to the lung hila with care taken to avoid injury to each nerve, staying at least 1 cm away. This is extended to the entire length of the chest. Cardiopulmonary bypass is initiated with bicaval and aortic cannulation. The aorta is clamped and divided just above the aortic valve and the cavae are divided at the entry into the right atrium. The heart is removed in its entirety including all of the left atrium, dividing the pulmonary veins usually with the electrocautery and the branch pulmonary arteries at the pericardial reflection. A small segment of main pulmonary can be left behind at the insertion of the ligamentum arteriosum to avoid injury to the recurrent laryngeal nerve. Each lung is then removed by dividing each bronchus and dissecting the remaining attachments of the lung to the mediastinum. The trachea and the two attached stumps of the bronchi are then dissected out posterior to the aorta. The trachea is divided just above the carina to allow a convenient length of trachea for the anastomosis of the heart-lung bloc. The heart-lung bloc is brought up onto the table and trimmed to accommodate aortic, tracheal, and caval anastomoses. Each lung is placed into the appropriate

pleural spaces through the openings made there posterior to the phrenic nerves. A left ventricular vent is placed into the left atrial appendage but not applied to the suction on the cardiopulmonary bypass machine. Rather, cold crystalloid solution is instilled at a relatively slow rate to keep the heart cold as well as evacuating air. There will be no pulmonary venous return to de-air the left-sided cardiac chambers after the clamp is removed. The tracheal anastomosis is performed first. Usually nonabsorbable polypropylene suture is used in a continuous fashion. The blood supply to the trachea is generally quite good following heart-lung transplant as it is received primarily from the coronary artery collateral circulation. Next the aortic anastomosis is performed. The aortic cross clamp can be removed at this point and the left ventricular vent is converted to suction and the crystalloid infusion is stopped. The caval anastomoses are performed and the transplant procedure is completed.

Early Posttransplant Care (ICU) and Long-Term Management

The care for these patients postoperatively is primarily directed at the lung. The filling pressures are kept relatively low and diuretics are used liberally. Early extubation is advisable. Inotropic support is weaned as tolerated. Immunosuppression is begun immediately following the transplant, generally with dosing and target levels typically used in lung transplant recipients. Endomyocardial biopsy and flexible bronchoscopy with transbronchial biopsies are performed 7–14 days following the transplant. Lung rejection is more common than cardiac rejection. Thus, some centers do not perform repeated cardiac biopsies unless there is clinical concern for cardiac rejection.

Outcomes and Their Risk Factors

Survival

The 5-year survival is around 45 %, similar to that for lung transplant [81]. This is also similar to survival of heart-lung transplant in adults. The most common cause of death early is graft dysfunction, accounting for around 40 % of all deaths. Approximately 20 % of the early deaths are due to technical factors, including bleeding. This is likely a reflection of the complex nature of the patients referred for heart-lung transplantation, having been screened for either heart or lung transplantation in isolation. From 1-year posttransplant beyond, bronchiolitis obliterans and infection join graft failure to account for nearly all deaths. Precisely why graft failure continues to appear as a cause of death is unclear. This may in truth be rejection, bronchiolitis obliterans, or posttransplant coronary vascular disease, but this is unclear.

Complications

Airway complications are extremely unusual following heart-lung transplantation. The tracheal anastomosis has excellent blood supply from the coronary artery collateral circulation. Injury to the recurrent laryngeal nerve may occur during the recipient cardio-pneumonectomy. Phrenic nerves are at risk of injury in the process of opening up the pleural spaces widely for the recipient pneumonectomies and subsequent implant of donor heart-lung bloc. Bronchiolitis obliterans occurs in equal frequency with heart-lung transplantation as with isolated lung transplantation. Posttransplant coronary artery vasculopathy seems less prevalent with heart-lung transplantation than with isolated heart transplantation. Posttransplant malignancies occur with equal incidence in heart-lung transplants as with isolated lung transplantation.

Future Considerations

Now into a third decade of experience, pediatric lung and heart-lung transplantation is firmly established as a therapeutic option for pediatric patients with end-stage pulmonary parenchymal and vascular disease. Notwithstanding improvements in survival during the past decade, long-term survival rates lag behind those of other solid organ transplants [8].

The foremost challenge to the pediatric transplant physicians remains identification and management of the risk factors for OB through identification of markers to facilitate earlier diagnosis and development of uniform and novel treatment approaches with the multicenter collaborations needed to power assessments of efficacy. Understanding the immunologic mechanisms behind the reduced incidence of rejection and BO in the naïve but developing immune system of infants [83, 124] may be a key research opportunity.

A second challenge, as a result of steadily increasing adult transplant numbers, will be to maximize the availability of donor organs by supporting public policy initiatives focused on increased donation and refining donor management strategies to increase the number of lungs suitable for transplantation (including the use of non-beating heart donors and the use of ex vivo perfusion strategies) [199–202]. In addition, current allocation strategies make access to heart-lung transplant very challenging in the United States. Improved allocation algorithms are needed to provide organs to the relatively small number of patients for whom heart-lung transplant is needed.

Finally, identifying the etiologies responsible for, and addressing the poor outcomes in, the adolescent population will remain an important area for study.

Limiting the toxicities associated with immunosuppressive regimens will involve developing more functional methods of assessing the efficacy of immunosuppression (in order to administer the lowest possible doses), a better understanding the pharmacogenomics of immunosuppressive medications (in order to better tailor immunosuppression based on the patients response to specific medications), and finally developing new agents and immunosuppressive strategies to limit toxicity.

In the past two decades, pediatric lung and heart-lung transplantation has provided a second chance at life for more than 2,400 children and adolescents. Hopefully during the next 20 years, even more children will be served through increasing the number of experienced centers able to offer these procedures, reducing the incidence of BO, improving donor organ availability, and minimizing the toxic effects of immunosuppression allowing outcomes for pediatric lung transplant comparable to other solid organs.

Diagnosis of Arrhythmias and Conductive Disorders

157

Salim F. Idriss and Ronald J. Kanter

Abstract

The ability to diagnose basic arrhythmias and conduction disorders in infants, children, adolescents, and adults with congenital heart disease is a fundamental of pediatric and adult congenital cardiovascular medicine. This chapter provides basic knowledge regarding the physiology of cardiac conduction, practical information on the diagnosis of common rhythm disturbances, and general instruction on the primary methods for acquisition of electrocardiographic data, including body surface electrocardiography, ambulatory monitoring, and provocative electrophysiology study. The knowledge obtained from this chapter will form a foundation for further understanding rhythm disturbances in even the most complex patients with congenital heart disease.

Introduction

The cardiac rhythm strip and multichannel electrocardiogram represent the summative contribution of structural, metabolic, hemodynamic, and electrical influences on the atrial and ventricular myocardia and on the specialized cardiac conduction system. The overarching intent of this chapter is to convey a practical approach toward diagnostic accuracy when confronted with cardiac arrhythmias and conductive disorders in children and all patients having congenital heart disease. However, most of the principles of arrhythmia interpretation are applicable to humans of all ages. This foundation will be augmented by more specific comments regarding certain arrhythmias, especially pediatric bradyarrhythmias and conduction defects, in an effort to supplement other chapters in this text. The remainder of this chapter is devoted to the technical acquisition of cardiac rhythm data in the youngster. To that end, noninvasive rhythm recording instruments will be emphasized, but an introduction to intracardiac electrophysiologic testing will also be included. This chapter will not emphasize electrocardiographic characteristics of specific pre- and postoperative congenital heart defects, rhythm strip interpretation from patients having implanted cardiac rhythm management devices, interpretation of immediate postoperative arrhythmias from temporary pacing wires, and arrhythmias related to orthotopic cardiac transplantation. Also, this chapter is not intended to be a primer for basic pediatric 12- or 15-lead electrocardiogram (ECG) interpretation.

Cardiac Electrophysiology

Cardiac electrogenesis is necessary for electromechanical coupling, and it initiates and proceeds in an anatomic sequence which optimizes hemodynamic performance. The primary molecular "parts" include plasma membrane-linked voltage- and ligand-gated channel proteins (and their interacting proteins) whose activities result in ionic flow according to their electrochemical gradients (e.g., the hyperpolarization-activated, cyclic nucleotide-gated (HCN) channels of the sinoatrial node and rapid and slow delayed rectifier potassium channels of cardiac muscle (Ikr and Iks)), cell-to-cell gap junction proteins for passive ion and other small molecule movement (e.g., connexin43 in working cardiac myocardium and connexin40 in the AV node), and energy-requiring ionic pumps and nonenergy-requiring exchangers for reestablishing cytoplasmic and organelle ion concentrations (e.g., the sodium/potassium ATPase pump, the sodium-calcium exchanger). Each cardiac cell type has its own constitution of these structures, especially of plasma membrane channels (Fig. 157.1). Tissue endowment of these fundamental structures changes through fetal and early postnatal development, under hypoxic and other metabolic stresses, and related to persistent electrical and mechanical (hemodynamic) changes.

The tissue "parts" capable of cardiac conduction include what is euphemistically considered the specialized conduction system and working myocardium. The only cardiac tissues normally incapable of electrical conduction are the annulus fibrosis and AV valves and the semilunar valves and annuli. Critical to this discussion is the concept of anisotropic conduction, which refers to the influences on cardiac conduction by cell geometry, cell alignment, and density of cell-to-cell connections [1]. This phenomenon is especially vital in understanding the electrical properties of the right atrium, with its regions of smooth walls and dense pectinate muscles. In temporal order, according to fastest automaticity, the specialized conduction system normally "begins" with spontaneous discharge by the sinoatrial node (SAN), a comma-shaped structure, which is subepicardial and lies along the superior portion of the sulcus terminalis. Wavefronts emanating from the SAN were once thought to activate the right atrium and preferentially conduct to the AV node and left atrium via four specialized tracts (of Thoral, of Wenckebach, descending tract, and Bachmann's bundle). Only Bachmann's bundle, which is a tract of working atrial myocardium connecting the superomedial right atrium posterior to the

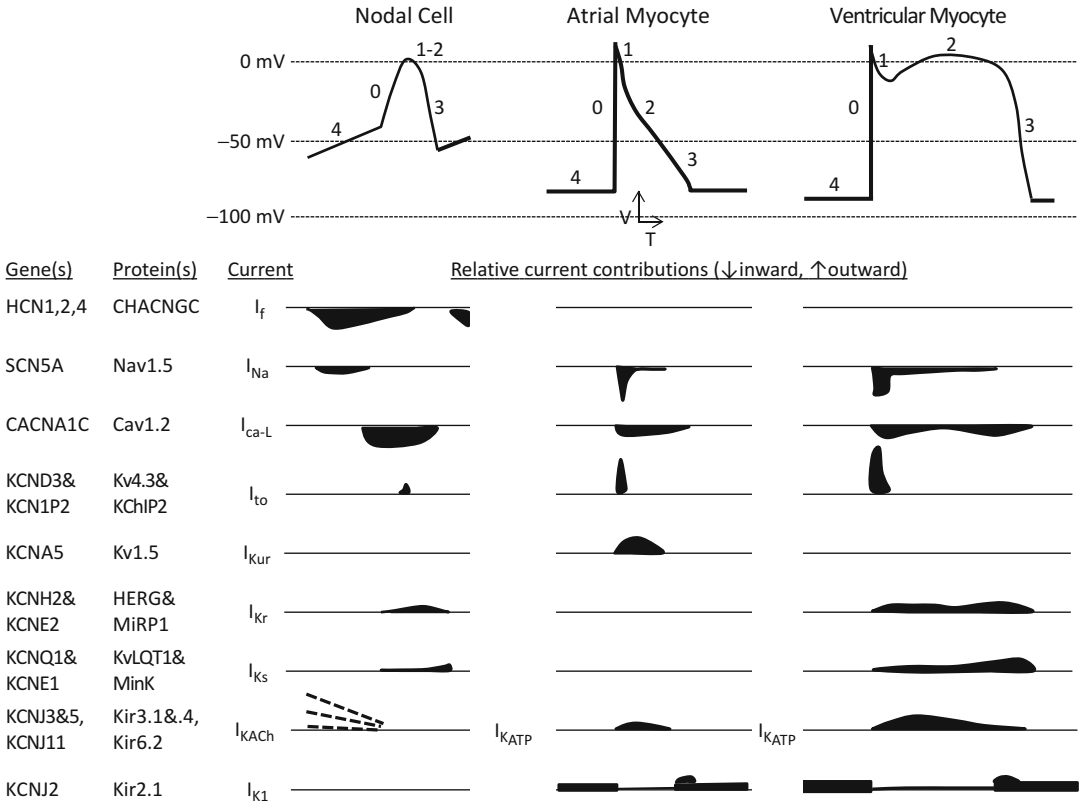

Fig. 157.1 Cardiac myocyte action potentials and the primary ion channels. In the *top portion* are illustrated idealized action potentials from cells from the major cardiac tissues: nodal (sinoatrial and atrioventricular) tissue, atrial myocardium, and ventricular myocardium (including His bundle, bundle branches, and Purkinje fibers). Voltages represent intra- versus extracellular potentials, and the numerals *0–4* represent the classical stages of the action potential: *4* is the resting membrane potential, *0* results from unopposed depolarization via inward currents, *1* and *2* result from competing inward depolarizing and outward repolarizing currents, and *3* results mostly from outward repolarizing currents. The specific currents and their time courses are depicted beneath each action potential. Each current results from specific ion flow along its electromotive gradient and through a (relatively) ion-specific channel. The channel pores, in turn, are formed from conformational changes that occur in multimeric channel proteins (listed to the *left*). Each channel protein multimer (usually tetramer) changes configuration based upon the voltage milieu, hence, resulting in channel pore "openness." The orderly opening and closing of myocyte cell membrane channels result in the action potential. This accounts for the following critical phenomena: (a) spontaneous (phase 4) depolarization of those tissues having the property of automaticity (sinoatrial and atrioventricular nodes); (b) Achievement of activation threshold (onset of phase 0) in resting cells downstream from already depolarized cells via passive movement of sodium ions across gap junctions; (c) Initiation of excitation-contraction, as inward calcium current activates calcium-induced calcium release from the sarcoplasmic reticulum; and (d) tissue refractoriness to protect against tetany and inappropriate reentry. *CHACNGC* = cationic hyperpolarization-activated, cyclic nucleotide-gated (pacemaker) channel; *dashed lines* by I_{KACh} imply variable influence of acetylcholine-gated potassium channel activity according to parasympathetic tone. *Steeper negative slope* enhances automaticity. Sinoatrial rate variability is influenced by this channel, the calcium clock (not pictured), and sympathetic nervous system influences on c-AMP gating portion of the HCN gene product

ascending aorta to the anterior roof of the left atrium, has survived in modern parlance. As with all working myocardium, atrial muscle has relatively rapid conduction properties, which is enhanced or subdued according to principles of anisotropy. The AV node (AVN) is an oval-shaped structure, which lies on the right side of the atrial septum, just posterior to the hinge-point

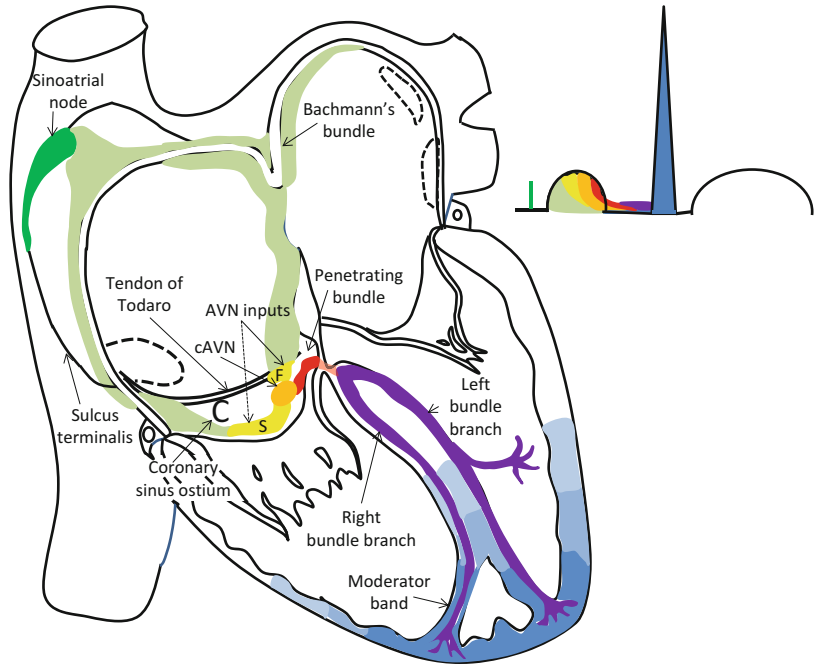

Fig. 157.2 Anatomical correlates of cardiac depolarization with the surface ECG. Note that AV nodal depolarization mostly occurs during the terminal portions of the P wave, and that the PR segment largely represents depolarization of the His-bundle branch-Purkinje system. *cAVN* compact AV node, *F* fast transitional cell inputs to the compact AV node, S slow transitional cell inputs to the compact AV node

of the septal leaflet of the tricuspid valve, anterosuperior to the coronary sinus ostium, inferior to the tendon of Todaro, posterior to the membranous septum, and anterosuperior portion of the triangle of Koch. Like the SAN, the AVN has slow conduction properties and capacity for automaticity, though at a slower rate than the SAN. Anatomical approaches to the AVN, especially from superiorly and from postero-inferiorly, contain cell types (so-called transitional cells) which are intermediate between atrial myocardium and AVN cells with respect to histological appearance, channel constitution, and cell-to-cell connections [2]. These characteristics may be important in potentiation of the common form of supraventricular tachycardia, AVN reentrant tachycardia. The anterosuperior portion of the AVN transitions into tissue containing parallel bundles of cells having fast conduction properties, the penetrating bundle (or "bundle of His"). This well-insulated structure penetrates the central fibrous body, whereupon it splits within the crest of the muscular septum into the cord-like right bundle branch (RBB) and the fan-shaped left bundle branch (LBB). The RBB is subendocardial within the anterior right ventricular septum, traveling in the moderator band and terminating in the right ventricular free wall. The LBB is very superficial on the surface of the left ventricular septum, where it roughly divides into anterior and posterior (actually, superior and inferior) divisions. Critically, the terminal elements of the bundle branches continue as the rapidly conducting – and definitively endocardial – Purkinje cell network. The left side of the base of the ventricular septum is the site of earliest ventricular myocardial depolarization from this network. Depolarization is completed within the working ventricular myocardium. There are differences in action potential characteristics of the different layers of the ventricular walls (endocardial, m-cell, and epicardium) and between right and left ventricles, according to differences in repolarizing channel constitutions. An anatomical summary of the specialized conduction system appears as in Fig. 157.2.

The cardiac rhythm is determined by the influences of intrinsic automaticity and conduction and refractoriness properties (as determined by features of channel endowment and anisotropic conduction) and by external influences of the

autonomic nervous system and of hemodynamic circumstances. Sympathetic nervous system influences enhance automaticity of automatic tissues and increase conduction velocity and shorten refractoriness of most tissues. Parasympathetic nervous system influences decrease automaticity of automatic tissues, slow conduction through sinoatrial and AV nodal tissues, and shorten refractoriness in working atrial myocardium. Arrhythmias occur related to congenital channel abnormalities, congenital abnormalities of elements of the specialized conduction system, congenital (or rarely acquired) accessory conducting pathways, abnormal automaticity or conduction in metabolically deranged tissue, or from mechanisms created by micro- or macroregions of fibrosis or artificial obstacles to conduction. Developmental changes that occur in channel properties, channel abundance, electrogenic pumps, channel interacting proteins, cell-to-cell connections, gross tissue and chamber structure, and autonomic innervation account for the normal changes in electrocardiographic intervals (especially heart rate, heart rate variability, PR interval, and QRS duration) and contribute to propensity to age-specific dysrhythmias. The remainder of this chapter is intended to serve as the foundation for other chapters in this textbook. Therefore, the definitions and concepts to follow are generic to the human cardiac conduction system; only the section on "Bradycardias" is specific to the pediatric age range.

Mechanisms of Tachyarrhythimia and of Improved Conduction

Reentry

When a conducting wavefront is capable of renegotiating a structure which it had just depolarized and it does so prior to ("faster than") depolarization from the ambient pacemaker, reentry is said to have occurred. Traditional criteria necessary for reentry to occur include a tissue source (site A) which is electrically conductive and bypasses a region which is transiently not electrically available (site B), subsequent capacity for conduction through site B in a retrograde direction, and recovery (from refractoriness) of site A after the wavefront has retrogradely traversed site B (Fig. 157.3). Reentry is by far the most common mechanism of pathological tachycardias. The reentry circuit may be

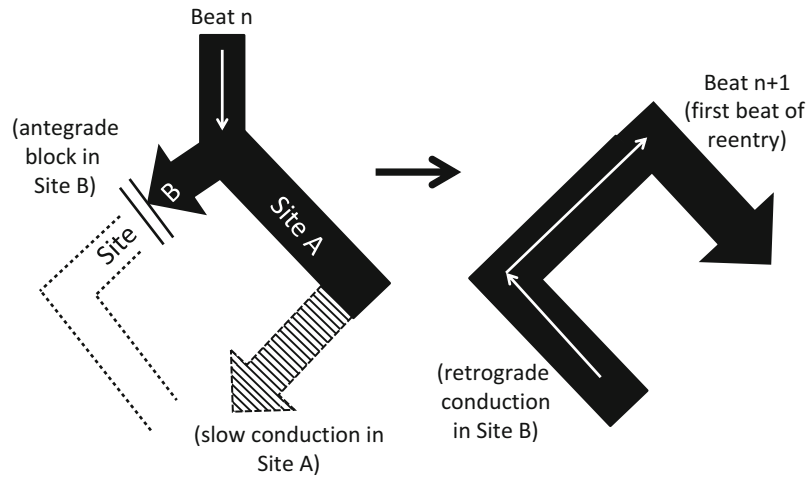

Fig. 157.3 Schematic of the reentry mechanism in cardiac tissue. Sites *A* and *B* may represent widely separated structures (e.g., the specialized AV conduction system and an accessory AV pathway, in the case of orthodromic AV reciprocating tachycardia), regions separated by normal anatomic obstacles to conduction (e.g., the tricuspid valve annulus, in the case of typical atrial flutter), or regions separated by acquired conduction obstacles (e.g., the atriotomy scar, in the case of postoperative intraatrial reentry tachycardia)

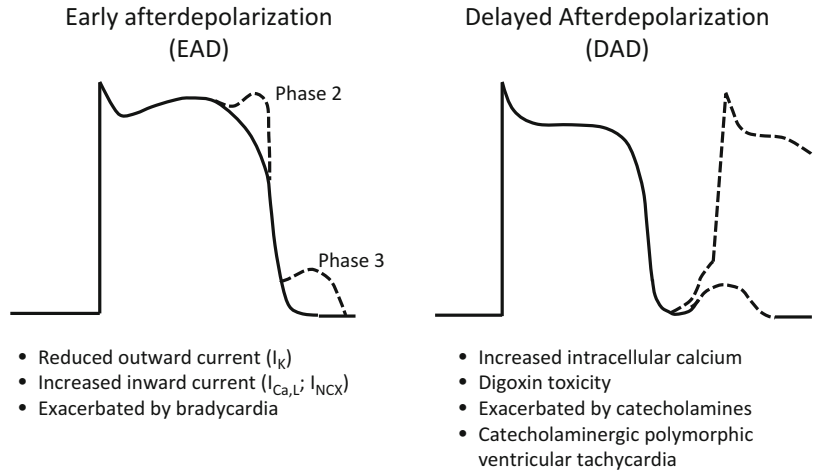

Fig. 157.4 Ventricular myocyte action potentials perturbated by after depolarizations (*dashed lines*). Illustrated on the *left* are early after depolarizations during phase 2 and phase 3 which do not result in fully regenerated action potentials. On the *right* are delayed afterdepolarizations, one of which results in a fully regenerated action potential

large (so-called macro-reentry), as in the case of AV reciprocating tachycardia (in which the critical circuit includes an accessory AV pathway, atrial muscle, the normal specialized AV conduction system, and ventricular muscle), or very small (so-called micro-reentry), involving a small region of atrial or ventricular muscle, some of which has altered conduction/refractoriness properties. In mathematical terms, reentry may only occur within an anatomical region whose net length is larger than the presenting electrical wavelength (λ), defined as the product of the conduction velocity (CV) times the functional refractory period (FRP) of that tissue [3]. (The FRP is defined as the minimum duration in milliseconds during which a particular structure can be depolarized twice.) Hence, structures having regions of slow conduction and having a net relatively short refractory period are conducive to reentry. This concept is also highly applicable to the mechanisms of antiarrhythmic and proarrhythmic drugs.

Reentry may occur within any conductive cardiac structure. When there is a single reentrant event (i.e., the wavefront extinguishes after a single revolution), the surface electrogram will register a single extrasystole involving those structures depolarized by the reentrant wavefront. Such a premature event is then called a *reciprocating beat* or *echo beat*. This may be indistinguishable from atrial or ventricular premature beats using other mechanisms of impulse formation.

Enhanced Automaticity

When the channel milieu results in spontaneous phase 4 depolarization in a sufficient volume of cells to enable depolarization of surrounding tissues and at a rate faster than the SAN mechanism, enhanced automaticity is said to be present. Although any diseased tissue is capable of such a rhythm, common examples include junctional tachycardia postcongenital heart surgery (emanating from the penetrating bundle or AVN), idiopathic atrial ectopic tachycardia, and ventricular tachycardia immediate postmyocardial infarction. Enhanced automaticity may also result from mechanical stretching and from hypokalemia, and it is enhanced by catecholamines. This mechanism is the second most common cause of pathological tachycardias. Due to their incessant nature, idiopathic automatic tachycardias which are sufficiently slow that they do not cause initial symptoms are notorious for eventually causing tachycardia-induced cardiomyopathy.

Triggered Activity

This term refers to early (EAD) or delayed afterdepolarizations (DAD) which result from very different action potential perturbations (Fig. 157.4). EADs result from action potential prolongation (phase 2 or 3 phenomenon) and are promoted by bradycardia, extracellular

hypokalemia, and potassium channel blocking drugs. Mechanistically, EAD's occur when there is reduced repolarization reserve due to limited outward potassium currents, and the countervailing depolarizing currents (such as L-type calcium current or sodium/calcium exchanger) are sufficiently strong to regenerate a full-action potential [4]. Some polymorphic ventricular tachycardias and torsades de pointes ventricular tachycardia are malignant arrhythmias caused by EADs. The pulmonary vein triggers for paroxysmal atrial fibrillation in adults likely also use this mechanism [5]. DADs result from excessive intracellular calcium loading during phase 4 of the action potential and are associated with digoxin toxicity and very serious genetic abnormalities of myocardial intracellular calcium trafficking, catecholaminergic polymorphic ventricular tachycardia (CPVT). In vulnerable patients, catecholamines contribute to DADs. Increased cytosolic calcium promotes DADs via the sodium/calcium exchanger. The hallmark tachycardia in digoxin toxicity and in CPVT is bidirectional ventricular tachycardia. In addition, less serious tachycardias thought to use triggered activity include some outflow tract monomorphic ventricular tachycardias and some focal atrial tachycardias.

Other Mechanisms

Parasystole refers to an automatic rhythm which eminates from a protected focus; that is, it depolarizes adjacent tissue which has recovered excitability but cannot, itself, be depolarized or reset by neighboring wavefronts. This focus is said to demonstrate "entrance block" but not "exit block." Although this phenomenon has been described in many cardiac tissues, ventricular premature beats caused by a ventricular parasystolic focus are best known. Classical parasytolic foci have a constant discharge rate, resulting in a rate of surface eletrocardiographic phenomena (e.g., wide complex QRS in the case of ventricular parasystole), which is a multiple of the underlying rate of discharge. Therefore, it is not associated with a regular coupling interval to normal electrical events from the same chamber (e.g., between the QRS of a sinus beat and the ventricular premature beat). Despite the presence of entrance block, electrotonic conduction from other ambient impulses may slightly delay the discharge rate of the parasystolic focus when that external influence occurs in the early portion of the parasystolic cycle and accelerate the discharge rate when it occurs in the latter portion, so-called modulated parasystole (Fig. 157.5). Some forms of the very common (and thought to be benign) automatic idioventricular rhythm (AIVR) may be due to a ventricular parasystolic focus, whose discharge rate is very similar to the ambient sinus rate.

Reflection is a potential form of reentry, in which a proximal area of tissue, usually electrically depressed, conducts to a distal area by slow electrotonic conduction, followed, in turn, by reactivation of the depressed region by normal depolarization (Fig. 157.6, left) [6]. *Summation* is a theoretical mechanism of improved conduction, wherein two wavefronts, each separately incapable of conduction through a depressed region, converge and successfully conduct across that zone (Fig. 157.6, right). Beyond the scope of this chapter, but worthy of mention, experimental evidence exists for the presence of relatively large and electrically stable *spiral waves* and *rotors* (Fig. 157.7) [7]. A kind of reentry in which involved tissue has a very short refractory period, these phenomena may be the source of some examples of atrial and ventricular fibrillations [7]. Depolarization of neighboring tissues which are repeatedly and irregularly terminated by wavebreaks due to their longer rectory periods results in the characteristic chaotic chamber electrograms.

Supernormal conduction is said to exist when conduction occurs at a time when it is not expected to do so, that is, during the tissue's refractory period. This phenomenon occurs when a wavefront encounters a tissue that is at the end of phase 3 of its repolarization and, therefore, nearing its activation threshold (from the opposite direction) (Fig. 157.8 top) [8]. A smaller than expected stimulus can elicit a depolarization

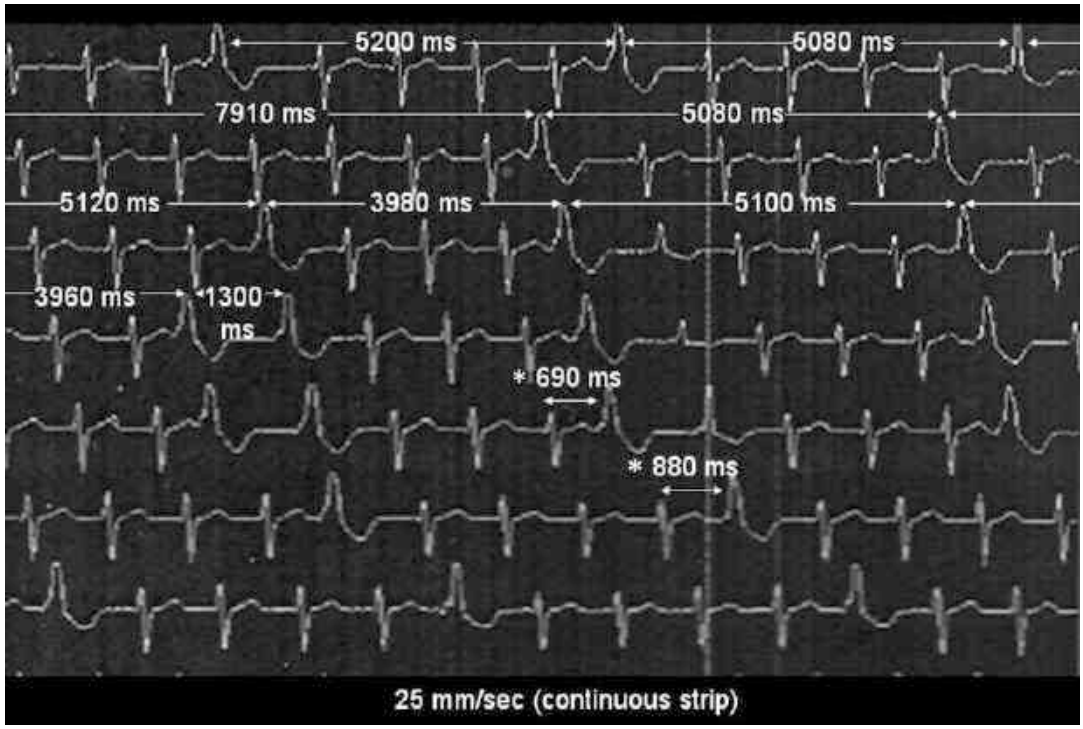

Fig. 157.5 A continuous rhythm strip illustrating "modulated parasystole." Uniform premature ventricular contractions (PVCs) have a fundamental discharge cycle length of about 1,300 ms. In parasystole, due to entrance block but not exit block (meaning that normal tissue cannot reset the parasystolic focus), all inter-PVC intervals should be a multiple of 1,300 ms. In modulated parasystole, the inter-PVC intervals vary slightly from a multiple of the fundamental discharge cycle length likely due to electrotonic influences (i.e., spread of current without creation of action potential) by surrounding normal tissue. * illustrates that the coupling interval from the sinus QRS to PVCs is variable, typical of ventricular parasystole

at that time. This form of excitability has been demonstrated in the bundle branch-Purkinje fiber system, Bachmann's bundle, and probably accessory AV connections. The *gap phenomenon* also represents improved conduction at a time when it does not seem like conduction should occur. It may be demonstrated in any portion of the heart beyond the sinoatrial node and occurs following wavefront delay in a structure (say, structure "A") proximal to the tissue in question (say, structure "B"). That is, a less premature event delivered to structure "A" encounters "B" in its effective refractory period and cannot depolarize "B," but a more premature event finds "A" in its relative refractory period, slowing the wavefront and allowing its presentation to a now recovered "B" (Fig. 157.8 bottom).

Mechanisms of Bradyarrhythmia and of Impaired Conduction

Reduced Automaticity

Since the SAN is the natural cardiac pacemaker, reduced automaticity in this structure is most clinically relevant. Mechanistically, reduced automaticity results either from a reduced slope of phase 4 spontaneous depolarization or from a lower (less negative) activation threshold of the involved pacemaking tissue. Intrinsic channelopathic, inflammatory/infectious, mechanical (stretch), autonomic, pharmacologic, and metabolic causes may cause transient or permanent impairment of automaticity. In the case of the sinus node, sudden sinus pauses

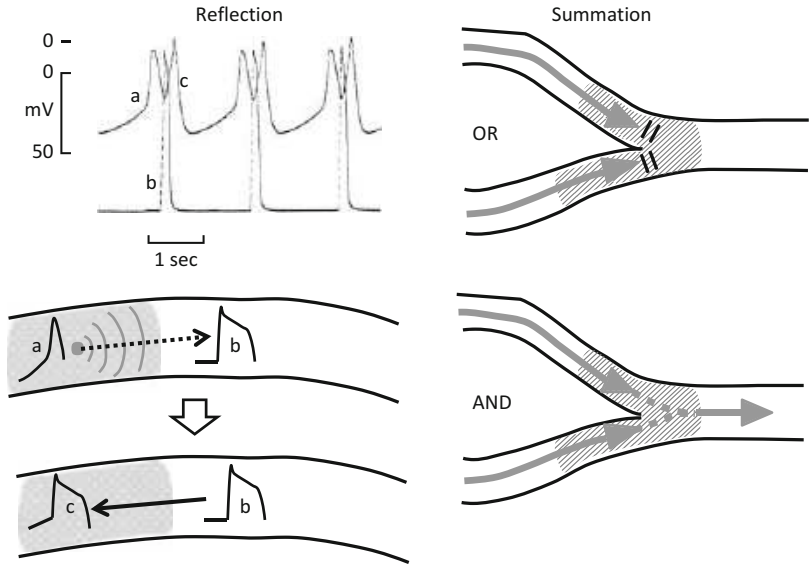

Fig. 157.6 "Reflection" has been demonstrated in ischemic canine Purkinje fibers. In this form of reentry, a spontaneous depolarization from partially depolarized ischemic tissue (*a*) conducts to healthy tissue by electrotonic influences (*dotted arrow*, *b*). The resulting action potential conducts back to the damaged tissue by normal cable conduction properties (*c*) after that tissue's refractory period has expired. The *stippled area* represents ischemic myocardium (The *top portion* is reproduced with permission from Rosenthal et al [6]). "Summation" is a theoretical mechanism by which conduction over an electrically depressed region (*cross-hatched* in figure) may only occur secondary to convergence of wavefronts, each arising in a separate anatomic structure and each of which, separately, cannot conduct across the depressed tissue. This mechanism has been hypothesized to account for some examples of unidirectional conduction block. The *double line* (//) represents conduction block

exceeding twice the prevailing sinus rate, or exaggerated sinus arrhythmia (in which there is slight sinus acceleration prior to any pause) should invoke consideration of sinoatrial exit block ahead of a defect in automaticity (see below).

Conduction Block

Although conduction *block* or *delay* may exist in any normally conductive cardiac tissue, the practical use of the term *block* is most commonly applied to structures of the specialized conduction system. However, the term *delay* may be applied to working myocardium. For example, when there is age-specific conduction delay in atrial depolarization, the surface ECG may or may not provide criteria for right or left atrial enlargement, and the intracardiac electrophysiologic study (EPS) may demonstrate specific regions of slow conduction in atrial muscle. Likewise, in the presence of age-specific QRS prolongation, if the ECG does not satisfy criteria for right or left bundle branch block, the term intra- or interventricular conduction delay applies. This is indicative of pharmacologic, fibrosis-related, hemodynamic, metabolic, or intrinsic channelopathic impairment of myocardial conduction. Irrespective of etiology, the mechanism of conduction delay or block may involve macrostructural fibrosis, impediment to cell-to-cell connectivity, functional molecular abnormality, or some combination thereof.

The concept of conduction block necessarily refers to cardiac structures which normally have a hierarchal sequence of conduction, that is, from a proximal to a distal structure. From the perspective of clinical relevance, the terms first-, second-, and third-degree conduction blocks are primarily applied to atrial-to-ventricular, or AV, conduction, although second-degree block may also be clinically applied to SAN-to-atrial muscle or

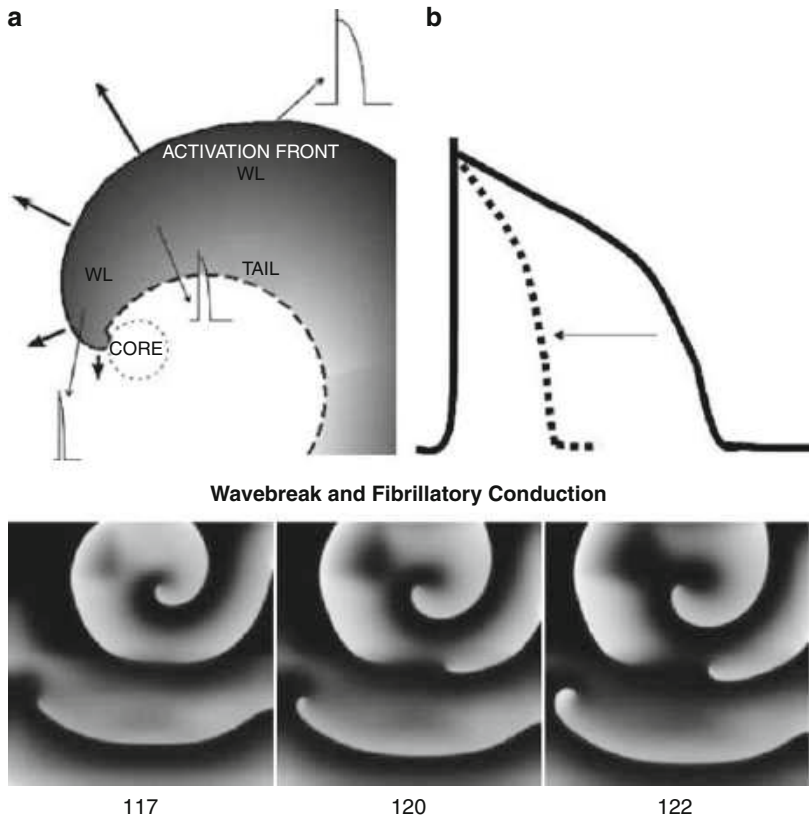

Fig. 157.7 *Top*: schematic example of a rotor, whose core has a very abbreviated action potential due to electrotonic effects, resulting in a very short wavelength (*WL*). The rotor's peripheral spiral wave has a longer wavelength at its periphery (action potential having *solid line* at *upper right*) than at its inner curvature (more abbreviated action potential having *dotted line* at *upper right*). This results in functional reentry. *Bottom*: computer-generated rotor illustrating fibrillatory conduction due to wavebreaks. Wavebreaks, themselves, may result from anatomic obstacles, thus creating daughter *spiral waves*. *Numbers* represent time in ms (Both figures are reproduced with permission from Vaquero et al [7])

sinoatrial conduction. First-degree block refers to delayed but persistent conduction from a proximal to a distal structure. Third-degree block implies complete absence of conduction between proximal and distal structures. Second-degree block can exist as "type I" and "type II." The concept of second-degree block is abstractly illustrated at the top of Fig. 157.9. In that figure, the proximal structure (triangle) and distal structure (diamond) represent the SAN and atrial muscle (P wave), respectively, when considering sinoatrial block and the P wave and QRS, respectively, for AV block. For AV block, the precise structure exhibiting blocked conduction (i.e., AVN or His bundle-Purkinje system) may be determined during EPS, because a septal atrial electrogram (representing the proximal extent of the AVN) and a His bundle electrogram (representing the distal extent of the AVN and the His bundle proper) may be recorded. Because the SAN does not produce an easily recordable electronic signal, SAN conduction block must be determined by inference. Hence, first-degree SAN block cannot be diagnosed, and third-degree SAN block cannot be discriminated from impaired SAN automaticity. However, as illustrated in Fig. 157.9, middle, a rhythm strip which shows a shortening P-to-P interval prior to a pause suggests type I second-degree SAN block, and one that shows a pause equivalent to two prevailing P-to-P intervals suggest type II second-degree SAN block. Likewise, in the case of type I second-degree AV block, the progressive PR interval prolongs but relatively less so with subsequent beats (resulting in R-to-R interval shortening), prior to the nonconducted P wave, whereas, in type II second-degree AV block, the PR interval (and, therefore, R-to-R interval) is constant prior to the nonconducted P wave. Type I mostly occurs in the AV node,

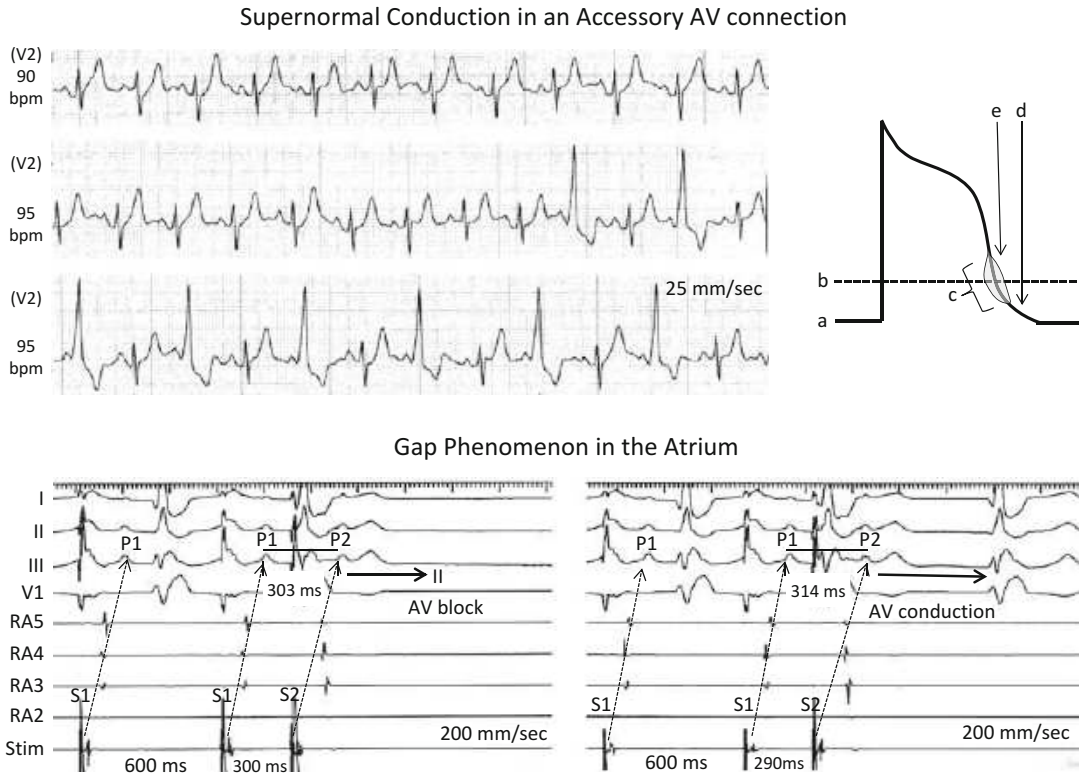

Fig. 157.8 "Supernormal conduction" and "gap phenomenon" are two examples of improved conduction at times when conduction is expected to be worse. *Top*: an example of absent conduction through an accessory AV connection at sinus rate of 90 bpm, followed by alternating beats having pre-excitation once sinus rate increased to 95 bpm. This is explained at the *top*, *right*, with an idealized action potential from accessory pathway tissue. A faster wavefront (*e*) encounters the accessory pathway tissue closer to its activation threshold voltage (*b*) than a wavefront at a slower rate (*d*). Hence, a wavefront occurring during the supernormal period (*c*) allows depolarization of the accessory pathway tissue. (*a*) represents the resting membrane potential. (*Top-right* figure is reproduced with permission from Kinoshita et al [8].) *Bottom*: During electrophysiologic testing and single atrial extrastimulus (S2, resulting in P2) placement following a drivetrain of 8 beats at 600 ms (100 bpm) (S1-S1, resulting in P1-P1), a less prematurely delivered atrial beat (S1-S2 coupled to the last beat of drivetrain by 300 ms, resulting in P1-P2) does not propagate to the ventricles, whereas a more premature atrial beat (S1-S2 of 290 ms, resulting in P1-P2) does propagate to the ventricles (note QRS following P2 in right example but not in left example). In this example, the "gap phenomenon" occurs in the atria between the pacing site and the atrial tissue near the AV node. This is indicated by a longer P1-P2 (314 ms) following S1-S2 of 290 ms than the P1-P2 (303 ms) following S1-S2 of 300 ms. *S* stimulation artifact, // represents conduction block

and it is not necessarily clinically important. Type II mostly occurs in the His-Purkinje system and is considered an unstable rhythm.

Other Mechanisms

Concealed conduction refers to a limited depolarization within a portion of the specialized conduction system (or, theoretically, an accessory pathway) which then leaves a wake of relative or absolute refractoriness. The next wavefront either dies out or traverses that region more slowly than expected. This is a form of *phase 3 block*. Since the normal specialized conduction system does not provide an electrocardiographic signature per se, the only evidence for concealed conduction is poorer than expected

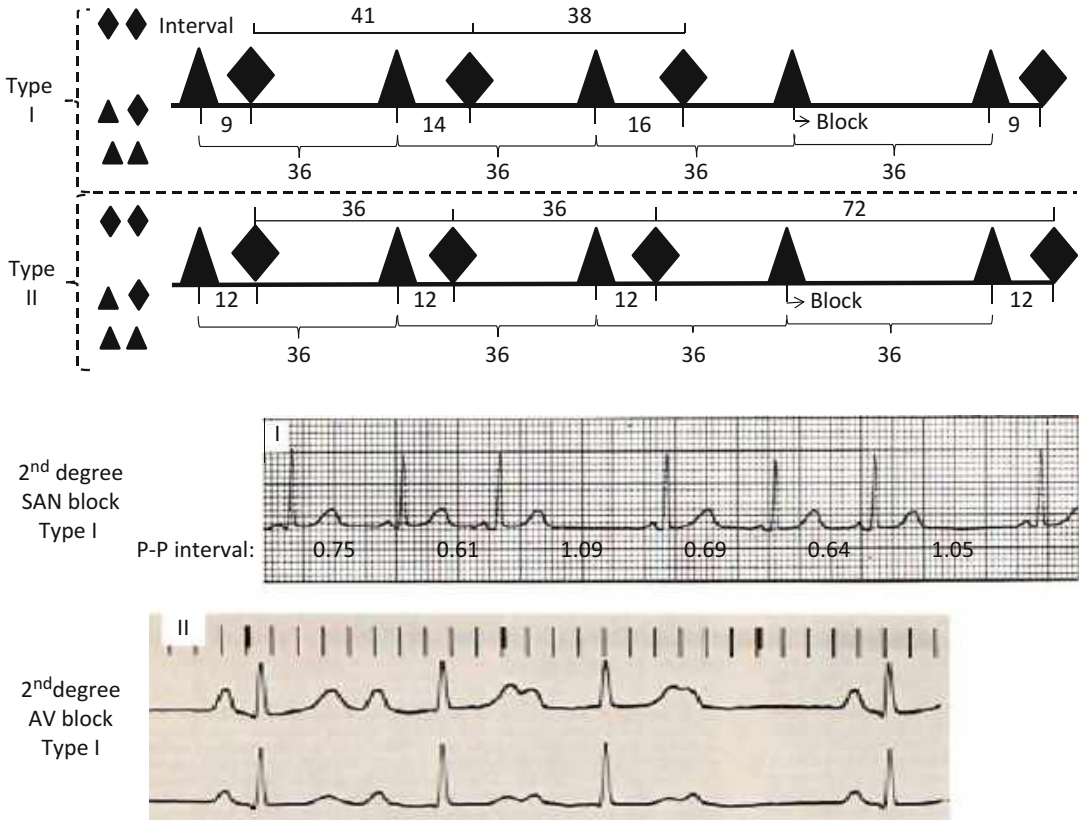

Fig. 157.9 The phenomenon of "second-degree block" may exist in any cardiac tissue. The concepts of types I and II second-degree block are illustrated at the *top*, using a *triangle* as a surrogate for the proximal cardiac structure and a *diamond* as a surrogate for the distal cardiac structure. *Numbers* represent arbitrary conduction intervals between structures. See text for further explanation. Below: type I second-degree block in sinoatrial nodal (*SAN*) and AV nodal structures

conduction by the subsequent impulse, manifesting as PR interval prolongation, bundle branch block, or even a completely blocked P wave (Fig. 157.10) [9]. *Phase 4 block* (known as *critical rate block*) also manifests with poorer than expected conduction, usually within the bundle branches. These are structures which ordinarily maintain a stable phase 4 resting membrane potential. However, when diseased, they may spontaneously slowly depolarize. A normally occurring wavefront would then encounter a partially depolarized membrane, resulting in a phase 0 slope which is less steep (i.e., more slowly conducting) than had the normal wavefront encountered that membrane earlier in phase 4. Hence, bundle branch block would occur at a slower but not faster rate.

Discriminating Supraventricular from Ventricular Tachycardia

Because this textbook includes separate chapters on the entities supraventricular tachycardia (SVT) and ventricular tachycardia (VT), this chapter will only provide diagnostic algorithms based upon the surface ECG and rhythm strip for discrimination of diagnoses within each entity. However, the ability to discriminate supraventricular from ventricular tachycardia is of paramount importance, due to the potential difference in hemodynamic consequences and to the differences in treatment; hence, this subject requires specific attention.

In the broadest sense, SVT refers to any nonsinus tachycardia that includes as a critical

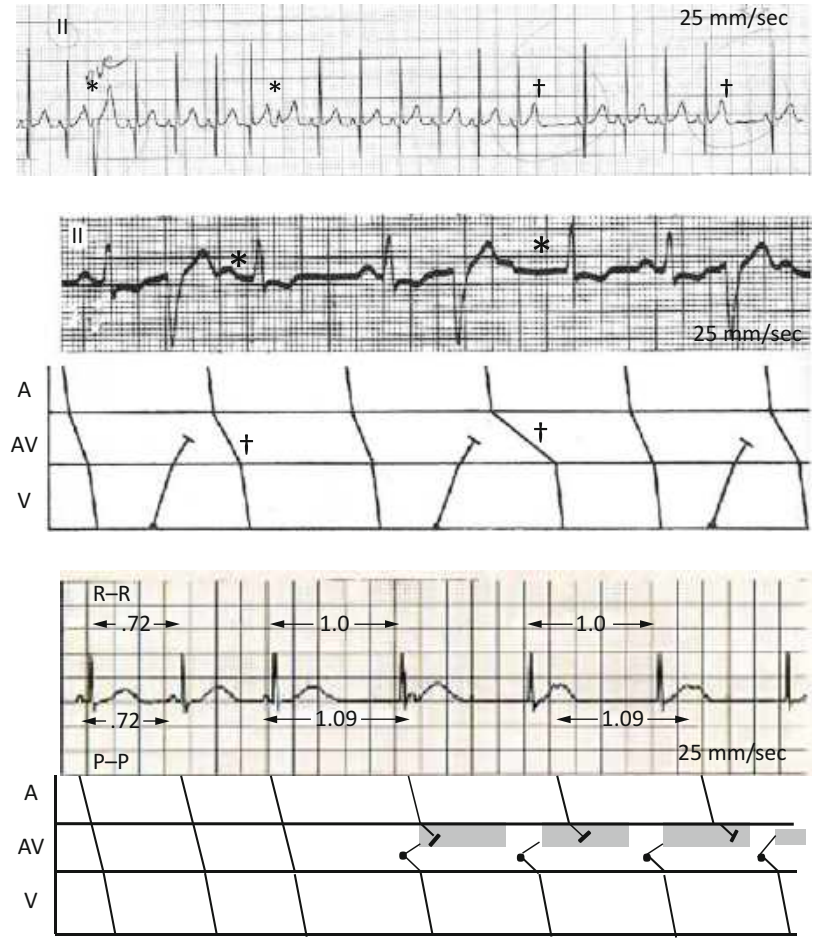

Fig. 157.10 In *top* rhythm strip, example of "phase 3 block" in one and then the other bundle branch (*) or the AV node (†) following premature atrial contractions (note P waves altering previous T waves). In *middle* rhythm strip, there is "concealed conduction" in the AV conduction system. Premature ventricular contractions retrogradedly penetrate into the AV conduction system, making these structures partially depolarized (but not completely refractory); this results in reduced conduction velocity by the ensuing atrial wavefront and a longer than normal PR segment (*). This phenomenon is graphically depicted by a *ladder diagram* below the *rhythm strip* as *lines* having *flatter slopes* in the AV panel (†). The *bottom rhythm strip* shows sinus rhythm, sinus slowing, and a junctional escape rhythm. Because the junctional escape mechanism does not retrogradedly conduct to the atrium, the slower sinus *P* waves should eventually be capable of conducting to the ventricles as "sinus capture beats." However, concealed retrograde conduction into portions of the AV junction that are proximal to the junctional escape focus (*black dot* in *ladder diagram*) renders that tissue entirely refractory (*gray region* in *ladder diagram*), an example of concealed conduction and phase 3 block. In this and all subsequent ladder diagrams, *A* atria, *AV* AV junctional structures, and *V* ventricles (*Middle rhythm strip* is reproduced with permission from Marriott & Conover [9])

anatomic component of its substrate any structure between and inclusive of the atrial muscle and His bundle. Ventricular tachycardia, therefore, necessarily includes some portion of the bundle branches, Purkinje system, or ventricular myocardium, as its substrate. Normal pacemaking tissues (the sinus node and, potentially, the AVN) will always discharge unless they are depolarized by a faster rhythm. With the single possible exception of junctional ectopic tachycardia, SVT does

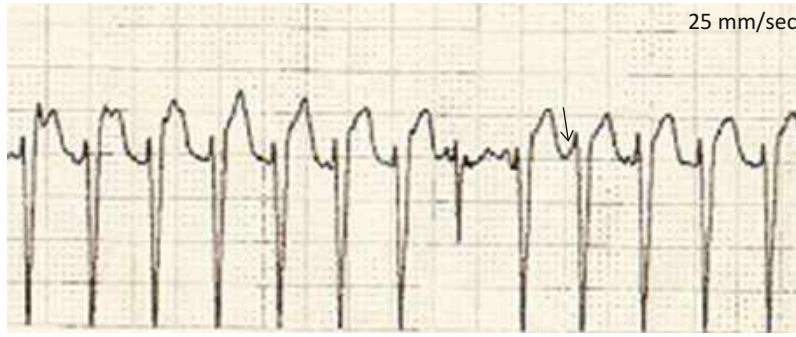

Fig. 157.11 Ventricular tachycardia at a rate of about 200 bpm. There is a sinus capture beat in the *middle* of the tracing. Discrimination of sinus P waves from baseline artifact is difficult in this tracing, but variable morphology of ST segments and T waves, especially during the first three beats, strongly suggests absence of retrograde (ventricular-to-atrial) conduction

indeed overdrive suppress the sinus node, but VT will only suppress the sinus and AV nodes if there is persistent retrograde (ventriculoatrial = VA) conduction from the VT substrate through the AV conduction system and into the atria. In the absence of VA conduction, sinus or junctional discharges during VT will occasionally penetrate the AV conduction system and depolarize a portion of or even the entire ventricular mass "between beats" of VT, resulting in what is referred to as "sinus capture beats" or "fusion beats" (Fig. 157.11). A relatively slow VT and/or rapid sinus rhythm improve the likelihood of this observation. This phenomenon strongly suggests the diagnosis of ventricular tachycardia (or junctional ectopic tachycardia). Frequent sinus capture or fusion beats can present a picture of a somewhat chaotic tachycardia. For completion's sake, if the R-R interval varies and the QRS morphology varies from beat to beat, there are two other entities to consider: complex SVTs with variable bundle branch aberrancy or pre-excitation and nonsustained but frequently repetitive VT (or SVT with bundle branch aberrancy).

In the presence of a tachycardia with regular R-R interval and a QRS duration *which is normal for age*, SVT is the diagnosis, although VTs eminating from the ventricular septum may have a relatively short QRS duration. A nonsinus tachycardia having a prolonged QRS duration has its own differential diagnosis: VT, SVT with bundle branch aberrancy, and a pre-excited tachycardia. If a prior ECG during sinus rhythm is available from the patient, the presence of inherent bundle branch block (as may occur following congenital heart surgery) or pre-excitation (especially the Wolff-Parkinson-White pattern) provides the clinician a template of the patient's baseline atrial-determined QRS morphology. That information notwithstanding, discriminating VT from SVT with bundle branch aberrancy is by far the most common dilemma. A 12-lead ECG during tachycardia with special attention to V1 is most helpful. Based upon nuances of the QRS morphology in either a basic right (RBBB) or left bundle branch blocklike (LBBB) pattern, the basic diagnosis can often be made (Fig. 157.12) [10, 11]. Pharmacological interventions may also be helpful. The use of a short-acting AV nodal blocking agent, such as adenosine, is diagnostic for a primary atrial tachyarrhythmia if it results in transient AV block but persistent of the atrial arrhythmia. Its ability to terminate a tachycardia suggests the presence of an AVN-dependent SVT, but some outflow tract VTs may also be terminated by these agents. Ultimately, intracardiac electrophysiological testing may be required. Algorithms such as the one in Fig. 157.12 are based upon adult data, and, unfortunately, analogous applications of electrocardiograms from infants and young children are not available. For example, a QRS duration of only 100 ms

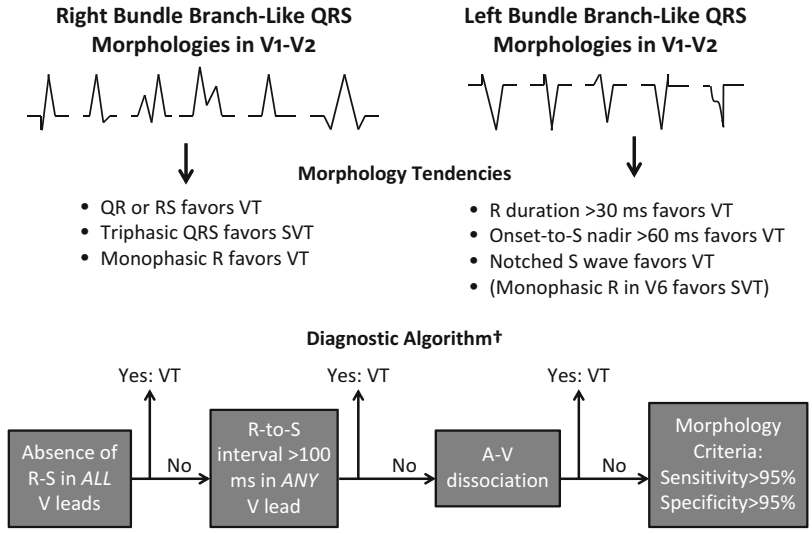

Fig. 157.12 Discrimination of supraventricular tachycardia (*SVT*) with bundle branch block from ventricular tachycardia (*VT*), based upon adult criteria. The intervals mentioned in this figure may not apply to infants and small children. †: This portion of figure is later referenced by Fig. 157.15 ("Diagnostic algorithm" is modified with permission from Brugada et al [10])

from a regular nonsinus tachycardia in a neonate would be considered ventricular tachycardia until proven otherwise.

Regular Narrow Complex Tachycardias

These tachycardias are best analyzed from a rhythm strip or, preferably, from a multichannel ECG. If the R-R interval is irregular, a primary atrial tachyarrhythmia is assumed, especially atrial fibrillation or atrial flutter. Other entities such as junctional ectopic tachycardia with sinus capture beats, certain septal VTs with sinus capture beats, and non-reentrant AV nodal tachycardia rounds out the differential diagnosis. Comprising the vast majority of narrow complex tachycardias are those with a regular R-R interval, in which that interval only varies (often as alternating intervals) by less than 40 ms. Attention to the inter-R-R electrogram is then necessary. This interval is comprised of fusion of T waves and atrial depolarizations. Here, again, knowledge of the patient's baseline ECG and T wave morphology may help inform that which is atrial. Likewise, the underlying ECG during sinus rhythm may provide clues about the SVT substrate, such as the delta wave of the Wolff-Parkinson-White pattern. The presence of two or more atrial depolarizations for every QRS nearly always makes the diagnosis of a primary atrial tachycardia. If there is a 1:1 QRS-to-P wave relationship, their temporal relationship becomes helpful. A "short R-P" interval (defined as QRS onset-to-onset of P wave being less than the P-to-next QRS) has a discrete differential diagnosis, as does a "long R-P" interval (defined conversely), though with significant overlap (Fig. 157.13). Tachycardias, which are incessant, show variations in rate according to autonomic nervous system milieu or show "warm-up" and "cooldown" behaviors most likely use enhanced automaticity as their mechanism. Nearly all others are paroxysmal, using either reentrant or, less commonly, triggered mechanisms. Following basic rhythm strip and multichannel ECG analysis and consideration of their spontaneous initiation and termination, pharmacologic maneuvers may be considered.

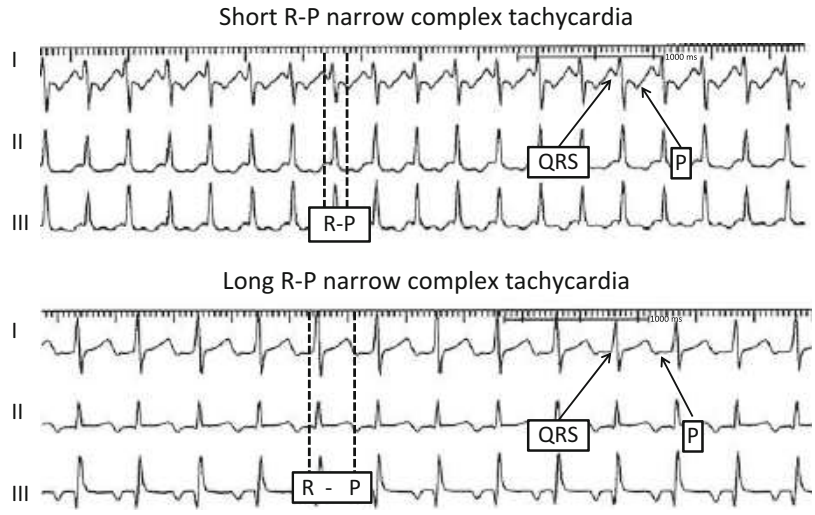

Fig. 157.13 Examples of short- and long-RP supraventricular tachycardia. The *top* tracing represents orthodromic AV reciprocating tachycardia from a 9-year-old male having a left lateral accessory pathway. The *bottom* tracing represents atypical variety of AV nodal reentrant tachycardia from an 18-year-old female

A diagnostic algorithm of SVT subtypes within the broader context of all nonsinus tachycardias and considering some of the above principles appears as in Fig. 157.14. In many patients, intracardiac electrophysiological testing is required to make a definitive diagnosis.

Regular Wide Complex Tachycardias

Discrimination of the three categories of wide complex tachycardia (VT, SVT with bundle branch aberrancy, and pre-excited tachycardias) is worthy of comment. Any form of SVT may exist in a patient coincidentally having pre-excitation and in which the accessory pathway alters the QRS but does not participate in the SVT mechanism. We say that the accessory pathway is an "innocent bystander." The only pre-excited SVT which utilizes the accessory pathway as a necessary antegrade portion of the tachycardia mechanism is the antidromic form of atrioventricular reciprocating tachycardia (AVRT). Hence, most of the concepts described in the narrow complex tachycardia section apply to both SVT with bundle branch aberrancy and to pre-excited tachycardias. A diagnostic algorithm for wide complex tachycardias in children appears as in Fig. 157.15, with the same caveats as for Fig. 157.14.

Bradycardias

Sinoatrial Node Dysfunction

The synonymous terms "sinus node dysfunction," "sinoatrial node dysfunction (SAND)," and "sick sinus syndrome" imply some combination of depressed SAN automaticity and sinoatrial conduction block. These terms are often used carelessly, depending upon the context: clinical signs and symptoms, rhythm strip observations, or observations in the electrophysiology laboratory. Most experts agree that the terms best apply when there is a combination of symptoms with electrocardiographic abnormalities. The term "tachy-brady syndrome" applies to the combination of SAND and paroxysmal atrial tachycardias, especially atrial flutter, which may occur long term following atrial surgery.

The symptoms associated with SAND in children relate to low cardiac output and may be

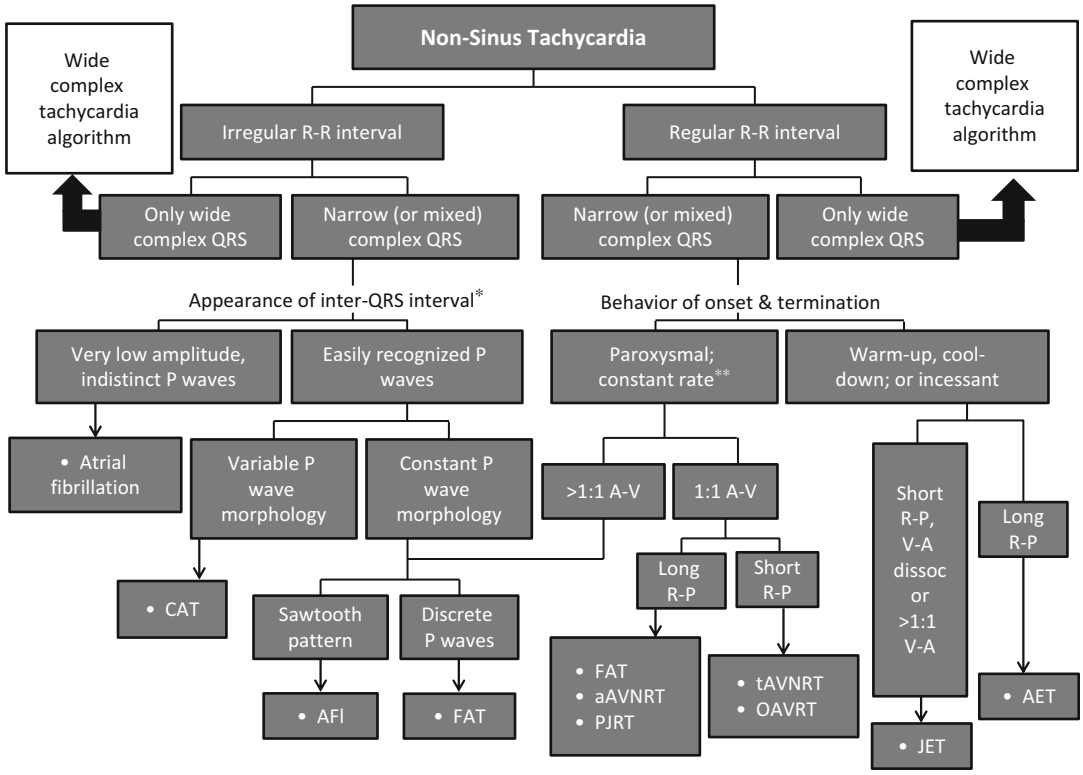

Fig. 157.14 Diagnostic algorithm for diagnosing types of nonsinus tachycardias, specifically, narrow-complex tachycardias. *aAVNRT* atypical form of AV nodal reentrant tachycardia, *AET* atrial ectopic tachycardia, *AFl* atrial flutter, *CAT* chaotic atrial tachycardia, *FAT* focal atrial tachycardia, *JET* junctional ectopic tachycardia, *OAVRT* orthodromic form of AV reciprocating tachycardia, *PJRT* permanent form of junctional reciprocating tachycardia, *tAVNRT* typical form of AV nodal reentrant tachycardia, and *, ** these portions of figure are later referenced by Fig. 157.15

paroxysmal and dramatic, such as syncope or presyncope or subtle and very nonspecific, such as persistent fatigue, nausea, irritability, daytime somnolence, behavior changes, declining school performance, and headaches. The electrocardiographic findings may be similarly nonspecific. These include persistent sinus bradycardia (with average heart rates $<$ 2SD for age); excessive pauses (greater than twice the ambient sinus interval), especially in the presence of exaggerated sinus arrhythmia; wandering atrial pacemaker; and subsidiary escape rhythms, especially nonaccelerated junctional or low atrial rhythms (Fig. 157.16).

Electrophysiologic features of sinoatrial node dysfunction may also be sought in the electrophysiology laboratory. Abnormally long sinus delays (relative to the ambient sinus rate) following $>$30-s periods of rapid atrial pacing, the so-called sinus node recovery time (SNRT), may indicate depressed sinus node automaticity [12]. It is even thought that the sinoatrial conduction time may be estimated by introducing progressively earlier single premature atrial events from the high right atrium into sinus rhythm (or a slow atrial-paced rhythm) and subtracting the prevailing sinus cycle length (or the slow-atrial-paced cycle length, S1-S1) from the – eventually

stable – return cycle (S2-S3, with S2 representing the premature stimulus and S3 the subsequent recovery sinus node-produced electrogram) [13, 14]. These techniques require certain assumptions, and they suffer from poor positive predictive accuracy and reproducibility [15]. In the past, SNRT measurement during pharmacologic blockade of autonomic influences has been championed in children to help improve the value of this test [16]. Clinical application of these techniques has waned greatly in the last two decades. More recently, specialized filtering and frequency settings have permitted direct measurement of sinoatrial node depolarization [17], but this technique has also not been embraced by clinicians.

Sinoatrial node dysfunction is a condition of advancing age, and it is rare in infants, children, adolescents, and young adults except following congenital heart surgery. A list of associations in the young appears in Table 157.1 [18–26].

Atrioventricular Conduction System Block

First- and Second-Degree Atrioventricular Block

First-degree AV block is defined as a prolonged PR interval while in sinus rhythm. This interval normally prolongs with age. The PR interval, ordinarily defined as the electrocardiographic

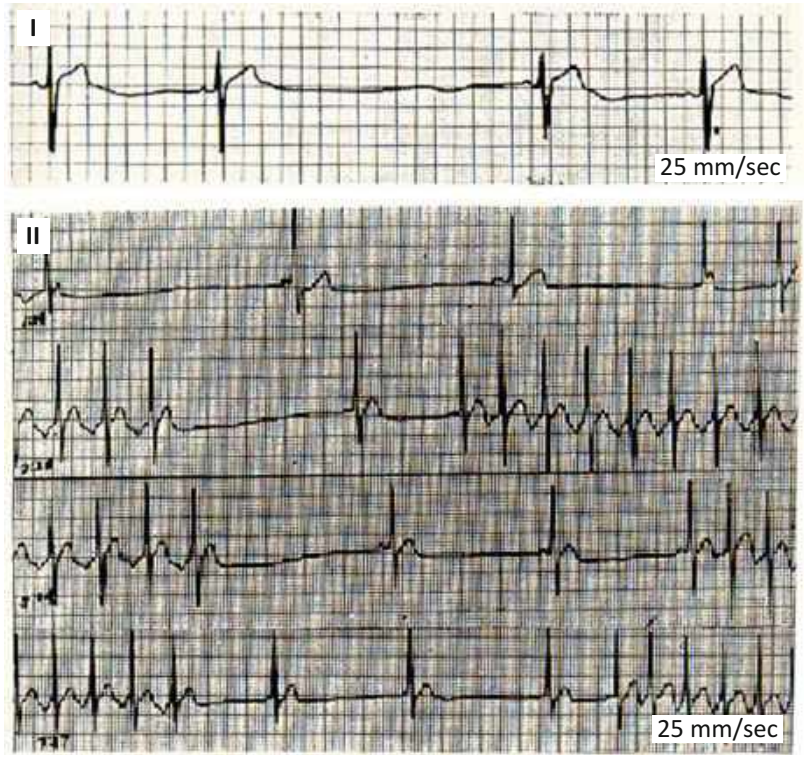

Fig. 157.16 Rhythm strips from patients having sinoatrial node dysfunction following congenital heart surgery. The *top strip* shows sinus bradycardia and a sinus pause. The pause could be due to failure of sinoatrial node discharge (decreased automaticity) or to second-degree sinoatrial conduction block. The *bottom strip* is continuous and shows junctional bradycardia and nonsustained episodes of atrial flutter

interval from the sinus P wave onset to the QRS onset, comprises the conduction time from the sinoatrial node transatrially to the AV node, the trans-AV nodal conduction time, and the conduction time through the His bundle, bundle branches, and Purkinje network. (A portion or the entirety of these structures may be bypassed by pathological accessory pathways, the subject of another chapter.) Hence, first-degree AV block may result from delay in any of these anatomic structures. Accordingly, the etiology and clinical significance of this common finding reflect the anatomic structure responsible for the delay. For example, first-degree AV block caused by right atrial volume overload due to an atrial septal defect does not predict progression to higher grades of AV block. However, the development of first-degree AV block, especially when combined with QRS axis change in a young person having a mitochondrial disease such as Kearns-Sayre syndrome, likely represents evolving HPS damage and is a harbinger of dangerous complete AV block. A nonexhaustive list of etiologies of all levels of AV block appears in Table 157.2. In the absence of congenital heart disease/surgery, acquired cardiac disease, metabolic or electrolyte disorder, acute infectious disease, neuromuscular disease, channelopathy, or drug/toxin effect, first-degree AV block in young people merely represents enhanced parasympathetic influences or is idiopathic and does not represent risk to the patient. It occurs in up to 12 % of ambulatory rhythm recordings from healthy teenagers [27] and in 0.65–1.1 % of random 12-lead ECGs in children [28]. Isolated first-degree AV block in young athletes is considered a normal variant, occurring in 23 % of ambulatory rhythm recordings from teenaged athletes [29]. Rarely, especially following surgery for congenital heart disease, very prolonged PR intervals result in ventricular contraction not yet being completed by the time of the next atrial contraction. Hence, atrial contraction against closed AV valves ensues, with possible symptoms of light-headedness, fatigue, and nausea, so-called pseudo-pacemaker syndrome [30].

Table 157.1 Sinoatrial node dysfunction: associations in the young

Genetic etiologies
Primary channelopathies
HCN4 gene mutations [18]
SCN5A gene mutations (with atrial standstill, due to sinoatrial conduction block?) [19]
Cx40 gene mutations (with atrial standstill) [20]
Secondary associations with other cardiac channelopathies
Long QT syndrome, type 1
Long QT syndrome, type 3
Brugada syndrome
Catecholaminergic polymorphic ventricular tachycardia
Transcription factors
TBX5 gene mutations (Holt-Oram syndrome, often with structural heart defects)
Nkx2.5 gene mutations (often with structural heart defects)
Congenital heart disease
Congenital
Heterotaxy (especially left atrial isomerism)
Associated with single left superior vena cava [21]
Postoperative (***, **, and * refer to relative prevalence)
Fontan operations with atrial inclusion ***
Atrial redirection operations (Mustard/Senning) ***
Sinus venosus atrial septal defect **
Total and partial anomalous pulmonary venous return repair **
Ross procedure ** [22]
Tricuspid valve surgery **
Orthotopic heart transplantation **

Cardiomyopathies
Left ventricular noncompaction (especially with WPW) [23]
Dilated (especially laminopathies, SCN5A mutations)
Hypertrophic (especially glycogen storage disease caused by PRKAG2 mutation)
Neuromuscular and neurodegenerative disorders
Emery-Dreifuss muscular dystrophy (X-linked)
Myotonic dystrophy, type I
Laminopathies (lamin AC mutations)
Mitochondrial myopathies
Fatty acid oxidation disorders
Congenital central hypoventilation syndrome [24]
Neuronal ceroid lipofuscinosis (Batten's disease) [25]
Infectious and immunologic
In utero exposure to maternal anti-SSA/Ro or anti-SSB/La antibodies (with AV block)
Chronic Kawasaki syndrome [26]
Acute myocarditis
Diphtheritic myocarditis
Typhoid fever
Acute dengue fever
Other
Elevated central nervous system pressure from any etiology
Central nervous system disorders affecting brainstem or hypothalamus
Hypothermia
Anorexia nervosa
Hypothyroidism
Medication/drug effect
Hypervagotonia from any etiology

Type I second-degree AV block usually results from blocked conduction in the AV conduction system, usually the AV node, and only requires therapy if clearly causing symptoms of dizziness, presyncope, or fatigue. This finding exists in up to 11 % of asymptomatic teenagers during sleep [27] and in up to 20 % of athletic teenagers [29], based upon ambulatory rhythm monitoring. Its presence during wakefulness is much less common and is probably worthy of long-term patient surveillance. Type II second-degree AV block usually represents infranodal AV conduction system disease and represents an unstable conduction system, but it too has been identified in apparently healthy young athletes [29]. It may be associated with bundle branch block. Knowledge of the underlying etiology or type of prior heart surgery also helps inform the anatomic level of block and attendant risk (Table 157.2). Treadmill exercise testing may be helpful in discriminating the anatomic level of second-degree AV block. As a rule, autonomic factors favor improved AV conduction at faster atrial rates when the disease is in the AV node and AV block worsens at faster atrial rates when the disease is infranodal.

Bundle Branch Block

Conduction abnormalities that manifest as perturbations in the QRS morphology and lengthening of the QRS duration represent abnormalities within the bundle branches, Purkinje fibers, and/or ventricular myocardium. In children, they are often components of an underlying condition, including many of those listed in Table 157.2. Progressive bundle branch block or nonspecific interventricular conduction delay is especially important, as it may represent disease progression to complete AV block (e.g., Kearns-Sayre syndrome). The coexistence of distal conduction system disease with other conditions appears in discussion of those underlying disorders. This section addresses isolated bundle branch disease.

Right bundle branch block (RBBB) is diagnosed by the electrocardiographic pattern of a dominant broad S wave in lead I (and often aVR) and R' in lead V1. "Complete" RBBB requires that the QRS duration be sufficiently long for the patient's age and that the conduction delay be concentrated in the terminal portions of the QRS. That is, if the QRS is uniformly prolonged, even with a dominant R versus S wave in V1, interventricular conduction delay with right ventricular hypertrophy is also possible. If the QRS duration is somewhat prolonged (but not having a z score of >2) and has a similar pattern as RBBB, "incomplete RBBB" (iRBBB) is diagnosed. Discriminating iRBBB from right ventricular hypertrophy in a youngster having a right ventricular volume overload condition may be impossible. These patterns are common in children, representing 2.9 % (iRBBB) and 0.16 % (RBBB) of healthy 6–17-year olds [31], with a female predominance. Incomplete RBBB having an rSr' pattern in V1 is now considered a normal variant in physically conditioned teenagers [32].

Isolated familial complete RBBB (i.e., not coexisting with a cardiomyopathy) has been recognized for decades, but its clinical significance remains in dispute. If there is, in addition, left axis deviation of the initial 40 ms of the QRS (therefore, comprising one form of bifascicular block), progression to complete AV block has been reported in some series [33, 34] but not in others [35]. Even in the presence of a normal initial QRS axis, progression to AV block has been reported in some series [36, 37] but not in others [38]. It is reasonable to obtain ECGs in first-degree family members and grandparents, when isolated complete RBBB is first identified in a child. The role of long-term surveillance when the family history is negative and ECGs are normal is unknown.

Complete left bundle branch block (LBBB) is diagnosed when the QRS duration exceeds a z score of 2, and there is a pure S or rS in V1. This diagnosis may be confused with the Wolff-Parkinson-White pattern and a right free wall accessory pathway; the PR interval should always be carefully measured, as it will be very short in the presence of Wolff-Parkinson-White pattern. As an isolated finding, LBBB in a youngster is rare and always raises the concern of progressive conduction system disease, with or without cardiomyopathy. Affected youngsters require ambulatory rhythm monitoring and exercise testing in order to identify periods of AV block, especially at higher atrial rates. At minimum, long-term surveillance is required. LBBB may occur following left ventricular outflow tract surgery.

Congenital Complete Atrioventricular Block

Congenital complete atrioventricular block (CCAVB) occurs in 1 in 11,000 live births [39]. Approximately two-thirds of cases are considered immune mediated, related to transplacental passage of anti-ribonucleoprotein antibodies (anti-SSA, Ro (especially anti-Ro52 and anti-Ro60); or anti-SSB, La) from women who are ANA positive, though only a minority of these women have active systemic lupus erythematosus or Sjögren syndrome. These antibodies result in an immune-mediated fibroelastic destructive process starting at about 18 weeks of gestation and resulting in CAVB (>90 %) and/or SAND (10 %). The pathogenesis of CAVB (and, less commonly, SAND or endocardial fibroelastosis) is incompletely understood, although there are currently three active theories: [1] The calcium channel theory, in which cell surface L-type calcium channel

proteins (Cav1.3) are targeted by maternal antibodies; [2] The apoptotic theory, in which the normally antibody-inaccessible ribonucleoproteins, Ro and La, are exteriorized during apoptosis, prompting an antibody-mediated inflammatory response with collateral damage to neighboring healthy myocytes; and [3] The serotoninergic theory, in which cross-reactivity between the 52 kD portion of the nuclear (and therefore unavailable) Ro antigen and cell surface 5-HT4 receptors, occurs. This causes reduction of L-type calcium channel proteins, because 5-HT4 receptor binding is important for L-type calcium channel activation. A combination of the first two theories is currently favored [40].

About 5 % of pregnancies in women having antibodies result in CCAVB, but after a first-affected infant, that incidence increases to about 18 % for subsequent pregnancies [39]. New data suggest that recurrences are more likely in older women and when the vulnerable portion of gestation (12–24 weeks) occurs during the months of January–March [41]. Affected newborns may also have transient rashes, hepatitis, or cytopenias, which may persist until about 6 months of age. The presence of isolated neonatal lupus rash is associated with a 6- to 10-fold increase risk of CCAVB in subsequent pregnancy [42]. Rarely, AV block does not occur until weeks to a few months postpartum.

Nonimmune CCAVB occurs with a higher than expected incidence in fetuses having certain structural congenital heart defects, especially congenitally corrected transposition and some forms of heterotaxy (particularly, left atrial isomerism, or "polysplenia"). Uncommon genetic etiologies, which may or may not have associated structural defects, include mutations in the Nkx2.5 transcription factor gene [43] or the Tbx5 transcription factor gene. When the latter is associated with Holt-Oram syndrome, sinoatrial node dysfunction may coexist or predominate [44].

CCAVB is a morbid condition, carrying a 20–30 % incidence of fetal or neonatal death. This risk is highest when there is associated SAND and endocardial fibroelastosis [45]. In the presence of hydrops fetalis, the mortality rate of immune-mediated CCAVB is 73–100 %. The diagnosis of congenital heart block is made during fetal ultrasound, and once identified, patients should be observed closely in utero for signs of heart failure and hydrops fetalis. Early delivery and immediate postbirth pacing may be indicated and weighed against the risks of prematurity. Among antibody-exposed fetuses, especially following a prior-affected infant, there are several ultrasound-guided methods of monitoring the mechanical AV interval. The goal is to identify progressive AV interval lengthening or development of second-degree AV block, in hopes of providing maternal therapy to prevent progression to CAVB. That said, there is still no conclusive proof that PR prolongation in these fetuses predicts progression to CAVB. Once CAVB is present, no therapies are effective. Several anecdotal series have championed the use of maternal steroids, plasmapheresis, and/or IVIG to prevent progression to CAVB and even reversal of second-degree AV block [46–49]. However, IVIG was shown not to be effective in a recent large experience [50], and the PRIDE study, in which dexamethasone was used in a randomized protocol, also failed

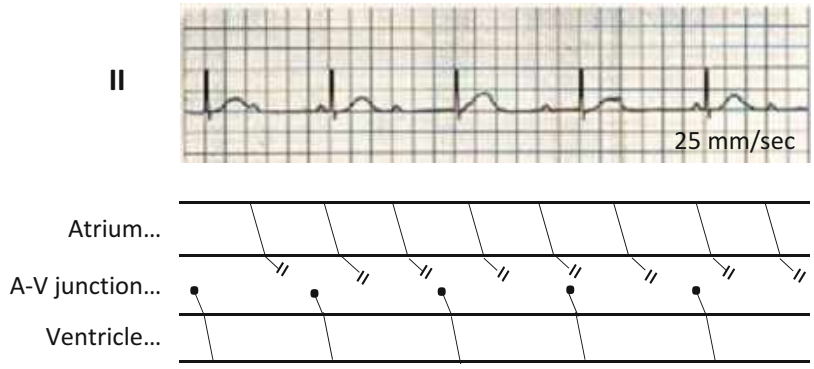

Fig. 157.17 Rhythm strip from a 6-year-old having congenital complete AV block. It illustrates AV dissociation, a faster P wave rate than QRS rate, and a regular R-R interval. The associated *ladder diagram* below illustrates blocked atrial impulses (symbol, //) in the upper portion of the AV node and an AV conduction system escape mechanism (symbol, •) from the more distal AV conduction system

to demonstrate efficacy [51]. For fetuses with CCAVB who have signs of hydrops or an excessively slow rate (<55 bpm) and in whom early delivery is felt to be highly undesirable, maternal administration of the beta-adrenergic agent, ritodrine, has been reported to be helpful [52].

Once an infant with heart failure is born, aggressive therapy is required for all other aggravating factors, including pleural and pericardial effusions, lung disease of prematurity, and coexisting structural heart defects. Duration of temporary transcutaneous pacing is limited by skin fragility, so placement of temporary transvenous or epicardial wires in the intensive care nursery may be necessary.

The rhythm strip from an affected patient demonstrates atrioventricular dissociation, usually with a normal sinus P wave rate (Fig. 157.17). However, in up to 10 % of infants having immune AV block, the sinus node will also be affected, resulting in sinus P wave bradycardia, as well. In the more common circumstance, the P wave rate is often coincidentally about twice that of the escape junctional pacemaker. This can result in the QRS having a relatively constant relationship with the preceding and following P waves, at least for brief periods of time. This can simulate second-degree AV block and 2:1 AV conduction. The true diagnosis will become evident after prolonged rhythm strip surveillance. Another interesting phenomenon is often observed in children having congenital AV block and periods of a relatively constant QRS and P wave relationship: The P-P interval bracketing the QRS is often slightly longer than the alternating P-P interval. Theories abound for this observation, including the mechanical effect of atrial stretch associated with right atrial contraction against a closed tricuspid valve and alterations in blood flow to the sinoatrial nodal artery.

Specific indications for permanent pacing in newborns and in children with congenital complete heart block are included in the 2008 guidelines for device-based therapy of cardiac rhythm abnormalities [53]. Even asymptomatic adults with CCAVB have a 5 % incidence of sudden death at long-term follow-up [54]. It has therefore become standard practice to permanently pace all such patients by their late teenage years. Among patients with congenital complete heart block who require pacing, perhaps up to 10 % will develop significant ventricular dysfunction [55]. Whether this is due to intrinsic muscle disease related to the initial immune-mediated process or whether this is purely due to dyssynchronous ventricular depolarization is unknown. Ventricular function benefits from ventricular resynchronization pacing in this patient group [56]. Lastly, an association

between immune-mediated CCAVB, but not non-immune CCAVB, and aortic root dilatation has recently been discovered [57].

Interpreting the Rhythm Strip

Rhythm strip interpretation can be most daunting in the presence of irregular rhythms. By categorizing the pattern of irregularity, the clinician may then reduce the differential diagnosis to more manageable considerations. All available clinical information should be brought to bear when weighing the possibilities within each category. For example, when considering an infant having just undergone surgery for AV septal defect and who now has "group beating" and a normal P wave appearance and rate, second-degree AV block would move to the top of the list. Or, in a teenager who has Wolff-Parkinson-White pattern and narrow QRS complex "premature beats," reciprocating beats related to the accessory pathway should come to mind. Based upon the classical textbook by Marriott and Conover, *Advanced Concepts in Arrhythmias Second Edition* [9], we have found certain sequential steps to be a good approach to complex arrhythmia interpretation. First, the clinician is advised to utilize as many leads as possible. This is critical for determining the origin of the atrial impulse, the type of bundle branch block, and the QRS axis and to identify events which may be isoelectric, and therefore not visible, in one lead or the other. Next, the QRS is identified, and even if the amplitude is very low, it is always followed by a T wave. One or the other is always visible. Third, the P wave should be sought. It may appear as only a distortion of the QRS, ST segment, or T wave. If available, the normal QRS, ST segment, and T wave will serve as an unaltered template. Finally, subtle changes in the rates of the P and QRS complexes should be measured, so that the perturbation of the rate of one can be related to that of the other; that is, depolarization of which chamber is dictating the rhythm? This provides mechanistic insight into the underlying arrhythmia. What follows is a summary of etiologies of various QRS arrhythmic patterns according to the arrhythmia phenotype, with some additional comments when appropriate. A "ladder diagram" is used to illustrate the anatomical electrical connections that account for some of these phenomena.

Etiologies of Premature QRS Complexes

Premature atrial complexes (PACs; often referred to as atrial premature beats, or APBs) result in early ventricular depolarizations only if the AV conduction system components have recovered from their refractory periods from the prior normal beat (Table 157.3). If not, a distortion of the prior T wave may be the only evidence that an atrial extrasystole has occurred. If only one or the other

Table 157.3 Etiologies of premature beats

Extrasystoles (atrial, ventricular, rarely manifest junctional)
When multiple, usually constant coupling interval to prior sinus beat

Better conduction interrupting poorer conduction
Example: Second-degree AV block, in which 2:1 AV conduction suddenly changes to 3:2 conduction for one cycle
Supernormal conduction during period of AV block
Spontaneous resolution of inapparent nonconducted atrial bigeminy
Note change (loss of distortion) in T wave following termination of atrial bigeminy

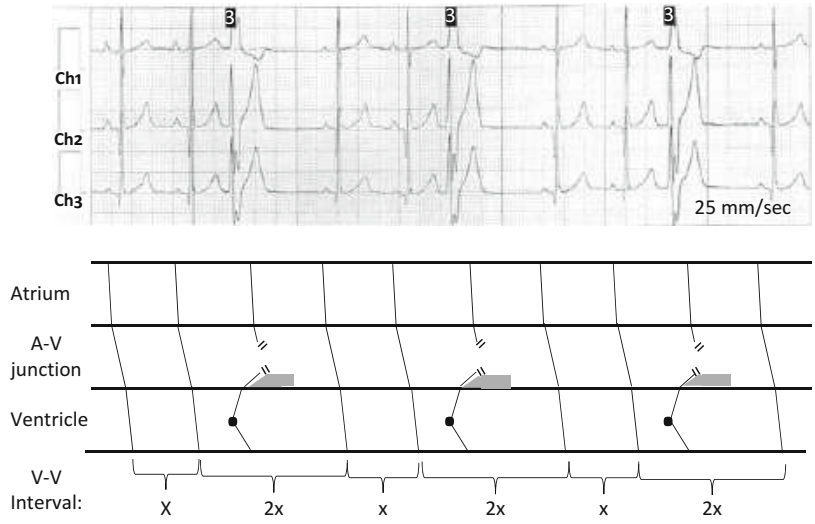

Fig. 157.18 A 3-channel rhythm strip showing monomorphic ventricular trigeminy with its associated ladder diagram. The premature ventricular focus (symbol • in the ladder diagram) blocks retrogradedly in the AV conduction system (indicated by the symbol, //), a common characteristic of the human heart. Therefore, sinoatrial discharges continue uninterrupted but block in the distal AV conduction system, which is refractory (*gray shaded* regions), due to concealed conduction from the ventricular extrasystoles. This results in a compensatory pause, because the interval between conducted QRS complexes is twice the ambient sinus rate

bundle branch has recovered from refractoriness, the resultant QRS will have a bundle branch block appearance. A rhythm strip showing both premature narrow and wide QRS complex beats should raise the suspicion of conducted PACs. Nonconducted PACs result in a QRS pause (see below) and may only be identified by distortion of the T wave corresponding the prior normal QRS. PACs are common in patients having an otherwise normal conduction system, especially in neonates, and usually do not require therapy. Premature junctional complexes (PJCs) are exceedingly rare, occur when there is abnormal automatic discharge from the AV node or His bundle, and are considered pathologic. Unapparent conducted PACs and low atrial PACs are sometimes miscategorized as PJCs. Premature ventricular complexes (PVCs; often referred to as ventricular premature beats, or VPBs) are also common normal variants and may eminate from any portion of the ventricular myocardium. The more septal their origin, the more narrow the QRS. PVCs are discriminated from PACs with bundle branch aberrancy, based upon the normal T wave associated with the prior sinus beat. If the PVC is available by full 12-lead ECG, the QRS morphology may also be useful (Fig. 157.12). When the PVC does not conduct retrogradedly through the specialized conduction system into the atria, sinus node discharges continue unabated. If the sinus discharge which occurs nearly contemporaneously with the PVC slows sufficiently in the AV conduction system, a propagated QRS may result. In that instance, the PVC is said to be interpolated. Otherwise, there is a post-PVC pause in the ventricular rhythm; the interval between the sinus-conducted QRS complexes which bracket the PVC would then be twice the ambient sinus rate, and the interval from the PVC to the next sinus conducted QRS is considered a "compensatory pause" (Fig. 157.18).

"Capture beats" occur when there are competitive rhythms and on occasion they fail to suppress each other. For example, this is seen in patients having SAND, a predominantly slow junctional escape rhythm, the absence of retrograde conduction from the AVN up to the atrium, and an occasional sinus node discharge which

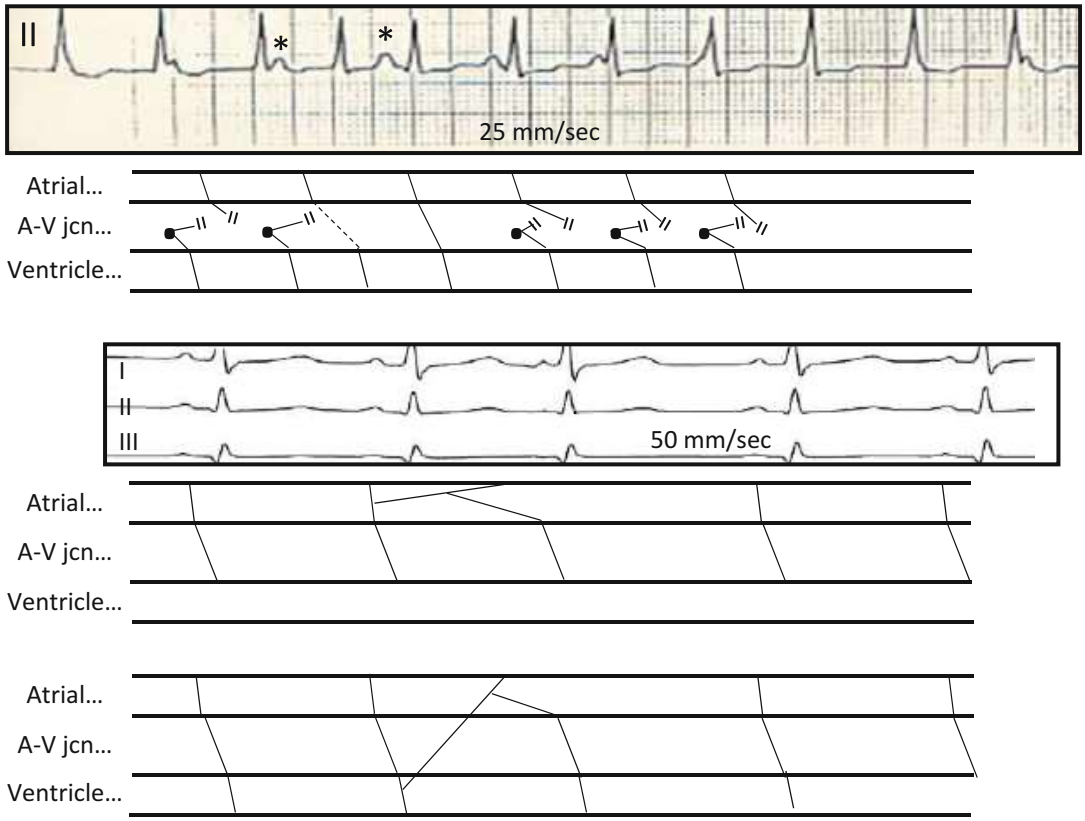

Fig. 157.19 Examples of premature beats with associated ladder diagrams. The *top* rhythm strip shows primary junctional rhythm (the discharging focus is indicated by the symbol, •, in the *ladder diagram*), no evidence for retrograde conduction from the junction into the atria, and a brief period of a faster atrial rhythm. The fourth and fifth QRS complexes are premature and are sinus "capture beats," which result from sinus P waves (*) conducting to the ventricles. The longer PR interval preceding the first of these two beats (and denoted by the dashed line in the ladder diagram) is due to slower antegrade conduction, because it is relatively refractory due to retrograde concealment from the prior junctional beat. // indicates conduction block. The bottom rhythm strip shows a single premature conducted P wave. The mechanism cannot be determined from this rhythm strip and, as indicated by the two *ladder diagrams* beneath it, could represent a true premature atrial contraction (*top ladder diagram*) or a reciprocating beat related to an accessory AV connection (*bottom ladder diagram*), among others

enters the AVN prior to the next expected junctional depolarization. Similarly, changes in autonomic nervous system tone or other dynamic influences may cause sudden improvement in AV conduction such that 1:1 AV conduction briefly interrupts constant high-grade AV block. "Reciprocating beats" can be viewed as single beats of a reentrant SVT, classically occurring when a sinus node-driven QRS reenters the atria via conduction up an accessory AV connection, followed by normal AV conduction back to the ventricles (Fig. 157.19).

Etiologies of Pauses of the QRS Complex

Most entities in this category have been previously discussed. Nonconducted atrial bigeminy of the fetus and neonate probably represents the most common cause of sustained QRS bradycardia in young humans (Table 157.4). The only clue to this diagnosis in a brief rhythm strip may be the distorted T wave by the PACs. A longer period of surveillance will likely reveal either resumption of sinus rhythm

without PACs or conducted PACs. Concealed junctional extrasystoles probably represent the most common manifestation of PJCs (see above). Using the mechanism of concealed conduction, as previously described, an early His bundle extrasystole may both find the distal conduction system refractory and leave its own wake of refractoriness; hence, it results in neither its own QRS nor AV conduction of the ensuing atrial depolarization (Fig. 157.20) [9]. This diagnosis is best made during intracardiac electrophysiologic testing.

Etiologies of Bigeminal QRS Complex Rhythm

A bigeminal rhythm implies a monotonous pattern of alternating QRS-to-QRS intervals (Table 157.5). Although the entities in this category overlap with "premature beats," 3:2 conduction deserves further mention. Either second-degree sinoatrial or AV block in which conduction block occurs after every third depolarization of the proximal structure will give the appearance of bigeminy, because there will always be an alternating inter-R wave interval.

Etiologies of Group Beating of QRS Complexes

"Group beating" means that there are repetitive clusters of ventricular impulses separated by a beat or several beats of a normal or, at least, slower rhythm (Table 157.6). The only forms of SVT which may fall into this category are those in which the AV node is not a portion of the reentrant circuit, i.e., primary atrial tachycardias. Orthodromic AV reciprocating tachycardia and nearly all forms of AV nodal reentrant tachycardia have a 1:1 VA relationship and do not present with QRS group beating. The only exception is the

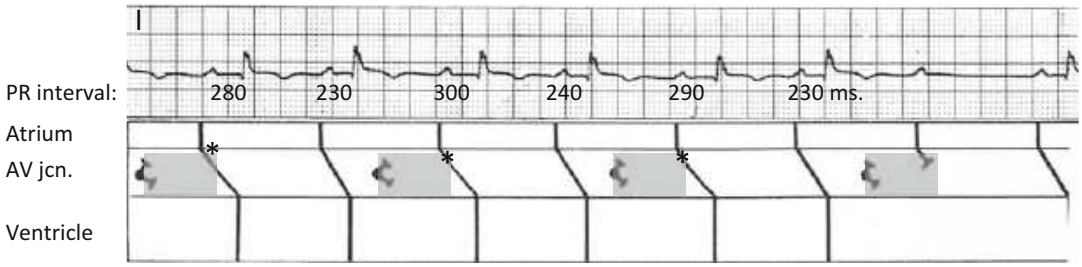

Fig. 157.20 In the differential diagnosis of QRS pauses, this rhythm strip illustrates the unusual diagnosis of "concealed junctional extrasystoles." These discharges (indicated by the symbol, •, in the *ladder diagram*) most likely originate in the His bundle. Although they do not conduct antegradedly to the ventricles, they do leave a wake of refractoriness in the AV junction (indicated by the *gray regions* and representing another example of concealed conduction). When the sinoatrial impulse encounters the AV junction partially depolarized in its relatively refractory state (*), conduction slows, as indicated by PR interval prolongation (beats 1, 3, and 5). When the sinoatrial impulse encounters the AV junction in its absolute refractory period, there is no conduction, resulting in the QRS pause. If, as in this case, the junctional extrasystoles do not result in a depolarizing signal on the surface ECG, the diagnosis must be made by inference, unless intracardiac electrograms are available (Modified with permission from Marriott & Conover [9], p. 375)

Table 157.5 Etiologies of bigeminal QRS complex rhythm

Conducted atrial, conducted junctional (rare), or ventricular bigeminy
Reciprocating atrioventricular or AV nodal beat after every sinus/atrial beat
Double AV nodal and ventricular activation by each sinus beat (rare)
Due to dual AV nodal physiology, *plus* very discrepant conduction times through "fast" and "slow" inputs to AV node, *plus* failure of concealment of "fast" inputs into "slow" inputs
Conducted atrial, conducted junctional (rare), or ventricular parasystole with fortuitous discharge rate a multiple of ambient sinus rate
3:2 conduction
Atrioventricular if atrial/sinus rhythm
Nodoventricular if junctional rhythm
Multilevel junctional block during atrial flutter (2:1 alternating with 4:1)

Table 157.6 Etiologies of group beating of QRS complexes

Second-degree sinoatrial or AV block having a ratio of 4:3 or greater
Atrial flutter having complex AV junctional block having a ratio other than 1:1, 2:1, or 3:2
Sinus/atrial rhythm repeatedly having >2 consecutive conducted atrial, conducted junctional (rare), or ventricular extrasystoles
Nonsustained but incessant conducted atrial, conducted junctional (rare), or ventricular tachycardia
Nonsustained but incessant permanent form of junctional reciprocating tachycardia
Frequent interpolated premature ventricular complexes

permanent form of junctional reciprocating tachycardia (a form of orthodromic AVRT), in which the tachycardia may spontaneously terminate and restart (after brief sinus rhythm) incessantly.

Etiologies of Regular QRS Bradycardia

The practitioner should always be cognizant of the developmental changes in the sinus rate when considering the presence of bradycardia. The relevance of sinus bradycardia must take into account the clinical milieu, especially in older children and teenagers, when there is a high incidence of isolated heightened vagal tone. In addition to some of the manifestations of SAND (sinus bradycardia, junctional bradycardia, and regular type II second-degree sinoatrial block (which cannot be diagnosed from the surface rhythm strip)), this category includes persistent nonconducted atrial bigeminy and third-degree (complete) AV block.

Electrocardiography

Electrocardiography is the measurement and interpretation of voltages generated by the heart and recorded on the body surface. While clinical interpretation of the electrocardiogram may be based solely on the recognition of patterns across leads on the recorded page, this methodology may ultimately lead to a flawed diagnosis when the basic assumptions about the recording of a patient's electrocardiogram are violated. Such can be the case in congenital heart disease, where anatomy and physiology vary vastly. Therefore, the interpretation of the electrocardiogram must be grounded in a basic understanding of its genesis.

Electrical Generator in a Volume Conductor

In the simplest form, the heart can be considered a battery within a bounded volume of electrically conductive fluid (the body). A battery in a conductive medium passes current from one pole to the other pole continuously, until exhausted, with the amount of current being determined by the resistance. The current is driven throughout the entire volume of the conductor. The direction and density of the current is determined by factors related to the uniformity of the conductive medium. The current density is highest close to the source and is less at farther points, such as the body surface. Nonuniformity of conductivity, the presence of nonconductive

objects, or irregularities of the boundaries can all affect the path of the electric current. In the body, there are many influences on these current paths. These include the shape, position, and mass of the myocardium as well as the lungs, vessels, rib cage, musculature, and skin. The volume and location of blood, or fluid, within the thorax is also influential.

Body Surface Potentials

The myocardium generates current in complex patterns throughout the heterogeneous conductive structure of the body. If these patterns were visible on the skin, a unique and abstract line drawing would be present that would be a representation of the underlying system. A battery in the thorax would generate a static pattern that would remain unchanged as long as energy remained in the battery and there were no changes in the conductivity of the system, such as no breathing. However, the heart is not static. With each beat, an electrically active wavefront propagates throughout the myocardium. This wavefront acts as thin layer of electric *bipoles* with positive and negative sides. In fact, one can think of the activation wavefront as tiny batteries adjacent to each other in a curvilinear formation that moves through the myocardium in time. At an instant in time, the wavefront generates a particular pattern of current on the body surface. The pattern is determined by the position, shape, and density of the wavefront within the myocardium. As these change during the cardiac cycle, so does the body surface pattern. The purpose of electrocardiography is to record and reconstruct the body surface patterns throughout the cardiac cycle in order to make inferences about the characteristics of the electrical generator that produced them. For further detailed information regarding the generation of cardiac and body surface biopotentials, see reference [58].

Leads

The body surface patterns of electricity must be sampled extensively in order to characterize the underlying myocardium. However, instead of measuring the current flowing at each point, it is practical to measure the electric potential. The driving force for current flow is the difference in electrical potential between two points, better known as the *voltage*. Electrode pairs are placed on the skin surface in order to measure the voltage between two points. An electrode pair is a "lead." The voltage recorded from a lead is one-dimensional. That is, without the knowledge of the positions of the electrodes, the measurement is only a value. However, in knowing the lead position on the body, two-dimensional information is obtained and more accurate inferences can be made regarding the source. With multiple leads, a three-dimensional picture can start to be constructed.

Yet, the cardiac cycle is not static. Therefore, the voltage from a lead must be recorded periodically over time at a *sampling rate* that is frequent enough to accurately measure and reproduce the continual changes in voltage. An *electrogram* is a tracing of how the voltage between two points on the body varies over time. Through the combination of *spatial* sampling by using multiple leads and *temporal* sampling by recording over time, a complete multidimensional representation of the cardiac cycle, as viewed from the body surface, is created.

Mapping the Cardiac Cycle

Since the inception of electrocardiography, there has been a quest for optimizing body surface measurements. The ultimate goal is to be able to fully infer the status of the cardiac electrical generator: its shape, function, position, and rhythm. The electrical potentials on the body, and within the body, are continuous. Therefore, there are an infinite number of electrode pairs that can be placed. From a mathematical standpoint, the equations that govern the flow of electrical current in time and space are known. Therefore, if the body shape and all of its contents and electrical characteristics were known, then a complete and accurate model of the

myocardium could be recreated from measurements on the skin. This is known as the *inverse solution* – perhaps the Holy Grail of electrocardiography.

Body surface mapping has been performed using vests with hundreds of electrodes to measure as many sites as physically possible in order to create a three-dimensional rendition of the electrical potentials on the human torso [59]. Imagine a topographical map of a mountainous area showing elevations with peaks and valleys. A body surface map is an electrical "topo map." Areas of negative or positive potential can be identified and tracked throughout the cardiac cycle. The time-dependent changes in the map can give diagnostic information. The increased number of lead sets and higher density of spatial sampling could potentially reveal more detailed information. However, both practical and clinical limitations are dominant and the standard approach is to use 12 leads.

Vectorcardiography

In *vectorcardiography*, changes in the body surface potentials are represented as a single vector centered in the chest in a three-dimensional coordinate system. The length of the vector represents the magnitude of the surface voltage. The direction and length of the vector changes with the cardiac cycle and the tip inscribes a *loop* during one cardiac cycle. The interpretation of the shape and direction of the loop in three dimensions is used to make diagnostic inferences. The benefit of the vectorcardiogram is that it incorporates both time and space to give a two-dimensional rendition of the cardiac cycle. In this manner, the activation wavefront in the myocardium is almost "visualized" as it propagates within the ventricles during the cardiac cycle. Alterations of the magnitude and direction of the vector loop can be used to identify abnormalities of conduction that could suggest the presence of cardiac structural abnormalities.

Standard Electrocardiogram

The mainstay of present day electrocardiography is the standard 12-lead electrocardiogram. The 12 leads are recorded using electrodes placed on each limb and across the chest in a reproducible pattern. The standardization is critical, since, from a practical standpoint, the interpreting physician is not typically performing the measurement. The interpreter is blind to the method of data collection and makes assumptions that the data are collected in the same manner each time. Correct electrode placement is critical in order to properly interpret the electrocardiogram.

For example, imagine that an object under frosted glass is photographed from multiple directions. You are handed a stack of pictures of the shadows on the glass created by the underlying object, and you are asked to draw the object in three-dimensions. Without knowledge of the direction from which the pictures were obtained, you would not be able to accurately perform the task. However, if you knew the positions of the camera, then you would have a chance. Furthermore, you would be able to perform the task repeatedly with different objects under the glass as long as the camera positions did not change with each instance.

Much like a camera lens having a *field of view* from which it gathers light, each set of electrodes has a *lead field*. A lead will be most sensitive to electrical events in the direction of its lead field. Therefore, to "reconstruct" the cardiac electrical cycle over time, multiple leads with different lead field directions are used. Lead sets are used in order to maximize recording sensitivity in two planes. In the frontal plane, lead fields most sensitive to measurement parallel to a coronal section of the body are used. In the horizontal plane, lead fields are used which are sensitive in a plane parallel to a transverse section.

For the frontal plane, the standard limb leads, labeled I, II, and III, (Fig. 157.21) are measured from the surface potentials recorded between electrodes placed on the distal extremities: lead I left arm(+)/right arm(-), lead II left leg (+)/right arm(-), lead III left arm(-)/left leg (+). A right-leg electrode is also placed and acts as a ground to reduce environmental electromagnetic noise. Note, there has been interest in moving the distal-limb electrodes to a proximal position on the torso. This is commonly employed in clinical

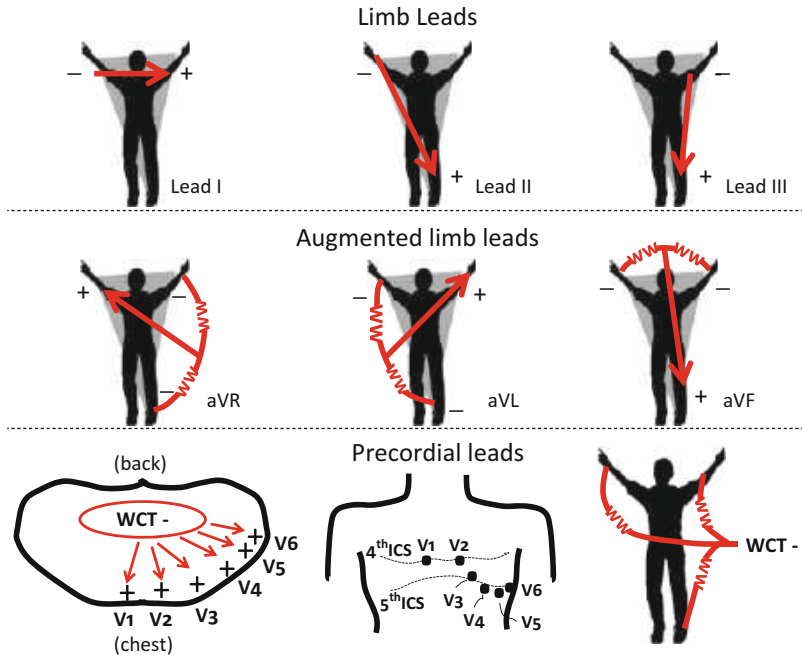

Fig. 157.21 Twelve ECG recording leads. The Einthoven's triangle (*shaded gray*) and the hexaxial reference system depicting frontal plane ECG leads are shown in the *top* and *middle panels*. Direction of chest (precordial) lead axis with corresponding recording sites on the chest is shown at the *bottom*, with grounding to the Wilson Central Terminal (*WCT*). *ICS* intercostal space

settings with bedside monitoring or with ambulatory monitors. Although an electrocardiogram is obtained and may help with rhythm interpretation, these electrode positions are not standard and final diagnosis should always be made using the standardized electrode positions and lead sets.

By convention, a lead "points" in the positive direction. That is, if activation in the heart is propagating in the direction of the lead (i.e., the "positive" electrode), then the measured voltage will be positive as well. However, if activation proceeds in the exact opposite direction, just as much information will be obtained, albeit as a negative deflection of the recorded electrogram. Similarly, if two activation wavefronts are proceeding in opposite directions simultaneously, then there will be cancelation of voltages in the electrocardiogram, and the degree of positive or negative deflection will depend upon the dominance of voltage from one wavefront or the other. Lead I is sensitive along the horizontal axis in the frontal plane, pointing to the left side. Leads II and III add sensitivity along an axis tilted at 60° and 120° below the horizontal, respectively. To record from more directions in the frontal plane, the *augmented* leads, aVR, aVL, and aVF, are added. The lead fields for these leads are created using combinations of the standard limb leads. For example, aVF is measured between the left leg electrode and a combination of right-arm and left-arm electrodes. This combination yields a lead field which "points" nearly vertically and inferiorly. The leads aVL and aVR add recording sensitivity along an axis tilted at 30° and 150° above the horizontal, respectively. The six frontal leads (I, II, III, aVF, aVR, and aVL) provide lead fields with nearly 360° of sensitivity in the frontal plane. Of note, leads II, III, and aVF are called the *inferior leads*. Since the positive electrodes of these leads are positioned below the horizontal axis, the lead fields are particularly sensitive to activation in a superior to inferior, or top to

bottom, direction. This directional information is valuable for determining the axis of activation and repolarization.

Measurements in the horizontal plane, orthogonal to the frontal plan, are accomplished using six leads created from *precordial* electrodes placed across the chest. Whereas the frontal lead fields are generated by measurements between physical electrodes, the horizontal lead fields are created by measuring between a single electrode on the skin surface and a reference point called the Wilson Central Terminal (WCT). The WCT is formed by connecting the right-arm, left-arm, and left-leg electrodes to each other via resistors. For the purpose of understanding the lead field directions, the WCT can be considered as an electrode centered in the heart in the thorax. Lead fields with differing directions of sensitivity are thereby created by measuring between an electrode on the chest surface and the WCT. The standard 12-lead electrocardiogram includes six positions for these electrodes on the chest, resulting in leads V1-V6.

The electrode placement for the precordial leads is standardized and specific with respect to landmarks on the thorax. The precordial electrodes are placed at the following positions: V1, *4th intercostal space at the right sternal border*; V2, *4th intercostal space at the left sternal border*; V3, *the midpoint between electrodes V2 and V4*; V4, *5th intercostal space aligned at the midclavicular line*; V5, *horizontally in line with V4 but at the anterior axillary line (or midway between V4 and V6)*; and V6, *horizontally in line with V4 but at the midaxillary line*.

Any deviation in placement of the electrodes (e.g., one interspace too high or too low) can result in significant changes of the signal and affect interpretation. This must be emphasized in training those who will be recording electrocardiograms. While hasty electrode placement and acquisition of signals may be desirable in a critical situation or with an uncooperative young child, attention to detail is critical since it is much more difficult for the interpreting individual to suspect abnormal precordial lead placement than inadvertent limb lead electrode reversal.

The lead fields for the precordial leads *fan* out in the horizontal plane. The lead field for V1 assumes more of an anterior and rightward direction. The remainder of the lead fields point to the left chest. In pediatric electrocardiography, additional precordial leads have been used with electrodes placed in mirror image positions on the right chest – such as lead V4r. Given the normal rotated position of the heart relative to the chest wall, the theoretical lead field axis for V4r, which points anterior and rightward, may deliver a better delineation of "right" and "left" cardiac electrical events compared to lead I, for example. In some institutions, lead V4r is added as a standard lead. Additionally, in dextrocardia, the right precordial leads may be used to record a "standard" set of the leads despite the abnormal cardiac position. In the presence of dextrocardia, some institutions have adopted variations of lead placement, including right-left mirror image placement of all leads (limb and precordial), right-left mirror image placement of the precordial leads only, or even sliding the precordial leads rightward (e.g., V1 placed in right fifth intercostal space in midaxillary line and V6 in left fourth intercostal space at left sternal border). These nonstandard arrangements may be confusing when viewed by clinicians unfamiliar with a particular institution's conventions.

Signal Recording and Processing

Low-amplitude biopotential signals in the body are difficult to record. Careful signal acquisition techniques must be employed to obtain an adequate signal-to-noise ratio for electrocardiographic interpretation. Reduction of noise begins with proper electrical isolation of the patient. Attention should be given to ensure there is no contact with noise sources, such as other medical equipment. Artifacts that are introduced by other sources can appear as a periodic signal in the electrocardiogram baseline. These artifacts could easily be mistaken for signals generated by the patient and misinterpreted as an arrhythmia, such as atrial

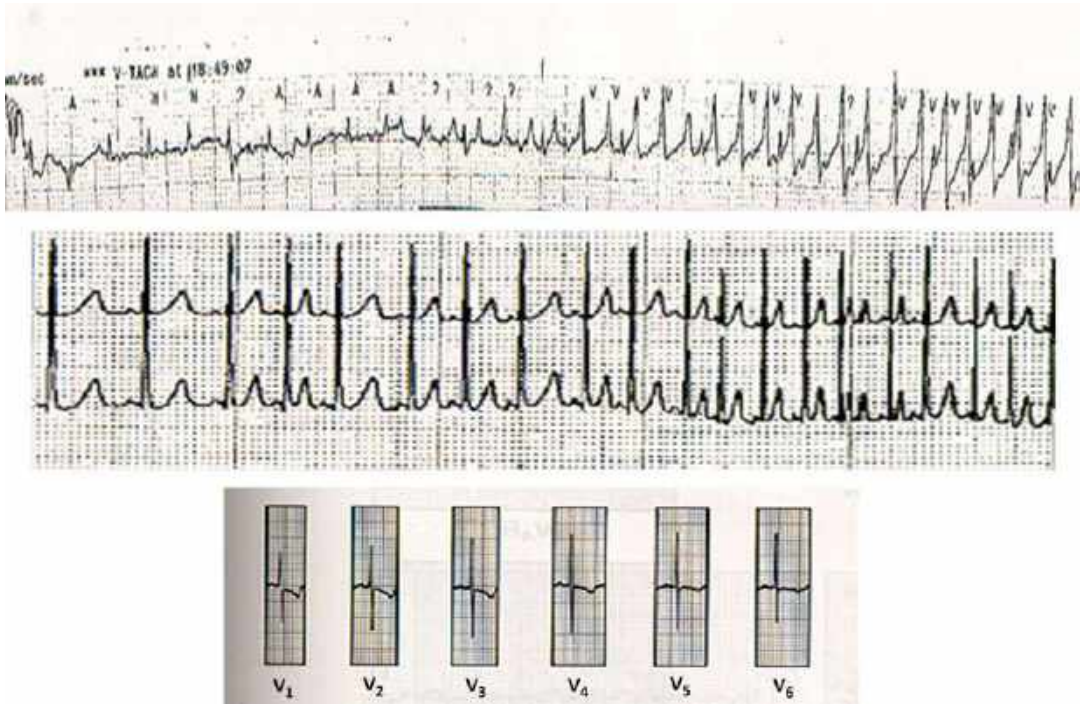

Fig. 157.22 Examples of electrocardiographic artifacts. *Top*: A rhythm strip generated during chest physiotherapy on an infant creates high-amplitude motion artifacts which simulate ventricular tachycardia. Narrow QRS complexes are seen marching through the artifact. *Middle*: A rhythm strip generated from a Holter's magnetic tape illustrates drag of the recording medium, causing crowding of the signal and suggesting tachycardia. The nonphysiologic abbreviation of the T waves provides the clue that this is artifactual. *Bottom*: A 12-lead ECG from an infant in which merging contact gel from overlapping electrodes creates a nearly identical QRS complex among all leads

flutter or fibrillation, by the interpreting individual. If possible, heating or cooling blankets or other equipment near or attached to the patient should be turned off. Electric and magnetic fields, such as those created by electric lighting, are present throughout our environment. Electric fields create small differences of electric potential in space that could be detected when there is high electrode resistance and high amplification – such as in electrocardiography. In addition, magnetic fields can induce small, but detectable, electric current in lead wires. Consideration should be given to turning off overhead fluorescent lighting to reduce the field. In addition, the wires to individual electrodes attached to the body should be twisted together and bundled, if possible, to reduce magnetic and electric field-induced currents in the wires themselves. Noise control at the tissue-electrode interface is also essential. Electron transfer must occur between the skin, the electrolyte gel, and the Ag/AgCl metal electrode interface. Simple attention to cleaning the skin prior to electrode placement reduces electrical impedance at this interface and reduces noise. In addition, the electrodes must not overlap or have any electrical connection between electrodes on the skin surface – such as fluid or electrode gel. This may be especially difficult in small infants where infant-sized electrodes may not all fit on the chest surface. In this setting, it may be necessary to reduce the number of electrode sites on the chest wall (Fig. 157.22). The electrical shielding of lead wires and the grounding of equipment is paramount in the high-amplification environment of an

electrocardiographic recording machine. The machines are manufactured with this noise protection in place. However, the ground for the machine is obtained through the wall socket power source. Yet, this ground may not be entirely adequate or "clean." If there is substantial noise in the recordings, consideration should be given to plugging the machine into a different power source to obtain a different ground point.

From a signal analysis standpoint, the electrocardiogram is complex and contains components having a variety of frequencies with varying periodicity. The challenge with signal processing of the electrocardiogram comes in being able to filter noise from the biological signal without removing clinically important wave frequencies. These range from the lower-frequency T wave to the higher-frequency QRS. Respiratory variation produces a low frequency baseline drift, generally slower (lower frequency) than that of the T wave. Electrical noise at higher frequencies can be present throughout the tracing. In the United States, the standard frequency for alternating current is 60 Hz. Unfortunately, this frequency falls in the range of useful frequencies obtained in the electrocardiogram. In addition to substantial noise that can alter the baseline, 60 Hz artifacts can alter the shape and amplitude of the QRS. Therefore, a combination of high-pass and low-pass filters in addition to "notch" filters (to remove specific frequencies such as 60 Hz) must be used to isolate the clinically useful frequencies from the recording. Filtering can be performed to make a very "clean" appearing signal. However, this may come at the expense of the fidelity of the cardiac waveform.

The electrocardiogram is classically presented on a printed page in a standard format with four columns and three leads per row in each column (4×3 format). The frontal leads are presented in the first two columns, and the precordial leads are presented in the last two columns. One or more rows of continuous tracings may be printed from left to right along the bottom of the paper as a rhythm strip. Tracings were originally only printed on thermal graph paper with gridlines having minor divisions every 1 mm and major divisions every 5 mm. At the standardized "paper speed" of 25 mm/s, the minor and major divisions represent 0.04 s (40 ms) and 0.2 s (200 ms), respectively. With 10 s of signal per page, each column in a 4×3 format presents 2.5 s of data. The amplitude of signals printed on the page is also standardized. At a "full standard" height, each 1 mm minor division (horizontal), represents 0.1 mV – or alternatively, as may be printed on the paper, 10 mm/mV. It is conventional for a rectangular wave to be printed at the edge of the printed page to act as a calibration mark. If the mark is a rectangle that is 10 mm in height (two major divisions), then full standard applies for the entire page. If the mark is a stair-step that is 10 mm initially, but "steps" down to 5 mm for the last half, then the first two columns (frontal leads) are at the full standard height, and the last two columns (precordial leads) are at a half-standard height of 5 mm/mV. Alternatively, the entire page may be presented at half standard. This is necessary when the lead voltages (especially the QRS) are so large that they overlap the tracings in a subjacent row. For proper interpretation, it is critical to recognize the format, paper speed, and amplitude calibration of the presented electrocardiogram. In the current age of paperless electronic recording and online interpretation, the presentation standards are preserved. However, at the user's discretion, the format can be changed. This flexibility presents a distinct benefit given that leads can easily be rearranged on the page, for example, as a simultaneous 12-lead rhythm strip for improved interpretation and diagnosis of nonsustained arrhythmias.

International standards are established for the methodology of recording the electrocardiogram with respect to sampling rate, amplification, electrical filtering, and presentation of the information. A comprehensive review of the recommended standards for electrocardiography, and their scientific basis, are found in the 2007 consensus statement from the American College of Cardiology/American Heart Association/Heart Rhythm Society/and the International Society for Computerized Electrocardiology [60].

Signal-Averaged Electrocardiography (SAECG) and Microvolt T Wave Alternans

The acquired signals from the body surface contain more information than that which is presented in the standard 12-lead electrocardiogram. Extremely low-amplitude and high- or low-frequency signals that are generated by the myocardium are either filtered out of the final electrocardiogram or of such low amplitude that they are not readily apparent. The signal-averaged ECG (SAECG) and microvolt T wave alternans (mTWA) acquisition methods are aimed at detecting some of these component signals. SAECG focuses on depolarization with analysis of the QRS. mTWA focuses on repolarization with analysis of the T wave. With both methods, multiple QRST complexes are acquired during a stable, periodic rhythm and then analyzed with mathematical techniques that take advantage of the repetition of beats over time to detect the small amplitude signals. Without delving deeply into concepts of signal processing, a periodic signal can be thought of as a summation of sine waves of different frequencies and amplitudes. Through the Fourier transform, a time-based signal (such as an electrocardiogram) can be analyzed to determine the combination of sine waves that, if added together, would reconstruct the signal. The output is a *transformation* to a histogram of frequencies that make up the original time-based signal. The height of the histogram at a particular frequency represents the relative contribution of the sine wave at that particular frequency. With Fourier transformation to the frequency domain and with multibeat averaging in the time domain, extremely low-amplitude signals, in the microvolt range, can be detected.

SAECG is utilized to detect low-amplitude potentials that occur late during the QRS. These *late potentials* represent the terminal events of activation in the cardiac cycle and are ordinarily buried in the low-amplitude "noise" of a standard electrocardiogram. The presence of prolonged, low-amplitude potentials at the end of the QRS would suggest that late activation occurs in areas of diseased or scarred myocardium and would furthermore imply that an arrhythmogenic substrate may be present. In order to detect these late, high-frequency, low-amplitude signals, different recording techniques are employed than are used for standard electrocardiography, including different lead sets on the body surface and different signal filters. The acquisition is performed at rest with as much noise reduction as possible, including particular attention to skin preparation and room electrical noise. The output of the SAECG is a filtered QRS (fQRS) based on a composite of all recorded beats and a statistical determination of the amount of late activation present relative to the amplitude of the fQRS. Clinical criteria are used to declare the presence or absence of abnormal late potentials. These criteria include the duration of the fQRS (normal, $<$114 ms), the magnitude of signal in the last 40 ms of the fQRS (normal, $>$20uV), and the duration of the signal having magnitude less than 40 uV (normal, $<$38 ms). A late potential is thought to be present if one or more of those three measurements are abnormal. SAECG testing is relevant in pediatrics, particularly as a minor criterion for the diagnosis of arrhythmogenic right ventricular dysplasia/cardiomyopathy [61].

T wave alternans (TWA) is present when the amplitude and/or duration of the T wave oscillates on a beat-to-beat basis. Visible TWA is seen with severe abnormalities of repolarization, such as in long QT syndrome (LQTS) or severe electrolyte disturbances. Invisible TWA at the microvolt level (mTWA) may also be present and represent electrical instability. These tiny beat-wise changes may be detected with specialized recording techniques, as with SAECG. As with SAECG, specific body surface leads and lead sets are used. Over 100 beats are acquired at stable heart rates. Fourier transformation and frequency analysis are used to detect the minute oscillations of the T wave. Since the criteria for abnormal mTWA includes its development after reaching a particular threshold heart rate, signal acquisition is performed during gradual exercise testing

using a treadmill or stationary cycle. The presence of mTWA above a particular amplitude, lasting for a particular duration and occurring at a low heart rate, is an indicator of repolarization instability in adults. The utility of mTWA in the pediatric population is undetermined.

Ambulatory Monitoring

Ambulatory monitoring is invaluable in the diagnosis of arrhythmias in pediatric patients. It is far more common for rhythm disturbances to occur sporadically than continuously. Common presenting symptoms of palpitations, "my heart is beeping" or "my heart hurts" in younger children, are unlikely to be occurring at the time of the office visit. Therefore, while the 12-lead electrocardiogram has the benefit of interrogating electrical activity in the myocardium from multiple vantage points, the recording period is limited. By sacrificing the advantage of many leads for prolonged recording time, ambulatory monitoring provides an opportunity to capture an arrhythmia "in the wild."

Ambulatory monitoring can be categorized by type. Typically this division is between continuous and event monitors. In nearly all circumstances, monitoring is performed noninvasively from the body surface. However, specialized long-term monitoring, in the form of an implantable loop recorder may be necessary [62]. Technological advances continue to blur the distinction between continuous and event monitors, simply because there are fewer electrical and mechanical limitations to recording and storing electrocardiographic data over long periods of time. A critical component, unique to event monitoring, is the ability to "call in" or transmit data for review and interpretation of the electrocardiogram in the immediate aftermath of a symptomatic event.

Continuous (Holter) Monitoring

The Holter monitor is an externally worn device for continuous recording of electrocardiograms from, typically, 1–3 body surface leads. Holter monitor recording has the benefit of continuous recording and storage of all electrocardiogram tracings without user input. The clinical indications for monitoring of this type are numerous and supplying an exhaustive list of clinical scenarios is not practical. Common uses in the outpatient pediatric cardiology setting include: quantitative assessment of atrial or ventricular ectopy, rhythm surveillance in patients with daily or more frequent symptoms, rhythm surveillance for conduction defects or ectopy in asymptomatic patients with congenital heart disease, and rhythm surveillance for pacing or sensing abnormalities in patients with pacemakers. Other uses take advantage of the modern age of sophisticated quantitative software analysis of the electrocardiogram. These include beat-wise QT interval analysis, heart rate variability, and beat-wise ST segment analysis.

Recording electrodes are adhered to the skin of the chest. As with the standard ECG, attention to detail regarding skin preparation and electrode adhesion is important for success. This is especially the case if the patient will be physically active while being monitored. Critical information may be missed if one or more electrodes become dislodged during the recording period. Typically, five electrodes are used: right and left "arms," right and left "legs," and a single precordial position. However, for practical purposes of patient comfort, the arm and leg positions are in a "proximal" position where all electrodes are placed on the torso. This allows lead wires to be worn completely under clothing – important for compliance in the adolescent concerned about appearance and in the young child. Since interpretation of the recordings is focused on the rhythm, conforming to the electrode position standards of the 12-lead ECG is not critical. Despite the thoracic location of all of the electrodes, lead field differences are still satisfactory.

Historically, Holter monitors were battery-powered devices slightly larger than a paperback book, and they had a shoulder strap for wearing, much like a purse or satchel. The recorded data from the electrodes were stored on an analog magnetic cassette tape. In these devices, at the

end of the recording period, the tape was removed from the device and "played" back to obtain the recorded signals. Analog to digital conversion was performed at the time of playback. Computer software was then used to analyze the recordings. Holter monitoring in the current age has benefitted greatly from solid-state miniaturized electronics. Current monitors are a fraction of the size of prior devices and can be worn clipped to a belt or even worn as a necklace. The device is silent, and there are no moving parts. The electronic circuitry now allows for direct digital sampling of the signals with high fidelity. The recordings are stored digitally on "flash" memory chips or inserted cards. While the most common Holter recording period is 24 h, perhaps dictated historically by electromechanical limitations, some of the newest devices allow continuous recordings for up to 14 days or more. At the end of the recording period, data from the memory card can be uploaded to a computer for analysis either using local software or by having the data sent remotely to the monitoring company via the internet.

Holter monitors provide a wealth of information. Automated analysis is performed for the entire recording period. Typical summary data include heart rate maximum, minimum, and average, in addition to histograms of heart rate and RR intervals. Following automatic creation of the individual's normal QRS template, detection of premature beats and discrimination of supraventricular versus ventricular beats is performed. A complete tabular and graphical summary of ectopic beats, couplets, and runs is provided as a function of time of day. This is critical for determining diurnal variation of arrhythmias or other influences on ectopy frequency, such as activity. Other data are also commonly available, such as heart rate variability analysis or QT interval measurement. Although less commonly relevant to pediatric populations, beat-wise ST analysis may also be performed. Following computerized data analysis, manual over-reading by a technician is then performed. The technician manually scans the data for rhythm disturbances and flags sections of data for further review by the clinician. This is especially important when a patient has maintained a diary of symptoms during the recording period. These periods of the recorded data can be evaluated closely for findings that may correlate with the patient's symptoms. Finally, at the clinician user level, "full disclosure" can be requested and the entirety of the recorded sample can be visually scanned for abnormalities.

Event Monitoring

There are two types of event monitors, loop and handheld. Loop monitors are similar to their Holter counterpart in that body surface recording is performed for a prolonged period. However, loop monitors are generally worn for up to 1 month as opposed to 24 h. Loop monitors utilize continual recording and storage of signals in a limited amount of memory. When the memory space is filled with data, then signals are saved to the beginning of the memory and overwrite the earliest recordings. In this manner, a "loop" is made, with only the most recent information being available. The continuous looping of the recording allows essentially endless monitoring periods, only limited by battery life.

The main value of these monitors is based upon the ability to save an event. If a patient experiences a symptom, then a button can be pressed on the monitor to signify an "event." When an event is signaled, the recorder stores a timed segment of the data in memory outside of the "loop." A period of time preceding the button press and a period after the press are stored. This allows the possibility of capturing a short-lived rhythm change that ended prior to the physical button push. Automation within the monitoring device also exists and can allow for auto-triggered event capture based upon predetermined rate and rhythm criteria. The utility of auto-triggered event capture in the pediatric population must take into account the fact that an active child's sinus tachycardia can easily exceed preset rates that would trigger an event capture for an adult. Once event data are stored, these data must then be "uploaded" or transmitted to a receiving facility for evaluation. For many

Table 157.7 Benefits, drawbacks, and indications for different monitor types

	Holter monitor	Handheld event monitor	Loop monitor	Implantable loop recorder
Benefits	Noninvasive Multiple leads	Convenient	Low noise Pre- and post event data capture	Long-duration recording User intervention not required to capture data
Potential drawbacks	Limited recording period	Single lead Noise artifacts Must be readily available Requires longer episodes	Worn continuously Not practical for very young children	Requires surgical implant and explant
General indications	Daily symptoms Need for heart rate, arrhythmia, or other trends throughout day and during sleep	Older children and adolescents, or child with adult available to perform monitoring, with frequent prolonged symptoms	Children and adolescents with frequent but brief symptoms	Very rare events (less than monthly) Severe symptoms Unable to record event with other methods

monitors, this is accomplished via transduction of the stored data to an audible signal. The audio signal is then transmitted to the receiving company simply by calling in, holding the monitor to the phone, and pressing a button for playback. At the receiving end, the audio signal is recorded and converted to an electrical signal for analysis and presentation as an electrocardiographic tracing. Newer monitors perform this task using cellular transmitters within the device; they automatically transmit the data to the receiving company immediately after an event has been signaled. Typically, the data from an event are reviewed by company technicians, and then, based upon established criteria that stratify an urgent versus nonurgent event, the ordering clinician is notified and can review the electrocardiographic recording.

Handheld event monitors are a type of ambulatory monitor that is not worn continually. The monitor is generally a thin, small device, approximately the size of a cellular phone, with two electrode contacts on the back of the casing. If an event is occurring and ongoing, the user places the monitor against the skin somewhere on the chest and then presses an event button on the device. The monitor records the electrocardiogram measured between the two external electrodes. Depending on the storage capabilities of the device, a number of event recordings can be saved. Then, as with the loop monitor, the data are uploaded via the telephone to the receiving company.

The decision regarding which type of monitor to recommend for a patient is not always straightforward. A short list of benefits, drawbacks, and general indications are given in Table 157.7 for each type of monitor. Holter monitors have a clear benefit of recording continually from multiple leads. Therefore, there is no dependence on the patient to "capture" an event, except to document symptoms if they occur. Holter monitors can be used for all ages, including infants. Event monitors require user input, and, as such, a decision must be made as to whether a child is mature enough to perform the task. For school-age children who are willing and capable, a loop monitor may be preferable, given that it is worn at all times and will not likely get lost or damaged. For children and teens who are self-conscious about a continuously attached "piece of medical equipment," a handheld device may be preferable. Nonetheless, the decision is also determined by the suspected cause of symptoms. If the patient is only experiencing symptoms for less than 30 s, then the likelihood of successfully capturing the event using a handheld device is low.

In general, the use of implantable loop recorders is limited, due to the need for surgical implantation and ultimate explantation. However, in the case of rare events with severe symptoms, such as syncope with concern for an arrhythmia mechanism in patients in whom it is impractical to record an event using other noninvasive means, an implantable loop recorder may be needed.

Exercise Testing

The exercise "stress" test is an important tool for the pediatric cardiologist. Testing may be useful in patients who present with symptoms that are only elicited during exertion, such as chest pain, light-headedness, or palpitations; all of which may be related to cardiac arrhythmias. However, exercise testing has many applications beyond the cardiac conduction system: patients having hypertrophic cardiomyopathy to determine if left ventricular outflow obstruction worsens or if the blood pressure response is normal, patients having exertional chest pain to determine the presence of exercise-induced reactive airway disease (requiring pre-/postexercise pulmonary function testing), and a general assessment of cardiopulmonary-neuromuscular function in patients with congenital heart disease or cardiomyopathy. In the latter example, full metabolic exercise testing is performed. This combines standard exercise testing with continuous measurement of respiratory gas exchange. The metabolic exercise test is a powerful tool for helping determine if symptoms are due to cardiac, pulmonary, or neuromuscular limitations or due to deconditioning. A complete description of exercise testing in children appears elsewhere in this textbook.

The remaining comments in this section will be directed toward the use of exercise testing for suspected or known cardiac arrhythmias or conduction abnormalities. In the presence of atrial or ventricular ectopic beats, exercise testing may be indicated for determining if increased levels of endogenous catecholamines exacerbate the arrhythmia. This may indicate the presence of a channelopathy, such as CPVT or certain forms of long QT syndrome. Exercise testing may be useful for sudden death risk stratification in asymptomatic patients with ventricular preexcitation (Wolff-Parkinson-White syndrome [63]). A list of arrhythmias or conduction abnormalities for which exercise testing in children is considered valuable appears in Table 157.8.

Table 157.8 Exercise testing for arrhythmia evaluation in children

Known condition or symptom	Goals of testing
Sinoatrial node dysfunction	Determine maximum heart rate
	Assess symptoms during postexercise heart rate decline
First- or second-degree AV block	Determine if conduction improves (suggesting AVN involvement) or worsens (suggesting His Purkinje system involvement) with exercise
Wolff-Parkinson-White pattern	Determine loss or persistence of pre-excitation
Premature ventricular contractions (PVCs)	Determine if PVCs become more prevalent and complex with exercise (suggesting certain channelopathies)
Consideration of long QT syndrome	Assess for QTc prolongation
Palpitations, syncope, or unusual dyspnea during exercise	Reproduce symptoms during rhythm monitoring
Nonspecific symptoms during exercise following repair of congenital heart disease	Identify exercise-related tachyarrhythmias, bradyarrhythmias, or conduction abnormalities
Cardiac rhythm management device in situ	Optimize programming
	Identify sensing abnormalities

The standard exercise test is performed in a clinic or hospital setting with resuscitation equipment available using a motorized treadmill or stationary cycle ergometer. At minimum, 12-lead electrocardiograms, pulse oximetry, and automated noninvasive blood pressure data are measured. The patient is asked to wear comfortable athletic clothing. Electrocardiographic

leads are attached after the skin is prepared to gain maximal adhesion and decrease the chance of electrode displacement during exercise due to perspiration. Typically, baseline measurements of blood pressure, heart rate, and ECG are recorded at rest in the supine and standing positions. Exercise is then begun in a graded fashion. The machine is typically programmed to perform a standard protocol where, for a treadmill, the rate and angle of incline are increased or, for a cycle ergometer, the load is increased, in a stepwise fashion after a specified amount of time. Coincident with these changes in loading conditions for the patient, 12-lead electrocardiograms are recorded as well as other vital signs including heart rate and blood pressure. Multiple protocols exist, including the Bruce or Balke protocols for treadmill and the James, McMaster, and Strong protocols for cycle ergometer [64]. The standard or a modified form of the Bruce protocol is commonly used in the pediatric cardiac population. For example, in a modified Bruce protocol, there are seven incremental stages, starting with a slow, walking rate and zero incline in stage one. The stages are changed every 3 min until an end point is reached: The patient reaches a goal heart rate (typically over 80 % of maximum predicted rate based on age), reproduction of symptoms, and occurrence of concerning changes in the electrocardiogram or blood pressure or the patient becomes too fatigued and cannot proceed. In the recovery stage, monitoring is continued, while the patient rests and recovers to baseline. While some arrhythmias may be induced during the initial or peak phases of exercise, others may appear during recovery. Therefore, ongoing observation is important during this stage.

Transesophageal Electrophysiology Testing

An esophageal, or *transesophageal*, electrophysiology study is a useful diagnostic test when noninvasive electrocardiography or ambulatory monitoring is not adequate for diagnostic purposes. An esophageal EP study is less invasive than an intracardiac catheter EP study. Among practitioners who use this modality, indications for esophageal EP testing include [1] in patients having recurrent symptoms suggestive of paroxysmal supraventricular tachycardia that occur too infrequently for practical ambulatory monitoring; [2] in patients having recurrent symptoms suggestive of paroxysmal supraventricular tachycardia and who are not able to successfully use an event recorder; [3] in infants having known supraventricular tachycardia in order to prove antiarrhythmic drug efficacy; [4] for risk assessment in asymptomatic patients with Wolff-Parkinson-White syndrome, in whom exercise testing and/or Holter monitoring show persistent pre-excitation [63], [5] therapeutically, for entrainment and termination of atrial flutter and its subtypes in newborns and in older children following congenital heart surgery; and [6] in currently asymptomatic toddlers who had had SVT as an infant. In the latter example, esophageal testing would be performed with the patient off medications to determine inducibility of SVT and the need for further treatment. The esophageal electrophysiology study is not useful for induction of ventricular tachycardia, since stimulation is supraventricular. The lone exception is fascicular left ventricular tachycardia, in which atrial pacing alone may induce the arrhythmia.

Esophageal electrophysiology studies are primarily performed in a cardiac catheterization laboratory setting. This is for both safety and practical reasons, given that sedation is typically necessary, there is a potential need for resuscitation, and electophysiologic recording equipment is present. To perform the study, intravenous sedation is given. Medications for this purpose include propofol, fentanyl, midazolam, ketamine, or some combination. If ketamine is selected, the addition of glycopyrrolate will reduce the associated increase in airway secretions. Once the patient is moderately sedated and electrocardiographic monitoring is underway, a 10-French bipolar esophageal catheter is lubricated with lidocaine jelly and is passed from the nares to the

Table 157.9 Indications for electrophysiology study in children

Class I (*general expert agreement*)
1. Symptomatic patients in whom sinus node dysfunction is suspected as the cause of symptoms but a causal relation between an arrhythmia and the symptoms has not been established after appropriate evaluation
2. Symptomatic patients in whom His-Purkinje block, suspected as a cause of symptoms, has not been established
3. Patients with second- or third-degree AV block treated with a pacemaker who remain symptomatic and in whom another arrhythmia is suspected as a cause of symptoms
4. Symptomatic patients with intraventricular conduction delay in whom the cause of symptoms is not known
5. Patients with an undiagnosed narrow QRS tachycardia that cannot be distinguished from sinus tachycardia
6. Patients with frequent or poorly tolerated episodes of narrow QRS tachycardia that do not adequately respond to drug therapy and for whom information about site of origin, mechanism, and electrophysiological properties of the pathways of the tachycardia is essential for choosing appropriate therapy (drugs, catheter ablation, pacing, or surgery)
7. Patients who prefer ablative therapy to pharmacological treatment
8. Patients with wide QRS complex tachycardia in whom correct diagnosis is unclear after analysis of available ECG tracings and for whom knowledge of the correct diagnosis is necessary for patient care
9. Patients with WPW being evaluated for catheter ablation or surgical ablation of an accessory pathway
10. Patients with ventricular pre-excitation who have survived cardiac arrest or who have unexplained syncope
11. Symptomatic patients with pre-excitation in whom determination of the mechanism of arrhythmia or knowledge of the electrophysiological properties of the accessory pathway and normal conduction system would help in determining appropriate therapy
12. Patients with congenital or suspected structural heart disease and syncope that remains unexplained after appropriate evaluation
13. Patients with palpitations who have a pulse rate documented by medical personnel as inappropriately rapid and in whom ECG recordings fail to document the cause of the palpitations
14. Patients with palpitations preceding a syncopal episode
15. Patients surviving cardiac arrest without evidence of an acute Q wave MI
16. Patients surviving cardiac arrest occurring more than 48 h after the acute phase of MI in the absence of a recurrent ischemic event
17. Patients with sustained VT or cardiac arrest, especially those with prior MI
18. Patients with AVNRT, AV reentrant tachycardia using an accessory pathway, or atrial fibrillation associated with an accessory pathway, for whom chronic drug therapy is planned
Class II (*divided expert opinion*)
1. Patients with documented sinus node dysfunction in whom evaluation of atrioventricular (AV) or ventriculoatrial (VA) conduction or susceptibility to arrhythmias may aid in selection of the most appropriate pacing modality
2. Patients with electrocardiographically documented sinus bradyarrhythmias to determine if abnormalities are due to intrinsic disease, autonomic nervous system dysfunction, or the effects of drugs so as to help select therapeutic options
3. Symptomatic patients with known sinus bradyarrhythmias to evaluate potential for other arrhythmias as the cause of symptoms
4. Patients with second- or third-degree AV block in whom knowledge of the site of block or its mechanism or response to pharmacological or other temporary intervention may help direct therapy or assess prognosis
5. Patients with premature, concealed junctional depolarizations suspected as a cause of second- or third-degree AV block pattern (i.e., pseudo AV block).
6. Asymptomatic patients with bundle branch block in whom pharmacological therapy that could increase conduction delay or produce heart block is contemplated
7. Patients with frequent episodes of narrow QRS tachycardia requiring drug treatment for whom there is concern about proarrhythmia or the effects of the antiarrhythmic drug on the sinus node or AV conduction
8. In patients with prolonged QT intervals, identification of a proarrhythmic effect of a drug in patients experiencing sustained VT or cardiac arrest while receiving the drug
9. Asymptomatic patients possibly at high risk for sudden arrhythmic death, such as the postoperative patient with complex congenital heart disease or a normal heart with complex ventricular arrhythmias (nonsustained VT or premature ventricular complexes that fail to suppress during exercise)
10. Patients with congenital complete AV block and wide QRS escape rhythm

(*continued*)

Table 157.9 (continued)

11. Patients who have equivocal abnormalities of QT interval duration or TU wave configuration, with syncope or symptomatic arrhythmias, in whom catecholamine effects may unmask a distinct QT abnormality
12. Asymptomatic patients with a family history of sudden cardiac death or with ventricular pre-excitation but no spontaneous arrhythmia who engage in high-risk occupations or activities and in whom knowledge of the electrophysiological properties of the accessory pathway or inducible tachycardia may help determine recommendations for further activities or therapy
13. Patients with ventricular pre-excitation who are undergoing cardiac surgery for other reasons
14. Patients with highly symptomatic, uniform morphology premature ventricular complexes, couplets, and nonsustained VT who are considered potential candidates for catheter ablation
15. Patients with ventricular ectopy with other risk factors for future arrhythmic events, such as a low ejection fraction, positive signal-averaged ECG, and nonsustained VT on ambulatory ECG recordings in whom electrophysiological studies will be used for further risk assessment and for guiding therapy in patients with inducible VT
16. Patients with recurrent unexplained syncope without structural heart disease and a negative head-up tilt test
17. Patients with clinically significant palpitations, suspected to be of cardiac origin, in whom symptoms are sporadic and cannot be documented. Studies are performed to determine the mechanisms of arrhythmias, direct or provide therapy, or assess prognosis
18. Patients surviving cardiac arrest caused by bradyarrhythmia
19. Patients surviving cardiac arrest thought to be associated with a congenital repolarization abnormality (long QT syndrome) in whom the results of noninvasive diagnostic testing are equivocal
20. Patients with sinus node reentrant tachycardia, atrial tachycardia, atrial fibrillation, or atrial flutter without ventricular pre-excitation syndrome, for whom chronic drug therapy is planned
21. Patients with arrhythmias not inducible during control electrophysiological study for whom drug therapy is planned
Class III (*general expert agreement against EP study*)
1. Symptomatic patients in whom an association between symptoms and a documented bradyarrhythmia has been established and choice of therapy would not be affected by results of an electrophysiological study
2. Asymptomatic patients with sinus bradyarrhythmias or sinus pauses observed only during sleep, including sleep apnea
3. Symptomatic patients in whom the symptoms and presence of AV block are correlated by ECG findings
4. Asymptomatic patients with transient AV block associated with sinus slowing (e.g., nocturnal type I second-degree AV block)
5. Asymptomatic patients with intraventricular conduction delay
6. Symptomatic patients with intraventricular conduction delay whose symptoms can be correlated with or excluded by ECG events
7. Patients with narrow QRS tachycardias easily controlled by vagal maneuvers and/or well-tolerated drug therapy who are not candidates for nonpharmacological therapy
8. Patients with VT or supraventricular tachycardia with aberrant conduction or pre-excitation syndromes diagnosed with certainty by ECG criteria and for whom invasive electrophysiological data would not influence therapy. However, data obtained at baseline electrohysiological study in these patients might be appropriate as a guide for subsequent therapy
9. Patients with congenital complete AV block and narrow QRS escape rhythm
10. Patients with acquired complete AV block
11. Asymptomatic patients with surgically induced bifascicular block
12. Patients with clinically manifest congenital QT prolongation, with or without symptomatic arrhythmias
13. Patients with acquired prolonged QT syndrome with symptoms closely related to an identifiable cause or mechanism
14. Asymptomatic or mildly symptomatic patients with premature ventricular complexes, couplets, and nonsustained VT without other risk factors for sustained arrhythmias
15. Patients with a known cause of syncope for whom treatment will not be guided by electrophysiological testing
16. Patients surviving a cardiac arrest that occurred during the acute phase (<48 h) of MI
17. Patients with cardiac arrest resulting from clearly definable specific causes such as reversible ischemia, severe valvular aortic stenosis, or noninvasively defined congenital or acquired long QT syndrome
18. Patients with palpitations documented to be due to extracardiac causes (e.g., hyperthyroidism)
19. Patients with ventricular fibrillation with a clearly identified reversible cause
20. Patients with isolated atrial or ventricular premature complexes

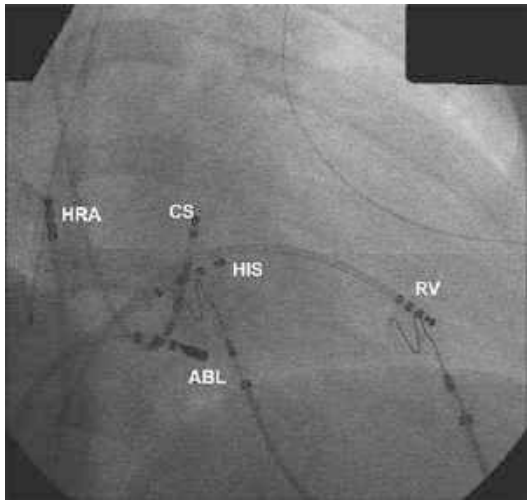

Fig. 157.23 Anteroposterior fluoroscopic image of EP catheters. Labels represent catheter positions: *HRA* high right atrial, *CS* coronary sinus, *HIS* His bundle, *RV* right ventricular apex, and *ABL RF* ablation catheter in area of posterior atrial septum

esophagus. A 5-French catheter is available for use in infants. The neck should be sharply flexed in order to avoid passage to the larynx. Ideally, the older child should be coached to swallow the catheter down, once they feel it in their hypopharynx. As the catheter is passed, the electrocardiogram recorded from the esophageal catheter is monitored. Typically, given the position of the esophagus posterior to the left atrium, an atrial and a ventricular electrocardiogram are visualized. Brief fluoroscopy may be helpful to verify position but is not always necessary. The catheter electrodes are then connected to an electrophysiologic stimulator. The stimulator must be capable of delivering at least 20 mA of current at a pulse width of 10 ms, since capture of the atrial myocardium from the esophagus requires high current output. This is partly due to the requirement of passing current through the esophageal wall and across a distance to the left atrium. The electrodes on an esophageal pacing catheter should be much larger than those on an intracardiac electrode catheter. Larger electrodes allow the delivered pacing current to be dispersed, thus, reducing the current density. This avoids potential esophageal damage, reduces capture of esophageal smooth muscle, and reduces discomfort.

Pacing is first performed during sinus rhythm to establish the output current necessary to capture and activate the left atrium. Subsequently, single, double, and triple atrial premature beats can be delivered during sinus rhythm to attempt arrhythmia induction. We prefer this strategy to extra-stimulation following drivetrains, in order to limit pacing and reduce patient discomfort. However, rapid atrial pacing can also be performed. In the case of WPW, atrial fibrillation can be induced for risk stratification purposes. Once atrial fibrillation is induced, the rhythm is recorded continually, and the patient is closely monitored for deterioration to ventricular fibrillation. The shortest R-R interval between consecutively pre-excited QRS complexes during atrial fibrillation is measured and is used to determine risk of sudden death. If supraventricular tachycardia is induced during testing, the relationship of the atrial and ventricular electrograms from the esophageal catheter provide helpful diagnostic clues as to the mechanism of the arrhythmia. Diagnostic information is also obtained when the tachycardia terminates – with or without intervention with intravenous adenosine or with atrial burst pacing. If no arrhythmias are induced with the initial round of pacing, isoproterenol, followed by isoproterenol plus atropine, can be infused and the testing repeated. Typically, if no arrhythmias are induced under these conditions, the study is considered negative and terminated. Sedation is discontinued and after recovery, the patient is discharged, within 2 h of completion of the procedure. This type of procedure is well tolerated in all age groups.

Experts believe that esophageal electrophysiology testing is thought to have high positive and negative predictive values for supraventricular tachycardia, although there is no rigorous proof of this belief.

Intracardiac Electrophysiology Testing

The intracardiac catheter electrophysiology (EP) study is an invasive diagnostic and potentially therapeutic procedure when combined with

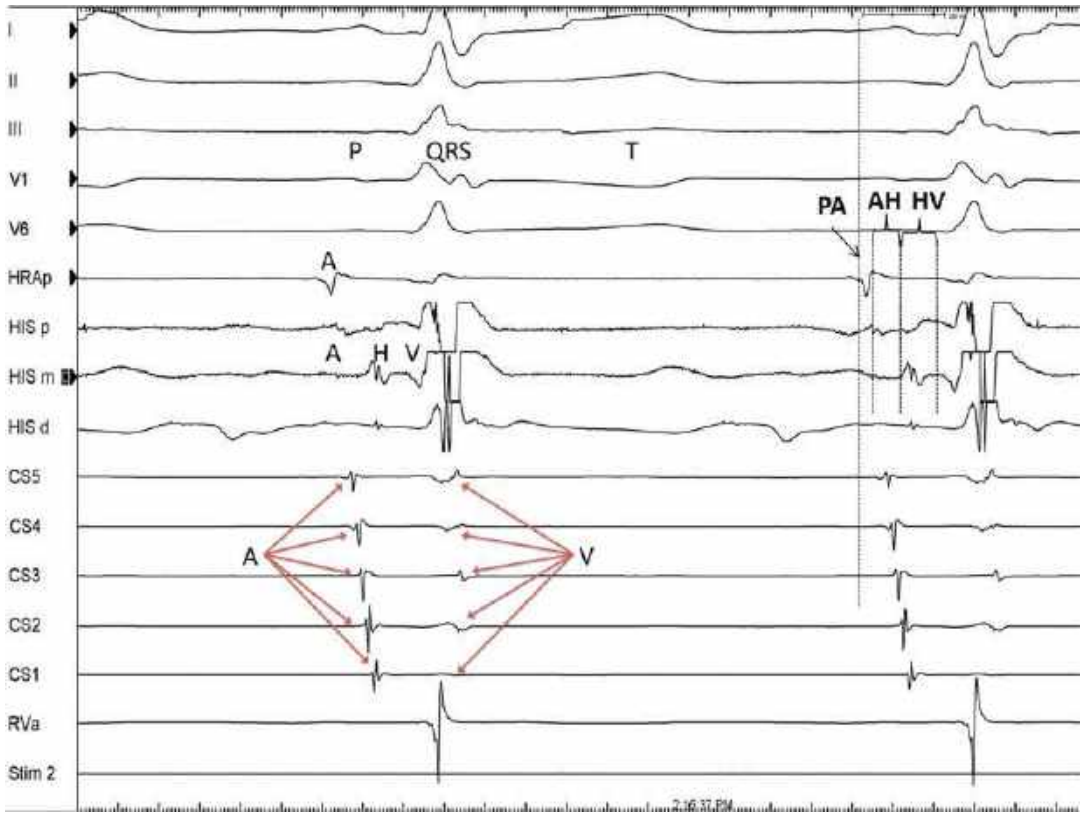

Fig. 157.24 Body surface and intracardiac tracings during sinus rhythm. Catheter labels at the *left side* of the image: *HRA* (high right atrium), *HIS* (His bundle location at mid septum), and *CS* (coronary sinus, electrode 5 is proximal at ostium, electrode 1 is distal at *lateral left* atrial margin). This demonstrates a normal right to left and superior to inferior atrial (*A*) activation sequence. Right atrial conduction time (*PA* interval), *AV* nodal conduction time (*AH* interval), and His-Purkinje system conduction time (*HV* interval) are normal

catheter ablation. Consensus and nonconsensus indications for this procedure in children appear in Table 157.9. To summarize this exhaustive list, the most common indications in children with structurally normal hearts include [1] exertional syncope, [2] nonsustained or sustained wide complex tachycardias, [3] symptomatic Wolff-Parkinson-White syndrome, [4] asymptomatic WPW when prior tests suggest that the accessory pathway may confer a high risk of sudden death, and [5] persistently symptomatic children (having palpitations) when other noninvasive diagnostic methods fail to document arrhythmia. In the case of supraventricular or ventricular tachycardia, indications for catheter-based EP study when combined with possible ablation are discussed in a separate chapter dedicated to ablative therapies in children. In patients with congenital heart disease, the threshold for intracardiac EP study is lowered. Patients with repaired or palliated congenital heart disease with unexplained syncope usually warrant electrophysiologic study. In addition, strong consideration of study should be given to patients with single ventricle physiology and who have a history of supraventricular or atrial tachycardia prior to their final staged repair, because catheter access to the heart will be severely limited following Fontan-style operations. Similarly, patients with Ebstein's anomaly of the

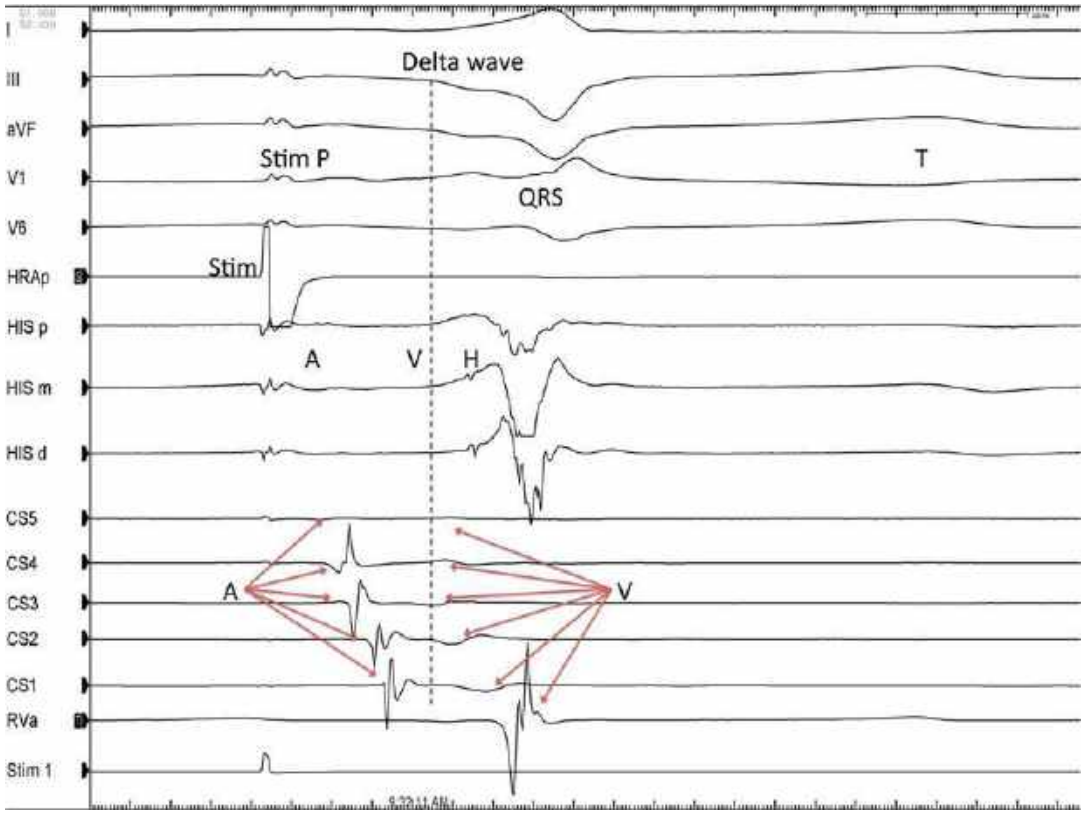

Fig. 157.25 Body surface and intracardiac recordings during atrial pacing demonstrating pre-excitation. A delta wave is present in the surface lead QRS. The HV interval is negative indicating ventricular activation is due to the presence of an atrioventricular accessory pathway

tricuspid valve should be considered for electrophysiology study prior to valvular operations, given the high incidence of atrioventricular accessory pathways in this form of congenital heart disease.

Catheter EP studies are performed in the cardiac catheterization laboratory with availability of fluoroscopy, resuscitation equipment, a multichannel electrophysiology recording system, an electrophysiology stimulator, and, in the current age, a nonfluoroscopic catheter tracking system. The planning of each case considers the child's size, type of arrhythmia (if known), coexisting structural heart disease, prior cardiac surgery, potential limitations of vascular access, current cardiac function, and other comorbidities. Antiarrhythmic drugs are generally stopped at least five half-lives prior to testing. Although procedures may be performed under moderate sedation and local anesthesia (with bupivacaine/procaine combination), there has been a trend toward the use of general anesthesia, especially if ablative therapy is being contemplated. The electrophysiological effects of anesthetic agents have been well described, and contemporary pediatric cardiac anesthesiologists provide superb sedation/anesthesia with minimal perturbation of electrophysiologic phenomena.

Multiple electrode catheter placement is required for electrogram recording and cardiac pacing. As in hemodynamic cardiac catheterizations, the femoral vessels are the preferred access sites. Femoral venous capacity is thought to accommodate up to a total of 5 Fr in infants weighing <2 kg, 6 Fr if 2–3 kg, 7 Fr if 3–5 kg, 9 Fr if 5–10 kg, 11 Fr if 10–25 kg, and 14 Fr if

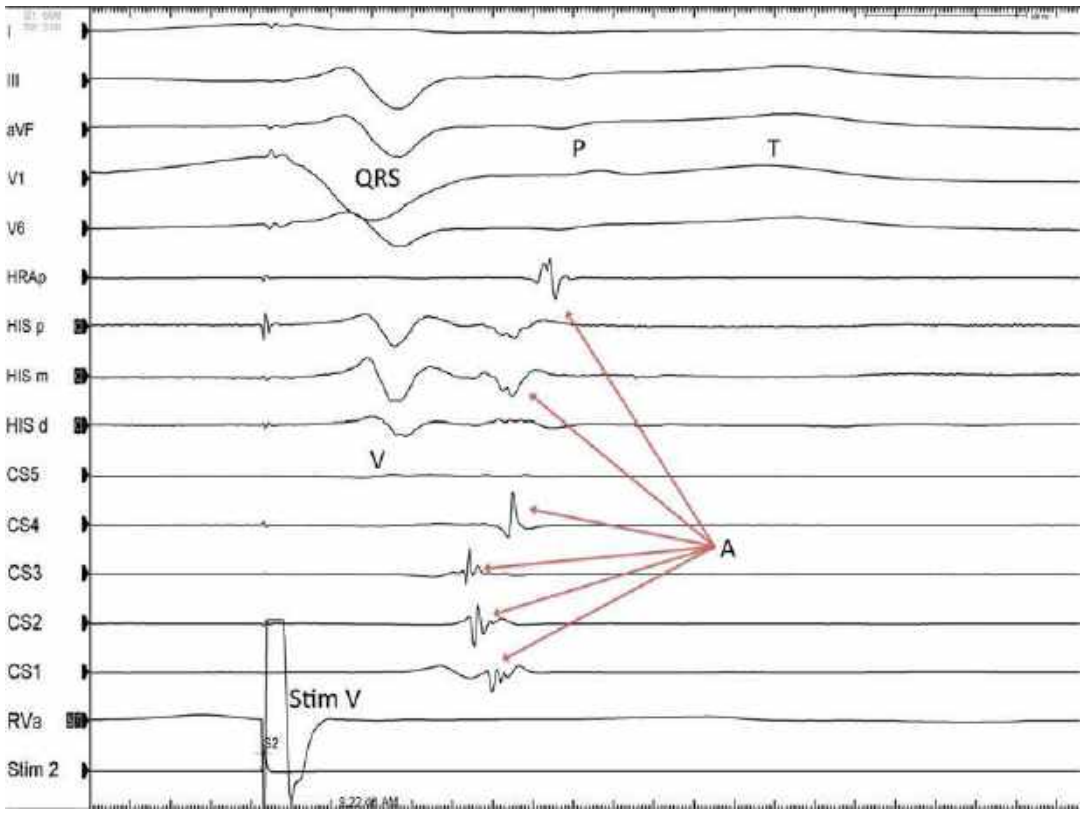

Fig. 157.26 Body surface and intracardiac tracings during ventricular pacing. Ventricular to atrial activation is *eccentric* with earliest atrial activation at the CS3 electrode in the left posterior atrium, suggesting retrograde conduction through a left posterior atrioventricular accessory pathway

>25 kg. Currently, decapolar electrode catheters down to only 4 Fr diameter are available. In small children or those otherwise having limited vascular access, useful data can be obtained by creative combinations of electrogram acquisition, including the esophagus, trans-hepatic access, internal jugular vein, and subclavian vein. For the typical youngster undergoing basic intracardiac EP study, the methodology is similar across institutions with minor variations based on practice preference. Multipolar catheters are advanced within the venous system and placed at multiple sites within the heart for the purpose of recording atrial, His bundle, and ventricular activations simultaneously. Typically, a quadripolar electrode catheter is placed in contact with the endocardium along the superior and lateral portion of the right atrium near the sinus node. A second quadripolar catheter is placed along the midportion of the atrial septum spanning the tricuspid valve annulus, at the location of the tricuspid valve septal commissure, in order to record a His bundle electrogram. Given the position of this catheter, atrial, His bundle, and ventricular electrograms are recorded from this channel (Figs. 157.23 and 157.24). A third quadripolar catheter is placed in the cavity of the right ventricle. These catheters record signals from the right heart. However, in order to obtain left-sided signals, a multipole (usually, decapolar) catheter can be inserted in the coronary sinus via the coronary sinus ostium. By spanning the length of the coronary sinus and much of the great cardiac vein at the level of the atrioventricular groove, the bipole pairs of electrodes on this

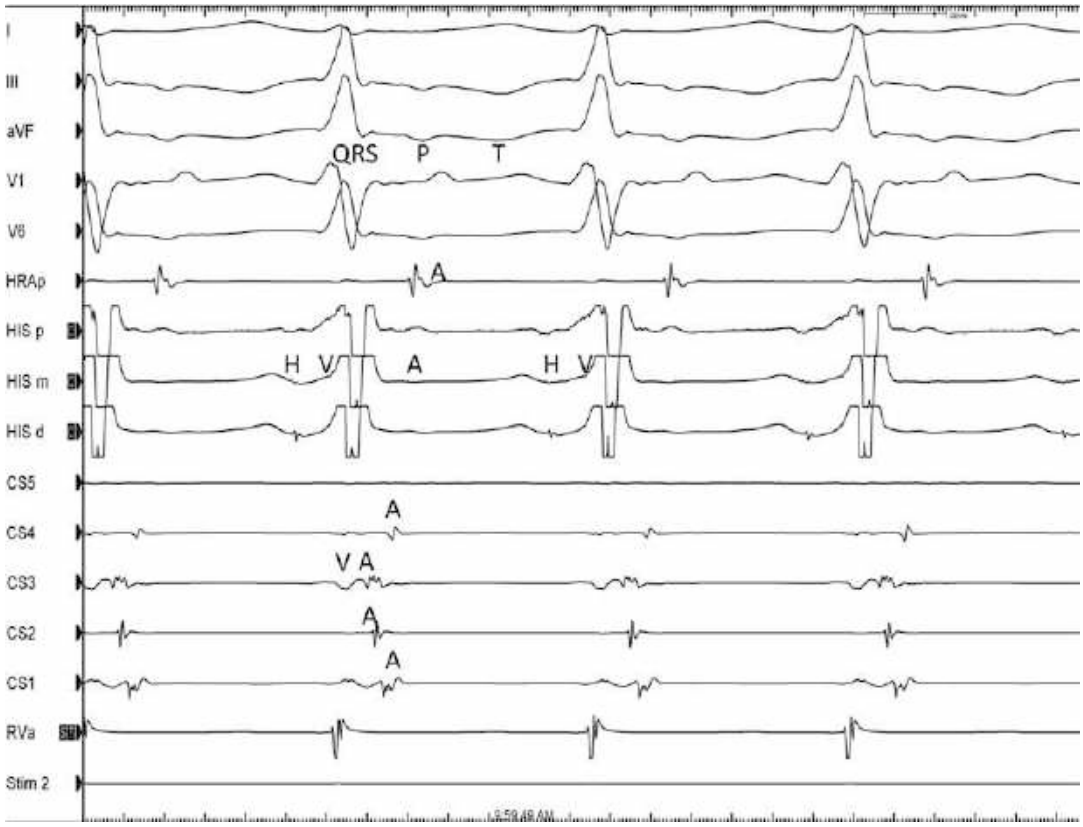

Fig. 157.27 Body surface and intracardiac tracings during supraventricular tachycardia, specifically orthodromic atrioventricular reciprocating tachycardia (ORT). The QRS is normal, without pre-excitation. The HV interval is normal. Earliest atrial activation is located at the CS3 electrode site. The VA interval (or RP interval) is shorter than the AV (or PR) interval, demonstrating a short RP tachycardia

catheter record both left atrial and left ventricular electrograms. These electrograms are important for determining arrhythmia mechanism as well as for the diagnosis of left-sided accessory pathways (Figs. 157.25–157.27).

Simultaneous recording and display of the catheter signals allows for precise measurement of timing at each site as well as "visualization" of activation as it proceeds past each recording site. The surface electrocardiogram is also recorded and displayed. Key timing intervals are measured, including the PA interval (conduction time from the sinus node to the AV node), the AH interval (conduction time within the AV node), and the HV interval (conduction time from the beginning of the His bundle through the Purkinje network). Programmed stimulation is performed to assess electrophysiologic characteristics of the atrial myocardium, the AV node, the His bundle/bundle branches/Purkinje network, the right ventricular myocardium, and, if present, accessory pathways. The chamber of interest is paced at a constant rate for approximately 8–10 beats. This sequence is then followed at a specific interval by a single premature paced beat. This sequence is repeated with the premature beat being delivered progressively earlier until the site no longer responds. This technique allows determination of "refractory periods" of the various cardiac structures. In addition, conduction characteristics may be investigated by pacing the cardiac structure of interest incrementally faster until a defined event occurs. To aid the nonelectrophysiologist in becoming conversant with intracardiac EP

Table 157.10 Glossary of terms used in electrophysiology study reports ([a]From reference [65])

Normal intracardiac conduction intervals		
Interval	What it measures	Normal values
PA interval (must be in sinus rhythm)	Right atrial conduction time	<30 ms (<2 years)
		<40 ms (>2 years)
AH interval	AV nodal conduction time (antegrade)	30–90 ms (<2 years)
		40–100 ms (2–10 years)
		45–110 ms (11–15 years)
		45–135 ms (>15 years)
HV interval	His-Purkinje system conduction time (antegrade)	25–50 ms (<2 years)
		27–55 ms (2–5 years)
		30–55 msec (5–10 years)
		35–55 ms (>10 years)

Sinus node evaluation				
Term	Abbreviation	Definition	What it tests	Normal values
Sinus node recovery time	SNRT	Longest interval in milliseconds from last atrial paced event to first recovery atrial event (or longest secondary pauses)	Sinus node automaticity	
Corrected sinus node recovery time	CSNRT	SNRT minus ambient sinus cycle length	Sinus node automaticity	31–275 ms[a]
Percent of corrected sinus node recovery time	%CSNRT	SNRT divided by ambient sinus cycle length	Sinus node automaticity	<165 %
Sinoatrial conduction time	SACT	2 methods (Strauss and Narula), see text	Sinoatrial conduction	48–200 ms[a]

Refractory periods (S1 = drivetrain stimulus, S2 = extrastimulus, A = atrial event, H = His bundle event, V = ventricular event)			
Term/pacing site	Abbreviation	Definition	What it tests
Atrial effective refractory period/atrium	AERP	Longest S1-S2 not resulting in an A2	Atrial muscle refractoriness
Atrial functional refractory period/atrium	AFRP	Shortest A1-A2 obtainable	Atrial muscle refractoriness and conduction velocity
Antegrade AV nodal effective refractory period/atrium	aAVNERP	Longest A1-A2 not resulting in an H2	AV nodal refractoriness
Antegrade AV nodal functional refractory period/atrium	aAVNFRP	Shortest H1-H2 obtainable	AV nodal refractoriness and conduction velocity
Retrograde AV nodal effective refractory period/ventricle	rAVNERP	Longest H1-H2 (or V1-V2) not resulting in an A2	AV nodal refractoriness
Retrograde AV nodal effective refractory period/ventricle	rAVNFRP	Shortest A1-A2 obtainable (via AV node)	AV nodal refractoriness and conduction velocity
Antegrade accessory pathway (AP) effective refractory period/atrium	aAPERP	Longest A1-A2 not resulting in a pre-excited V2	AP refractoriness
Antegrade accessory pathway (AP) functional refractory period/atrium	aAPFRP	Shortest V1-V2 obtainable (both beats pre-excited)	AP refractoriness and conduction velocity
Retrograde accessory pathway (AP) effective refractory period/ventricle	rAPERP	Longest V1-V2 not resulting in A2 via AP	AP refractoriness
Retrograde accessory pathway (AP) functional refractory period/ventricle	rAPFRP	Shortest A1-A2 obtainable (both beats via AP)	AP refractoriness and conduction velocity
Ventricular effective refractory period/ventricle	VERP	Longest S1-S2 not resulting in a V2	Ventricular muscle refractoriness

(*continued*)

Table 157.10 (continued)

Refractory periods (S1 = drivetrain stimulus, S2 = extrastimulus, A = atrial event, H = His bundle event, V = ventricular event)			
Term/pacing site	Abbreviation	Definition	What it tests
Ventricular functional refractory period/ventricle	VFRP	Shortest V1-V2 obtainable	Ventricular muscle refractoriness and conduction velocity
Other terms			
Term/pacing site	Abbreviation	Definition	What it tests
Antegrade AV block cycle length/atrium	AVBCL or aAVBCL	During incremental pacing, the longest paced cycle length resulting in AV block	Features of antegrade conduction
Retrograde VA block cycle length/ventricle	VABCL or rAVBCL	During incremental pacing, the longest paced cycle length resulting in VA block	Features of retrograde conduction

testing reports, a glossary of terms appears in Table 157.10 [65]. Just as there are developmental changes in the surface ECG intervals, so, too, do the intracardiac conduction intervals show changes with age. Some of these appear in Table 157.10. If inducibility of a tachyarrhythmia does not occur with single extrastimulus testing as described above, stimulation with multiple premature beats or bursts of pacing is performed. As with esophageal electrophysiology studies, if provocative testing under baseline conditions does not induce the expected tachycardia, testing is repeated during adrenergic stimulation with isoproterenol infusion, isoproterenol plus atropine, or epinephrine infusion.

The goals of the EP study are to assess the electrophysiologic characteristics of the myocardium, to determine if an arrhythmia substrate is present, to determine if a clinically relevant arrhythmia is inducible, to determine the mechanism of the arrhythmia, and occasionally to evaluate the pharmacological response of a tachyarrhythmia. Accurate diagnosis of the arrhythmia mechanism is important to help determine therapeutic approaches, including potential antiarrhythmic medications, ablation strategies, or need for an implantable defibrillator. Typically, the diagnostic EP study is performed in a setting where the ability to proceed with therapeutic ablation is seamless.

Supraventricular Tachycardias

158

Carolina Escudero, Nico A. Blom, and Shubhayan Sanatani

Abstract

Supraventricular tachycardia is common in the pediatric population and is the most common cardiac emergency encountered. Supraventricular tachycardia can be subdivided into reentrant and automatic tachycardias, which each have differing mechanisms and clinical presentations. The various forms of supraventricular tachycardia can be differentiated by their clinical presentation, ECG appearances, and response to therapy. This chapter reviews the presentation and epidemiology of supraventricular tachycardia in infants and children. The mechanisms and anatomic substrates leading to this arrhythmia in children with and without structural heart disease are also discussed. The different types of supraventricular tachycardia that occur in the pediatric population are described including their mechanisms, ECG characteristics, and clinical features.

Introduction

Supraventricular tachycardia (SVT) is an important arrhythmia managed by pediatricians, emergency room physicians, and pediatric subspecialists. It is the most common pediatric cardiac emergency encountered globally. SVT originates in the atria or the atrioventricular (AV) junction and is defined as any tachycardia that requires the participation of tissue above the bifurcation of the bundle of His for sustaining the tachycardia. In children, SVT is the most common symptomatic arrhythmia. Although the exact incidence is unknown, SVT has been estimated to affect between 1 per 1,000 and 1 per 250 children; however, this estimate is based on extrapolation of single center data [1]. A general population-based study reported a prevalence of SVT of 2.25 per 1,000 persons with an incidence of 13/100,000 persons per year in children less than 19 years of age [2]. Geggel et al. reported that 12.7 % of emergency department consultations were for evaluation of arrhythmias, most commonly SVT, while Clausen et al. reported an incidence of 11.5 non-arrest arrhythmias per 10,000 emergency room presentations, with SVT representing the majority [3, 4].

In the pediatric population, the SVT substrate is determined by age. The vast majority of children with SVT have structurally normal hearts. Atrioventricular reciprocating or reentrant tachycardia (AVRT) due to an overt accessory pathway (Wolff–Parkinson–White or WPW) or a concealed pathway, atrioventricular nodal reentrant tachycardia (AVNRT), and ectopic atrial tachycardia (EAT) are the three most common types of SVT [5]. SVT commonly presents during fetal life and is usually due to atrial flutter or AVRT [6]. It is estimated that 50–60 % of the initial episodes of SVT occur in the first year of life, with a number of these infants also having had fetal tachycardia. In infants and young children, AVRT is the most common type of SVT and accounts for approximately 90 % of SVT in infants [7]. In the majority of infants, SVT will spontaneously resolve by the age of 6 months up to 1 year, or even sooner [8]. After infancy the incidence of SVT increases again at the end of the first decade and in adolescence. However, more than 30 % will experience recurrences at a mean age of 8 years. Spontaneous remission is less likely in those older than 1 year of age at presentation [7, 9–11]. AV nodal reentrant tachycardia (AVNRT) is rare before the age of 2 years but becomes more frequent with increasing age, especially in females, and accounts for around 50 % of SVT at the end of the second decade [12, 13]. Ectopic atrial tachycardia is less common and accounts for only 10 % of pediatric SVT occurring throughout infancy, childhood, and adolescence [5].

The clinical presentation of SVT is also related to the age of the patient and is dependent on the rate, duration, and the type of SVT. In infants and young children with paroxysmal SVT (AVRT), the heart rate is usually in the range of 220–320 beats/min. Parents may report the tachycardia based on their observation of rapid pulsations of the child's neck veins or chest. Signs and symptoms of SVT are usually nonspecific, including pallor, irritability, feeding problems, and vomiting. Often parents of infants with SVT do not notice any clear symptoms. However, if an SVT remains unrecognized for hours to days, the infant can present with progressive congestive heart failure symptoms or profound cardiovascular collapse, and at this stage SVT has become a life-threatening condition. In fact, greater than 50 % of infants are in heart failure at presentation [14–16].

The presentation of paroxysmal SVT in school-aged children and adolescents is different than that of infants and young children. In verbal children, one can appreciate that most episodes of pediatric SVT occur as a paroxysmal event and are characterized by sudden onset and termination of palpitations. The heart rate is slower, usually between 160 and 280 beats/min. In this age group paroxysmal SVT rarely presents with heart failure symptoms due to the shorter duration, owing to the ability of the patients to report symptoms. Symptoms are comparable to those in the adult population

and, in young otherwise healthy children, are typically limited to palpitations, although many will complain of exercise intolerance, clammy skin, chest pain, dizziness, presyncope, and/or dyspnea. A sensation of a pulsation in the throat or visible precordial activity is commonly reported. Syncope is an exceptional but alarming symptom of SVT and may represent a life-threatening arrhythmia such as atrial fibrillation in patients with WPW syndrome or poorly tolerated fast SVT in patients with complex congenital heart disease. The triggering events are highly variable and a distinct pattern may not be identified. The duration of episodes varies from seconds to hours, and episodes may occur daily or there may be symptom-free intervals of months or years. One episode does not predict the occurrence of a subsequent one [17, 18]. The initial episodic complaints are often discounted by families or health-care providers.

Incessant types of SVT, such as EAT and permanent junctional reciprocating tachycardia (PJRT), can affect children of all ages, and they usually do not present with palpitations, although the heart rate is chronically raised. They may present with progressive fatigue, decreased exercise tolerance, or dyspnea due to the development of a tachycardia-induced cardiomyopathy [7].

The recording of a rapid pulse or one that is "too fast to count" allows for a presumptive clinical diagnosis, though other arrhythmia substrates must be considered. In order to confirm the diagnosis, an electrocardiographic tracing during symptoms is needed. Short SVT episodes are often difficult to document on a 12-lead ECG, and sometimes this confirmation remains elusive. Newer forms of monitoring systems such as short-term loop recorders or smartphone applications may be helpful. Occasionally, the diagnosis can be confirmed using ambulatory monitoring or cardiac event recorders. The diagnostic yield of exercise testing is very low [19]. The ECG will demonstrate a narrow complex tachycardia in the absence of a preexisting bundle branch block pattern or rate-related aberrancy. Some forms of SVT can be associated with a wide QRS, such as antidromic tachycardia in WPW or preexcited atrial fibrillation.

Children and adults with congenital heart disease have an increased risk of SVT and arrhythmia substrates may be related either to the congenital abnormality itself or may result from anatomical barriers due to suture lines and scars after surgical correction in combination with chronic hemodynamic stress [20, 21].

Mechanisms of Supraventricular Tachycardia

The mechanisms by which SVT occurs are *reentry* and *abnormal impulse formation*, with reentry being responsible for >90 % of clinically relevant cases of SVT [22]. Reentry involves the repetitive propagation of electrical activity to its site of origin to reactivate that area [23]. The reentrant mechanism requires the presence of distinct electrophysiological pathways separated by an anatomical or functional obstacle, unidirectional block of one of the pathways, and a delay in conduction in the other pathway (Fig. 158.1) [23, 24]. Reentry also requires an initiating trigger and a critical tissue mass to sustain the circulating wave of activation [23]. The dual pathways must have different electrophysiologic properties with disparate conduction velocities and refractory periods. In *classic reentry* there is a distinct additional conduction pathway, such as an accessory pathway. Reentry is also possible in the absence of accessory pathways when there are areas of altered conduction in the atrial or ventricular muscle, which occur with chamber dilation, fibrosis, diseased myocardium, and scarring; or if there are pathways with differential conduction properties in specialized tissue such as the AV node or SA node. *Functional reentry* occurs in the absence of anatomic obstacles due to heterogeneity in the electrophysiologic properties of the involved tissues [23]. Interventions which interrupt conduction or alter conduction velocity or refractoriness lead to termination of the reentrant arrhythmia.

Supraventricular tachycardias may also be caused by abnormal impulse formation, more

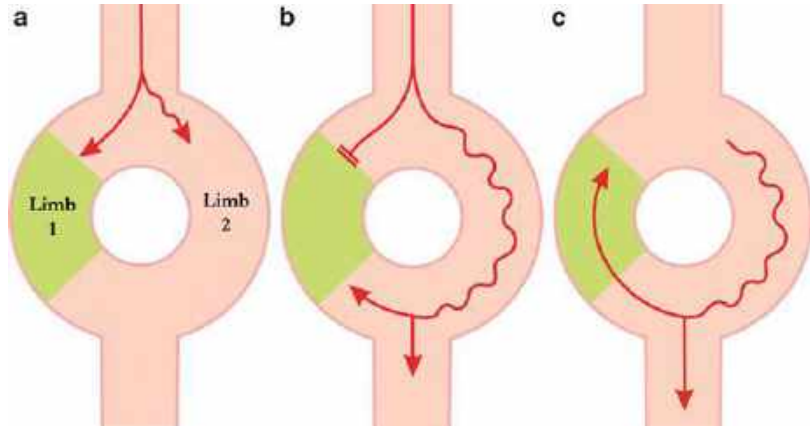

Fig. 158.1 Classic reentry occurs when a stimulus encounters *limb 2* when it is excitable and *limb* 1 when unidirectional block (*shaded area*) is present (**a**) The unidirectional block may be temporary (e.g., the stimulus was premature) encountering *limb 1* during its refractory period or may be more permanent if *limb 1* only allows unidirectional conduction in the opposite direction. After travelling down *limb 2*, the stimulus can enter *limb 1* when it is excitable (**b**) In order for this circuit to perpetuate, there must be sufficient conduction delay (indicated by *wavy line*) in order for the returning stimulus to arrive at *limb 1* once its refractory period is complete. Impulse propagation continues in this manner to give the classic reentry mechanism for arrhythmia generation (**c**)

commonly referred to as abnormal automaticity. Automaticity is the ability of cardiac cells to undergo spontaneous depolarization to independently initiate an electrical impulse [23]. Normally, such automaticity is only apparent in the pacemaker tissue in the heart, though all cells demonstrate some degree of automaticity, with the sinoatrial node having the fastest rate of spontaneous depolarization. In abnormal automaticity, a focus outside of the sinoatrial node, such as atrial myocardial cells or cells in the AV node–His bundle complex, discharges at a rate faster than the sinus rate. The frequency of action potential generation is dependent on the maximum diastolic potential, the slope of phase 4 depolarization, and the threshold potential. Alterations in these factors or elevated catecholamines can increase the frequency of discharge from an abnormal focus [23, 24]. Tachycardias caused by abnormal automaticity are referred to as *automatic* tachycardias and include sinus tachycardia, junctional ectopic tachycardia, and ectopic atrial tachycardia.

The clinical features of reentrant and automatic arrhythmias can assist in differentiation of these two mechanisms to narrow the differential diagnosis and guide therapy. Typical clinical features of SVT caused by a reentrant mechanism include sudden arrhythmia onset and termination, the ability to initiate and terminate the tachycardia with appropriately timed premature beats, and a narrow heart rate range during tachycardia with minimal beat-to-beat variation [25]. The response of the arrhythmia to treatment is also typical of reentrant arrhythmias, including termination with direct current shock and elimination with ablation of one limb of the circuit [25]. In contrast, automatic tachycardias are suggested by a wider variation in heart rate proportional to sympathetic tone, atypical pharmacologic response, and resistance to direct current cardioversion [25]. Automatic tachycardias typically display a gradual increase in rate at initiation of the tachycardia, known as a "warm-up" period, as well as a gradual decrease in rate at their termination, the "cooldown" period. These tachycardias also cannot usually be initiated or terminated using pacing protocols. Automatic tachycardias display *overdrive suppression*, such that pacing at a faster rate than the automatic focus will suppress the arrhythmia temporarily, but the arrhythmia will resume once pacing is terminated or the rate of pacing is slowed to a rate of firing slower than that of the automatic focus.

The majority cases of SVT are manifest as a narrow complex tachycardia due to rapid electrical conduction through the myocardial mass through utilization of the normal His–Purkinje conduction system as the anterograde limb regardless of the mechanism. Abnormal propagation of electrical activation through the ventricles leads to a wide complex SVT. This aberrant depolarization is present in the setting of preexisting bundle branch block or due to a "functional" bundle branch block occurring when parts of the His–Purkinje system are in a refractory or relative refractory period secondary to the increased ventricular rate [26]. Abnormal ventricular depolarization also occurs when the anterograde conduction is via an accessory pathway, as seen in antidromic reentrant tachycardias or in preexcited atrial tachycardias (see below).

Types of Supraventricular Tachycardia

There are a variety of different types of SVT encountered in children (Fig. 158.2). The types of SVT will be divided into three broad categories in this chapter: reentrant SVT utilizing an accessory pathway, reentrant SVT without an accessory pathway, and automatic SVT. This section will focus on the mechanism and clinical characteristics of the different types of SVT encountered in children. For details on treatment of these arrhythmias, please refer to the chapter on arrhythmia treatment.

Reentrant Supraventricular Tachycardia Utilizing an Accessory Pathway

Reentrant SVT utilizing an accessory pathway is the most common type of arrhythmia in infants and young children. Reentrant tachycardias utilizing an accessory pathway are referred to as AV reentrant (or reciprocating) tachycardias (AVRT). There are several different types of accessory pathway that can predispose patients to AVRT. The best-known accessory pathway is

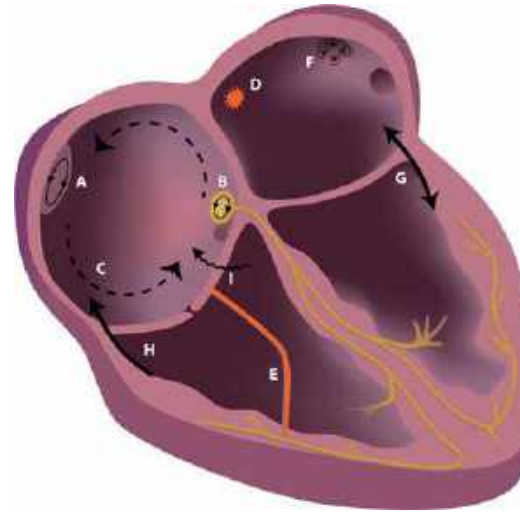

Fig. 158.2 Schematic illustrating different types of SVT and their anatomical substrates. *A*. Sinus node reentry occurring within or around the sinus node. *B* Atrioventricular (AV) node reentry occurring within the AV node complex. *C* Atrial flutter occurring as a macro-reentrant circuit in the right atrium. *D* Ectopic atrial tachycardia from an atrial focus with enhanced automaticity. *E* Atriofascicular (Mahaim) fiber. *F* Atrial fibrillation originating in the pulmonary veins. *G* Bidirectional accessory pathway as occurs in Wolff–Parkinson–White syndrome. *H* Unidirectional accessory pathway allowing only retrograde conduction (concealed accessory pathway). *I* Unidirectional accessory pathway with decremental retrograde conduction as is present in permanent junctional reciprocating tachycardia

that of Wolff–Parkinson–White syndrome (WPW), which is associated with *preexcitation*. Other forms of accessory pathway include concealed accessory pathways, which are not apparent on the resting ECG, as they only conduct retrogradely; Mahaim fibers; and slowly conducting retrograde pathways implicated in permanent junctional reciprocating tachycardia.

Wolff–Parkinson–White (WPW) Syndrome

WPW is a relatively common condition with an estimated prevalence of 1–4/1,000 individuals having a WPW ECG pattern [27, 28]. WPW syndrome includes an ECG pattern of preexcitation as well as paroxysmal episodes of

Fig. 158.3 Wolff–Parkinson–White (WPW) ECG. This ECG in sinus rhythm from a patient with WPW syndrome demonstrates the classic short P–R interval, slurred upstroke of the QRS complex (delta wave), and the widened QRS complex

Fig. 158.4 Intermittent preexcitation mimicking bigeminy. The ventricular complexes alternate between those conducted only via the atrioventricular (AV) node (narrow QRS, normal P–R interval) and those conducted through the accessory pathway (short P–R interval, delta wave, and widened QRS) and AV node

tachycardia. In the absence of symptoms or episodes of tachycardia, the diagnosis is referred to as *asymptomatic WPW*, isolated ventricular preexcitation, or a WPW ECG pattern [27]. Anterograde conduction occurs through the accessory pathway during normal sinus rhythm to depolarize a portion of the ventricle prior to normal activation through the AV node–His–Purkinje system, giving rise to a short P–R interval and a premature and slurred deflection of the QRS referred to as a *delta wave* (Fig. 158.3). The presence of the delta wave results in a widened QRS. Although most cases of WPW are sporadic, familial occurrence of WPW has also been reported [29].

In 1930, Wolff, Parkinson, and White published the first series of patients with the syndrome of functional bundle branch block, a short P–R interval, and paroxysmal tachycardia or atrial fibrillation, although there were a few isolated cases reported prior to their landmark paper [30, 31]. Identification of the presence of an accessory pathway as the underlying mechanism of this syndrome, however, did not occur until 1933 [32]. Histologic confirmation of the presence of an accessory pathway in WPW syndrome was first reported in 1943, although lateral AV connections were initially found in the late 1800s and early 1900s but mistakenly thought to be part of the normal conduction system [30, 33–35]. The term "bundle of Kent" is still occasionally used to refer to the accessory pathway in WPW.

The degree of preexcitation is dependent on the location of the pathway as well as the relative conduction velocities through the AV node and the accessory pathway [36]. In the presence of subtle preexcitation, vagal maneuvers which slow AV node conduction can make preexcitation more evident [36]. The preexcitation pattern can be persistent or may be variably present, which is referred to as *intermittent preexcitation* (Fig. 158.4). The mechanism of intermittent preexcitation is not well understood, although numerous mechanisms have been proposed and substantiated by single cases [37, 38]. Multiple accessory pathways may also be present, with the appearance of different preexcited morphologies on the ECG.

Accessory pathways are typically made up of thin strands of normal myocardium located in the subendocardium or subepicardium [36]. During the embryologic formation of the heart, the atrial and ventricular muscle masses are initially contiguous and are later separated by the ingrowth of the annulus fibrosus [36, 39]. Defects in the annulus fibrosus allow for continuity between the atria and ventricles in the form of an accessory pathway. In the majority of patients with WPW, the intracardiac anatomy is otherwise normal. However, any congenital abnormality of the insulating annulus fibrosis, including Ebstein's anomaly, congenitally corrected transposition of the great arteries, and hypertrophic cardiomyopathy (see below), increases the incidence of accessory pathways [27]. The accessory pathways in WPW can occur anywhere along the AV groove. Left lateral pathways are the most common and occur in approximately 40 % of cases, with the next most common locations (in order of decreasing frequency) being posteroseptal, right lateral, anteroseptal, and midseptal pathways [36].

The presentation of symptomatic WPW depends on age as well as the location and conduction properties of the accessory pathway. The diagnosis may be made in infancy after an episode of AVRT [27]. The frequency of episodes of

SVT often decreases over the first year of life, with loss of anterograde conduction in up to 40 % of patients [10, 27]. After this quiescence of SVT episodes in later infancy, tachycardia recurs in approximately 30 % of patients at an average of 7–8 years [27]. Children and adolescents may also present with their first episode of tachycardia. If symptomatic WPW is present after the age of 5 years, the majority of patients will continue to have recurrent episodes, although spontaneous resolution is possible as accessory pathways tend to lose their arrhythmic functionality with time [27, 28].

The most common arrhythmia in WPW is an *orthodromic* reciprocating tachycardia. *Orthodromic* conduction refers to anterograde conduction through the AV node and retrograde conduction through the accessory pathway (Fig. 158.5). In the presence of orthodromic conduction, a narrow complex tachycardia occurs as long as aberrant conduction is not present. Preexcitation is not seen during tachycardia in this mechanism as the accessory pathway is no longer undergoing anterograde conduction, and the ventricles are depolarized normally (Fig. 158.6). *Antidromic* conduction occurs much less commonly and involves anterograde conduction through the accessory pathway and retrograde conduction via the AV node or a second accessory pathway (Fig. 158.5) [40]. Due to the wide QRS pattern in antidromic tachycardia, it may be difficult to differentiate from ventricular tachycardia initially (Fig. 158.7). Antidromic AVRT has been reported to occur in only 2.6 % of children with WPW undergoing an EP study [40]. In both antidromic and orthodromic reciprocating tachycardias, P waves can be seen in the ST segment and are inverted in the inferior leads due to retrograde activation of the atrium [41]. These arrhythmias display the typical clinical characteristics of reentrant arrhythmias, as described above. In the presence of multiple pathways, complex reentrant circuits can be formed. The accessory pathway may also act as a *bystander pathway*, indicating that it is not part of the tachycardia circuit [42]. The bystander pathway may continue to conduct the tachycardia to the ventricles, despite not being a part of the tachycardia circuit, to give a wide complex SVT [42].

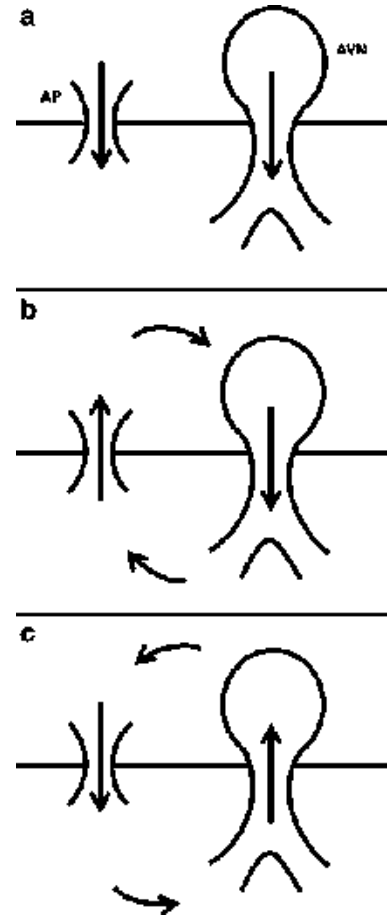

Fig. 158.5 Conduction in Wolff–Parkinson–White syndrome. (**a**) In normal sinus rhythm, conduction occurs anterograde through the accessory pathway (*AP*) as well as through the atrioventricular (AV) node (*AVN*) to give preexcitation. (**b**) During orthodromic tachycardia, anterograde conduction occurs through the AV node with retrograde conduction in the accessory pathway. A narrow complex tachycardia results due to the normal anterograde conduction in the AV node. (**c**) During antidromic tachycardia, anterograde conduction occurs through the accessory pathway with retrograde conduction through the AV node. Anterograde conduction through the accessory pathway gives maximal preexcitation and a wide complex tachycardia

Many algorithms have been developed in adults to determine the likely location of the pathway based on the appearance of the delta wave and QRS deflection [43–45]. A pediatric-specific algorithm has been created, which is more accurate at prediction of pathway localization in children than adult-based algorithms

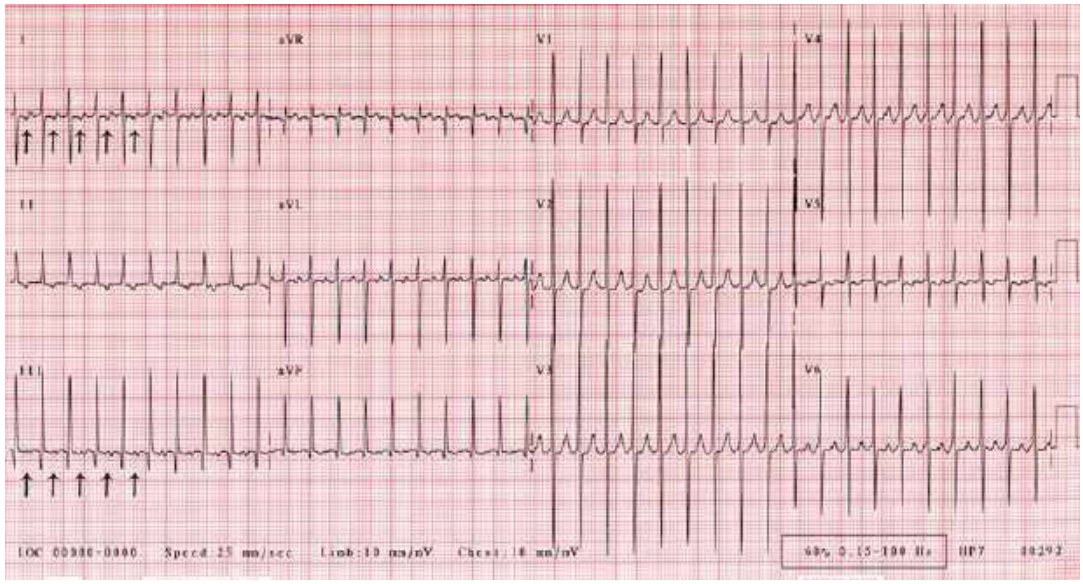

Fig. 158.6 Orthodromic tachycardia characterized by a narrow complex tachycardia. Note the P waves seen within the T waves, particularly in lead III (*arrows*)

(Fig. 158.8) [46, 47]. In non-Ebstein's congenital heart disease, all algorithms have poor accuracy [46]. Another clue to localization is the presence or absence of R–R interval variation when an orthodromic tachycardia changes to a narrow complex after a transient functional bundle branch block pattern from aberrant conduction resolves [48]. If the pathway is ipsilateral to the bundle branch block, the R–R interval will increase in the presence of a transient bundle branch block as the anterograde activation through the AV node must travel down the contralateral bundle and then across the myocardium to reach the accessory pathway and conduct retrogradely (Fig. 158.9). If the pathway is contralateral to the bundle branch block, there will be no change in the R–R interval during the narrow complex tachycardia and the transient bundle branch block pattern.

WPW syndrome is distinct among the SVT substrates due to the potential for sudden cardiac death in a subset of patients. In the normal heart, the conduction of an atrial arrhythmia to the ventricle is determined by the refractory periods of the AV node and His–Purkinje system. If the rate of the atrial arrhythmia exceeds the conduction properties of the AV node, some of the atrial impulses will be blocked from conduction to the ventricles. If, however, an accessory pathway with rapid conduction velocity and a short refractory period is present, each beat of a rapid atrial arrhythmia may be conducted to the ventricle. Rapid accessory pathway conduction of atrial fibrillation may lead to ventricular fibrillation, hemodynamic decompensation, and death [49]. Although uncommon, ventricular fibrillation or cardiac arrest may be the first presentation of WPW, particularly in older children [27, 50–52]. The rapidity of anterograde conduction in the accessory pathway is measured by the shortest preexcited R–R interval, with an interval of less than 220–250 ms conferring increased risk [27]. Children with WPW are also at increased risk of developing atrial fibrillation, with a risk of 12 % in a large prospective study [53]. The ECG during preexcited atrial fibrillation demonstrates a baseline of fine and irregular atrial activity, an irregularly irregular wide complex tachycardia, and occasional narrow QRS complexes from normally conducted impulses (Fig. 158.10) [36, 41]. Other risk factors for sudden cardiac death are age less than 30 years, male gender, history of atrial fibrillation, syncope, congenital or other heart disease, and familial WPW [27]. In the

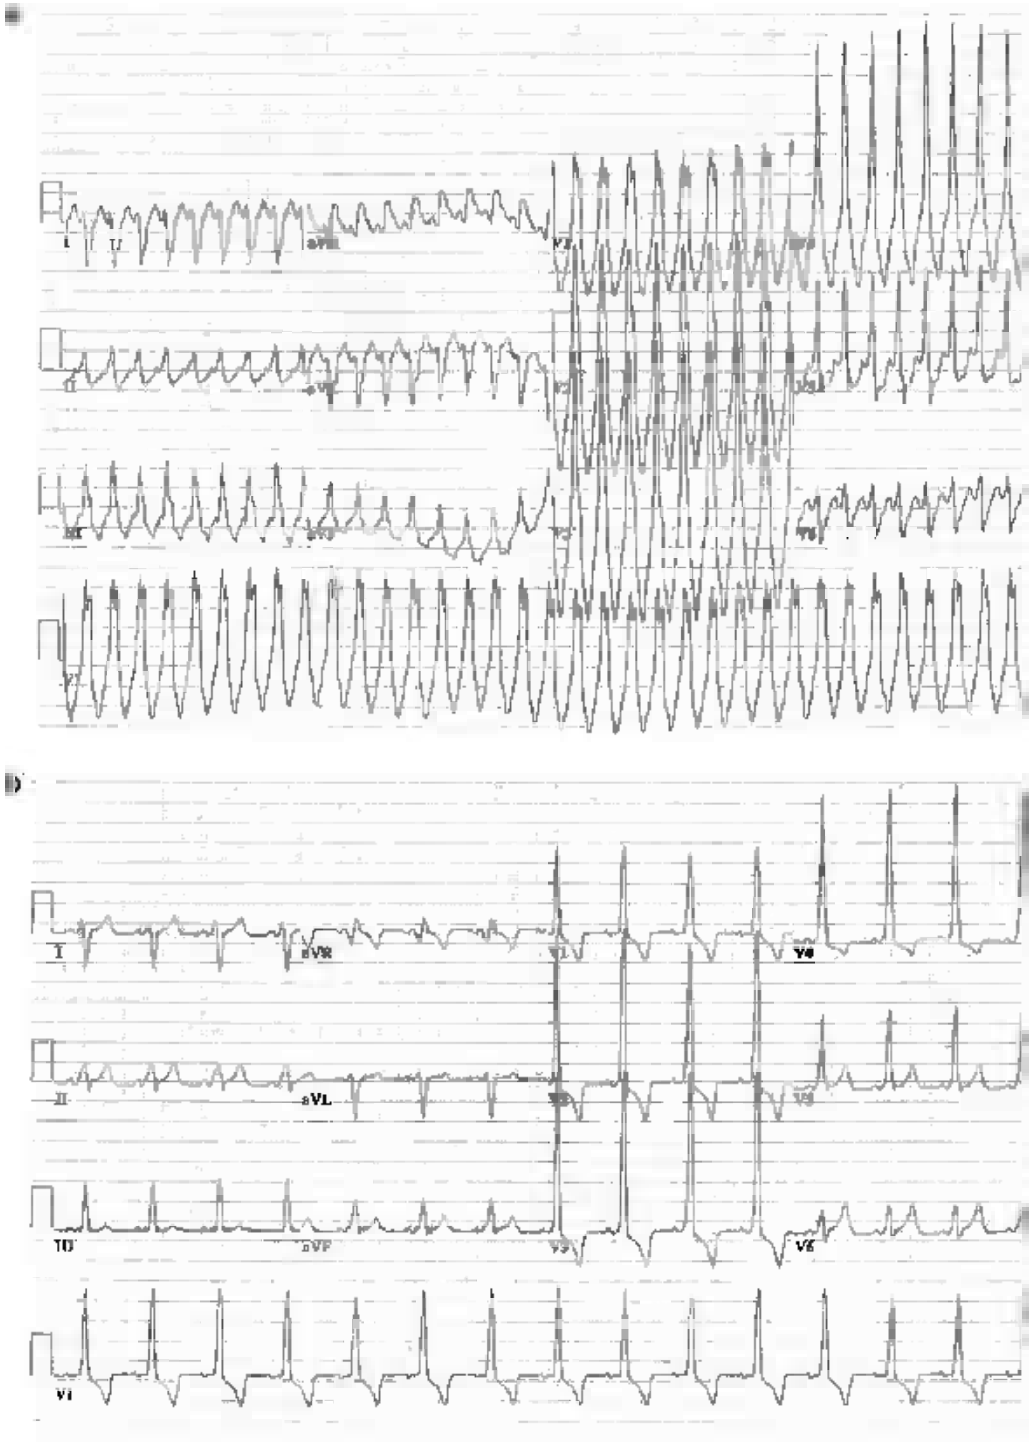

Fig. 158.7 (**a**) Antidromic atrioventricular reentrant tachycardia (AVRT) with a wide QRS complex. (**b**) This patient's baseline ECG shows preexcitation

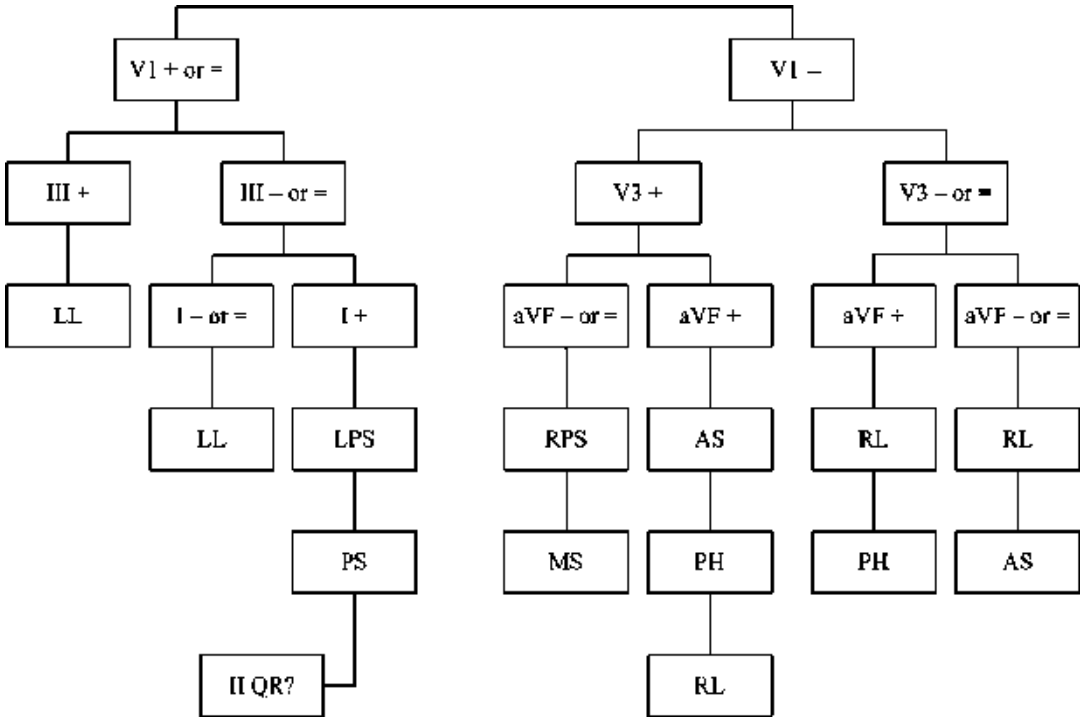

Fig. 158.8 Algorithm for pathway localization in Wolff–Parkinson–White syndrome. The symbols +, –, and = indicate the direction of QRS polarity in the different leads as being positive, negative, or intermediate, respectively. The locations of the pathways are abbreviated as follows: *AS* anteroseptal, *LL* left lateral, *LPS* left posteroseptal, *MS* midseptal, *PH* parahisian, *PS* posteroseptal, *RL* right lateral, and *RPS* right posteroseptal (Reprinted from Boersma L, Garcia-Moran E, Mont L et al. Accessory pathway localization by QRS polarity in children with Wolff–Parkinson–White syndrome. J Cardiovasc Electrophysiol 13(12):1222–1226, Copyright (2002) with permission from Elsevier)

Fig. 158.9 Orthodromic tachycardia with initial left bundle branch block morphology secondary to transient conduction block. When the aberrant conduction ceases, the tachycardia continues with a normal QRS morphology. The R–R interval during the aberrantly conducted orthodromic tachycardia (cycle length *A*) is longer than the R–R interval during narrow complex tachycardia (cycle length *B*), indicating an ipsilateral (or left-sided) accessory pathway

absence of rapid atrial arrhythmias, unrecognized prolonged AVRT can also lead to hemodynamic compromise and collapse [14]. This is a particular issue in infants who are unable to verbalize symptoms and may present with nonspecific irritability and appearing unwell.

It has been estimated that 65 % of adolescents with a WPW pattern on a resting ECG are

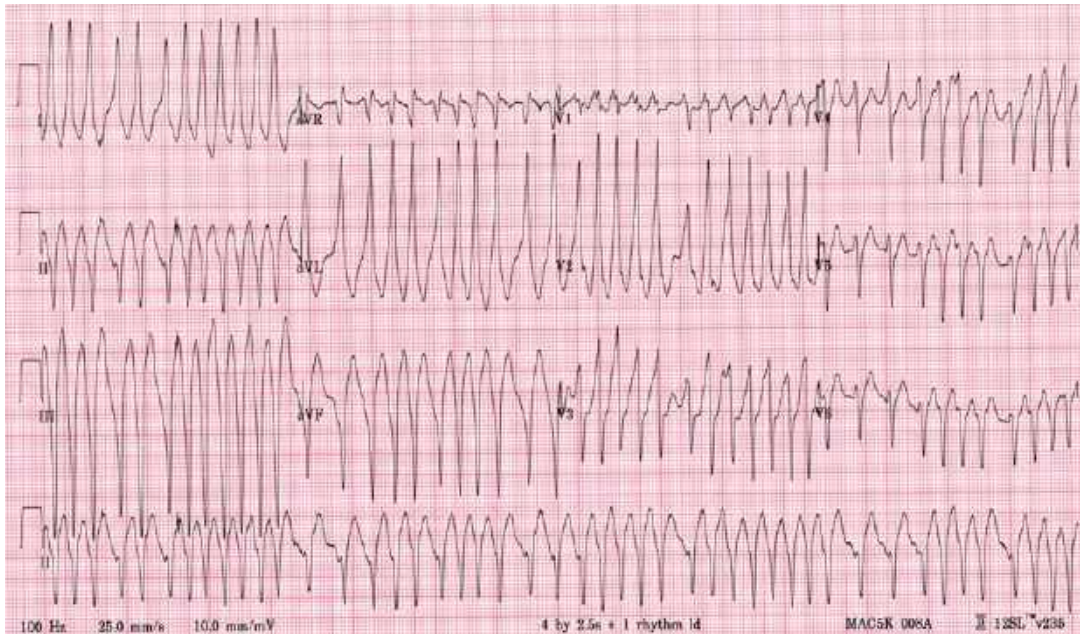

Fig. 158.10 Preexcited atrial fibrillation. This patient was known to have preexcitation on a baseline ECG. This ECG demonstrates no discernable organized atrial activity, an irregularly irregular rhythm, and predominately wide QRS complexes due to abnormal ventricular depolarization through the accessory pathway

asymptomatic [27]. These patients may become symptomatic in the future with the development of SVT or palpitations or may have spontaneous resolution of preexcitation. However, it is well documented that these patients are at risk of developing rapid conduction of atrial fibrillation leading to ventricular fibrillation and sudden cardiac death, especially at younger ages (see above) [27, 28, 50–52]. As such, risk stratification is important in this patient group. Initial investigations are noninvasive and include ECG and exercise stress testing. Intermittent loss of preexcitation on the ECG and abrupt, complete loss of preexcitation at physiologic heart rates during exercise testing indicate a lower risk of sudden death [27]. More invasive testing including transesophageal or intracardiac electrophysiology studies are indicated if noninvasive testing is not reassuring. If invasive testing shows that the shortest preexcited R–R interval with induced atrial fibrillation or rapid atrial pacing is less than or equal to 250 ms, it is reasonable for catheter ablation to be performed [27]. If the shortest interval is greater than 250 ms, patients are at a reduced risk of sudden death, and ablation may be deferred if pathway location or patient characteristics give an increased risk of adverse events with ablation [27].

Since preexcitation leads to premature activation of segments of the ventricle prior to the normal spread of depolarization occurring through the AV node and His–Purkinje system, this asynchronous spread of depolarization can lead to dyssynchronous ventricular contraction and reduced ventricular function. Studies have demonstrated that children with right septal or posteroseptal pathways can have visible ventricular dyssynchrony echocardiographically as well as LV dilation and reduced LV ejection fraction [54–56]. Ablation of these pathways has led to improvements and normalization in LV dimension and function [54–56].

Acute termination of the tachycardia occurs through interruption of the reentrant circuit, which can be accomplished through interventions that slow or block AV node or accessory pathway conduction such as vagal maneuvers and antiarrhythmic medications. In the case of hemodynamic instability, immediate electrical

cardioversion is necessary. Chronic pharmacologic therapy may be required to decrease the frequency of tachycardia episodes and depends on the patient's age, episode frequency, episode duration, and ease of termination using vagal maneuvers. Preexcited atrial fibrillation requires careful treatment consideration since medications such as adenosine, digoxin, beta-blockers, and calcium channel blockers are contraindicated as they may decrease the refractory period of the accessory pathway which can increase the ventricular response rate and promote ventricular fibrillation [57]. Catheter ablation of the accessory pathway is a definitive therapy for WPW. Success rates range between 92 % and 100 % with recurrence rates of 0–13 % [27]. The highest recurrence rates are for right lateral and septal accessory pathways and the lowest are for left lateral and left septal accessory pathways [58]. The success of ablation is lessened with multiple accessory pathways and structural heart disease [27].

Concealed Accessory Pathways

Some accessory pathways are only able to conduct retrogradely from ventricle to atrium and are referred to as *concealed pathways* due to the lack of preexcitation on the resting ECG. In the presence of SVT with an isolated accessory pathway, tachycardia is orthodromic with anterograde conduction in the AV node and retrograde conduction in the accessory pathway. The tachycardia is typically narrow complex with the retrogradely conducted P wave seen in the ST segment. Concealed accessory pathways are most commonly located in the left ventricular free wall [59]. Some patients with WPW syndrome can lose anterograde conduction through the accessory pathway with time resulting in a concealed accessory pathway which maintains the ability for retrograde conduction [10, 60]. Patients with concealed accessory pathways typically present with episodic AVRT and a normal ECG in sinus rhythm. These pathways do not have the ability to conduct from atrium to ventricle, and therefore, there is no risk of sudden death from rapid conduction of atrial fibrillation in these patients.

Mahaim Fibers

Mahaim fibers are a type of *atriofascicular* pathway which originates in the right atrial free wall and terminates distally at the level of the RV apex or the distal right bundle [61]. Mahaim initially described anatomic connections between the normal AV conduction system and the ventricles [62]. A classification of Mahaim fibers was later developed which divided these connections into nodoventricular (connect AV node to ventricle), nodofascicular (connect AV node to fascicular system), and fasciculoventricular (connect fascicles to ventricle) pathways [62]. With advancements in catheter ablation, it was later realized that the Mahaim connections were in fact atriofascicular connections originating away from the AV node rather than the nodoventricular, nodofascicular, or fasciculoventricular pathways that were originally described [62].

Mahaim fibers are rare in children and occur with increased incidence in Ebstein's anomaly. These pathways conduct slowly and decrementally and typically only exhibit anterograde conduction [61]. Mahaim fibers have also been described as an AV node-like structure [63]. Unlike WPW, the slow conduction properties of Mahaim fibers result in minimal or no preexcitation during sinus rhythm [61, 63]. Preexcitation can be intermittent and is manifest as a left bundle branch block pattern with a normal P–R interval [63] (Fig. 158.11). Patients who do not demonstrate preexcitation may have a deficiency of normal septal Q waves in the lateral leads, which can be a subtle clue for the presence of a Mahaim fiber (Fig. 158.11) [63].

The most common type of tachycardia associated with Mahaim fibers is an antidromic reentrant tachycardia with anterograde conduction in the Mahaim fiber and retrograde conduction through the AV node [64]. Since the right ventricle is depolarized first in tachycardia, a wide complex tachycardia with a left bundle branch block pattern ensues [64]. Retrograde P waves are difficult to visualize in this tachycardia as they usually fall in the terminal portion of the QRS [64]. Other forms of tachycardia are possible in the presence of a Mahaim fiber but are less

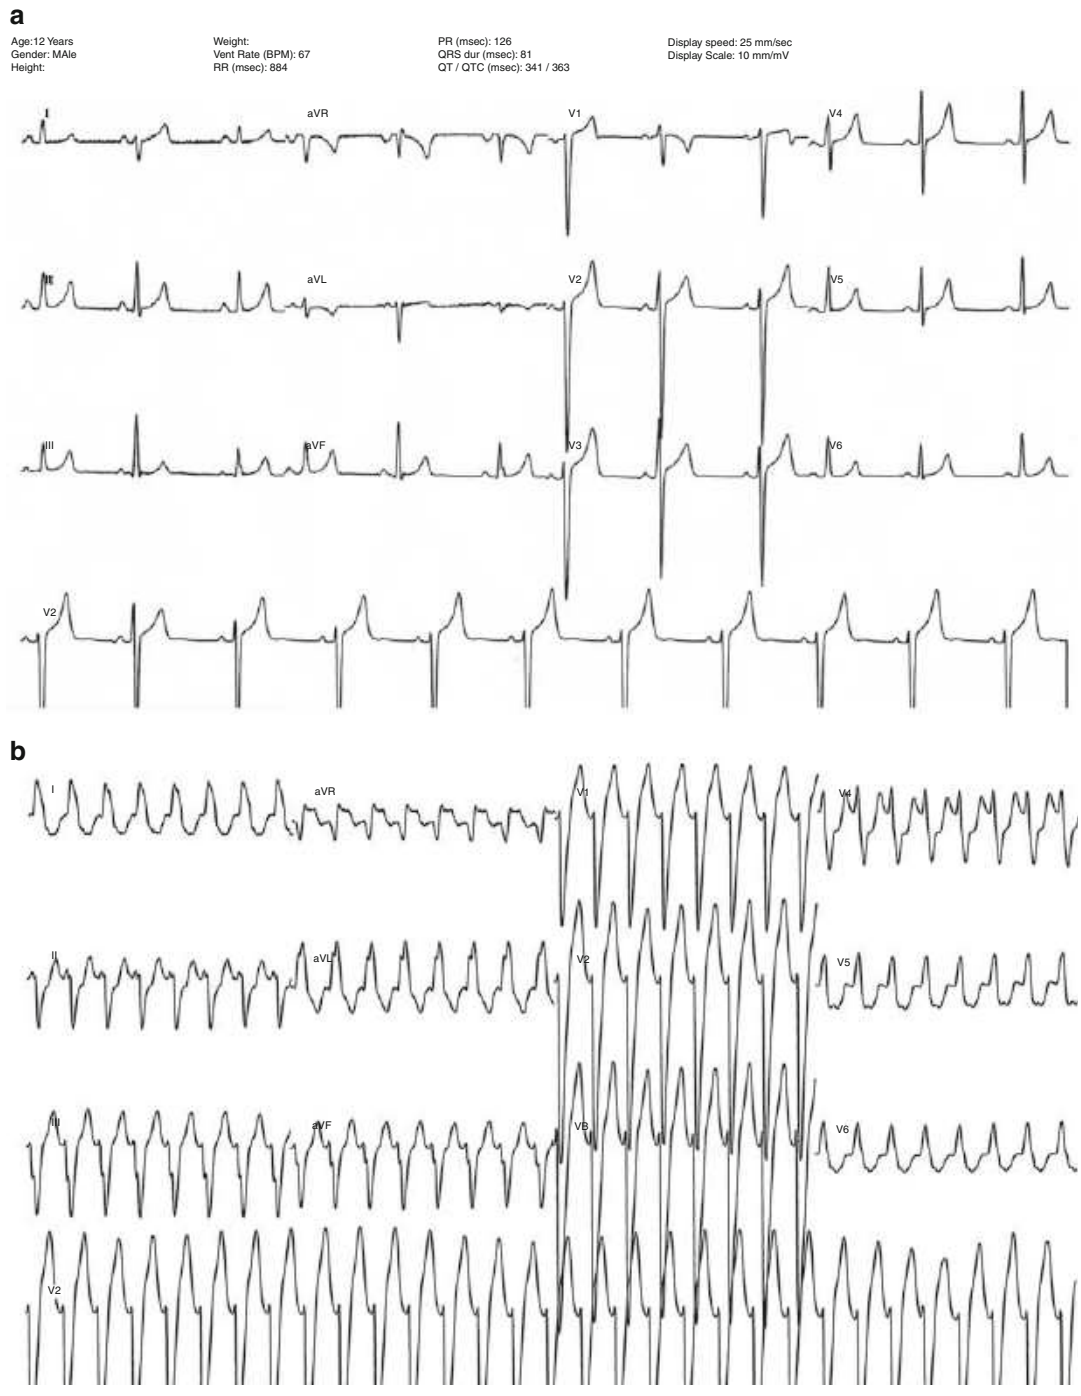

Fig. 158.11 (**a**) ECG during sinus rhythm in a patient with a Mahaim fiber. Note the normal P–R interval and the intermittent subtle preexcitation giving a different QRS morphology. This ECG also demonstrates lack of the normal septal Q waves in the lateral leads. (**b**) Tachycardia in the presence of a Mahaim fiber. Tachycardia secondary to a Mahaim fiber is typically due to antidromic conduction through the accessory pathway giving a wide complex tachycardia of left bundle branch block morphology

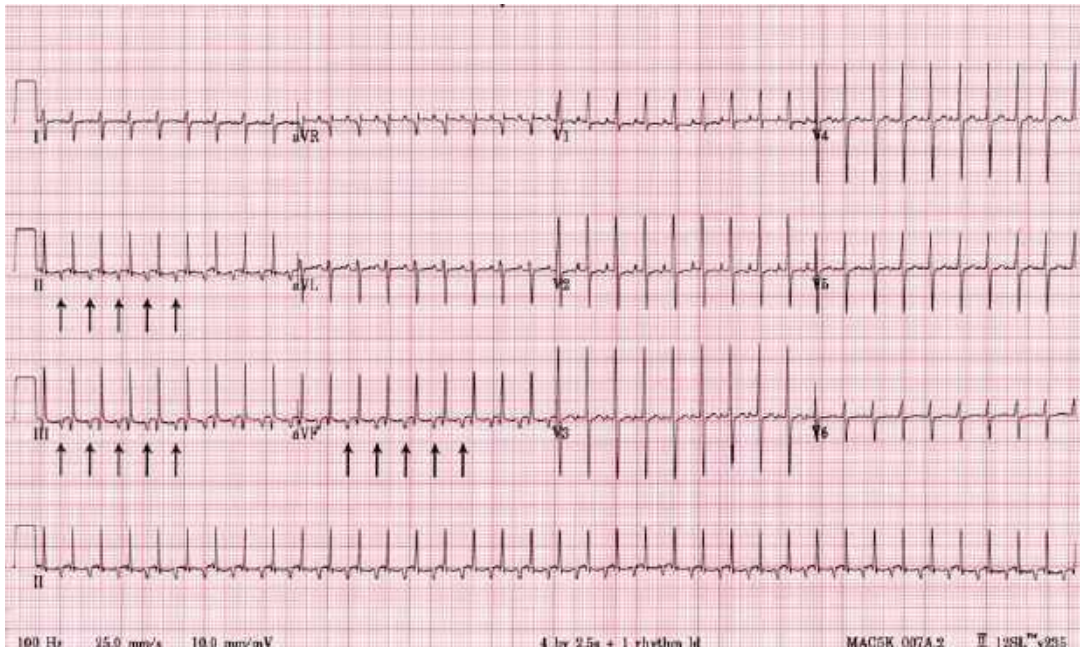

Fig. 158.12 Permanent junctional reciprocating tachycardia. The ECG during tachycardia is characterized by a narrow QRS complex, long R–P interval, and negative P waves in leads II, III, and AVF (arrows)

common. AV nodal reentrant tachycardia is found in up to 10 % of patients with a Mahaim fiber, such that the Mahaim fiber is a bystander pathway that is not a part of the tachycardia circuit but will conduct the impulses in an anterograde fashion to give a wide complex tachycardia [61, 64]. Rarely, Mahaim fibers can produce tachycardia via spontaneous automaticity originating from the fiber [61, 64]. Unlike WPW, the slow conduction of Mahaim fibers does not allow for rapid conduction of atrial tachycardia.

Cessation of the tachycardia occurs with interruption of the reentrant circuit. Adenosine is effective in blocking conduction in both the AV node and the Mahaim fiber [64]. Mahaim fibers can also be successfully ablated [63].

Permanent Junctional Reciprocating Tachycardia

Permanent junctional reciprocating tachycardia (PJRT) is an uncommon arrhythmia which predominates in infants and children, although affected individuals may not be diagnosed until late adolescence or adulthood [65, 66]. The tachycardia is caused by a concealed accessory pathway with slow and sometimes decremental conduction of the electrical impulse [67]. The accessory pathway is typically isolated and located in the posteroseptal region at the tricuspid valve annulus, in the vicinity of the mouth of the coronary sinus [66, 67]. The accessory pathway only conducts in a retrograde fashion in the setting of intact AV node conduction [65]. Anterograde conduction has been reported, particularly after disruption of normal AV node conduction [68]. Data regarding this in the current era, in which the pathway is the target of the ablation, are lacking.

During tachycardia, the AV node is the anterograde limb and the pathway is the retrograde limb, giving a narrow complex tachycardia. PJRT is characterized by a long R–P interval due to slow conduction through the accessory pathway and negative P waves in leads II, III, and AVF with a 1:1 AV relationship (Fig. 158.12) [67, 68]. The heart rate during tachycardia can range from 100 to 250 beats/min and decreases with age, with mean heart

rates of 211 in infants to 165 and 138 in children and adolescents, respectively [65]. The tachycardia is typically incessant and can lead to a tachycardia-induced cardiomyopathy, with heart failure as the initial presenting feature [66]. Symptomatic congestive heart failure with PJRT is more likely in patients who present at a younger age and resolves with treatment of the tachycardia [66].

Prior to the elucidation of the tachycardia mechanism in PJRT, it was unclear if the mechanism was due to atypical AVNRT or a concealed accessory pathway with a long conduction time [68]. Studies involving ablation of the His bundle demonstrated the presence of conduction through a decremental accessory pathway and eliminated AVNRT as a possible mechanism. This established that an accessory pathway acts as the retrograde limb in the tachycardia circuit [68].

The differential diagnosis for PJRT comprises other tachycardias with a long R–P interval, including ectopic atrial tachycardia, atypical (or "fast–slow") AVNRT (see below), or intra-atrial reentrant tachycardia [69]. The 1:1 AV relationship is characteristic of this tachycardia, and the presence of AV block during tachycardia excludes PJRT as the diagnosis [70]. Spontaneous termination of the tachycardia can occur with an inverted P wave followed by a pause, in contrast to ectopic atrial tachycardia in which spontaneous termination occurs with a QRS complex after the final P wave of the tachycardia. In addition, ectopic atrial tachycardia typically exhibits a "warm-up" and "cooldown" phase (see above), whereas PJRT may demonstrate some decremental properties resulting in a shortening R–P interval over the initial few cycles of the tachycardia. A Holter monitor is often helpful in PJRT in order to visualize the initiation and termination of the tachycardia, which helps differentiate PJRT from other diagnoses.

PJRT can be refractory to pharmacologic therapy [66]. If episodes are infrequent and the rate of the tachycardia is slow, therapy may not be required [65]. Spontaneous resolution occurs in approximately 20 % of patients [66]. Catheter ablation can provide definitive treatment of PJRT and may be utilized in older patients or for cases that are refractory to medical management, particularly in the setting of incessant arrhythmias with ventricular dysfunction.

Reentrant Supraventricular Tachycardia not Involving an Accessory Pathway

A reentrant circuit can exist in the absence of an accessory pathway. Altered conduction properties in one area of the myocardium, such as a scar, can set up the necessary substrate for reentrant tachycardias. In structurally normal hearts, such areas exist as well. A reentrant circuit can be macro-reentrant or micro-reentrant, depending on size. Several such circuits can exist in the right atrium, involving the SA node, the AV node, and the entire right atrium in the case of the typical atrial flutter circuit. These naturally occurring pathways have differential conduction properties fulfilling the criteria for a reentrant circuit. Arrhythmias within this category include AV nodal reentrant tachycardia, atrial fibrillation, atrial flutter, and sinus node reentry.

Atrioventricular Nodal Reentrant Tachycardia

Atrioventricular nodal reentrant tachycardia (AVNRT) is a reentrant tachycardia involving discrete conduction pathways within the AV node complex. These conduction pathways are referred to as the *fast pathway* and the *slow pathway*; however, one or more *intermediate pathways* can occur as well. The fast pathway conducts electrical impulses relatively quickly to give a normal P–R interval but has a long effective refractory period [71]. In contrast, the slow pathway conducts more slowly to give a long P–R interval but has a shorter effective refractory period [71]. This results in *dual AV node physiology*, in which the 2 AV nodal pathways can be identified by the presence of 2 distinctly different P–R intervals in normal sinus rhythm or following a premature atrial complex. During the electrophysiology study, this is

manifest as a "jump" phenomenon due to an increase of 50 ms or more in the atrial–Hisian interval with the delivery of a premature atrial complex [71]. Dual AV node physiology is present in approximately 63 % of children with structurally normal hearts and 29–35 % of children with congenital heart disease [72–74]. However, only a minority will develop AVNRT, with the incidence increasing with age [72]. As well, the presence of demonstrable dual AV node physiology is not a requirement for the development of AVNRT [75]. Maturational changes of the AV node occur with aging, which may contribute to increased AVNRT incidence with age [72, 76, 77].

AVNRT is classified into *typical* and *atypical* subtypes, with typical AVNRT occurring more commonly. In both subtypes, AVNRT presents as a narrow complex tachycardia, unless there is rate-related aberrancy or a bundle branch block present. Typical AVNRT involves anterograde conduction down the slow pathway with retrograde conduction in the fast pathway and is also referred to as the *slow–fast* variant. The ECG demonstrates retrograde P waves that are often difficult to visualize as they occur within or at the terminal portion of the QRS complex, usually occurring less than 65–70 ms after the QRS onset (Fig. 158.13) [78]. Atypical AVNRT involves retrograde conduction in the slow pathway and anterograde conduction in the fast pathway (referred to as *fast–slow* conduction). Variations in conduction during atypical AVNRT include anterograde conduction down a slow pathway and retrograde conduction in another slow pathway or retrograde conduction in an intermediate pathway rather than a slow pathway [71]. Due to retrograde activation through a slowly conducting pathway, the P waves during atypical AVNRT are located at least 80 ms after the QRS complex [78]. The ventricular rate during AVNRT can range from 120 to 300 beats/min with rates usually between 180 and 250 beats/min [78]. Some patients with AVNRT can experience 2:1 AV block without interruption of the tachycardia since the block occurs below the level of the reentrant circuit [71, 79]. Accessory pathways may also be present in the setting of AVNRT to act as "bystander" accessory pathways (see above). In these circumstances, the reentrant circuit is confined to the AV node, but the pathway conducts anterogradely to give preexcitation and a wide complex tachycardia [42]. Differentiation from antidromic AVRT can be difficult in this setting.

The important differential for typical AVNRT is orthodromic AVRT due to a concealed accessory pathway. In children, ECG factors favoring AVRT due a concealed pathway include visible P waves, an R–P interval $\geq$100 ms, and ST depression of $\geq$2 mm during tachycardia [80]. AVNRT should be suspected when the ECG during tachycardia demonstrates terminal deflections in the QRS complex giving pseudo r' waves in lead V1 and pseudo S waves in the inferior leads, which are manifestations of the retrograde P (Fig. 158.14) [80]. It is important to compare the baseline ECG to the ECG in tachycardia to look for subtle changes in the QRS complex (Fig. 158.13). Atypical AVNRT must be differentiated from other tachycardias with long R–P intervals, including ectopic atrial tachycardia and PJRT. Ectopic atrial tachycardia may differ from AVNRT in its clinical characteristics since ectopic atrial tachycardia typically has a "warm-up" and "cooldown" phase during tachycardia initiation and termination, whereas AVNRT characteristically has a sudden onset and offset. Differentiation from PJRT may be difficult, although PJRT tends to be a more incessant tachycardia than atypical AVNRT.

Although AVNRT accounts for approximately 80 % of adult-onset SVT, it is less common in children and adolescents comprising only 13–16 % of SVT cases [75]. The incidence of AVNRT increases with age, however, AVNRT can occur in the newborn period [81]. Some reports of AVNRT in infants have found an association with left-sided obstructive lesions, although the majority of cases of AVNRT in children are seen in the setting of a structurally normal heart [81]. Dual AV node physiology is demonstrable in 56–62 % of patients with AVNRT [75, 82]. Patients with rare, brief, or only mildly symptomatic episodic AVNRT may not require chronic treatment and can have spontaneous resolution [75]. Episodes which are more

Fig. 158.13 ECG in normal sinus rhythm (**a**) and in typical atrioventricular nodal reentrant tachycardia (AVNRT) (**b**). A subtle difference in the terminal deflections of the QRS complexes is seen between the ECG in normal sinus rhythm and in tachycardia, which are best seen in leads I, II, III, AVL, AVF, and V1. These subtle changes in the QRS complex are due to the retrograde P wave (*arrows*) (Courtesy of Dr. Elizabeth Sherwin)

Electrocardiographic differentiation of typical atrioventricular node reentrant tachycardia from atrioventricular reciprocating tachycardia mediated by concealed accessory pathway in children. Am J Cardiol 91(9):1084–1089, Copyright (2003), with permission from Elsevier)

severe or prolonged may require therapy. Acute tachycardia termination is accomplished by interventions to temporarily block AV node conduction, including vagal maneuvers or pharmacologic therapy, or direct current cardioversion if hemodynamic instability is present. Chronic therapy can be accomplished with medical treatment, which is effective in the treatment of AVNRT in pediatrics [75]. Catheter ablation of the slow pathway is highly successful in treatment of AVNRT in children; however, recurrence rates are not insignificant [75]. Cryoablation and radiofrequency ablation have been used with pediatric studies showing similar acute efficacy and safety with these two methods but higher recurrence risks with cryoablation [83, 84]. Inadvertent AV block can result from ablation for AVNRT, and thus, the risks and benefits of the procedure must be thoroughly reviewed prior to this intervention.

Atrial Fibrillation

Atrial fibrillation is an uncommon arrhythmia in the pediatric population and occurs more frequently in adolescents than in young children. If left untreated, atrial fibrillation can lead to tachycardia-induced cardiomyopathy or systemic thromboembolism [85]. Atrial fibrillation is characterized by rapid and disorganized atrial activity with atrial rates ranging from 300 to 700 beats/min [86]. The characteristic features of the ECG include irregular and disorganized atrial activity with an "irregularly irregular" ventricular rate (Fig. 158.15). The QRS complex is typically narrow, in the absence of preexisting conduction abnormalities or functional conduction delay. Wide complexes can intermittently be seen following a short R–R interval preceded by a long R–R interval, which is known as the *Ashman phenomenon* (Fig. 158.16) [87]. The Ashman phenomenon occurs because the refractory period of the myocardium is proportional to the preceding R–R interval, such that the longer R–R interval prolongs the refractory period leading to the subsequent shorter R–R interval giving an aberrantly conducted beat [87].

The mechanism of atrial fibrillation is incompletely understood, with theories including multiple wandering atrial reentrant wavelets which collide with each other to terminate or produce new wavelets, rapidly firing ectopic foci, and multiple small reentrant circuits [88]. Electrical remodelling and abnormal function or expression of ion channels are also mechanisms implicated in persistent atrial fibrillation [89]. One of the key factors for induction of atrial fibrillation is a critical mass of atrial tissue to support multiple reentrant circuits, which may explain why atrial fibrillation is much less common in children than adolescents and adults [90]. The typical locations of the abnormal foci in children and adolescents include the pulmonary veins, left atrium, and crista terminalis [85].

Conditions which increase the risk of atrial fibrillation include hyperthyroidism, myocardial disease, prior operative procedures involving the atria, or congenital heart disease causing atrial dilation such as Ebstein's anomaly, atrial septal defects, and AV valve regurgitation (see below) [86, 91]. Although isolated atrial fibrillation with a normal heart can be seen in children, in earlier reports approximately half of pediatric atrial

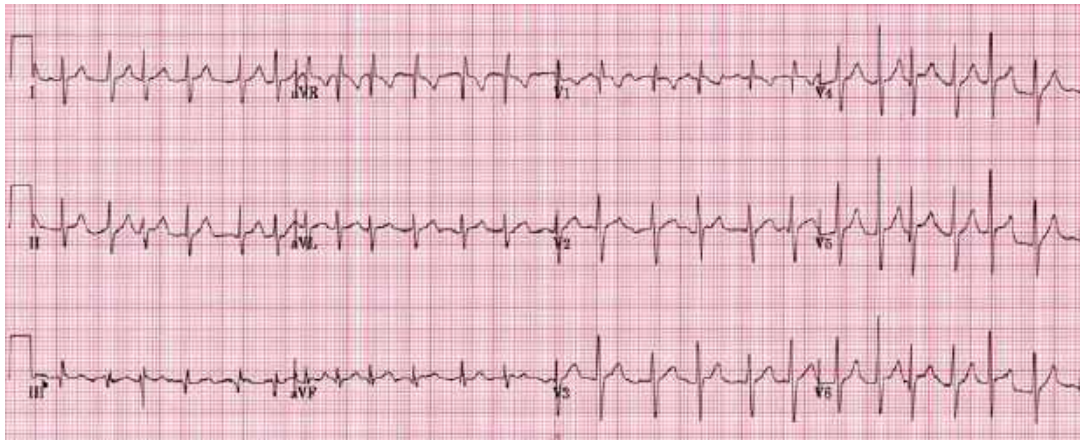

Fig. 158.15 Atrial fibrillation. Disorganized atrial activity is seen as a flattened baseline and lack of definitive P waves. The typical "irregularly irregular" ventricular rate is demonstrated in this ECG

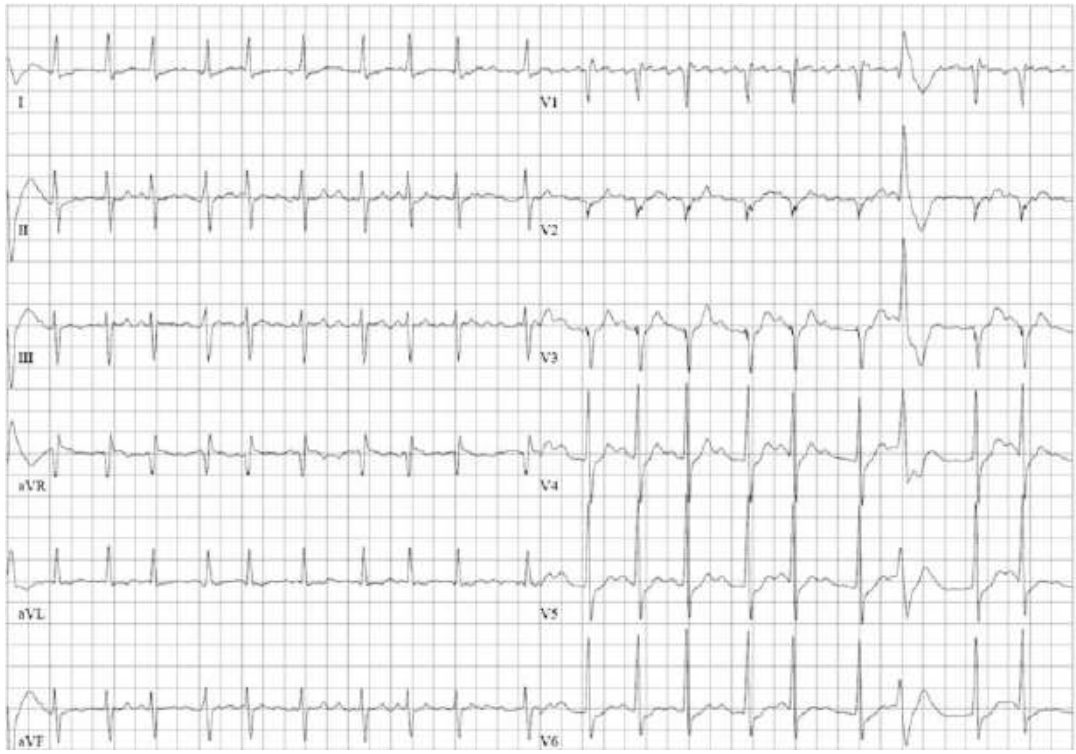

Fig. 158.16 Ashman phenomenon. A long R–R interval followed by a short R–R interval results in an aberrantly conducted, wide QRS

fibrillation was related to underlying congenital heart disease [92]. Familial cases of atrial fibrillation have been reported and can manifest in the pediatric age group [93, 94]. Toxic exposures and metabolic abnormalities can also predispose children and adolescents to atrial fibrillation, including digoxin toxicity, hypokalemia, sympathomimetics, alcohol, and other illicit

Fig. 158.17 Atrial flutter occurring in a neonate. Note the broad "saw-toothed" atrial waves (most apparent in lead III) and variable atrioventricular (*AV*) block which are characteristic of atrial flutter

drugs [95, 96]. Patients with systemic illnesses, including patients with oncologic diseases, are also more prone to developing atrial fibrillation. As discussed previously, patients with WPW are predisposed to atrial fibrillation. In adult patients, AVNRT can degenerate to atrial fibrillation, and ablation of the slow pathway can eliminate atrial fibrillation, although this has not been well reported in pediatric patients [97–100].

An important consideration in atrial fibrillation is the potential for thromboembolism secondary to stasis in the atria [101]. In long-standing cases of atrial fibrillation, atrial thrombi should be excluded by echocardiography or anticoagulation performed for 2–3 weeks prior to cardioversion [86]. Electrical cardioversion is used if hemodynamic instability is present; otherwise medical cardioversion can be used. Catheter ablation has also been shown to be an effective treatment for atrial fibrillation in adolescents [85].

Atrial Flutter

Atrial flutter refers to a high-frequency atrial tachycardia with atrial waves that give continuous oscillation without flattening of the baseline [102] (Fig. 158.17). The tachycardia circuit is a macro-reentrant circuit, typically occurring in the right atrium, with areas of anatomic and functional block [69]. The anatomical block can be due to normal structures in the right atrium including the crista terminalis, tricuspid annulus, and Eustachian ridge or can be due to scars from prior atriotomy or fibrosis [69, 102]. The tachycardia circuit allows continuous atrial activation with the electrical wave front travelling around these barriers [102]. In the structurally normal heart, an atrial flutter circuit is much less likely to occur in the left atrium due to the absence of the typical right atrial anatomic barriers [102].

Atrial flutter is classified into *typical* and *atypical* variants. In typical atrial flutter the reentrant circuit encircles the tricuspid annulus and involves a narrow isthmus between the tricuspid valve and the inferior vena cava, called the cavo-tricuspid isthmus [102, 103]. The cavo-tricuspid isthmus is an area of slower conduction which allows for the reentrant substrate to occur [104]. Typical atrial flutter occurs in a counterclockwise direction, while reverse typical atrial flutter

occurs in a clockwise rotation [69, 102]. Atypical atrial flutter occurs when the tachycardia circuit differs from the typical circuit and is usually associated with a faster atrial rate [69, 103]. In the setting of congenital heart disease, an atrial flutter circuit occurring around scar, including an atriotomy scar, is typically referred to as *intra-atrial reentrant tachycardia* (*IART*) and is discussed further below.

The ECG typically shows *broad*, "*saw-toothed*" atrial waveforms (Fig. 158.17). In typical atrial flutter with counterclockwise conduction, the flutter waves are negative in the inferior leads and positive in V1. If conduction is in a clockwise direction, the flutter waves are positive in the inferior leads and negative in V1 [69]. Atrial rates in older children and adults range from 240 to 340 beats/min, with a typical atrial rate of 300 beats/min associated with 2:1 AV block resulting in a ventricular rate of 150 beats/min [69]. In infants, atrial rates are higher and have been reported to range from 350 to 580 beats/min with a mean rate of 424 beats/min [105]. The ventricular response depends on the refractory properties of the AV and His–Purkinje system, such that conduction can occur with every atrial beat (1:1 conduction) or with every second, third, or fourth beat, referred to as 2:1, 3:1, or 4:1 block, respectively. The degree of block may vary to give irregularity of the ventricular rate. The presence of irregularity of ventricular rate itself can help in making the diagnosis. With irregular ventricular rates the atrial flutter waves may be more apparent in the longer R–R intervals. The atrial flutter waves may be obscured in the presence of regular 2:1 block, in which case vagal maneuvers or administration of adenosine can make the flutter waves more apparent.

Atrial flutter occurring in the fetal or neonatal period is typically associated with a structurally normal heart [92, 105]. Presentation in the fetus or newborn is seen as tachycardia with variable block. Fetal atrial flutter is the most common type of atrial flutter in pediatrics and often resolves spontaneously. If prenatal atrial flutter is persistent, it can lead to hydrops fetalis, which is associated with risk for mortality and neurologic morbidity [106]. Fetal atrial flutter can persist into the neonatal period. Atrial flutter in neonates can be poorly tolerated and leads to hemodynamic compromise, which is more strongly associated with the duration of the arrhythmia rather than the ventricular rate [105]. After conversion to normal sinus rhythm, there is a low risk of arrhythmia recurrence in the infant age group [105]. An echocardiogram is useful despite the low incidence of structural heart disease, as a significant portion of these infants can have ventricular dysfunction [105]. Neonatal atrial flutter therefore has the potential to cause significant early morbidity but has an excellent long-term prognosis [105]. In contrast to neonates, atrial flutter occurring in older children is most often associated with an underlying cardiac abnormality [92]. Atrial flutter occurring in later childhood is more likely to be a persistent or chronic arrhythmia and does not have the same benign prognosis as neonatal atrial flutter [92].

As with atrial fibrillation, atrial thrombus formation can occur secondary to stasis in the atrium [107]. In cases of persistent atrial flutter, atrial thrombi should be excluded or anticoagulation performed prior to cardioversion [86]. Electrical cardioversion may be required in the presence of hemodynamic instability. Transesophageal pacing may also help to restore sinus rhythm [105]. Pharmacologic therapy can be used for rate control or medical cardioversion. Catheter ablation is also possible for atrial flutter.

Sinus Node Reentrant Tachycardia

Sinus node reentrant tachycardia (SNRT) is an uncommon tachycardia that can be seen in children with and without congenital heart disease [108]. It is caused by a reentrant circuit entirely within the sinoatrial node or as a circuit travelling circumferentially around the sinus node within the atrial tissue [109]. The ECG during tachycardia demonstrates a narrow complex QRS, in the absence of aberrancy or preexisting bundle branch block, with a long R–P interval. The P wave morphology is identical to the normal sinus P waves, typically upright in the inferior

leads [109, 110]. It is possible to also have a short R–P tachycardia with SNRT due to normal decremental properties of AV node conduction [110]. The history is helpful to differentiate SNRT from sinus tachycardia as patients report paroxysmal episodes with sudden onset and offset, which is less consistent with sinus tachycardia [110]. Even with demonstration of an abrupt onset of tachycardia with a normal appearing P wave, it can be difficult to differentiate from an ectopic atrial focus near the SA node. Inappropriate sinus tachycardia can usually be differentiated by history and the association with other evidence of dysautonomia [110]. Termination of SNRT is possible with the use of adenosine or vagal maneuvers [110]. Ablation is a possible management strategy, although sinus node dysfunction is a potential complication [110].

Automatic Tachycardias

Automatic tachycardias involve areas of enhanced automaticity; an arrhythmia results when the tissue is distinct from the normal pacemaker tissue, i.e., the SA node. These arrhythmias are less common than reentrant arrhythmias and are more resistant to standard pharmacologic therapy. Tachycardias included in this group include sinus tachycardia, junctional ectopic tachycardia, ectopic atrial tachycardia, and multifocal atrial tachycardia.

Sinus Tachycardia

Sinus tachycardia is defined as a rate of sinus node discharge faster than the normal for the patient's age and is the most common type of supraventricular tachycardia, though not considered an arrhythmia per se [86]. Sinus tachycardia is the result of the effects of the autonomic nervous system on the SA node, which receives both sympathetic and parasympathetic innervation. It is always important to exclude an organic cause for a persistent or inappropriate sinus tachycardia (Table 158.1). Treatment should be directed at the underlying cause of the sinus tachycardia.

Table 158.1 Etiologies of sinus tachycardia

Causes of Sinus Tachycardia
Pain
Fever
Anxiety
Anemia
Hypovolemia
Hyperthyroidism
Infection
Sepsis
Hypotension and shock
Pheochromocytoma
Myocardial ischemia
Congestive heart failure
Pulmonary embolism
Hypoxia
Stimulants (caffeine, nicotine, cocaine, amphetamines)
Medication effects (salbutamol, atropine, sympathomimetics)

Treatment to correct the heart rate alone may be harmful as the tachycardia is a compensatory mechanism to sustain cardiac output [111].

Inappropriate sinus tachycardia occurs when there is an exaggerated increase in heart rate out of proportion to the level of physiologic or pharmacologic stress [112]. Mechanisms for inappropriate sinus tachycardia include enhanced automaticity and abnormal autonomic regulation of the sinus node including excess sympathetic and decreased parasympathetic tone [112]. Some patients with inappropriate sinus tachycardia are treated with beta-blockers for symptom management [110].

Ectopic Atrial Tachycardia

This arrhythmia accounts for approximately 10 % of pediatric SVT and is the most common cause of incessant SVT in children [113]. Ectopic atrial tachycardia (EAT) is due to enhanced automaticity of non-sinus atrial foci. EAT is typically incessant, although paroxysmal and non-sustained episodes are also possible [114]. The typically incessant nature of EAT can lead to presentation with congestive heart failure or

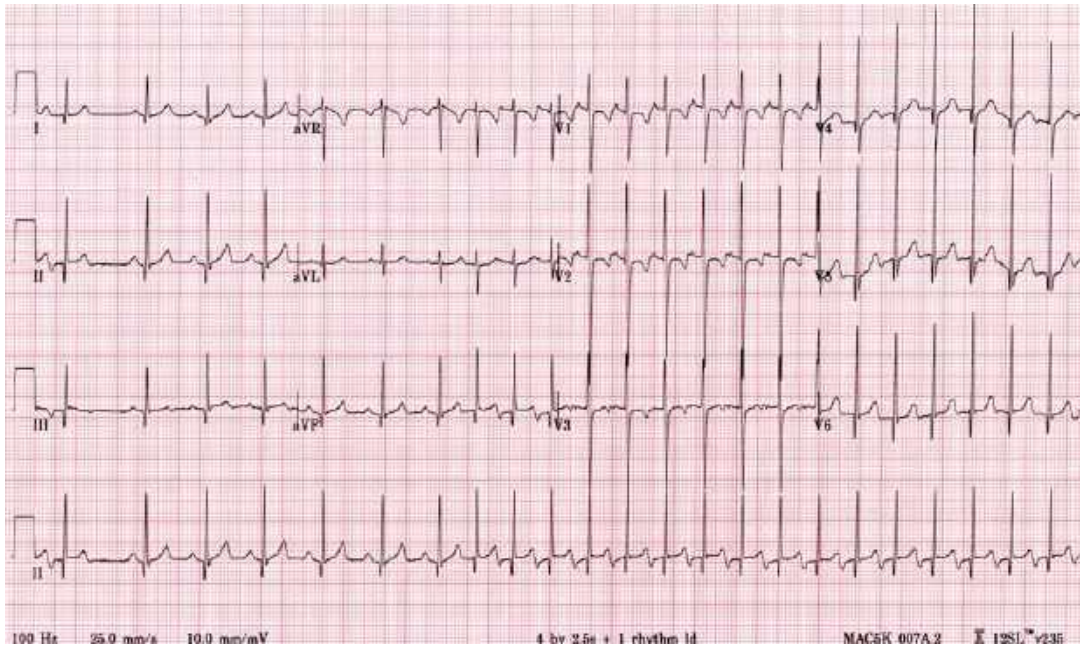

Fig. 158.18 Ectopic atrial tachycardia. The ECG initially demonstrates a normal sinus rhythm followed by an abrupt change in the P wave to give a bizarre P wave morphology from an ectopic atrial tachycardia

a tachycardia-induced cardiomyopathy, which is associated with a tachycardia rate of greater than 150 beats/min [113]. The ECG shows a narrow complex tachycardia and a P wave that differs from that seen in sinus rhythm (Fig. 158.18). The P wave morphology, often bizarre, depends on the location of the ectopic focus and will generally be monomorphic. Algorithms to localize the ectopic focus from the ECG have been developed [115]. At tachycardia initiation, there is usually a "warm-up" period with a gradual increase in the tachycardia rate. Wide variability in the tachycardia rate is seen, which differentiates it from a reentrant mechanism. First or second degree AV block can also be seen, with higher degrees of AV block not causing interruption of the atrial rhythm. Administration of adenosine shows the atrial impulses continuing at the same cycle length despite AV node blockade [113]. Differentiation from PJRT can be difficult, as described above. As with other automatic tachycardias, EAT displays overdrive suppression, catecholamine responsiveness, and inability to terminate with direct current cardioversion or vagal maneuvers.

The ectopic foci in children may occur in the right atrium, left atrium, or atrial appendages, and multiple ectopic foci are common [113]. Children with EAT may be symptomatic or asymptomatic. EAT should be suspected when a patient presents with an inappropriately elevated heart rate for the child's age, variable AV block, or a bizarre P wave or P wave axis. Children who present at less than 3 years of age are more likely to have spontaneous resolution of EAT and more likely to achieve control of the tachyarrhythmia using antiarrhythmics than children presenting after the age of 3 years [114]. Spontaneous resolution occurs in approximately 70 % of patients presenting at a younger age and in only 30 % of older children [114]. Arrhythmia control, particularly in older children, may be difficult with antiarrhythmics alone, and ablation may be necessary for definitive treatment [114]. EAT can also occur as a postoperative rhythm in children undergoing cardiac surgery for congenital heart disease. Risk factors for postoperative EAT may include younger age, lower preoperative oxygen saturations, increased inotropic support, longer cross-clamp and cardiopulmonary

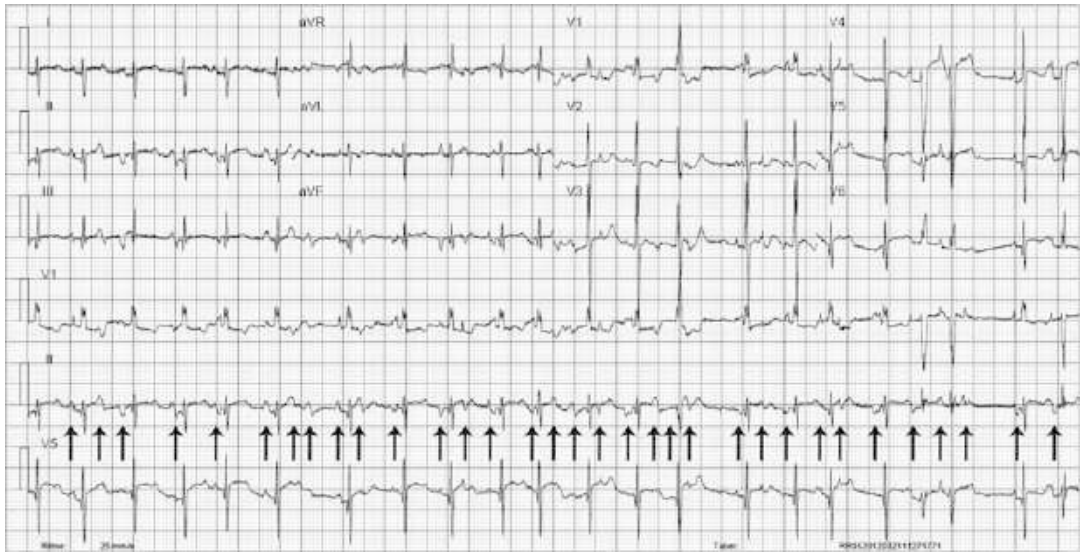

Fig. 158.19 Multifocal atrial tachycardia. As is characteristic of this tachycardia, multiple P wave morphologies (indicated by the *arrows*) with irregular P–P, P–R, and R–R intervals are seen

bypass times, and atrial septostomy [116]. Most patients with postoperative EAT have sporadic episodes and did not experience a hemodynamic deterioration [116].

Multifocal Atrial Tachycardia

Multifocal atrial tachycardia (MAT) is a rare arrhythmia in children that is characterized by organized, discrete, non-sinus P waves of at least three different morphologies in the same electrographic lead (Fig. 158.19) [117]. The P–P, P–R, and R–R intervals are typically irregular, and the baseline between P waves is isoelectric [117]. The mechanism of MAT is incompletely delineated and may be related to multiple atrial ectopic foci or a single focus with varied propagation of the P wave [118].

In adults, this arrhythmia is seen in elderly patients who have severe pulmonary or cardiovascular disease [117]. MAT in children is associated with respiratory illnesses and structural heart disease but less frequently than is seen in adults. Patients with Costello syndrome also have a high risk of developing MAT [119]. The majority of children with MAT have structurally normal hearts [118]. Atrial rates can be up to 500 beats/min with ventricular rates of 150–300 beats per minute [120]. Although it can cause hemodynamic compromise, this arrhythmia frequently causes mild symptoms and few sequelae [118]. The majority of pediatric patients are diagnosed before the age of 1, and tachycardia may be initially recognized prenatally [118]. In most cases, MAT resolves spontaneously during follow-up [118]. Antiarrhythmic medications may be used in symptomatic patients, while asymptomatic patients may not require treatment. Successful treatment with radiofrequency ablation has been reported [118]. Direct current cardioversion is ineffective for termination of MAT.

Junctional Ectopic Tachycardia

Junctional ectopic tachycardia (JET) is a rare arrhythmia which predominately occurs in the pediatric population. It is caused by enhanced automaticity of a focus within the AV node or in the proximal bundle of His. The most common clinical situation in which JET occurs is as a postoperative arrhythmia. Less commonly, JET can occur as an incessant congenital

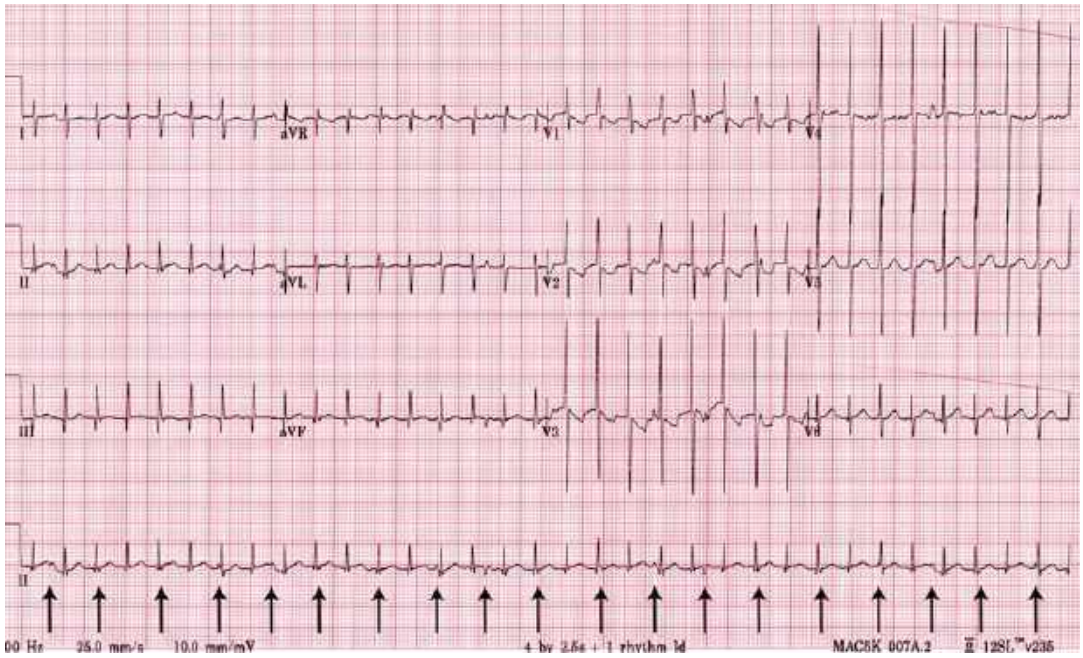

Fig. 158.20 Junctional ectopic tachycardia. The ECG demonstrates the characteristic narrow complex tachycardia with atrioventricular (*AV*) dissociation. The arrows indicate the dissociated P waves

arrhythmia or can occur outside of the neonatal period as an episodic or sustained arrhythmia [121]. The heart rate typically ranges between 140 and 300 beats/min [122]. This arrhythmia usually presents with a narrow QRS tachycardia and AV dissociation, with the ventricular rate exceeding the atrial rate (Fig. 158.20). As with all SVTs, the QRS may be wide due to an underlying bundle branch block or rate-related aberrancy. Some irregularity of the heart rate may be present secondary to sinus capture beats. In younger children, the AV node can retrogradely conduct rapid junctional rates, and AV dissociation may not be present [122]. If AV dissociation is absent and the diagnosis is in question, adenosine can be administered which will lead to continuation of JET and loss of retrograde AV node conduction [122]. JET displays the clinical features common to automatic tachycardias including "warm-up" in the rate with arrhythmia initiation, responsiveness to catecholamines, overdrive suppression, and lack of effect of direct current cardioversion [122]. Similar to AVNRT, JET may also present with anterograde 2:1 AV block if the block occurs below the level of the ectopic focus. Differentiation from other arrhythmias, including sinus tachycardia with first degree AV block or ventricular tachycardia, is essential to appropriate patient management.

Approximately 1–11 % of postoperative courses for congenital heart surgery are complicated by JET [123]. JET typically occurs within 24–48 h after congenital heart surgery and resolves after 2–4 days [122]. Surgical procedures in the vicinity of the AV node including tetralogy of Fallot repair, closure of VSDs, AVSD repair, and other complex surgical procedures are at increased risk of developing JET. Surgeries in these areas can lead to damage of components of the AV node, bundle of His, or AV node artery to give changes in the cell membrane ionic integrity which can lead to enhanced automaticity [122]. JET can also occur after arterial switch for transposition of the great arteries, which may be due to a reperfusion injury of the nodal area associated with coronary artery relocation [122, 123]. Other risk factors include young age at the time of repair, a longer duration of cardiopulmonary bypass,

and high inotropic requirements [113, 123]. Despite being a transient rhythm, the elevated heart rate and loss of AV synchrony in the setting of a compromised postoperative heart can lead to life-threatening hemodynamic compromise. JET has been associated with an increased length of stay in the ICU and increased mortality [123]. Slowing the ventricular rate and reestablishing AV synchrony are key components in the treatment of JET. Treatment strategies include limiting adrenergic stimuli, minimizing inotropes, correcting electrolyte disturbances, systemic cooling, overdrive atrial pacing to reestablish AV synchrony, and the use of pharmacologic agents to decrease the ventricular rate.
