Junctional ectopic tachycardia can also occur in a structurally normal heart in the absence of cardiac surgery. These children can be asymptomatic or can present with cardiac failure or cardiogenic shock [113]. Congenital JET usually presents in infancy and is associated with a high morbidity and mortality [121, 124]. The initial presentation of congenital JET may occur in fetal life and can be associated with hydrops [121, 124]. JET presenting beyond the first 6 months is associated with a slower heart rate and appears to have a more favorable course [121]. JET is more likely to be an incessant tachycardia if it presents within the first 6 months of life and is more commonly sporadic if presenting at greater than 6 months of age [121]. Non-postoperative JET is associated with a positive family history in 20–50 % of cases [113, 121, 124]. This arrhythmia may be resistant to pharmacologic treatment and can require ablation for definitive treatment, which carries a risk of complete heart block [121]. A small proportion of patients with non-postoperative JET may have spontaneous resolution or may have a decrease in the JET heart rate and be able to wean off of antiarrhythmic mediations with time [121].

Congenital Heart Disease and Arrhythmia Substrates

Children and adults with congenital heart disease are at increased risk of SVT. Intrinsic malformations of the conduction system, structural cardiac abnormalities, and the hemodynamic effects of these structural abnormalities contribute to the propensity for arrhythmias. After surgical repair or palliation, patients may be further predisposed to SVT secondary to hemodynamic abnormalities and the presence of suture lines and scarring (Fig. 158.21). This section will outline the anatomic substrates leading to the propensity for development of SVT in congenital heart disease.

Abnormalities of the annulus fibrosis of the AV junction can lead to the presence of accessory pathways which predispose these patients to reentrant arrhythmias (see Wolff–Parkinson–White above). Ebstein's anomaly is characterized by displacement of the septal leaflet of the tricuspid valve and is associated with accessory pathways in approximately 30 % of patients [125–127]. One-third of patients with Ebstein's and AVRT have multiple accessory pathways [126]. In congenitally corrected transposition of the great arteries (CCTGA), the morphologic tricuspid valve is Ebsteinoid in 15–50 % of patients, which increases the risk of accessory pathways in this subset of patients [125]. Accessory pathways and WPW syndrome have also been seen in many other types of CHD including heterotaxy syndromes, AV septal defects, functionally univentricular hearts, ventricular septal defects, atrial septal defects, left-sided obstructive lesions, tetralogy of Fallot, and transposition of the great arteries [10, 128]. Patients with CHD and accessory pathways are at risk of developing AVRT.

A rare accessory connection called the Mönckeberg sling is seen exclusively in congenital heart disease. In 1913, Mönckeberg first described the presence of two distinct AV nodes, His bundles, and bifurcating ventricular bundles in complex CHD [129, 130]. The Mönckeberg sling exists when there are two AV nodes with distinct His bundles that are connected by a sling of conduction tissue [131]. This unique abnormality of the conduction system predisposes patients to reentrant tachycardia utilizing one AV node as the anterograde limb and the other as the retrograde limb. Twin AV nodes with a Mönckeberg sling are classically

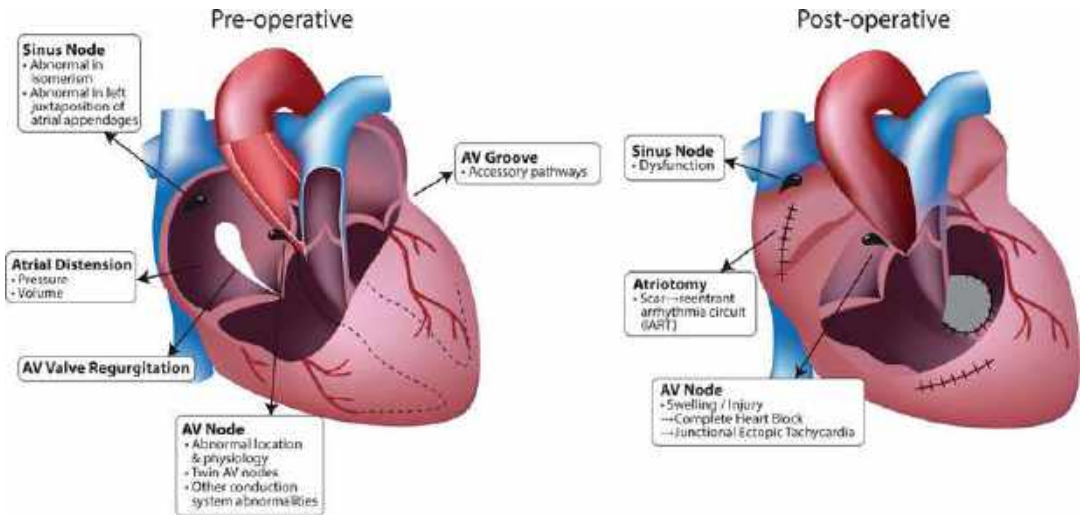

Fig. 158.21 Anatomic substrates predisposing patients with congenital heart disease to the development of supraventricular tachycardia (*SVT*) in preoperative and postoperative states

seen in right atrial isomerism where duplication of the morphologic right atrium frequently leads to the presence of two distinct SA and AV nodes [132]. A Mönckeberg sling can also be seen in other types of complex CHD including left atrial isomerism, CCTGA, and double outlet right ventricle with AV concordance or AV discordance [129]. The presence of a Mönckeberg sling should be considered in patients with complex congenital heart disease, two discrete and non-preexcited QRS morphologies, and a history of SVT which is consistent with AVRT.

Hemodynamic abnormalities that lead to atrial dilatation can predispose patients with CHD to atrial flutter or fibrillation. Fibrosis and dilation of the atria can lead to functional reentry due to altered conduction properties (as described above) and the development of atrial flutter or fibrillation. Right atrial dilation predisposes patients to atrial arrhythmias in Ebstein's anomaly and atrial septal defects. Atrial fibrillation can also be seen in lesions causing hemodynamic stress on the left atrium, including aortic stenosis, mitral valve abnormalities, and unrepaired functionally univentricular hearts [133]. Other causes of atrial fibrillation include tricuspid atresia, rheumatic heart disease, and AV valve regurgitation [86]. Persistent atrial flutter and fibrillation are the most common causes of tachycardia-induced cardiomyopathy and have the propensity to lead to hemodynamic compromise in CHD [134].

In patients with surgical repair or palliation for CHD, conduction barriers caused by scarring and suture lines can lead to the development of reentrant arrhythmias (as discussed above). The most common type of supraventricular arrhythmia in CHD is intra-atrial reentrant tachycardia (IART) (Fig. 158.22). The macro-reentrant circuit in IART occurs in the atrial muscle in the presence of functional and fixed barriers including scar tissue, suture lines, and the typical anatomic structures implicated in atrial flutter [20]. Residual hemodynamic abnormalities can lead to deterioration of cardiac function as well as pressure and volume loading which can also predispose patients to the development of IART [135]. The specifics of the reentrant circuits can differ between patients due to the variability in the location of scars, suture lines, and fibrosis based on the specific type of congenital heart disease and the interventional procedures performed. Due to this variability, the ECG appearance of this arrhythmia is not uniform. IART is the most frequent symptomatic arrhythmia in the adult congenital heart disease

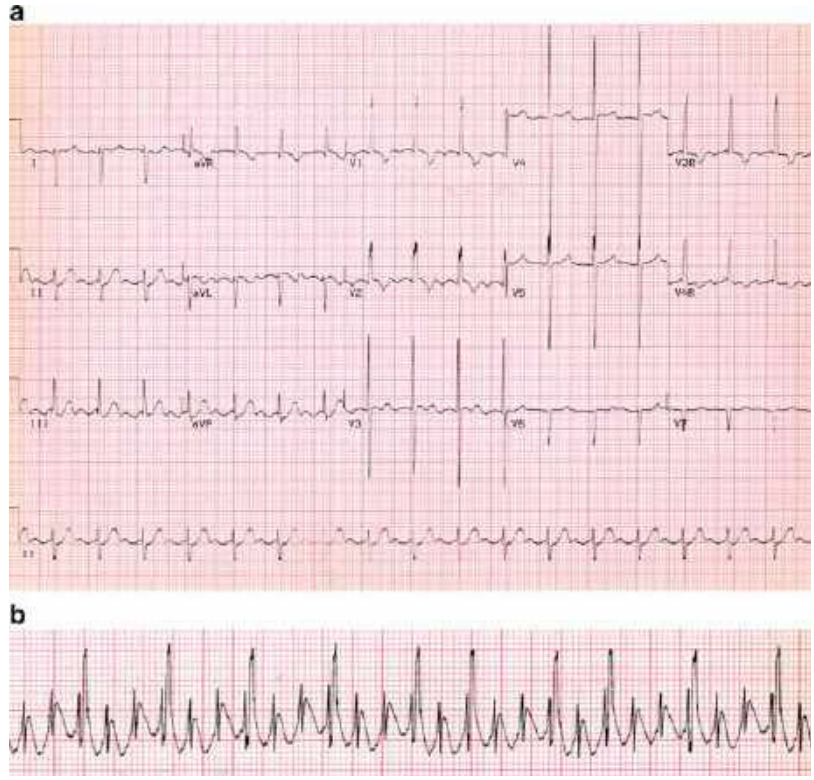

Fig. 158.22 Intra-atrial reentrant tachycardia (IART). (**a**) IART in a patient with a Mustard atrial switch operation. The flutter waves can be seen, particularly in leads V2 and V4R, but are subtle. (**b**) An atrial wire study in the same patient seen in (**b**) shows clear flutter waves and variable block in lead V1

population [135]. The atrial activity is usually slower than in typical atrial flutter and ranges from 130 to 230 beats/min [20]. The slower atrial rate increases the likelihood of 1:1 AV conduction in comparison to typical atrial flutter [20]. The incidence of IART is increased in patients with Mustard and Senning procedures, Fontan connections, atrial septal defect repairs, tetralogy of Fallot, and Ebstein's anomaly [20, 135]. IART can lead to hemodynamic compromise in patients with congenital heart disease, especially in the setting of the Fontan circulation or with residual hemodynamic abnormalities [20]. Conversely, IART may be a symptom of worsening hemodynamics, and these patients should have a full assessment to identify potentially correctable abnormalities [20]. The presence of atrial tachycardias in patients with congenital heart disease has been associated with sudden death [136]. Patients with IART and congenital heart disease are at particular risk of thrombus formation, which has been documented in 42 % of patients with congenital heart disease and non-fibrillation atrial arrhythmias [20, 137]. Prior to cardioversion, the presence of atrial thrombi must be excluded or anticoagulation performed [86]. If the patient is hemodynamically unstable, electrical cardioversion may be required. Catheter ablation is available with high acute success rates in IART, however, recurrence rates are high, particularly in patients with a Fontan circulation [20].

Ventricular Tachycardiac and Sudden Arrhythmic Death

159

Georgia Sarquella-Brugada, Oscar Campuzano, Antonio Berruezo, and Josep Brugada

Abstract

Ventricular tachycardia is rare in children and is typically associated with a structurally normal heart, although those presenting with VT require careful evaluation for early manifestations of underlying cardiac disease. Ventricular tachycardia is well described in infancy, and although symptoms are less common compared to older children, it may be incessant leading to ventricular dysfunction. Infantile ventricular tachycardia usually shows a left bundle branch block morphology suggesting a right ventricular origin in 86 % of cases and shows a high rate of spontaneous resolution.

Sudden death syndrome in children is defined as the natural and unexpected event that occurs in an apparently healthy infant or young child or whose disease was not severe enough to predict a fatal outcome, and in which a thorough postmortem examination fails to demonstrate an adequate cause of death. Sudden death syndrome affects pediatric population with an individual risk of 1–3 per 100,000 person-year. It accounts for 10 % of infant mortality in the first year of life. It is a disorder with many mechanisms resulting in or predisposing to its development, including infections and several genetic abnormalities. In the last 20 years, the advance in genetics of sudden death has been tremendous and has

identified hundreds of mutations in several genes encoding cardiac proteins. The majority of sudden death syndrome cases in this population are due to hereditary and congenital cardiac channelopathies, cardiomyopathies, coronary artery anomalies, and/or aortic root dissection.

This chapter will provide an overview of the ventricular tachycardia and sudden death syndrome.

Ventricular Arrhythmias

Ventricular tachycardia (VT) is rare in children representing only 1.8 % of children undergoing electrophysiological study (EPS) [1]. VT in children is typically associated with a structurally normal heart, although those presenting with VT require careful evaluation for early manifestations of underlying cardiac disease.

Ventricular tachycardia is well described in infancy, and although symptoms are less common compared to older children (22 % vs. 34 %), it may be incessant leading to ventricular dysfunction. Infantile VT usually shows a left bundle branch block morphology suggesting a right ventricular origin in 86 % of cases and shows a high rate of spontaneous resolution (89 %).

Accelerated Idioventricular Rhythm

Typically seen in infants, this is normally a benign type of tachycardia characteristically running at a slightly faster frequency than the sinus rates with the left or right bundle branch morphology and QRs duration below 100 ms. No treatment is required (Fig. 159.1).

Outflow Tract Ventricular Tachycardia

Outflow tract VT most frequently originates from the right ventricular outflow tract (VT with left bundle branch blocklike pattern and inferiorly directed axis, Fig. 159.2) and less commonly the left (typically left aortic sinus cusp – VT with a QRS morphology showing a dominant r wave in lead V2 and inferior axis, Fig. 159.3) [2]. The mechanism is usually an adrenergically mediated triggered activity caused by cyclic adenosine monophosphate (cAMP) induced afterdepolarizations that are sensitive to fluxes in intracellular calcium. Due to antagonism of cAMP by adenosine, outflow tract VT is typically adenosine sensitive. Symptoms range from absent to severe including syncope and ventricular dysfunction [3].

These types of right ventricular outflow tract VT should be differentiated from those seen in arrhythmogenic right ventricular cardiomyopathy (ARVC) which may at times be

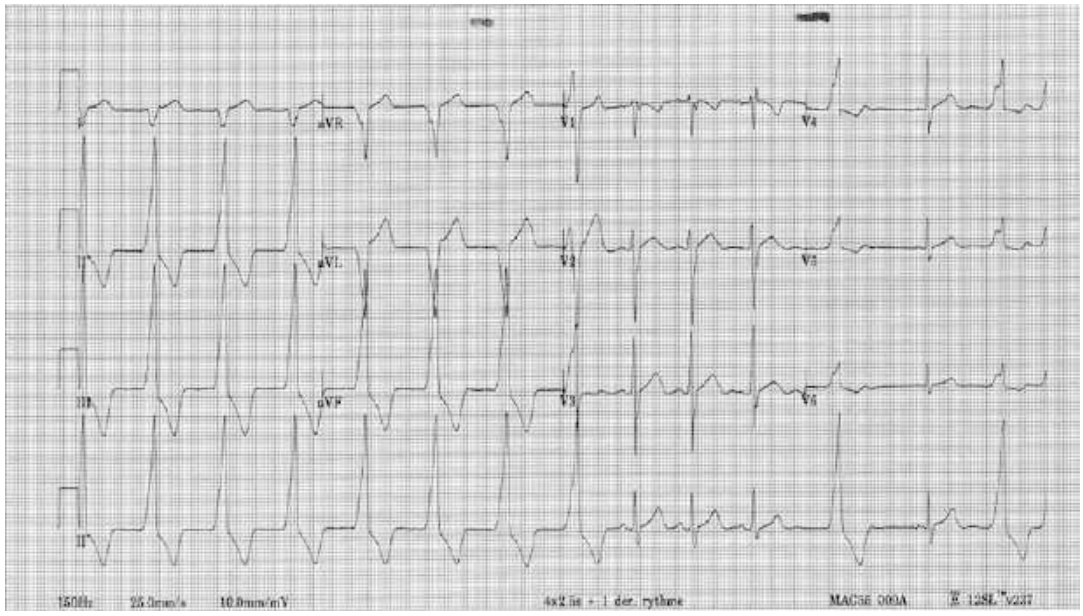

Fig. 159.1 12-lead ECG showing idioventricular rhythm: sinus rhythm alternates with slightly wide QRS complexes not preceded by P wave at a faster rate than sinus rhythm

difficult if based solely in the QRS configuration during VT.

When symptomatic, medications such as beta-blocking agents or calcium channel blockers are usually sufficient to control the arrhythmia. Ablation should be considered in case of failure to control symptoms.

Fascicular Ventricular Tachycardia

Fascicular VT is a reentrant arrhythmia that involves the fascicles of the left bundle branch, typically posterior (Fig. 159.4), but in rare cases anterior, producing the right bundle branch block QRS morphology and the left superior or right inferior axis during VT, respectively. The QRS during VT is usually no more than 140 ms width because of the fast depolarization of the ventricles through the fascicles. Fascicular VT is highly sensitive to verapamil, one of the identifying characteristics of this arrhythmia, suggesting a calcium-dependent mechanism. Similar to outflow tract VT, symptoms in children may be absent or include syncope and tachycardia-induced ventricular dysfunction.

Fascicular tachycardia can be controlled in some cases by using beta-blockers, verapamil (used with caution in infants), and amiodarone. If uncontrolled, catheter ablation is a highly successful alternative.

Bidirectional Ventricular Tachycardia

Bidirectional ventricular tachycardia (BiVT) is the hallmark arrhythmia of catecholaminergic polymorphic ventricular tachycardia (CPVT), although it may also be seen in Andersen–Tawil syndrome and digitalis toxicity. BiVT results from delayed afterdepolarization-induced triggered activity occurring alternatively in the Purkinje fibers of the right and left bundle branches [4]. The surface ECG displays a characteristic pattern beat-to-beat 180° alteration in QRS polarity consistent with the alternate sites of Purkinje fiber activation (Fig. 159.5).

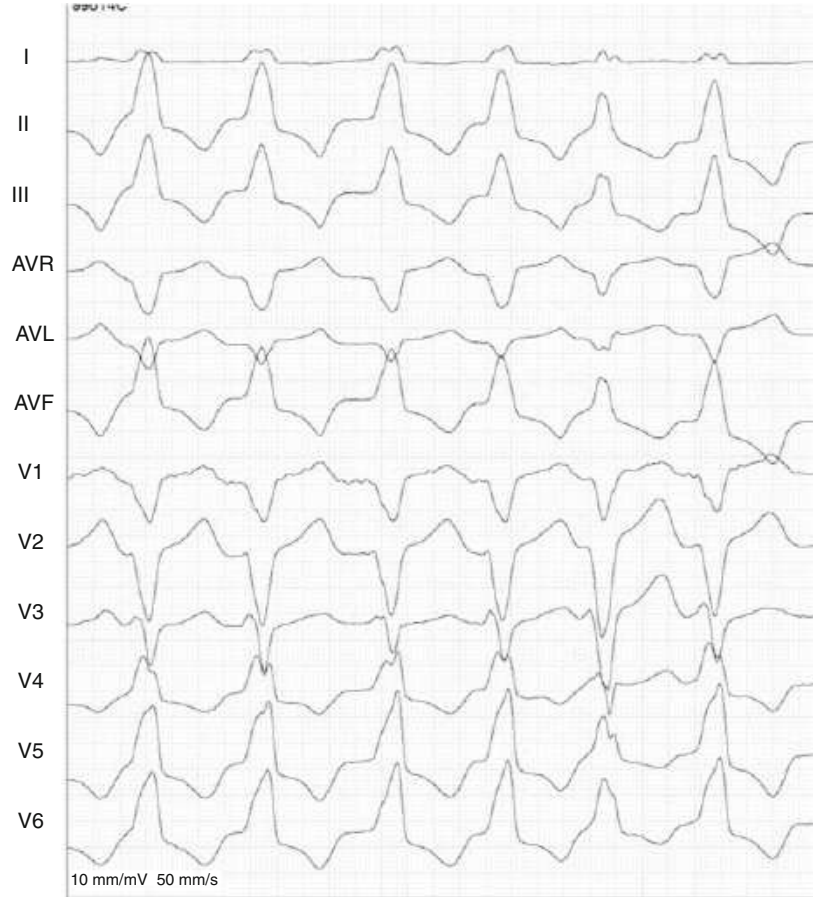

Fig. 159.2 12-lead ECG with right ventricle outflow tract tachycardia with left bundle branch block and inferior axis

Idiopathic Ventricular Tachycardia

Idiopathic ventricular extra beats are very common in children, with a bimodal peak in neonates and adolescents. These extra beats are considered benign if they disappear with exercise. When they are symptomatic, they can be controlled with beta-blockers (propranolol 2 mg/kg/day), calcium channel blockers, or in severely symptomatic cases flecainide 2–4 mg/kg/day and eventually ablation [3, 5, 6]

Sustained VT is very rare in normal hearts. Thus, deep research has to be made in order to rule out the underlying cause. Degeneration of idiopathic ventricular tachycardia into ventricular fibrillation or sudden death essentially does not generally occur, but certain patients may suffer from syncope or heart failure.

Torsade des Pointes

Torsade des pointes (TdP) is a polymorphic VT characterized by a QRS morphology that appears to rotate around an imaginary baseline and is typically associated with congenital long QT syndrome in children [7] (Fig. 159.6). Torsade frequently terminates spontaneously, due to either the development of further functional conduction block or wave front collision within ventricular myocardium.

Ventricular Arrhythmias in Congenital Heart Disease

Isolated ventricular premature beats frequently occur in the early period after cardiac surgery, often as a result of hypokalemia. *Sustained*

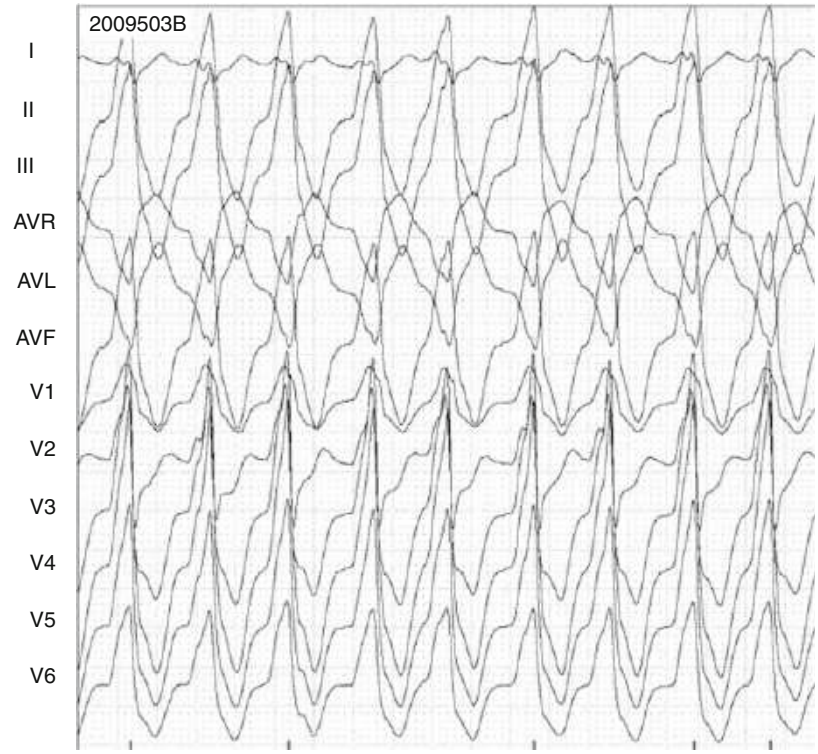

Fig. 159.3 12-lead ECG with left ventricle outflow tract tachycardia with prominent R waves in V2 and inferior axis

ventricular tachycardias are rare, and they commonly arise in the setting of myocardial ischemia or myocardial infarction. VT is facilitated by disruption of the ventricular myocardium caused by (1) areas of scar due to the ventriculotomy, (2) fibrotic tissue as a result of long lasting cyanosis, or (3) valvular regurgitation causing ventricular dilatation. Ventricular tachycardias are mainly observed after correction of tetralogy of Fallot [8] – which on long-term suffers from VT in up to 12 % of patients and with a sudden death rate of nearly 8 % at 21 years of follow-up [9] – but also the left ventricular outflow tract defects; nonetheless, these arrhythmias also arise in other types of congenital defects such as transposition of the great arteries, univentricular hearts, double outlet right ventricle, and ventricular septal defects. Risk factors for developing sustained ventricular tachycardia are older age at the time of surgery, longer duration of postsurgical follow-up, poor hemodynamic status, and prolongation of the QRS complex.

Minimally, symptomatic ventricular extra beats should be treated with beta-blockers. Severely symptomatic patients and/or inducible VT are considered for ablation with acute success rates from 50 % to 100 %, recurrence rates from 9 % to 40 % in a mean follow-up period from 30.4 to 45.6 months [3, 10, 11].

Antiarrhythmic drugs with a low risk for proarrhythmias (amiodarone) may be indicated for the prevention of arrhythmia recurrence following catheter ablation or as an adjunctive treatment to an internal cardioverter/defibrillator (ICD).

Antiarrhythmic Drug Therapy in Children with Documented Wide QRS Tachycardia

Ventricular tachycardia (VT) affects all age groups, including newborns and small children. Potentially detrimental, VT should always be

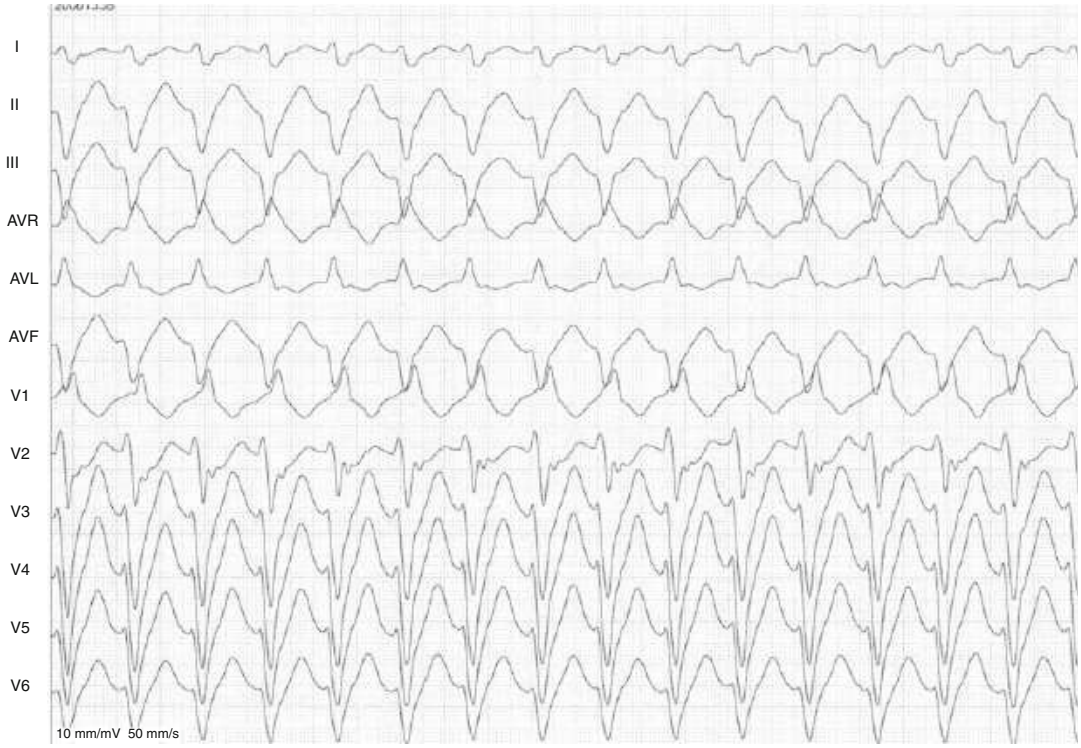

Fig. 159.4 12-lead ECG with left posterior fascicular tachycardia with right bundle branch block and left superior axis. Note QRS duration below 140 ms

considered when facing any wide QRS tachycardia and treatment should be directed as for VT unless proven otherwise, as the potential harm of treating an SVT as a VT is very little compared to the converse.

Sustained wide QRS tachycardia requires immediate treatment. If the patient is hemodynamically unstable, electric cardioversion is always the first therapeutic option, at a starting energy of 1–2 J/kg body weight. The energy should be doubled for each attempt if electric cardioversion is unsuccessful.

If the patient is stable, pharmacological treatment can be tried, starting with a bolus injection of lidocaine followed by an infusion. If ineffective, mostly in reentrant VTs, the next step is a loading dose of amiodarone, followed by an infusion. As an alternative to amiodarone, one may try esmolol in bolus together with magnesium sulfate provided that antidromic conduction through an accessory AV pathway has been excluded. Electrical cardioversion should always be considered even in stable patients.

Sudden Arrhythmic Death

Sudden death syndrome (SDS) in children is defined as the natural and unexpected event that occurs in an apparently healthy infant or young child or whose disease was not severe enough to predict a fatal outcome, and in which a thorough postmortem examination fails to demonstrate an adequate cause of death [12]. Despite these attempts, the definitions and protocols used for diagnosing SDS still remain a diagnosis of exclusion [12].

SDS affects pediatric population (fetus, newborns, children, and adolescents), with an individual risk of 1–3 per 100,000 person-year [13–15].

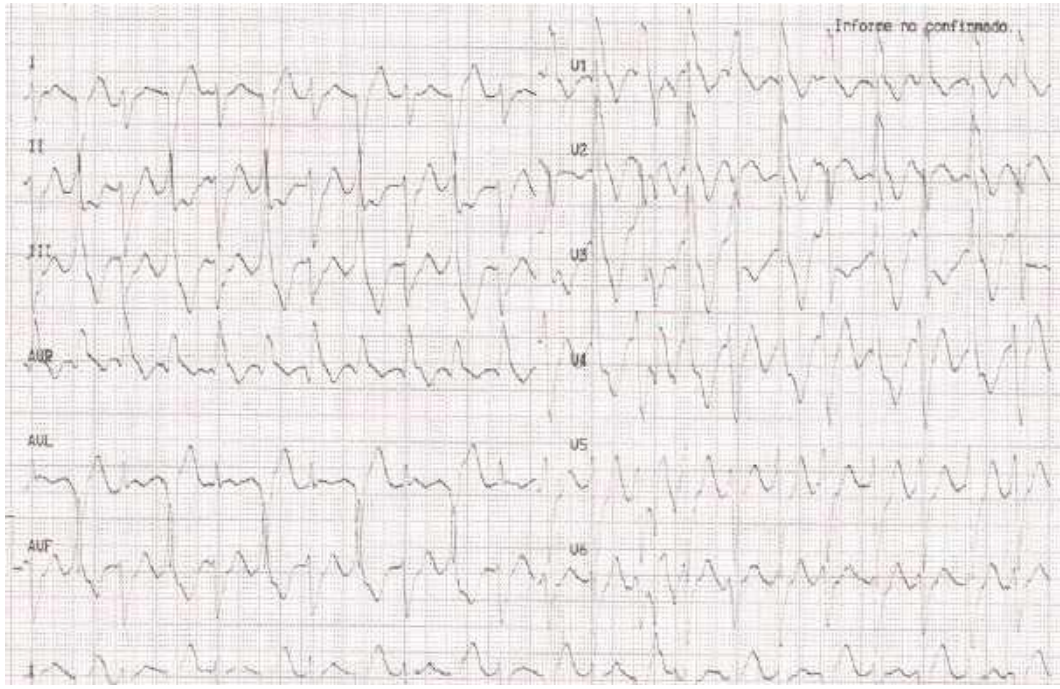

Fig. 159.5 12-lead ECG with bidirectional ventricular tachycardia, beat-to-beat 180° alternation in QRS polarity

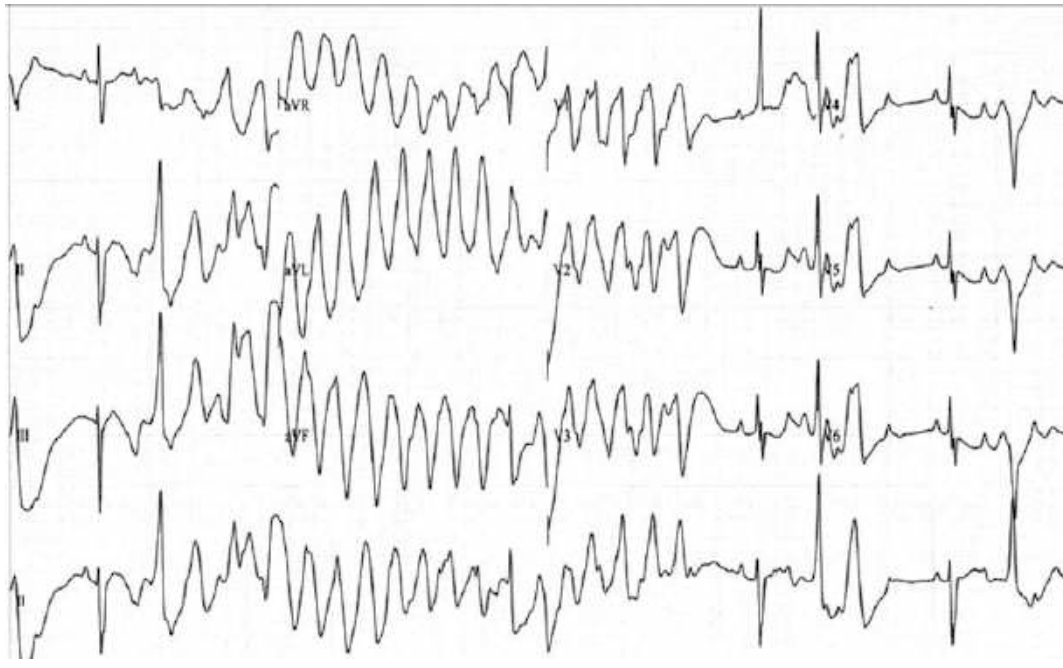

Fig. 159.6 12-lead ECG with Torsade des pointes, polymorphic ventricular tachycardia that appears to rotate around an imaginary line

It accounts for 10 % of infant mortality in the first year of life [12, 16–19]. The number of quality-adjusted years of life lost is considerable, as most of these victims would have been expected to have a normal life expectancy with a minimum of symptoms with the optimal treatment.

SDS is a disorder with many mechanisms resulting in or predisposing to its development, including infections and several genetic abnormalities [20]. In the last 20 years, the advance in genetics of sudden death has been tremendous and has identified hundreds of mutations in several genes encoding cardiac proteins. The majority of SCD in children and young people are due to hereditary and congenital cardiac channelopathies, cardiomyopathies, coronary artery anomalies, and/or aortic root dissection [19, 21].

There are various elements necessary to achieve coordinated cardiac activity responsible for transmitting electrical and mechanical impulse through the cardiac myocytes, including ionic currents, ion channels, and structural proteins. The complexity of this process remains the major limitation for understanding arrhythmogenesis [22]. Functional analysis of ion channels has enabled a better understanding of basic arrhythmogenic mechanisms, but it was not until the development of genetics and the discovery of disease-causing mutations in families when it has been extrapolated from basic science to clinical practice [23].

Channelopathies

Channelopathies are heart diseases induced by mutations in genes encoding cardiac ion channels. It is not associated with structural cardiac abnormalities and its first manifestation may be SCD. Moreover, some of these diseases are not accompanied by changes in the electrocardiogram (ECG), which makes it a more difficult diagnosis. Given that these diseases are determined by a genetic defect, it is hoped that genetic testing can contribute substantially to the diagnosis, prevention, and treatment.

In 1976, the first association between sudden infant death syndrome (SIDS) and a cardiac disorder, the long QT syndrome was published [24, 25]. Since this association, genetic and/or clinical correlations between channelopathies and SIDS have been found in several studies [26]. To date, up to 35 % of cases of SCD in young people may be caused by a genetic mutation in ion channels [27].

Long QT Syndrome

Long QT syndrome (LQTS) is a clinically and genetically heterogeneous cardiac channelopathy with a prevalence of 1 in 2,500 individuals. It is characterized by a prolongation of the QT interval (QTc $>$ 480 ms) (Fig. 159.7). The clinical presentation can be variable, ranging from asymptomatic patients to episodes of syncope and SCD due to ventricular tachyarrhythmias (*torsade de pointes*) in the setting of a structurally normal heart in otherwise healthy individual [28, 29]. Due to the ability to identify the individuals at risk through ECG analysis, massive population screening by ECG has been performed in certain regions, with success of lowering rates of SCD among infants and athletes [30–33]. LQTS is a major cause of SCD among young people [26], and recent progress in molecular biology has clarified that LQTS partly contributes to SIDS [18, 34].

LQTS can be congenital or acquired, the latter being a consequence of QT-prolonging drugs and less frequently heart block and myocardial infarction [35]. The congenital form is associated with mutations in ion channels and/or associated proteins. Inheritance of LQTS can follow an autosomal dominant (Romano–Ward syndrome) or recessive (Jervell and Lange–Nielsen syndrome) transmission pattern. To date, more than 600 mutations and splice-site-altering mutations have been identified in 14 LQTS-susceptibility or LQTS overlap-susceptibility genes (Table 159.1) [36]. Approximately a 75 % of clinically definite LQTS are caused by mutations in 3 genes: *kcnq1* (LQT1), *kcnh2* (LQT2), and *scn5a* (LQT3). The remaining 25 % have been identified in a variety of ion channels or channel-interacting proteins [37]. The most common

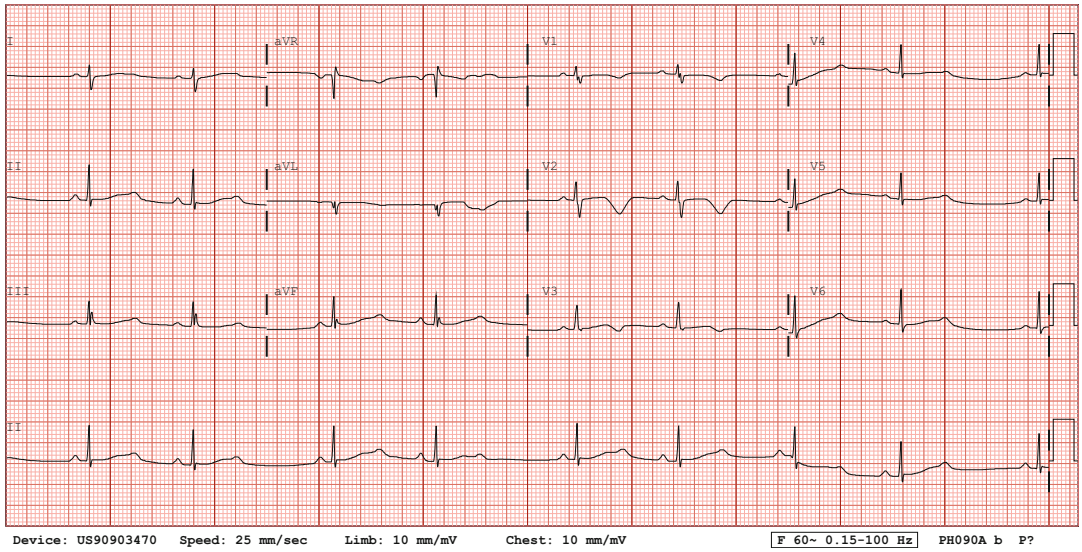

Fig. 159.7 12-lead ECG with long QT interval in a patient with long QT 2

form, LQTS type 1, caused by mutations in *kcnq1* is responsible for 40–50 % of the cases of prolonged QT interval [38, 39]. It was also described the gene *kcnh2* (*hERG, human-ether-à-go-go-related*) that codifies the α-subunit of Ikr. The mutations in this gene suppose a 35–45 % of cases (LQTS type 2) [40, 41]. The β-subunit is codified by *kcne2* (MiRP1 protein); the mutations in *kcne2* gene induce LQTS type 6, a rare type (<1 %) that also induces a loss of function. Another gene is *kcne1*, responsible for 2–5 % of cases (LQTS type 5), which can alter both Iks and Ikr [42]. The *kcnj2* gene is also implicated in LQTS. It codifies Kir2.1 protein; the mutations are associated with loss of function (LQTS type 7 or Tawil–Anderson syndrome). The incidence is very low and infrequently is associated with SCD [43]. Recently, *kcnj5* gene (Kir3.4 – also named GIRK4) has been associated with LQTS (LQTS type 13). The mutation induces a loss of function [44]. Mutations in the LQTS give rise especially to a gain of function in the sodium current (inappropriate prolonged entry of Na^+ into the myocyte), by mutations in *scn5a* (LQTS type 3), the third gene most prevalent in LQTS [45, 46]. Mutations in this gene induce gain of function. The LQTS type 10 is caused by mutations in *scn4b* that codifies for β-subunit of sodium cannel (NaVβ4). The β-subunit plays a key role both in the kinetic regulation and in the α-subunit expression of the sodium channel [47]. In 2008, mutations in *snta-1* gene were associated to LQT (type 12) thought a gain of function of the fast sodium channel [48, 49]. It encodes alpha-1-syntrophin protein. The LQTS type 9 is caused by mutations in *Cav3* gene [50]. Mutations in this gene induce gain of function of sodium channels, similar as LQTS type 3. Calcium channels are also associated with LQTS. Type 8 LQTS (Timothy syndrome) has been described with a mutation in the *cacna1c* gene that encodes the pore (Cav1.2) of the L-type cardiac calcium channel. This type of LQTS is uncommon, but it has the highest associated mortality. The mutation induces an enhanced function with Ica abnormality and loss of the channel dependent voltage, leading to a prolongation of the action potential [51, 52]. This gives rise to an ECG with an extremely long QT interval. Recently, a long QT interval was also associated with a patient that showed a mutation in the cardiac ryanodine receptor gene *ryr2* [53]; however, further studies were required in order to clarify this case report. Type 11 LQT is a disorder of the QT interval caused by a mutation (S1570L) in *akap9* gene, which

encodes the protein kinase-A anchor protein-9 (chromosome 7q21-q22). The severity of this type of QT may vary; the most common symptoms are angina, partial or total loss of consciousness, and in some cases the SCD [54]. There are other genes as *ank2* (chromosome 4, 4q25-27), which is involved in type 4 LQT syndrome. Although not specific to a channel, it is included in the group of channelopathies. This gene encodes the protein ankyrin-B which is to adapt different structures in the cell membrane as the Na/K ATPase, Na/Ca, and inositol triphosphate receptor. A decrease in the role of ankyrin-B alters calcium homeostasis prolonging repolarization and fatal ventricular arrhythmias is generated [55–57]. The syntrophins are cytoplasmic proteins that are part of the protein complex associated with dystrophin.

How to Follow a Child with Long QT Syndrome

In all patients, adults [58] and children [29], beta-blocker administration at high doses is highly recommended. The dose is adjusted according to the medical tolerance to these drugs [59]. However, controversy exists regarding the efficacy of cardioselective β-blockers such as atenolol [60–64].

Despite β-blockade, some patients may remain at risk as they persist symptomatic. Different strategies have been proposed: despite ICD implantation, some may consider left cardiac sympathetic neural denervation [65]. Defibrillator implantation is mandatory for those patients having had an aborted SCD and for those at risk of fatal arrhythmias [66, 67]. Avoidance of QT-prolonging drugs is crucial for these patients (www.torsades.org). Intense exercise and water activities should be contraindicated in all types of LQTS [23]. For those patients with long QT syndrome, exercise should be limited to recreational activity.

Study of the Relatives of a Patient with LQT

In patients with LQTS, it is important to have a good family history and do a baseline ECG to all family members (parents, children, siblings).

Data on the clinical presentation and genotype–phenotype correlation of patients with congenital LQTS diagnosed at perinatal through infantile period are limited [68–70]. A nationwide survey was conducted to characterize how LQTS detected during those periods is different form that in childhood or adolescence. Patients with LQTS

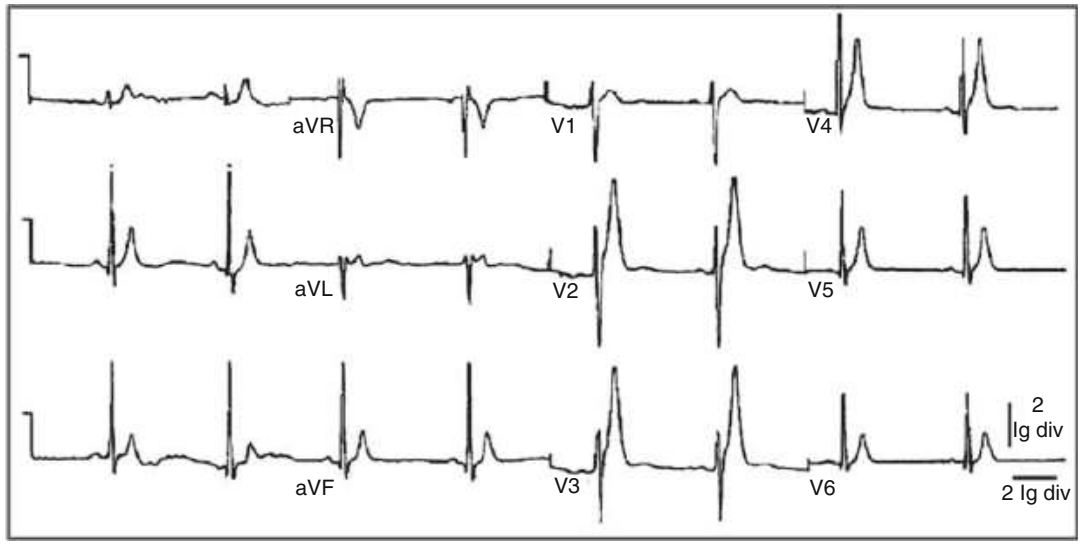

Fig. 159.8 12-lead ECG with short QT interval

who showed life-threatening arrhythmias at perinatal periods were mostly those with LQT2, LQT3, or no known mutations. Independent of the genotype, aggressive intervention resulted in effective suppression of arrhythmias [71].

A prolonged QT interval corrected for heart rate (QTc) is a major risk factor in patients with LQTS. However, heart rate-related risk in this genetic disorder differs among genotypes. Therefore, risk stratification for life-threatening cardiac events in LQTS patients can be improved by incorporating genotype-specific QT correction for heart rate [72].

It is advisable in the genetic study of these patients. In the case of a known mutation, family members should be studied to rule out that they are carriers [23].

What Should be Done with Asymptomatic Gene Carriers?

The gene carrier should avoid competitive sports and should be treated with beta-blockers (level of evidence IIa) because use of beta-blockers decreases the risk of SCD [59] although does not provide full protection.

Short QT Syndrome

Short QT syndrome (SQTS) – first described in 2000 [73] – is a highly malignant condition characterized by a short QT interval (<330 ms), with a high sharp T wave and a short interval between the peak and the end of the T wave, leading some clinical manifestations from lack of symptoms to recurrent syncope and high risk of SCD [74–76] because of ventricular arrhythmias (Fig. 159.8). Atrial fibrillation (AF) is also commonly seen in patients with SQTS [77–79]. Clinical manifestations may appear as early as childhood, and so it is considered a possible cause of SD in nursing infants [26, 80, 81].

The genetic origin of this condition has been recently reported, with an autosomal dominant pattern of transmission and a high penetrance (Table 159.1). The mutations that induce this syndrome are located on six genes, of which three (*kcnq1*, *kcnj2*, and *kcnh2*) encode potassium channels, with enhanced function and, therefore, shortened repolarization [80]. The SQTS type 1 has been associated with two mutations in *kcnh2* (hERG protein) that induce a rapid activation of potassium currents, with a gain of function of IKr and a shortening of ventricular action potentials. Generally, cardiac events are associated with

adrenergic in situations such as noise or exercise but also occurred at rest [82]. The SQTS type 2 has been associated with two mutations in the gene *kcnq1* (KvLQT1 protein) [39] which leads to a gain of potassium channel function, leading to a shortening of action potential with AF. There is a particular entity, by affecting the same gene that is expressed in uteru in the form of bradycardia in the neonatal period was diagnosed as AF and SQTS [79]. The SQTS type 3 has been associated with a mutation in the gene *kcnj2* (Kir2.1 protein) located on chromosome 17, involving a speeding of phase 3 of action potential, resulting in a gain of function [83]. The association of BrS pattern with a shorter QT interval has been associated with mutations in the gene *cacna1c* that cause a change in the unit α calcium channel L-type inducing a loss of channel function related to the association to BrS and QT interval shorter than normal, with autosomal dominant inheritance pattern. With the same phenotype and pattern of inheritance, *cacnb2b* mutations cause a change in the unit-type calcium channels, L, giving the association BrS and shortened QT interval [84]. Recently, it has been published a relation between *cacna2d1* and SQTS [85]. However, more studies must be performed to establish a clear clinical genetic association.

How to Follow a Child with Short QT Syndrome

Being a rare entity, there are no clinical guidelines for the monitoring of these patients. Quinidine has been tested as a treatment to try to prolong the QT. In cases associated with AF, has raised the use of antiplatelet drugs to prevent embolic complications. The medication does not reverse or control AF.

In cases where the ventricular response is too slow, these authors recommend the implantation of a pacemaker. Given the high risk of malignant arrhythmias, caregivers may consider the possible inducibility of arrhythmias and defibrillator implantation, although the young age of these patients has created much controversy plating in the management. As SQTS is a highly malignant disease, the genetic study of family members is necessary, and baseline ECG should be performed in all patients [23].

Brugada Syndrome

Brugada syndrome (BrS) [86] is characterized by an ECG pattern consisting of coved-type ST-segment elevation in atypical right bundle branch block in leads V1 to V3 (often referred to as type 1 Brugada ECG pattern) without structural heart disease (Fig. 159.9). BrS is also characterized by an increased risk for SCD resulting from episodes of polymorphic ventricular tachyarrhythmias with an incidence of about 26–38/100,000 person-year. Although the average age of onset of events is about 40 years, sudden death can affect people of all ages, especially men (75 %). Of the patients, between 20 % and 50 % had family history of sudden death [87].

The penetrance and expressivity of the disorder are highly variable; BrS is generally considered a disorder involving young male adults, with an arrhythmogenic symptom first occurring at the age of 40 years and SCD typically occurring during sleep, particularly in Asia, where it manifests as sudden unexpected nocturnal death syndrome (SUNDS), the most common cause of natural death in young Asians [88]. The ECG pattern can be present at baseline or it may be intermittent. In the latter it can be unmasked during a drug challenge with a sodium channel blocker (ajmaline or flecainide in children). The description of acute inducers of the ECG pattern is of paramount importance, as some individuals may be at risk during anesthesia, when they take some oral medications (antidepressants or antiarrhythmics) or, of special importance in children, during a febrile episode. Patients with BrS are at risk for life-threatening tachyarrhythmias. After surviving a cardiac arrest or the occurrence of syncope, the only treatment having any proven effect on the prevention of SD is the implantable cardioverter-defibrillator (ICD) [87].

To date, 12 genes have been associated with BrS (Table 159.1). Approximately 20–30 % of patients with BrS have a mutation in the *scn5a* gene, classified as BrS type 1. The *scn5a* gene

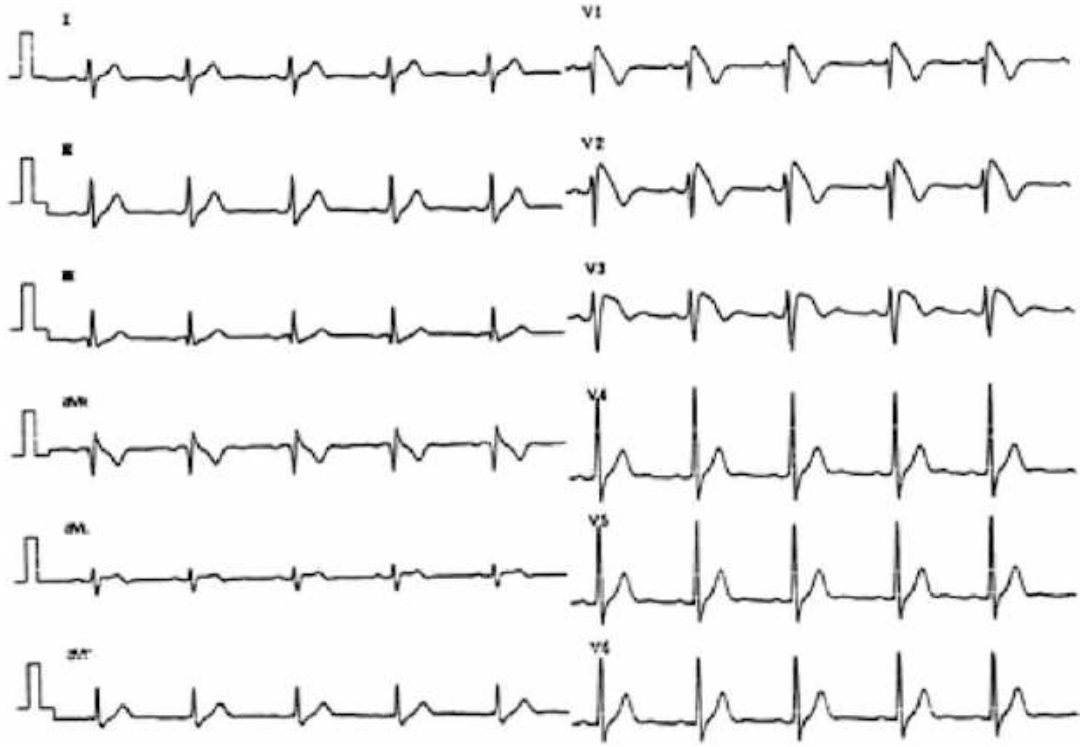

Fig. 159.9 12-lead ECG with Brugada syndrome. Note ST segment elevation in right precordial leads

(alpha subunit of the cardiac sodium channel) is responsible for the phase 0 of the cardiac action potential, a key player in the cardiac electrical activity. Mutations in *scn5a* result in "loss of function" of the sodium channel [87]. Another sodium channel that has been reported to induce BrS is *gpd1-l* gene. It has been shown that mutation of the *gpd1-l* gene reduces the surface membrane expression and reduces the inward sodium current. In addition, *gpd1-l* has been shown to be the cause of some of the SCD in nursing infants [89, 90]. Additionally, studies on mutations in *scn1b* (sodium channel beta-1 subunit) and *scn3b* (sodium channel beta-3 subunit) also associated with BrS have been published [65, 91]. In the heart, β1-subunit modifies Nav1.5 increasing I_{Na}. The mutation described in *scn3b* alters Nav1.5 trafficking, decreasing I_{Na}. Another gene associated with BrS is *kcne3* which codifies MiRP2 protein (β-subunit that regulates the potassium channel I_{to}). The KCNE peptides modulate some potassium currents in the heart. The *kcne3* gene encodes the regulatory subunit of the potassium channel Ito. The relationship between mutations in this gene and the BrS was detected in a Danish family [92]. Mutation in the *cacna1c* gene is responsible for a defective a unit of the type-L calcium channels. This induces a loss of channel function, linked to the combination of BrS with shorter QT interval. Transmission follows an autosomal dominant pattern. With the same phenotype, mutation of the *cacnb2b* gene leads to a defect in the L-type calcium channel, giving rise to a combination of BrS and shorter QT interval [84]. In 2009, BrS was associated with *hcn4* gene [93] that codifies for HCN4 channel or If channel. The HCN4 channel controls the heart rate, and its mutations also predispose to inherited sick sinus syndrome and LQTS associated with bradycardia. Another gene described associated with BrS is *kcnj8*, also previously related to early repolarization syndrome (ERS) [94]. The report implicates *kcnj8* as a novel J-wave syndrome susceptibility gene and

a marker gain of function in the cardiac $K_{(ATP)}$ Kir6.1 channel [95]. Recently, Kattygnarath et al [96]. published a study supporting that *mog1* gene can impair the trafficking of Nav1.5 to the membrane, leading to INa reduction and clinical manifestation of BrS. Also in 2011, Giudicessi et al. provide the first molecular and functional evidence implicating novel *kcnd3* gain-of-function mutations (Kir4.3 protein) in the pathogenesis and phenotypic expression of BrS, with the potential for a lethal arrhythmia being precipitated by a genetically enhanced I_{to} current gradient within the right ventricle where *kcnd3* gene expression is the highest [96]. Finally, and also in 2011, a study was published recommending *kcne5* gene screening for BrS- or IVF-affected patients. Therefore, *kcne5* gene modulates I_{to} and its novel variants appeared to cause IVF especially BrS in male patients through gain-of-function effects on I_{to} [97].

How to Follow a Patient with Brugada Syndrome

Type 1 Brugada ECG pattern is rare in children. Genetic testing will help to diagnose these kids. When genetic testing is not available, children being at risk of BrS (brother/sister or son/daughter of a parent affected with BrS) should be followed as if they had the syndrome; thus avoidance of Brugada-inducing drugs is mandatory (www.brugadadrugs.com).

As fever is one of the promoters of the Brugada pattern, fever control is highly recommended.

These authors perform a flecainide test around the age of 8 years. If it is positive, we perform an electrophysiological study to assess the inducibility of arrhythmias and possible ICD implantation. We are aware of the concerns of implanting a defibrillator in a child.

In patients with BrS and presence of syncope, aborted SD, nocturnal agonal breathing, or seizures, is indicated for ICD implantation. If they also show arrhythmias, treatment with quinidine is indicated.

Competitive exercise is contraindicated, but low-intensity sports are allowed [98–100].

Particularly challenging is the control of electrical storm in BrS patients, which has been anecdotally treated with isoproterenol, disopyramide [71], orciprenaline [101], and quinine [102].

That BrS can associate AV conduction disturbances and supraventricular tachycardia should be considered special, so we question the presence of palpitations and eventually treat these arrhythmias with ablation.

Study of the Relatives of a Patient with Brugada Syndrome

In patients with BrS, as in other channelopathies, good family history is crucial. All first grade relatives should be screened by a basal ECG. When in doubt, flecainide test has to be performed.

In the case of a known mutation, family members should be studied to rule out that they are carriers despite the negativity of the basic ECG and flecainide test.

Lev-Lenègre Syndrome

Lev-Lenègre syndrome is a rare entity characterized by disruption of the conduction system, in which a block gradually develops, resulting in ventricular arrhythmias or asystole [103, 104]. The amount of sodium and the speed with which it enters the cell determine the velocity of conduction of the electric impulse through the sodium-dependent cells (muscle cells of the ventricle and atrium and cells of the His-Purkinje system). If a mutation leads to a reduction in the quantity of sodium that enters the cell, the velocity of conduction of the impulse is reduced resulting in a loss of function in phase 0 of the action potential (channel opening). This is the case in the Lev-Lenègre syndrome. In 1995, chromosomal abnormalities (19q13.2-13.3) associated with bundle branch block were reported [105]. In 1999, the first mutation was described, located on the *scn5a* gene [106, 107]. Additionally, mutations in *nkx2.5* gene (5q35) that codifies the transcription factor NKX2.5 (also named CSX) [108] have been described. The conduction block is due to a congenital heart defect.

Recently, it has also been described a mutation in *trpm4* gene (19q) [109]. The *trpm4* gene is a causative gene in isolated cardiac conduction disease, with mutations resulting in a gain of function and TRPM4 channel being highly expressed in cardiac Purkinje fibers (Table 159.1).

In these cases, pacemaker implantation should be indicated when development of the heart block is seen.

Catecholaminergic Polymorphic Ventricular Tachycardia

In 1975 catecholaminergic polymorphic ventricular tachycardia (CPVT) was first reported [110]. CPVT is a familial arrhythmogenic disorder characterized by a 2-way polymorphic ventricular tachycardia characterized by severe arrhythmias in young patients with apparently normal hearts [111]. It is triggered exclusively by adrenergic stimulus (vigorous exercise, fear) and has a high mortality (30 % by the age of 30 years) [93, 112]. When doubt exists, it is recommended to perform and exercise ECG and Holter monitoring in order to rule out the bidirectional tachycardia. The CPVT is associated with a normal ECG at rest (occasionally with bradycardia and U waves). It was thought that the event happened exclusively in childhood (before age 10), but recent studies show that the first manifestation may occur from infancy to age 40 [113].

Three genetic variants have been identified (Table 159.1), an autosomal dominant one caused by mutation in the gene encoding the ryanodine receptor *ryr2* and a recessive one, caused by mutation in the calsequestrin isoform gene *(casq2)* [47, 114]. Both genes are implicated in regulating intracellular calcium, and both types of defect lead to increased function of these proteins, and so outflow of calcium from the sarcoplasmic reticulum is increased. This excess calcium is associated with abnormalities in the sarcolemmal membrane potential, leading to late depolarizations that cause a predisposition to arrhythmias [26]. Similarly, some patients diagnosed with CPVT type 3 on the basis of the presence of bidirectional ventricular tachycardia on exercise have been identified as possessing *kcnj2* mutations, which are associated with the rarely lethal Andersen–Tawil syndrome (ATS1, LQT7) [115]. The misdiagnosis of Andersen–Tawil syndrome as the potentially lethal disorder CPVT may lead to a more aggressive prophylactic therapy (i.e., implantation of an ICD) than necessary. Genetic testing may provide a clear differential diagnosis between atypical LQT1 and CPVT and between CPVT and ATS1 [116].

Untreated, the mortality rate is very high, reaching 30–50 % in young adulthood. The earlier episodes appear, the worse the prognosis, and there is a correlation between the age at which syncope occurs for the first time and the severity of the disease. The first line treatment in patients with CPVT is beta-blockers, which have significantly reduced syncope and SCD [23]. Given that the first symptom may be the SCD, it is recommended to treat all individuals genetically identified as mutation carriers and patients who are asymptomatic but who have ventricular arrhythmias during exercise. The sport is contraindicated, including patients treated with beta-blockers [117].

How to Follow a Child with Catecholaminergic Polymorphic Ventricular Tachycardia

CPVT should be suspected in any form of dizziness, syncope, or aborted SD in a child not only during exercise but also after an episode of fear or running after a bus. We may see sinus bradycardia at the resting ECG, with or without *U* waves.

When CPVT is suspected, exercise test up to maximum effort may give the diagnostic, but it should be carefully performed. Any type of ventricular premature beat or couples should be carefully observed, as the following phase may show non-sustained ventricular tachycardia and sustained ventricular tachycardia that may give the diagnostic. Physical activity is completely contraindicated in these patients [118].

Beta-blockers at very high doses should be given. The dose is adjusted according to the medical tolerance to these drugs. If arrhythmias persist, verapamil can be added. Cardiac sympathectomy has been suggested to control CPVT in patients refractory to beta-blockers [65], although relief after this surgical procedure can be temporary or of delayed onset [119].

Flecainide suppressed delayed afterdepolarizations (DADs) in mutant Purkinje fibers [120] and effectively prevented CPVT in mice and humans [121–123]. Defibrillator is indicated in case of aborted SCD and in those cases of uncontrolled ventricular tachycardias.

Idiopathic Ventricular Fibrillation

Idiopathic ventricular fibrillation (IVF) is a spontaneous ventricular fibrillation without identifiable structural or electrical heart disease – may account for up to 10 % of SCD in the young [124–126]. Haplotype-sharing analysis has identified a genetic basis for IVF [127]. The shared chromosomal segment contained the *dpp6* gene, which encodes a putative regulator of the transient outward Ito current [128]. DPP6 mRNA levels were increased 20-fold in hearts of human carriers in one study [128]. To date, this seems to be a founder risk locus, but nonetheless, it suggests that an increase in DPP6 imparts a higher risk for ventricular fibrillation (VF).

Furthermore, previously thought to be a benign and common ECG finding present in up to 5 % of the population, three separate case-control studies [117, 129, 130] suggest that "J-point elevation" (manifested as either terminal QRS slurring or notching, or ST-segment elevation with upper concavity and prominent T waves in inferolateral leads) is significantly more prevalent (16–60 %) in patients with IVF. Mutations in genes encoding subunits of the L-type Ca2 channel (*cacna1c, cacnb2*, and *cacna2d1*) [33] and a subunit of the KATP channel encoded by *kcnj8* [94] have been implicated in this new "J-wave syndrome" or ERS [131].

Cardiomyopathies

Cardiomyopathies are heart diseases induced by mutations in genes that encode contractile and structural proteins as well as proteins for cardiac energy production. They are responsible for lethal arrhythmogenic disorders, mainly hypertrophic cardiomyopathy (HCM) and arrhythmogenic cardiomyopathy (arrhythmogenic right ventricular cardiomyopathy), both associated with SCD [132].

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is one of the most common cardiovascular disorders, self-characterized by an unexplained asymmetric hypertrophy of the left ventricle with findings indicative of myocyte disarray and fibrosis [133], often mostly pronounced in the interventricular septum. It has a prevalence of 1/500, affecting children and young people [134], and it is also the cause of death in about a 10 % of the SCD identified at autopsy [21].

Clinical manifestations appear initially as diastolic dysfunction and systolic–diastolic dysfunction in more advanced stages. Thus, a patient may be asymptomatic or present with SCD. Mortality is higher in young patients (often athletes) than in adults, and the first manifestation of the disease may be SCD itself. The risk stratification of SCD in patients with HCM remains at the forefront of clinical research. Both a wall thickness of the left ventricle with a z-score >6 and an abnormal blood pressure response to exercise are clinical factors for SCD in children. The differential diagnosis between HCM and the so-called athlete's heart is not easy, but testing such as ECG, echocardiogram, and genetic analysis is a useful tool to resolve the dilemma [13, 100, 135]. Patients considered at high risk of SCD should be aimed at prevention and/or management of ventricular tachyarrhythmias with antiarrhythmic drugs (amiodarone). ICD implantation is the most reasonable option for patients at greatest risk. Special emphasis should be put on risk stratification in childhood because evidence points to a higher

risk of SCD in this population than in adults [136]. Competitive exercise is an absolute contraindication for children with HCM; leisure activities, however, are possible if the cardiac function permits.

The disease is considered inherited in 90 % of the cases, generally with an autosomal dominant pattern of transmission (Table 159.2), except for cases with mutations in mitochondrial DNA (mtDNA), which are inherited from the mother [137, 138]. Mutations have been described in several genes encoding essential sarcomeric proteins, such as heavy chain β-myosin (*myh7*) and myosin-binding protein C (*mybpc3*); others encode heavy chain a-myosin (*myh6*), troponin I (*tnni3*), troponin T (*tnnt2*), α-tropomyosin (*tpm1*), essential myosin light chains (*myl3*), regulatory light chain (*myl2*), titin (*ttn*), and α-actin (*actc*) [139]. Mutations have also been detected in genes implicated in the metabolism of the heme and $Fe2^{+}$ group and in genes involved in mitochondrial bioenergetics. Genetic studies of families with left ventricular hypertrophy have shown metabolic myocardiopathies with mutations in the *prkag2* and *lamp2* genes. Recently, missense mutations that cause defective interaction between nexilin and α-actin have been described in HCM [137]. Nexilin (*nexn*) is a cardiac Z-disc protein that has a crucial function to protect cardiac Z-discs from forces generated within the sarcomere [140].

Up until present, mutations have not been thought to predict phenotype because individuals with different degrees of hypertrophy or with a greater predisposition to SCD may be present in the same family and have the same mutation. This is due to the intervention of modifying genes and polymorphisms, which requires more exhaustive studies to achieve a full understanding. It is assumed that interruption of mitochondrial energy metabolism in the heart is the cause of HCM in patients with problems of sarcomeric contraction; this sheds some light on several clinical observations such as heterogeneity, variability in clinical presentation, and asymmetry in hypertrophy. The identification of the genotype may contribute to risk stratification, but future genotype–phenotype studies need to be done to confirm whether this is useful.

How to Follow a Child with Hypertrophic Cardiomyopathy

Practice of sport is clearly contraindicated and any isometric exercise (lifting weights). In all patients we recommend the administration of beta-blockers at high doses. The dose is adjusted according to the medical tolerance to these drugs [141–143].

The implantation of an ICD will depend on the presence of symptoms, septal thickness, presence of family history of arrhythmias, and SD.

Study of the Relatives of a Patient with Hypertrophic Cardiomyopathy

In patients with HCM it is important to perform echocardiography and ECG to their relatives. It is advisable that the genetic study of these patients is done. In the case of a known mutation, family members should be studied to rule out if they are carriers.

Arrhythmogenic Right Ventricular Cardiomyopathy

Arrhythmogenic right ventricular cardiomyopathy (ARVC) is an inherited cardiomyopathy characterized by right ventricular dysfunction and ventricular arrhythmias. Patients with ARVC show fibrofatty replacement of right ventricular infarction. However, ARVC may involve both ventricles and in very isolated cases only the left ventricle. The ECG is not always altered, but the presence of epsilon waves and T negative ϵ, from V1 to V3, may provide a pathological diagnosis [144]. About 50 % of ARVC cases are familiar with variable penetrance. It affects approximately 1/5000 individuals, although the prevalence is higher in men (80 %), particularly young athletes. Most cases are diagnosed before the age of 40 years. Usually, affected individuals have symptomatic ventricular arrhythmias that originate in the right ventricle, with syncope and a high risk of SD. This entity is responsible for 5 % of all SCD.

The disease has 2 different patterns of transmission: autosomal dominant pattern (the most common) and an autosomal recessive pattern (Table 159.3). The recessive pattern has been reported on the Greek island (Naxos), giving rise to the Naxos syndrome. This syndrome comprises ARVC, palmoplantar keratoderma, and typically curly hair. To date, several genes are described as capable of inducing disease (http://www.arvcdatabase.info/). Most cases involve genes encoding proteins responsible for the junctions of intercalated discs, especially in desmosome, which led to the appointment of ARVC as a desmosomal disease with a disorder of the connections between myocytes [145].

The clinical picture may include (a) a subclinical stage hidden structural defects, during which the affected person may have a cardiac arrest/SCD as the first manifestation of the disease; (b) an electrical disorder with palpitations and syncope tachyarrhythmias arising from the right ventricle, often triggered during stress; and (c) the failure of the pump of the right ventricle, sometimes severe enough to require a heart transplant [146].

How to Follow a Child with ARVC

Imaging tests such as echocardiography (presence of fat, impaired mobility, hypokinesia, aneurysms, and hypertrabeculated) and cMRI (late gadolinium enhancement) allow us to see signs of disease when either patent. Ultrasound and normal ECG do not rule out ARVC.

The Holter will guide caregivers as a criterion for dysplasia when there are >500 premature ventricular contractions. The exercise test demonstrates the presence of extrasystoles.

Endomyocardial biopsy is not indicated as it is a patchy disease and appears in the epicardium to endocardium, so that a negative result does not rule out the presence of the disease.

These patients should be treated with the highest dose of sotalol in order to maintain the QT below 360 ms. Sport is clearly discouraged. In patients with positive genotype without structural alteration, the recommendation is a restricted physical activity but with sotalol.

Study of the Relatives of a Patient with ARVC

In patients with ARVC it is important to have a complete family history and do a baseline ECG to make immediate family and stress test. It is advisable to perform the genetic study of these patients. In the case of a known mutation, family members should be studied to identify carriers.

Dilated Cardiomyopathy

Dilated cardiomyopathy (DCM) is characterized by left ventricular dilatation and left ventricular systolic dysfunction. Right ventricular dilatation and dysfunction may also be present but are not necessary for the diagnosis. Patients present signs of heart failure or palpitations [147, 148] and SCD is not a frequent manifestation [23]. There are many factors that can trigger DCM, making it a highly heterogeneous entity. Despite this, systematic studies show that at least 35 % of cases are hereditary. Arrhythmias that occur in patients with familial DCM are usually the same as in the acquired forms, with defects in atrioventricular and intraventricular conduction, ventricular arrhythmias, and AF. Normally, a progressive decline in ventricular function occurs in these patients, and they die of either heart failure or arrhythmic events.

In adults, the prevalence is 1/2,500 individuals, with an incidence of 7/100,000 per year (but it could be underdiagnosed). This disorder develops at any age, in either sex, and in people of any ethnic origin. In adults, DCM arises more commonly in men than in women. In children, the yearly incidence is 0.57 cases per 100,000 per year overall but is higher in boys than in girls (0.66 vs. 0.47 cases per 100,000, $p < 0.006$), in black people than in white people (0.98 vs. 0.46 cases per 100,000, $p < 0.001$), and in babies younger than 1 year than in children (4.40 vs. 0.34 cases per 100,000, $p < 0.001$). Two-thirds of children are thought to have idiopathic disease.

DCM is an extremely complex disease, and so the clinical usefulness of genetic analysis is limited. Even so, systematic studies of relatives of patients with DCM indicate that at least 35 % of the cases are hereditary (Table 159.4). Three patterns of transmission are described in the inherited forms: (*a*) autosomal dominant disease, a locus for which has been reported in several genes (*actin, desmin, lamin A/C, δ-sarcoglycan*, and *β-sarcoglycan*); (*b*) X-linked disease, associated with mutations in *dystrophin* and *tafazzin*. Although mutations in the *dystrophin* gene are not a common cause of DCM, direct mutations in this gene give rise to Duchene- or Becker-type muscular dystrophy, which affects both cardiac and skeletal muscle; (*c*) Mitochondrial diseases, which typically affect other tissues besides the myocardium; so far, 2 loci of DCM have been reported in association with primary arrhythmias, one not being the cause of the other. These families had autosomal dominant disease. In 1994, the first locus of DCM with atrioventricular block was identified on chromosome 1. To date, there are mutations in genes that code for proteins of the cytoskeleton, cell nucleus, and sarcomere [149, 150]. In 30 % of the cases, the mutation occurs in the *lamin A/C* gene (*lmna*), which encodes a protein that is expressed in almost all

Table 159.4 Dilated cardiomyopathy

cell types and whose function is to contribute to the integrity of the nucleus by providing mechanical support. Other genes, such as *myh7, mybpc3, tnni3, tnnc1, tcap, vcl, csrp3, pln, ttn, tpm1, actc*, and *tnnt2*, can also cause DCM. Moreover, a mutation in the *scn5a* gene was identified in a large family with DCM [151]. A recent new addition to the long list of DCM candidate genes is nebulette (*nebl*), which encodes a 107 kDa protein that aligns thin filaments and connects them with the myocardial Z-disc [49]. Another is dynamin-1-like (*dnm1l*) gene, which is known to be critical for mitochondrial fission and has also been implicated in causing DCM by reducing levels of mitochondrial enzyme complexes and cardiac ATP depletion [152].

DCM is associated with complex remodeling of one or both ventricles, resulting in a change of the ventricle shape and the architecture of the myocardium fibers. In the most severe cases, affected individuals present signs and symptoms of heart failure – diaphoresis, breathlessness at rest or with exertion, orthopnea, exercise intolerance, early onset fatigue, abdominal pain, and pallor. Heart failure symptoms can be exercise induced or persistent at rest.

How to Follow a Child with Dilated Cardiomyopathy

The degree of dilatation limits physical activity. Patients with heart failure should be treated, regardless of the presence or absence of arrhythmias. If there is dyssynchrony, assess the implementation of a resynchronization. In those cases in which malignant arrhythmias are induced, implantation of an ICD is recommended [23, 153, 154].

Study of the Relatives of a Patient with Dilated Cardiomyopathy

In patients with DCM, echocardiography should be performed to their families. It is important to have a good history of family history and make a family tree. It is advisable that a genetic study of these patients is performed [155]. In the case of a known mutation, family members should be studied to rule out if they are carriers [156].

Left Ventricular Noncompaction

Left ventricular noncompaction (LVNC) is a rare disorder characterized by multiple deep trabeculations within the left ventricular myocardium and is increasingly being recognized as a cause of ventricular tachyarrhythmia and SCD in young patients [157]. Overlapping genetic predisposition to LVNC, HCM, and DCM, suggesting a continuum of disease associated with sarcomeric gene mutations, has been proposed [158]. Interestingly, distal chromosome deletion at 22q11.2 [159] and 1p36 [160, 161], though previously associated with atrial and ventricular septal defects, has been more recently described in patients with LVNC (Table 159.5).

Medical Management of Arrhythmias and Conduction Disorders

160

Anthony C. McCanta and Kathryn K. Collins

Abstract

Though invasive therapies are available and widely used for both tachy- and bradydysrhythmias, medical management remains an integral part of the management of arrhythmias and conduction disorders. This chapter reviews the cornerstones to the understanding of medical management of arrhythmias: normal cardiac conduction and mechanisms of antiarrhythmic medications. These concepts are then applied to the diverse and growing substrates of pediatrics and congenital heart disease, providing a substrate-specific approach to individual arrhythmias in patients of different ages and with the varied structural diagnoses of congenital heart disease.

Keywords

Antiarrhythmic medications • Bradycardia • Congenital heart disease • Dysrhythmias • Pediatrics • Tachycardia

Introduction

Disorders of cardiac rhythm can cause significant morbidity and mortality in fetuses [1–4] neonates [5, 6], children [7, 8], adolescents, and adults with congenital heart disease [9]. The etiologies and natural histories of cardiac rhythm disorders are dependent upon the specific anatomical and physiological substrates. For instance, both brady- and tachydysrhythmias affect fetuses and neonates with different severity and frequency than adolescents. Similarly, the abnormal cardiac morphologies and hemodynamics of patients with unrepaired congenital heart disease increase the likelihood for certain dysrhythmias and may make the consequences of dysrhythmias more drastic than in people with structurally normal hearts. With repaired congenital heart disease, insults such as cardiopulmonary bypass and circulatory arrest may increase dysrhythmias in the immediate postoperative period, whereas suture lines and scar formation provide dysrhythmic substrates in the months to years following

cardiac surgery. For those reasons, this chapter emphasizes developmental and anatomic substrates in the discussion of medical treatment of dysrhythmias.

Overview of Cardiac Conduction

Cellular Conduction: The Action Potential

Cardiac conduction is initiated by action potential formation. This involves the transfer of electrically charged ions across the cell membrane forming electrical current. The net sum of the electrical currents generated by ion movement both inward and outward across the cell membrane determines its transmembrane potential. The primary ions involved with transmembrane current generation are sodium ions, potassium ions, and calcium ions. The action potential is divided into five phases in cardiac cells, though the mechanisms and currents involved with each phase differ from pacemaker cells (in the sinus and atrioventricular nodes), specialized conduction tissue (in the His-Purkinje system), and in cardiac myocytes. Understanding of the phases of the action potential is crucial in the treatment and prevention of dysrhythmias, and most antiarrhythmic medications seek to disrupt the action potential across one or more of the phases. Likewise, the proarrhythmic side effects of certain medications, including antiarrhythmic medications, are most often mediated by disturbances in the action potential.

The phases of the cardiac action potential are characterized as follows (see Fig. 160.1):

- *Phase 0*: The rapid depolarization of the cell from a negative transmembrane potential (−40 to −70 mV (mV) in pacemaker cells and −95 to −80 mV in cardiac myocytes) to a positive or nearly positive, transmembrane potential. In normal cardiac myocytes and specialized conduction tissue, the net inward current that depolarizes the cell is an inward sodium current (I_{Na}) mediated by an inward sodium channel (Nav1.5, SCN5A gene) [10]. Medications that block inward sodium channels (class I antiarrhythmics) tend to slow conduction by decreasing the slope of phase 0 depolarization. In pacemaker cells, inward calcium current ($I_{Ca(L)}$) through L-type calcium channels (Cav1.2 α subunit protein, CACNA1C gene) [11, 12] is responsible for phase 0 depolarization.
- *Phase 1*: Marked decrease in inward current, caused by decreased inward calcium or sodium current, characterizes phase 1 of the cardiac action potential. Coupled with transient outward current (I_{TO}), most of which is mediated by outward potassium currents (Kv4.3 protein, KCND3 gene, and KCHIP2 and KCNIP2 gene) [13, 14], the decrease in inward current manifests a brief but abrupt drop in membrane potential prior to phase 2 of the action potential.
- *Phase 2*: A plateau of inward current is observed in phase 2 of the action potential. This net positive current is maintained by slow inward calcium current via the L-type calcium channels. The inward current is balanced by the activation of rapid, delayed rectifier outward potassium current I_{Kr} (hERG protein, KCNH2 gene) [15, 16]. Medications that block calcium channels (class IV antiarrhythmics) can decrease early afterdepolarizations (EAD) and therefore triggered dysrhythmias, at phase 2. Phase 0 through phase 2 constitute the absolute refractory period, during which stimulation does not cause further depolarization and action potential generation.
- *Phase 3*: Inward calcium current decreases and slow, delayed rectifier outward potassium current I_{Ks} (KvLQT1 protein, KCNQ1 gene) increases during phase 3 of the action potential, bringing the membrane potential from positive back to the resting membrane potential. Another outward potassium current which is reactivated during phase 3, after a period of inactivation during rapid depolarization, is called the inward rectifier current or I_{K1} (Kir2.1, KCNJ2 gene) [17]. This current remains active throughout phase 3 and into phase 4 for atrial, ventricular, and His-Purkinje cells, but it is notably absent in sinus node and atrioventricular nodal cells. The absolute refractory period extends into

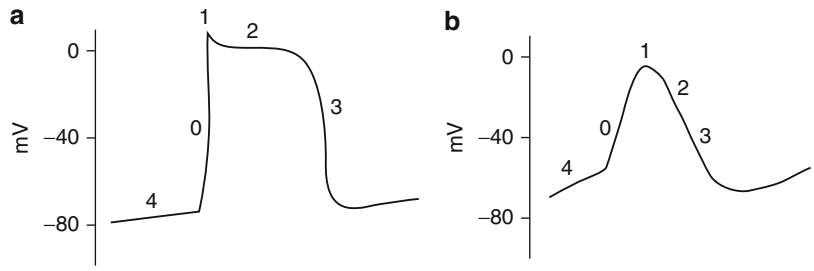

Fig. 160.1 The cardiac action potential in cardiac myocytes (**a**) and nodal (sinus and atrioventricular) cells (**b**)

the beginning of phase 3, but refractoriness becomes relative as phase 3 finishes. During the relative refractory period, stimulation of sufficient magnitude can depolarize the cell and cause another action potential. Genetic mutations or pharmacological blockade of the channels responsible for phase 3 including the potassium channel blocking effects of amiodarone and sotalol (class III antiarrhythmics) prolongs refractoriness which can disrupt the propagation of dysrhythmic wave fronts. However, prolonging refractoriness can cause malignant dysrhythmias if the cell is activated during the relative refractory period, which is a mechanism of the proarrhythmic effects of class III medications.

– *Phase 4*: Sinus and atrioventricular nodal cells manifest automaticity during phase 4 of the action potential through diastolic depolarization (see Fig. 160.2). Several inward currents have been implicated in this spontaneous diastolic depolarization including sodium-calcium exchange I_{NCX} (NCX1.1 protein, SLC8A1 gene) and the so-called funny current $I_{f,}$ an inward current, which is activated at hyperpolarized potentials and carried by sodium and potassium ions [18]. In the sinus and atrioventricular nodes, these inward currents are not opposed by the I_{K1} current, as is the case in atrial, ventricular, and His-Purkinje cells. This results in diastolic depolarization until the threshold potential is reached at (−60 to −50 mV in the sinus node) and the L-type calcium channels are activated to initiate phase 0. Again, the outward I_{K1} current may help maintain the relatively flat and negative (−95 to −80 mV) resting membrane potential of atrial, ventricular, and His-Purkinje cells during phase 0, thus making automaticity slower in these cells under normal conditions compared to pacemaker cells. Beta-blocking medications (class II antiarrhythmics) decrease the slope of phase 4 depolarization in sinus cells and cells expressing abnormal automaticity, thus suppressing automaticity. Because of the multiple channels responsible for phase 4 depolarization and abnormal automaticity, medications which block sodium channels (class I), sodium and potassium channels (class III), and calcium channels (class IV) can depress phase 4 depolarization in automatic cells and thus suppress abnormal automaticity.

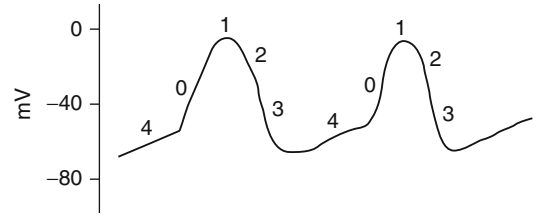

Fig. 160.2 Automaticity of sinus and atrioventricular nodal cells with spontaneous phase 4 depolarization

Mechanisms of Antiarrhythmic Medications

The original classification of medications for tachydysrhythmias, known as the Vaughan-Williams classification, was based on the primary or known mechanism of action at the time of discovery [19]. It is now known that most

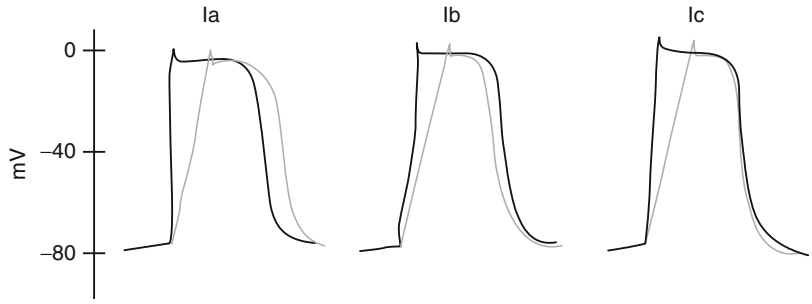

Fig. 160.3 The varied effects of Class I antiarrhythmic medications on the cardiac action potential. All class I medications slow phase 0 depolarization. Class Ia medications prolong refractoriness (a); Class Ib medications shorten refractoriness; Class Ic medications have minimal effect on refractoriness

antiarrhythmic medications have multiple cellular mechanisms and physiological effects. For instance, flecainide was classified as a sodium channel blocking medication, but potassium channel and calcium channel blockade has also been observed with flecainide [20, 21]. And so, while flecainide's primary electrophysiological effect is to slow conduction through the myocardium, this effect may be the result of the sum of multiple mechanisms, not just sodium channel block. Such is the case with nearly all of the antiarrhythmic medications. However, the Vaughn-Williams classification remains a valuable framework to help understand the common features of these medications. For this reason, each class of medication is described below with the primary electrophysiologic effect via the primary mechanism, knowing that more than one mechanism may be responsible for this effect.

Class I Antiarrhythmics: Slow Conduction Through Myocardium

The primary effect of sodium channel blocking medications is to slow conduction by decreasing the slope of phase 0 depolarization (see Fig. 160.3). The medications are further divided into subclasses based on their effects on refractoriness, which is variable. Class Ia medications, which include procainamide and quinidine, *prolong refractoriness*. Lidocaine, mexiletine, and phenytoin *shorten refractoriness* and are considered class Ib antiarrhythmics. The class Ic medications flecainide, encainide, and propafenone have *minimal effects on refractoriness*. These medications are used for all mechanisms of tachydysrhythmias, reentrant, automatic, or triggered, and predictably they act on sodium-dependent atrial and ventricular myocardium with virtually no effect on the calcium-dependent automatic tissues of the sinus node and atrioventricular node. Many of these medications have local anesthetic effects due to the slowing or complete inhibition of action potentials in pain fibers when injected locally. Class I agents that are commonly used in pediatrics and congenital heart disease include the following:

– *Procainamide* is usually given as an intravenous medication for SVT [22], VT with adequate function, or junctional ectopic tachycardia (JET) with a loading dose of 3–6 mg/kg/dose over a minimum of 5 min and a continuous infusion of 20–80 μg/kg/min. Its half-life is 1.5–4.5 h, depending on age (increasing with increasing age). It can worsen heart failure, and long-term administration can cause a lupus-like reaction or agranulocytosis. It is metabolized in the liver and excreted in the urine. Procainamide levels and levels of its metabolite *N*-acetyl procainamide should be checked in patients with renal failure. Overdose can cause sinus bradycardia or arrest; prolongation of PR, QRS, and QT intervals; ventricular dysrhythmias; and depression of myocardial contractility.
– *Lidocaine* is used primarily for ventricular dysrhythmias including ventricular

fibrillation, as it has very little action in the atrium and AV node. It is given as a 1 mg/kg loading dose followed by 20–50 μg/kg/min continuous infusion. Lidocaine has a rapid onset of action of less than 1 min with a half-life of 2–3 h, and its metabolism is via the liver. For that reason, decreased cardiac output states with decreased liver perfusion require decreased dosing. Lidocaine toxicity includes neurological effects of sedation, seizures, paresthesias, ataxia, and the cardiovascular effects of AV block, asystole, and hypotension. Lidocaine levels should be checked, with normal being 1.5–5 mcg/mL, and potentially toxic >6 mcg/mL.

- *Mexiletine* is also used mainly for ventricular arrhythmias and was shown to be effective in such rhythms in congenital heart disease [23]. It is an oral medication with dose of 1.4–5 mg/kg/dose every 8 h. It has a half-life of 10–14 h, and it undergoes hepatic metabolism before it is excreted in the urine. Mexiletine toxicity is similar to that of lidocaine, with neurological effects of sedation, seizures, paresthesias, ataxia, and cardiovascular effects of AV block, asystole, and hypotension. Serum levels may also be checked with normal being 0.5–2 mg/mL. Mexiletine readily crosses the placenta with equal maternal and cord blood levels [24], and so it may be used for fetal VT.
- *Flecainide* is a versatile antiarrhythmic that is effective for nearly all atrial, junctional, and ventricular tachycardias in neonates and children [25]. It is also a first-line therapy for atrial fibrillation in adults with no history of ischemia [26]. There is evidence that flecainide is active on accessory atrioventricular bypass tracts, causing disappearance of preexcitation in patients with Wolff-Parkinson-White [27]. Flecainide is administered orally at doses of 50–200 mg/m^2/day divided every 8 h, with hepatic metabolism and renal elimination. Renal insufficiency can significantly increase levels. The half-life is variable and age dependent, with half of up to 27 h in neonates to as little as 8 h in children. Of importance in pediatrics, administering flecainide with milk decreases the absorption, and likewise, with elimination of milk from the diet, absorption increases requiring decreased dosing. Flecainide can prolong PR, QRS, and QT intervals, and even nontoxic dosing can be proarrhythmic [28, 29]. There is increased risk of sudden death in adults with ischemic heart disease, and it has also been associated with sudden death in congenital heart disease [30]. Toxicity can present with life-threatening with ventricular arrhythmias, hypotension, asystole, or AV block. Flecainide levels should remain between 0.2 and 1 mcg/mL, and often levels <0.5 mcg/mL are effective in children.
- *Propafenone* is also quite versatile with effects for atrial, junctional, and ventricular arrhythmias [31]. Propafenone is also used in adults with atrial fibrillation [32]. It is an oral medication with dose of 150–600 mg/m^2/day. Hepatic metabolism is variable with a half-life of 2–8 h in fast metabolizers and up to 32 h in slow metabolizers. It is excreted in the urine. Propafenone can prolong PR, QRS, and QT intervals, and it can be proarrhythmic even at normal dosing levels. Toxicity can be life-threatening with ventricular arrhythmics, hypotension, asystole, or AV block. Neurologic and gastrointestinal symptoms are also observed.

Class II Antiarrhythmics: Decrease Automaticity and Slow Conduction Through the AV Node

Sympathetic stimulation of the heart is mediated by β_1-adrenergic receptors causing increased chronotropy and inotropy. The effects of β_1 receptors are greater at the sinus and atrioventricular nodes, and so by competitively blocking these receptors at these sites, heart rate is decreased and atrioventricular nodal conduction and refractoriness are prolonged. For these reasons, these medications are used to prevent atrioventricular reentrant tachycardias involving the atrioventricular node. Automaticity is decreased by decreasing the slope of phase 4 for automatic tissues, so these medications can be effective for automatic dysrhythmias. For dysrhythmias triggered by early afterdepolarizations (EADs)

(torsades de pointes of long QT syndrome) or by delayed afterdepolarizations (DADs) (ventricular tachycardia of catecholaminergic polymorphic ventricular tachycardia), beta-blockers have also been shown to be effective [33]. This class of medications is distinguished by selectivity to the cardiac β_1 receptors, including esmolol, atenolol, and metoprolol, versus nonselective medications which cause inhibition of β_2 receptors, causing smooth muscle and bronchial constriction, as well β_1 receptors. These medications include propranolol and nadolol. Commonly used class II medications in pediatric and congenital heart disease patients include the following:

- *Esmolol* is beta-blocker with a short half-life of 3–10 min. It is administered as a 50–500 μg/kg intravenous bolus followed by a 50–200 μg/kg/min continuous infusion. It is for the acute treatment of perfusing supraventricular tachycardias and for termination or decreasing the ventricular response to atrial dysrhythmias. Esmolol is metabolized in the blood. With β_1 selectivity, esmolol is also used as an acute antihypertensive agent, especially in the postoperative care of coarctation of the aorta [34]. Higher doses can cause bronchospasm, hypotension, bradycardia, and AV block.
- *Atenolol* also has β_1 selectivity. It is utilized as a first-line medication for the control of atrial, AV nodal-dependent, and idiopathic ventricular tachycardias [35, 36]. Oral pediatric dosing of atenolol is 0.8–2 mg/kg/day divided once or twice daily, and adult dosing is 25–100 mg/day. Its half-life is 9–10 h, and it is eliminated with minimal metabolism in the urine so dosing should decrease with renal impairment. Overdose of atenolol may cause bradycardia, asystole, and hypotension.
- *Metoprolol* is another short-acting β_1-selective agent with a half-life of 3–8 h. It is used primarily in adults for atrial and ventricular tachycardias, as well as for hypertension and congestive heart failure [37, 38]. Pediatric dosing is 1–2 mg/kg/day divided twice daily in immediate-release formulations and once daily in extended-release formulations. Adult dosing is 100–450 mg/day divided twice daily for immediate release or 25–400 mg/day extended release.
- *Propranolol* is used in both the acute and chronic treatment of neonatal SVT and VT [39]. Besides nonselective β_1 and β_2 blocker, propranolol displays membrane stabilizing properties with its actions on sodium channels [40]. With a half-life of 3–6 h, it must be administered every 6–8 h. Propranolol can be given intravenously at doses of 0.01–0.15 mg/kg/dose use to 1 mg/dose in neonates and 0.01–0.1 mg/kg dose up to 3 mg/dose in children. In adults, intravenous dosing ranges from 1 to 5 mg/dose. Oral propranolol dosing is 1–5 mg/kg/day divided three or four times daily in neonates and children and 40–320 mg/day divided three or four times daily in adults. Propranolol is metabolized in the liver and excreted in the urine. Hypoglycemia is seen in neonates and infants on propranolol, and so blood glucose should be carefully monitored after beginning the medication.
- *Nadolol* is nonselective for β_1 and β_2 receptors. It is longer acting than the other beta-blockers, with a half-life of 7–15 h in children and 10–24 h in adults [41]. This allows for daily administration, which is advantageous in terms of compliance. The dose is 0.5–2.5 mg/kg/day once daily in children or 40–320 mg/day once daily in adults. Nadolol is not commonly used in infants because its half-life remains short at 3–4 h. Nadolol has slow absorption and hepatic metabolism, with renal excretion. Effects of nadolol overdose include bradycardia, asystole, AV block, and hypotension.

Class III Antiarrhythmics: Prolong Refractoriness

Prolonging refractoriness is the primary electrophysiologic effect of class III medications, including amiodarone and sotalol, as well as

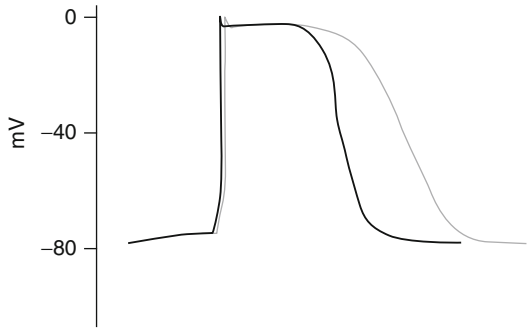

Fig. 160.4 The effect of Class III antiarrhythmic medications on the cardiac action potential, prolonging refractoriness

dronedarone, dofetilide, and ibutilide (see Fig. 160.4). Blockade of potassium channels responsible for phase 2 and phase 3 of the action potential is one of the mechanisms responsible for this [42]. However, these medications have also been shown to slow conduction through sodium channel blockade [43] and suppress automaticity through decreasing the slope of phase 4 depolarization [44]. Due to these diverse effects, these medications are effective for all mechanisms of tachydysrhythmias.

– *Amiodarone* is among the most versatile medications for acute and chronic atrial, junctional, and ventricular tachycardias for pediatric and congenital heart disease patients [45, 46], though it is also used to treat atrial fibrillation in adults [41]. For acute supraventricular and ventricular tachycardias with poor perfusion, amiodarone can be administered as a 5 mg/kg intravenous bolus followed by a 5–15 μg/kg/min continuous infusion. The 5 mg/kg bolus can be repeated up to 20 mg/kg until the tachycardia is terminated or slowed. For adults with poorly perfusing VT, amiodarone may be given as a 300 mg intravenous bolus, with 150 mg boluses should the tachycardia not terminate. For the treatment of chronic tachydysrhythmias, oral amiodarone is given as 10–15 mg/kg/day (or 600–800 mg/1.73 m^2/day in children less than 1 year of age) divided twice daily for 4–14 days loading, followed by 5 mg/kg/day (200–400 mg/1.73 m^2/day in children less than 1 year of age) divided twice daily. For adults, the oral dose is 800–1,600 mg/day divided once or twice daily for 1–3 weeks, followed by 600–800 mg/day divided twice daily. Both pediatric and adult doses should be lowered to the lowest effective dose to minimize side effects. Amiodarone undergoes hepatic metabolism with biliary and renal elimination, and it is highly lipid soluble. Due to its long half-life that ranges from 20 to 55 days, but slightly less in children, for both intravenous and oral forms, the effects of amiodarone persist long after administration has ceased. Amiodarone's many side effects limit its long-term usage. The cardiovascular effects include prolongation of all conduction intervals including the QTc, proarrhythmia, myocardial depression, and hypotension. Interstitial pulmonary fibrosis is one of the many malignant systemic side effects of long-term amiodarone, and this can be irreversible. Therefore, pulmonary function testing should be performed regularly in this medication. Thyroid function can be affected, both hyperthyroidism and hypothyroidism can develop. Hepatotoxicity has been observed as well as hematologic abnormalities including pancytopenia and coagulopathy. Skin discoloration with a blue tinge is observed with sun exposure and amiodarone. Overdose includes bradycardia, AV block, and QT prolongation.

– *Sotalol* is also utilized for the treatment of atrial and ventricular tachycardias [47], although its oral administration limits it to perfusing tachycardias or chronic treatment. It is also effective for atrial fibrillation in adults. Dosing in children is started at 90 mg/m^2/day divided three times daily and can be increased to 180 mg/m^2/day. For children less than 2 years of age, an age-related nomogram exists which decreases the dose by factor for the first 2 years of life. As infants get older and larger, the dose should be increased by both the increase in body surface area and the factor

on the nomogram [48]. Adult dosing is 160–320 mg/day divided twice daily. Sotalol is not metabolized, and it is eliminated in the urine. The dose should be decreased with renal insufficiency. Its half-life ranges from 7 to 12 h. Due to sotalol's proarrhythmic potential, initiating therapy in the hospital is recommended for close monitoring of QT prolongation. The dose should be decreased if the QTc prolongs to $\geq$ 550 msec. Sotalol overdose can cause ventricular dysrhythmias, hypotension, and bradycardia.

– *Dronedarone*, *dofetilide*, and *ibutilide* are medications used in adults for atrial fibrillation [41], but there is currently no evidence for their use in pediatric or congenital heart disease patients.

Class IV Antiarrhythmics: Slow AV Nodal Conduction and Automaticity

Calcium channel block is the primary mechanism of class IV medications, which include verapamil and diltiazem. This results in slowing of conduction and prolonging of refractoriness for tissues dependent on calcium current for phase 0 depolarization, most notably the atrioventricular node (see Fig. 160.5). Therefore, these medications are used to terminate or prevent AV nodal-dependent tachycardias and to slow the ventricular response to atrial tachycardias, including atrial fibrillation. Their actions on diastolic depolarization during phase 4 of automatic tissues make them useful for automatic tachydysrhythmias as well.

– *Verapamil* can be administered intravenously to terminate AV nodal-dependent SVT [49]. It is a first-line therapy for idiopathic left posterior fascicular VT or Belhassen's tachycardia [50]. Verapamil administration is avoided in neonates and infants due to risk of severe myocardial depression and cardiovascular collapse because young patients have calcium-dependent myocardial activation and inotropy. The intravenous dose in children is 0.1–0.2 mg/kg slow push up to 5 mg, with frequent blood pressure monitoring and intravenous calcium (10 mg/kg) at the bedside. This can be repeated every 30 min until the tachycardia terminates. Oral dosing for older children is 4–8 mg/kg/day divided three times daily. For adults, the intravenous dose is 5–10 mg per dose and the oral dosing is 240–480 mg/24 h divided three times daily. Sustained release, with twice daily dosing, and extended release, with daily dosing, are also available. Verapamil undergoes hepatic metabolism and renal excretion, with a half-life of 4–12 h. Overdose is characterized by hypotension and bradycardia with neurologic and gastrointestinal effects. Myocardial depression should be treated with intravenous calcium 10–20 mg/kg.

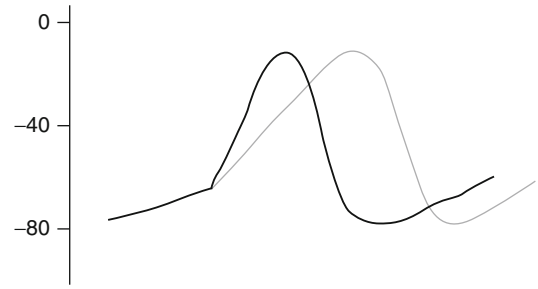

Fig. 160.5 The effect of Class IV antiarrhythmic medications on atrioventricular nodal tissue, slowing phase 0 conduction and prolonging refractoriness

– *Diltiazem* is most commonly used to slow the ventricular response in adults with atrial fibrillation or other atrial tachycardias, and it can be used for the same in children. In the acute setting, intravenous diltiazem can be given with a 0.15–0.45 mg/kg bolus followed by a 2 μg/kg/min infusion in children or a 0.35 mg/kg bolus followed by a 10–15 mg/h infusion in adults. Oral dosing is 1.5–3.5 mg/kg/day divided three to four times daily in children and 180–420 mg/day in adults divided daily or twice daily. Diltiazem undergoes hepatic metabolism, and the half-life is 3–4.5 h. Overdose can cause bradycardia, AV block, and asystole as well as severe myocardial depression. Myocardial depression should be acutely treated with calcium chloride 10–20 mg/kg intravenous push.

Digoxin: Slows AV Nodal Conduction and Increases Parasympathetic Tone

The cardiac effects of digoxin are among the oldest known and most varied of all medications [51]. Through the secondary effects of blockage of the sodium-potassium ATPase, digoxin increases intracellular calcium which increases ionotropy of atrial and ventricular myocardium. Its use for tachydysrhythmias, most notably neonatal supraventricular tachycardias, appears to result from direct slowing of AV nodal conduction and from its indirect systemic parasympathetic effects which decrease cardiac automaticity.

– Digoxin can be dosed as a loading dose over 24 h with the first half of the total loading dose given first, followed by two quarter doses given 8 h and 16 h after the first dose. After the loading, maintenance doses can be divided twice daily. The doses vary significantly based on age, weight, and intravenous versus oral, with intravenous doses being 75–90 % of the oral dose. The oral loading dose, otherwise known as the total digitalizing dose, is 25–35 μg/kg in neonates and 35–60 μg/kg in infants, and it decreases to 10–15 μg/kg in older children. The daily maintenance dose, to be divided twice daily, is 5–10 μg/kg/day in neonates, 10–15 μg/kg/day in infants, and 2.5–5 μg/kg/day in older children. The oral loading dose in adults is 0.75–1.5 mg followed by 0.125–0.250 mg daily. However, often when initiating chronic treatment for SVT in an otherwise stable neonate or infant, loading is not performed and a 5–15 μg/kg/day maintenance dose is started. Digoxin's half-life is as long as 60–170 h in preterm infants to as short as 10 h in toddlers. The half-life is 35–48 h in children and adults. Digoxin is renally excreted, and it cannot be dialyzed if it is overdosed. Decreased dosing is required in renal insufficiency. Digoxin toxicity can cause life-threatening ventricular dysrhythmias, particularly a so-called bidirectional ventricular tachycardia with two distinct QRS complexes which can degenerate into ventricular fibrillation. Sinus bradycardia or AV block can also be observed with digoxin toxicity, as well as supraventricular or junctional dysrhythmias. Treatment of digoxin poisoning requires the administration of digoxin immune Fab, which is an antibody against digoxin.

Adenosine: Rapid AV Nodal Block and Generalized Decreased Automaticity

By slowing inward calcium current and increasing potassium conductance, adenosine increases the refractory period of calcium-dependent conduction, particularly in the AV node. Because of its short half-life of less than 10 s, it is primarily used for brief AV nodal block to terminate AV nodal-dependent supraventricular tachycardias or to help diagnose non-AV nodal-dependent supraventricular tachycardias. However, several other tissues are also adenosine sensitive, including the sinus node and other automatic atrial foci which may pause or terminate. Ventricular tachycardias, particularly of the idiopathic outflow tract tachycardias, may be adenosine sensitive and terminate with adenosine as well.

– Adenosine dosing is 0.05–0.3 mg/kg/dose of an intravenous push. Because of its metabolism in the blood causing a short half-life of <10 s, adenosine should be administered through the largest intravenous line possible or the lumen closest to the heart, and it should be followed by a rapid saline flush. A running electrocardiogram strip, and preferably a 12-lead electrocardiogram, should be running during its administration to document the rhythm change, which is often essential to make a specific diagnosis of a supraventricular tachycardia. Also, adenosine administration occasionally causes atrial fibrillation, which, when pre-excited, has the potential to cause ventricular fibrillation. Adenosine can also cause asystole with sinus nodal block as well as the intended AV nodal block. For these reasons, it is important to have defibrillator patches in place and connected to

a defibrillator in anticipation of urgent defibrillation or transcutaneous pacing. Overdose or prolonged toxicity is rare due to adenosine's short half-life, but acute hypotension or bronchospasm can be observed. Post-adenosine hypotension is often followed by reflexive sinus tachycardia.

Beta-Agonists: Isoproterenol and Epinephrine, Enhance Automaticity

For profound bradycardia resulting from AV nodal block or asystole from sinus node dysfunction, β_1 agonists increase automaticity and potentially improve AV nodal conduction. Isoproterenol acts primarily on β receptors only, which limits its effects to cardiac tissue, with chronotropic and mild inotropic effects, as well as significant vasodilation with accompanied hypotension. Isoproterenol is used in neonatal complete heart block to increase automaticity and possibly AV nodal conduction. Due to enhancing AV nodal conduction, isoproterenol is widely used in the electrophysiology laboratory to mimic exogenous adrenergic stimulation in the sedated or anesthetized patient. It is also effective in enhancing automaticity during the immediate postoperative period for the transplanted heart with a low intrinsic heart rate due to denervation [52]. Epinephrine is a nonselective adrenergic agonist which acts on α and β receptors, causing vasoconstriction with the chronotropic and inotropic effects. Epinephrine is the first-line pharmacologic therapy in most advanced life support algorithms for asystole, though it is also used in the postoperative setting to treat hypotension and low cardiac output.

- *Isoproterenol* has β_1 and β_2 agonist effects, including bronchial dilation and systemic vasodilation. It has a rapid onset and short half-life of 2–5 min requiring continuous infusion as the mechanism of administration. The dose is 0.05–5 μg/kg/min in neonates and children and 2–20 μg/min in adults. Isoproterenol overdose can cause flushing, hypotension, atrial, or ventricular arrhythmias.
- *Epinephrine* can be given intramuscularly, subcutaneously, intratracheally, intraosseously, or intravenously for asystole, bradycardia, or profound hypotension related to vasodilation. The starting dose intravenous dose is 0.01 mg/kg, which can be repeated or even increased up to 0.1 mg/kg, though there is minimal evidence to support the so-called high dose of 0.1 mg/kg over lower doses. It has a rapid onset of less than 1 min and a short half-life of 2–3 min. Continuous infusion of 0.02–1 μg/kg/min is required to prolong the effects of epinephrine. Epinephrine undergoes hepatic and renal metabolism and renal excretion. Hypertension and tachycardia is observed with overdose, as well as the potential for tachydysrhythmias and sudden death.

Cholinergic-Receptor Blocker: Atropine, Inhibits Parasympathetic Input, Enhancing Automaticity

By inhibiting muscarinic receptors responsible for parasympathetic input to the sinus node, atrium, and AV node, atropine increases heart rate and AV nodal conduction by enhancing automaticity. It is used in vagally mediated asystole or even as prophylaxis for vagally mediated asystole during the intubation of neonates [53]. Atropine is also utilized in the electrophysiology laboratory to enhance automaticity and increase the chance of inducing atrial or AV nodal-dependent tachycardias. Systemically, this parasympathetic blockade causes bronchodilation, mydriasis, cycloplegia, and generalized decreased secretions. Because its half-life is 2 h, tachycardia and the systemic side effects persist long after the indication for administration has resolved.

- *Atropine* can be given intratracheally or intravenously at 0.02 mg/kg/dose up to 1 mg dose. It is metabolized in the liver and has a half-life of 7 h in infants and toddlers and 2.5 h in children and adults with renal excretion. Dilated, unreactive pupils with blurred vision, hyperthermia, hypertension, and tachycardia are seen with overdose.

Medical Management of Specific Dysrhythmias by Substrate

Structurally Normal Heart

Fetal Tachycardia

Fetal tachycardias, defined as fetal heart rate >180 beats/min, can significantly decrease fetal cardiac output causing hydrops fetalis and fetal demise. Although transabdominal electrocardiogram (ECG) or magnetocardiogram (MCG) may be of value in the diagnosis, most commonly fetal tachycardias are assessed by fetal echocardiographic M-mode or Doppler techniques which aim to characterize the rate and the atrial-ventricular relationship. Common mechanisms of fetal tachycardias include atrial flutter, atrioventricular reentrant tachycardia (AVRT), and long VA tachycardias like the permanent form of junctional reciprocating tachycardia (PJRT) or ectopic atrial tachycardias (EAT). Occasionally ventricular tachycardia or junctional ectopic tachycardia (with VA dissociation) is observed. Medical treatment is primarily through maternal administration of oral medications, though intravenous maternal administration of amiodarone and lidocaine can be used. Direct injection of adenosine, digoxin, or amiodarone into the umbilical vein has been performed. For profound hydrops in a fetus that has reached viability, delivery and postnatal treatment may be necessary.

- First-line medications: digoxin sotalol
- Second-line medications: flecainide, amiodarone, procainamide (for ventricular tachycardia, lidocaine and mexiletine have been used [54])

Fetal Bradycardia

Fetal heart rate <100 beats per minute defines fetal bradycardia. Transient sinus bradycardia is common and usually well tolerated in most fetuses. On the other hand, fetal heart block, and particularly complete heart block, can cause low output with hydrops with up to 43 % mortality. Like with fetal tachydysrhythmias, fetal bradycardia is most commonly diagnosed through ultrasound assessment, with the A-V relationship crucial to the diagnosis. Immunologic damage to the AV node through the passage of maternal antibodies beginning in the second trimester is a common mechanism of complete heart block, although it may occur sporadically in the absence of passage of maternal antibiotics. Maternal administered therapies are attempted, but delivery and postnatal treatment of the fetus with isoproterenol or pacing may be required.

- Medications to consider: steroids (primarily dexamethasone [2] and β agonist (salbutamol))

Neonatal SVT

Supraventricular tachycardia in the neonatal period is relatively common. Mechanisms include orthodromic AVRT, atrial flutter, or ectopic atrial tachycardia (EAT). Atrioventricular nodal reentrant tachycardia (AVNRT) is rare in neonates [55]. Neonatal SVT, when reentrant or triggered, tends to respond to cardioversion, either via direct current, medical (adenosine for AVRT, AVNRT, and some EATs), or transesophageal burst pacing. Often, no further medical therapy for atrial flutter is required after cardioversion. Orthodromic AVRT, EAT, and AVNRT tend to require preventative medications after cardioversion, particularly since neonates cannot communicate symptoms of tachycardia and, therefore, may be in SVT for prolonged periods without caretakers becoming aware. Many neonatal SVTs will resolve completely by in the first 1–2 years of life and require no further medical therapy [8, 56, 57].

- First-line medications:
  - Acute: adenosine, esmolol IV infusion, procainamide IV infusion, amiodarone IV bolus followed by IV infusion, propranolol IV, digoxin IV
  - After conversion: digoxin (if there is no preexcitation), propranolol
- Second-line medications: acute – procainamide IV infusion, amiodarone IV infusion; after cardioversion – flecainide, propafenone, sotalol, amiodarone

Neonatal VT

Ventricular tachycardia can have a relatively narrow QRS complex in neonates and tends to be better tolerated in neonates compared to VT in older children and adults [58]. Enhanced automaticity is the most common mechanism, although these can be triggered in this population. Reentrant VT is rare in neonates. Occasionally, adenosine can be effective in cardioverting idiopathic VT before direct current cardioversion is required. Frequent premature ventricular contractions or nonsustained VT is rarely life-threatening but can cause a decrease in ventricular function. Therefore, premature ventricular contractions occasionally require medical therapy to decrease their frequency.

- First-line medications:
  - Acute: adenosine, amiodarone IV infusion, lidocaine IV infusion, procainamide IV infusion
  - After cardioversion: propranolol, atenolol
- Second-line medications: oral amiodarone, flecainide, mexiletine, propafenone, phenytoin (sodium channel blocker), sotalol

Neonatal Bradycardia

Neonatal bradycardia is most likely related to outside conditions, particularly hypoxia or vagal stimulation, which can cause sinus bradycardia without adequate junctional escape. Bradycardia in neonates tends to improve relatively rapidly by improving the inciting factor. Non-transient causes of bradycardia in neonates include congenital complete atrioventricular block. If bradycardia is prolonged, oxygen should be administered, bag-mask ventilation may need to be administered, the neonate should be stimulated, and chest compressions or external pacing may be required.

- First-line medications: atropine, epinephrine IV bolus
- Second-line medications: isoproterenol IV infusion, epinephrine IV infusion

Child and Adolescent SVT

Supraventricular tachycardia in children and adolescents is also relatively common. The frequency of the different mechanisms changes during childhood, in that orthodromic atrioventricular reentrant tachycardia (OAVRT) is the more common, and atrioventricular nodal reentrant tachycardia (AVNRT) is less common, in younger children [70]. In teenagers and young adults, AVNRT is the most common mechanism of SVT, while accessory pathway-mediated SVTs are less commonly observed. Unlike the neonate, accessory pathways and the presence of OAVRT are unlikely to resolve after the age of 2 years. Ectopic atrial tachycardia (EAT) and atrial flutter (AFL) are observed in this population, but much less frequently. Intracardiac radiofrequency or cryoablation can be safely performed in children, and this is offered as a treatment option for children starting at 15–25 kg. Other suitable treatment options include symptomatic care or treatment, as SVT is not considered life-threatening, and many parents desire for their child not to be subjected to an invasive procedure or to the potential side effects of medications.

- First-line medications:
  - Acute, incessant, or poorly tolerated: adenosine, propranolol IV, verapamil IV (in the adolescent, through not to be used in the infant or younger child), esmolol IV infusion, procainamide IV infusion, amiodarone bolus followed by IV infusion
  - After cardioversion: atenolol, propranolol, digoxin
- Second-line medications: flecainide, propafenone, sotalol, amiodarone PO

Non-Postoperative JET

Junctional ectopic tachycardia is rare in the non-postoperative setting. When VA dissociation is present, hemodynamic compromise from this dysrhythmia can be greater than SVT and even VT at similar rates. The hemodynamic compromise may require extracorporeal support [59]. Treatment is geared toward decreasing autonomic influence on the patient with sedation, cooling, and withdrawal of beta-agonist medications. Overdrive atrial pacing (either transvenous or esophageal) can improve hemodynamics by providing AV synchrony until therapy can be initiated.

- First-line medications: amiodarone IV infusion or oral, propranolol or other beta-blockers, digoxin, narcotics, and sedatives

– Second-line medications: procainamide, flecainide, sotalol, propafenone

Child and Adolescent JET

Junctional ectopic tachycardia (JET) in the child and adolescent with a structurally normal heart can have similar untoward hemodynamic effects as JET in the neonate. The most common presentation of JET in pediatrics is with rapid or irregular heart rate, but the second most common is heart failure [60]. Many different medical combinations have been attempted, with amiodarone being the most common.

– First-line medications:
  • Acute, poorly tolerated: amiodarone IV infusion, esmolol IV infusion lidocaine IV infusion, procainamide IV infusion
  • Subacute, well tolerated: amiodarone PO, beta-blocker, digoxin
– Second-line medications: flecainide, propafenone, mexiletine, verapamil

Child and Adolescent VT

Ventricular tachycardia in the structurally normal heart is most commonly due to an automatic mechanism, and like for the neonate, macroreentry remains rare with the exception of left posterior fascicular and "verapamil-sensitive" ventricular tachycardia which has been shown to be a reentrant mechanism [61]. In general, idiopathic ventricular tachycardia tends to be well tolerated with low chance of degeneration into ventricular fibrillation and sudden cardiac death.

– First-line medications:
  • Acute, poorly tolerated: lidocaine IV infusion, amiodarone IV infusion, verapamil IV infusion, esmolol IV infusion
  • Subacute, well tolerated: beta-blocker, verapamil PO
– Second-line medications: amiodarone PO, flecainide, sotalol, mexiletine

Child and Adolescent Bradycardia

Chronic bradycardia in pediatrics and adolescents tends to be well tolerated, whether due to sinus node dysfunction or various forms of atrioventricular block. Even complete atrioventricular block can be asymptomatic provided that the junctional escape rate is adequate. Pacing is the treatment for chronic, symptomatic bradycardia that is not expected to improve. Acute-onset bradycardia most often occurs in the setting of a profound vagal response, but it can also occur in response to coronary ischemia in the setting of thrombosis from coronary aneurysms in Kawasaki disease. Also, bradycardia and heart block can occur as the result of infiltrative autoimmune diseases, like rheumatic heart disease, or infection, Lyme disease.

– First-line medications:
  • Acute, poorly tolerated: atropine IV bolus, epinephrine IV bolus
– Second-line medications: isoproterenol IV infusion, epinephrine IV infusion

Child and Adolescent Channelopathies

Genetic diseases involving cell wall channels which regulate depolarization and subsequent repolarization are called channelopathies. They represent a heterogenous group of conditions resulting in life-threatening tachydysrhythmias and sudden death in people with normal heart structure and function. The cardiac channelopathies include long QT syndrome, short QT syndrome, Brugada syndrome, and catecholaminergic polymorphic ventricular tachycardia (CPVT). Several known channel defects exist for each of these diseases, and so medical treatment of similar phenotypes can vary based on genotype. For example, beta-blocker is quite effective at preventing life-threatening tachydysrhythmias and sudden death in long QT type 1 (KCNQ1 gene), but not so in long QT type 3 (SCN5A gene) [48], where mexiletine has been proposed as a gene-specific treatment [62], though clinical studies in humans have not demonstrated its effectiveness. For catecholamine-related channelopathies, long QT type 1 and CPVT, surgical sympathetic ganglionectomy has been performed to prevent life-threatening arrhythmias [63].

– Long QT 1 and 2: beta-blocker (nadolol, atenolol, propranolol)

- Long QT type 3: +/− mexiletine
- Catecholaminergic polymorphic ventricular tachycardia (CPVT): beta-blocker (nadolol, atenolol, propranolol), flecainide [64]
- Brugada syndrome: +/− quinidine [65] +/− mexiletine [66].

Adult-Atrial Fibrillation

Atrial fibrillation is the most common tachydysrhythmia in adults >50 years of age [67]. The etiology is multifactorial, with anatomical substrates, thoracic vein to atrial connections, and the ligament of Marshall, combining with autonomic influences triggering rapid and chaotic atrial depolarization with ineffective contraction. The resulting hemostasis in the left atrium increases the risk of stroke in patients with chronic atrial fibrillation. Anticoagulation with aspirin and/or Coumadin is recommended for patients with increased risk based on a risk-assessment scoring system [68]. Recurrent paroxysmal or persistent atrial fibrillation requires treatment to control rate or maintain sinus rhythm. Though ablation with radiofrequency or cryothermal energy from an endocardial, or even a combined endocardial/epicardial, approach is becoming increasingly effective for refractory atrial fibrillation, medical therapy to maintain sinus rhythm remains the first-line approach [81].

- First line with minimal or no heart disease: flecainide, sotalol, dronedarone, propafenone
- Second line with minimal or no heart disease: amiodarone, dofetilide
- First line with coronary artery disease: sotalol, dronedarone, dofetilide
- Second line with coronary artery disease: amiodarone

Congenital Heart Disease

Acute Postoperative SVT

The hemodynamic effects of supraventricular tachycardia in patients with repaired congenital heart disease in the acute postoperative period can be magnified due to recent ischemia from circulatory arrest and cardiopulmonary bypass causing profound hypoperfusion and resulting in further ischemia. These patients are often on adrenergic stimulating medications which increase heart rate and enhance automaticity. Mechanisms of SVT in postoperative patients include atrial reentry (micro-reentry or macro-reentry) due to atriotomies from atrial cannulation for cardiopulmonary bypass and automatic atrial tachycardia due to atrial reperfusion. Moreover, increased atrial automaticity or premature atrial beats provoked by indwelling lines can expose existing substrates for SVT such as concealed (retrograde-only) accessory pathways, dual AV nodal physiology, or conduction delay across the cavo-tricuspid isthmus. Diagnosis of the precise mechanism of SVT by surface electrocardiograms in the postoperative patient is complicated by already elevated heart rates which can obscure the P waves within the T wave. When temporary atrial epicardial pacing wires are placed, atrial electrograms can be obtained to evaluate the relationship between atrial and ventricular depolarization (A-V or V-A relationship). Atrial pacing wires can also be used to terminate reentrant rhythms (either intra-atrial reentry or atrioventricular reentry) by burst atrial pacing. When atrial pacing wires are not available for diagnosis and treatment, adenosine can be given to evaluate and treat SVT. However, adenosine may need to be given at higher doses than initially recommended due to low cardiac output states to allow the medication to get through the right heart, lungs, and left heart to the coronary arteries. Medications that depress cardiac contractility must be avoided. Enteral medications usually cannot be used in the acute setting, but patients can be transitioned to enteral medications to maintain sinus rhythm.

- First line:
  - Acute, poorly tolerated: adenosine, amiodarone IV bolus followed by IV infusion
  - After cardioversion: amiodarone IV infusion, procainamide IV infusion
- Second line:
  - Acute, poorly tolerated: procainamide IV bolus followed by infusion

- After cardioversion: procainamide IV infusion, esmolol IV infusion (only if the blood pressure is adequate), propranolol PO, sotalol PO

Postoperative JET

Postoperative junctional ectopic tachycardia is often related to sutures or traumatic stretch during the closure of ventricular septal defects [69]. Although it is frequently self-limited and tends to resolve 2–3 days after surgery, the hemodynamic effect of tachycardia with VA dissociation in the immediate postoperative period can be profound. In patients with postoperative diastolic dysfunction, loss of the atrial contribution to ventricular filling can cause hypotension and decreased perfusion even at rates which are normally tolerated when there is atrial-ventricular synchrony. Therefore, the first-line approach is to overdrive atrial pace patients with JET faster than the rate of the tachycardia. However, as an automatic dysrhythmia, junctional ectopic tachycardia is exacerbated by catecholamines which are required by most patients immediately after surgery for inotropic support. Therefore, improving analgesia and sedation with narcotics and sedating medications is frequently required. Induction of hypothermia has been proposed as a treatment of postoperative JET as well. The α2-agonist dexmedetomidine, which is increasingly used as sedation in the intensive care unit, has been suggested as a treatment for postoperative JET, but this is currently being studied [70]. When the rate of the tachycardia is too fast to overdrive pace or pacing wires are not readily available, antiarrhythmic medications are required, though usually only until the dysrhythmia resolves spontaneously.

– First line: amiodarone IV infusion [71], procainamide IV infusion [72], digoxin IV, esmolol IV infusion
– Second line: dexmedetomidine IV infusion, propranolol IV.

Acute Postoperative VT

Postoperative ventricular tachycardia in repaired congenital heart disease can be life-threatening and usually requires urgent or emergent intervention, including direct-current cardioversion or defibrillation. The combination of endocardial ischemia related to cardiopulmonary bypass and newly created surgical scars in the face of increased metabolic demands from the infusion of catecholamines and the mechanism of postoperative ventricular tachycardia can be reentrant, automatic, or triggered. Treatment can involve decreasing metabolic demands, decreasing catecholamines, improving sedation, overdrive atrial pacing of automatic arrhythmias, and pace termination of reentrant tachycardias. Medical therapy can be required for cardioversion, but more frequently it is used for prophylaxis after the rhythm has been terminated.

– First line: amiodarone IV bolus followed by infusion, lidocaine IV bolus followed by infusion, esmolol IV infusion
– Second line: digoxin IV, propranolol IV, flecainide

Acute Postoperative Bradycardia

Postoperative bradycardia can be the result of surgical stretch or direct injury to the sinus node or AV node, injury to the arterial supply to the sinus node or AV node, or simply insufficient rate to meet increased metabolic demands secondary to autonomic denervation during the surgical repair. Atrial and/or ventricular pacing is the first-line approach, and temporary epicardial pacing wires are commonly placed by surgeons after repair of congenital heart disease. Intrinsic conduction system injury often improves several days after surgery and can require no long-term intervention. If improvement of AV block or sinus node dysfunction is not observed by 10–14 days after surgery, placement of a permanent pacing system is recommended [73]. In the immediate postoperative period, β-adrenergic stimulation is used to increase the heart rate. Acute bradycardia is treated with atropine.

– First line: epinephrine IV infusion, isoproterenol IV infusion, dopamine IV infusion, atropine

Chronic Postoperative SVT

Patients with repaired congenital heart disease, and particularly those with extensive atrial

suture lines such as atrial switch repairs for d-transposition of the great arteries and total cavopulmonary (Fontan) repairs for single ventricle lesions, are at increased risk for intra-atrial reentrant tachycardia (IART). IART and other supraventricular tachycardias can have a profound effect on postoperative patients with marginal systolic and diastolic function. The presence of IART or other SVTs is linked with increased mortality in postoperative d-transposition of the great arteries [74] and Fontan patients [75]. Therefore, supraventricular tachycardias are treated more aggressively in these populations, and radiofrequency ablation is recommended with more urgency when these patients develop SVT.

Chronic postoperative supraventricular tachycardia is medically treated similarly to non-postoperative SVT with a few exceptions. Due to increased mortality observed in adults with structural or ischemic heart disease and children with underlying heart disease [30], flecainide is not recommended. Also, like chronic therapies in all patients, the long-term side effects of medications weight into the decision more than in the acute setting. For example, amiodarone use for chronic arrhythmias is recommended much more cautiously as long-term thyroid dysfunction, pulmonary fibrosis, and liver dysfunction are considered.

- First line: propranolol, atenolol, digoxin,
- Second line: sotalol, amiodarone, propafenone

Chronic Postoperative JET

Treatment of chronic postoperative junctional ectopic tachycardia is similar to the treatment of non-postoperative JET, with the similar caution with flecainide in structural or ischemic heart disease.

- First line: beta-blocker, digoxin
- Second line: amiodarone, sotalol, propafenone, mexiletine

Chronic Postoperative VT

Ventricular tachycardia in repaired congenital heart disease has been well studied in tetralogy of Fallot, and in that population, VT is a known risk factor for sudden cardiac death [76]. VT in patients with systemic right ventricles, as in patients with atrial switch repairs of d-transposition of the great arteries, also significantly increases the risk of sudden cardiac death [77]. For this reason, nonmedical therapies including radiofrequency ablation and implantable cardioverter-defibrillators are often utilized as the first-line approach to VT in surgically repaired tetralogy of Fallot and d-transposition of the great arteries. Medical therapy is often adjunctive to the invasive therapies. As with other repaired congenital heart disease, flecainide is avoided to do increased risk of sudden death.

- First line: beta-blocker, sotalol, amiodarone
- Second line: propafenone, mexiletine

Chronic Postoperative Bradycardia

Pacing is the mainstay of treatment of chronic postoperative bradycardia in patients with congenital heart disease due to sinus node dysfunction or postoperative AV nodal block. Patients with relatively minimal sinus node dysfunction or with adequate escape mechanisms may be asymptomatic in baseline states, but they can develop symptoms of fatigue, pre-syncope, or syncope due to chronotropic incompetence during exercise or other physiological stress, like infections.

Unrepaired Cardiac Defects and SVT, JET, and VT

The principles of arrhythmia management in unrepaired congenital heart disease are similar to those in patients with structurally normal hearts, with special consideration required for certain arrhythmogenic substrates. One or more accessory atrioventricular connections are associated with Ebstein's anomaly of the tricuspid valve [78] and can be observed with Ebsteinoid valves of L-transposition of the great arteries [79], leading to increased risk of AVRT and possibly of pre-excited atrial arrhythmias. Twin AV nodes have been observed in patients with right atrial isomerism, other heterotaxy syndromes, and complete AV septal defects [80, 81]. Atrioventricular reentry is then possible utilizing one node as an antegrade limb and the other node for retrograde conduction. Also, a direct

electrical connection between the twin AV nodes called a Mönckeberg's sling [82] can be a potential dysrhythmic substrate for SVT in these patients.

Unrepaired Cardiac Defects and Bradycardia

Bradycardia in patients with unrepaired congenital heart disease is treated identically to patients with structurally normal hearts. Medical treatment of acute bradycardia includes beta-adrenergic stimulation with epinephrine or isoproterenol and vagal inhibition with atropine in conjunction with appropriate cardiopulmonary resuscitation. Chronic bradycardia is treated with pacing. Certain anatomical considerations make chronic bradycardia more likely. Sinus node dysfunction is observed in patients with heterotaxy syndromes with left atrial isomerism [83]. The sinus node is a right atrial structure, and so impulse formation in patients without a right atrium is through subsidiary atrial pacemakers which may be insufficient to meet metabolic demands. Patients with L-transposition of the great arteries, or L-looped ventricles in general, have increasing AV block with time which is likely sub-AV nodal due to the prolonged course of His bundle from a right-sided right atrium transseptal to a left-sided right ventricular septum [84].

Temporary and Permanent Pacemakers and Automated Internal Defibrillators

161

Elizabeth A. Stephenson and Charles I. Berul

Abstract

While many of the principles of device-based arrhythmia management are universal, there are important differences between typical adult management and that of pediatric and congenital heart disease patients. This chapter will provide an overview of device management, with particular focus on issues most relevant to these unique patient populations.

Introduction

While many of the principles of device-based arrhythmia management are universal, there are important differences between typical adult management and that of pediatric and congenital heart disease patients. This chapter will provide an overview of device management, with particular focus on issues most relevant to these unique patient populations.

The decision to institute permanent pacing is a complex one, particularly in pediatric and congenital heart disease populations. A balance of risk and benefit is essential, with primary goals of maximizing patient safety while ameliorating symptoms. Evidence-based guidelines are available and updated regularly in a joint document published by the American Heart Association (www.americanheart.org), the American College of Cardiology (www.acc.org), and the Heart Rhythm Society (www.hrsonline.org) [1] (Appendix I). The recommendations have been formalized by a class ranking and weight of evidence grade. Class I includes conditions for which there is evidence or general consensus that therapy is useful and effective. Class II includes conditions for which there is conflicting evidence and/or divergence of opinions and is divided into Class IIa (weight of evidence/opinions favors usefulness/efficacy) and IIb (evidence/opinions not as clear). The weight of evidence is then subcategorized as to whether the data were derived from multiple randomized clinical trials involving large numbers of patients (A), limited number of randomized trials with small numbers of patients or careful analyses of nonrandomized studies or observational registries (B), or expert consensus was used to decide the recommendation (C). Class III includes conditions for which there is evidence or general agreement that the treatment (i.e., ICD therapy) is not useful or effective and might be harmful.

Permanent Pacing: Bradycardia-Related Indications

Complete Atrioventricular Block

Complete atrioventricular block (CAVB), also known as complete heart block or third-degree heart block, exists when there is no conduction of electrical impulses from the atria to the ventricles. This can be either congenital or acquired. It occurs in approximately 1 in 20,000 live births [2, 3]. Congenital atrioventricular block is associated with maternal anti-Ro and anti-La antibodies and occurs in 5 % of fetuses of affected mothers [4]. However, 85 % of children born with CAVB are born to mothers without connective tissue disease. Recent studies have shown a correlation with increasing antibody titers and the likelihood of development of CAVB [5]. Other possible etiologies include structural heart disease such as corrected transposition, as well as inherited conduction system diseases such as SCN5A channelopathy [6].

The rationale for antibradycardia pacing for CAVB is to prevent syncope and sudden death, as well as reduce symptoms of chronotropic incompetence [3].

Class I indications for pacing in CAVB include those with symptoms due to bradycardia, ventricular dysfunction, a wide QRS escape, and complex ventricular ectopy [1] (Fig. 161.1). At times, symptoms may be subtle and more challenging to identify, such as the need for prolonged naps and nightmares [7]. Another Class I indication for pacing in this group is based on heart rate; an infant with a ventricular rate less than 55 beats per minute or with congenital heart disease and a ventricular rate less than 70 beats per minute meets criteria for pacing. Although the original studies reporting these thresholds did not have 24-h Holter data, this is frequently interpreted as an average heart rate over 24 h [2, 8].

For those children with atrioventricular block (either advanced second degree or third degree)

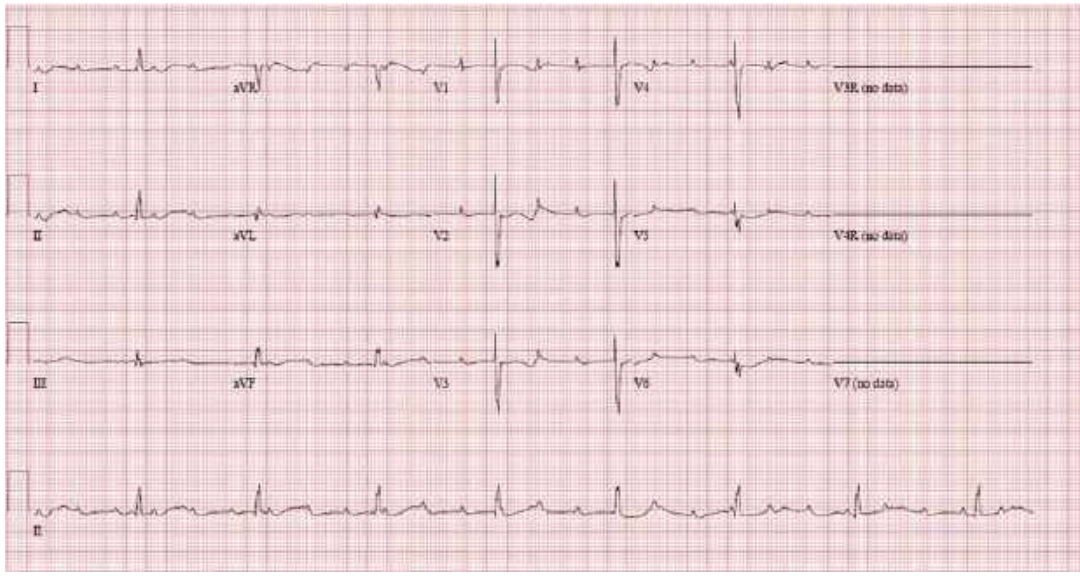

Fig. 161.1 Complete atrioventricular block with slow escape rhythm in a neonate

older than a year, a heart rate of less than 50 is a Class IIa recommendation, leaving more room for interpretation [1]. Other indications in that recommendation include abrupt pauses of two to three times the original cycle length or symptoms due to chronotropic incompetence. Long abrupt pauses in ventricular rate suggest the possibility of junctional exit block which may represent an unstable escape mechanism.

Advanced Second-Degree Atrioventricular Block

Managing advanced second-degree block can be challenging, as prediction of potential progress, as well as underlying escape rhythm, may be difficult. Wenckebach or Mobitz I block is typically more benign and unlikely to progress to higher-grade block. Mobitz II, on the other hand, may represent infra-Hisian block and thus is less predictable. As in all heart blocks, it is important to rule out any possible reversible causes of AVB before considering permanent pacing. Individual evaluation using the recommendations for CAVB is often helpful. For example, symptoms, a wide QRS escape, a prolonged corrected QT interval, or complex ventricular ectopy may be reasons to proceed with anti-bradycardia pacing.

Long QT syndrome is a unique subset of patients who may require pacing, most often due to functional 2:1 atrioventricular block or sinus bradycardia with pause-dependent ventricular tachycardia or torsades de pointes. A prolonged QTc in the setting of congenital complete atrioventricular block is considered by some as an indication for anti-bradycardia pacing and is discussed in the guidelines [1, 3, 7, 9, 10].

Any patients with significant bradycardia who do not currently meet pacing indications require careful follow-up with serial electrocardiograms, Holter monitors, and echocardiograms. Echocardiographic monitoring can document ventricular size and function as well as mitral valve regurgitation [7]. Ventricular dysfunction is a Class I recommendation for pacing, and dilatation and/or mitral regurgitation might be considered relative indications to pace, in the settings of other concerning findings.

Some authors have recommended that all patients with CAVB be paced by the time they

reach adolescence because a risk of syncope or sudden death exists, even in the absence of poor prognostic signs. This is balanced by the increased feasibility and ease of transvenous pacing in these near-adult-sized patients. This is currently a Class IIb recommendation and is becoming increasingly accepted [3, 7, 11].

Postoperative Atrioventricular Block

Those children with postoperative high-grade second-degree AVB and CAVB reflect a particularly high-risk patient group, due to the well-documented risk of sudden death [12]. However, there is a very high rate of recovery of conduction in the early postoperative period, and thus, unless the surgeon is confident of extensive damage to the conduction system, it is important to wait at least seven to nine postoperative days [13, 14].

Patients in whom postoperative advanced second- or third-degree atrioventricular block has resolved and in whom conduction returns to normal have a good prognosis and pacing is not indicated, and this is represented as a Class III recommendation in the guidelines [1, 15]. However, if there is incomplete recovery with new residual bifascicular block (complete right bundle branch block and left axis deviation), uncertainty remains about the stability of this conduction. This is included as Class IIb, and although most physicians will not initiate permanent pacing, these patients clearly require meticulous monitoring. Long-term instability of the conduction system has been suggested in patients with even transient postoperative heart block and is thought to contribute to late sudden death in some patients [16]. Thus, these patients should be monitored for any recurrence of heart block with regular Holter monitors.

Sinus Node Dysfunction

Symptomatic bradycardia may be due to either sinus node dysfunction or AV node dysfunction. Sinus node dysfunction is particularly common in those patients who have had congenital heart disease surgery. However, it is frequently asymptomatic and thus may not require pacing. Sinus node dysfunction may be due to sinus bradycardia, sinus pauses, or sinoatrial block and may occur in isolation or as part of tachycardia-bradycardia syndrome [17].

With respect to sinus bradycardia, the primary criterion for prescribing permanent pacing is the concurrent observation of symptoms. The clinical significance of any given level of bradycardia is age dependent; for example, a resting heart rate of 45 may be a normal finding in a fit adolescent but in a neonate represents a profound bradycardia. Symptomatic bradycardia is defined as a documented bradyarrhythmia that is directly responsible for the clinical manifestations of syncope or near syncope, transient dizziness or lightheadedness, or confusional states resulting from cerebral hypoperfusion. Fatigue, exercise intolerance, and congestive cardiac failure may also result from bradycardia, and these may occur at rest and/or with exertion [1].

Guidelines for the Holter diagnosis of sinus bradycardia have been proposed based on normative data, but unfortunately much of the data does not distinguish between the sleep and wake states: in neonates and infants less than 60 beats per minute while sleeping and less than 80 beats per minute during waking hours; in children aged 1–6 years, less than 60 beats per minute; and in children aged seven to eleven, less than 45 beats per minute. Adolescents and young adults in the general population may be classified as bradycardic under 40 beats per minute, but that drops to less than 30 beats per minute in trained athletes [17].

Symptom-rhythm correlation is required prior to determining the need for permanent pacing in sinus bradycardia. Caution must be exercised not to confuse physiologic sinus bradycardia (which can be quite impressive in many adolescents and trained athletes) with pathological bradyarrhythmias. Alternative etiologies must be considered and excluded as causing either the symptoms or the bradycardia. These include anemia, iron deficiency, hypothyroidism, apnea, seizures, space-occupying lesions of the central

nervous system, Arnold-Chiari malformations, breath holding, and other neurally mediated mechanisms. On occasions, symptoms may only become apparent in retrospect after institution of anti-bradycardia pacing, particularly if the bradycardia was gradual in onset.

In patients with congenital heart disease, abnormal physiology and ventricular performance can result in symptomatic bradycardia at rates that would not be symptomatic in those with more normal physiology. In these patients, a lower threshold for pacing is based on the correlation of symptoms with relative bradycardia.

Tachycardia-Bradycardia Syndrome

In some patients, the presence of sinus bradycardia allows for the emergence of atrial arrhythmias such as atrial fibrillation, atrial flutter, intra-atrial reentry tachycardia, or sinus node reentry tachycardia. When the atrial arrhythmias are transient, profound bradycardia can result following termination due to sinus node suppression in the setting of sinus node dysfunction. This is a recognized problem following surgery for congenital heart disease, particularly in the adult congenital heart disease population. Anti-bradycardia pacing may be part of a management plan that often also includes antiarrhythmic medication. This might be done with or without atrial antitachycardia pacing (as will be discussed later in this chapter). Other strategies may include catheter ablation or surgical revision with creation of "lines of block" to prevent intra-atrial reentry [18, 19].

Syncope and Breath-Holding Spells

In adult practice the use of pacing for patients with neurally mediated syncope may have a role for those who have minimal or no prodrome or those who fail standard therapy or those who have profound bradycardia or asystole during syncope [20]. For such patients, pacing may increase the time from the onset of symptoms to loss of consciousness, providing critical time for evasive action. The practice, however, is controversial with considerable evidence of a placebo effect [21]. The use of pacing for this indication in pediatrics is rare. Pacing has been used for the exceedingly rare child with severe breath-holding spells associated with profound bradycardia and major pauses, but this should be considered only after all other options are excluded and no behavioral or medical remedy is found, due to the recognized morbidity of permanent pacing [22].

Long QT Syndrome

As alluded to above, pacing can be an adjunctive therapy in long QT syndrome. It is instituted with a moderately high baseline heart rate (usually a lower rate of 80–90) and used with concomitant beta-blockade [23]. An increased heart rate is thought to shorten the QT while minimizing pause-related QT prolongation. This use of pacing (which is not entirely protective) has diminished somewhat since the widespread use of implantable cardioverter-defibrillators. Some patients (particularly neonates) with a very long QT may have functional 2:1 block and these patients may benefit from pacing (Class IIa); however, this presentation of long QT syndrome is associated with a high risk of sudden death despite pacing (Figs. 161.2 and 161.3). Established pause-dependent initiation of ventricular tachyarrhythmias with or without a long QT is a Class I indication. Pacing may also used in patients with long QT syndrome and sinus bradycardia, which may be exacerbated by beta-blockade. The use of implantable defibrillators in some high-risk long QT patients is of proven benefit and is likely to be safer than pacing alone but does raise the potential of a defibrillator shock causing an adrenaline surge, triggering electrical storm [24].

Hypertrophic Cardiomyopathy

Dual-chamber pacing has been theorized to diminish left ventricular outflow obstruction in

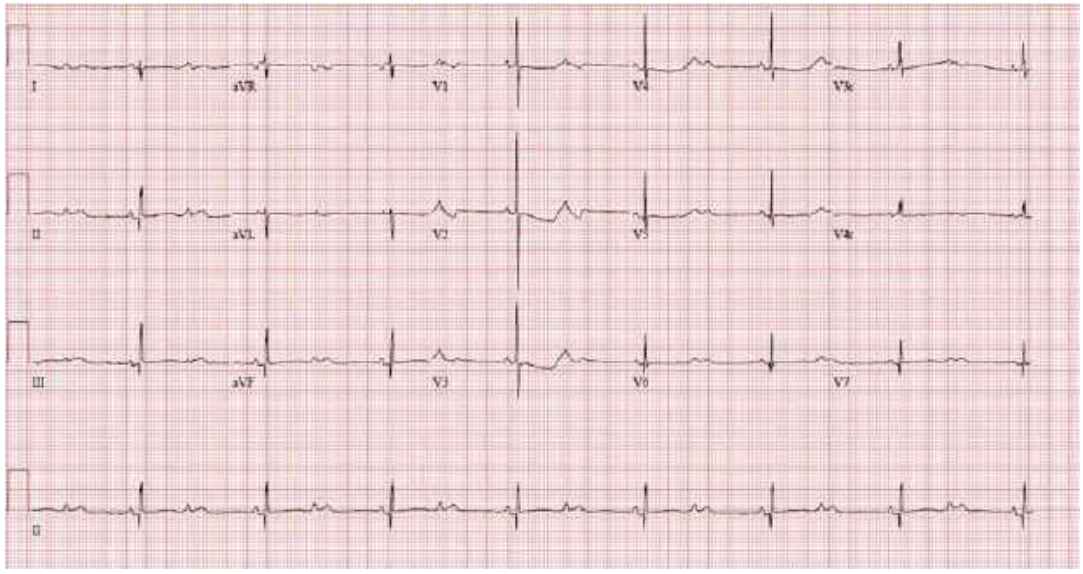

Fig. 161.2 2 to 1 AV block due to prolonged QT interval

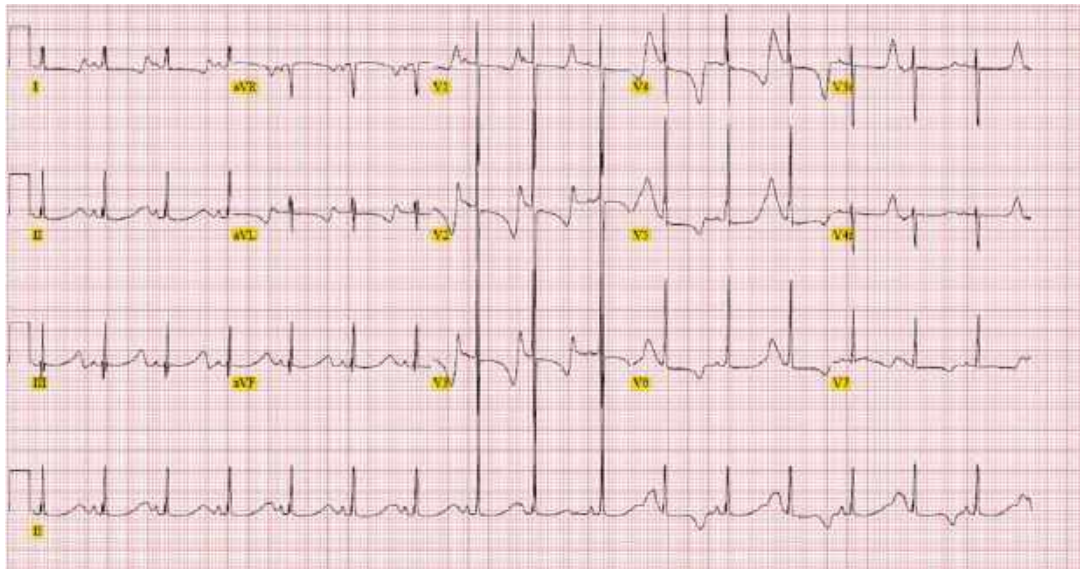

Fig 161.3 T wave alternans in Long QT Syndrome

hypertrophic cardiomyopathy by altering the activation sequence of the ventricular myocardium. If intrinsic conduction is intact, a short atrioventricular interval must be utilized to allow capture of the ventricular tissue. The response to pacing in hypertrophic cardiomyopathy is variable and its use controversial. Of note, randomized trials have failed to demonstrate benefit [25]. Given the strong data showing the efficacy of the implantable defibrillator in decreasing sudden death in this population, these patients are now more likely to undergo implantation of a defibrillator rather than a bradycardia device.

Pacemaker Function

Implantation Considerations

In pediatric and adult congenital cardiology, practitioners face a unique set of challenges including complex anatomy, small patient size, growth, intracardiac shunts, the need for long-term venous access, impaired myocardial performance, surgical scarring, and late postoperative arrhythmias. An understanding of the anatomy, surgical procedures, and electrophysiologic characteristics must be combined with principles of pacing, allowing individualized decisions to be made for each patient.

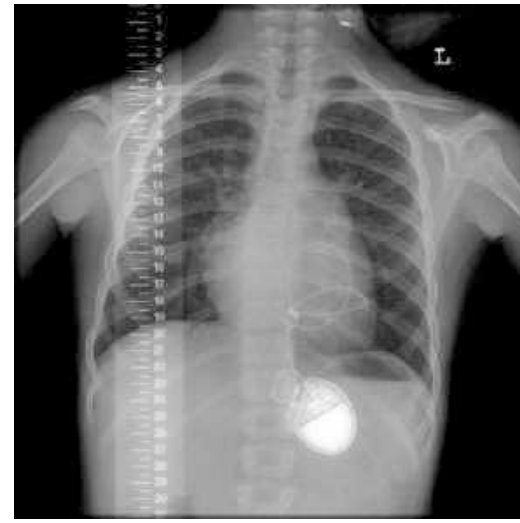

Fig 161.4 Epicardial pacing wires causing cardiac strangulation with lead fractures

Epicardial Versus Endocardial Implantation

Once a decision has been made to place a permanent pacemaker in a patient, the method of accessing myocardial tissue must be determined. Leads may be placed via several routes: transvenous, epicardial, or (far less commonly) transmural. Pacing leads are by necessity flexible and are exposed to years of mechanical stress. This makes them a vulnerable part of a pacing system, and the majority of pacemaker system problems are related to lead issues. This is particularly the case in pediatrics and congenital heart disease, where growth and an active lifestyle typically add to the demands on the leads [26]. Most of these patients also have a lifelong need for pacing, and thus, protecting vascular access is a critical issue. Endocardial leads in smaller patients increase the risk of venous obstruction or thrombosis, which in turn increases the risk of loss of vascular access. In neonates and infants, most centers use an epicardial lead system for initial pacemaker system. Controversy remains as to what weight at which transvenous pacing becomes acceptable, but it typically ranges between 10 and 18 kg.

Epicardial pacing is typically performed using steroid-eluting leads which decrease inflammation at the lead-myocardial interface, decreasing the risk of exit block and improving performance over the previous generation of epicardial leads [27, 28].

There are important potential complications associated with epicardial lead placement. Pericardial effusion can occur after epicardial pacemaker implantation (and also rarely after endocardial implantation), and postpericardiotomy syndrome must be considered if a patient is displaying symptoms consistent with this phenomenon [29]. Cardiac strangulation is also a rare and likely under-recognized complication of epicardial lead placement that can lead to death [30, 31] (Fig. 161.4). Surgical care must be taken during implantation to ensure that leads cannot migrate around the heart, and any symptoms that may be compatible with ischemia must be carefully investigated. AP and lateral X-rays are recommended at implantation to confirm that initial lead placement is not potentially encircling the heart or ventricular apex.

There are also challenges that must be considered when placing transvenous leads. In an attempt to identify a size at which transvenous lead placement might be safe, predictors of venous obstruction have been sought. One retrospective study created a predictive index to evaluate the risk of venous obstruction [32]. The sum

of the cross-sectional area of the leads was indexed to body surface area, and a result greater than 6.6 mm^2/m^2 predicted venous obstruction with a sensitivity of 90 % and a specificity of 84 %. This index has been used by some centers to help determine the use of an epicardial versus a transvenous system. Subsequent studies however have had conflicting results and the issue remains controversial [33, 34]. As well as possible lead-related complications in transvenous systems, the implanter must consider the risk of generator-related problems, such as the increased risk of pocket erosion in small infants with transvenous devices. Although transvenous pacing has been shown to be possible in infants, it should be avoided if possible because of these risks, as well as possible growth-related problems such as tension on a pacing lead [35, 36]. The standard location for the generator in a transvenous system is a left infraclavicular pocket, but this is far from universal. Right infraclavicular pockets may be used if anatomy or lifestyle dictates this, as well as axillary approaches which may offer an improved cosmetic outcome [37].

Traditionally, endocardial ventricular pacing leads were placed with the electrode at the right ventricular apex for stability and ease of placement. This was in part due to the passive fixation design of early leads. However, evidence regarding the role ventricular dyssynchrony plays in the development of myocardial dysfunction has led many away from this practice, and many leads are now placed on the ventricular septum, which appears to create less ventricular dyssynchrony [38].

Pacemaker Modes

Once the decision has been made to implant a permanent pacemaker, the optimal mode must be determined. Pacing modes are classified by a five-character code, commonly shortened to the first three characters [39]. The first position describes the chamber/s paced (V = ventricle, A = atrium, D = dual chamber) the second the chamber/s sensed, and the third position describes the response to sensing (I = inhibit, O = no response, D = track or inhibit). If used, the fourth position indicates rate modulation, and the fifth position indicates multisite pacing.

An example of applying this code: AAI indicates that the atrium alone is paced and sensed and the response to sensing is to inhibit pacing. An added "R" in position 4 would refer to the additional feature of rate response. Thus, AAIR is the same as AAI except that the rate of pacing can vary in response to sensors in the device. Although there are a variety of sensors available, the most commonly used sensors in current pacing systems track activity with either accelerometers or minute ventilator or a blended sensor with multiple indicators.

In dual-chamber pacing, the most commonly used mode is DDD. This allows atrial and ventricular pacing and sensing, as well as either inhibition or tracking in response to sensing, depending on what is sensed [40]. Other complex modes of pacing exist, such as DDI, DVI, and VDD. These are less commonly used but can be helpful in patients with unusual pacing needs or system problems such as impaired sensing [40].

An understanding of the underlying physiology is essential to choosing the optimal pacing mode. For example, AAIR may be an appropriate mode for sinus node dysfunction with intact atrioventricular node function and VDD or DDD, an appropriate mode for atrioventricular block with normal sinus node function. The physician must be cognizant of the possibility of changes in the underlying electrophysiology, such as advancement of atrioventricular conduction disease or sinus node dysfunction. Recent guidelines have been released on device and mode selection in adult pacemaker patients, and while much of it may be helpful in pediatric and adult congenital cardiology, the guidelines are explicitly not intended for that population, and thus, any extrapolation must be done with caution [41].

Unipolar and Bipolar Pacing Leads

In order to effectively capture myocardium and cause cardiac contraction, an electrical signal must be passed through the pacing lead and into

the myocardium. There are two styles of leads available, bipolar or unipolar. In bipolar pacing systems the lead tip is the cathode (the negative electrode) and the lead ring, only a few millimeters away, is the anode (the positive, or "ground"). In the case of epicardial electrodes, a second lead button placed close to the first is the anode. Unipolar pacing systems instead use the lead tip as the cathode and the pacemaker generator as the anode (ground), with the pacing circuit travelling through the patient to reach the generator. Sensing occurs via these same vectors. Unipolar leads have the disadvantage of an increased possibility of oversensing due to inclusion of noncardiac signals, such as skeletal muscle activity or electromechanical interference. They also have higher rates of skeletal muscle stimulation, due to inclusion of those muscles in the electrical circuit. In many centers bipolar systems are preferred (due to better sensing performance) however, if lead dysfunction occurs it is possible in many devices to reprogram sensing, pacing, or both to either unipolar or bipolar mode. This may allow the programmer to bypass a malfunctioning electrode without replacing the lead. In addition, some pacing systems only work with unipolar leads or only sense in unipolar mode; thus, it is important to consider this when selecting a device.

Single- Versus Dual-Chamber Pacing

The decision of whether to place a single- versus dual-chamber pacemaker has been controversial for some time in adults with structurally normal hearts [42]. Recent guidelines have been released which help practitioners decide the most appropriate system for their adult patients [41]. However, these guidelines do not address the pediatric population and in fact explicitly exclude them. In pediatrics, although maintaining atrioventricular synchrony is intuitively appealing, there is evidence to support greater importance of minimization of ventricular pacing, particularly given the extremely long duration of pacing in many patients [43]. In pediatrics and congenital heart disease, individual consideration must be made in each patient. Frequently younger, smaller children require a smaller single-chamber system as their first device due to their physical size and then are converted to a dual-chamber system at the time of a required system revision. The development of pacemaker syndrome, although uncommon in children, may also drive the decision to switch to dual-chamber pacing [44].

Patients with altered hemodynamics may also benefit from having atrioventricular synchrony and thus are more likely to have dual-chamber devices early in life. Some current devices allow use of compound modes that give preference to intrinsic atrioventricular conduction to minimize ventricular pacing while monitoring for the need for ventricular pacing in the event of atrioventricular block.

Pacemaker Timing Cycles

Programming the current generation of pacemakers requires an understanding of the complex modes and timing cycles that are now in use. Without such an understanding, it is not possible to identify pacemaker system dysfunction or optimize pacemaker settings. However, the task is often made easier by using the diagnostic features built into devices that provide labeling of events.

All pacemaker generators contain a number of in-built timing cycles which are measured in milliseconds and often programmable. These include periods where sensing circuits are open to sensing and periods when they are refractory, i.e., temporarily switch off their sensing function [40]. In single-chamber pacing, such as VVI or AAI, each sensed or paced event is followed by a refractory period to ensure that associated depolarization and repolarization are not sensed as an additional event by the device.

Dual-chamber pacemakers have a greater number of programmable intervals. The atrioventricular interval (AVI) begins with a sensed or paced atrial event and ends with a sensed or paced ventricular event. Setting the AVI and lower rate limit determines the atrial escape interval, during which an intrinsic atrial event is sought to initiate the next cycle, or if no sensed event from either

chamber occurs, an atrial-paced event occurs at the appropriate interval.

The post-ventricular atrial refractory period (PVARP) is present to prevent atrial sensing of P waves which have conducted retrograde and/or far-field ventricular repolarization. The goal of this is to prevent pacemaker-mediated tachycardia, which may occur when a retrograde or far-field signal is sensed in the atrium and tracked in the ventricle. Pacemaker-mediated tachycardia is a reentrant rhythm, with one limb of the reentrant loop being the patient's retrograde conduction and the other the pacemaker.

Atrial sensing is refractory during the atrioventricular interval, and together the atrioventricular interval and the post-ventricular atrial refractory period constitute the total atrial refractory period which will restrict the upper tracking rate of the pacemaker.

This is a brief overview of programming options; a detailed understanding of timing cycles and refractory periods is required by those who program pacemakers. The default settings are based on typical adult patients and are almost universally inappropriate for pediatric patients. Younger patients have higher heart rates, and attention needs to be given to the potential for pacemaker-mediated Wenckebach and even 2:1 paced atrioventricular block to occur at higher rates.

Congenital Heart Disease

There is consensus that patients with significant intracardiac shunts should have epicardial devices, as endocardial leads carry a greater than twofold increased risk of a systemic embolic event than those with epicardial leads [45]. Patients with small left-to-right shunts may also be at risk of systemic embolism due to the possibility that pacing creates brief periods of right-to-left shunting [46]. In patients with poor epicardial thresholds from scarring due to congenital heart surgery, placing the lead transmurally with only its tip extending into the cardiac chamber may prove useful [47]. This technique allows access to the potentially healthier endocardial surface while limiting the amount of thrombogenic material in the cardiac chamber. However, there is an endocardial lead ultimately in place, and thus, this is likely not advisable in patients with significant right-to-left shunts.

Pacemaker Follow-Up

All patients with any implanted cardiac rhythm devices require continuous follow-up so that appropriate programming or hardware revisions can be made if necessary. An important potential complication of device insertion is system infection, which can occur both in the early postoperative period and extremely late. Most centers routinely prescribe prophylactic perioperative antibiotics, but this is not completely protective. System revision, prolonged procedure time, hematoma formation, and the presence of trisomy 21 are all known risk factors for infection in pediatric patients [48]. Management of deep-pocket infection should involve removal of the device and the leads in their entirety, and patients with endocardial leads should be monitored for the possibility of endocarditis [49].

Interrogation of the device will reveal diagnostic information including device warnings, estimated remaining battery life, lead function, and information about percentage of sensed and paced rhythm. If set up to record and capable of storing rhythms, tachyarrhythmias may be detected, sometimes including annotated electrograms of the rhythm. Shifts in lead impedance may suggest imminent lead dysfunction. For example, a rise in impedance should arouse suspicion of a lead fracture, and a fall in lead impedance may indicate an insulation break.

The patient's underlying rhythm should be documented if possible, by slowly reducing the pacing rate until intrinsic rhythm emerges. If the patient displays any symptoms related to the iatrogenic bradycardia, the testing for intrinsic rhythm should be halted and the patient returned to their typical rate. Most devices do not allow the rate to be turned down less than 30 beats per minute, and if there is no underlying ventricular rhythm visible at that stage, the patient is

classified as "pacemaker dependent." It is essential that pacing never be abruptly ceased, as suppression of the intrinsic rhythm is likely to be seen at physiologic pacing rates, and thus, unacceptably long pauses might be seen, whereas if the rate is lowered slowly, suppression is less likely and intrinsic rhythm more likely to be encountered.

The timing of pacemaker follow-up depends on the complexity and stability of both the patient and the pacing system. Typically devices are checked the day following implantation, in 2–4 weeks, and then at 3–6 months. The frequency of long-term follow-up is determined by a variety of factors related to the device, the patient, and the pacemaker clinic routines. Those with pacemaker dependency, cardiac resynchronization devices, and implantable defibrillators require more frequent follow-up, and utilization of remote follow-up may be quite helpful in these patients [50].

Patients with transvenous leads often have a chest X-ray intermittently performed to look at lead position and the effects of growth. Many centers are decreasing the frequency of routine X-rays due to concerns over radiation exposure and are only performing them if there are clinical concerns or if there has been an unusual growth spurt. A regular chest X-ray for those with epicardial leads is appropriate to look for the rare but important complication of cardiac strangulation [51]. Although this has only been rarely reported, it can be fatal, and strangulation can still occur after a lead has been abandoned.

A Holter monitor may be used to check pacemaker function over a 24-h period and screen for the emergence of any tachyarrhythmias in those patients who may be at risk. Sometimes premature ventricular contractions are not sensed as well as intrinsic ventricular rhythm, and one of the better ways to diagnose this is on Holter. There is a potential risk of ventricular arrhythmias if premature ventricular contractions are undersensed, as pacing may then occur as an "R on T" phenomenon and initiate a ventricular arrhythmia.

A periodic echocardiogram is important to check ventricular function and any mechanical lead effect on valvar function (particularly tricuspid). Maintaining accurate and searchable database information for all pacemaker patients is important so that patients can be easily identified and screened in the event of any device-related advisory.

Pacemaker Dependence

Patients with no underlying intrinsic rhythm may become symptomatic or even syncopal in the event of a loss of ventricular capture. In these patients some centers set broader safety margins than usual or more frequent follow-up. Individual decisions should be based on apparent risk of threshold change versus the cost to battery longevity of the higher outputs. Use of remote or home monitoring may be appropriate in this particular group and has been seen to identify a problem prior to system failure [52].

Testing

Sensing

Appropriate sensing of intrinsic rhythm is critical for pacemaker function. The sensing setting is the amplitude in millivolts that the device can perceive in order that it recognizes the presence of an intrinsic beat. Typically the device is then set with at least a doubled sensing margin of safety. When testing sensing, the rate is slowly decreased to below the rate of the intrinsic rhythm, so no pacing occurs. The sensing is then set at a low level and then increased incrementally until appropriate sensing of the intrinsic rhythm is lost and pacing occurs. The last millivolt level at which appropriate sensing was seen is the sensing threshold.

Intrinsic atrial signals generally have a lower amplitude than ventricular signals as they are created by a smaller muscle mass. Thus, to adequately identify the amplitude of intrinsic atrial signals, one must start at very low levels, such as 0.5 mV, while in the ventricular initial settings, it may be at 1.0 or 2.0 mV.

The possibility of oversensing should also be examined and is most commonly seen in unipolar systems. Isometric maneuvers involving the muscles close to the implantation site should be performed during paced rhythm. If oversensing occurs muscle noise will be picked up inappropriately and pacing will be inhibited.

Capture Threshold

The pacing, or capture threshold, is the minimum electrical stimulus required to consistently capture the myocardium and trigger contraction. The stimulation threshold is a square wave, a function of both amplitude (measured in volts) and pulse width (measured in milliseconds). The threshold is generally tested by keeping the pulse width stable and decreasing the amplitude (or vice versa) until capture no longer occurs. It is important to note that bipolar systems may not show the pacing spike that is clearly seen on a surface electrocardiogram with a unipolar system, and thus, electrogram morphology of the P wave and QRS must be relied upon to indicate capture of the paced chamber in bipolar pacing. When testing capture threshold the paced rate needs to be faster than the underlying rate (unless pacing in an asynchronous mode) or pacing will not occur. Output should then be set at three times the pulse width or twice the amplitude at threshold to ensure an adequate safety margin, given the recognized variability of cardiac thresholds.

Temporary Pacemakers

Temporary pacemakers are an essential part of postoperative management following congenital heart surgery. The uses of pacemakers in this population are to treat bradycardia (complete AV block or sinus bradycardia most commonly), diagnose arrhythmia through wire studies, and treat arrhythmias such as overdrive pacing for junctional ectopic tachycardia.

Sensing and pacing thresholds should be tested daily in any actively used temporary pacing wires, as temporary wire thresholds change rapidly and unpredictably. This is particularly important in those patients with postoperative AV block and little or no identifiable intrinsic rhythm. All patients having temporary pacing should have both electrocardiogram monitoring and physiological monitoring (arterial line or O2 saturation probe) as pacing spikes without capture can be interpreted by electrocardiogram monitoring systems and bedside staff as cardiac rhythm.

Tachycardia: Device Management

Worldwide, it is estimated that three million persons die per year from sudden cardiac death (SCD), predominantly in adults with preexisting structural or functional heart disease [53, 54]. It has been over 30 years since the first implantable cardioverter-defibrillator (ICD) placement in humans, and the number of implant procedures has since grown exponentially [55–57]. ICDs have been proven in multicenter randomized trials to prevent SCD in adults with depressed ventricular function following myocardial infarction (MI) and other ventricular arrhythmia substrates [54, 58]. However, in less common disease populations, identification of precise indications for ICD therapy becomes more challenging.

Criteria for ICD Implantation in Adults

There are many articles on indications for ICD therapy in primary and secondary prevention of SCD in adults [1, 9, 59]. Briefly, the Class I indications include (a) resuscitated cardiac arrest documented due to ventricular tachyarrhythmia; (b) sustained VT associated with structural heart disease; (c) unexplained syncope with inducible sustained VT/VF at electrophysiology study (EPS) or in association with severe heart disease; (d) nonsustained VT in association with coronary disease, prior MI, ventricular dysfunction, and inducible sustained VT/VF at EPS that is not suppressible by a Class I antiarrhythmic agent; or (e) spontaneous sustained VT without concomitant structural heart disease not amenable to other treatments.

Class IIa indications include ventricular dysfunction (ejection fraction $\leq$30 %) at least 1 month post-MI and 3 months after coronary artery revascularization. This specific guideline was added in the 2002 revision, based on a large randomized clinical trial. Class IIb indications include (a) cardiac arrest presumed due to VF but without confirmation by EPS; (b) severe symptoms presumed attributable to ventricular arrhythmias in patients awaiting heart transplant; (c) familial arrhythmia syndromes at high risk for sudden death; (d) nonsustained VT associated with coronary disease, prior MI, LV dysfunction, and inducible VT/VF at EPS (without drug suppression caveat noted for Class I); (e) syncope of unexplained etiology and family history of sudden death in association with inherited arrhythmia disorder; and (f) syncope in patients with advanced heart disease and no etiology despite thorough invasive and noninvasive investigation.

Criteria for Secondary Prevention in Pediatrics and Congenital Heart Disease Patients

The recommendations are not age specific for secondary prevention and therefore are similar to the adult guidelines. However, there have not been randomized controlled trials in pediatric and congenital heart patients that provide evidence for extrapolation from adult data. There are retrospective studies that do demonstrate efficacy of ICD therapy in these patients [60–62].

Class I indications in pediatric and congenital heart patients include those resuscitated from SCD and without a reversible cause (such as Wolff-Parkinson-White syndrome with preexcited atrial fibrillation, myocarditis, electrolyte/metabolic derangements, drug induced). Sustained VT associated with structural heart disease may be extrapolated to congenital heart disease, with a caveat that some VT may be amenable to catheter ablation or surgical resection. Those patients with hemodynamically significant sustained VT without a reversible cause or potential cure have an indication for ICD therapy.

Criteria for Primary Prevention in Pediatrics and Congenital Heart Disease Patients

There is less data to support recommendations for pediatric primary prevention. However, weighing the risks and benefits of ICD therapy versus other treatment options, expert consensus, and extrapolation from adult studies has led to recommendations for primary prevention based on Class IIb (C) levels of evidence, as discussed in further detail below.

ICD Implant Criteria for Specific Disease Substrates in Pediatric Patients

Inherited Arrhythmias/Electrical Myopathies

Inherited arrhythmia syndromes are electrical myopathies with genetic etiologies and may present at any age. There is clinical and genetic overlap, although specific diseases may have stereotypic but variable onset and severity and similar treatment options, including ICD therapy.

Long QT Syndrome (LQTS)

The ACC/AHA/HRS and ESC guidelines suggest that an ICD be recommended for SCD survivors and patients with recurrent syncope or VT on beta-blockers. Primary prevention ICD therapy is recommended in selected high-risk patients, such as those with a strong family history of SCD, or medication intolerance or noncompliance. ICDs have been shown to be efficacious in several LQTS series. In the International LQTS Registry, there was 16 % mortality in patients treated without an ICD versus only 1.3 % among the ICD-treated cohort. A study of young LQTS patients observed aborted SCD in 74 %, syncope in 17 %, and torsades de pointes in 9 %, with no deaths. Another study of symptomatic LQTS patients with ICDs found 37 % appropriate shocks, more so in SCD survivors and those with longer QTc. Pediatric ICD series show that children with LQTS experience both a high appropriate and inappropriate shock

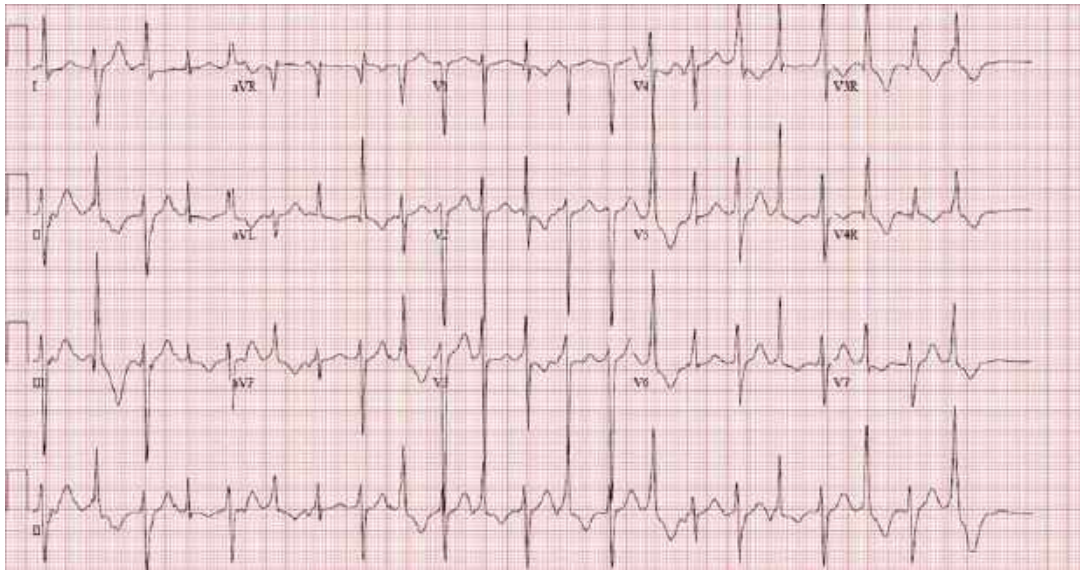

Fig 161.5 Bidirectional ventricular tachycardia in catecholaminergic polymorphic ventricular tachycardia

rate [63–66]. Jervell Lange-Nielsen LQTS is more malignant, with studies showing higher mortality in medically treated compared with ICD-treated patients [67–69].

Short QT Syndrome (SQTS)

A related inherited disorder is SQTS, with similar presentation as LQTS, including recurrent syncope and malignant ventricular arrhythmias. Reports involve small numbers of patients but advise ICD as primary therapy for symptomatic SQTS, given the high SCD incidence and less well-defined efficacy of medical therapies [70]. Indications are less clear for asymptomatic SQTS patients or affected family members. Better insight of ICD efficacy for SQTS, as monotherapy or with medications, may be gained with further experience [71, 72].

Catecholaminergic Polymorphic VT (CPVT)

CPVT is characterized by syncope or SCD due to ventricular arrhythmia during exercise or emotional stress, as the stereotypical presentation is bidirectional VT in children with stress-induced syncope, structurally normal hearts, and normal resting ECGs (Fig. 161.5). Polymorphic VT can be induced with exercise or catecholamines. Beta-blockade alone in high doses may be sufficient, but other medications such as flecainide or verapamil have been shown to be useful. When medical therapy is not adequately suppressing VT, either a left cardiac sympathetic denervation can be performed at experienced centers, or ICDs are recommended. In one study, 50 % of CPVT patients with ICDs had appropriate discharges over 2-year follow-up. Due to the catecholaminergic trigger, the risk of arrhythmic storm is particularly concerning [73].

Brugada Syndrome (BrS)

The BrS is characterized by intermittent right bundle branch block, right precordial ST-segment elevation, and vulnerability to SCD from ventricular arrhythmias [74]. The high incidence of SCD and lack of efficacious medical therapy warrant ICD placement in symptomatic or otherwise high-risk individuals. Implant indications are less clear for asymptomatic BrS patients or affected family members, particularly those without a persistent ECG phenotype or malignant family history. Since pharmacologic therapy is not as effective as it is for LQTS, an ICD is often suggested for

primary prevention. The 2nd Consensus BrS Conference recommended an ICD for BrS patients with spontaneous ECG pattern and aborted SCD (Class I), symptomatic patients without clear etiology (Class I), and asymptomatic patients with *either* a positive family history and/or a positive EP study (Class IIa). If the ECG pattern is only elicited with Na^+ channel blockade, ICD is recommended for aborted SCD (Class I), symptomatic patients without other cause (Class IIa), and asymptomatic patients with both a positive family history and a positive EP study (IIb) [75, 76]. There are no pediatric-specific BrS guidelines for ICD implantation.

Cardiomyopathies

Dilated Cardiomyopathy

The risk of arrhythmias and SCD is significant in dilated cardiomyopathies, and management is predominantly symptom based, with medications and devices forming the basis of therapy. In pediatric patients with advanced heart failure awaiting heart transplantation, one retrospective study found a high rate of ICD shock therapy, with nearly half of patients receiving a shock, many within the first year of implant. However, other series have shown a lower ventricular arrhythmia rate in pediatric dilated cardiomyopathy, with mortality dominated by pump failure rather than sudden death [77].

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy (HCM) is a common genetic disorder, occurring in 1:500 people. Phenotypic presentation can vary from asymptomatic to SCD in childhood. ICDs are efficacious in HCM, with a high incidence of successful shocks in a high-risk population. AHA/ACC/HRS and ESC guidelines for ICD implantation place HCM as a Class I indication in patients with cardiac arrest and a Class II indication in patients thought to be high risk due to clinical presentation, echocardiography and exercise-testing results, and family history. Primary prevention ICD guidelines for HCM, however, have mainly been extrapolated from adult series [78, 79].

Arrhythmogenic Right Ventricular Dysplasia/Cardiomyopathy (ARVD/C)

ARVD/C is a myocardial disease characterized by gradual replacement of myocytes with fibrosis and adipose tissue, leading to cardiomyopathy and arrhythmias. ICD implantation has a Class I indication for ARVD/C patients with sustained VT and a Class II for primary prevention according to both ACC/AHA/HRS and ESC guidelines. ARVD/C patients have a high rate of appropriate ICD therapy. Studies show a shock rate for 1^o prevention ARVD/C was 39 % versus 85 % in the 2^o prevention group [80–82]. There are no pediatric-specific ARVD/C guidelines.

Congenital Heart Disease (CHD)

There are subsets of repaired CHD patients that are at higher risk for SCD, including aortic stenosis, tetralogy of Fallot, and d-transposition of great arteries. However, clinical evaluation and risk stratification is challenging. Syncope in these patients may have several potential etiologies, including conduction abnormalities and bradyarrhythmias, atrial and/or ventricular arrhythmias, and non-electrophysiologic causes. Programmed stimulation may be useful in identifying inducible VT and also to determine atrial arrhythmia vulnerability. ICD therapy is considered a Class IIb indication for syncope and inducible sustained VT/VF.

In summary, the indications for ICD therapy in primary and secondary prevention of SCD continue to progress, with new indications as additional data and experience are obtained. Identification of appropriate ICD candidates involves a careful balance of the risks of SCD versus the risks inherent with ICD therapy. One of the challenges involves presymptomatic recognition of at-risk patients, as many of the SCD episodes occur in previously asymptomatic patients, and SCD may be the sentinel event. As technology advances and ICD therapy includes additional features (such as cardiac resynchronization therapy, chronic arrhythmia recording, and fluid management remote monitoring), further expansion of ICD indications will evolve. Extrapolation of adult randomized clinical trials and use of retrospective small series and clinical

expert consensus recommendations are truly only a surrogate for well-designed prospective pediatric clinical ICD trials, which, three decades after development of the ICD, are now only beginning.

ICD Implantation in Children

The implantation of ICD systems in older teenagers with structurally normal hearts may not technically differ much from implantation in adults. However, placement of ICD systems in children and CHD patients involves individualized pre-procedural planning, which may require customized techniques to provide optimal benefit, while taking into account their size, anticipated future growth, and level of physical activity. Young patients are expected to outlive the predicted longevity of current-generation generators and leads, often necessitating complex extraction and multiple replacement procedures.

Previously, pediatric ICD recipients were predominantly restricted to epicardial systems, due to size limitations and transvenous lead dimensions [83]. Technological improvements, including a biphasic defibrillation waveform and active can to lower energy requirements, combined with a progressive reduction of generator and lead size, allowed transvenous ICD systems for pediatric patients. Transvenous leads carry risks of complications such as venous occlusion, embolic vascular events in the presence of an intracardiac shunt, endocarditis, and lead failure. Endocardial lead positioning in the presence of CHD and surgical corrections may be suboptimal. Conversely, epicardial ICD systems involve more invasive procedures, higher incidence of lead failure, and a possibility of developing restrictive "pericardial" physiology related to the defibrillation patches. Lead malfunctions are common in pediatric patients regardless of implant technique.

Implanting a device in a child also necessitates the consideration of emotional and psychosocial development issues. The increased life expectancy in the younger ICD recipient needs to be addressed at the initial implant in order to minimize long-term physical and psychosocial impact.

Issues with Using Off-the-Shelf ICD Products Designed for Adults

The most obvious differences in needs for defibrillator systems in children relate to size. The relative size of the generator compared to the patient, and the relative size (diameter and length) of the leads compared to the height of the patient may be substantial concerns. These size discrepancies may preclude standard techniques and trigger alternate procedural strategies, such as abdominal generator placement or nontransvenous lead placement, particularly in very small children or those with particular forms of congenital heart disease. Besides the size issues, there are important considerations regarding shock strength, programming issues, and overlap of tachycardia detection criteria with normal pediatric heart rates.

Pediatric-Specific Customized ICD Implantation

Limitations with standard transvenous and epicardial ICD systems in children and CHD patients have prompted individual clinical investigators to develop novel implantation techniques. Animal models and computer modeling studies have shown the feasibility of functional ICD systems without the need for transvenous shocking coils or epicardial patches.

For example, subcutaneous array and coils were originally designed for adjunctive use in order to lower the defibrillation threshold. However, several independent groups nearly simultaneously reported innovative use of subcutaneous arrays or coils for defibrillation in children [84–86]. These subcutaneous ICD systems negated the requirement for transvenous coils or epicardial patches but still utilized epicardial leads for pacing and sensing (Fig. 161.6). Subcutaneous ICD systems have been reported in pediatric multicenter studies, with appropriate tachycardia detection and effective delivered therapies during intermediate-term follow-up [87]. There are also completely leadless ICD systems currently in early clinical use [88, 89].

Fig 161.6 Nontransvenous implantable cardioverter defibrillator with subcutaneous array

However, current-generation leadless ICDs may not be suitable for small children as the generators are relatively large in order to accommodate the significantly higher (at least twofold) defibrillation outputs necessary. Furthermore, the currently available totally subcutaneous ICD system does not have the capability for chronic antibradycardia pacing (other than emergent post-shock transcutaneous pacing) or antitachycardia pacing, which may be indicated in a substantial proportion of pediatric and congenital ICD recipients.

Nonstandard configurations for pediatric implantable defibrillator systems have also been designed with the placement of leads in the pericardial or pleural space, without the need for epicardial patches or transvenous hardware [90, 91]. Transvenous ICD leads, SVC leads, or subcutaneous coils have been used for this purpose, placed in the posterior pericardium. Pacing/sensing leads can be placed on the epicardium.

Nontransvenous ICD systems have been shown in a small series to have poorer longevity than traditional transvenous ICD systems in children [26]. Therefore, nontransvenous ICD systems are not ready to supplant standard ICDs in the majority of patients but still have an important role for those patients with limited alternative approaches.

In summary, there are several methods from which to choose when implanting devices in pediatric patients. The advantages and disadvantages of current reported methods for ICD lead placement are summarized in Table 161.1. The risks and benefits of each approach need to be considered for each patient and disease type. Although there are no specific weight or size cutoff criteria, a clinical practice of limiting placement of transvenous ICD leads in small children is reasonable due to concerns of venous patency and lead failure with patient growth and potentially more difficulty with lead extraction [3, 17]. This strategy of using a nontransvenous lead for their initial system allows the protection of an implantable defibrillator in small children without limiting future vascular accessibility. The pediatric electrophysiology community has an imperative to provide the best means of achieving long-term safe and effective ICD therapy for children. Although progress in ICD technology has been truly remarkable over the past three decades, the current limitations in pediatric patients should be an impetus for device manufacturers, biomedical engineers, researchers, and physicians to work together in designing optimal ICD systems for children. While market forces may not be the driver for pediatric ICD research and development, the unique needs of this patient population, the potential life-years saved per patient, and corporate charitable goodwill, along with anticipated governmental regulations for pediatric devices, should hopefully be a sufficient impetus for moving forward with designing a pediatric ICD.

It is also important to consider usage of non-implantable defibrillator therapies, such as automated external defibrillators and wearable defibrillators, in certain patients. A small subset of patients such as those who have a particularly

Table 161.1 Implantable defibrillator lead route options in pediatrics

	Advantages	Disadvantages
Transvenous	Relatively easy implant; common use; approved indication	Lead fractures; extractions difficult; vascular obstruction
Epicardial patch	Long history, follow-up; approved use; surgeons familiar; good DFT	Patch failure; buckling; restrictive pericardial physiology
Subcutaneous array or coil	No transvenous coil or epicardial patch; minimally invasive	Limited long-term data; higher DFT
Pericardial coil	No need for transvenous access or epicardial patch; low DFT	Requires surgeon; adhesions may limit VATS; limited follow-up data
Subcutaneous leadless ICD	No need for transvenous or epicardial access; minimally invasive	Limited long-term data; higher DFT; no chronic pacing or ATP

Note: The subcutaneous and pericardial techniques are not FDA-approved indications for these devices
DFT defibrillation threshold, *VATS* video-assisted thoracoscopic surgery, *ATP* antitachycardia pacing

high operative risk or have need of temporary defibrillation capabilities may benefit from the use of these technologies.

Defibrillation Threshold Testing

At the time ICDs were first introduced, exacting defibrillation threshold (DFT) testing was performed in the majority of patients. Ventricular fibrillation can be induced with a low-energy shock (0.5–2 J) delivered on the vulnerable phase of the T wave, programmed ventricular extra-stimulation, or rapid cycle (50 Hz) stimulation. DFT testing typically consisted of a multishock step-up or step-down algorithm until the margin between failed and successful shock was narrowed to identify the defibrillation threshold. As the technology of ICDs improved, including biphasic waveforms, nonthoracotomy transvenous lead designs, and higher energy outputs, many practitioners converted to a "Lowest Energy Tested" (LET) strategy to establish a safety margin (often 10 J) between a successful defibrillation and the programmed high energy output.

Recently the clinical practice of routine DFT or LET testing has come into question, as the possible adverse consequences of DFT testing and shocks are increasingly recognized [92–94]. Hemodynamic compromise, increased anesthetics, and possible myocardial injury from multiple high energy shocks can lead to complications from DFT testing. However, there is a potential failure of defibrillation, and thus, completely eliminating DFT testing will inevitably leave a small proportion of patients with unrecognized high DFTS and inadequate energy outputs [95, 96]. Several recent studies in adult patients revealed no difference in outcomes between those with and without DFT testing at time of ICD placement. Single-shock threshold testing protocols have also been examined; in a study of 318 adults, ICD patients were randomized to a full DFT protocol versus a single 14-J shock. They found that the successful spontaneous conversion rate of ventricular fibrillation was similarly successful between the two groups, suggesting that the additional testing and multiple shocks provided no enhanced safety while increasing potential added risk [97]. One recent study compared the 2-year mortality and the frequency of ICD shocks and found a similar rate between DFT and no-DFT groups [98].

In certain patients at particular high risk from the DFT testing, such as those with restrictive cardiomyopathy or severe cardiac dysfunction, physicians may opt to omit DFT testing. The risk of DFT testing may vary from patient to patient, and the clinical context must be taken into account when assessing the need for a DFT. Alternatively, one successful defibrillation at 15–20 J below the maximum output has also

been shown to provide an adequate margin of safety when the first shock is then programmed at maximum output [99]. In a recent study, a small group of pediatric patients evaluated prospectively were shown to have low DFTs and would all have been within the probabilistic margin of safety if the devices had simply been programmed at maximal output [100].

Upper Limit of Vulnerability

An alternative to DFT testing at implant is examining upper limit of vulnerability (ULV) to evaluate expected efficacy of defibrillation. ULV utilizes the existence of a "vulnerable period" in the cardiac cycle, at the peak of the T wave; a lower energy shock delivered into that period will induce ventricular fibrillation (VF) [101]. However, at increasing strengths of shocks delivered into the vulnerable period, there is a threshold at which VF will not be induced. The ULV is the weakest shock that, when delivered into the vulnerable period, will not induce VF. This measurement has been shown to correlate with DFT and can be used with far fewer inductions of VF. If one can establish an adequate safety margin with the ULV, it may not be necessary to induce VF [102]. Although this form of evaluating defibrillation efficacy has not been widely adopted in pediatric and congenital electrophysiology, it may have a role in minimizing VF in higher-risk patients.

Equipment and Personnel Readiness for Defibrillation Testing at Implant

It is essential that appropriate measures be in place to ensure patient safety, as complications of DFT testing do rarely occur. In a series of over 19,000 adults undergoing peri-implant DFTs, there were 3 deaths, 5 cerebrovascular events, and 27 episodes of prolonged resuscitation [94]. Not surprisingly, patients with poor ventricular function have a higher risk during DFT testing [103]. In the highest-risk patients, such as those with severe ventricular dysfunction, it may be prudent to have mechanical support, such as extracorporeal membrane oxygenation available, if it is felt that a DFT must be performed. Alternatively, it may be prudent to skip, or at least defer, DFT testing until this type of patient becomes more clinically stable.

Retesting of the DFT in Pediatric and Congenital Heart Disease

There is little data focussed specifically on DFTs in the pediatric and congenital population. One study found that the majority of routine defibrillation threshold testing did not uncover any clinically significant findings. However, in patients in whom there was evidence of a clinical change which lead to the obtaining of the DFT (such as change on radiographic screening, inappropriate shocks, or a change in pacing or sensing parameters), threshold testing revealed abnormalities that led to important programming or hardware modifications [104]. This was a retrospective, small series with potential for selection bias, so it may not be directly extrapolated to all pediatric patients.

Cardiac Resynchronization Therapy

Cardiac resynchronization therapy (CRT) is an effective intervention in adult patients with heart failure who do not improve after optimization of medical therapy [9]. In multiple randomized controlled studies, CRT has been shown to decrease mortality and hospitalizations and improve functional class, exercise performance, and quality of life [105–110]. However, CRT is not free of morbidity, and approximately 30 % of patients do not achieve a beneficial response [111].

Data are limited on CRT efficacy in pediatric patients or in patients with CHD. There is evidence that chronic right ventricular stimulation can adversely influence left ventricular performance over time [112, 113]. Studies in patients with CHD have shown that CRT acutely improves hemodynamic measurements after cardiac surgery and could be beneficial in patients

with congenital heart disease and late ventricular dysfunction [114–121]. However, longer-term follow-up is limited, and reports have widely heterogeneous clinical management.

Congestive heart failure is a major cause of morbidity and mortality in the adult population with normal cardiac anatomy, but the magnitude of this problem in pediatrics and congenital heart disease is less well defined. The Pediatric Cardiomyopathy Registry has reported a congestive heart failure annual incidence of 1.13 cases per 100,000 children in the United States, and patients with dilated cardiomyopathy have a 2-year mortality of 13.6 % [122]. Improvements in clinical diagnoses, surgical techniques, and medical management have extended long-term survival of patients with CHD, and a significant portion of this group will eventually develop congestive heart failure. It is known that 25–75 % of pediatric patients with congestive heart failure have underlying diagnoses of CHD [123]. CRT has the potential to be an important adjunctive therapy for congenital heart disease survivors and children with cardiomyopathy. In a recent study which examined the clinical response to CRT in patients at a tertiary care CHD center, CRT was associated with improved outcomes in 87 % of those with adequate follow-up [124]. This was the first report of a positive response to chronic CRT in individuals with single-ventricle morphology. The types of patients treated at pediatric cardiac centers are diverse and reflected in this study's cohort. Therefore, the indications, surgical approaches, and responses to CRT reflect this heterogeneous population. Using a composite end point of improvement in either EF or NYHA class, the left ventricular and single-ventricle group had the best response to CRT, however, patients with systemic right ventricles were older at CRT implantation compared to patients with systemic left or single ventricles. This may partly explain why this study differed from those previously reported for CHD patients with systemic right ventricles [120, 125, 126]. Dubin and colleagues observed clinical improvement in 13 of 17 patients with systemic right ventricular morphology [120].

Among single-ventricle patients, the Boston group found improvement with CRT, which contrasts with the report by Dubin and colleagues, in which there was no change in EF and only two of seven single-ventricle patients had clinical improvement. The single-ventricle group would be expected to be the most complex in terms of patient selection, lead placement, and associated comorbid factors. This expected complexity in selecting and performing CRT in single-ventricle patients may explain the difference in results between a single-center series and those obtained from a multicenter survey. Ultimately, the role of CRT in improving outcomes in single-ventricle patients will require larger numbers with detailed analysis of multiple factors.

However, the implant indications are not straightforward in this population, and predicting the response to CRT prior to implantation remains a continuing challenge.

A considerable number of patients will require epicardial left ventricular lead placement, particularly young patients, those with complex CHD, and patients undergoing concomitant congenital heart surgery.

Quantitative accurate assessment of ventricular function by standard echocardiography remains problematic in CHD patients, especially in the group with single-ventricle and systemic right ventricular anatomy. Evaluation of ventricular function and dyssynchrony using advanced imaging techniques such as tissue Doppler imaging, three-dimensional echocardiography, tissue synchronization imaging, and cardiac computerized tomography may be useful in future CRT studies in pediatric and CHD patients and may help guide optimization of programming [127].

Impact of Having an ICD as a Child

While an ICD may be lifesaving, there are some psychosocial concerns related to having a device. Adult studies have shown a higher degree of anxiety and depression among ICD patients, somewhat related to the underlying cardiac

disease. In a study by DeMaso et al., a psychological survey was administered to adolescent ICD patients to assess quality of life and psychosocial impact of having a defibrillator. Whereas parents of teenage ICD patients did not report any adverse effects on family dynamics, some adolescent ICD patients reported mild anxiety and depression, which impacted family functioning and quality of life. The children were equally concerned between how it will feel when the ICD fires and what happens if the ICD does not work. These worries should be taken in consideration when deciding on ICD implantation in pediatric patients.

Other issues that are important in young ICD recipients are the restrictions on sports and driving. There are published guidelines which summarize the experts' consensus regarding athletics and are beyond the scope of this article. However, having an ICD should not impose additional restrictions above and beyond the recommended athletic restrictions for the underlying disease. In other words, patients with cardiomyopathy that is significant enough to warrant an ICD would have the same restrictions whether or not they have an ICD. It is prudent to advise restriction from high-level and/or hard-contact sports to minimize the risk of damage to an ICD. Participants in contact sports should wear adequate protection to safeguard the device from impact damage. The rules and restrictions regarding driving with an ICD vary by state and are often extrapolated from other diseases such as epilepsy. Many states either recommend or require abstention from driving for an arbitrary period of time (usually around 6 months) after a syncopal event, ICD implantation, or receipt of an appropriate shock.

Children with implanted pacemakers and ICDs are often restricted from other activities for a variety of reasons, usually without much scientific rationale. For example, the amusement parks hang signs that read "Do not go on this ride if you have heart disease." Many summer camps do not allow children with heart disease and/or implanted devices to attend. Special camps for children with pacemakers and ICDs are being developed around the world, where children with implanted devices can participate in overnight camp and may provide special experiences for this unique group of children.

Restrictions for Patients with Implanted Devices

Pediatric cardiologists should encourage their patients to lead a healthy, active lifestyle. However, some sporting activities with a high risk of bodily impact have the potential to damage the pacemaker system and may not be recommended in patients who are pacemaker dependent. Consideration of underlying heart disease, rhythm, potential for tachyarrhythmias, and quality of life must occur when making recommendations on activity levels in patients. Ideally, then physicians and families together make informed medical decisions.

Surgery and Magnetic Resonance Imaging

When patients with cardiac devices undergo surgery, particularly noncardiac surgery, a plan must be made in advance about intraoperative pacing. Problems that can be encountered include the electrical signals from cautery being falsely sensed as myocardial signals, resulting in inappropriate inhibition of pacing. Bipolar cautery is preferred, as the signal is more localized, but still may result to some electrical interference particularly if the surgical site is close to the pacing system. In some cases it is safer to change the device to a non-sensing mode (VOO or DOO) for the duration of the surgery, particularly if cautery cannot be avoided. Electrocardiographic monitoring during the surgery is essential [128]. If no intraoperative changes are made, a pacemaker check after surgery is generally recommended to make sure there has been no electrical or hardware damage to the device.

In most of older pacing systems, performing magnetic resonance imaging in patients with an implanted device is contraindicated. There are

a variety of mechanisms by which MR can affect pacemakers and ICDs, involving multiple components of the device, including the leads, circuitry, battery, reed switch, and capacitors. There may however be some situations in which MR is an acceptable risk if the information to be obtained is potentially lifesaving, particularly in the non-pacemaker-dependent patient. Device manufacturers are currently releasing devices that are magnetic resonance imaging safe, and slowly these types of devices are likely to be more available [129–131].

Appendix I: Implantation Guidelines for Pediatric and Congenital Heart Disease Patients

Pacemaker implantation guidelines for children, adolescents, and patients with congenital heart disease are found below [1, 9]. The pediatric and congenital heart disease-specific guidelines are brief, and the patient population is very heterogeneous, thus, patient-based interpretation is essential [132].

Class I (Reasonable Evidence and/or Consensus that Pacing Is Beneficial and Effective)

1. Advanced second- or third-degree atrioventricular block associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output.
2. Sinus node dysfunction with correlation of symptoms during age-inappropriate bradycardia. The definition of bradycardia varies with the patient's age and expected heart rate.
3. Postoperative advanced second- or third-degree atrioventricular block that is not expected to resolve or persists at least 7 days after cardiac surgery.
4. Congenital third-degree atrioventricular block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction.
5. Congenital third-degree atrioventricular block in the infant with a ventricular rate less than 55 beats per minute or with congenital heart disease and a ventricular rate less than 70 beats per minute.

Class IIa (Conflicting Evidence and/or a Divergence of Opinion, Weight of Evidence Supports Pacing)

1. Congenital heart disease and sinus bradycardia for the prevention of recurrent episodes of intra-atrial reentrant tachycardia; SND may be intrinsic or secondary to antiarrhythmic treatment.
2. Congenital third-degree AV block beyond the first year of life with an average heart rate less than 50 bpm, abrupt pauses in ventricular rate that are 2 or 3 times the basic cycle length, or associated with symptoms due to chronotropic incompetence.
3. Sinus bradycardia with complex congenital heart disease with a resting heart rate less than 40 bpm or pauses in ventricular rate longer than 3 s.
4. Patients with congenital heart disease and impaired hemodynamics due to sinus bradycardia or loss of AV synchrony.
5. Unexplained syncope in the patient with prior congenital heart surgery complicated by transient complete heart block with residual fascicular block after a careful evaluation to exclude other causes of syncope.

Class IIb (Conflicting Evidence and/or a Divergence of Opinion, Evidence Is Less Established)

1. Transient postoperative third-degree AV block that reverts to sinus rhythm with residual bifascicular block.
2. Congenital third-degree AV block in asymptomatic children or adolescents with an acceptable rate, a narrow QRS complex, and a normal ventricular function.
3. Asymptomatic sinus bradycardia after biventricular repair of congenital heart disease with a resting heart rate less than 40 bpm or pauses in ventricular rate longer than 3 s.

Class III (Not Indicated)

1. Transient postoperative AV block with return of normal AV conduction in the otherwise asymptomatic patient.
2. Asymptomatic bifascicular block with or without first-degree AV block after surgery for congenital heart disease in the absence of prior transient complete AV block.
3. Asymptomatic type I second-degree AV block.
4. Asymptomatic sinus bradycardia with the longest R to R interval less than 3 s and a minimum heart rate more than 40 beats per minute.

Electrophysiology of Heart Failure and Cardiac Re-synchronization Therapy

162

Jan Janoušek

Abstract

Besides heart rate, contractility, preload, and afterload, mechanical atrioventricular (AV) and inter- and intraventricular synchrony are major determinants of cardiac output and cardiac contraction efficiency. Chronic intraventricular electromechanical dyssynchrony, as caused by an electrical activation delay, may lead to dyssynchronous heart failure accompanied by significant structural and cellular remodeling. Electrical retiming of the heart using temporary or permanent cardiac resynchronization pacing (cardiac resynchronization therapy, CRT) has been used both to acutely manipulate cardiac output in the postoperative setting as well as to chronically treat dyssynchronous heart failure. CRT has been shown to induce reverse cellular remodeling in experimental studies and to improve systolic ventricular function in both adults and children. In large randomized adult trials, CRT also decreased heart failure-related morbidity and improved overall survival. Although published evidence on CRT efficacy in children lags behind studies on adult patients with idiopathic and ischemic cardiomyopathy, principal effects seem to be the same. This chapter will summarize the knowledge on the electrophysiology of heart failure as well as on temporary and permanent cardiac resynchronization pacing in children.

Introduction

To understand the electromechanical dyssynchrony as a therapeutic target, the pathophysiology will be discussed first, followed by the principles of cardiac resynchronization therapy (CRT) and its use for both acute electrical management of low cardiac output and treatment of chronic dyssynchronous heart failure.

Pathophysiology of Electromechanical Dyssynchrony

The electromechanical synchrony of the heart consists of three distinct components: (1) atrioventricular (AV) synchrony, (2) interventricular synchrony, and (3) intraventricular synchrony. Whereas the importance of the atrial kick to ventricular filling and cardiac output has been recognized quite early, the other two components have been largely overlooked, and ventricular dyssynchrony has not been clinically accepted as a major player in the pathophysiology of both acute and chronic heart failure until the late 1990s. During normal cardiac rhythm, ventricular depolarization is fast, resulting in a homogeneous mechanical activation and synchronous contraction of both ventricles. If ejection of one of the ventricles is delayed, an interventricular dyssynchrony is present. This will be reflected by unequal pre-ejection periods. The intraventricular dyssynchrony is present if mechanical activation of one ventricular wall is delayed as compared to the opposite one (e.g., due to bundle branch block). Experimental studies documented mechanical consequences of the intraventricular electrical activation delay. Wymen et al. [1] studied mechanical LV deformation by segmental circumferential strain in dogs paced from the right ventricular (RV) apex. They found an early contraction close to the pacing site with accompanying stretch of the remote segments followed by subsequent contraction of late activated segments, along with relaxation of the early activated sites. Prinzen et al. evaluated the consequences of dyssynchronous electromechanical activation on local myocardial work with decrease in the early sites contracting with a low local preload and increase in the late sites whose preload was increased by preceding stretch [2]. At the same time, the idea to treat dyssynchrony by electrical pre-activation of the late contracting segments of the left ventricle (LV) entered the clinical practice. CRT emerged as a completely new option of heart failure therapy.

Further studies documented the negative influence of mechanical dyssynchrony on both myocardial energetics and cellular remodeling. In an elegant study, Nelson [3] showed that LV dyssynchrony is accompanied by decreased maximal + dP/dt and increased myocardial oxygen consumption. As opposed to catecholamines, CRT improves dP/dt while decreasing myocardial oxygen demands, an effect similar to adjusting an engine's ignition system and getting more power at lower petrol consumption. Experimental studies looked at the cellular events associated with dyssynchronous heart failure. In an animal model, Chakir et al. [4] showed that mediators of fibrosis and apoptosis are disproportionately more expressed in the late activated lateral wall of the canine LV. Vanderheyden et al. [5] found disturbed excitation–contraction coupling due to decreased calcium cycling between the sarcoplasmic reticulum and the cytosol of the myocardial cell, and Mullens et al. [6] demonstrated decreased response to adrenergic stimulation due to lower β-adrenoreceptor gene expression. Finally, Spragg et al. [7] reported lateralization of connexin 43 in the late contracting segments leading to decrease in conduction velocity closing a vicious circle of dyssynchronous heart failure-related further increase of the electrical activation delay. CRT has been shown to lead to reverse remodeling of this cellular pathology, and this effect is regarded to be an important part of its long-term efficacy besides acute restoration of contraction synchrony.

Wide introduction of CRT into clinical practice led to discussion about selection of proper therapy candidates. Markers of electrical dyssynchrony (QRS duration) have been

compared to complex measurements of mechanical dyssynchrony using echocardiography. A single large prospective multicenter study [8], however, failed to demonstrate the utility of echocardiography for increasing the response rate to CRT in the adult population. One of the reasons may be a more complex nature of mechanical dyssynchrony in heart failure patients than that reflected by the currently used echocardiographic dyssynchrony indices. As beautifully demonstrated by Kass et al. [9], mechanical dyssynchrony may not be caused just by a temporal activation delay but also by contractile disparity in a diseased myocardium. Diseased less contractile segments may be pre-stretched by those better contracting, and their peak systolic deformation will be delayed, causing a dyssynchrony pattern most probably not amenable to CRT. Dyssynchrony due to contractile disparity may have a dispersed rather than a clustered pattern [10] (Fig. 162.1) and cannot be corrected by currently used CRT techniques.

Comprehensive data on the prevalence of cardiac dyssynchrony in children amenable to CRT has not been published, and information has to be retrieved from several sources. First, looking at three available larger studies on CRT in children and patients with congenital heart disease [11–13] (Table 162.1), presence of a left bundle branch block along with LV dysfunction (most frequent indication for CRT in adult heart disease) is rather uncommon (9.2 %) as CRT indication in the congenital heart disease population. In 1/2 to 2/3 of the cases, CRT was applied as an upgrade of conventional ventricular pacing because of pacing-associated heart failure. Seventy to eighty percent of the patients had structural congenital heart disease with a systemic RV in up to 1/3 of cases. Additional data is specifically available for the systemic RV population with 9.3 % of the patients after the atrial baffle procedure for d-transposition of great arteries, and 6.1 % of patients with congenitally corrected transposition fulfilling the currently applied CRT indication criteria if including New York Heart Association class II patients [14]. Thus, the functional and structural substrate in the congenital heart disease cohort amenable to CRT is significantly different from its adult idiopathic or ischemic heart disease counterpart.

Numerous clinical and experimental studies have so far shown that electromechanical dyssynchrony causes a sequence of events which may result in pathological structural and cellular ventricular remodeling and eventually failure. This process can be counteracted by CRT. Although evidence in children lacks behind adult studies, it is conceivable to presume that pediatric and adult dyssynchronous heart failure shares the same pathophysiologic and prognostic components, enabling application of similar therapeutic approaches tailored to the anatomic and functional heterogeneity of pediatric heart disease.

Principles of CRT

CRT is aimed at correction of intraventricular mechanical dyssynchrony [9], and several studies have shown this to be the prerequisite for CRT efficacy. Figure 162.2 displays a simple scheme of CRT in a patient with LV activation delay due to left bundle branch block. Although anatomical and functional situations may vary, this scheme is generally valid for any CRT application. CRT is routinely used to treat systemic ventricular failure, although anecdotal data have shown its acute efficacy for improvement of the subpulmonary ventricular function as well [15, 16]. CRT is currently mostly realized by biventricular pacing, but single-site atrial synchronized pacing in fusion with spontaneous ventricular activation using a pacing lead located in the late activated area may be as effective [17, 18]. The reasons for the prevailing use of biventricular pacing lie (1) in the inability to optimize the mechanical AV delay by single-site pacing of the late activated area, in case of prolonged spontaneous AV conduction (excessive shortening of AV delay would induce an inverse dyssynchrony pattern), and (2) in difficulties to adapt AV delay to a wide range of heart rates (pacing may occur too late or too early to achieve effective fusion with spontaneous activation). In case of biventricular pacing, one of the leads is generally placed transvenously

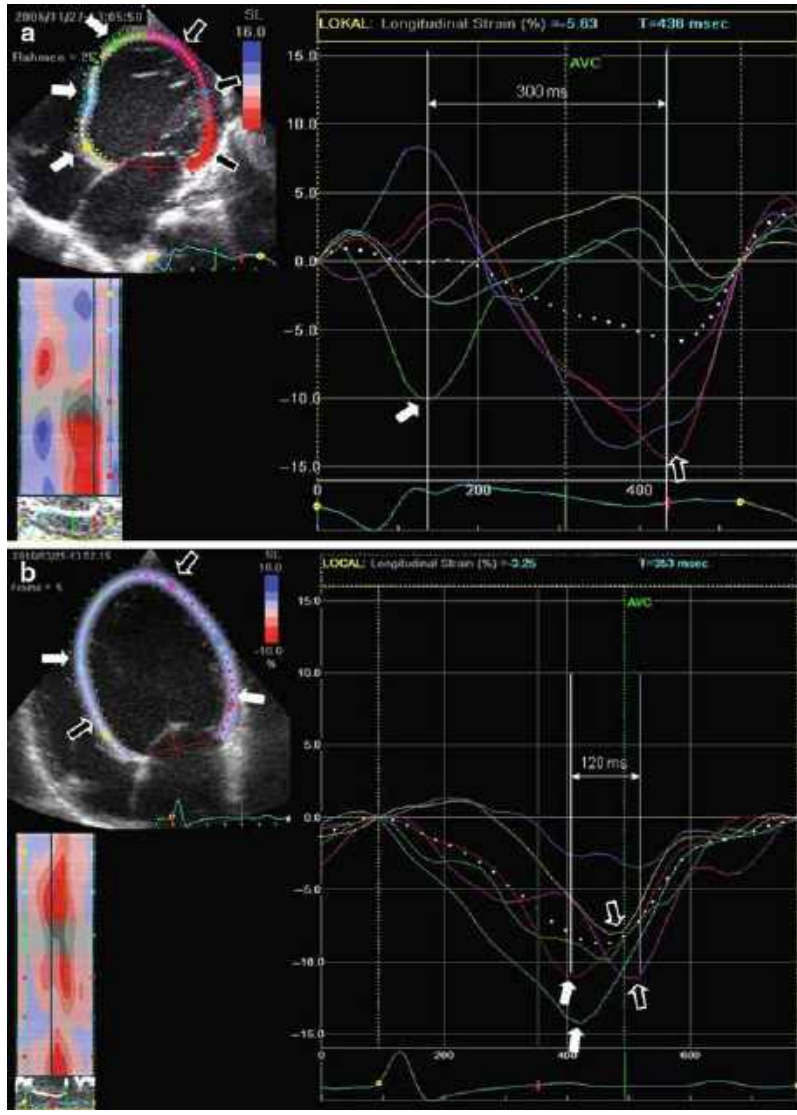

Fig. 162.1 The new echocardiographic technique of speckle tracking-derived two-dimensional strain is able to detect the timing of segmental myocardial deformation. The *upper left* picture in each panel displays color-coded LV segments in the apical four-chamber view with corresponding *strain curves* on the *right hand* (negative strain = contraction, positive strain = relaxation or stretch). (**a**) Clustered pattern of LV dyssynchrony due to RV pacing with early septal (*white arrows*) and late free wall (*black arrows*) contraction. Septal contraction causes stretch of the LV free wall followed by late contraction of the latter at the time of septal relaxation. This results in an excessive septal to free wall mechanical delay of 300 ms and severe LV dyssynchrony. (**b**) Dispersed pattern of LV dyssynchrony in a patient with dilated cardiomyopathy and normal QRS duration caused presumably by contractile disparity and resulting in a maximum intersegmental mechanical delay of 120 ms. Early (*white arrow*) and late (*black arrow*) contracting segments are interspersed

in the apex or septum, or epicardially close to interventricular septum of the subpulmonary ventricle, and the other lead is located at the late activated systemic ventricular free wall. The resynchronized ventricle should lie between these two electrodes so that a sufficient spatial and electrical separation between both leads is achieved. Generally, different combinations of

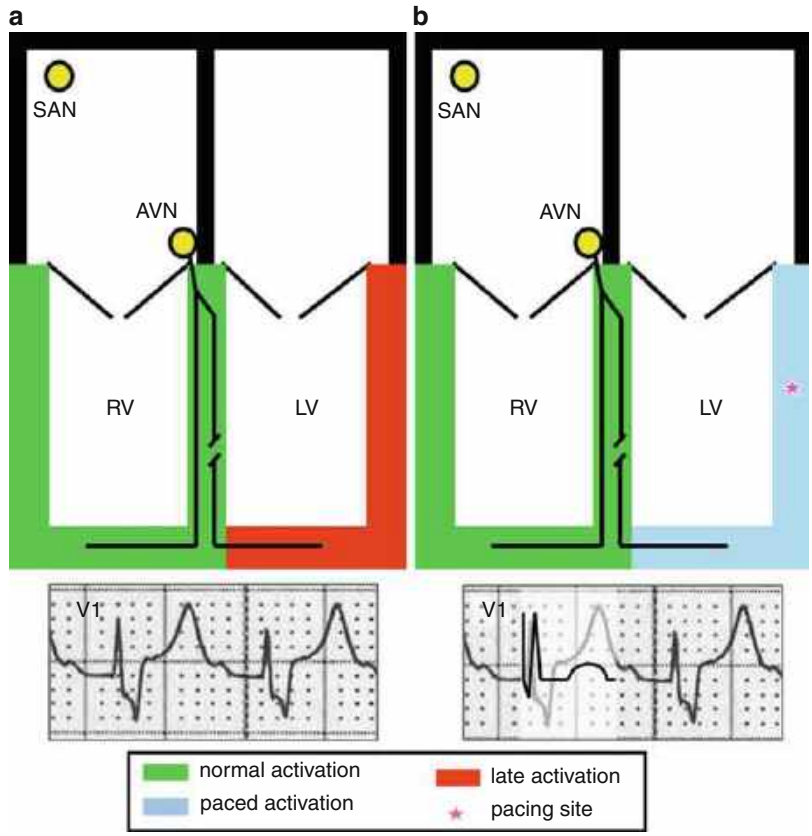

Fig. 162.2 Simple scheme of CRT in a patient with left bundle branch block and LV dysfunction. (**a**) During native conduction, electrical and mechanical LV free wall activation is delayed because of the left bundle branch block. This results in septal to lateral LV dyssynchrony. (**b**) CRT is applied by properly timed LV free wall preexcitation and carries fusion between spontaneous (septal) and paced (free wall) activation reflected by a narrowed QRS complex and restoration of LV contraction synchrony. Single-site LV or biventricular pacing may be used to achieve this goal (see text for details). *AVN* AV node, *LV* left ventricle, *RV* right ventricle, *SAN* sinoatrial node (Reproduced with permission from Heart 2009;95:940–947)

transvenous and thoracotomy leads may be used in adaptation to patient's age and cardiac anatomy to achieve this goal.

When placing the systemic ventricular lead, recording of local electrograms may be useful to seek a site with the latest electrical activation as compared to QRS onset. As shown in patients with left bundle branch block, LV activation sequence may vary [19], and hence, intraprocedural electrical mapping may be helpful to confirm optimal lead position. Helm et al. [20] evaluated how precise lead placement has to be to achieve a certain percentage of maximum CRT response. In that study, placement within an

area corresponding to 17 % of the LV free wall surface around the optimal pacing site guaranteed at least 90 % of the maximum response; placement within an area of 42 % gave ≥70 % of maximal response. Thus, lead placement need not be extremely precise to achieve an acceptable CRT benefit.

Acute Electrical Management of Low Cardiac Output

Postoperative junctional ectopic tachycardia. Postoperative junctional ectopic tachycardia (JET) is the index arrhythmia to observe the negative hemodynamic effects of missing AV synchrony in the pediatric cardiac intensive care unit. Besides high heart rates, the absence of atrial kick may be especially deleterious in the setting of naturally decreased myocardial performance after open heart surgery [21] and short ventricular filling periods. The arrhythmia comes along with either AV dissociation or 1:1 retrograde atrial conduction. ECG from the atrial epicardial pacing wires and observation of the central venous pressure curve (irregular in the former and regular in the latter) may help to distinguish between these two forms (Fig. 162.3). From the hemodynamic viewpoint, regular fast retrograde conduction is worse because of activating the atria at the time of closed AV valves. Every atrial contraction causes a reverse flow of blood into the large veins and potentially leads to impaired fast passive ventricular filling once the AV valves open.

The principles of postoperative JET management have evolved over time and include supportive measures, administration of antiarrhythmic drugs, mild hypothermia, and electrical restoration of AV synchrony [22]. As many patients with postoperative JET have impaired antegrade AV conduction, either as a part of the surgical junctional damage or as a consequence of antiarrhythmic treatment [23, 24], simple atrial overdrive pacing is mostly not sufficient to optimize the mechanical AV synchrony and results in first or higher degree of AV block.

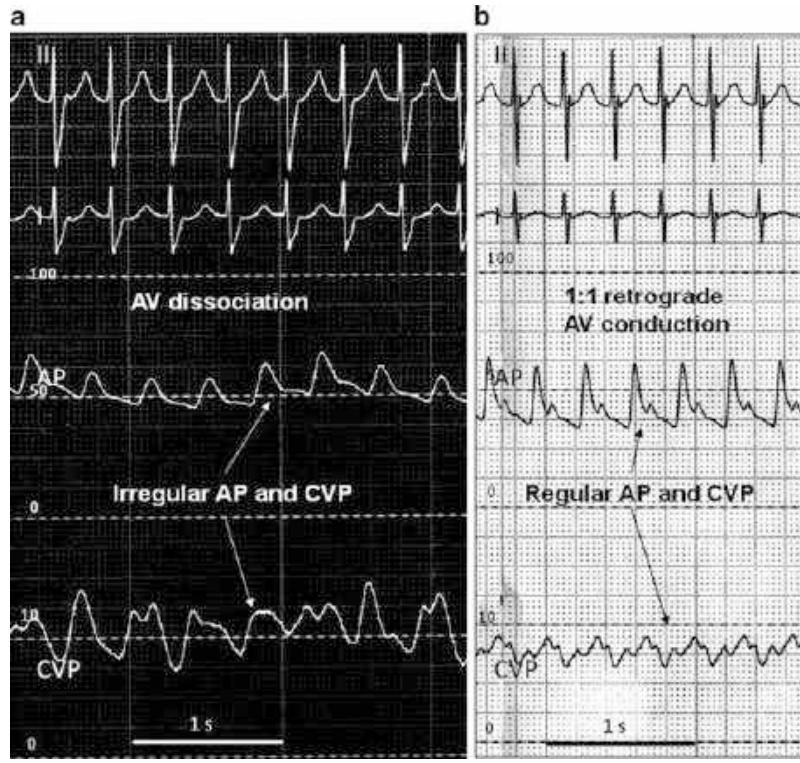

Fig. 162.3 Two forms of junctional ectopic tachycardia (JET). (**a**) JET with atrioventricular dissociation. The ventricles are beating faster than the atria, and P waves are occasionally visible in the ECG tracing. AP and CVP curves are irregular due to random and changing atrioventricular mechanical synchrony. (**b**) JET with 1:1 retrograde atrial conduction. P waves are hidden in the QRS complexes and hence not visible. Because of the regular atrioventricular relationship, AP and CVP curves are also regular. *AP* arterial pressure, *CVP* central venous pressure, scaling in mmHg

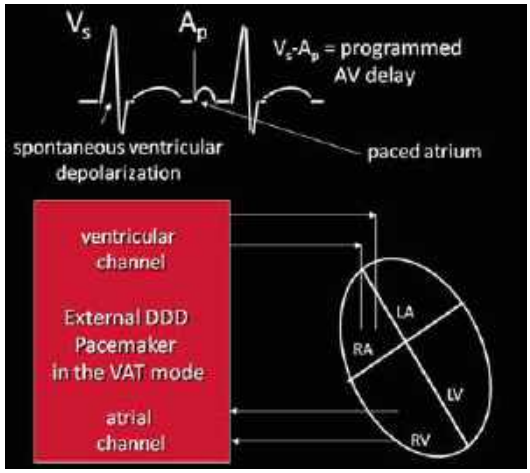

Fig. 162.4 Connection of the external dual-chamber pacemaker during R wave synchronized atrial pacing. *Ap* atrial pace event by ventricular pacemaker channel, *AV* AV, *LA* left atrium, *LV* left ventricle, *RA* right atrium, *RV* right ventricle, *Vs* ventricular sense event by atrial pacemaker channel

Atrioventricular sequential pacing may overcome this problem at the price of potential ventricular desynchronization due to single-site ventricular pacing, which may offset the benefit gained from restoration of AV synchrony. In the early 1980s, Till et al. [25] came up with a brilliant idea of R wave triggered atrial pacing (AVT pacing using the current pacing mode nomenclature). The principles are depicted in Fig. 162.4. This method has several important advantages: (1) no need for increasing the heart rate to achieve overdrive, (2) restoration of AV synchrony without the need for ventricular pacing, and (3) spontaneous adaptation of the programmed pacing mode to mild changes in the tachycardia rate. A further study [24] has described successful use of temporary AVT pacing in the clinical setting using a commercially available dual-chamber external pacemaker. Such equipment has to fulfill two basic requirements: (1) The post-ventricular atrial refractory period has to be programmable to short values (~100 ms), and (2) maximum tracking rate has to be high enough (230 BPM in the published article) to cover the range of the JET. Pacing should be used as a "free of charge" first-line therapy carrying a significant increase in systolic, mean, and pulse pressure of around 10 % [24]. In some patients, pacing may be applied as a single measure, and the use of cooling and antiarrhythmic drugs which may have significant side effects can be reserved for more severe cases. AVT pacing will significantly improve hemodynamics and thus allow for decrease in catecholamine support, one of the main drivers of the ectopic focus. Given its efficacy and lack of significant side effects, AV resynchronization should be an integral part of postoperative JET management.

Restoration of ventricular synchrony. In the postoperative setting, ventricular dyssynchrony is most commonly caused either by single-site ventricular pacing in the instance of AV block or by the presence of complete right bundle branch block. It is avoidable in the first situation and correctable in the latter.

In the case of temporary anti-bradycardia pacing, care should be taken to select an appropriate pacing site to minimize the electromechanical dyssynchrony of the systemic ventricle. Acute experimental and clinical pacing studies [26, 27] have convincingly shown hemodynamic benefit from pacing the apex of the systemic LV as opposed to both RV and LV free wall pacing. Apical pacing preserves septal to lateral LV synchrony and produces a relatively physiologic sequence of electromechanical activation from the apex to base, which translates into minimum decrease of maximum + LV dP/dt, when compared to normal spontaneous ventricular activation. Although not proven by any study, the same may apply for apical stimulation of a systemic RV. At least one temporary ventricular pacing wire should be placed at the systemic ventricular apex in patients at risk of AV block requiring ventricular pacing.

Complete right bundle branch block is a common arrhythmia after surgery for congenital heart defects specifically associated with certain types of repair like tetralogy of Fallot. Albeit well tolerated in the majority, it may have significant consequences in patients with severe RV failure, both in the subpulmonary and systemic position. RV resynchronization may be simply achieved by atrial synchronized pacing of the RV free wall in fusion with spontaneous

activation or by biventricular pacing in case of prolonged AV conduction [15, 16]. The goal is to restore mechanical synchrony between the early activated septum and late activated RV free wall and to optimize the mechanical AV delay if necessary. In patients with right bundle branch block and a potential for RV failure, one temporary pacing wire should be placed at the RV free wall and the other one at the LV apex as described previously. Such setup will allow for adaptation of pacing to the most common combinations of AV and intra-RV dyssynchrony.

The hemodynamic effects of temporary resynchronization pacing can be easily seen observing the directly monitored arterial and filling pressures and pacing can be fine-tuned accordingly. Several studies have evaluated the effects of acute electrical management of low cardiac output in the congenital heart disease population. All have shown hemodynamic improvement. Three of them focused partially or totally on the resynchronization of a failing subpulmonary RV [15, 16, 28]. Successful resynchronization of a single ventricle was reported in two studies [28, 29]. Mechanical resynchronization of a single ventricle could be even achieved despite normal baseline QRS duration (mean 94 ms) in one study [29]. This has opened a space for further research looking at mechanical dyssynchrony as a potential and correctable substrate contributing to heart failure in single-ventricular patients. In some of the reported patients, temporary resynchronization was a very powerful tool to enable discontinuation from cardiopulmonary bypass, when all other measures were unsuccessful. The method has a potential for interrupting the vicious circle of dyssynchrony-associated acute heart failure. In this situation, increase in catecholamine support leads to exaggerated heart rates due to sinus tachycardia and carries a combination of inefficient dyssynchronous ventricular contraction with severe limitation of diastolic ventricular filling due to short cardiac cycle duration and prolongation of systole and both isovolumic periods. Cooperation with the cardiac surgeon, identification of the failing and resynchronizable ventricle (either systemic or subpulmonary), and appropriate placement of temporary pacing wires at areas of late electromechanical activation are, however, essential. Most commonly pacing can be discontinued early in the postoperative course after spontaneous improvement in myocardial function [21].

Permanent Cardiac Resynchronization Therapy (CRT)

Over the last decade, CRT has evolved to a powerful treatment option of systolic heart failure associated with LV mechanical dyssynchrony. Studies in adult patients with idiopathic and ischemic cardiomyopathy reported restoration of LV contraction efficiency, reverse structural and cellular remodeling, functional improvement, and decrease in heart failure-associated morbidity and mortality [30–33].

Available pediatric data. Besides reports on small patient series, two multicenter surveys [11, 12] and one large retrospective single-center study [13] have so far mapped response to CRT in a total of 272 pediatric and congenital heart disease patients whose demographic data are summarized in Table 162.1. Efficacy of CRT may vary with the underlying structural and functional substrate like anatomy of the systemic ventricle (left, right, or single), presence and degree of structural systemic AV valve regurgitation, presence of primary myocardial disease or scaring, and type of electrical conduction delay. The following findings have been reported:

1. Systemic ventricular dyssynchrony caused by conventional single-site ventricular pacing was the most prevalent (63 %) indication for CRT.
2. The prevailing New York Heart Association (NYHA) class II was (58 % of patients reported) reflecting a more proactive approach to CRT as compared to adult guidelines available at the time of the sampling period.
3. There has been a consistent mean increase in the systemic ventricular ejection fraction (EF) of 6–14 EF units after CRT.
4. Systemic LV was an independent predictor of better response to CRT in terms of

improvement of systolic ventricular function [12], with those patients who were upgraded to CRT from conventional RV pacing being the most rewarding responders [34].

5. CRT has been effectively used in combination with corrective or palliative cardiac surgery and was also successful as a part of a combined strategy aimed at resynchronization and decrease or abolition of systemic AV valve function regurgitation [12, 35].
6. The proportion of CRT-D systems was low (18–25 %) as compared to adults with idiopathic or ischemic heart disease.
7. Almost 40 % of the heart transplant candidates referred to CRT could be delisted [34], suggesting that young patients awaiting heart transplantation should be specifically screened for the presence of mechanical dyssynchrony as a potential substrate for improvement by resynchronization.
8. The number of nonresponders to CRT (14 %) was lower than in the prospective adult trials. This observation likely reflects the retrospective nature of the pediatric studies and soft response definition rather than a true higher efficacy in pediatric patients compared to adults.
9. The presence of primary dilated cardiomyopathy and a high NYHA class seemed to predict nonresponse to CRT [12]. It should be stated that the number of patients available for analysis was too low and variety of substrates too high to perform a valid multivariable analysis.

Indications for CRT in pediatric heart disease.

Indications for CRT have been so far derived from adult guidelines [36, 37] that state the following:

1. CRT by biventricular pacemaker (CRT-P) or biventricular pacemaker combined with an implantable cardioverter-defibrillator (CRT-D) is indicated for patients who remain *symptomatic* in *NYHA classes III–IV despite optimal medical therapy*, with an *LV ejection fraction of* $\leq$*35 %, LV dilatation* and a *wide QRS complex* ($\geq$*120 ms*), with the following options:
   - Implantation of a CRT-P device to reduce morbidity and mortality (class I, level of evidence A).
   - CRT-D is an acceptable option for patients who have expectancy of survival with a good functional status for more than 1 year (class I, level of evidence B).
   - Primary implantation of a biventricular pacemaker or upgrade of conventional pacemaker in heart failure patients with concomitant indication for permanent pacing (class IIa, level of evidence C).
   - Implantation of a CRT-D system in heart failure patients with primary indication for an implantable cardioverter-defibrillator (class I, level of evidence B).
   - Implantation of a biventricular pacemaker in heart failure patients with permanent atrial fibrillation and indication for AV junctional ablation (class IIa, level of evidence C).
2. CRT preferentially by CRT-D has also been recommended to reduce morbidity or to prevent disease progression in patients with *NYHA function class II*, *LVEF of* $\leq$*35 %*, *QRS of* $\geq$*150 ms*, and *sinus rhythm* being *on optimal medical therapy* (class I, level of evidence A) [32, 33, 37].

The practice in pediatric and congenital heart disease may, however, differ in several aspects. As stated previously, CRT systems with a defibrillation capability (CRT-D) have not been used as frequently as in the adult population because of the relative paucity of indication for primary preventive ICD implantation in the pediatric heart failure population. Data from the pediatric heart transplant registry showed a very low incidence of sudden cardiac death in children awaiting heart transplantation [38] indirectly arguing against the automatic use of LV ejection fraction of $\leq$35 % as a criterion for primary preventive ICD implantation in young patients with dilated cardiomyopathy. Also, a more proactive approach using CRT extensively in NYHA class II patients or as part of a pro-synchronization strategy when electively associated with other cardiac surgery differs from the majority of adult CRT patients.

The following caveats and amendments of the current adult CRT indication guidelines

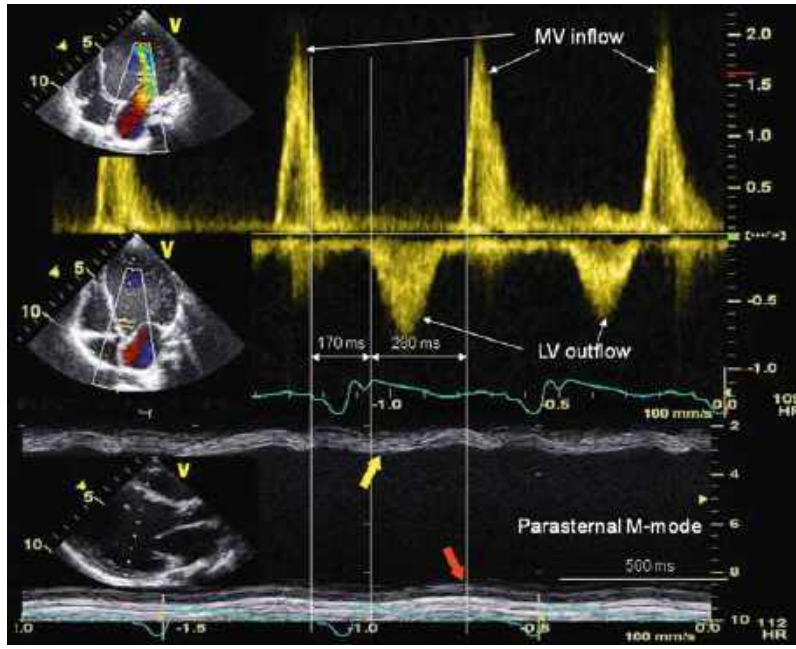

Fig. 162.5 Mounted picture using different echocardiographic techniques aligned to the same time scale to display global LV timing. From *top to bottom*: pulsed Doppler from the mitral valve, pulsed Doppler from the LV outflow tract, ECG, M-mode from the parasternal long axis view. The LV pre-ejection period of 170 ms reflects slow systolic LV pressure rise due to dyssynchrony evident by a septal (*yellow arrow*) to posterior (*red arrow*) wall motion delay of 280 ms. Ejection (see LV outflow Doppler tracing) starts by septal contraction at the time of maximum end-diastolic stretch of the LV posterior wall. Peak LV posterior wall contraction appears after aortic valve closure (end of ejection as depicted by the LV outflow Doppler) and corresponds with onset of the LV filling (mitral valve inflow). Energy put into LV posterior wall contraction is partially wasted because not contributing to LV ejection. *LV* left ventricle, *MV* mitral valve (Reproduced with permission from Heart 2009;95:940–947)

for patients with pediatric and congenital heart disease should be mentioned:

- The need for primary preventive defibrillation capability of a planned CRT device should be assessed individually and should not be based just on the value of systemic ventricular ejection fraction.
- The indication cutoff value of QRS duration may be adapted for age using the 98th percentile of normal values [39], if associated mechanical dyssynchrony is confirmed.
- Evaluation of mechanical dyssynchrony of the systemic ventricle should be performed in patients with nonstandard structural or functional CRT substrate (systemic right or single ventricle, right bundle branch block, presence of conventional ventricular pacing from an atypical pacing site, QRS duration <120 ms); see further.
- CRT device implantation may be considered within other planned cardiac surgery in the presence of significant systemic ventricular dyssynchrony (e.g., surgery aimed at repair of structural systemic AV valve regurgitation) even if the patient does not fulfill all indication criteria with respect to the systemic ventricular function [12, 35].
- CRT indication should be considered carefully and individually in patients with specific progressive forms of dilated cardiomyopathy (ventricular noncompaction, neuromuscular and mitochondrial disease), where CRT effect has not yet been clearly proven.

Pre-procedural assessment and follow-up. Functional, electrocardiographic, and echocardiographic assessment should be an integral part of the pre- and post-procedural long-term workup. Functional assessment should include NYHA class grading or the Ross heart failure score in infants, evaluation of functional capacity (6-min walking distance or spiroergometry, if applicable), and biochemical congestive heart failure markers. Analysis of the 12-lead electrocardiogram should focus on QRS complex duration as well as the type of electrical conduction delay with regard to the morphology of the systemic ventricle. Left bundle branch block along with a systemic LV and right bundle branch block along with systemic RV, respectively, are indicative of a significant intraventricular conduction delay and potential mechanical dyssynchrony. As shown by a recently published sub-analysis of a major adult CRT trial [40], the presence of left bundle branch block is a major predictor of CRT efficacy irrespective of other variables. Thus, not only QRS duration but also morphology should be assessed carefully to select proper therapy candidates.

Although none of the echocardiographic indices have been shown to have sufficient reproducibility and predictive power in terms of CRT response in the multicenter PROSPECT trial [8], several single-center studies reported on the utility of septal to posterior wall motion delay, tissue velocity imaging, speckle tracking [41, 42], vector velocity imaging or 3D techniques [43, 44] in the analysis of global and segmental LV dyssynchrony, and prediction of CRT efficacy. In the congenital heart disease patients with a diversity of structural and functional CRT substrates, echocardiography put in context with other findings may still play an important role for the confirmation of mechanical dyssynchrony amenable to CRT. Hence, besides the measurement of systemic ventricular size and function, global and segmental cardiac contraction timing should be assessed as an integral part of the pre-procedural evaluation and decision process, at least in patients with nonstandard CRT substrates (systemic right or single ventricle, right bundle branch block, presence of conventional ventricular pacing from an atypical pacing site, QRS complex $<$120 ms). Special attention should be paid to ventricular contraction occurring after the end of the ejection phase, or even continuing through the beginning of systemic ventricular filling which is a simple marker of significant mechanical dyssynchrony. In a more sophisticated way, the echocardiographic assessment should identify early and late contracting systemic ventricular segments and their geographic (spatial) clustering into larger wall areas and confirm myocardial viability. These are the two major prerequisites of CRT efficacy [9]. A careful integration of available data on the electrical and mechanical activation sequence, myocardial viability, and global cardiac timing (Fig. 162.5) may be very helpful in individual cases to support CRT indication and to guide lead placement. Further, echocardiography may be used for post-procedural AV delay optimization [45, 46]. The VV delay is mostly set to zero. In the usual pediatric situation of absent scarring and homogenous myocardial conduction velocity, there is no evidence that VV delay optimization would be of any utility. Evaluation of systemic ventricular size and function should be repeated using the same measurement method during regular device follow-up to assess long-term reverse ventricular remodeling.

Technical issues. In young patients, CRT device implantation is often challenging because of inaccessibility of the systemic ventricular free wall through a transvenous route, due to either small vessel size or abnormal cardiac anatomy. Individually tailored approaches have to be used. No data exist on the long-term behavior of coronary sinus leads in growing or young individuals, on the incidence of coronary sinus thrombosis, and complications of lead removal. As a consequence, 56–72 % of patients reported in the three larger pediatric and congenital heart disease CRT studies [11–13] had either thoracotomy or mixed lead systems. Coronary sinus leads should probably be reserved for older children and adults with a normally sized cardiac venous system, where complication rates should be acceptable and comparable to those reported in the adult CRT series. Younger patients or

individuals with inaccessible pacing sites through the transvenous route will be referred to a thoracotomy implantation. There should be a close cooperation between the implanting surgeon and the cardiologist/electrophysiologist during the procedure to ensure placement of the systemic ventricular lead in the area of latest electrical and mechanical activation, as mapped by preoperative echocardiography and perioperative measurements of local activation times during the baseline rhythm. Such measurement can be performed using commercial pacing system analyzers, by placing the systemic ventricular lead at various parts of the epicardial surface before choosing the optimal site. Local electrical activation should occur at the end or even behind the surface QRS complex. Optimal position of an epicardial subpulmonary ventricular lead has not yet been specified. In parallel to the transvenous procedure, lead placement may be attempted close to the interventricular septum. The subpulmonary and the systemic ventricular leads should be spatially, as well as electrically, separated as much as possible across the systemic ventricle. In patients with a single ventricle, successful resynchronization has been shown when achieving maximal distance between the two ventricular leads and aiming for the midventricular regions rather than the base [13]. Use of single-site resynchronization pacing has been anecdotally reported in the pediatric literature [18]. Sufficient fusion between the spontaneous (mostly septal) and paced (mostly free wall) activation wave fronts is the prerequisite of success and may be achieved in patients with normal baseline AV conduction times. Still, accurate adaptation of the AV interval to changes in heart rate may pose a challenge. Thus, this technique should be limited to patients with normal and relatively fix PR intervals during rest and exercise. CRT by single-site pacing may, however, save considerable surgical effort and decrease the potential for procedure-related complications. A typical example may be a single-ventricular patient with bundle branch block and normal AV conduction in whom placement of two leads on opposite walls may be very challenging.

Ablation Therapy for Arrhythmias and Conductive Disorders

163

Jennifer Silva and George Van Hare

Abstract

Invasive electrophysiology study is one of the most reliable tools for a pediatric electrophysiologist, allowing for accurate diagnostics and the potential for intervention. Technology has progressed rapidly over the past 20 years and continues to do so. The current era of electrophysiology studies involves more than a standard pacing study with transcatheter ablation. It has evolved to include 3-dimensional electroanatomic mapping, noncontact mapping, and intracardiac echocardiography. The fundamentals of the electrophysiology study, however, remain the same.

Keywords

Ablation • AH interval • Atrial flutter • Atrioventricular nodal reentrant tachycardia • Atrioventricular reciprocating tachycardia • AV Wenckebach • Cryoablation • Ectopic atrial tachycardia • Effective refractory period (ERP) • Electrograms • HV interval • IART • Mahaim pathways • Permanent junctional reciprocating tachycardia • Supraventricular tachycardia • Radiofrequency • Temporary pacing wires • Transesophageal pacing • Ventricular tachycardia • Wolff-Parkinson-White

Introduction to Electrophysiology Study

Technology associated with electrophysiology (EP) studies has advanced significantly in the past two decades. Initial transvenous ablations performed with direct current (DC) energy were unpredictable and often unsuccessful and were never applicable to the pediatric population. Technologic advances in energy sources, catheters, fluoroscopic imaging, and mapping have proceeded rapidly. Currently, transcatheter ablations are performed routinely in pediatric patients for various arrhythmia substrates as the indications for EP studies have gradually expanded over time [1] (Table 163.1). This chapter will explore the details of the electrophysiology study, including equipment, diagnostic maneuvers, and therapeutic interventions for various arrhythmias.

Table 163.1 Indications for Pediatric electrophysiology testing

Class I
1. Incessant supraventricular tachycardia (SVT) with signs of ventricular dysfunction
2. WPW with syncope or aborted sudden cardiac death
3. Ventricular tachycardia (VT) with hemodynamic compromise amenable to catheter ablation
Class IIa
1. Medically refractory SVT in children >4 yrs
2. SVT in children with impending CHD surgery
3. Chronic or incessant SVT without LV dysfunction
4. Chronic or frequent recurrent incisional atrial reentrant tachycardia (IART)
Class IIb
1. Asymptomatic WPW in children >5yrs
2. SVT in children >5 yrs when medications are effective
3. SVT in children <5 yrs where medications are ineffective or show side effects
Class III
1. Asymptomatic WPW in children <5yrs
2. SVT in children <5 yrs that is controlled with conventional medications
3. Non sustained VT with no LV dysfunction
4. Minimally symptomatic non-sustained VT
5. Infrequent IART episodes
Class I: There is consistent agreement and/or supportive data that catheter ablation is likely to be medically beneficial or helpful for the patient.
Class II: There is a divergence of opinion regarding the benefit or medical necessity of catheter ablation. **II A:** The majority of opinions/data are in favor of the procedure. **II B:** There is clear divergence of opinion regarding the need for the procedure.
Class III: There is agreement that catheter ablation is not medically indicated and/or the risk of the procedure may be greater than benefit for the patient.

Equipment

A variety of intracardiac electrophysiology catheters are available to choose from when deciding the cohort of catheters to use in a given case. Limited studies can employ as few as a single catheter positioned successively in the various chambers of interest; however, the most common catheter setup involves four catheters. The usual locations for these catheters are the high right atrium, His bundle, coronary sinus, and right ventricular (RV) apex. Catheters can range from single bipoles to multiple (as many as 20) poles and from 4 to 7 French in size. They may also include a lumen, useful for angiography in the coronary sinus.

Catheters are connected to a digital recording and pacing system. Surface ECG leads as well as intracardiac electrograms can be displayed simultaneously to allow for real-time analysis. Signals are filtered and then displayed at a computer work station. In the digital era, electronic data is saved and stored, allowing for tracings to be frozen, annotated, and printed as needed. Pacing is performed via the programmable stimulator where amplitude, pulse width, and cycle length are all controlled.

Positioning of catheters is typically done utilizing fluoroscopic guidance. Most pediatric laboratories have biplane fluoroscopy to provide orthogonal views for precise catheter localization. Minimizing radiation exposure during the EP study has become an active area of interest in the pediatric electrophysiology community. Utilizing lead shields and fluoroscopic shutters are techniques employed to minimize radiation exposure to both patient and operator. Non-fluoroscopic imaging allows for visualization of catheters without the use of fluoroscopy and has gained a foothold in many pediatric laboratories [2–4]. Examples of non-fluoroscopic imaging methods include intracardiac echocardiography and 3-dimensional electroanatomic mapping (Fig. 163.1).

Finally, it is important to always have a defibrillator and code cart in the room for quick resuscitation since pacing protocols can potentially evoke hemodynamically unstable rhythms. Ideally, the defibrillator should be connected to the patient via hands-off patches throughout the entire procedure.

Catheter Positions

High Right Atrium (HRA): The HRA catheter is typically positioned near the sinoatrial node, by the superior vena cava to right atrial (SVC-RA) junction. Another location frequently used is the

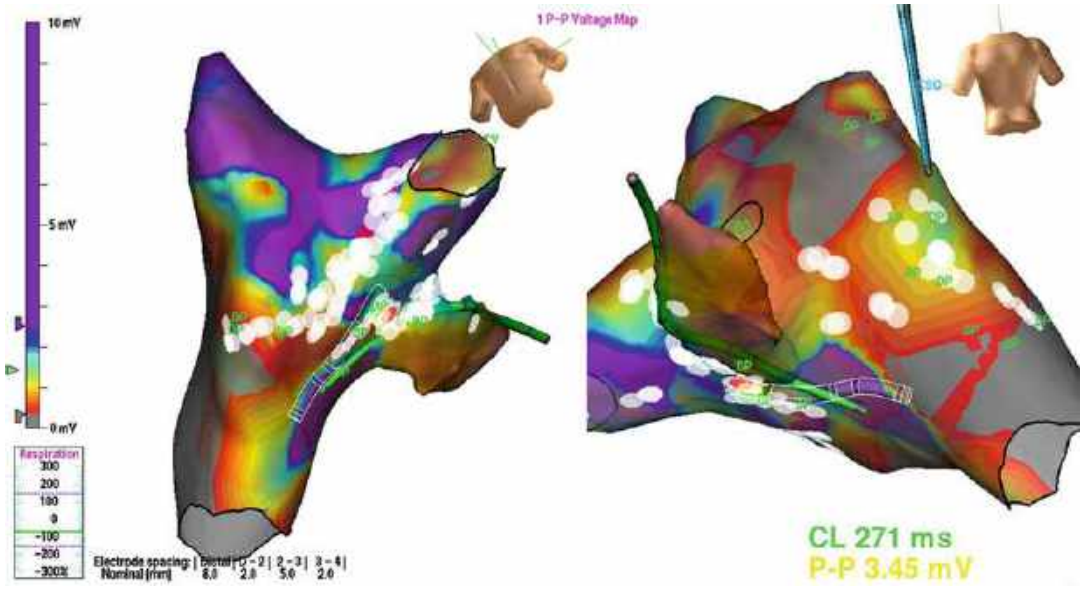

Fig. 163.1 Three-dimensional non-fluoroscopic imaging of a right atrium. These 3-dimensional maps were created in a teenager who had recurrent intra-atrial reentrant tachycardia (IART) and had undergone a takedown of the Fontan circuit. These voltage maps demonstrate areas of healthy tissue and scar tissue. Areas of healthy tissue are purple, with areas of scar in red (see scale). This map identifies areas of slow conduction that contribute to the IART circuit. The white circles denote where RF lesions were placed. Two RF lines were generated to interrupt the reentrant circuits

right atrial appendage (RAA), as catheter stability is much greater in this location. The usual electrogram from an RAA location has a large sharp atrial electrogram with a smaller ventricular component (Fig. 163.2). Pacing from this catheter allows the operator to define the properties of both the sinoatrial (SA) and atrioventricular (AV) nodes and is useful in the induction of abnormal rhythms.

His Bundle Electrogram (HBE): The HBE catheter is placed near the His bundle and sits across the tricuspid valve. The ideal electrogram has an atrial component nearly equal in amplitude to the ventricular component and a clear sharp His deflection (Fig. 163.2). Pacing from this catheter at low energy tends to capture the RV outflow tract with a wide complex QRS but at higher energy may actually capture both the RV outflow tract and the His bundle itself resulting in a relatively narrower QRS. The ability to pace the His bundle allows for diagnostic maneuvers to help distinguish whether retrograde conduction is via the AV node or a septal accessory pathway [5]. Measurements of ventriculoatrial (VA) times during para-Hisian pacing can identify the presence of septal accessory pathways.

Coronary Sinus (CS): The CS catheter is usually a multipolar (decapolar) catheter positioned within the CS. Anatomically, the CS wraps around the mitral valve annulus, and electrograms from this catheter typically have annular (atrial and ventricular) signals (Fig. 163.2). The atrial signal on this catheter is a left atrial signal and is important in identifying left-sided accessory pathways. Occasionally, accessory pathways may be located within the coronary sinus itself. These pathways, though unusual, are often associated with abnormalities of the CS, such as CS diverticula [6–8]. Angiography of the CS can help delineate these abnormalities (Fig. 163.3).

Right Ventricular Apex (RVa): The RVa catheter positioned in the apex of the RV is typically in a stable position. The electrogram obtained at this location is a pure sharp ventricular signal (Fig. 163.2). Pacing from this catheter defines properties of the ventricle and retrograde

Fig. 163.2 Baseline intervals in a patient undergoing electrophysiology study in normal sinus rhythm. The first four signals are surface ECG signals, with leads I, II, aVF, and V1 represented. Next is the high right atrium (HRA) catheter. There is a sharp atrial electrogram followed by a low amplitude ventricular electrogram. This catheter is positioned in the right atrial appendage. On the His bundle electrograms, there is a small atrial electrogram, followed by a high-frequency His electrogram, followed then by a large amplitude ventricular electrogram. The coronary sinus catheters are next, labeled CS 1, 2 through CS 9, 10 with CS 1, 2 representing the most distal pair of electrodes and CS 9, 10 representing the most proximal pair (close to the mouth of the coronary sinus). There both atrial and ventricular electrograms on the CS electrodes since this catheter outlines the left AV valve annulus. Finally, the right ventricular catheter is positioned in the apex of the right ventricle and has a sharp ventricular electrogram

conduction and is helpful in the induction of both supraventricular and ventricular tachyarrhythmias. Occasionally, the RV catheter is placed into the RV outflow tract for pacing and recording.

Baseline Intervals

Once catheters have been positioned into the locations described above, baseline intervals are collected. Surface electrocardiographic intervals, including PR interval, QRS duration, and QT interval, are measured. These values are age dependent and normal standards have been published [9, 10]. In addition, intracardiac intervals are measured. The AH interval, measured on the HBE catheter as the time between the A and H components, is an estimate of the conduction time through the AV node. A normal AH interval is 55–125 ms [1]. The AH interval may be abnormally prolonged in patients with high vagal tone, intra-atrial conduction delays, antiarrhythmics, or AV nodal disease and tends to shorten with increased catecholamine states. The HV interval is measured from the onset of the His on the HBE catheter to the earliest recorded ventricular signal (including surface ECG) [11]. An HV interval of 35–55 ms is considered normal [1]. A short HV interval is seen in preexcitation syndromes, including Wolff-Parkinson-White (WPW). A long HV interval suggests His-Purkinje disease and may also be seen in patients with repaired congenital heart disease [11] and those with left bundle branch block.

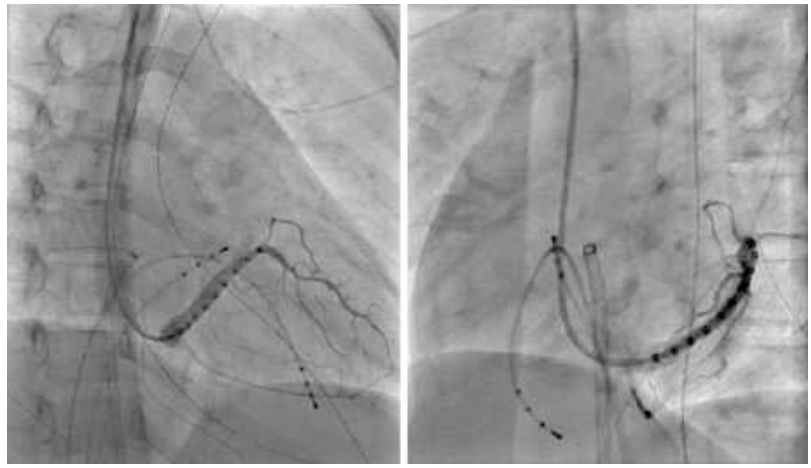

Fig. 163.3 Coronary sinus (CS) angiograms. These angiograms are taken in the right anterior oblique (on the *left*) and left anterior oblique (on the *right*) projections by injecting contrast through the CS catheter. The cardiac venous branches are also opacified in this angiogram. Obtaining this picture helps to define where the CS ostium lies and is important in the ablation of various arrhythmias. There are no diverticula noted in this patient

Diagnostic Maneuvers

Once baseline intervals have been measured, the pacing portion of the EP study follows. Various pacing maneuvers are performed to assess the sinoatrial and atrioventricular nodes, as well as the refractory periods.

SA Node: The sinus node recovery time, or SNRT, is the time it takes for the restoration of sinus rhythm after HRA pacing. To determine the SNRT, the HRA is paced at a rate faster than the underlying sinus rhythm for 30 s. Once HRA pacing is terminated, there is a pause followed by resumption of sinus rhythm. This pause is the SNRT. When the SNRT is prolonged, this indicates sinus node dysfunction. However, the SNRT varies with the sinus rate, so the corrected sinus node recovery time (cSNRT) is calculated by subtracting the sinus cycle length from the SNRT. Normal values for cSNRT are $<$275 ms in children [12].

AV Node: There are two maneuvers for assessing the functionality of the AV node – Wenckebach rate and the AVN effective refractory period. The AV Wenckebach cycle length is determined by overdrive pacing the atrium (usually the HRA) at rates faster than intrinsic sinus rate and assessing AV conduction. The rate at which the HRA is paced is increased until there is loss of 1:1 conduction, or Wenckebach. Typically, AV Wenckebach is seen in children at cycle lengths of $<$380 ms [12]. This measurement is reassessed in the presence of adrenergic stimulation (using an isoproterenol infusion).

The AV node effective refractory period (ERP) is assessed by single extrastimulus testing. This is done by delivering a pacing drive train of typically 8 beats (S1) followed by the introduction of a single premature beat (S2). This premature beat is subsequently introduced earlier and earlier in 10 ms increments. The effective refractory period is the interval at which the premature beat fails to either conduct or capture. Typically, as the S2 becomes earlier, the AH interval prolongs or decrements, a normal property of the AV node. The AV ERP in children typically ranges between 220 and 350 ms [12]. Similarly, the atrial ERP is that S1S2 interval at which there is failure to capture the atrial muscle. The usual range for the atrial ERP in children is 170–250 [12].

Ventricle: Just as overdrive pacing and extrastimulus testing are performed in the atrium, they are also performed in the ventricle. Overdrive pacing in the ventricle tests for the presence and pattern of retrograde conduction, as well as the interval of retrograde Wenckebach. The placement of single premature beats (a series of S1 followed by S2) allows for assessment of the ventricular ERP, typically in children between 200 and 300 ms [12]. Decremental properties of

the AV node may also be seen when testing for retrograde conduction. Decremental conduction is defined as conduction delay resulting from progressive prematurity or progressively more rapid stimulation.

Induction of Tachycardias

After baseline data has been obtained, the next step is to characterize the arrhythmia substrate. This is often accomplished by the induction of tachycardia with pacing maneuvers performed during sustained tachycardia.

Supraventricular Tachycardia: Most patients brought to the EP lab have documented supraventricular tachycardia, either by 12-lead ECG or event monitor. During the initial assessment of Wenckebach cycle lengths and ERPs, there may be induction of tachycardia. If that does not happen, a more aggressive approach for the initiation of SVT may be undertaken which may include the infusion of isoproterenol. Isoproterenol is a β1- and β2-receptor agonist that produces an increase in heart rate, shortening of the PR interval, AV node refractory period, AV block cycle length, an increase in cardiac contractility [13], and systemic vasodilation. Repetitive pacing of the HRA, coronary sinus, and RV is performed in the presence of isoproterenol for the induction of tachycardia. Once SVT has been induced, it is possible to determine mechanism and to devise a scheme for the precise mapping of potential ablation targets.

Ventricular Tachycardia: Programmed ventricular stimulation is a systematic ventricular pacing protocol designed to elicit ventricular arrhythmias. While the details of the protocol may vary by institution, there are some overall similarities. Both overdrive pacing and extrastimulus testing with single, double, and triple extrastimuli are performed from 2 ventricular sites, typically the RV apex and the RV outflow tract [12]. The protocol is performed both on and off isoproterenol. The response to this testing can vary from the induction of monomorphic VT to polymorphic VT. While it may be possible to pace-terminate a stable monomorphic VT, the ability to quickly cardiovert or defibrillate patients is mandatory when performing this type of electrophysiology study.

Ventricular stimulation studies are important for several reasons. They may allow for a better mechanistic understanding of the patients' tachycardia. This in turn allows for better treatment of these patients either with pharmacologic agents or with device therapy. Also, programmed ventricular stimulation has been shown to better risk stratify patients with congenital heart disease. Patients with positive programmed ventricular stimulation studies are at increased risk of decreased survival and serious arrhythmic events compared to those with failure of induction of tachycardia. Unfortunately, the test has a high false-negative rate [12, 14, 15].

Diagnostic Considerations and Ablation of Supraventricular Tachycardias

AV Nodal Reentrant Tachycardia: AV nodal reentrant tachycardia (AVNRT) is a common mechanism for SVT in the adolescent population [16, 17]. Dual AV node physiology is usually but not always present in patients with inducible AVNRT. In the most common form of AVNRT (typical AVNRT), the reentrant circuit involves a slow pathway and a fast pathway. Slow pathway inputs into the compact AV node are inferior while fast pathway fibers input superiorly. The slow pathway fibers have a shorter effective refractory period with slower conduction time, while the fast pathway fibers have a longer effective refractory period with a faster conduction time. Mechanistically, typical AVNRT arises when antegrade conduction of a premature atrial beat blocks in the fast pathway and instead conducts antegrade down the slow pathway. If conduction time down the slow pathway is slow enough to allow for recovery of the fast pathway, the impulse will then conduct retrograde up the fast pathway. Propagation of this reentrant circuit results in sustained AVNRT (Fig. 163.4).

During the EP study, it is common to encounter a "jump" in the AH interval during single

Fig. 163.4 Intracardiac tracing of atrioventricular nodal reentrant tachycardia (AVNRT). This snapshot is obtained during sustained AVNRT. The ECG leads demonstrate a narrow complex tachycardia with no obvious retrograde P wave. The intracardiac electrograms demonstrate a very short VA time (<60 ms) with the atrial electrograms (seen on the HRA, His, and CS catheters) occurring during the QRS complex. This finding is characteristic of typical AVNRT

atrial extrastimulation. A jump is defined as a >50 ms increase in the AH interval for a given 10 ms decrease in A1A2. Once antegrade atrioventricular conduction has jumped onto the slow pathway, single atrial reentrant beats called echo beats may be seen due to the retrograde conduction up the fast pathway. AV nodal echo beats typically have a short retrograde conduction time with a VA interval of <60 ms [18]. It is important to note that the presence of dual AV node physiology does not automatically imply the presence of AVNRT. In fact, dual AV node physiology may be seen in up to 1/3 of all children [19]. Sustained AVNRT should be induced before undertaking an AVNRT ablation. The infusion of isoproterenol in combination with atrial pacing near the Wenckebach cycle length is often effective in the initiation of tachycardia.

Ablation is directed at the slow pathway inputs at the base of the triangle of Koch. The borders of the triangle of Koch include the septal leaflet of the tricuspid valve anteriorly, the tendon of Todaro posteriorly, and the CS inferiorly. Slow pathway ablation is usually guided by an anatomic approach. So-called slow pathway potentials have been demonstrated in adults and may be another ablation target [20]. During radiofrequency (RF) ablation of the slow pathway, it is common to see accelerated junctional rhythm. Given the proximity of the slow pathway to the compact AVN and the risk of the development of heart block, it is important to monitor conduction during lesion application. This may be done with atrial pacing during the ablation lesion [21] or by monitoring retrograde conduction during junctional rhythm [22] (Fig. 163.5). After ablation, reassessing for jumps, atrial echo beats, and AVNRT initiation is all important in determining the success of the ablation. In some patients, there may be no residual evidence of slow pathway, while in others there may be a residual jump and atrial echo, particularly on

Fig. 163.5 Accelerated junctional rhythm during radiofrequency (RF) ablation of atrioventricular nodal reentrant tachycardia (AVNRT). During this RF lesion, we see the development of AJR for the first 4 beats, followed by resumption of sinus rhythm. It is important to monitor for retrograde conduction during AJR as it is a surrogate marker for intact nodal conduction. If there is loss of VA conduction during a lesion, the lesion should be terminated immediately

the edge of refractoriness [12]. For this reason, most pediatric clinicians use the loss of AVNRT inducibility, rather than the elimination of dual AV node pathways, as the appropriate endpoint for an effective ablation, and will accept single nodal echo beats if inducibility has been abolished.

The risk of heart block is low with radiofrequency ablation, perhaps 1–2 % based on published reports. This risk can be completely eliminated by the use of cryoablation, making this an attractive option for many pediatric electrophysiologists [23, 24]. During cryoablation, there has been reported PR prolongation and transient 2nd-degree AV block that have resolved once the lesion has terminated [25]. However, the recurrence rates are higher than in those patients undergoing RF ablation for AVNRT [26]. It is at the discretion of the operator to select the energy source they feel comfortable with for ablation.

Atrioventricular Reciprocating Tachycardia: This form of SVT is the most common in infants and children [16]. It may be seen in infants as well and if incessant can result in hydrops fetalis or even fetal demise. Infants may present with tachycardia-mediated cardiomyopathy since the duration of the antecedent tachycardia may be quite long. It is possible for infants to outgrow their tachycardia in the first year of life. As the AV valves continue to develop, accessory pathways that traverse the annulus can be interrupted and may no longer be capable of supporting SVT. Older children are typically able to communicate the presence of symptoms correlating with tachycardia and are more likely to seek out medical attention sooner so as to not present with compromised cardiac function.

Accessory pathways can be manifest (antegrade +/- retrograde conduction) or concealed (retrograde conduction only). An example of a manifest AP is Wolff-Parkinson-White syndrome (discussed later in this chapter). Most pathways are concealed. Accessory pathways may be

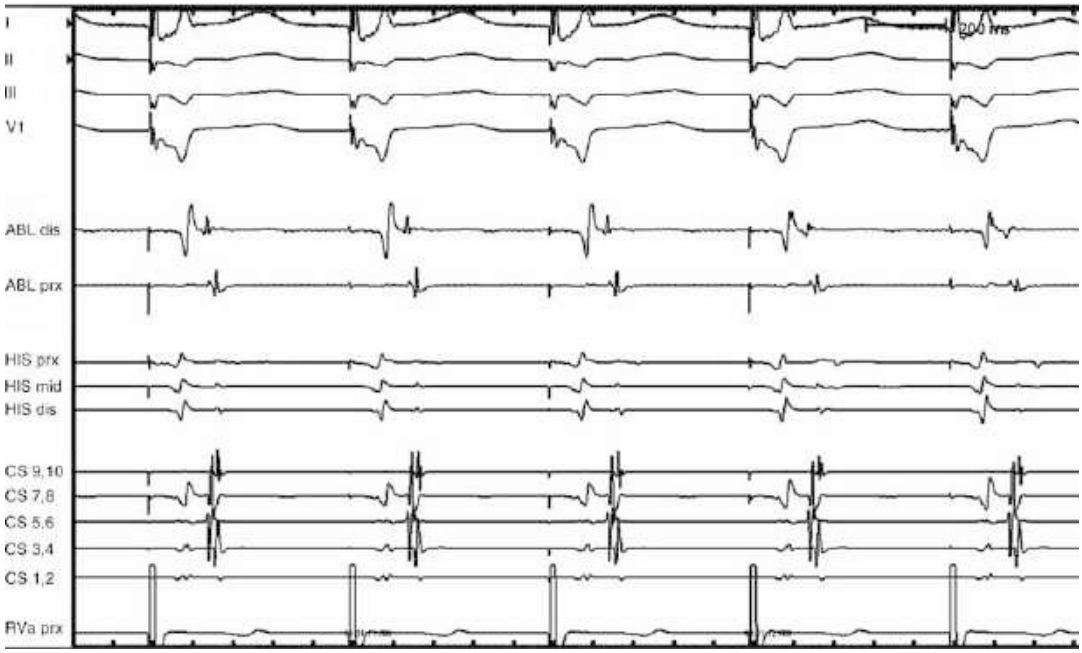

Fig. 163.6 Right ventricular pacing demonstrates retrograde conduction via a left lateral accessory pathway (AP). In this case, pacing the right ventricle (as seen by pacing stimulus artifact on the RV catheter as well as a wide complex QRS on the surface leads) demonstrates the earliest atrial activation at CS 5,6 which is at a left lateral location. The ablation signals have sharp ventricular and atrial electrograms, indicating that the catheter is appropriately positioned on the AV valve annulus

located on the right or left AV valve annulus. Usually there is only 1 AP, though multiple APs can be seen in up to 10 % of patients [27]. Multiple APs are more commonly seen in patients with underlying congenital heart disease [12] particularly Ebstein anomaly of the tricuspid valve. The mechanism for accessory pathway-mediated tachycardia occurs when retrograde conduction of an impulse from the ventricle to the atrium up the accessory pathway is followed by antegrade conduction down the AV node. This type of tachycardia is called orthodromic tachycardia.

Localizing accessory pathways during EP study may be done by recognizing eccentric retrograde activation with ventricular pacing (Fig. 163.6). Sometimes retrograde conduction is fused with conduction up both the accessory pathway and the AV node simultaneously. It then becomes particularly important to induce tachycardia with atrial or ventricular pacing and may require the presence of isoproterenol. The site of the accessory pathway will be at the earliest site of retrograde atrial activation. Left-sided pathways can be visualized on the CS catheter. Septal pathways are more challenging to diagnose and accurately map, as retrograde conduction up this type of accessory pathway may be mistaken for retrograde AV nodal conduction. One useful diagnostic maneuver to differentiate retrograde conduction through the AV node versus a septal AP is to pace the His bundle. Retrograde VA times are measured when pacing the RVOT only (wide complex QRS) versus the RVOT with the His bundle (narrower complex QRS). When pacing the His bundle (+ RVOT), a shorter VA time suggests retrograde conduction via the AVN. Conversely, if the retrograde conduction time is identical for RVOT versus RVOT + His pacing, this suggests retrograde conduction is through a septal accessory pathway, because His capture should be irrelevant if conduction is via an accessory pathway [5, 28].

Once the site of the accessory pathway has been determined, ablation is directed at that site.

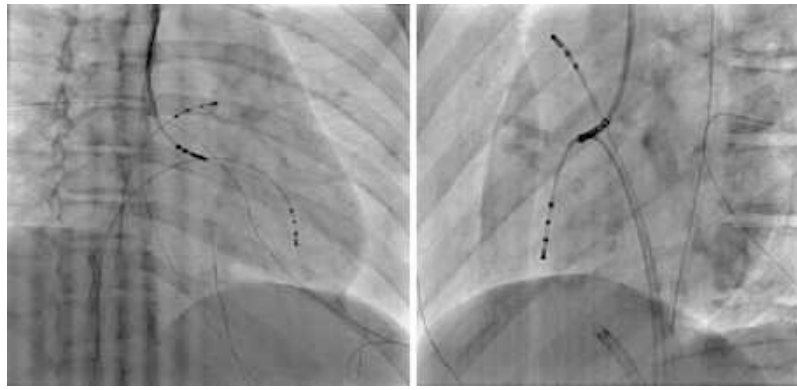

Fig. 163.7 Radiofrequency (RF) ablation of a right anterior-lateral accessory pathway (AP). These fluoroscopic images, obtained in the right anterior oblique and left anterior oblique projections (on the *left*- and *right-hand* sides, respectively), demonstrate a superior approach to a right anterolateral AP. The RF catheter is advanced from the right internal jugular vein into the right atrium and then curved underneath the right AV valve annulus to ablate the AP in this location. Additionally, two intracardiac catheters are seen at in the HRA and RVa

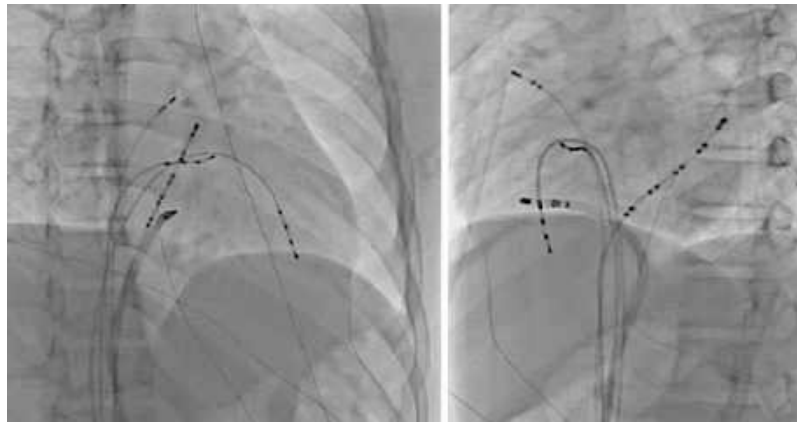

Fig. 163.8 Radiofrequency (RF) ablation of a right lateral accessory pathway (AP). These fluoroscopic images, obtained in the right anterior oblique and left anterior oblique projections (on the *left*- and *right-hand* sides, respectively), demonstrate the use of a preformed curved sheath to maintain adequate contact of the RF catheter with the lateral right AV valve annulus. In this location, it is often difficult to maintain catheter contact, and sheaths can help stabilize catheter position. There is a family of preformed curved sheaths available for stabilization at all locations on both the right and left AV valve annuli

Either radiofrequency or cryoablation is chosen depending on the site of the accessory pathway. For right-sided APs, a straightforward antegrade approach from the femoral vein is usually sufficient to ablate the pathway. Sometimes, approaching the right AV valve annulus from a superior approach via the right internal jugular vein is used for anteroseptal APs (Fig. 163.7). Ablation of right-sided APs is technically challenging, and often preformed curved long sheaths are used to increase catheter stability, particularly along the lateral right AVV annulus [29] (Fig. 163.8). In patients with Ebstein anomaly, localization of the right AVV annulus is particularly difficult given the inferior displacement of the valve. In these patients, an intracoronary

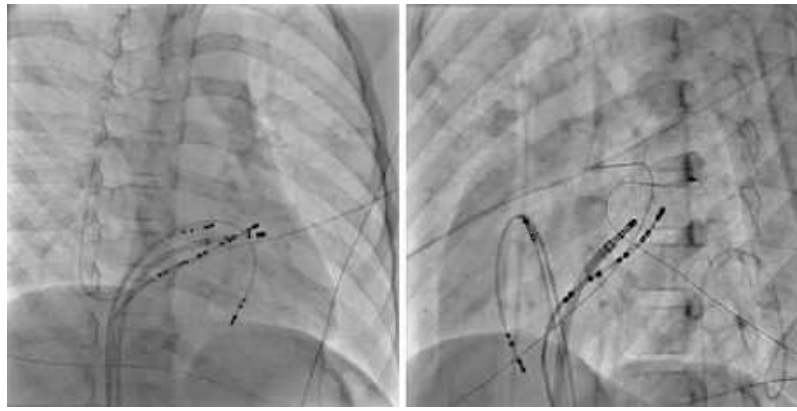

Fig. 163.9 A transseptal approach to a left lateral accessory pathway. In these right anterior oblique and left anterior oblique images (on the *left* and *right* sides respectively), a radiofrequency catheter is advanced into the left atrium through a transseptal sheath following a Brockenbrough transseptal puncture. In addition, there are catheters in the RV apex, His region, and the CS, outlining the left AV valve annulus

(right coronary artery) EP catheter can be placed to not only define the electrical right AV valve annulus but also to help in immediate localization of multiple accessory pathways [30]. Occasionally accessory pathways may be found within the coronary sinus [8, 29]. Often times this is associated with abnormalities of the CS, such as CS diverticula. CS angiography is helpful in delineating these abnormalities and provides a road map for mapping these diverticula [31].

Left-sided accessory pathways can be approached via two methods. The first is a transseptal approach, where access to the left atrium is through a preexisting or created atrial septal defect (Fig. 163.9). This allows for antegrade mapping of the left AV valve annnulus [29]. The other approach is the retrograde approach where access is obtained in the femoral artery and an ablation catheter is introduced retrograde into the left ventricle across the aortic valve allowing for retrograde mapping of the left AV valve annulus [32] (Fig. 163.10) and delivery of energy on either the ventricular or atrial aspect of the mitral annulus.

Mapping of multiple accessory pathways can be difficult. Typically, the presence of additional accessory pathways is only seen after ablation of the dominant accessory pathway mediating tachycardia. Ablation of all arrhythmia substrates should be undertaken at the time of procedure if possible.

Success rates are highest for left lateral accessory pathways with rates >97 %. In general, success rates for accessory pathway ablations are quite high, with rates >85 %. Septal pathways tend to be the most difficult owing to their proximity to the normal conduction system [33, 34] and the complexity of the posteroseptal space.

Wolff-Parkinson-White: The most common form of preexcitation is that seen in Wolff-Parkinson-White syndrome. These accessory pathways have the ability to conduct antegrade to the ventricle, causing the delta wave seen on surface ECG (Fig. 163.11). The HV interval is usually short, as ventricular activation does not depend on activation of the His bundle first. The varying degrees of preexcitation seen on the surface ECG are directly related to the amount of ventricular myocardium depolarized by the accessory pathway versus the AV node. The larger the bulk of myocardium "preexcited" by the accessory pathway, the more overt the delta wave on surface ECG. In general, in normal sinus rhythm, operators observe more preexcitation with right-sided accessory pathways than left-sided pathways, due to the proximity of the sinus node to the atrial insertion of right-sided pathways. The pattern of the surface delta wave

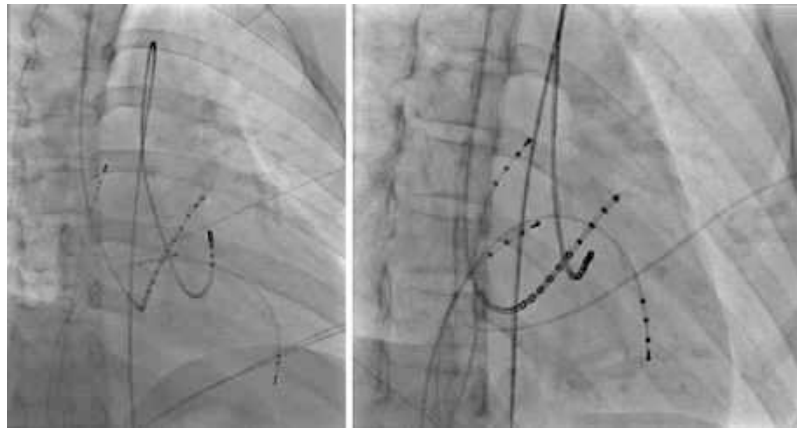

Fig. 163.10 A retrograde approach to a left lateral accessory pathway. In these right anterior oblique and left anterior oblique images (on the *left* and *right* sides respectively), a radiofrequency catheter is advanced from the right femoral artery retrograde through the aortic valve and into the left ventricle. It is then deflected underneath the left AV valve annulus to record annular signals. Also imaged are catheters in the RV apex, HRA, and coronary sinus

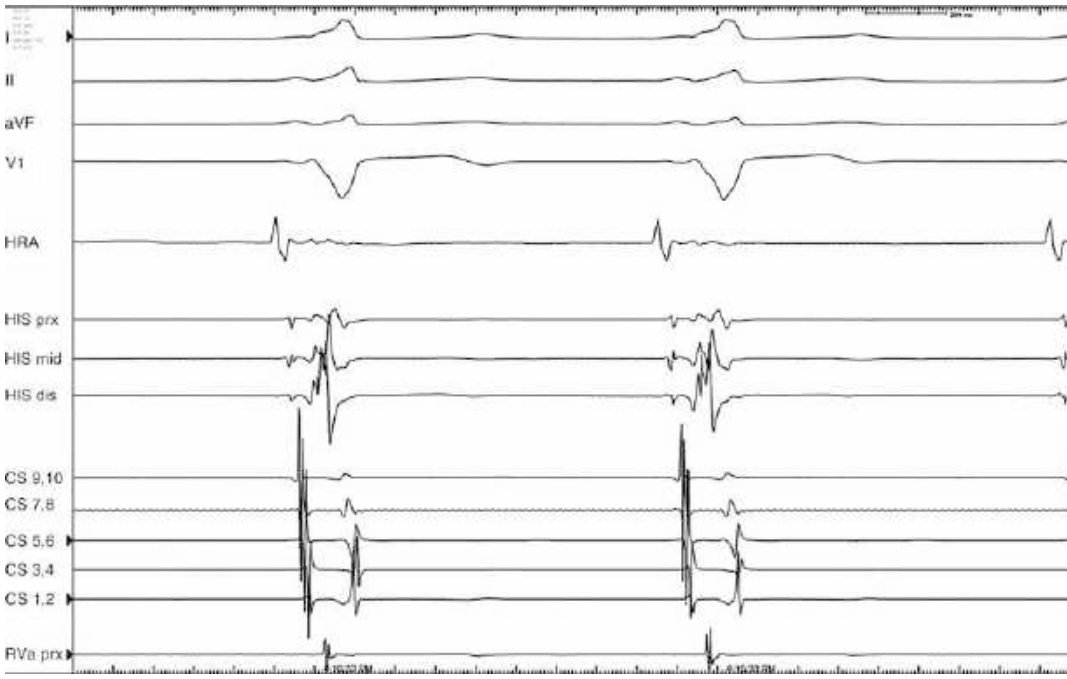

Fig. 163.11 Baseline intervals in a patient in preexcited sinus rhythm. Preexcitation is defined as having a very short (<30 ms) or negative HV interval. In this patient, the HV interval is 5 ms as recorded on the His catheter. In fact, the His electrogram is nearly fused with the ventricular electrogram

has been studied extensively such that several different algorithms have been developed for the localization of the accessory pathway based on surface ECG [35–37]. These algorithms have varying degrees of accuracy but are less accurate in patients with congenital heart disease or multiple accessory pathways [38].

Manifest accessory pathways may have retrograde conduction properties in addition to antegrade conduction properties, thus allowing them to sustain orthodromic tachycardias where the antegrade limb of the tachycardia is down the AV node and the retrograde limb from ventricle to atrium is up the accessory pathway. This is the most common form on tachycardia that these pathways support. However, manifest pathways have the capability of also supporting antidromic tachycardia, where the antegrade limb of the tachycardia is down the accessory pathway and the retrograde limb is up the AV node (or up a second accessory pathway). This results in a wide complex tachycardia. This type of tachycardia may be stimulated in the EP laboratory but is not often seen clinically in children. Preexcited atrial fibrillation results when the pathway has variable conduction of atrial fibrillation down to the ventricles, resulting in a wide complex irregular rhythm. If atrioventricular conduction is very rapid, this can result in ventricular fibrillation and sudden cardiac arrest. If a patient is diagnosed with preexcited atrial fibrillation, immediate EP study and ablation is warranted (Table 163.1).

Special Considerations with Wolff-Parkinson-White: Intermittent preexcitation is a phenomenon where there is preexcitation seen on some but not all QRS complexes in a given patient. There are data that support that pathways with intermittent preexcitation are less likely to be malignant [39]. Asymptomatic Wolff-Parkinson-White is another controversial entity in clinical practice. These patients present for an ECG for a variety of reasons and are incidentally found to have Wolff-Parkinson-White. Recent data suggests that these patients have good outcomes without ablative therapy [40]. The treatment for these groups varies widely by institution, though arguably the most reliable risk stratification is performed in the EP laboratory [41–43].

The decision about when to take patients with WPW to the EP laboratory remains controversial. Certainly, there are some patient populations where there is consensus. Patients who present with sudden cardiac arrest or syncope should be taken to the EP laboratory immediately for EPS and transcatheter ablation (Table 163.1). For patients presenting with tachycardia who weigh >15 kg, the benefits of EP studies and ablation outweigh the risks. The groups in question are those with asymptomatic WPW and intermittent preexcitation and those patients <15 kg. A recent consensus document published in 2012 [44] did support the use of invasive risk stratification in young asymptomatic patients who did not have clear noninvasive testing results for risk stratification.

During the EP study, it is important to define the properties of the accessory pathway in order to accurately risk stratify the patient. In general, an accessory pathway effective refractory periods of <250 ms [40] can be used to identify pathways as high risk. However, even more useful is the measurement of the shortest preexcited RR interval during atrial fibrillation, with shorter intervals (≤220–250 ms) correlating with higher risk [41–43] (Fig. 163.12). Mapping of these pathways can be performed in multiple ways. Mapping can be done in preexcited sinus rhythm looking for the earliest ventricular signal. In left-sided pathways, this may be readily apparent on the CS catheter (Fig. 163.13). Mapping can also be performed with ventricular pacing or in sustained orthodromic tachycardia looking for the earliest retrograde atrial signal. In cases of subtle preexcitation, pacing near the site of the accessory pathway will often result in more prominent preexcitation and may aid in mapping (Fig. 163.14).

Mahaim-Mediated Tachycardia: Mahaim fibers, most of which are atriofascicular fibers, are a kind of preexcitation syndrome. These accessory pathways typically originate in the anterolateral aspect of the right AV valve annulus [45] and insert on the right bundle branch [46]. These antegrade conducting fibers have conduction properties similar to the AV node (decrementally conducting, adenosine sensitive)

Fig. 163.12 Pacing the high right atrium (HRA) in a patient with Wolff-Parkinson-White. When pacing the HRA in this patient, the AP is at first capable of antegrade conduction (note the wide QRS on surface ECG with a short HV interval on intracardiac electrograms from the His location) but then blocks, and antegrade conduction continues down the AV node (the QRS normalizes as does the HV interval). It is important to define the cycle length at which these accessory pathways block as it helps to risk stratify the patients. This particular pathway blocks at 400 ms, categorizing it as a lower-risk pathway

and conduction results in preexcitation with a left bundle branch block pattern on surface ECG. The tachycardia is antidromic in nature with the antegrade limb of the tachycardia down the Mahaim accessory pathway with retrograde conduction up the AV node. Occasionally, retrograde conduction may be up another accessory pathway. When mapping these pathways, a Mahaim potential may be seen at the site of the pathway [47]. The Mahaim potential is a high-frequency signal similar to the His deflection, though not in the usual His location. It is best sought during right atrial pacing, at a rate adequate to bring out maximal preexcitation. At such a paced rate, the HV interval will be short or negative, while the Mahaim signal will occur well in advance of the surface QRS.

Ablation of these pathways can be performed anywhere along the length of the pathway. Typically, the most successful lesions are placed at the ventricular aspect of the AV valve annulus, usually at the site of Mahaim potential. During successful ablation, there is often Mahaim automaticity, recognized as acceleration with maximal preexcitation. Ablation of a Mahaim pathway may have a higher recurrence rate compared to more common accessory pathways.

Permanent Junctional Reciprocating Tachycardia (PJRT): PJRT is mediated by a slowly conducting, concealed (retrograde only) accessory pathway, resulting in a long RP tachycardia [48]. Given the incessant nature of the tachycardia, there is often associated ventricular dysfunction. These patients are good candidates for ablation therapy as it can be difficult to medically control the pathway. Classically, these pathways are found in the right posteroseptal region [49], though they have been reported to

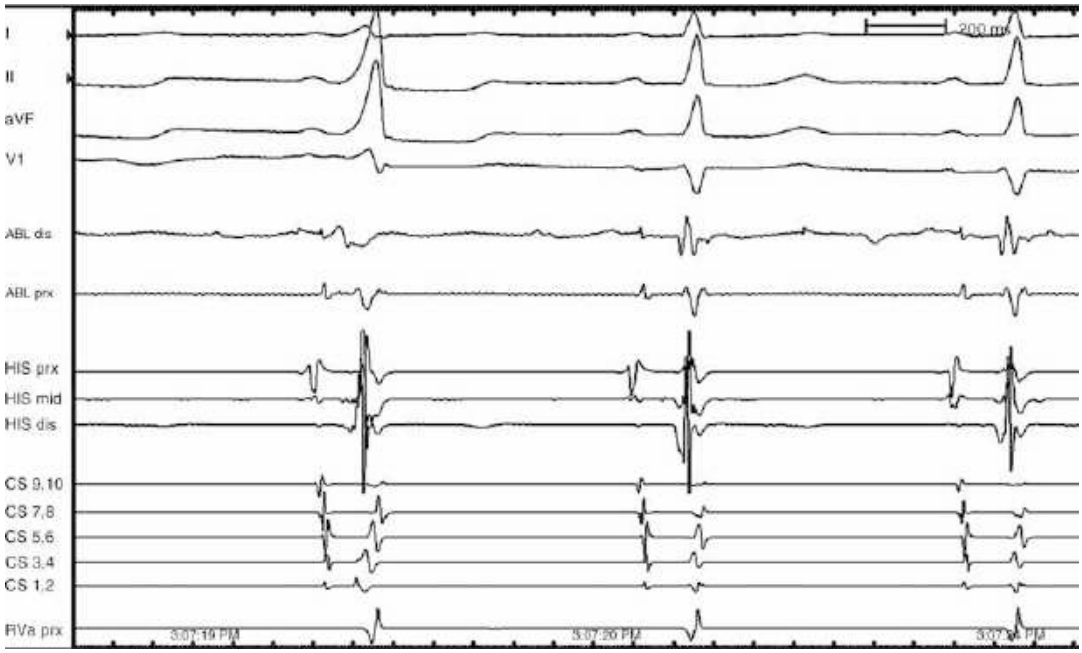

Fig. 163.13 Ablation of a left lateral manifest accessory pathway. During radiofrequency ablation, the first beat is preexcited with a short HV. On the coronary sinus catheter, CS 1, 2, the ventricular electrogram component is quite early, suggesting it is close to the site of the accessory pathway on the left lateral AV valve annulus. The subsequent beats are sinus rhythm with a narrow complex QRS and a normal HV interval. Also, on the CS catheter, the AV timings have all lengthened and now the earliest ventricular signal in on the His catheter. This coincides with ablation of the manifest accessory pathway

be localized all over the annulus, and may occasionally be found on the left side of the heart. These pathways present with an orthodromic tachycardia as the antegrade limb of the tachycardia proceeds down the AV node followed by retrograde conduction up the slow-conducting AP. This accounts for the overall slower rates of tachycardia as well as the incessant nature.

Mapping of a PJRT accessory pathway is typically done during tachycardia. Ablation of these pathways may be performed with radiofrequency or cryoablation. Given the majority are in the posteroseptal region, successful ablation may occur near the mouth of the CS (Fig. 163.15).

Ectopic Atrial Tachycardia (EAT): Ectopic atrial tachycardia is due to an automatic focus within the right or left atrium that overtakes the pacemaker function from the SA node. Common sites for EAT foci include the right atrial appendage (Fig. 163.16), along the cristae terminalis, and pulmonary veins [50]. These tachycardias can be intermittent or incessant. P-wave morphology during tachycardia can help elucidate the likely location [51–54].

The EP study for these patients can be very challenging, particularly in those patients with intermittent tachycardia. Thought should be given regarding the use of procedural sedation versus general anesthesia, as ectopy is often suppressed during general anesthesia. Intraprocedural maneuvers can be used to evoke ectopy including rapid atrial pacing and isoproterenol infusion. Mapping of the tachycardia is best achieved during sustained ectopic tachycardia with the ablation target being the earliest site of atrial activation. Successful ablation targets are typically at least 30 ms before the onset of the surface P wave. If tachycardia cannot be

Fig. 163.14 Pacing the high right atrium (HRA) brings out preexcitation. In this tracing, the HRA is being paced, and it brings out manifest accessory pathway conduction as evidenced by the wide QRS on the surface leads and the short (almost zero) HV interval on the His catheter. With the cessation of pacing toward the end of the tracing, there is a narrower QRS complex with a normal HV interval on the His catheter. Pacing near the site of a manifest accessory pathway will often bring out maximal preexcitation and may make mapping the accessory pathway easier

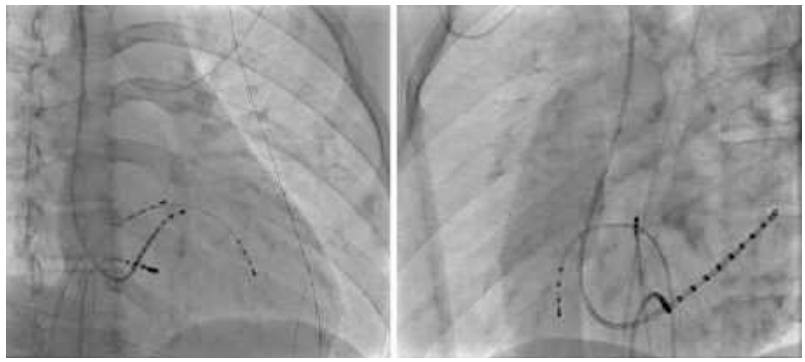

Fig. 163.15 Radiofrequency ablation of a permanent junctional reciprocating tachycardia pathway. In these right anterior and left anterior oblique images (*left* and *right* sides, respectively), the RF catheter is positioned in the right posteroseptal region. This is the most frequent site for PJRT pathway ablations

sustained, pace mapping may be employed to localize the ectopic focus [55]. This involves pacing from a certain location and then comparing the paced P wave to the spontaneously abnormal P wave. While not as reliable as mapping performed during sustained tachycardia, pace mapping can be used in patients with little or no ectopy during the procedure.

Ablation of right-sided foci is often undertaken via an antegrade approach with the ablation

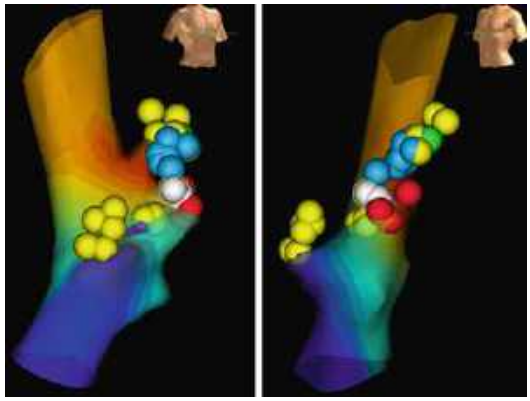

Fig. 163.16 Three-dimensional electroanatomic maps of the right atrium in a right anterior oblique and left anterior oblique projection (*left* and *right* sides, respectively). In this patient, an ectopic atrial tachycardia was mapped to the right atrial appendage. In this color scale, the area of red represents the area of earliest atrial activation, and blue represents the area of latest atrial activation. Both radiofrequency lesions (*yellow marks*) and cryoablation lesions (*blue marks*) were placed in the RAA at the earliest site of atrial activation (*red*)

catheter advanced from the femoral vein into the right atrium. For left-sided foci, traversing the atrial septum either through an ASD or via transseptal puncture is the preferred approach. Accessing pulmonary veins is particularly important in this entity, as there are sleeves of electrically active tissue that extend from the left atrium within the pulmonary veins that can act as foci for tachycardia.

Atrial Flutter: This type of tachycardia is only rarely seen in children with structurally normal hearts but can be seen in those with congenital heart disease, either repaired or unrepaired. Lesions that result in right atrial dilation are predisposed to atrial flutter prior to repair. Atrial flutter is a macro reentrant arrhythmia with the circuit contained within the atrium. Type I flutter propagates in counterclockwise direction around the tricuspid annulus (viewed from beneath) and results in negative P waves in leads II, III, and aVF. This is in contrast to type II flutter, which moves in a clockwise directionality around the tricuspid valve and results in positive P waves in II, III, and aVF [56].

Entrainment mapping is often used in atrial flutter mapping. This involves pacing during sustained tachycardia at a rate slightly faster than the tachycardia cycle length. The post-pacing interval is measured after the termination of pacing and is the time from the last paced beat to the local paced electrogram. If the value of the post-pacing interval minus the tachycardia cycle length is less than 20 or 30 ms, this suggests that the site of pacing is within the reentrant circuit.

The target for ablation of type I flutter is the cavo-tricuspid isthmus [56, 57]. This is often the critical area of slow conduction necessary for sustaining tachycardia as well as the narrowest segment of circuit and therefore the most amenable to ablation. A series of lesions creating a transmural line of block through the isthmus does not allow for further propagation of the flutter circuit (Fig. 163.1). Once the isthmus is blocked, it is important to establish that there is bidirectional block [58]. To demonstrate bidirectional block, pacing from the low right atrium and coronary sinus is performed while assessing atrial activation patterns. 20-pole catheters can be used in atrial flutter ablations as a way to assess for atrial activation. The catheter is typically positioned around the tricuspid valve annulus with the tip of the catheter extending into the mouth of the CS. Appropriate positioning of the catheter allows for prompt identification of bidirectional block. The loop needs to be placed inferior to the crista terminalis and close to the AV annulus. Sometimes, other lines of block are needed to terminate flutter circuits. Common sites include lines from the CS to the IVC or from the CS to the tricuspid valve [57].

Intra-atrial Reentrant Tachycardia (IART): IART is a macro reentrant tachycardia caused by surgical scars and areas of slow conduction. Here, the reentrant circuit propagates around a surgical scar, such as an incision or patch. Often, these patients have multiple circuits making transcatheter mapping and ablation very difficult. Entrainment mapping is frequently used in these complex ablations. Electroanatomic mapping has improved transcatheter ablation outcomes [58]. Creating electroanatomic maps during sustained tachycardia helps to clarify the tachycardia circuit and to identify the boundaries for an ablation line. The ablation lines need to be

anchored by electrically inactive tissue and as such may extend from scar to IVC or SVC, scar to scar, scar to patch, or scar to tricuspid valve (Fig. 163.1). The difficulty arises when tachycardia circuits seamlessly jump from one to another, which at times may be solely manifested by a change in the atrial cycle length. Greater than 40 % of patients undergoing IART ablation often have recurrence of tachycardia [59].

Ablation of Ventricular Tachycardias

Ventricular tachycardias (VT) can originate from the right ventricle, left ventricle, either outflow tract, pulmonary artery, or aortic cusps. Also, there are those VTs that have an epicardial focus, rather than endocardial focus, which require an epicardial approach (Fig. 163.17). The surface 12-lead ECG can help to localize the region of interest for a particular tachycardia [60, 61]. For example, left bundle branch block morphology with an inferior axis suggests a RVOT focus. A right bundle branch block morphology with an inferior axis is usually from a left anterior fascicular tachycardia, while a superior axis suggests a left posterior fascicular tachycardia.

Mapping of tachycardia may be difficult for several reasons. Sustained ventricular tachycardia may be hemodynamically compromising to the patient. It is possible to give antiarrhythmics to try to slow the tachycardia cycle length and minimize the hemodynamic compromise, though this may result in elimination of ectopy all together. On the other end of the spectrum, there may be little ectopy to map once anesthesia has been induced. Attention to level of anesthesia is important, and the use of dexmedetomidine should be avoided, as it has an antiarrhythmic effect. A continuous infusion of isoproterenol or the administration of a dose of phenylephrine may help in unmasking ectopy. Activation mapping of sustained VT with localization of the earliest ventricular activation is the preferred method for mapping hemodynamically stable VT [62]. Typically, sites of successful ablation demonstrate ventricular activation at least 30 ms prior to onset of surface QRS. During ablation lesions, there may be increased automaticity seen during successful lesions (Fig. 163.18). Pace mapping is often performed while mapping VT. This is done by placing the ablation catheter in the area of interest and pacing from the distal tip of the ablation catheter [63]. The resultant QRS

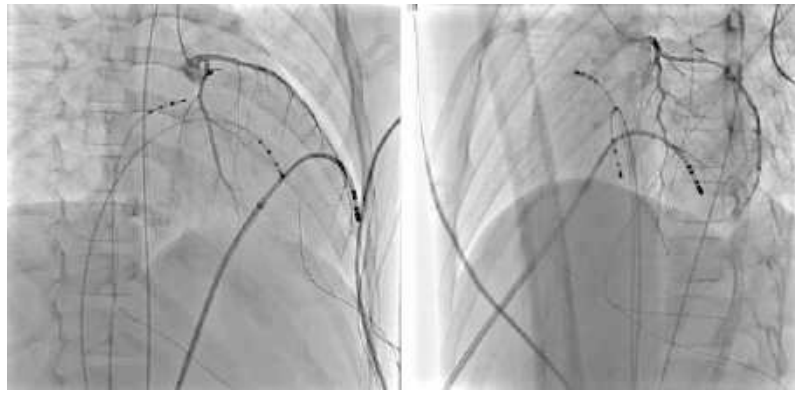

Fig. 163.17 Epicardial ablation of a left ventricular tachycardia. In these fluoroscopic images (*right* anterior oblique and *left* anterior oblique, respectively), there is an irrigated-tip radiofrequency ablation catheter that has been introduced into the pericardial space via subxiphoid puncture through a long sheath. The ablation catheter is placed at the site of interest, and a left coronary angiogram is obtained to define the proximity of the target ablation site to the coronary artery tributaries. In this case, the ablation target was distant from coronary arteries and ablation could be safely performed. There are two intracardiac catheters in the high right atrium and the right ventricle for pacing

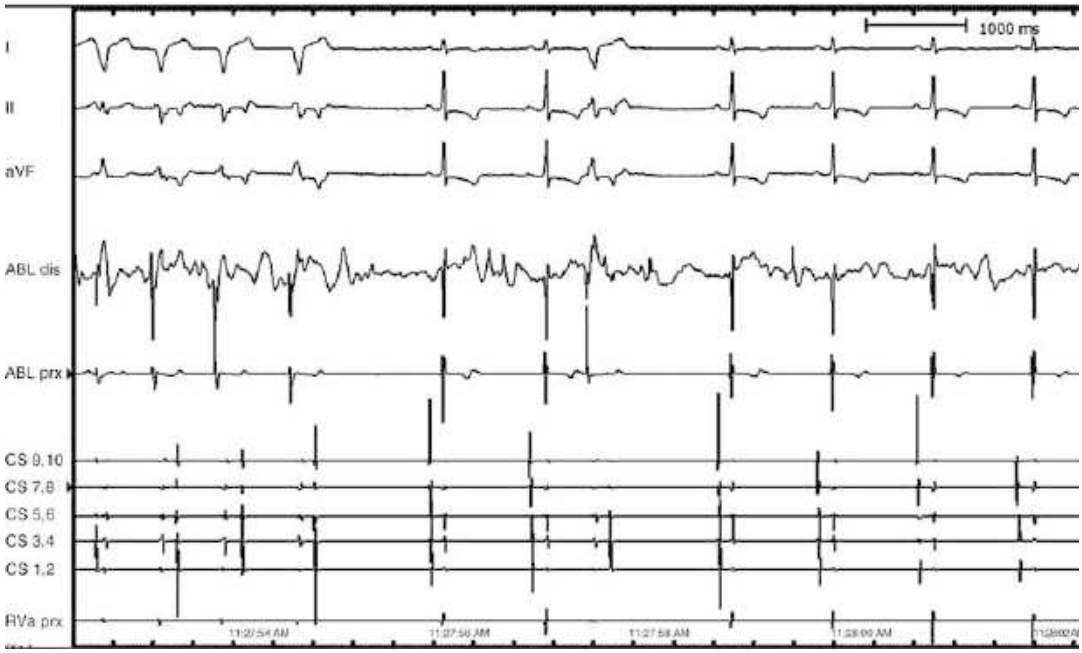

Fig. 163.18 Radiofrequency ablation of a right ventricular tachycardia. During this radiofrequency ablation, there is slowing of the ventricular tachycardia cycle length followed by resumption of sinus rhythm. There is a single PVC noted following two sinus beats

complex is then compared to spontaneous ectopy. Electroanatomic maps can also be helpful in the mapping of VT. Noncontact balloon array catheters may be used to map VT [64]. This involves a multipolar balloon catheter which is inflated in the region of interest, such as the right ventricular outflow tract. This allows for high-resolution mapping of even a single abnormal beat of tachycardia. The utility of this technology is limited as it is a 9 French catheter and not suitable for small children.

Patients with repaired congenital heart disease present a unique population of patients for which there may be substrate-specific targets. Patients who have undergone repair of tetralogy of Fallot have been well studied [65]. Four discrete isthmuses that most frequently support VT have been identified. They include the superior aspect of the tricuspid valve to the right ventricular scar, pulmonary valve annulus and RV scar, between the VSD patch and the tricuspid valve, and between the VSD patch and pulmonary valve. As such, when undertaking an ablation in a patient with repaired TOF, it is important to keep these critical isthmuses in mind.

Ablation Energy Sources

Radiofrequency Energy: Radiofrequency (RF) energy is the most common energy source used in pediatric ablations. RF works by conductive heating of the tissue located adjacent to the tip of the RF catheter, coupled with convective heat loss to the surrounding blood pool and coronary vessels. The balance between the two results in discrete lesion formation. Successful lesions are formed at temperatures >49° C and last for up to 60 s. Longer tip ablation catheters and irrigated-tip catheters ("cool-tip" catheters) circumvent issues of low power by creating deeper, higher power lesions without charring due to impedance rise [66].

Outcomes of RF ablations have been studied in pediatrics [33] and shown to have high success rates (96 %). The complication rate was low with AV block rates of 1.2 %. There have been rare reported cases of damage to coronary arteries, cardiac valves, and proarrhythmia in the literature [67–69]; in the current era of ablations, these complications are rare.

Fig. 163.19 Cryoablation of supraventricular tachycardia (SVT). This cryolesion is applied during a sustained accessory pathway-mediated SVT. There is slowing of the tachycardia cycle length followed by cessation of SVT. Importantly, the SVT blocks in the retrograde limb (accessory pathway block) as demonstrated by termination in the ventricle with no retrograde conduction up the accessory pathway. The mode of termination is important to determine. If the tachycardia terminates in the antegrade limb (AV node block), the lesion should be immediately terminated as heart block will likely ensue

Cryoablation: Cryoablation works by the formation of ice crystals both intracellular and extracellular space which result in cell rupture and death. As the temperature drops below 0° C, an ice ball forms on the tip of the catheter and the catheter tip adheres to the adjacent tissue. Reversible cryolesions can be created at temperatures around −40° C (called cryomapping), and permanent lesions are created during a 4–6 min lesion at −80° C (Fig. 163.19). This results in well-demarcated hemispherical lesions that are free of surface thrombus [70].

Other Tests Performed in the EP Laboratory

There are other tests that are often performed in conjunction with an EP study. Patients with congenital heart disease or cardiomyopathy may undergo hemodynamic assessment or angiography. Angiography may be particularly useful in postsurgical patients in providing a road map for ablation targets.

Drug infusions are commonly performed in the EP laboratory. As mentioned above, an infusion of isoproterenol is often used for the induction of both ventricular and supraventricular tachycardias. Other provocative drug challenges are also performed in the EP laboratory. Provocative testing using epinephrine has also been shown to be useful for revealing the phenotype in patients with long QT syndrome [71]. There are genotype-specific variations in the response to adrenaline which a recent pediatric study showed is less clear than compared to adult LQTS patients but nonetheless remains a useful potential diagnostic tool. Drugs that block the sodium current (I_{Na}), particularly ajmaline (in Europe) and procainamide (in the USA), can

unmask the typical Brugada syndrome ECG pattern [72]. Provocative testing with intravenous adrenaline has been used to unmask the phenotype in catecholaminergic polymorphic ventricular tachycardia (CPVT). In a Canadian study in 2005, drug testing in a cohort of patients with unexplained resuscitated cardiac arrest revealed a diagnosis of CPVT in 50 % of patients [73].

Voltage maps can also be created using the 3-dimensional non-fluoroscopic mapping sources. Typically these are 3-dimensional ventricular maps which are created to visualize areas of low endocardial electrogram voltages which correlate with areas of diseased myocardium. This is particularly useful in patients with arrhythmogenic right ventricular dysplasia [74].

Alternatives to Invasive Electrophysiology Studies

Transesophageal Studies and Pacing: The esophagus runs just posterior to the left atrium. The proximity of these structures allows for us to place electrodes in the esophagus to both record and pace left atrium when needed (Fig. 163.20). Adequate positioning of the esophageal catheter is important as locations too high in the esophagus or too deep (in the stomach) are unlikely to produce useable signals or reliable pacing. Positions with the largest amplitude atrial electrogram are preferred. Detailed tables for depth of esophageal placement given length of patient have been published [75]. Ventricular pacing while possible is not reliable using this technique.

Transesophageal electrograms are useful in rhythm analysis. Not surprisingly, transesophageal pacing requires higher output than leads in direct contact with myocardium. Atrial overdrive pacing can be used to pace-terminate reentrant rhythms such as AVRT and atrial flutter.

Temporary Wires: Patients often return from the operating room with temporary pacing wires. By convention, the wires to the right of the sternum are atrial wires and those to the left are ventricular wires. These leads can be connected to perform limited noninvasive EPS in the postoperative setting.

Implanted Devices: Patients with implanted devices can also undergo limited EPS using the transvenous or epicardial pacing leads. Using the device-specific programmer, electrograms from the leads can be displayed and various pacing protocols applied.

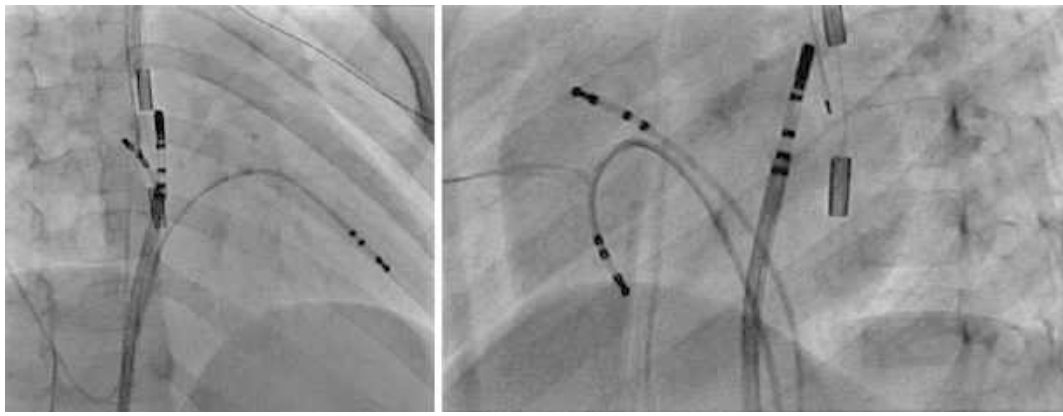

Fig. 163.20 Cryomapping of an ectopic left atrial tachycardia. These fluoroscopic images, in right anterior and left anterior oblique views, demonstrate a cryocatheter advanced into the left atrium via transseptal puncture through a long sheath. The area of earliest atrial activation mapped to the posterior wall, just anterior to the esophagus. A transesophageal pacing catheter is positioned in the esophagus to pace and record left atrial activation. Note that the location of interest is on the posterior wall with the ablation catheter pointed directly toward the transesophageal pacing catheter

Conclusion

Progression in the understanding and development of pediatric electrophysiology studies over the past two decades has been substantial. Currently, transcatheter ablations are routinely and successfully performed in pediatric patients with most types of arrhythmias.

Surgical Therapy of Arrhythmias and Conductive Disorders

164

Constantine Mavroudis, Barbara J. Deal, and Carl L. Backer

Abstract

Arrhythmia surgery has evolved from an isolated procedure for refractory arrhythmia to incorporation into the repair of concurrent hemodynamic problems. Recognition of the increasing incidence of arrhythmias following repair of congenital heart disease and the need for reoperations to improve hemodynamics has led to a combined electrical-hemodynamic approach to congenital heart surgery. Knowledge of the specific arrhythmia mechanisms, anatomic variants posed by congenital lesions, and the basics of arrhythmia surgical techniques available for therapy will lead to routine incorporation of this strategy into surgery for congenital heart disease. Improvements in device technology have led to more widespread application of pacing and device therapies at younger ages. The next phase of arrhythmia surgery will be the incorporation of prophylactic antiarrhythmia strategies into the initial repairs of complex congenital heart disease.

Introduction

Highly successful arrhythmia surgery techniques to treat medically refractory tachycardia developed in the era prior to the availability of transcatheter ablation, most often in the setting of a structurally normal heart. Sealy and Cobb and colleagues developed and refined endocardial resection techniques of the atrioventricular (AV) groove to treat Wolff-Parkinson-White (WPW) syndrome beginning in 1968 [1, 2], and Guiraudon published the closed-heart epicardial surgical approach for the same substrate in 1972 [3]. Success rates over 95 % were achieved, with mortality in uncomplicated cases less than 1 % [4, 5]. Cryosurgery for accessory connections was reported by Gallagher et al. in 1977 [6], and discrete cryoablation lesions were applied to treat AV nodal reentry tachycardia (AVNRT) in 1982 by Holman and Cox et al [7]. After extensive studies of atrial fibrillation in the dog model by Boineau and Cox and colleagues in St. Louis, left atrial isolation techniques and subsequently the Maze procedures were developed for atrial fibrillation [8, 9]. The majority of the early arrhythmia surgeries were performed in adult populations, with fewer than 10 % undergoing concurrent surgical repairs, most often for coronary artery bypass or mitral valve repairs. During the same period, several endocardial resection techniques were developed to treat ischemic ventricular tachycardia, particularly in the setting of left ventricular aneurysms [1, 10–12].

Arrhythmia surgery for younger patients was reported in 1985 by Holmes and Danielson et al. from Mayo Clinic, operating on 27 young patients with a mean age of 15 years with accessory connections [13]. Crawford and colleagues reported a series of younger patients with mean age under 3 years undergoing surgery for WPW, without associated repairs, achieving 95 % cure [14]. Ott and Garson and colleagues from Houston extended arrhythmia surgery beyond accessory connections to include atrial and ventricular focal tachycardia with a large series in 1985, with limited success for ventricular tachycardia [15]. It was not until 1991 to 1992 that reports of concurrent repair of congenital heart disease with accessory connection surgery appeared, initially involving AV valve repairs in patients with Ebstein anomaly and later extending to more complex repairs. In these early series, operative mortality of about 9 % owing to ventricular failure was reported in young patients undergoing concurrent congenital heart defect repairs [16]. The widespread application of the transvenous catheter ablation approach for arrhythmias beginning in the early 1990s largely eliminated an operative approach as the sole indication for arrhythmia surgery for accessory connections, atrial reentry, or AVNRT [1]. However, surgical approaches for atrial fibrillation continued to evolve and were extended to adult patients undergoing valve repairs, coronary artery bypass, or atrial septal defect (ASD) closure.

During this period of development of arrhythmia surgery techniques, successful surgical repair of complex congenital heart defects advanced dramatically, resulting in large numbers of patients surviving into young adulthood [1]. Sudden death resulting from ventricular arrhythmias, heart block, and the later appearance of atrial arrhythmias as causes of significant morbidity and mortality were recognized as profound sequelae in patients with each successful form of repaired complex congenital heart lesions [1]. Thus, repaired tetralogy of Fallot was associated with a 7–10 % risk of sudden death [17–19] and more recently an incidence of atrial tachycardia approaching 35 % [20–22], resulting in heart

failure and need for hospitalization. Atrial repairs of transposition of the great arteries were associated with the development of atrial tachycardia in 30–50 % of patients [23, 24] and contributed to the risk of sudden death. The Fontan repair of single ventricle physiology is associated with more than 60 % of patients developing atrial arrhythmias during long-term follow-up [25]. The high incidence of associated arrhythmias contributed to alterations in surgical techniques for both initial repairs (arterial switch for transposition, lateral tunnel, or extracardiac connections for single ventricle) and timing of reinterventions (pulmonary valve insertion for tetralogy of Fallot). Successful treatment of existing arrhythmias in patients with repaired complex lesions and the prevention of the development of arrhythmias in lesions known to be at high risk for this complication pose a new challenge for the successful management of congenital heart disease.

The recognition of arrhythmia development as an electromechanical problem led to fresh attempts to integrate arrhythmia surgery with the repair of congenital heart disease [1, 26]. Beginning in 1994, Mavroudis et al. began extending arrhythmia surgery to patients with refractory atrial arrhythmias associated with prior Fontan repairs of single ventricle [1], in addition to conversion of the Fontan circuit and repair of associated valve or pulmonary artery lesions [27–29]. In this most complex group of patients with single ventricle physiology, operative mortality of less than 5 % can be achieved [29]. Right atrial reentry tachycardia can be essentially eliminated with modifications of the right atrial Maze procedure, and atrial fibrillation is successfully treated with the addition of the left atrial Cox-Maze III. Recurrence of organized atrial tachycardia occurs in approximately 15 % of patients [1, 29] following the left atrial Maze procedure. The current authors' clinical experience has shown that concomitant arrhythmia surgery can be incorporated into the repair of all types of congenital heart operations [1], although atrial arrhythmia surgery continues to be more successful than operative interventions to eliminate ventricular tachycardia. The next challenge for congenital heart disease repair is to introduce prophylactic measures to reduce the likelihood of developing arrhythmias over time.

Arrhythmia surgery when performed in patients with complex congenital heart disease is highly dependent on the anatomic substrate, the types of arrhythmias, and the conditions associated with the reparative operations. Irregular AV connections, discordant ventricle to great vessel arrangements, juxtaposed atrial appendages, pulmonary and systemic venous anomalies, and the anatomic variants of heterotaxy syndrome challenge the intended arrhythmia operation. In addition, owing to previous surgical scars or electrically inactive tissue, intracardiac hemodynamic jet lesions, atrial dilatation, myocardial tumors, and ventricular dysfunction are all important etiologic factors that contribute to arrhythmia development [1, 30]. Complex anatomy complicates the tenets of traditional arrhythmia surgery techniques [31]. For example, double-outlet right ventricle with subaortic conus has discontinuity between the aortic annulus and the mitral annulus where an accessory connection can exist. Heterotaxy syndrome with functionally single ventricle often is associated with absence of the coronary sinus, presence of a left superior vena cava, separate atrial entry of the hepatic veins, and/or juxtaposition of the atrial appendages, as well as two AV nodes, all of which challenge the intended arrhythmia operation. Congenitally corrected transposition of the great arteries often is associated with accessory connections and Ebstein anomaly of the systemic tricuspid valve [31]. This chapter reviews the operative techniques of arrhythmia surgery in patients with and without congenital heart disease, with specific attention to anatomic variants and electrophysiologic possibilities faced by the congenital heart surgeon.

Surgery for Supraventricular Tachycardias

Effective arrhythmia ablative surgery requires a thorough understanding of the tachycardia mechanism and specific anatomic variants [1].

Table 164.1 Tachycardia mechanism-specific arrhythmia surgery

Tachycardia mechanism	Congenital heart disease	Arrhythmia surgery
Macro-reentry atrial tachycardia	Single ventricle, s/p Fontan	RA or LA Maze procedure
	TOF, s/p repair	
	ASD	
	TAPVR	
	AVSD, VSD	
Focal atrial tachycardia	Single ventricle, s/p repair	EP guided resection and/or ablation
	Unrepaired CHD	
	Structurally normal heart	
AV nodal reentry tachycardia	TGA, s/p Mustard/Senning	Isthmus ablation
	Heterotaxy syndrome	
	AV septal defect	
Accessory connection mediated tachycardia	Ebstein anomaly	EP guided ablation
	Congenitally corrected TGA	Dissection of atrioventricular groove, endocardial or epicardial
	ASD	
	Hypertrophic cardiomyopathy	
Atrial fibrillation	Single ventricle, s/p repair	LA Cox-Maze III plus modified RA Maze
	TGA, s/p Mustard/ Senning	
	Left heart obstructive lesions	
	Mitral valve disease	
	ASD	
	Ebstein anomaly	
	Hypertrophic cardiomyopathy	
VT, reentrant	s/p repair TOF, DORV, VSD, unrepaired VSD	Hemodynamic repair, EP guided resection/ cryoablation , +/− AICD
Torsades de pointes	Ion channelopathy, structurally normal heart	AICD
		Left cervical sympathectomy

Arrhythmia mechanisms, the more common congenital heart lesions associated with these tachycardias, and the corresponding surgical techniques are summarized in Table 164.1 [1, 31]. Often, the surgeon is confronted with

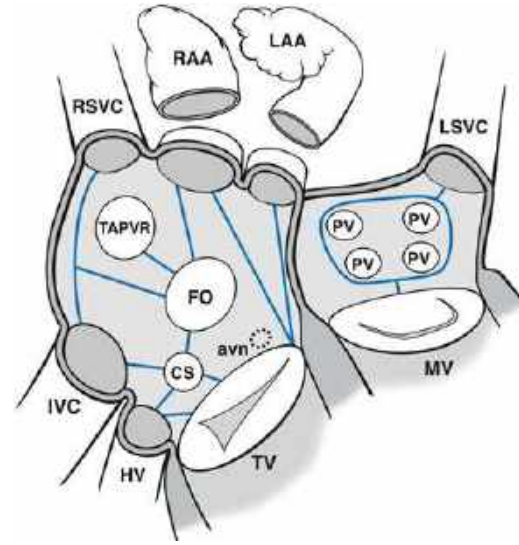

Fig. 164.1 Schematic representation of the possible lines of ablation to treat macro-reentrant atrial tachycardia in the presence of various atrial anomalies associated with complex congenital heart disease. Abbreviations: *avn* atrioventricular node, *CS* coronary sinus, *FO* foramen ovale, *HV* hepatic vein, *IVC* inferior vena cava, *LAA* left atrial appendage, *LSVC* left superior vena cava, *MV* mitral valve, *PV* pulmonary valve, *RAA* right atrial appendage, *RSVC* right superior vena cava, *TAPVR* total anomalous pulmonary venous return, *TV* tricuspid valve (Reproduced with permission from [32])

anomalies that defy the accumulation of data and prospective studies to prove that a certain set of lesions will treat the arrhythmia. Figure 164.1 [32] depicts many of the central systemic and pulmonary venous anomalies, as well as the possibilities of juxtaposed atrial appendages. The lines represent potential ablative lesions that are applied for right-sided and left-sided Maze procedures [31, 32]. There are many anatomic variants; however, the tenets of ablative therapy are constant. The idea is to transform areas of *slow conduction* into areas of *no conduction* using ablative techniques. The areas of *slow conduction* usually exist between closely related anatomic barriers such as the orifices of the superior vena cava, inferior vena cava, and coronary sinus as well as the right AV valve, when present, and the patent foramen ovale. The depicted lines of block in Fig. 164.1 are meant to be guidelines for therapy; the preoperative electrophysiologic study will also help guide

the therapeutic procedure based on the established sets of published lesions [31, 32]: right-sided Maze for atrial reentry tachycardia; biatrial Maze for atrial fibrillation. Variations include biatrial Maze if previous suture lines extend into the left atrium or if an anomalous left superior vena cava is present.

Macro-reentrant atrial tachycardia or atrial reentry tachycardia occurs most frequently in the right atrium. Less frequently, reentrant circuits may be found in the left atrium owing to the presence of prior suture lines or atrial dilatation related to anomalous pulmonary venous drainage or left-sided AV valve lesions. Anatomic barriers contributing to slowed conduction necessary for reentrant right atrial tachycardia include the superior vena cava; the inferior vena cava; the tricuspid valve; the coronary sinus; the atrial appendage; the fossa ovalis or ASD; and the right atrial isthmus between the inferior vena cava, the tricuspid valve, and the coronary sinus (Fig. 164.2) [32]. The region of this right atrial isthmus is critical in as many as one third of right atrial reentrant arrhythmias [1]. Ablative lesions, either cryoablation or radiofrequency, are delivered to convert the areas of *slow conduction* into areas of *no conduction* and interrupt the zone of slowed conduction that supports the reentrant circuit [1, 33]. Figure 164.3 [31, 34] shows the ablative lesions, which are performed in anatomically normal hearts with identifiable intracardiac structures. Anatomic barriers in congenital heart disease may be misplaced, absent, or anomalous. These circumstances require creative measures as well as application of the basic tenets of ablative surgery. For instance, tricuspid atresia, by necessity, precludes lesions placed to this annulus; the lesions therefore are placed as noted in Fig. 164.4a [35]. In the same light, Fig. 164.4b, c show the lesions that are placed for functionally single right ventricle/mitral atresia and functionally single ventricle with unbalanced AV canal, respectively [31, 35]. Table 164.2 [1, 31] shows the types of various atrial arrhythmias that were encountered in patients who underwent arrhythmia surgery from 1987 to 2010 at Children's Memorial Hospital in Chicago and the Cleveland Clinic Children's Hospital.

Focal or automatic atrial tachycardia is characterized by a localized area of electrical impulse generation (Fig. 164.5) [32, 33], which may be caused by discrete micro-reentry or by an automatic focus. The operative arrhythmia procedure requires resection or cryoablation of the pathologic atrial tissue [31]. More extensive areas of focal tachycardia can be managed by anatomic

electrical isolation. Excellent outcomes have been reported with cryoablation and excision of automatic foci [36, 37]. Multiple ectopic foci responsible for arrhythmia recurrence stimulated the application of more extensive techniques such as pulmonary vein isolation, left atrial isolation,

right atrial isolation, and His bundle cryoablation with pacemaker insertion [31]. Localized automatic atrial foci are often found in the right atrial appendage, which is amenable to curative resection. The current authors have applied these principles to seven patients (two infants and five older children; Fig. 164.6) [34]. Arrhythmia surgery was performed during concurrent repair of structural heart disease in five patients (Norwood procedure, ASD or ventricular septal defect [VSD] closure). Patients with no associated anatomic lesions undergoing arrhythmia surgery are rare, and surgical ablation was performed owing to incessant or refractory tachycardia and ventricular dysfunction [31].

Accessory connection-mediated tachycardia can be associated with either manifest accessory connection function during sinus rhythm (delta wave on electrocardiogram or WPW) or concealed accessory connections, with only retrograde conduction possible. Orthodromic reciprocating tachycardia [1] is most commonly encountered; the circuit is formed by antegrade conduction through the AV node to ventricular myocardium, and retrograde conduction via the accessory connection at the AV groove back to atrial tissue (Fig. 164.7) [32]. As accessory connections can be treated using transcatheter ablation, this approach is recommended before planned surgical repair. As patients with Ebstein anomaly have a high incidence of accessory connections, the patients seen by the authors undergo preoperative electrophysiologic study to assess and treat associated accessory connections when possible, even in the absence of clinical supraventricular tachycardia. The strategy of this staged therapy is to save cross-clamp time during the reparative operation. However, owing to technical issues related to multiple accessory connections and the abnormal AV groove, some patients are optimally treated with an operative arrhythmia approach. For instance, patients who have a right to left shunt are at risk for an embolic stroke if the transcatheter approach is employed. Once an operative procedure is planned for anatomic and electrophysiologic indications, the operative team must consider all variables that are associated with the eventual repair. The question arises, whether the ablation procedure should precede the anatomic repair, or should the anatomic repair and the ablation procedure be performed concomitantly in the operating room. The considerations include, but are not limited to, patients with a right to left shunt, projected cross-clamp time for the planned procedures, facility and experience of the operating team using ablative procedures for accessory connections, number and location of accessory connections, and

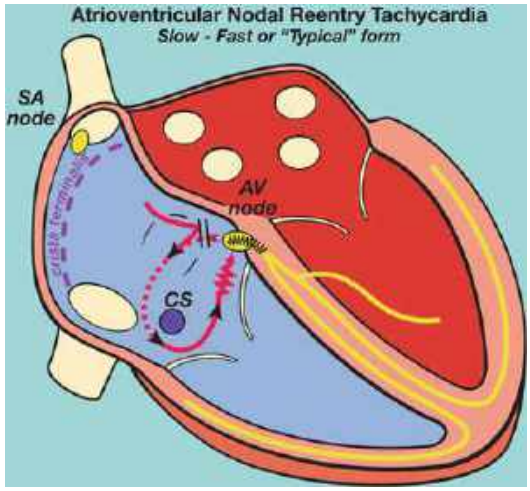

Fig. 164.8 Cartoon of nodal reentry tachycardia. Abbreviations: *SA* Sinoatrial, *CS* Coronary Sinus, *AV* Atrioventricular (Reproduced with permission from [32])

ventricular dysfunction. It cannot be overemphasized that collaboration between the electrophysiologist and surgeon will determine the best approach for each patient based on these considerations.

Atrioventricular nodal reentry tachycardia results from a reentrant circuit that is situated between the AV node, coronary sinus, and the inferior vena cava with unidirectional block in one direction and slowed conduction in the other (Fig. 164.8) [32]. Interruption of the reentrant circuit can be accomplished by cryoablation lesions being placed at the inferior isthmus location [1]. Clinical experience with transcatheter ablation has shown that an anatomic approach to slow pathway modification effectively treats AVNRT [31]. The pathway modification is performed surgically by placing ablative lesions from the posterior inferior rim of the coronary sinus os to the inferior vena cava [1]. An additional lesion is placed from the right-sided AV valve, when present, to the posterior os of the coronary sinus. These lesions will be modified in those patients with congenital heart defects where there is no right-sided AV valve (e.g., tricuspid atresia) or absence of the coronary sinus (e.g., heterotaxy syndrome). The operative procedure, when necessary, mirrors the transcatheter approach. Transcatheter ablation before reoperation for residual defects in patients with congenital heart disease is highly effective and typically recommended. Exceptions to this practice occur in patients with prior Senning or Mustard procedures who are undergoing anatomic baffle revision. In order to avoid the retrograde catheter approach to the pulmonary venous atrium, this group of clinicians prefers to perform intraoperative AVNRT ablation directly [31, 38].

Atrial fibrillation is defined by rapid oscillations (fibrillatory waves), which originate principally from the left atrium or central pulmonary vein orifices [1, 31]. Predisposing factors for atrial fibrillation development in congenital heart disease include left atrial dilatation caused by AV valve regurgitation or stenosis, or prior surgical suture lines in the left atrium. In the adult population with unrepaired ASDs, atrial flutter and fibrillation occur in 14–22 % [1, 31, 39–41] of cases. When ASD closure is performed after age 40, atrial fibrillation occurs or recurs in a high percentage of patients [1, 31, 39–41] if arrhythmia ablation is not accomplished [1, 31, 42, 43]. Because atrial fibrillation is a left atrial arrhythmia, right-sided Maze procedures are ineffective in preventing recurrence. In the current authors' practice, older patients are thoroughly evaluated for arrhythmias to determine if a concomitant ablative procedure should be performed. When atrial fibrillation is present, the Cox-Maze III procedure is very effective (over 90 % success rate); AV conduction is preserved and atrial contractility is generally unaffected [1, 31, 42–44], especially in patients with mitral valve procedures, ASD closure [1, 31, 42, 43], or coronary revascularization [1, 31, 44]. The current authors have applied these principles to patients in association with complex congenital heart operations such as the Fontan conversion, ASD closure, and mitral valve procedures in infants, children, and young adults (Fig. 164.9) [29, 31, 45]. Patients have been free from atrial fibrillation recurrence, although up to 20 % may develop a later organized atrial reentry tachycardia [32]. Transvenous catheter techniques for atrial fibrillation in adults with normal hearts have shown

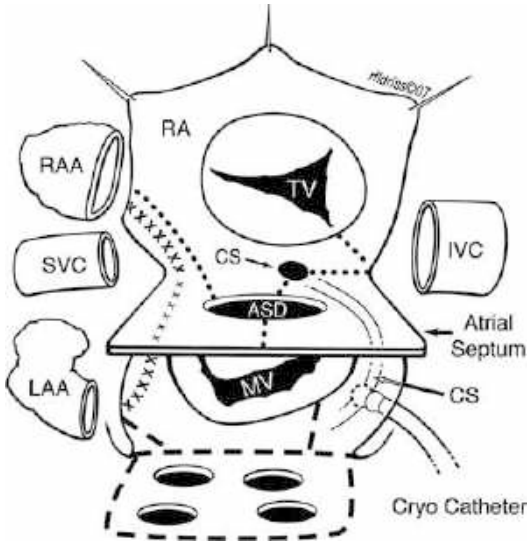

Fig. 164.9 Diagrammatic representation of the modified right-sided Maze procedure for right atrial reentry tachycardia (*dotted lines*) and the left atrial Cox-Maze procedure (*dashed lines*) for atrial fibrillation and left atrial reentry tachycardia. Abbreviations: *ASD* atrial septal defect, *CS* coronary sinus, *IVC* inferior vena cava, *LAA* left atrial appendage, *MV* mitral valve, *RA* right atrium, *RAA* right atrial appendage, *SVC* superior vena cava, *TV* tricuspid valve (Reproduced with permission from [29])

progressive improvement, with a low incidence of serious complications such as pulmonary vein stenosis and esophageal perforation. This approach may not be applicable for patients with congenital heart disease for many reasons, including a different etiologic substrate related to significant anatomic variants, excessive atrial wall thickness, and catheter access challenges.

Surgery for Ventricular Tachycardia

Idiopathic ventricular tachycardia in older patients usually originates from the right ventricular outflow tract or the septal surface of the left ventricle, and transcatheter ablation techniques have success rates of 70–80 % [1, 31, 46, 47]. In rare cases, ventricular tachycardia originates from the ventricular epicardial surface. Surgical intervention for ventricular tachycardia in the structurally normal heart is exceedingly uncommon, and was successfully performed for an

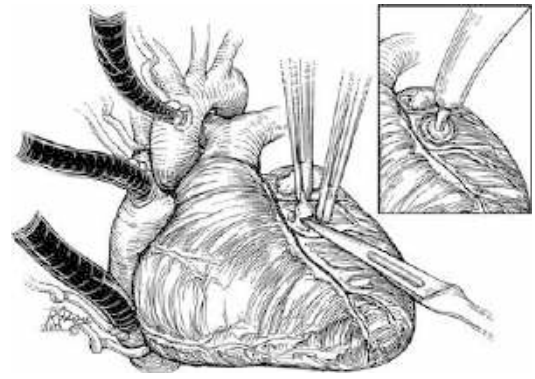

Fig. 164.10 A fat pad dissection in the area of the left anterior descending coronary artery between the first and second diagonal branch coronary arteries which responded to the area of ventricular activation. (Inset) Cryoablation probe on the area of dissection to ensure arrhythmia focus ablation (Reproduced with permission from [34])

epicardial focus of ventricular tachycardia arising from the left ventricular outflow tract in a young boy with recurrent exertional syncope, and failing multiple attempts at transcatheter ablation. (Fig. 164.10) [1, 31, 34, 48]. Preoperative and intraoperative electrophysiologic mapping in association with precise map-guided surgical ablation is essential if successful arrhythmia management is to be achieved in these complicated cases [1, 31].

Arrhythmia management in patients with structural heart disease, either operated or nonoperated, is particularly challenging [1, 31]. Patients with tetralogy of Fallot or double-outlet right ventricle are prone to develop late sustained ventricular tachycardia in approximately 5–8 % of cases [1, 26, 31, 49, 50] and late sudden death in 2–6 % [1, 17, 31]. Associated risk factors are older age at initial repair, residual right ventricular hypertension, right ventricular outflow tract patch or aneurysm, significant pulmonary regurgitation, prolonged QRS duration over 180 milliseconds on resting electrocardiogram, abnormal signal-averaged electrocardiogram, and longer duration of follow-up [1, 17–19, 26, 31, 49, 50]. In approximately 15–30 % of patients, late reoperations will become necessary for residual defects, pulmonary valve regurgitation, or severe right ventricular outflow tract problems [1, 31, 51].

In the present era, electrophysiologic studies are recommended for individuals with palpitations, syncope or cardiac arrest, sustained wide-QRS tachycardia, or QRS prolongation greater than 180 milliseconds. In most cases, transvenous catheter ablation is performed before structural heart disease is corrected. In cases where catheter ablation fails or if not elected in favor of combined surgical therapy, cryoablation of the ventricular tachycardia focus and endocardial resection can be combined with the congenital heart repair. Origins of ventricular arrhythmia reentry have been mapped to the right ventriculotomy site, the right ventricular outflow tract patch, and superior perimeter of the VSD patch [1, 31, 52]. The goal is to free the patient of antiarrhythmic drugs or an implanted defibrillator. These objectives are not always achieved because successful surgical ablation in these situations occurs in approximately 50 % and 70 % [1, 31, 52, 53].

In rare circumstances, individuals may develop sustained ventricular tachycardia owing to congenital heart disease without a previous congenital heart operation [1, 31]. The present authors have experience in two young individuals, each with a perimembranous VSD and recurrent ventricular tachycardia. Both were symptomatic; one had syncope, and the other experienced dizziness. The origin of both tachycardias was mapped to the anterior septal surface of the right ventricular outflow tract, opposite to the jet caused by the VSD. Catheter ablation was not attempted preoperatively because VSD closure was indicated. The plan was to treat both problems at the time of the operation. During cavitary exploration, large white plaque lesions were identified in the ventricle opposite the presumed VSD jet. These were carefully resected and cryoablated. There was no inducible ventricular tachycardia during the postoperative study in either patient [1, 31].

Torsades de pointes owing to long QT syndrome or catecholaminergic polymorphic ventricular tachycardia (CPVT) occurs in structurally normal hearts owing to ion channel disease, which is usually familial [1, 31, 54]. Ion channelopathies are typically due to sodium or potassium channel disorders (long QT syndrome). Disorders of ryanodine receptors (RYR2) and calsequestrin (CASQ2) have been identified as causes of CPVT. Medical treatment with beta-blocking medications is the current first-line therapy, with implantable automatic internal cardiac defibrillators (AICD) used for primary or secondary prevention of cardiac arrest. Left cardiac sympathetic denervation (LCSD) by surgical ablation of the left thoracic sympathetic chain using thoracoscopic techniques has been effective in reducing the catecholamine surge caused by sympathetic nervous system activation [1, 31, 55]. This surgical technique can be considered for symptomatic patients with intractable ventricular tachycardia episodes and therefore limit the number of AICD shocks [1, 31].

Pacemaker and Device Therapy

Antibradycardia Pacing

The American College of Cardiology/American Heart Association Task Force on Practice Guidelines has published guidelines and principles of management for implantation of cardiac pacemakers and antiarrhythmia devices [1, 56–58]. In North America, the most common indication for pacemaker insertion in young patients is sinus node dysfunction following surgical repair of congenital heart disease. Other indications include individuals with postoperative AV block, congenital AV block, and isolated sick sinus syndrome in the absence of structural heart disease [1, 59]. The guidelines noted that complete or advanced second-degree surgical AV block is associated with an important risk of sudden death. In addition, AV block lasting longer than 7–10 days postoperatively is a class I indication for pacemaker implantation [1, 56]. Current guidelines for antibradycardia pacing were developed as a measure to prevent sudden death secondary to asystole or ventricular arrhythmias in the setting of bradycardia and as treatment for symptoms clearly related to bradycardia. Among patients with repaired congenital heart disease and atrial arrhythmias, there is evidence that avoidance of atrial bradycardia will

decrease the frequency of episodes of tachycardia [60]. In patients with univentricular physiology, the presence of junctional rhythm elevates atrial pressure and is deleterious to this circulation. Newer guidelines for optimization of atrial rates to improve long-term hemodynamic status are lacking. Prophylactically, epicardial atrial leads can be placed at the time of initial Fontan repair to limit the need for resternotomy when antibradycardia pacing for chronotropic incompetence is needed.

In the pediatric age group, the two most important time periods for device implantation occur in infancy and later childhood. Infants under 12 months of age may require pacemaker implantation for congenital AV block, while older children most often undergo pacemaker implantation owing to postoperative AV block or sinus node dysfunction associated with complex anatomy [1]. Despite improvements in technique and pacing systems, device implantation in infants is associated with mortality as high as 30 % within the first year [61, 62]. As many as 10 % of patients with congenital AV block and chronic right ventricular apex pacing may develop left ventricular dysfunction based on abnormal sequence of contractility [63]. Device implantation for congenital AV block is occurring at younger ages as a result of technological improvements in generator size and medical indications brought about by the recognition of the untoward events associated with prolonged bradycardia [1, 63, 64]. Optimal pacing strategies for infants include the mode and route of pacing. Because of newer transvenous leads, 4 French and smaller, the possibility exists for transvenous implantation in infancy as transvenous leads tend to outlast epicardial leads. With the introduction of steroid-eluting epicardial leads, the difference in lead longevity and function between the two approaches has narrowed [1, 65–68]. There are advantages and disadvantages with both endocardial and epicardial leads. Transvenous lead placement in small children can be attended by lead dislodgement and hemothorax, generator erosion, concerns for venous occlusion in the long term, tricuspid regurgitation, and the substantial risks associated with subsequent lead extraction [1, 65–67]. Epicardial lead and pulse generator placement have the potential for generator migration, wound complications, and the important risk of lead fracture with activity.

The current practice in most institutions is to implant epicardial systems in infants and small children weighing less than 15 kg [1, 58] and in children undergoing surgery for structural heart disease. These systems are maintained as long as the leads continue to function. The transvenous method is employed principally for children weighing over 35 kg, although this weight requirement is undergoing a change in some institutions implanting transvenous systems at lower patient weights. Dual chamber pacing can be performed in the majority of infants using a subxiphoid approach [1, 61]. At the present time, there are no data to support the superiority of dual chamber pacing over rate responsive ventricular pacing in the small child in the absence of coexisting heart disease. However, in children with complex heart disease and heart block, dual chamber pacing affords a considerable advantage in increased cardiac output owing to AV synchrony [1, 61].

Transvenous lead access may be challenging in certain patients with congenital heart disease, particularly single ventricle patients following Fontan type repairs, transposition of the great arteries following atrial repairs, and congenitally corrected transposition of the great arteries [69].

In patients with right to left intracardiac shunts, chronic anticoagulation is required to counterbalance the risk of systemic embolization. Alternatively, an epicardial approach [1] can be used. While transvenous pacing can be established in patients with atriopulmonary Fontan connections, circular and sluggish intracavitary blood flow in the presence of a dilated atrium induces clot formation even with optimal anticoagulation, thereby increasing the risk of a cerebrovascular accident. In addition, systemic venous baffle constriction is a common complication in individuals with transposition of the great arteries who had atrial baffle operations. Stent placement within the baffle may become necessary to facilitate pacing lead placement.

For most patients, venous angiograms or advanced imaging to clarify anatomy and access are recommended before attempting lead placement.

Antitachycardia Pacing. The ability to automatically detect and terminate episodes of atrial tachycardia is desirable in patients with repaired congenital heart disease who require pacing. Nevertheless, current generators have significant drawbacks which include (1) specialized software to terminate tachycardia with 1:1 AV conduction and (2) therapeutic limitations during peak upper heart rate conditions [1, 56, 57]. Antitachycardia therapy programming is preceded by electrophysiologic testing to determine tachycardia detection accuracy, pulse generator protocols for efficacy and safety, and response to catecholamine challenge. Because young children can experience sinus tachycardia at rates up to 200 bpm, atrial tachycardia detection and therapeutic protocols must reflect these potential conditions. Because of this, beta-blocker therapy is usually recommended to moderate the peak heart rate [1].

Lead Extraction: Lead extraction techniques have been developed to manage the increasing number of anticipated complications associated with transvenous leads in growing children. Lead failure, industrial recall, and the emergence of newer generations of pacing devices have resulted in increasing requirements for lead extraction [1, 69, 70]. Laser or radiofrequency energy is currently used for lead extraction. Success and complication rates of 90 % and 6 %, respectively, have been reported [1, 70]. Rapid initiation of cardiopulmonary bypass may be needed should vessel laceration/cardiac perforation occur. Performance of lead extractions should be performed ideally in selected centers with demonstrated expertise in this procedure.

Cardiac Resynchronization Therapy: Cardiac resynchronization therapy has been highly effective in restoring mechanical synchrony, improving heart failure symptoms, and prolonging life expectancy in adult patients with dilated or ischemic cardiomyopathy, ventricular dilatation, and QRS prolongation [1, 56, 57]. Indications for resynchronization therapy in adult patients are left ventricular ejection fraction $\leq$ 35 %, QRS duration $\geq$ 120 milliseconds, and symptoms of heart failure (New York Heart Association class III to IV) despite optimal medical management [1, 71, 72]. Technical considerations for biventricular or multisite pacing center around strategic electrical and special distances between ventricular pacing leads [1, 56]. Congenital heart disease populations, which might benefit from biventricular pacing, include patients with ventricular dysfunction secondary to chronic right ventricular pacing for congenital heart block, patients with dilated cardiomyopathy, and patients with systemic right ventricles or complex ventricular anatomy failing systemic right ventricles. Dramatic improvement in ventricular function has been reported in some cases, avoiding or delaying the need for cardiac transplantation [73].

Automatic Implantable Defibrillators. The efficacy of implantable defibrillators in reducing the incidence of sudden cardiac death owing to ventricular tachycardia and fibrillation is well established [74, 75]. National data from the defibrillator implantation registry (pediatric and congenital heart disease patients) show that the majority of patients receive implants for (1) complications after repaired congenital heart disease (2) primary electrophysiologic disturbances, and (3) the various forms of cardiomyopathy [1, 76–79]. Implantation for secondary prevention is now more common than for primary prevention, a change since the earliest application of defibrillators, with appropriate shocks occurring in 32 % of patients receiving AICD therapy for secondary prevention as opposed to 18 % of patients who received AICD therapy for primary prevention [1, 76]. Defibrillator implantation therapy has also been successfully employed as an effective bridge to cardiac transplantation in those individuals with severe ventricular dysfunction and risk for sudden cardiac death [1].

Compared with adults, pediatric patients experience a higher rate of inappropriate shocks, 21 % in a recent multicenter series [76]. To avoid delivering shocks for nonsustained arrhythmias, devices are noncommitted and perform a second look after device charging; shock delivery using

a biphasic rather than monophasic waveform allows lower defibrillation thresholds.

For more widespread application in small patients or those with congenital heart disease, there is an ongoing need for improvements in lead technology and smaller implantable generators.

Automatic internal cardiac defibrillators size and mediastinal geometric requirements have challenged the implantation techniques in infants and children. Epicardial AICD placement has undergone many surgical modifications ranging from a large subcutaneous ventricular patch to current strategies involving a coil in the transverse pericardial sinus or in the subcutaneous tissue of the left chest wall [1]. Atrial and ventricular epicardial leads are applied as usual and connected to the AICD. The generator is implanted within the right rectus muscle and serves as an excellent vector across the heart for defibrillation [1]. Mavroudis et al. have employed this method in a 3-month-old infant with recurrent torsades de pointes secondary to long QT syndrome. The child was observed in the hospital, monitoring weight gain, until reaching 6 kg at which time device implantation was performed [1]. Newer device technology applicable to patients with congenital heart disease is needed to reduce the increasing risk of sudden death in this population.

Prophylactic Arrhythmia Surgery

Traditionally, modifications in surgical techniques have been developed to limit the potential for arrhythmogenicity, by avoiding the region of the sinus node, approaches to the AV node, and the crista terminalis. With the availability of follow-up studies on large numbers of adult congenital heart disease patients, largely from registries in Canada and The Netherlands, the ever-increasing incidence of late arrhythmias is well documented [80–83]. In patients who reach the age of 18 years without arrhythmia, more than 50 % will develop significant arrhythmias in the next five decades more than doubling their risk of stroke and heart failure [80]. The lifetime risk of developing atrial arrhythmias is significantly greater in patients with isolated right-sided lesions as compared with patients with isolated left heart lesions [81]. The burden of repeat hospitalizations and developing heart failure related to arrhythmias in adult congenital heart disease is steadily increasing. As the incidence of reoperation tracks with the risk of developing arrhythmias, each reoperation in the patient with congenital heart disease becomes an opportunity to not only improve hemodynamics but to attempt to alter the course of arrhythmia development.

These findings mandate that efforts to minimize the development of late arrhythmias are needed and may require creative measures. In patients at increased risk for developing bradycardia, either owing to sinus node dysfunction or AV block, anticipatory epicardial lead placement can be considered. The advantage of this approach is avoidance of tranvenous lead placement in young patients, those at increased risk for worsening AV valve regurgitation by the presence of a transvenous lead, or those with limited venous access. Patients with congenitally corrected transposition of the great arteries are at significant risk for developing complete AV block; at the time of VSD closure or redo surgeries, consideration can be given for epicardial dual chamber lead placement. Patients with single ventricle physiology undergoing Fontan type repairs may benefit from maintenance of atrial rhythm, avoiding both the deleterious hemodynamic effects of junctional rhythm, and perhaps limiting the development of atrial arrhythmias. Patients with bundle branch block or ventricular dyssynchrony may have epicardial leads placed with optimization of lead placement for ventricular resynchronization. Finally, patients at significantly increased risk of developing atrial tachycardia may be considered for either right or biatrial Maze procedures. Patients over the age of 40 years undergoing surgical ASD closure may be considered for biatrial Maze procedures [41–43, 84], and patients with right-sided pathology undergoing reoperations may benefit from right atrial Maze procedures [53]. Clearly these interventions ideally would be standardized and outcomes tracked in large registries over many

years in order to assess their efficacy; these interventions are no less necessary than studies for timeliness of valve replacements or conduit changes.

Abstract

Airway management of an infant, child, or adolescent may quickly change a stable, routine clinical scenario to a life-threatening loss of the airway. In view of the importance of a potentially emergent situation, it is imperative for clinicians to have a sound understanding of the causes, clinical presentations, and management of upper airway anomalies. Our chapter will focus on this content.

Introduction

Airway management of an infant, child, or adolescent may quickly change a stable, routine clinical scenario to a life-threatening loss of the airway. In view of the importance of a potentially emergent situation, it is imperative for clinicians to have a sound understanding of the causes, clinical presentations, and management of upper airway anomalies. Our chapter will focus on this content. The information presented is complemented by related information in the sections of this textbook that are dedicated to cardiovascular anesthesia and cardiopulmonary interactions.

Age-Related Anatomic Differences in the Larynx

Although the three portions of the larynx (supraglottis, glottis, and subglottis) are the same in children and adults, there are a number of age-related differences that play a role in determining appropriate management.

Laryngeal Size

The infant larynx is approximately one third the size of the adult larynx; however, it is proportionally larger than the adult larynx relative to the rest of the tracheobronchial tree. The infant vocal fold also differs in length from the adult vocal fold; it is approximately 7–8 mm long, whereas the adult vocal fold is 14–23 mm long. In the infant, half of the length of the true vocal fold is composed of the vocal process of the arytenoid. In the adult, the vocal process occupies only one fourth to one third of the total length of the true vocal fold. The subglottis is the narrowest part of the airway because of the complete ring structure of the cricoid cartilage. In the infant, the subglottis is approximately 4.5–7 mm in diameter. A child with a subglottic diameter of 4.0 mm or less has subglottic stenosis (SGS) [1].

Laryngeal Location

The position of the larynx in relation to other structures of the neck is different in infants and adults. In the infant, the superior border of the larynx is located as high as the first cervical vertebra, with the cricoid cartilage positioned at approximately the level of the fourth cervical vertebra. This results in the hyoid overriding the superior larynx in an infant, with the thyroid notch usually being impalpable as a consequence. Because of the superior positioning of the larynx, the epiglottis approximates the dorsal surface of the soft palate. This contributes to the obligate nasal breathing seen in the first months of life. As the child grows into adulthood, the larynx gradually descends and the cricoid cartilage eventually rests at the level of the sixth cervical vertebra. The infant epiglottis is the structure that demonstrates the most dramatic change in configuration. At birth, the epiglottis, which is shaped like the Greek letter omega (Ω), is narrower and softer than the epiglottis in older children and adults. It has a less stable base, and there is a more acute angle between the epiglottis and glottis, allowing the epiglottis to fall into the laryngeal inlet. As the child grows, cartilaginous support of the epiglottis becomes more rigid, and the angle of the thyroid cartilage changes from 110° to 120° to an angle of 90° in the adolescent male. In the adult female, this angulation remains more obtuse, as in childhood. Because cartilage, muscle, and submucosal tissues are more pliable and less fibrous in the infant than in the adult and because the airway is so narrow at the subglottis, any process that produces edema can cause significant airway obstruction. Circumferential mucosal edema of 1 mm within the larynx of an infant narrows the subglottic space by more than 60 % [2]. Within the fixed ring of the cricoid cartilage, edema will cause a marked diminution in potential airflow. This diminution is best explained by Poiseuille's Law, which relates resistance to air flow (Q) across an area of narrowing to the inverse of the radius of the lumen to the fourth power ($Q \approx 1/r^4$). Thus, 1 mm of edema in an infant results in a 75 % decrease in luminal diameter and a 16-fold

increase in resistance through the airway. This same degree of narrowing in the adult reduces the diameter of the airway by only 30 % and doubles airway resistance.

Upper Airway Anomalies

Upper airway anomalies occur at various anatomic levels, and their presentation and management are influenced by both the level at which obstruction occurs and the severity of the obstruction. The most frequently encountered airway anomalies within an anatomic framework, progressing from proximal at the nares to distal at the carina, will be discussed.

Congenital Nasal Pyriform Aperture Stenosis

Congenital nasal pyriform aperture stenosis (CNPAS) is an uncommon form of nasal airway obstruction that typically presents during the first few months of life when infants are obligate nasal breathers. Bony overgrowth of the medial aspect of the nasal process of the maxilla is the characteristic feature of this disorder. Because the pyriform aperture is the narrowest section of the bony nasal skeleton, even minor anatomic abnormalities in the cross-sectional area of the aperture significantly affect airflow by increasing nasal airway resistance. CNPAS is generally associated with a single central upper incisor; however (Fig. 165.1a), it occasionally occurs as an isolated anomaly. Although rare, an association with holoprosencephaly has been described [3].

This disorder presents in the neonatal period with a spectrum of symptoms resulting from nasal obstruction. These symptoms are similar to those seen in patients with bilateral choanal atresia and include cyanosis, apnea, feeding difficulties, and labored breathing. Because of this similarity, evaluation for suspected choanal atresia is sometimes performed, yielding negative results. Clinicians may thus be falsely reassured that there is no significant nasal obstruction.

Diagnosis is made on anterior rhinoscopy, which reveals an anterior bony obstruction of the nasal vestibule. It is confirmed by computed tomography (CT), which may also confirm the presence of a single central upper incisor (Fig. 165.1b).

Patients are managed on the basis of the severity of their symptoms. Those with mild symptoms can be managed expectantly, and this may be all that is necessary until growth results in increased nasal airway size. In patients with moderate disease, overnight polysomnography (PSG) may be useful in quantifying the degree of obstruction that occurs during sleep (e.g., moderate to severe obstructive sleep apnea). This provides the surgeon with information required in determining if the patient should undergo surgical management.

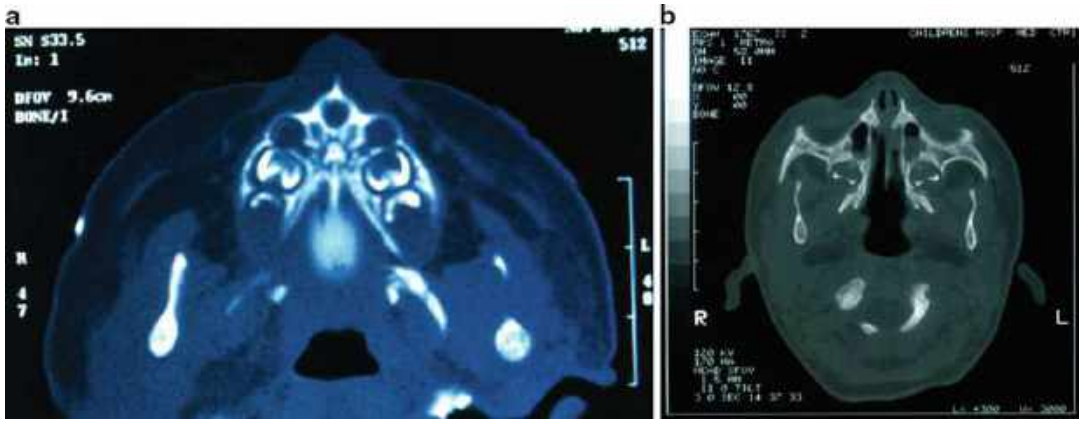

Fig. 165.1 (**a**) CT scan of a child with pyriform aperture stenosis, demonstrating a central incisor; (**b**) CT scan showing pyriform aperture stenosis

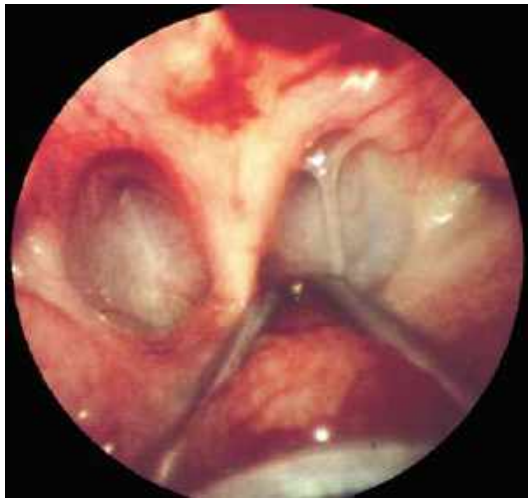

Fig. 165.2 Endoscopic transoral view of choanae, demonstrating bilateral choanal atresia

In a small number of cases, nasal balloon dilation and/or re-stenting are all that are needed to achieve a good surgical outcome. In severe cases, surgical enlargement is almost always indicated. Enlargement is best performed via a sublabial approach, exposing the pyriform aperture and using a diamond burr to remove the excessive bone of the nasal process of the maxillary crest. Nasal stents are usually placed for 2–4 weeks. Recurrence of symptoms is rare, and most children who undergo surgical correction will not require revision surgery.

Choanal Atresia

Choanal atresia is thought to be a consequence of the persistence of the nasal buccal membrane. The obstruction may be membranous, bony, or a combination of both, with the latter being the most commonly seen. The atresia may be unilateral or bilateral (Fig. 165.2) and although the relative incidence of these two presentations is unclear, the ratio of unilateral to bilateral cases is likely 1:1. Whether unilateral or bilateral, choanal atresia may be associated with a number of other congenital anomalies. The best recognized association is with CHARGE syndrome (*c*oloboma, *h*eart defects, *a*tresia, *r*etardation of growth and development, *g*enitourinary disorders, and *e*ar abnormalities) [4].

Because neonates are obligate nasal breathers during the first 6 weeks of life, regardless of whether their nasal obstruction is caused by CNPAS, a tumor, or choanal atresia, they will present with apnea during quiet respiration; however, this is not observed when they are upset, as they mouth breathe when crying. Once the infant settles down, apnea again becomes a risk. Complete obstruction of the posterior nasal passage by choanal atresia does not allow the normal drainage of nasal secretions into the nasopharynx. These secretions must thus passively drain anteriorly and are characteristically copious and tenacious.

These authors recommend evaluating nasal passages with a thin (2.2 mm) flexible nasal endoscope. The initial management of a child with bilateral choanal atresia is best accomplished by placement of an oral airway or intubation. This will stabilize the child until CT scanning can be performed and, if appropriate, until genetic evaluations can be undertaken. Radiological evaluation with bone/window high-resolution, close-cut CT scanning is recommended (Fig. 165.3). Removing all nasal secretions with a soft suction catheter immediately before the scan greatly enhances the quality of the study. Characteristic findings are of a thin atretic plate at the posterior choana that is commonly both bony and membranous. Associated prominence of the bony margins of the choana with either bony overgrowth of the vomer in the midline or medialization of the lateral nasal walls is also frequently seen.

The recommended treatment is early surgical repair, [5] unless there is a contraindication such as extreme prematurity or multiple congenital anomalies. In this setting, a temporizing tracheostomy may be the most appropriate treatment. Surgical approaches may be either transpalatal or transnasal. The latter approach is preferable in most children and involves endoscopic removal of the atretic plate using urethral dilators, backbiting forceps, drills, powered microdebrider cutters, or a combination of these instruments. Removal of the posterior aspect of the vomer to

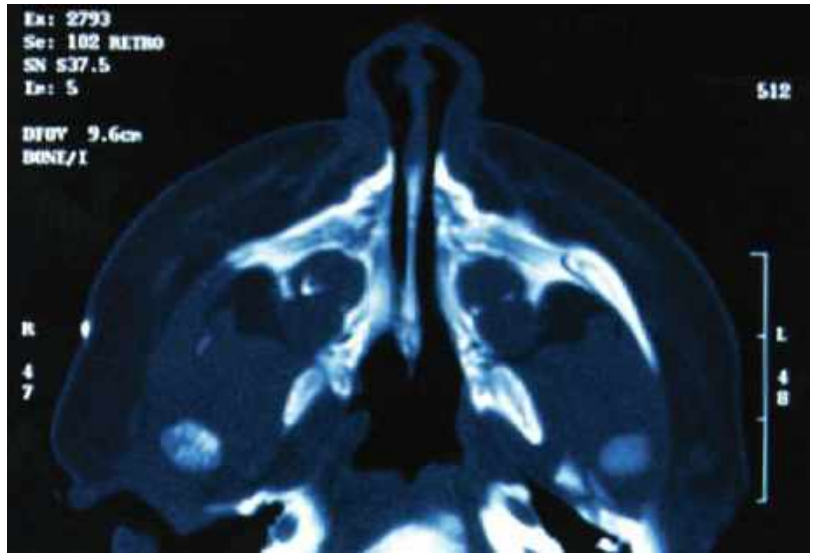

Fig. 165.3 CT scan showing right choanal atresia

form a common cavity at the level of the atretic plate significantly increases the success of the surgery. Transnasal stents are often placed for several weeks postoperatively until the repair has stabilized. Current trends are for shorter periods of stenting or no stenting at all, though both options carry the risk of the development of secondary choanal stenosis. Adjuvant therapy, such as the topical application of mitomycin C, is sometimes useful in recalcitrant cases. In most children, application of topical Ciprodex can decrease postoperative granulation and restenosis.

Patients with unilateral disease are generally not diagnosed until later in childhood when they present with unilateral rhinorrhea and nasal obstruction. CT evaluation is indicated and transnasal repair of the unilateral atresia is usually performed after 2 years of age. Children with choanal atresia associated with CHARGE syndrome are unlike other patients with choanal atresia in two respects. Firstly, the degree of their nasal obstruction at birth is more severe, and as the level of obstruction is not restricted to the choana, repair of the choanal atresia may not prevent the need for tracheostomy placement. Other frequent levels of obstruction include pharyngomalacia, hypopharyngeal collapse, laryngomalacia, and SGS. If these levels of obstruction are recognized initially, placement of a tracheostomy tube and late repair of the choanal atresia may be the most appropriate management strategies. Secondly, the results of surgical repair, whether unilateral or bilateral, early or late, are not as successful as in other patients. This is partially attributed to abnormalities in the skull base seen in patients with CHARGE syndrome. In some cases, using the lateral sinus cavities (e.g., posterior ethmoids, sphenoid) to help enlarge the surgical airway may improve success rates.

Retrognathia and Glossoptosis

Retrognathia is associated with a variety of abnormalities, including Pierre Robin sequence (short mandible cleft palate), Treacher Collins syndrome (mandibulofacial dysostosis), and Stickler syndrome. In children with moderate to severe retrognathia, a cleft of the secondary palate is common. The severity of retrognathia is not always a reliable indicator of the severity of obstruction or of problems that may occur with intubation. Although obstructing retrognathia is generally seen during the neonatal period, problems may develop during childhood or much later in life. Such problems are often triggered by incidental surgical procedures or with the insidious gradual onset of severe sleep apnea.

Initial management in neonates involves prone positioning and the use of high-flow nasal cannula; occasionally, a nasal trumpet is useful. Continuous positive airway pressure (CPAP) is often unsuccessful, as the mask frequently tends to exacerbate the retrognathia. Because infants have difficulty feeding, placement of a nasogastric tube is often required. For children with persistent airway compromise, intubation is desirable though challenging.

In infants who suffer with significant obstructive symptoms or feeding difficulties, surgical intervention is warranted. Tracheotomy placement is standard procedure, and in most children, catch-up growth of the mandible will allow for decannulation within 1–2 years. If catch-up growth does not occur by 1 year of age, it is prudent to consider mandibular distraction [6]. In select cases, this procedure may be an effective alternative to placing a tracheotomy [7].

Because of the association between retrognathia and tracheobronchomalacia, some children continue to be affected by symptoms of obstruction after tracheotomy placement. Performing flexible bronchoscopy through the tracheotomy tube is diagnostic and management with CPAP, bi-level positive airway pressure (BiPAP), or ventilation is sometimes necessary. In infants with isolated tracheomalacia, replacing the tracheotomy tube with a longer tube that lies close to carina may be all that is required. A surgical alternative for the management of severe intrathoracic tracheomalacia is aortopexy.

Laryngomalacia

Laryngomalacia is the most frequently encountered cause of stridor in neonates [8]. Symptoms are generally observed at birth or within the first several days of life. Stridor is generally mild, but typically exacerbates with feeding, crying, and lying in a supine position. In 50 % of patients, stridor worsens during the first 6 months of life. A subset of children with severe laryngomalacia (5 %) may present with a spectrum of symptoms, including apnea, cyanosis, severe retractions, and failure to thrive. Also, many patients suffer from clinically significant gastroesophageal reflux (GER). In extremely severe cases, cor pulmonale is seen. Although laryngomalacia usually resolves spontaneously by 1 year of age, severe disease requires surgical intervention.

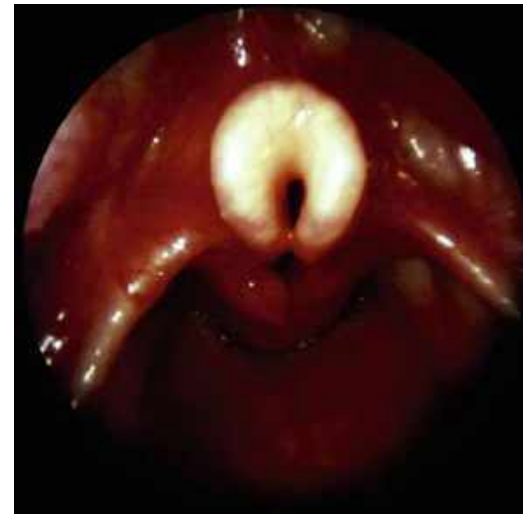

Fig. 165.4 Endoscopic view of child with severe laryngomalacia, showing short aryepiglottic folds and an omega-shaped epiglottis

Diagnosis is confirmed by flexible transnasal fiberoptic laryngoscopy. Characteristic findings include short aryepiglottic folds, with prolapse of the cuneiform cartilages (Fig. 165.4). In some patients, a tightly curled (Ω shaped) epiglottis is observed. Because of the Bernoulli effect, collapse of the supraglottic structures is typically seen on inspiration. Inflammation indicative of reflux laryngitis may also be seen.

Determining whether or not to intervene surgically is based more so on the severity of symptoms than on the endoscopic appearance of the larynx. Patients with laryngomalacia rarely present with acute airway compromise. For the small subset of children who require surgical intervention, this may be performed within 1–2 weeks of presentation. Preoperative management of GER is prudent.

Supraglottoplasty (also called epiglottoplasty) is currently the operative procedure of choice. This procedure is quick and effective and can be adapted to individual laryngeal pathology. Both aryepiglottic folds are divided and one or both

cuneiform cartilages may also be removed. If the aryepiglottic folds alone are divided, postoperative intubation is generally not required. If more extensive surgery is performed, overnight intubation is recommended.

Following supraglottoplasty, patients should be observed overnight in the intensive care unit. In some children, obstruction persists postoperatively. Repeat fiberoptic laryngoscopy at the bedside is helpful in determining whether this can be attributed to laryngeal edema or persistent laryngomalacia that necessitates further surgery. Reflux management is helpful in minimizing laryngeal edema. Occasionally, although the postoperative appearance of the larynx is adequate, obstructive symptoms are ongoing. Such cases may have an underlying neurologic component, which becomes more evident with time. Supraglottoplasty in these children often fails, thus requiring tracheotomy placement.

Complications include persistent or worsening aspiration following surgery, and this risk is higher when surgery is performed with a CO_2 laser versus cold instrumentation. Predisposing factors for supraglottic stenosis include extremely aggressive surgery, use of the CO_2 or other high-thermal-injury lasers, and severe inflammation in the early postoperative period.

Vocal Fold Paralysis

Vocal fold paralysis is the second most common cause of stridor in newborns and may be either congenital or acquired [9]. Congenital paralysis generally manifests bilaterally. Although it is usually idiopathic, it is sometimes seen in children with central nervous system pathology (e.g., hydrocephalus and Chiari malformation of the brainstem). Most children with bilateral paralysis present with significant airway compromise, though with an excellent voice or cry. They usually do not aspirate. Acquired disease is generally, though not always, a unilateral condition arising from iatrogenic injury to the recurrent laryngeal nerve (RLN). Because of the length and course of the left RLN, this is far more likely to be damaged than the right RLN. As such, acquired disease usually affects the left vocal fold. Risk factors for acquired paralysis include patent ductus arteriosus repair, the Norwood palliation, and esophageal surgery, particularly tracheoesophageal fistula repair. In older children, thyroid surgery is an additional risk factor. Unlike children with bilateral vocal fold paralysis, most children with unilateral disease have an acceptable airway but a breathy voice. These children are at a slightly higher risk of aspiration.

The diagnosis is established with awake flexible transnasal fiberoptic laryngoscopy and/or stroboscopy. Once paralysis has been confirmed, management depends on a number of factors. Children with acquired paralysis (whether unilateral or bilateral) may experience spontaneous recovery several months after nerve injury; however, this occurs only if the nerve is stretched or crushed but is otherwise intact.

Children with unilateral paralysis can be initially managed with observation, temporary injection medialization, or speech and voice therapy. Determining the appropriate option is based on a discussion with the patient's family, taking into account the need for restoration of normal voice and improvement of aspiration. Regardless of which option is chosen, these children should be observed for at least 1 year prior to any permanent intervention. If paralysis persists after this period of time and there is a functional deficit, long-term interventions such as ansa cervicalis reinnervation, permanent medialization laryngoplasty, or long-term injection medialization (fat or Radiesse) are considered. These options are discussed with the family and are often influenced by the age of the child and the presence of comorbidities. Medialization laryngoplasty is best performed after puberty.

For patients with bilateral paralysis associated with an underlying disease process, successful treatment of that disease may reverse the paralysis; however, up to 90 % of these infants ultimately require tracheotomy placement. Because up to 50 % of children with congenital idiopathic bilateral paralysis have spontaneous resolution of their paralysis by 1 year of age, surgical intervention to achieve decannulation is almost always delayed until patients are older than 1 year of age.

Several surgical options have been used for patients with bilateral paralysis, and no particular option offers a universally acceptable outcome. The aim of surgery is twofold: (1) to achieve an adequate decannulated airway while maintaining functional voice and (2) to prevent aspiration. Surgical options include laser cordotomy, partial or complete arytenoidectomy (endoscopic or open), vocal process lateralization (open or endoscopically guided), and posterior cricoid cartilage grafting. In a child with a tracheotomy, it is often prudent to maintain the tracheotomy to ensure an adequate airway prior to decannulation. In a non-tracheotomized child, a single-stage surgical procedure can be carried out. Acquired bilateral vocal fold paralysis that does not resolve spontaneously is usually less responsive to treatment than idiopathic vocal fold paralysis. In these cases, more than one operative intervention may be required to achieve decannulation. In patients who have undergone such interventions, post-extubation stridor may respond to CPAP or high-flow nasal cannula. The postoperative risk of aspiration should be evaluated by a video swallow study (VSS) before the child returns to a normal diet. During the initial postoperative weeks, some children have an increased risk of aspirating with certain textures, especially thin fluids.

Laryngeal Webs

Congenital laryngeal webs result from a failure of airway recanalization during embryogenesis (Fig. 165.5). In many children, webs extend into the subglottis. In view of the fact that 40 % of children with a congenital laryngeal webs also have velocardiofacial syndrome, all children with congenital webs should be evaluated for this syndrome [10]. Children with significant webs typically exhibit symptoms of airway obstruction early in life. They often have a weak cry and can be aphonic or mildly dysphonic. Some patients, however, have good voices and strong cries and are minimally symptomatic. The length of the web can influence the vocal quality by altering voice pitch.

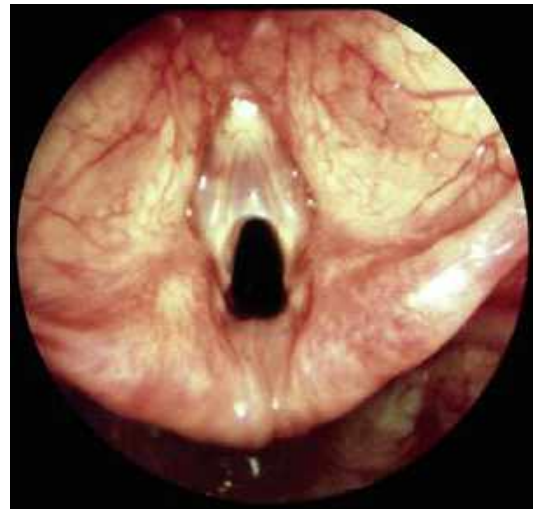

Fig. 165.5 Endoscopic view of a laryngeal web

Endoscopy reveals a web with variable thickness and vibratory qualities.

Management of laryngeal webs is often focused on improvement of the airway. The thickness and the length of the web play a critical role in voice outcome following surgery. Treatment of thick webs often yields minimal voice improvement and, in some cases, may result in a worse voice. Postoperatively, the vibrating surface of the vocal fold is scarred and has poor vibratory characteristics. Treatment of thin webs often yields improvement in voice, as the postoperative vocal fold generally has better vibratory characteristics. Treatment of longer webs often has a positive impact on voice outcome, whereas treatment of shorter webs may result in only minimal improvement. Families should be counseled regarding these aspects of web management and should be advised as to specific management goals (e.g., airway improvement and/or voice improvement).

Webs are managed either endoscopically or with an open procedure [11]. Endoscopic management is usually reserved for thin webs and webs without a significant associated subglottic stenosis. Through the use of a suspension microlaryngoscopy setup, the web is divided with cold instruments. A thin silastic keel is then placed and sutured across the anterior

commissure. This prevents re-formation of the web. The keel is left in place for 2–3 weeks.

In an open procedure the web is divided under endoscopic guidance and a complete laryngofissure is performed. The edges of the web are then sutured down to prevent readhesion. A small anterior graft is placed in the subglottis to address the stenosis; however, it should not extend through the anterior commissure. A stent is placed to prevent reformation of the web.

Subglottic Stenosis

Subglottic stenosis (SGS) can be either congenital or acquired. Congenital SGS in the neonate is defined as a lumen 4.0 mm in diameter or less at the level of the cricoid. SGS is thought to result from a failure of the laryngeal lumen to recanalize and is one of a continuum of embryologic failures that include laryngeal atresia, stenosis, and webs. Congenital SGS is often associated with other congenital head and neck lesions and syndromes (e.g., a small larynx in a patient with Down syndrome). Acquired SGS is far more common and is typically a sequela of prolonged neonatal intubation, often with an inappropriately large endotracheal tube. Other cofactors for the development of acquired SGS include GER and eosinophilic esophagitis (EE).

Levels of SGS severity are graded according to the Cotton–Myer grading system [12]. In its mildest form (no obstruction to 50 % obstruction), congenital SGS appears as a normal cricoid with a smaller than average diameter, usually elliptical in shape. Mild SGS may manifest in recurrent upper respiratory infections (often diagnosed as croup) in which minimal subglottic swelling precipitates airway obstruction. In a young child, the greatest obstruction is usually 2–3 mm below the true vocal folds. More severe cases may present with acute airway compromise at delivery. If endotracheal intubation is successful, the patient may require intervention before extubation. When intubation cannot be achieved, tracheotomy placement at the time of delivery may be life saving. Important to note, infants typically have surprisingly few symptoms.

Fig. 165.6 Endoscopic view of a grade 3 subglottic stenosis

Even those with grade III SGS (71–99 % obstruction) (Fig. 165.6) may not be symptomatic for weeks or months.

Children with mild acquired SGS may be asymptomatic or minimally symptomatic. Observation rather than intervention may thus be appropriate. This is often the case for children with grades I or II SGS. Those with more severe SGS (grades III and IV) are often symptomatic, with either tracheal dependency or stridor and exercise intolerance.

Radiologic evaluation of an airway that is not intubated may provide the clinician clues about the site and length of the stenosis. Useful imaging modalities include inspiratory and expiratory lateral soft-tissue neck films, fluoroscopy to demonstrate the dynamics of the trachea and larynx, and a chest x-ray. However, the single most important investigation is high-kilovoltage airway films. These films are taken not only to identify the classic "steepling" observed in patients with SGS but also to identify possible tracheal stenosis. The latter condition is generally caused by complete tracheal rings, which may predispose the patient to a life-threatening situation during rigid endoscopy.

Whether SGS is congenital or acquired, evaluation requires endoscopic assessment, which is

considered the gold standard. Endoscopy is necessary for the diagnosis of laryngeal stenosis. Precise evaluation of the endolarynx should be carried out, including grading of the subglottic stenosis. Stenosis caused by scarring, granulation tissue, submucosal thickening, or a congenitally abnormal cricoid can be differentiated from SGS with a normal cricoid, but endoscopic measurement with endotracheal tubes or bronchoscopes is required for an accurate evaluation.

In a patient with congenital SGS, the larynx will grow as the patient grows. After initial management of SGS, the patient may therefore not require further surgical intervention. However, if initial management requires intubation, the risk of developing an acquired SGS in addition to the underlying congenital SGS is considerable.

Unlike congenital SGS, acquired SGS is unlikely to resolve spontaneously and thus requires intervention. Reconstruction of the subglottic airway is a challenging procedure and the patient should be optimized before undergoing surgery.

Endoscopic and Surgical Management

Endoscopic management of laryngeal stenosis is successful in most cases involving grade I or II stenosis when there are no factors that predispose to failure (e.g., significant loss of cartilaginous framework, combined laryngotracheal stenosis, circumferential cicatricial scarring, fibrotic scar tissue in the interarytenoid area of the posterior commissure). Grades III and IV stenoses are more likely to require an open surgical approach. Endoscopic techniques include dilatation, division or micro-trapdoor flap, endoscopic resection with or without stenting, and laser excision.

Although endoscopic laser management of laryngeal stenosis yields success rates ranging from 66 % to 80 %, [13] careful patient selection is essential. The advantages of successful endoscopic management include precise surgical excision, low surgical morbidity, minimal damage to underlying or surrounding tissues, and the ability to vary the amount of energy delivered. Endoscopic management allows a successful outcome without a tracheotomy. Endoscopic laser techniques that use high energy over prolonged periods and damage underlying cartilage may create or worsen stenosis. In light of bacterial colonization of the aerodigestive tract, prophylactic antibiotic therapy is recommended.

Balloon dilatation of the airway using high-pressure noncompliant balloons has become a valuable addition to the tools used to manage airway stenosis. The best candidates for balloon dilatation are patients with stenoses involving either thin or weblike scars or those with relatively fresh stenoses. Repeated dilatation, at 1- to 3-week intervals, on up to four occasions may provide the optimal outcome. Adjunctive interventions, such as scar division (whether with a sickle knife or a laser) and steroid injection may further enhance the outcome of balloon dilation. Selection of balloon size is based upon the expected size of the normal airway; for example, a 4-year-old should be intubated with a 5.0-mm endotracheal tube, with an outer diameter of nearly 7 mm. Therefore, the balloon size selected would be 7–8 mm for the larynx and 8–9 mm for the trachea.

If endoscopic management is unsuccessful or there are factors predisposing to endoscopic failure, a wide variety of open surgical techniques are available for managing laryngeal stenosis. This is generally the case in the setting of severe advanced acquired stenoses. Endoscopic diagnosis is imperative in selecting the appropriate surgical technique. The status of vocal fold mobility, the involvement of the posterior commissure, and a complete evaluation of the upper and lower airways are essential to the assessment.

Open Surgery

The goal of open surgery for correcting laryngotracheal stenosis is to optimize voice function and permit early decannulation. Relative contraindications to open reconstructive surgery include (1) a significant risk in administering a general anesthetic, (2) the continued need for tracheotomy, and (3) significant laryngeal inflammation (e.g., gastroesophageal reflux disease (GERD), EE) [14].

Open surgical techniques for reconstruction of the airway compromised by laryngotracheal

stenosis are usually considered in patients who are tracheotomy dependent and in patients who do not have a tracheotomy but who have significant exercise intolerance or sleep disturbance.

Otolaryngologists should have several open surgical techniques in their armamentarium to enable successful management of a variety of pathologic conditions. Airway surgery should be tailored to the specific pathology of each patient, as no single procedure can adequately deal with all manifestations of laryngeal stenosis.

Anterior Cricoid Split

The anterior cricoid split procedure can be used instead of tracheotomy in the neonate who has failed extubation. Criteria for using this approach include two or more extubation failures secondary to laryngeal conditions, a child weighing more than 1,500 g, no assisted ventilation for 10 days before evaluation, supplemental oxygen requirement less than 30 %, no congestive heart failure for 1 month before evaluation, no acute upper or lower respiratory tract infection at the time of evaluation, and no antihypertensive medication is taken for 10 days before the evaluation [15]. It is important to eliminate other causes of airway obstruction, such as laryngomalacia, tracheomalacia, choanal atresia, and retrognathia. Management in this age group requires careful endoscopic examination and management of reversible conditions (e.g., subglottic edema, laryngeal granulation) by intubation, steroid therapy, or laser excision. More severe laryngeal injury, especially with extensive mucosal injury, may be treated with an anterior cricoid split, allowing extubation without tracheotomy [15]. Because the level of the anterior commissure in the infant lies at the junction of the upper two thirds and lower one third of the thyroid cartilage, the anterior laryngofissure should only extend to the lower one third of the thyroid cartilage. The infant requires intubation for 7–10 days following the split, although this time period may be reduced if a thyroid alar cartilage cap is placed over the split site. In our experience, the addition of a thyroid alar graft offers the potential advantage of higher success rates while adding little operative morbidity [16].

Laryngotracheal Reconstruction: Anterior Cartilage Graft

For grade I or II SGS, an anterior autogenous costal cartilage graft is a highly effective method for reconstruction of the airway when endoscopic management is either not possible or unsuccessful [17,18]. This approach may also be effective in selected grade III lesions. A boat-shaped flanged graft is placed between the divided anterior lamina of the cricoid cartilage and, if required, may extend inferiorly across two or three tracheal rings. It should not transgress the anterior commissure. Other options for graft material include thyroid alar and auricular cartilage, although neither has the same structural integrity as costal cartilage.

Laryngotracheal Reconstruction: Posterior Cartilage Graft

Posterior glottic stenosis is a common sequela of prolonged intubation and is often misdiagnosed as bilateral vocal fold paralysis. There may be associated fibrosis or ankylosis of the cricoarytenoid joints. A posterior costal cartilage graft placed after division of the posterior cricoid lamina may be performed as a single- or two-stage procedure [19]. A narrow graft (<6 mm) is usually adequate and excessive augmentation risks aspiration. The same technique is employed for grade II or III SGS with primarily posterior cricoid scarring. Although a complete laryngofissure allows excellent access to the posterior cricoid, particular care should be taken to both accurately divide and reconstruct the anterior commissure to ensure perfect cord alignment and to minimize the risk of long-term vocal dysfunction. It is possible to split the posterior cricoid without a laryngofissure, even in a neonate, but placing sutures to stabilize a cartilage graft in the posterior cricoid is very challenging in a younger child if a laryngofissure is not performed. An alternative is the placement of a flanged posterior cartilage graft, where stability precludes the need for sutures. This procedure

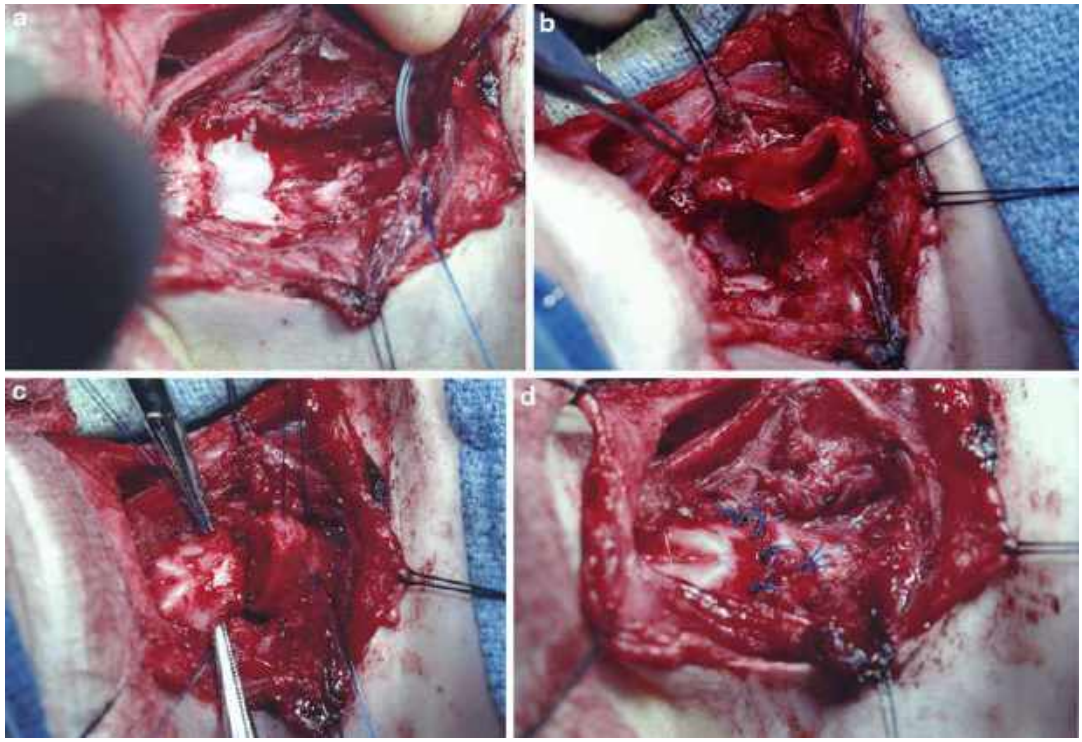

Fig. 165.7 Serial photographs illustrating a cricotracheal resection. (**a**) Removed portion of the cricoid cartilage; (**b**) distal tracheal segment with mucosal flap; (**c**) initial closure; (**d**) completed anastomosis

may also be performed using an endoscopic approach. The posterior cricoid plate is divided endoscopically with cold instrumentation or lasers. The graft is then placed endoscopically. This may be performed with or without a tracheotomy [20].

Laryngotracheal Reconstruction: Anterior and Posterior Cartilage Grafts

Grades III and IV SGS usually require anterior and posterior costal cartilage graftings. Following placement of the posterior cartilage graft, the anterior airway can be closed over an appropriately sized endotracheal tube to estimate the size of the anterior graft required. If the anterior cricoid can be closed without tension, an anterior graft may not be required. A variation of this procedure is an anterior graft with a posterior split of the cricoid lamina–an option usually limited to younger children. Grade IV SGS usually requires more than one procedure to achieve decannulation using cartilage expansion techniques [21].

Cricotracheal Resection

An alternative to anterior/posterior cartilage grafting is cricotracheal resection, [22, 23] involving removal of the diseased portion of the airway and the introduction of healthy tissue into the subglottis. This is a more technically challenging procedure than anterior/posterior cartilage grafting and is therefore usually reserved for patients with severe SGS. It also has particular application in the reconstruction of the airway that has failed previous laryngotracheal reconstruction (Fig. 165.7a, b). There is a higher chance of achieving decannulation after a single procedure with cricotracheal resection than with standard cartilage augmentation laryngotracheal reconstruction. The advantages of the procedure include glottic sparing, avoidance of donor site morbidity, and a near-normal appearing and

mucosalized airway. The disadvantages include a risk to the recurrent laryngeal nerves and anastomotic dehiscence. Patient selection is important, and subglottic scarring within 3 mm of the vocal folds is a relative contraindication.

Stenting Options

The primary decision that needs to be made regarding stenting is the required duration of stent placement. The more unstable the airway reconstruction (e.g., following an anterior/posterior graft) or if there is a history of previous failed reconstruction, the longer the period of stenting required. Long-term stenting may be achieved with a T-tube (Montgomery or Hood) or a silastic/silicon Rutter stent. Although once the mainstay of laryngotracheal reconstruction, the wired-in stent has become an increasingly rare method of postoperative airway stabilization. Generally, in children younger than age 4, a T-tube is best avoided, as T-tubes with less than an 8-mm outer diameter carry a higher risk of mucus occluding the lumen of the tube. Shorter-term stenting may be adequately achieved with a suprastomal Teflon stent, but this should ideally be removed after several weeks to prevent stenosis occurring between the distal end of the stent and the tracheotomy tube. Newer generation silicone suprastomal stents carry less risk of inducing stenosis at the distal tip of the stent [24].

If the period of stenting is less than 2 weeks and lung function is adequate, consideration may be given to a single-stage procedure, using an endotracheal tube as a stent. This technique is highly dependent upon access to a first-class intensive care unit. Paralysis is best avoided to allow the child an opportunity to maintain his or her own airway in the event of an accidental extubation. Most children younger than age 3 require sedation, whereas many children older than age 3 do not. The period of intubation depends upon the surgery performed and may vary from 1 day for selected anterior cartilage grafts to 14 days for an anterior/posterior cartilage graft.

In some circumstances, a stent may not be required for a two-stage reconstruction. An anterior costal cartilage graft laryngotracheal reconstruction rarely needs a stent, and selected cricotracheal resections may not need a stent.

Decision Making

Before deciding on an open surgical reconstructive technique, conservative endoscopic treatment of laryngeal stenosis should be considered. This approach may include endoscopic dilatation, laser therapy, tissue removal by endoscopic microsurgical techniques, local and systemic steroid therapy, and antibiotic therapy. If these techniques are unsuccessful, open reconstruction of the airway can be considered.

Several factors may influence the timing of surgical correction in children. Patients with acquired laryngeal stenosis caused by long-term intubation frequently have underlying chronic pulmonary disease. Lung disease, such as bronchopulmonary dysplasia, must be addressed medically before surgical correction of the airway. In many children with laryngeal stenosis, other congenital or acquired anomalies require surgical repair. Reconstruction of the airway can be delayed until the other surgical procedures are completed because the existing tracheotomy tube allows easy and safe access to the airway.

In adults and children, any indication of significant GERD should be corrected medically or surgically before airway reconstruction is undertaken. If this is not successfully treated before reconstruction, the reconstructed airway may suffer repeated injury by acidic gastric contents, causing granulation tissue and further stenosis. Patients with EE require similar intervention and stabilization prior to undergoing airway surgery.

The variety of open surgical procedures available for reconstruction, including some that are not outlined here, allows the surgeon to manage the stenotic larynx regardless of etiologic factors. Severe stenosis frequently requires more than one surgical correction for successful reconstruction. Therefore, early stenotic lesions should be treated aggressively to maintain an opening in the airway.

Complications

Complications related to airway reconstruction may occur intraoperatively, early postoperatively, or late postoperatively. Intraoperative complications include hypoxia, pneumothorax (usually related to harvesting rib cartilage), and pneumomediastinum. Similar problems may occur postoperatively, as may wound infections, graft displacement, stent dislodgement, aspiration, and mucous plugging of the tracheotomy tube. Single-stage reconstruction carries particular risks, including endotracheal tube obstruction, unplanned extubation, glottic edema, and narcotic withdrawal.

Resection techniques are associated with two significant additional complications: vocal fold paralysis (4 %) and dehiscence (6 %). Vocal fold paralysis is bilateral, and in some cases, it is managed expectantly with close monitoring. Patients with significant airway obstruction are managed as described earlier in this chapter (section on bilateral paralysis). Dehiscence is a relative emergency. Once it is recognized, the patient should be intubated under direct visualization. An endotracheal tube is advanced over a rigid telescope or flexible bronchoscope into the distal airway. The airway is then reconstructed by reconnecting the dehiscent portion. Frequently, a tracheotomy is concurrently placed and patients are stented with a suprastomal stent or a T-tube.

All patients who are discharged with tracheotomy tubes should be taught tracheotomy care and given spare tracheotomy tubes, including one a size smaller than that which resides in the patient in case of difficulty with reinsertion in an emergency. The family should be instructed in tracheotomy care, including suctioning and changing the tracheotomy tube.

Emergencies

Emergent complications in the care of laryngeal stenosis include airway obstruction, aspiration of a wire or stent, hemorrhage or hematoma formation, and pneumothorax with resulting respiratory distress.

Airway obstruction may be caused by mucous plugs or granulation tissue. Humidified air should be provided, and changing of the inner cannula or tracheotomy tube should be performed regularly to prevent plugging. Mucous plugs should be carefully suctioned. Granulation tissue may be treated with steroids (e.g., dexamethasone, 0.5 mg/kg/day to a maximum of 20 mg per day) by mouth or with topical or aerosolized steroid/antibiotic drops such as ciprofloxacin/dexamethasone through the tracheotomy tube, depending on the site of granulation tissue. If granulation tissue is causing significant obstruction, the patient may need to be admitted and closely monitored during therapy. Solitary pedunculated granulomas may be safely removed with forceps during removal of the stent or during an interval examination postoperatively. These patients may be placed on a short-pulsed dose of oral steroids, oral antibiotics, proton pump inhibitors, and topical ciprofloxacin/dexamethasone through the tracheotomy tube.

To avoid some of these complications, the surgical technique should include the use of drains and, in open airway procedures, closure of the skin that allows the escape of air. A radiograph of the chest should always be obtained postoperatively for open reconstructive procedures. If an anterior costal cartilage graft is harvested, sterile saline should be placed in the wound and a positive pressure breath given to determine the possibility of an air leak. Good surgical technique with careful hemostasis and education of ancillary personnel and family can minimize these emergencies.

Dysphonia Following Airway Reconstruction

Nearly 50 % of children who undergo airway reconstruction will be dysphonic [25,26]. Many children present with complaints years after airway reconstruction, often during the teenage years. Complaints generally involve concerns about voice quality and loudness. Concerns

related to voice quality often stem from social interaction with peers who may call attention to the dysphonia. Loudness concerns involve difficulty being heard in noisy environments and difficulty with voice projection and intelligibility.

Risk factors for poor voice outcomes include complete laryngofissure, posterior grafting, cricotracheal resection, and multiple airway reconstructions [27, 28]. On endoscopy, children demonstrate glottic, mixed glottic, or supraglottic phonation. Perceptually, patients exhibit a mild to severe dysphonia [27]. Patients with supraglottic and mixed glottic phonation will often have perceptually worse voice outcomes [29]. Many of these patients have problems with glottic incompetence or glottic diastasis (always open glottis); typically, closure of the posterior glottis during phonation is problematic [30].

Treatment of dysphonia following airway reconstruction is highly individualized. Decisions regarding treatment are usually based on understanding the details of the laryngeal mechanics as seen on stroboscopy, taking into account the perceived severity of the voice disorder by both experts and the patient and defining what is surgically and medically achievable regarding voice improvement. Voice therapy plays a crucial role in both initial and postoperative management.

Many children with postoperative airway reconstruction dysphonia have a persistent glottic gap, typically in the posterior glottis. This gap is caused either by prior surgical intervention to improve the airway or by injury from intubation earlier in childhood. Initial surgical management may involve reversible procedures or procedures that have a minimal impact on respiration. One such procedure is temporary medialization laryngoplasty. This is similar to the procedure described earlier in this chapter for the management of unilateral vocal fold paralysis; however, in children with postoperative dysphonia, both vocal folds may require medialization. Following surgery, there is typically an improvement in supraglottic phonation but not in glottic phonation. More specifically, improvements are seen in loudness, clarity, and intelligibility. If the initial temporary procedure is successful, a more permanent procedure involving injection with autologous fat is often performed.

For children whose vocal folds are either misaligned or have a large anterior gap, the best correction is provided by an open surgical procedure to divide the anterior commissure to realign the vocal folds or close the anterior gap. For children with posterior glottic diastasis, there are two surgical options, and both are generally reserved for children who have gone through puberty and have a fully grown airway. One option is to perform an endoscopic arytenoid flap. During this procedure, a portion of the aryepiglottic fold and the supra-arytenoid tissue are rotated as a pedicled flap into the posterior glottis. This helps close off some of the posterior gap, leading to improved supraglottic phonation. A conceptually better option is the removal of a portion of the posterior cricoid plate, narrowing the posterior glottis. This can be performed either through an open or endoscopic approach. The main risk of this procedure is the potential for postoperative airway obstruction. In view of this risk, families seldom choose this option.

Posterior Laryngeal Clefts

Posterior laryngeal clefts result from a failure of the laryngotracheal groove to fuse during embryogenesis (Fig. 165.8). In a widely used anatomic classification system, these clefts are divided into four subtypes associated with varying levels of severity; type 1 cleft is the least severe and type 4 cleft is the most severe [31]. Other associated anomalies are common and may be divided into those that affect the airway and those that do not. Associated airway anomalies include tracheomalacia (>80 %) and tracheoesophageal fistula formation (20 %). Non-airway associations include anogenital anomalies and GER. The most common syndrome associated with posterior laryngeal clefting is Opitz–Frias syndrome, which is characterized by hypertelorism, anogenital anomalies, and posterior laryngeal clefting.

Although aspiration is the hallmark clinical feature of this disorder, signs and symptoms may be nonspecific, making the diagnosis elusive. Symptoms may also include apnea,

Fig. 165.8 Endoscopic view of a type 3 laryngeal cleft

recurrent pneumonia, feeding difficulties, and airway obstruction.

VSS and FEES may suggest the risk of aspiration for children with clefts. Definitive diagnosis requires rigid laryngoscopy and bronchoscopy, with the interarytenoid area being specifically probed to determine if a posterior laryngeal cleft is present.

Operative Intervention

Presurgical Considerations

In the absence of other more severe anomalies, a posterior laryngeal cleft should be repaired as soon as possible in order to prevent chronic microaspiration with consequent long-term pulmonary compromise. In some children, however, there may be minimal symptomatology and it may be justifiable to delay the repair. For many children, there may be other medical problems that take precedence over the laryngeal cleft repair. The most common problem is the need for repair of a tracheoesophageal fistula (TEF) and esophageal atresia. The complex nature of these disorders requires an interdisciplinary approach.

Prior to the repair, consideration should be given to whether a tracheotomy, a gastrostomy tube, a fundoplication, or a combination of all these is needed. A tracheotomy is often warranted in the presence of significant stridor or airway compromise due to vocal ford paralysis, SGS, or, most commonly, severe tracheobronchomalacia. An advantage of a tracheotomy is that there is no pressure on the suture line of the repair from an endotracheal tube, as may occur with a single-stage repair. In certain cases, however, a tracheotomy may have negative consequences. If a tracheotomy is placed in a child with moderate to severe tracheomalacia but relatively few airway symptoms, the child may not be able to be decannulated for months or years.

A gastrostomy has the advantage of eliminating the need for oral feeding, hence limiting the potential for aspiration. In a single-stage procedure, it also has the advantage that the repair site will not lie between a nasogastric tube and an endotracheal tube. However, a gastrostomy tube does not prevent aspiration of saliva and does not prevent GER. A gastrostomy may only be required for a few weeks after a successful cleft repair. Prolonged gastrostomy use without oral stimulation ultimately leads to oral aversions and other feeding problems.

GERD is usually present, and the refluxate may adversely affect the healing of a fresh repair site. Possible solutions include acid suppression, a gastrojejunal tube, or a jejunal tube. However, a fundoplication remains the most definitive intervention.

Surgical Procedures

Type I clefts are uncommon and may be overdiagnosed. They do not necessarily require operative intervention, but surgery is warranted when associated symptoms are present. Repair may be either endoscopic or open. In our experience, types III and IV clefts require open repair. In most cases, surgical intervention reveals that a cleft is more extensive than previously suspected on endoscopy. Although a lateral pharyngotomy was the mainstay of operative intervention for many years, it carried significant risks to the recurrent laryngeal nerves. Also, access is suboptimal with a longer cleft.

Endoscopic Repair

Type 1 and type 2 laryngeal clefts are best repaired endoscopically, as this approach does not require a complete laryngofissure and therefore does not place the vocal folds or voice at risk. However, if laryngeal exposure is inadequate, access may be a problem; in such cases, an open approach may be required. Similarly, an open approach may be preferable in children with associated SGS, as this allows both lesions to be addressed concurrently.

The technique is to position the patient with the larynx suspended on a suitable laryngoscope (e.g., medium Lindholme) and exposed with vocal fold spreaders. We denude the mucosa of the inner aspect of the cleft, with particular attention to the apex of the cleft. The raw surfaces are opposed by the placement of 4-0 PDS sutures on a taper needle. These sutures are placed in a horizontal mattress fashion. The first throw of the distal suture commences at the mucosal edge of the esophageal side and exits at the mucosal edge of the tracheal aspect on the same side of the larynx, with the suture having incorporated a large "bite" tissue. The second throw of the needle is on the opposite side of the larynx from close to the mucosal edge on the tracheal side, exiting close to the mucosal edge on the esophageal side. The suture may be tied down with at least 6 throws, as PDS is notoriously slippery. If required, additional sutures are then placed more proximally, with the most proximal suture involving the cuneiform cartilage if possible to minimize the risk of the suture pulling through.

Open Repair

These authors recommend a transtracheal approach for repair of types III and IV and some type II clefts. Anesthesia is provided through a shortened oral RAE endotracheal tube placed through the tracheal stoma in a child with a preexisting tracheotomy. In a single-stage procedure, after induction with an oral or nasal endotracheal tube, a temporary low tracheotomy can be placed and a shortened oral RAE tube introduced through the low tracheotomy to maintain anesthesia. An esophageal bougie is then placed.

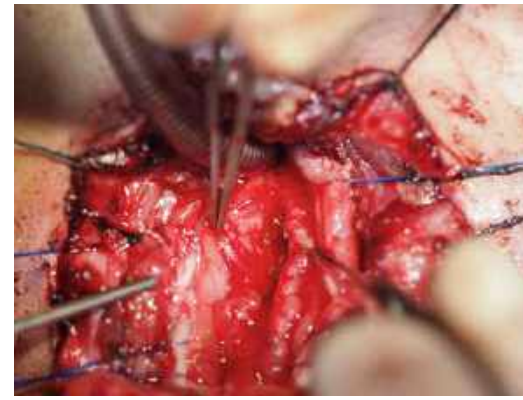

Fig. 165.9 Operative view, demonstrating the separated cleft

A transverse neck incision is made in a skin crease close to the level of the cricoid cartilage. Subplatysmal skin flaps are raised, and the strap muscles and thyroid isthmus divided and carried laterally. This exposes the anterior trachea. A beaver blade is used to enter the airway, and care is taken to stay strictly in the midline. The anterior trachea is opened from the second or third tracheal ring up through the cricoid cartilage and cricothyroid membrane. In children with a long laryngotracheoesophageal cleft, the incision in the anterior trachea is carried as inferiorly as is necessary to gain good exposure to the posterior cleft.

The larynx must then be split. To avoid damage to the vocal folds, this procedure should be done exactly in the midline, through the anterior commissure. In young children, the level of the anterior commissure lies one third of the way between the superior and inferior notches of the thyroid cartilage, closer to its inferior border. This procedure is most accurately performed with an assistant providing a televised view of the glottis with a rigid 30 Hopkins rod telescope.

The larynx is distracted with Prolene sutures and the full extent of the cleft can be observed (Fig. 165.9). A significant amount of redundant mucosa is typically present. This requires removal to prevent airway compromise while still maintaining a tension-free 2-layer repair. The edges of the cleft are infiltrated with 1 %

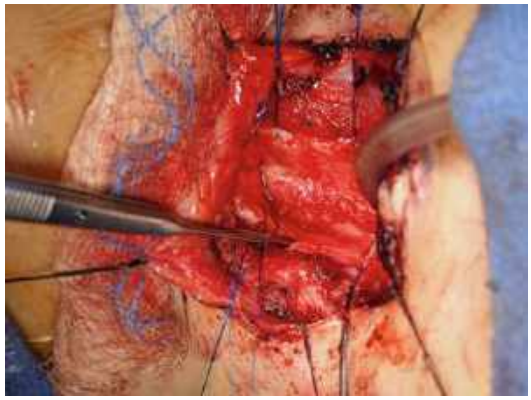

Fig. 165.10 Operative view of the repaired posterior cleft shown in Fig. 165.9

lidocaine and 1:100,000 epinephrine, and 3.0 Monocryl stay sutures are placed along the edge of the cleft to provide traction. The mucosa along the edge of the cleft is then incised or excised, depending on the amount of redundant mucosa present. Particular care should be taken at the apex of the cleft distally and over the arytenoid cartilages proximally. The aim is to repair the cleft 3–4 mm above the level of the true vocal folds.

The esophageal mucosa is closed with interrupted 4-0 or 5-0 sutures over the esophageal bougie, with the knots lying in the esophageal lumen. This closure commences distally, and the suture at the apex of the cleft should be tied like a purse string. Each suture can act as a retractor to allow placement of the following suture before being cut. After the esophageal mucosa is closed, we place a thin layer of fibrin glue on the suture line prior to closing the tracheal mucosa. The tracheal mucosa is then closed distally to proximally in an identical fashion to the esophageal mucosa. Sutures are placed with the knots lying in the tracheal lumen and particular care is taken over the most distal and proximal sutures. This layer is further reinforced with a very thin film of fibrin glue (Fig. 165.10).

In a single-stage procedure (i.e., without a tracheostomy), the patient is then nasally intubated. The tip of the tracheotomy tube should lie distal to the repair site. The anterior trachea is then closed using 4-0 PDS sutures through the tracheal rings and cricoid and 5.0 Vicryl sutures in the cricothyroid membrane if required. The larynx must be closed with particular care so as not to overlap the vocal folds at the anterior commissure. The neck is then closed in layers over a Penrose drain. If closure of the cricoid over an age-appropriate endotracheal tube cannot be accomplished without tension, a small anterior cartilage graft will allow tension-free closure. The graft may be costal cartilage or thyroid alar cartilage.

Revisions

Laryngeal cleft repairs have a recognized failure rate. The repair is at the greatest risk of breakdown either at the distal end of the repair with TEF formation or at the proximal end with cleft recurrence. Laryngeal cleft failures usually occur within weeks of the initial repair; however, late occurrences have been described several years after a successful initial repair.

Type IV (Long) Clefts

Infants born with a long type IV cleft are challenging to manage for a variety of reasons. Severe aspiration is inevitable. Airway maintenance may be problematic, as an endotracheal tube may reside in the esophagus or trachea, with the "tracheoesophagus" being a common cavity. Other congenital anomalies are common and the closer the cleft is to the carina, the greater the likelihood of other major congenital anomalies; these may be classified as airway and non-airway anomalies. Airway anomalies associated with long laryngeal clefts include bronchial stenosis and bronchomalacia, which is usually left sided. Cartilage abnormalities of the laryngotracheal complex are common and may include areas of cartilage aplasia and conjoined tracheal rings.

Non-airway anomalies include microgastria, polysplenia, and annular pancreas. Microgastria may result in uncontrollable GER and is not amenable to a fundoplication. Prior to embarking on surgical repair of the laryngeal cleft, a decision must be made as to whether the child is salvageable.

There are many methods to repair a type IV cleft, primarily because none of the approaches is ideal. The dilemmas fundamentally relate to

issues of access and issues of oxygenation. Access may be through a lateral thoracotomy approach, a transsternal approach, or a cervical approach, either transtracheally or from an extended lateral pharyngotomy. Both short- and long-term mortality are high. These rare cases are therefore best reserved for otolaryngologists with special expertise.

Outcomes

Success rates for posterior laryngeal cleft repair vary between 50 % and 90 %. Breakdown of the repair usually occurs within a month of surgery, but a late breakdown (even years later) may also occur. The success of an operative repair is negatively influenced by several factors. The more severe the cleft, the higher the incidence of breakdown or fistula formation through the repair. The type of operation chosen influences outcome, and a transtracheal repair remains superior to a lateral pharyngotomy or an endoscopic repair because of the excellent exposure provided by this approach. Revision surgery, whether for a recurrent cleft or a secondary H-type TEF, is less successful than primary surgery.

The most common site of breakdown is the most distal end of the cleft repair, usually seen as a persisting TEF, and acquired H-type fistulae are notoriously difficult to find. Success may also be compromised by excessive redundant mucosa obstructing the airway, which may require trimming with a CO_2 laser. Additional complications after cleft repair include vocal fold paralysis (especially after a lateral pharyngotomy) and a collapsing larynx caused by an inadequate posterior cricoid. Although the current mortality rate is unknown, it is presumed to be less than 10 %. Certainly, mortality and morbidity rates rise with the severity of the cleft.

Tracheal Anomalies and Reconstruction

166

Michael J. Rutter, Alessandro de Alarcón, and Peter B. Manning

Abstract

Tracheal stenosis is a relatively rare disorder in the pediatric population and is usually congenital rather than acquired. Congenital tracheal stenosis is usually due to complete tracheal rings, with or without associated vascular compression of the airway. The stenosis may be associated with Down syndrome, VACTERL association, or craniosynostosis. If the stenosis is not severe, it may be a late presentation or an incidental finding. Acquired tracheal stenosis is generally traumatic in origin, either the result of direct injury or more commonly the result of trauma from the cuff or tip of an endotracheal tube. Tracheal stenosis may also occur at the site of a tracheotomy. Tracheal stenosis may coexist but should not be confused with tracheomalacia or vascular compression of the airway. The management of these pathologies is different from the management of tracheal stenosis. A rare cause of congenital tracheal stenosis is a tracheal web, which is usually thin and amenable to endoscopic treatment. This chapter will provide an overview of the diagnosis and management of these entities.

Congenital tracheal stenosis • Complete tracheal rings • Sleeve trachea • Slide tracheoplasty

Introduction

Unlike subglottic stenosis (SGS), tracheal stenosis is a relatively rare disorder in the pediatric population and is usually congenital rather than acquired. SGS requiring operative intervention has 10 times the prevalence of tracheal stenosis and is usually a consequence of prolonged intubation of a premature infant. The predilection for acquired airway stenosis to occur at the subglottic level is because the narrowest portion of the infant or child's airway is the cricoid ring, normally the only complete cartilaginous ring in the airway.

Congenital tracheal stenosis is usually due to complete tracheal rings (CTRs), with or without associated vascular compression of the airway. The stenosis may be associated with Down syndrome, VACTERL association, or craniosynostosis. If the stenosis is not severe, it may be a late presentation or an incidental finding. Currently, the genetics of congenital tracheal stenosis are poorly understood.

Acquired tracheal stenosis is traumatic in origin in most cases, either the result of direct injury (e.g., clothesline injury) or more commonly the result of trauma from the cuff or tip of an endotracheal tube. Tracheal stenosis may also occur at the site of a tracheotomy, with either an A-frame deformity or a suprastomal collapse.

Although tracheal stenosis may coexist with tracheomalacia or vascular compression of the airway, it should not be confused with tracheomalacia or compression. The management of these pathologies is different from the management of tracheal stenosis. Vascular compression of the airway is discussed in a specific chapter elsewhere in this textbook but will also be briefly discussed in this chapter, with particular attention given to the association of CTRs and the pulmonary artery sling (PAS).

A rare cause of congenital tracheal stenosis is a tracheal web, which is usually thin and amenable to endoscopic treatment. Some authors believe that severe tracheal webs are often inadvertently treated at birth by emergent intubation causing disruption of the web.

Congenital Tracheal Anomalies

Congenital tracheal obstruction may be due to vascular compression, tracheomalacia, tracheal stenosis, or a combination of these diseases. Tracheomalacia may be an isolated finding but is more often associated with other airway anomalies, such as a tracheoesophageal fistula or laryngeal cleft. The typical pattern is of a widened posterior trachealis; rarely, however, tracheomalacia may be due to cartilage anomalies of the anterior circumference of the trachea. Even rarer, part or all of the trachea may be absent (tracheal agenesis), with the carina or bronchi arising from the esophagus. Tracheal reconstruction is usually required for tracheal stenosis, but not for vascular compression or tracheomalacia.

Complete Tracheal Rings

Although CTRs are rare, they are the most common cause of congenital tracheal stenosis. In a normal trachea, luminal support is provided by incomplete rings of cartilage, with a posterior sheet of muscle (the trachealis) completing the circumference of the trachea. In patients with CTRs, the cartilaginous rings are circular and may affect varying lengths of the trachea; also, the trachealis muscle is absent. The diameter of the complete cartilage rings is always smaller than the trachea above the affected segment, although the severity of the stenosis may vary. Certain patterns of CTRs may be recognized [1]. The most common patterns are (1) CTRs that are of reasonable size proximally but cone down to a small distal ring close to the carina; (2) the

"stovepipe" airway with a long segment of CTRs of similar diameter; (3) "a short-segment stenosis," often in the mid-trachea; and (4) complete tracheal rings associated with a high tracheal (or pig) bronchus. More than 75 % of patients also have other congenital anomalies that may be severe. In a large series at Cincinnati Children's Hospital Medical Center, 60 % of patients with CTRs had cardiovascular abnormalities, particularly a PAS (21 %) [2].

Children with CTRs typically present with progressive worsening of respiratory function over the first few months of life. Stridor, retractions, "dying spells," and marked exacerbation of symptoms during intercurrent upper respiratory tract infections are the typical presentation. Children with distal tracheal stenosis usually have a characteristic biphasic wet-sounding breathing pattern that transiently clears with coughing; this pattern is referred to as "washing machine breathing." Because the growth of the trachea is not commensurate with the growth of the child over the first few months of life, decompensation frequently occurs around 4 months of age, with the child presenting in respiratory failure [3]. However, even in a neonate with a life-threatening tracheal stenosis, there may be surprisingly few symptoms.

The initial evaluation should include plain airway films, as these may indicate that congenital tracheal narrowing is present. Although imaging studies may be very useful, they may also be potentially misleading. Definitive assessment is therefore made with rigid bronchoscopy. This should be performed with extreme care, as rough instrumentation in an area of stenosis may cause enough swelling to convert a narrow airway to a critical airway, necessitating abrupt intervention. Because of this, it is indicated to routinely administer Dexamethasone (0.5 mg/kg) on induction, and it is preferable to identify only the proximal extent of the tracheal stenosis without fully evaluating the distal airway, rather than forcing a telescope through a narrow stenosis, to avoid the risk of decompensation. Good communication with anesthesia colleagues is advisable, and to facilitate the bronchoscopy, it is preferable that the child is spontaneously ventilating utilizing both sevoflurane and propofol. The trachea is then suctioned with a soft 6 French catheter and the patient is preoxygenated. Next, a further propofol bolus is delivered to temporarily halt respiratory efforts during the bronchoscopy.

Ideally, the aims of endoscopic evaluation are to confirm the diagnosis of tracheal stenosis, establish whether this is due to complete tracheal rings, estimate the size of the smallest ring, estimate the percentage of the airway involved with complete tracheal rings as well as the position of the rings within the trachea, and evaluate the bronchial anatomy. This evaluation should be performed with utmost caution, using the smallest possible telescopes, as any airway edema in the region of the stenosis may turn a compromised airway into an extremely critical airway.

In patients with distal tracheal stenosis, adequate evaluation cannot be made with a ventilating bronchoscope. Rather, the Hopkins rod telescope (removed from the bronchoscope) should be introduced independently into the airway to evaluate the stenosis. The initial bronchoscopic view is often sufficient to establish the diagnosis, thereby avoiding the risk of airway edema.

An estimate of the size of the airway is valuable. In a normal full-term neonate, the narrowest point of the airway is at the cricoid and should measure 4.5–5.5 mm. SGS is defined as an airway diameter of less than 4.0 mm (by comparison a 2.5 mm endotracheal tube has an outer diameter of 3.6 mm). Although the trachea should be of greater capacity than the cricoid, with CTRs the airway may be too small to easily permit safe passage of any form of instrumentation. For comparative purposes, the smallest Storz 2.5 ventilating bronchoscope has an outer diameter of 3.7 mm. The smallest available endotracheal tube with a 2.0 mm inner diameter has an outer diameter of 2.9 mm. The smallest 20017 Hopkins rod telescope (as found in the Storz 2.5 ventilating bronchoscope) has an outer diameter of 1.9 mm.

Because 50 % of children with CTRs have a tracheal inner diameter of approximately

2 mm at the time of diagnosis, the standard interventions for managing a compromised airway are not applicable. More specifically, the smallest (2.0 mm) endotracheal tube and the smallest tracheotomy tube (2.5 mm) cannot pass through the stenotic segment without severe damage to mucosa or tracheal rupture. And as the stenosis usually extends to carina, bypassing the stenosis risks bronchial intubation. This may leave extracorporeal membrane oxygenation (ECMO) as the only viable alternative for stabilizing the child in the event of decompensation following bronchoscopy. In an effort to avoid ECMO in a child decompensating and poorly ventilating, intubation proximal to the complete rings is advisable. The endotracheal tube should be sized to the cricoid, with the Murphy eye just below vocal fold level. Given that it is unusual for the proximal two tracheal rings to be complete, shallow intubation is achievable in most children with CTRs. A nasal intubation to allow tube stabilization (as it is so shallow) is advisable. Ventilation requires a long inspiratory and even longer expiratory phase to allow air to pass the stenosis, higher than typical ventilator pressures may be tolerated, as the stenosis ensures that the lungs are not exposed to the same pressures as the subglottis. Maintenance of high humidity levels is a key factor, as mucus accumulation may be lethal and is often heralded by rising CO_2 rather than low oxygen saturation. In a crisis, one mL of 1:10,000 epinephrine delivered down the endotracheal tube may assist ventilation. If possible, extubation is desirable, as most children with CTRs maintain ventilation more effectively themselves than on a ventilator. To prevent mucus accumulation, saline may be regularly nebulized if required.

In view of the high proportion of patients with other congenital anomalies, a thorough diagnostic investigation should include a contrast-enhanced computed tomography (CT) scan of the chest with three-dimensional reconstruction and an echocardiogram. These tests will identify any coexisting cardiovascular pathology, which should be repaired concurrently with the tracheal repair (Fig. 166.1). The most common cardiovascular anomaly is the PAS, though intracardiac anomalies and a the presence of a persistent left superior vena cava draining to the coronary sinus with absence of the innominate vein are also common. Other anomalies may be truly incidental (e.g., limb or CNS anomalies) or may also affect the airway. Nearly one third of children with CTRs have a tracheal (or pig) bronchus (Fig. 166.2); SGS is present in 20 % of cases. Rarely, CTRs may coexist with a tracheoesophageal fistula or laryngeal cleft. Peripheral pulmonary anomalies may also

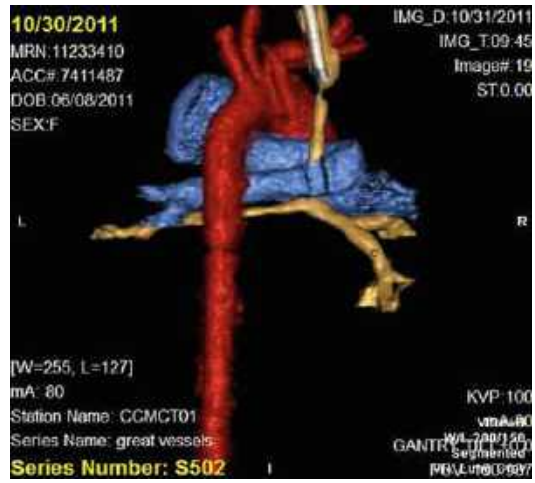

Fig. 166.1 CT with contrast enhancement and 3D reconstructions showing complete tracheal rings and a pulmonary artery sling

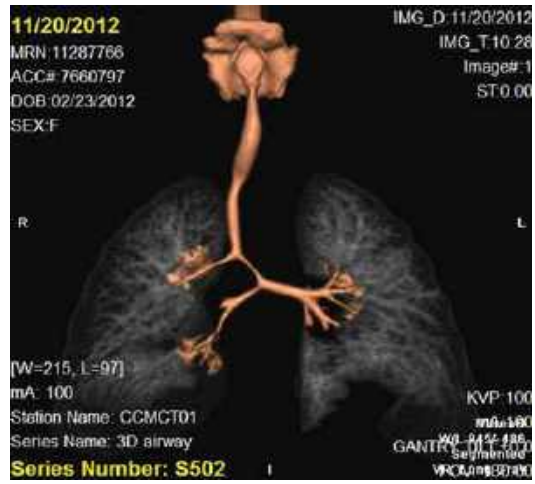

Fig. 166.2 CT of complete tracheal rings and a tracheal bronchus

occur, with subsegmental branching patterns almost universally aberrant, though of limited significance. Pulmonary hypoplasia or agenesis, more commonly affecting the right lung, is more significant, as it may cause mediastinal shift and aortic compression of the already stenotic trachea.

Although most children with CTRs require early tracheal reconstruction, 10–15 % of patients have sufficient tracheal growth to avoid the need for tracheal reconstruction. A further 10–15 % eventually outgrow their trachea and require late repair. The recommended surgical technique is the slide tracheoplasty. This approach yields significantly better results than any other tracheal reconstruction technique and is applicable to all anatomic variants of CTRs.

Most children with CTRs have distal tracheal involvement. If the distal one third of the trachea is involved or if there are coexistent cardiovascular anomalies that require repair, it is recommended to repair utilizing cardiopulmonary bypass. More than 90 % of children requiring slide tracheoplasty for CTRs fall into this category. If only the upper or mid-trachea is involved, repair may be performed with routine anesthesia through a cervical approach. Hyperextension of an infant's neck over a shoulder roll will allow good access to the upper two thirds of the trachea through a cervical approach. Exposure can be further enhanced through a limited upper sternotomy if required.

Although three decades ago this diagnosis carried a mortality rate as high as 50–80 %, a survival rate exceeding 90 % is now expected. In the current era of the slide tracheoplasty, a patient's prognosis is less about the trachea than about other coexisting anomalies.

Other Congenital Anomalies

While CTRs are rare (less than 100 births per year in the USA), other forms of congenital tracheal stenosis are even less common. Another noteworthy type of congenital tracheal stenosis is the *sleeve trachea* [4]. In this condition, the trachea is not composed of 15–20 separate tracheal rings, but of a single sheet of cartilage, which may extend proximally into the cricoid and distally into the bronchi. This is universally associated with one of the following craniosynostoses: either Pfeiffer syndrome, Crouzon syndrome, or Apert syndrome. Only a minority of patients with craniosynostosis have a sleeve trachea, and an even smaller minority have associated tracheal obstruction with the posterior aspects of the tracheal cartilage overlapping, effacing the trachealis muscle. In these cases, a slide tracheoplasty is still an effective reconstructive option although technically more challenging than a simple CTR repair. Of note, these patients typically have several levels of airway obstruction, from the choana to the bronchi, and a slide tracheoplasty may not prevent the need for a tracheotomy. In fact, in some children, it allows for the safe placement of a tracheotomy.

While congenital tracheal stenosis is usually a consequence of abnormal cartilage structure, a *congenital absence of cartilage* may present as tracheal stenosis or collapse [5]. This is also a rare condition that typically presents in an otherwise normal child with an isolated segment of trachea (usually just proximal to the carina) missing cartilage in a 2–3 ring segment (Video 166.1). Presentation is similar to complete tracheal rings, but bronchoscopically the stenotic segment lacks cartilage and is therefore distensible. While most of these children are otherwise normal, this entity may be associated with congenital left vocal fold paralysis and esophageal atresia. Repair may be achieved with either tracheal resection or with resection and a mini-slide tracheoplasty (short-segment slide tracheoplasty) (Video 166.2). While this condition usually affects the distal trachea, it may also affect the proximal right main bronchus, with the resultant ball-valving effect causing hyperinflation of the right lung, mediastinal shift, and collapse of the left lung. The bronchoscopic findings are characteristic (Fig. 166.3, Video 166.3), and reconstruction requires transection of the bronchial insertion at the carina, splitting the distal posterior wall of the bronchus and the proximal anterior wall of the trachea, and sliding the bronchus further up the trachea (Fig. 166.4, Video 166.4).

Video 166.2 Same patient as Video 166.1, following short-segment slide tracheoplasty

Vascular Compression

Vascular compression of the airway, particularly innominate artery compression, is not uncommon. In most cases, however, it is asymptomatic or minimally symptomatic. Although symptomatic vascular compression of the trachea or bronchi is rare, it is associated with marked symptoms, including biphasic stridor, retractions, a honking cough, and "dying spells." Symptoms tend to exacerbate when the child is distressed. Forms of vascular compression affecting the trachea include *innominate artery compression*, *double aortic arch*, and *pulmonary artery sling*. Vascular rings that result from a right aortic arch, retroesophageal left subclavian artery, and a left-sided ligamentum arteriosum are less likely to be associated with airway compromise. Bronchial compression by either the pulmonary arteries or aorta may be significant, but in the absence of associated major cardiac anomalies, it is typically a unilateral problem. The diagnosis of airway compression is best established with rigid bronchoscopy. Thoracic imaging then assists in determining the relevant vascular anatomy. Imaging modalities generally include high-resolution CT with contrast enhancement and three-dimensional reconstruction, MRI, magnetic resonance angiography (MRA), and echocardiography. Although imaging is used primarily to assess intrathoracic vasculature, excellent images of the airway and the thymus gland can also be obtained, and this comprehensive anatomic view will aid in planning surgical options.

In a child in whom vascular compression contributes to airway compromise, CPAP frequently offers a degree of temporary improvement, as segmental tracheomalacia may be present in the region of the vascular compression. In a neonate with acute airway compromise, intubation may be required to stabilize the airway prior to definitive treatment. Prolonged intubation should be avoided because of risk of forming an arterial fistula from erosion of an endotracheal tube into the area of compression. Similarly, while tracheotomy will establish an unobstructed airway, there is also an increased risk of an arterial fistula into the airway.

The surgical management of symptomatic vascular compression must be individually tailored to address specific pathology. Strategies for managing innominate artery compression include thymectomy and aortopexy; however, if little thymus is present, an alternative procedure is reimplantation of the innominate artery more proximately on the aortic arch. A double aortic arch requires division of the smaller of the two arches, which is usually the left.

The very high association of CTRs and a PAS should be acknowledged [6]. In the experience at Cincinnati Children's Hospital Medical Center, one third of children with CTRs have a PAS and

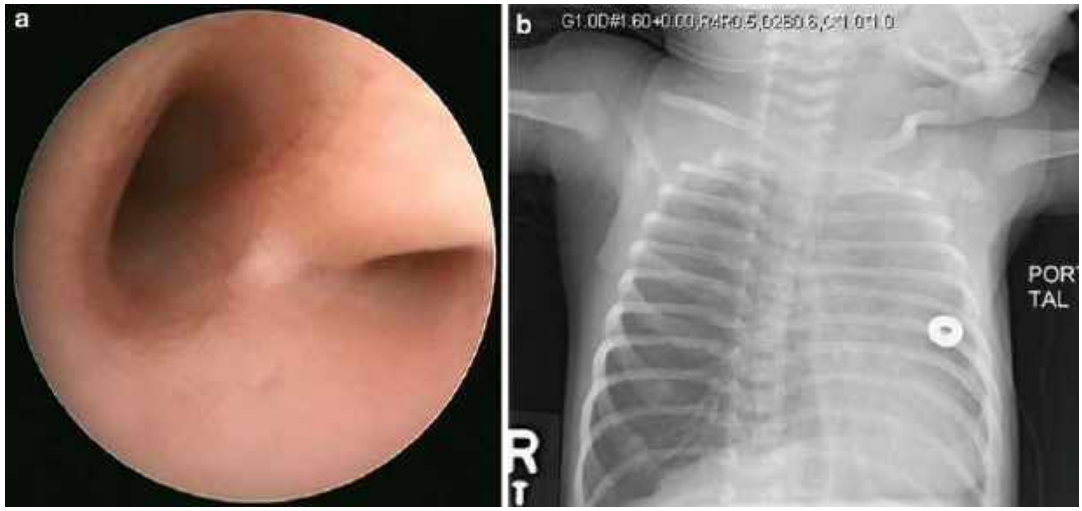

Fig. 166.3 (**a**) Right bronchial cartilaginous anomaly with ball-valving of the right main bronchus (**b**) CXR of same patient

Video 166.3 Right bronchial cartilaginous anomaly with ball-valving of the right main bronchus

over two thirds with a PAS have CTRs. Hence, *either diagnosis demands a preemptive evaluation for the other pathology*. While in the Cincinnati Children's Hospital Medical Center series [2] not all children with CTRs required operative reconstruction, all those with coexistent PAS have required it. In this institution, the preference is to repair both anomalies concurrently, with reimplantation of the left pulmonary artery onto the main pulmonary artery in a normal anatomic position anterior to the trachea. Children with right lung agenesis or severe hypoplasia are an exception to this. In these cases, it is advocated to transect the trachea and repair it (slide tracheoplasty) anterior to the PAS.

Although alleviating vascular compression improves the airway, it takes time for the airway to completely normalize. This is a consequence of long-standing vascular compression having adversely affected the normal cartilaginous development of the compressed segment of trachea, with resultant cartilaginous malacia or stenosis. Until the airway normalizes, children who are persistently symptomatic may require stabilization with a tracheotomy. Tracheal stabilization with the use of intratracheal stents is alluring, but the incidence of complications under such circumstances is nevertheless high [7]. Placement of a temporary tracheotomy is thus a more desirable alternative.

Tracheomalacia

Tracheomalacia is the most common congenital tracheal anomaly. Most children are either asymptomatic or minimally symptomatic, and most cases involve posterior malacia of the trachealis, with associated broad tracheal rings. Commonly associated abnormalities include

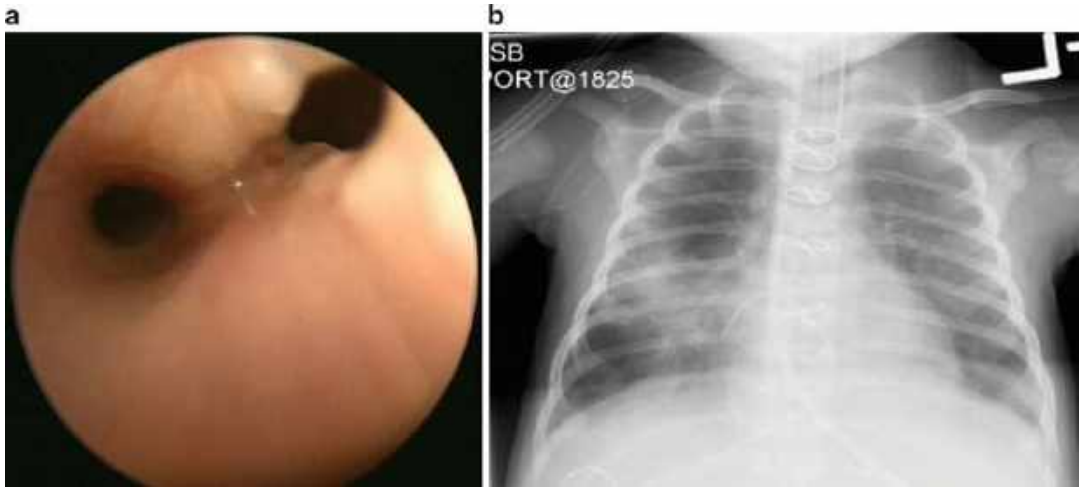

Fig. 166.4 (**a**) Patient in Fig. 166.3 following slide tracheobronchoplasty (**b**) Postoperative CXR of same patient

Video 166.4 Patient in Fig. 166.3 following slide tracheobronchoplasty

laryngeal clefts, tracheoesophageal fistulae (TEFs), and bronchomalacia. Presenting symptoms include a honking cough, wheezing, respiratory distress when agitated, and "dying spells." Diagnosis is established with rigid or flexible bronchoscopy, while maintaining spontaneous respiration. The key elements of diagnosis include (1) ascertaining the severity of the malacia; (2) ascertaining the location of the malacia, particularly the possible presence of associated bronchomalacia; and (3) determining whether positive pressure support improves the malacia. Management is symptom driven, not based on bronchoscopic appearances. Although mild tracheomalacia is watched expectantly and anticipated to improve with time, more severe symptoms warrant intervention [8]. Tracheotomy placement, with the tip of the tracheotomy tube bypassing the malacic segment, remains the most common intervention. Positive pressure support delivered down the tracheotomy tube assists with associated bronchomalacia. An alternative surgical procedure for isolated tracheomalacia is aortopexy, with thymectomy and anterior suspension of the aortic-innominate artery junction to the posterior periosteum of the sternum. As with tracheomalacia following surgery to alleviate vascular compression, the placement of intratracheal stents is discouraged.

Acquired Tracheal Stenosis

Acquired tracheal stenosis is usually a consequence of intubation or trauma. In some cases, it may occur at a tracheotomy site. It is therefore usually a problem affecting the cervical trachea and amenable to a cervical approach if reconstruction is required. Reconstructive techniques include costal cartilage grafting, tracheal resection, and cervical slide tracheoplasty. Given that these techniques are discussed in a specific chapter in this

textbook (the management of SGS), they will not be described herein.

The Child with a Tracheotomy

In a child with a tracheotomy, cardiac surgery may be required irrespective of the trachea. However, a chronic tracheotomy site may harbor a high bacterial count and may be an undesirable infective risk close to a proposed sternotomy site. Often the tracheotomy may be temporarily closed so that the site may be isolated from the sternum. Before closing off a stoma and intubating orally from above, airway evaluation is essential. If the airway is normal, a cuffed endotracheal tube may be placed nasally or orally, with the cuff lying just distal to the tracheotomy site. The tracheotomy site may be temporarily closed with either a purse-string suture or quilting sutures, but this should be done with a sponge or iodoform gauze packing in the tracheostoma (but not in the trachea). This allows the tracheotomy to be easily replaced a few hours or days later, as without stenting the stoma open, it may rapidly shrink or even close, requiring a revision tracheotomy to replace the tracheotomy tube.

If, however, SGS is present, a smaller endotracheal tube is required that will not exacerbate the stenosis. Alternatively, intubation through the tracheostoma may be required. Stenosis of the upper trachea, usually at the tracheotomy site, may present similar problems.

The stoma site should also be evaluated for the presence of a suprastomal granuloma. If ignored, intubation from above risks both bleeding and avulsion with displacement of the granuloma distally into a bronchus. It is better to identify and remove the granuloma prior to intubation, preferably electively prior to cardiac surgery.

Reconstructive Techniques

Technical Approach

Endoscopic techniques such as balloon dilation rarely have a role in the treatment of congenital tracheal stenosis. More specifically, they are contraindicated in the management of CTRs, as the risk of tracheal rupture is high. Balloon dilation may, however, have a role after reconstruction if restenosis occurs.

With open surgery, while standard anesthetic techniques or jet ventilation techniques may allow access to the distal trachea without relying on cardiopulmonary bypass, it may be preferable to use the latter, as it allows the heart and lungs to be partly deflated to enhance exposure of the distal airway.

There are several methods for repair of CTRs, and the approach to the management of this anomaly has evolved over the last 25 years. A brief overview of popular surgical techniques that have historically been used is presented below [9].

Tracheal Resection

Tracheal resection is excellent for treating short-segment CTRs involving less than one third of the trachea. It is also excellent for treating acquired stenosis of the trachea.

Nonetheless, two precautions should be mentioned. Firstly, there are often more CTRS noted when the airway is actually opened than were noted during the endoscopic evaluation. Secondly, more caution is required with resections involving the distal third of the trachea, as it is important trying to avoid an anastomosis close to the carina. This is because any anastomotic problems may ultimately require placement of a tracheotomy tube, and the tip of the tracheotomy tube must lie between the anastomosis and the carina, which may be problematic if there is only 2–3 mm between the anastomosis and carina. Another potential disadvantage of this technique is that a direct, end-to-end anastomosis concentrates the reconstruction in a very short segment of airway, thus concentrating the risk of restenosis to a single zone on a small airway.

Cartilage Graft Tracheoplasty

Cartilage graft tracheoplasty was an early technique for managing CTRs, yielding results that were unpredictable. In the neck, cartilage graft laryngotracheal reconstruction is very effective as the cartilage grafts survive well, deriving their blood supply from overlying strap muscles. However, intrathoracic cartilage grafts have less

access to a muscle-derived blood supply and a much higher risk of graft loss.

Anterior Pericardial Patch

The anterior pericardial patch was the workhorse of tracheal reconstruction for many years. It is effective in children with moderate stenosis; however, in children with severe stenosis, the choice is between a narrow patch resulting in an airway that is wider but still stenotic or a wider patch with resultant anterior malacia of the patch. Pericardial patches also tend to granulate, and many months of bronchoscopic debridement may be required postoperatively.

Tracheal Autograft Patch

The tracheal autograft patch is an elegant operation conceived by Carl Backer [10]. This technique involves resecting the middle third of a segment of CTRs, anastomosing the upper and lower ring segments, and splitting these remaining rings anteriorly. The resected segment of rings is then laid open and used as an anterior graft through the remaining rings. While conceptually superior to the pericardial patch, in practice there was still a significant incidence of restenosis.

Slide Tracheoplasty

The reconstructive techniques described above have been replaced by the slide tracheoplasty (Figs. 166.5 and 166.6; Videos 166.5 and 166.6). This operation is a watershed in the management of CTRs, as the outcomes have significantly improved. The operation was conceived by Goldstraw [11] in the 1980s and popularized by Grillo [12] in the 1990s. It was originally designed as an operation to repair congenital tracheal stenosis caused by CTRs (Fig. 166.7, Video 166.7). Most infants presenting with this anomaly have long-segment stenosis, with the most severe stenosis being in the distal trachea. Although the slide tracheoplasty may be performed using ECMO or jet ventilation, at Cincinnati Children's Hospital Medical Center, it is preferred to use cardiopulmonary bypass to facilitate the repair

Fig. 166.5 Complete tracheal rings

[2, 13, 14]. Aside from the advantage of not requiring ventilation during the procedure, access is also enhanced, as the lungs and heart may be relatively "deflated." Typically, a sternotomy allows for exposure of the trachea, placement of atrial and aortic cannulae, and repair of any coexisting cardiovascular anomalies. Removal of the carinal lymph nodes facilitates tracheal exposure and mobilization. The extent of the tracheal stenosis is then assessed. The assessment usually requires bronchoscopic examination of the airway while a 30 gauge

needle is placed into the trachea from the mediastinal side; this allows the proximal and distal extent of the stenosis to be precisely identified within the chest. The length of the stenosis is then measured and its midpoint is marked. Next, the trachea is transected at or just proximal to the midpoint of the stenosis, with the transection being slightly bevelled (anterior proximal to posterior distal). The transected trachea is mobilized by dissecting free the soft tissue attachments between the trachea and the esophagus of both the proximal and distal segments. Care is taken to preserve some lateral attachments to maintain a blood supply as well as to protect the vagus and recurrent laryngeal nerves. The distal segment is split posteriorly through all complete rings (to carina or down a bronchus if required), and the proximal segment is split anteriorly through the area of stenosis and into normal trachea. At the split, the trachea may be trimmed to round off either end at the transection margins to facilitate the closure. The anastomosis is commenced from distal posterior (carinal) in a running fashion using appropriate sized double-armed PDS sutures (usually 6-0 PDS in infants). Four to six throws of the suture are generally placed at the carina and tightened with a nerve hook. The anastomosis is then continued up the left and right sides of the trachea, with the sutures placed through cartilage and mucosa, therefore being exposed intraluminally. An effort is made to evert the lateral sides of the anastomosis to prevent internal bunching of the anastomotic lines (a "figure 8" trachea). Before the anastomotic suture lines rejoin in the midline at the proximal anterior aspect of the repair, the trachea is suctioned clear. The anastomosis is completed with a single proximal knot being thrown, leak tested (to 35 cm water pressure), and marked with Ligaclips applied to the proximal and distal ends of the anastomosis (for aid in radiographic positioning of the endotracheal tube). Fibrin glue is then applied to the anastomosis. The patient is reintubated and taken off cardiopulmonary bypass, and the chest is closed. At completion of the procedure, the airway is reevaluated with a flexible bronchoscope to ensure that the repair is adequate and that blood and secretions are suctioned. A 2.8 mm flexible bronchoscope with a suction port can be placed into a 3.5 mm endotracheal tube and still allow for ventilation during the evaluation. If the patient's cardiovascular status permits, extubation is usually achieved within 24 h [14].

The slide tracheoplasty is a versatile procedure [2]. If required, it is possible to slide the entire length of the trachea; slide down a bronchus; slide into the anterior cricoid; or slide past a tracheal (pig) bronchus. The intrathoracic slide tracheoplasty may also be used to repair stenosis

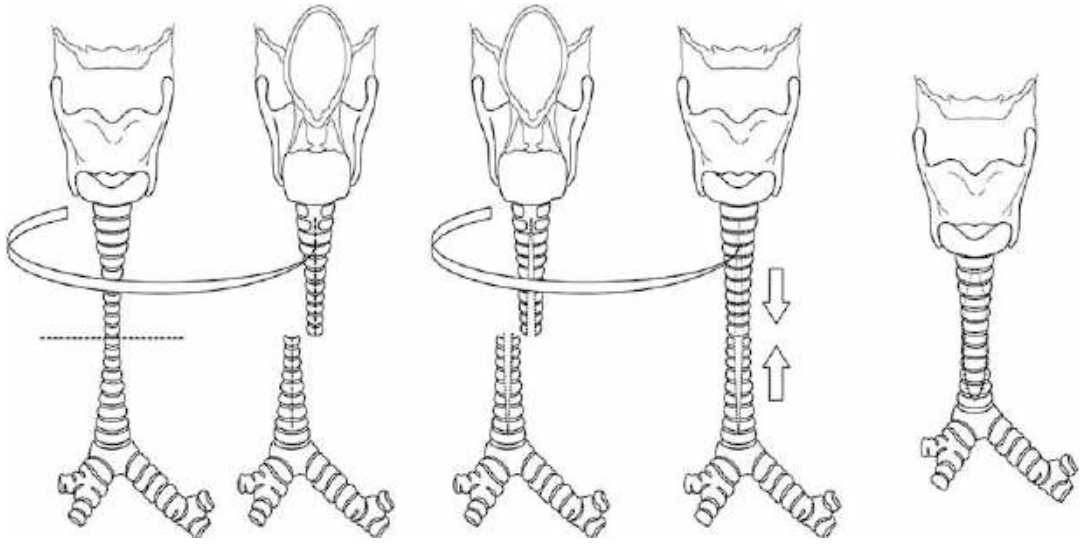

Fig. 166.7 Slide tracheoplasty

Video 166.7 Technique for the slide tracheoplasty

associated with absent tracheal rings, a sleeve trachea, or distal tracheoesophageal fistula repair. In addition, it may be used to repair an acquired tracheal stenosis.

The success of the intrathoracic slide tracheoplasty for long- or short-segment tracheal stenosis prompted the Cincinnati Children's Hospital Medical Center team to use this technique to manage tracheal stenosis involving the more proximal trachea [15]. The upper half to two thirds of the trachea is accessible through a cervical approach, and the slide tracheoplasty is an effective method of repairing upper trachea acquired stenosis, often in conjunction with partial

resection of the most severely stenotic tracheal segment. The technique is similar to the intrathoracic slide, with the anastomosis commencing at the distal posterior aspect of the repair. In older children with a more proximal stenosis, the risk of developing a "figure 8" trachea is higher, and a temporary intrathoracic silicone stent may be placed for a week or more if required.

Postoperative Care

Following tracheal repair the aim is to extubate a child within 24–96 h. During this time it is important to try to avoid positive pressure ventilation so as not to threaten the anastomosis. Chest drains are ideally left in place until after the extubation. Some children may preoperatively present extremely unstable and ventilated and in very rare cases even on ECMO support. In this circumstance, postoperative ECMO may be required. The aim is to establish endotracheal ventilation and remove the child from ECMO as rapidly as possible.

Outcomes

Tracheal reconstruction, especially for CTRs, carries a significant complication rate and failure rate. Forty years ago, the mortality rate was over 50 % with or without surgery. Following reconstruction, regardless of surgical technique, the incidence of restenosis, granulation, and tracheotomy was over 30 % in the survivors. As techniques improved, mortality and morbidity rates steadily dropped. The greatest change, however, came with the slide tracheoplasty. Previously, outcomes were influenced by length of stenosis, severity of the stenosis, whether the carina was involved, and bronchial stenosis. Currently, the mortality rate is close to 10 %, and quite unlike the past, it is no longer the trachea that is the primary determinant of outcome but rather the overall health status of the child [2]. A significant proportion of children born with CTRs also have other significant health issues that a slide tracheoplasty does not address. These issues have become the dominant influence on long-term outcome. Bronchial stenosis, lung agenesis or hypoplasia, and complex cardiac disease are now the most significant issues affecting outcome [16].

While there are complications associated with slide tracheoplasty, these are mostly not of long-term consequence. The "figure 8" trachea (lateral bunching of the anastomosis) seen in the majority of patients tends to spontaneously resolve over subsequent months in most patients and rarely causes obstruction or requires intervention. Recurrent laryngeal nerve palsy occurs in less than 20 % of patients and is usually unilateral and transient. Restenosis is rare, as is anastomotic dehiscence. Restenosis is more likely to occur at the proximal end of a slide tracheoplasty when a tracheal bronchus is present at this apex; it may be prevented by extending the slide 2 or 3 rings higher, proximal to the tracheal bronchus, into normal trachea. However, the slide tracheoplasty is clearly an operation with a learning curve, and the best results are achieved with a team approach at a center of excellence [17].

Revision Surgery

Should restenosis occur following any form of tracheal reconstruction, the challenges of surgery are greatly magnified. Surgical management options may be endoscopic or open and will depend not only on the presenting anatomy but also on the history and timing of past surgery. Endoscopic management includes cautious balloon dilation, temporary stent placement (hollow silicone or expandable wire), and the use of topical medications to hamper granulation reformation (e.g., nebulized steroids and antibiotics). Stent placement should always be performed with circumspection, as stents have the potential to induce as many problems as they resolve. Children with intratracheal stents should therefore be frequently monitored with surveillance bronchoscopy.

Despite endoscopic salvage techniques, open revision surgery may be required. This is influenced by the length of the trachea (previous resection), posterior mobilization of the trachea (anterior graft or pericardial patch vs. resection or slide tracheoplasty), cartilage loss (infection may have damaged cartilage), and timing from 3 to 9 months postoperatively revision surgery is most challenging due to fibrosis). When revision surgery is required, slide tracheoplasty is still the operation of choice. Nevertheless, an individualized approach is prudent.

The loss of cartilage remains the greatest challenge. Although a slide tracheoplasty may be able to introduce cartilage to an area deficient in cartilage, if an area of no cartilage is slid into an area of no cartilage, while the lumen may be adequate, severe tracheomalacia is inevitable. Under these circumstances, tracheal homografting or transplantation to introduce new cartilage is a viable alternative. Currently, despite the media frenzy surrounding a few highly publicized cases, tracheal homografting should remain an operation of last resort when standard techniques such as slide tracheoplasty have failed or where there is severe cartilage loss (e.g., tracheal agenesis). Tracheal homografting was originally described in [18] utilizing acellular trachea preserved in formalin and acetone. Prolonged periods of stenting were required to support the graft, and results were inconsistent. Current models involve implanting a synthetic scaffold or a scaffold of acellular donor trachea that was pre-seeded with the patient's own respiratory epithelium in a bioreactor prior to implantation. Longer grafts require a blood supply, typically an omental flap. Issues regarding the ideal "cocktail" of preimplantation growth factors, the ideal time in a bioreactor for epithelial cell adhesion, the preferable scaffold, and the need for a blood supply remain unresolved. Furthermore, acellular scaffolds do not grow and revision surgery is therefore inevitable in a young child. The potential benefit of a pre-epithelialized trachea scaffold is nevertheless enormous and may represent the next paradigm shifting advance in the surgical management of tracheal stenosis [19].

Extra-Cardiac Issues and Complications

Jonathan Kaufman and Steven Choi

Mechanical Ventilation, Cardiopulmonary Interactions, and Pulmonary Issues in Children with Critical Cardiac Disease

167

William L. Stigall and Brigham C. Willis

Abstract

The respiratory care of the child with critical heart disease has profound effects on overall outcome. While often simplified or ignored, a focus on the intricacies and vagaries of pulmonary issues and their management can help pediatric cardiac surgical patients. The intent of this chapter is to describe specific pulmonary and ventilatory issues that arise most frequently during the care of a child with critical heart disease. First, a thorough description of the relevant cardiopulmonary interactions involved in caring for the ventilated patient with critical heart disease is attempted, including the effects of positive pressure ventilation on both right and left heart performance, as well as detailed information on the effects of blood gas manipulation on cardiac and circulatory function. Second, practical management strategies for patients with specific cardiac conditions are described, including the management of patients with cardiopulmonary bypass-induced lung injury, passive pulmonary circulation, open sternum, pulmonary hypertension and right ventricular dysfunction, tetralogy of Fallot with absent pulmonary valve, diaphragmatic injury, and others. Finally, specific, practical, evidence-based management strategies are provided for ventilator management, ventilator

Introduction

For children with critical heart disease, the appropriate and thoughtful management of mechanical ventilation along with general pulmonary care is essential. While a comprehensive discussion of pediatric pulmonary care, general principles of mechanical ventilation, and basic respiratory physiology is beyond the scope of the current discussion, the intent of this chapter is to describe specific pulmonary and ventilatory issues that arise most frequently during the care of a child with critical heart disease. By doing this, it is hoped the reader will focus on the essential and unique aspects of ventilation seen commonly in this incredibly specialized patient population, without rehashing basic principles already discussed much more eloquently and in depth in general pediatric, critical care, and pulmonary sources [1–3]. Evidence suggests it may be the most important factor in determining a number of patient outcomes, including length of stay; as such, a thorough understanding of the nuances of the cardiopulmonary interactions in the child with critical heart disease, along with a strong practicing knowledge of mechanical ventilation and modern pulmonary care, truly is essential to optimizing patient outcomes.

Cardiopulmonary Interactions

"Cardiopulmonary interaction" primarily refers to the relationship between airway pressures, lung volumes, and cardiac output. In the postoperative cardiac patient, this is practically seen in asking the question, "How does manipulation of the ventilator augment or diminish cardiac output?" Ventilator manipulation may also be understood in terms of responses to and goals for blood gas values, to which a further set of cardiopulmonary interactions would be queried: the effects of CO_2, O_2, acidemia, and alkalemia on preload, afterload, contractility, and vascular resistances. Below, the relevant cardiopulmonary interactions are reviewed, and an outline of how they affect the care of the child with critical heart disease is provided.

Airway Pressures, Lung Volumes, and Cardiac Output

Cardiac output (CO) is the combination of stroke volume (SV) and heart rate (HR) [4]. SV is determined by a ventricle's preload, afterload, and contractility. That is, how much blood is ejected in each heartbeat (SV) is a function of the volume of the ventricle at end systole (preload), how much force is generated by the myocardium in

systole (contractility), and the force resisting blood flow (afterload) out of the ventricle(s). Both static and dynamic processes of mechanical ventilation will affect CO; in addition, the effects of increasing or decreasing intrathoracic pressure (ITP) may have divergent effects on the right and left heart, respectively. Thus the beneficial or detrimental effect of mechanical ventilation is generally dictated by the response of the more severely affected ventricle. The static application of positive end-expiratory pressure (PEEP) will affect both right and left ventricular (RV and LV) preload and afterload [4]. The dynamic insufflation of tidal volumes (Vt) will also affect RV preload (and therefore LV preload), RV and LV contractility, and RV and LV chronotropy [5]. Each of these effects will be considered in turn.

The Effects of Positive Pressure Ventilation on RV Preload

Functionally, RV preload is the venous return from the systemic circulation and is determined by the pressure difference between the upstream mean systemic circulatory pressure (Pms) and the downstream right atrial pressure (RAP). This was classically shown by Guyton in dogs in 1957 [6] and verified recently in humans with intact circulation [7]. PEEP increases RAP by increasing ITP. The increase in RAP will then cause a decrease in the difference between Pms and RAP and therefore a decrease in the driving pressure for venous return [4]. As a result, positive pressure ventilation will decrease RV preload.

Despite this, a number of caveats are necessary to show why positive pressure ventilation and systemic venous return do not have an absolute linear relationship. First, ITP is not a pressure, per se, but can refer to any and all of a number of pressures during the respiratory cycle. The immediate surrounding pressure of the RA is the pericardial pressure, which is itself influenced by the pleural pressure, which is often estimated by the esophageal pressure. Despite the fact that these various pressures generally move in the same direction, airway pressures are not uniformly transmitted to the pericardial space. Despite this fact, the primary determinant of pleural pressure and pericardial pressure during positive pressure ventilation is lung volume; therefore, the simplification of understanding changes in airway pressures as determinative of changes in ITP is appropriate. Second, PEEP has been shown to increase Pms in canine models, thus obviating at least some of the effects of raising RAP [8]. Lastly, RV preload is the volume at the end of diastole. RV end-diastolic pressure (RVEDP) is related to this volume via the compliance of the ventricle. RAP as a measure of RV preload is inaccurate by another order of approximation, in that RAP and RVEDP are related but are not equivalent. How easily the ventricle fills is determined by the configuration of the ventricle at the end of systole and will change through diastole depending on the physical properties of the cellular structures that make up the ventricular wall and the efficiency of the active cellular processes involved in relaxation [9, 10].

The Effects of Positive Pressure Ventilation on RV Afterload

RV afterload is the load that RV cardiac myocytes must overcome to contract [11]. Pulmonary artery pressure (and pulmonary vascular resistance (PVR) in the setting of normal cardiac output) is the common metric of RV afterload. PEEP affects PVR in at least four ways. First, as described above, PEEP affects RV cardiac output by affecting RV preload [4], and PVR will be related to CO via Ohm's law. Second, PEEP affects end-expiratory lung volume (EELV) which affects PVR [2]. PVR is related to EELV in a "U"-shaped curve whereby elevated PVR is found at the extremes of EELV (toward both residual volume and total lung capacity) and is minimized when EELV is at functional residual capacity (FRC). This bimodal distribution is created by opposite effects of lung expansion on the resistance of intra-alveolar vessels compared to extra-alveolar vessels. As shown in Fig. 167.1, total pulmonary vascular resistance

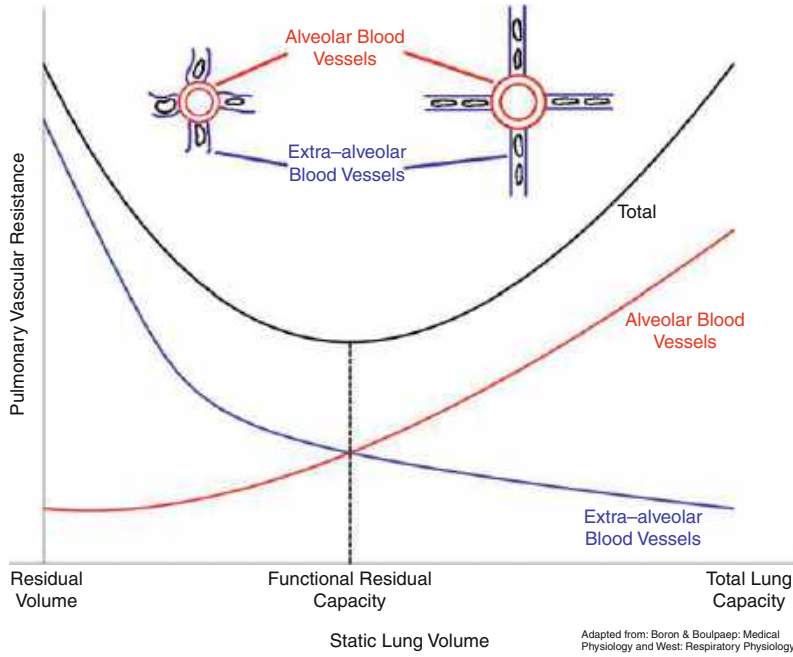

Fig 167.1 The U-shaped relationship between end-expiratory lung volume (EELV) and pulmonary vascular resistance (PVR). *Blue* = extra-alveolar blood vessels. *Red* = alveolar blood vessels. Total PVR is the sum of extra-alveolar and alveolar vascular resistances. The lowest PVR will be found when EELV is equal to functional residual capacity (FRC)

is the sum of the vascular resistances of alveolar and extra-alveolar vessels. Third, PEEP is frequently applied for the purposes of alveolar recruitment. As alveoli are exposed to intra-alveolar oxygen, hypoxic vasoconstriction of alveolar vessels will be diminished, thus decreasing their contribution to pulmonary vascular resistance [4]. Finally, a remarkable feature of the pulmonary vascular bed is the ability for PVR to diminish in the face of higher pulmonary artery pressure, thereby allowing increased CO [2]. This phenomenon occurs due to closed pulmonary capillaries being recruitable and distensible when faced with higher upstream pressures. Recruiting of pulmonary vessels occurs when previously closed pulmonary capillaries are opened by higher pressures. The recruitment of previously closed capillaries increases the total volume available for RV CO and thus reduces resistance to flow. Distension of already open pulmonary vessels occurs as the pulmonary capillaries stretch in response to higher pressures, thus allowing greater flow at reduced resistance. If PEEP induces a decrement in RV preload and RV output, then pulmonary capillaries may be de-recruited and lose distension, both tending to increase total PVR. Therefore, PVR is minimized when all lung segments are fully recruited and maintained at FRC.

The Effects of Positive Pressure Ventilation on LV Preload

Left ventricular preload is determined by the pressure differentials between the pulmonary venous system and the LA/LV, as well as resistance to flow ($Q = P/R$). The RV CO will necessarily become LV preload following circulation in the pulmonary vascular system in the absence of intracardiac or intrapulmonary shunt. Thus the effects of PEEP on RV CO will affect LV preload within several cardiac cycles. In addition, the phenomenon of ventricular interdependence may allow direct reduction in LV volume by increases in RV volume and thus impair LV compliance [4]. Ventricular interdependence refers to the changes in the size, shape, and compliance of one ventricle that may affect the other through direct mechanical distortions [11]. Diastolic ventricular interdependence occurs when RV overdistension causes the interventricular septum to bow into the LV. This causes the LV volume to

decrease, thereby reducing LV compliance. The reduction in LV compliance will decrease LV preload at a given filling pressure.

The Effects of Positive Pressure Ventilation on LV Afterload

LV afterload is the force opposing the shortening of the LV cardiac muscle fibers and is determined not only by systemic vascular resistance (SVR) but also by LV chamber pressure, dimension, and wall thickness [12]. In cases of spontaneous respiration, ITP becomes negative on inspiration and creates an opposing force to systolic contraction, thus increasing afterload. The opposite occurs with the application of positive pressure, as ITP remains positive throughout the respiratory cycle. During systole, positive ITP will assist systolic contraction and thereby reduce afterload [4].

Lung Volumes and Ventricular Contractility

Ventricular contractility is determined by preload-dependent and preload-independent variables [13]. Preload-dependent variables determining ventricular contractility are those described in the Frank-Starling mechanism: increases in preload will result in increases in contractility of cardiac muscle, up to a point. The reverse is also true: decreases in preload result in decreases in contractility. These preload-dependent mechanisms will be affected by PEEP.

Preload-independent variables determining ventricular contractility are primarily a function of calcium regulation within and without the cardiomyocyte sarcoplasmic reticulum. Sympathetic and parasympathetic nervous regulation and endogenous and exogenous inotropic agents all have calcium as their final common pathway. These preload-independent mechanisms will not be affected by PEEP, but they will be affected by Vt and thoracic pressures by their activation of lung stretch receptors, which in turn affect chronotropy, inotropy, and systemic vasodilation.

Lung stretch receptors via vagal afferents can activate a "lung-inflation vasodepressor reflex" whereby lung stretch induces dilation of systemic vessels, bradycardia, and negative inotropy [5]. These reflexes have been implicated in explaining the nonlinear fall in CO associated with linear increases in PEEP implying that another mechanism is at work [14]. In addition, these reflexes have been implicated in explaining differential improvements in hemodynamics of respiratory failure patients with and without heart failure when ventilated with high-frequency jet ventilation (HFJV) compared to conventional ventilation [15]. It was found that for patients with respiratory failure but *without* heart failure, HFJV offered improvements in CO over conventional ventilation only when HFJV mean airway pressure (Paw) was less than conventional Paw. In patients with *both* respiratory failure and heart failure, HFJV patients had improvements in CO even at the same Paw as conventionally ventilated patients. The authors concluded that small Vt swings utilized in HFJV did not engage the lung stretch receptors as vigorously as conventional ventilation, thereby limiting the lung-inflation vasodepressor reflex associated with the larger Vts.

Summary of Positive Pressure Ventilation (PPV)-Induced Cardiopulmonary Interactions

Table 167.1 provides a summary of the cardiopulmonary interactions induced by positive pressure ventilation. How these myriad interactions will bear out in patients depends on respiratory and cardiovascular disease states [16]. In patients with systolic heart failure and fluid overload, the reduction in LV afterload will dominate: the patient will not be preload sensitive given their congested state, and the reduction in work of breathing will also decrease demand for oxygen delivery. In patients with lung disease characterized by hypoxia and poor airway compliance, the decreases in RV preload and contractility will dominate: the patient may be very preload sensitive, and the elevated PEEP and lung stretch required to ventilate and

Table 167.1 Positive pressure ventilation-induced cardiopulmonary interactions

RV preload	RV afterload	LV preload	LV afterload	Contractility
Decreases	Depends on:	Depends on:	Decreases	Decreases
	EELV relation to FRC	RV cardiac output		As a preload-dependent determinant of contractility
	Effects of recruitment and distension of pulmonary vasculature	Ventricular Interdependence		Vt decreases contractility and chronotropy via lung-inflation vasodepressor reflex
	Recruitment of alveoli, thereby limiting hypoxic vasoconstriction			

oxygenate will cause greater reflex negative inotropy. In patients with lung disease and heart disease, the effects will depend on the relative states of pathology in the patient. For example, use of high-frequency ventilation to avoid large Vt pressure changes may improve cardiac output [15]. However, RV dysfunction can be induced or worsened if the use of high-frequency ventilation results in higher Paw than produced with conventional ventilation [17]. Overall, a thorough understanding of the above-described physiologic mechanisms is needed, and must be applied to each individual patient in a unique way, given their specific clinical situation.

Cardiopulmonary Interactions: O_2, CO_2, and pH Effects on Preload, Afterload, and Contractility

A second approach to cardiopulmonary interactions is to ask what sort of relationship there is between respiratory gases, acid–base balance, and hemodynamics. This will be addressed below.

Physiologic Effects of Changes in $PaCO_2$

An important caveat when discussing the effects of carbon dioxide (CO_2) on airways and vasculature is that it is difficult to tease out which physiologic changes are direct effects of CO_2, direct effects of acidosis, and indirect effects of either or both.

Pulmonary Effects of CO_2

Hypercapnic acidosis (HCA), primarily as a function of acidosis, decreases pulmonary compliance by increasing surfactant secretion [18]. There are conflicting reports on the effects of HCA on pulmonary vascular tone likely depending on whether the pH changes of elevated CO_2 were buffered [19]. Acidemia causes increased pulmonary vascular tone and thereby increased pulmonary vascular resistance (PVR), whereas alkalemia causes decreased PVR. This effect is useful in that acute hypocapnia is an effective (temporary) response to pulmonary hypertensive crises to decrease PVR and RV work. Hypercapnia improves ventilation-perfusion (V/Q) matching [18] by inhibiting conducting airway tone and thereby improving CO_2 removal while at the same time decreasing alveolar blood flow to underventilated alveoli by increasing pulmonary vascular tone. This combination improves V/Q matching but may exacerbate pulmonary hypertension. Conversely, hypocapnia can cause bronchoconstriction, decrease pulmonary compliance (and therefore effective tidal volume), reduce collateral ventilation, and reduce hypoxic

pulmonary vasoconstriction, thereby increasing intrapulmonary shunt and worsening V/Q matching.

Cardiovascular Effects of CO_2

Hypercapnia increases CO by increasing both contractility and preload while decreasing afterload. CO_2 directly inhibits cardiac contractility, but this is countered by sympathoadrenal reflex stimulation of heart rate and contractility [18]. The sympathoadrenal reflex to hypercapnia increases preload by stimulating increases in systemic venous return. Hypercapnia decreases afterload by arteriolar vasodilation. In addition, hypercapnia protects against ischemic-reperfusion injury following cardiopulmonary bypass by inhibiting calcium-mediated injury and stimulating coronary vasodilation. Hypocapnia induces opposite cardiovascular effects of hypercapnia: decreased CO via decreased contractility, decreased preload, and increased afterload. Hypocapnia is potentially arrhythmogenic due to increased risk of coronary vasospasm. Hypocapnia worsens ischemic injury and abolishes the protective effects of preconditioning [19].

Central Nervous System Effects of CO_2

Hypercapnia stimulates ventilatory drive, attenuates hypoxic-ischemic brain injury via anti-inflammatory effects to be discussed below, and increases cerebral blood flow. This last effect is an effect of acidemia rather than hypercapnia, per se. Hypocapnia increases brain injury following hypoxia-ischemia through at least two mechanisms. First, neuronal excitability and transmission are increased leading to increased O_2 consumption and uncoupling of metabolism to cerebral blood flow. Second, hypocapnia is directly neurotoxic via changes in cell membrane permeability. That said, hypocapnia may be useful in cases of impending brainstem herniation due to elevated intracranial pressure. However, prophylactic and prolonged hypocapnia has been shown to worsen outcome [19].

Tissue Oxygenation Effects of CO_2

Overall, hypercapnia increases O_2 supply and decreases demand at the tissue and cellular level. Hypercapnia causes a rightward shift of the oxyhemoglobin dissociation curve facilitating release of oxygen to tissues via the Bohr effect, suppresses cell metabolism, and leads to less O_2 consumption as well as less glycolysis in anaerobic conditions as seen by less lactic acid production [19]. In addition to these cellular effects, hypercapnia up to 150 mmHg will increase microvascular flow [20]. Hypocapnia reverses these effects.

Immunomodulatory Effects of CO_2

In addition to the hemodynamic and cardiovascular effects, changes in CO_2 have been shown to have significant immunomodulatory consequences. Hypercapnia attenuates lung PMN recruitment, pulmonary and systemic cytokine levels, and free radical injury. These effects are seen in both infectious and noninfectious causes of ALI/ARDS. Via similar mechanisms, hypercapnia decreases severity of ventilator-induced lung injury and inhibits hypoxic pulmonary vascular remodeling. Hypocapnia increases pulmonary edema by increasing microvascular permeability and impairing alveolar fluid resorption. In acute sepsis and pneumonia, CO_2 immunomodulation is protective against injury and infection; however, in prolonged sepsis, there is a concern that reduced bacterial killing may potentiate infection. It should be noted that the immunomodulatory effects of hypercapnic acidosis have been shown to be less clinically significant when using lung-protective strategies of ventilation (Vt 6–8 mL/kg) compared to larger

Vt (12 mL/kg) presumably because of less inflammation due to volutrauma [19].

Physiologic Effects of Changes in PaO_2

Hyperoxia and hypoxia cause differential effects when found in the systemic and pulmonary circulations and therefore are discussed individually.

Effects of Hyperoxia on the Systemic Circulation

Hyperoxia causes acute reduction in resting heart rate and cardiac index and increases in mean arterial pressure (MAP), SVR, and large artery stiffness [21]. In a dose-dependent manner as measured by cardiac MRI, hyperoxia causes decreases in LV perfusion, cardiac output, and heart rate. Despite an increase in total blood oxygen content (CaO_2), the hemodynamic changes induced by hyperoxia actually caused systemic and coronary O_2 delivery to fall [22]. Similar changes in hemodynamic variables (increases in MAP, SVR; decreases in CI and stroke index) have been observed in children with congenital heart disease [23].

Hyperoxia-induced vasoconstriction has been implicated in decreases in O_2 delivery to the cerebral, coronary, and renal circulations, among others [24]. Potential explanatory mechanisms implicated in hyperoxic vasoconstriction include generation of reactive oxygen species that decrease bioavailability of the vasodilator NO, changes in endothelial potassium and calcium channels leading to direct vasoconstriction, and release of vasoconstrictors such as angiotensin I and 20-HETE [25].

A large retrospective study of adults following cardiac arrest showed hyperoxia to be a significant independent risk factor for in-hospital mortality in a dose-dependent fashion. A 100 mmHg increase in PaO_2 was associated with a 24 % increase in overall mortality [26]. A retrospective analysis of 1875 PICU patients having suffered cardiac arrest also found an increase in mortality associated with hyperoxia (odds ratio up to 1.25), although this risk was less than that associated with hypoxia (odds ratio up to 1.92) [27].

The Effects of Hyperoxia on the Pulmonary Circulation

Hyperoxia causes increased pulmonary blood flow and pulmonary blood volume while decreasing heart rate and cardiac output as measured by oxygen-enhanced ventilation MRI [28]. This is consistent with an ex vivo model showing hyperoxia to decrease pulmonary vascular resistance by reduction of pulmonary capillary vascular resistance [29]. Implicated mechanisms of hyperoxic pulmonary vasodilation include increased NO synthesis, potassium channel activation resulting in hyperpolarization of pulmonary smooth muscle cells, and loss of hypoxic pulmonary vasoconstriction [30].

The Effects of Hypoxia on the Systemic Circulation

Until a critical point, oxygen consumption (VO_2) is independent of oxygen delivery (DO_2); that is, diminishing oxygen supply to organs will not result in changes in oxygen consumption [31]. Following failure of local and systemic mechanisms to maintain oxygen delivery, oxygen consumption and delivery are directly and linearly related, and increasing evidence of tissue hypoxia commences such as acidosis and hyperlactatemia [32]. This phenomena results whether DO_2 is compromised by hypoxemia, anemia, or low cardiac output [33].

VO_2-DO_2 independence is possible because of the interplay of local and systemic responses that maintain O_2 delivery. Local responses to hypoxia include increases in extraction of O_2 from efferent blood supply [32], capillary recruitment [34], improved O_2 offloading from hemoglobin in an acidotic environment via the Bohr effect [35], and autoregulation. Autoregulation refers to reflexive changes in vascular resistance to

maintain a constant flow in the face of changes in perfusion pressure. This has been shown to occur in multiple vascular beds including cerebral, coronary, skeletal muscle, and splanchnic circulations [36].

Experiments detailing the pulmonary and cardiovascular responses to various forms of hypoxia have shown both etiology-specific and pan-etiologic responses [37]. Hemodynamic responses to hypoxia per se are relatively blunted compared to the same degree of diminished oxygen delivery caused by hypovolemia or normovolemic anemia in experimental models. Across all etiologies, respiratory rate and systemic O_2 extraction increase immediately and progressively with the onset and worsening of hypoxia. However MAP, HR, SV, pulmonary artery pressure, and VO_2 remain in the normal range until the critical point of VO_2-DO_2 coupling occurs. Prior to the critical point, MAP and SVR only gradually rise, maintaining CO nearly unchanged. Beyond the critical point, VO_2 decreases steadily with decreasing DO_2, MAP decreases, SVR abruptly increases, and CO consequently decreases. Increases in lactate and decreases in pH are not evident until after the critical point has been reached [31, 38].

Regional differences in response to hypoxia abound. At significant levels of sustained hypoxia ($FiO_2 = 0.12$ [39] and $FiO_2 = 0.08$ [40]), blood flow increases both in absolute amount and relative to total cardiac output to the brain, heart, respiratory muscles, and liver. Blood flow decreases as a fraction of total CO to the GI tract, spleen, pancreas, and skin but does not change in absolute terms. Blood flow decreases both as a fraction of total CO and in absolute terms to the stomach and fat.

It should be clear that the question of "where is the critical point lies" is an important one. However, the exact point at which VO_2-DO_2 coupling occurs cannot be given with precision. This is because the critical point at which VO_2 becomes dependent on DO_2 is not a fixed value across individuals, organs, and conditions. CO will respond to local metabolic demands, giving the heart a more passive rather than active role in determination of DO_2 [41, 42]. For example, the brain normally has 3× the DO_2 needed to meet normal VO_2, but the heart in resting conditions has DO_2 only 1.5× in excess of VO_2. These discrepancies mean that increased extraction of DO_2 to meet VO_2 will be more efficacious in the brain than in the heart [43]. In addition, DO_2 is more properly a function of CaO_2 rather than PaO_2; therefore, hemoglobin concentration (Hb) and arterial oxygen saturation (SaO_2) will also be determinants of the critical point. Also, VO_2 should not also be thought of as static. VO_2 will increase in situations of metabolic demand such as fever, ARDS, sepsis, and recovery from surgery [44], but VO_2 can also decrease during periods of decreased DO_2 [43].

The Effects of Hypoxia on the Pulmonary Circulation

The control of pulmonary vascular tone is myriad and includes neural, humoral, and endothelial effectors [45]. Alveolar oxygen content is also a powerful effector of pulmonary vascular tone. That said, alveolar hypoxia appears to exert a more profound vasoconstrictor effect than alveolar hyperoxia does a vasodilatory effect. Hypoxia induces increased pulmonary vascular resistance via vasoconstriction in pulmonary arteries and capillaries [29]. Acidemia potentiates the hypoxic vasoconstrictor response, while alkalemia blunts the response [46]. The hypoxic vasoconstrictor response also appears to be more active in the young than in the old [47]. Disease states and exposure to various chemicals also affect the hypoxic vasoconstrictor response. Lungs treated with hyperoxia, H_2O_2, and endotoxin exhibit a diminished hypoxic vasoconstrictor response, as do atelectatic lungs. Lungs treated with TNF-α on the other hand exhibited enhanced hypoxic vasoconstrictor reactivity [45].

Physiologic Effects of pH

It has been argued that acidemias with pH <7.2 should be corrected with alkali therapy because below this point, acidemia causes decreased

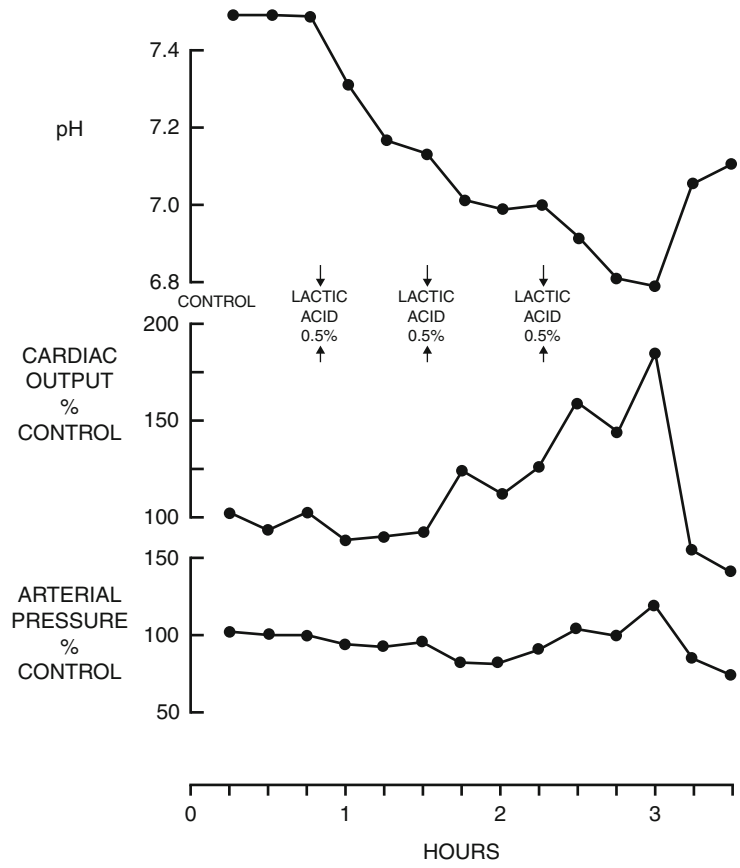

Fig. 167.2 The relationship between primary metabolic (lactic acid) acidosis and cardiac output (CO). CO increases with increasing metabolic (lactic acid) acidosis to a pH as low as 6.8

Metabolic acidosis: mean values from eight animals receiving 8.5% lactic acid.

cardiac output, maldistribution of blood flow, arrhythmias, and resistance to catecholamine administration [48, 49]. However, when these effects have been investigated specifically, it is clear that acidoses are more often the *effects* of underlying pathology rather than the *causes*. For example, it is the critical aortic stenosis causing decreased cardiac output that leads to obstructive shock *and* acidemia rather than acidemia leading to decreased cardiac output, per se. This distinction is important in that it is imperative to ameliorate the underlying primary pathology rather than focus efforts on signs of that pathology.

While most clinically encountered acidemias are benign, there are points at which acidemia, per se, is pathological. The point of primary pathology due to acidemia appears to be at least below a pH of 7.0. In a study of isolated metabolic acidosis, achieved by injection of lactic acid, CO was found to *increase* to 185 % of baseline when pH had been decreased to 6.8. MAP was unchanged throughout the experiment, as was HR, indicating improvements of CO were brought about by increases in SV presumably from lowered SVR and/or increases in contractility [50] (see Fig. 167.2). In the same study, isolated respiratory acidosis, achieved by inhalation of CO_2, increased CO to 182 % of baseline when pH had been decreased to 6.7. Again, MAP and HR were unchanged throughout the experiment leading the authors to conclude that SV was augmenting CO due to lowered SVR [50] (see Fig. 167.3). These results are consistent with a later study evaluating microcirculatory flow which showed that increasing hypercapnia and associated acidemia increases arteriolar diameter,

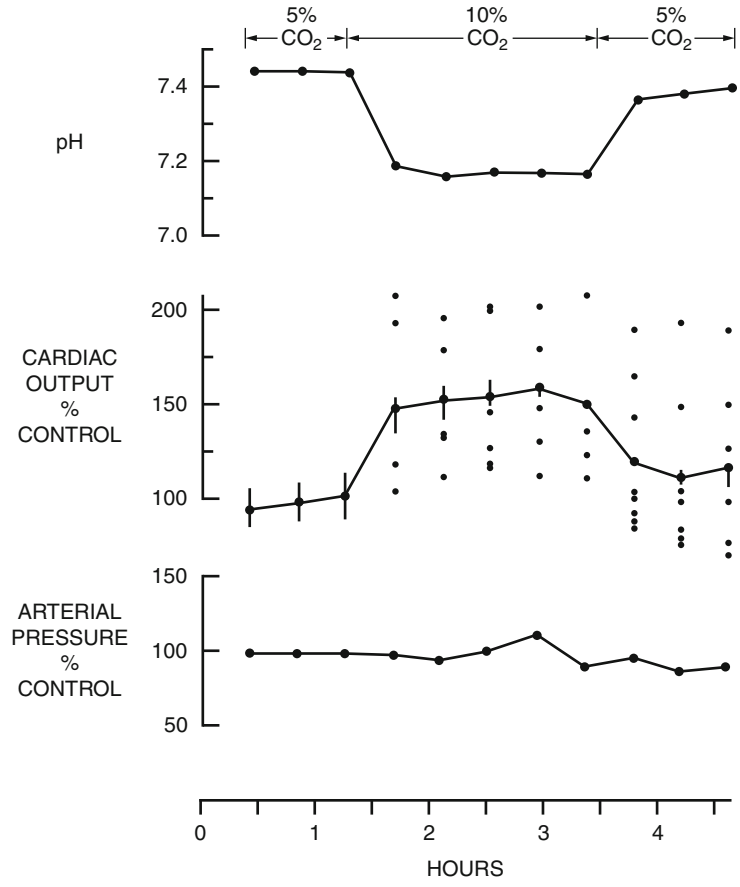

Fig. 167.3 The relationship between primary respiratory (hypercarbic) acidosis and cardiac output (CO). CO increases with increasing respiratory (hypercarbic) acidosis to a pH as low as 7.2

Respiratory acidosis: mean values from eight animals receiving 10% CO_2 Individual values for cadiac output are shown as well as the means

blood flow velocity, SV, and CO until $PaCO_2 > 80$ (pH 7.18). These increases then regress and reach baseline at a $PaCO_2$ of 120 mmHg (pH 6.99). It is not until $PaCO_2 > 150$ mmHg (pH 6.9) that blood flow velocity, SV, and CO were compromised by hypercapnic acidosis [20].

In reviews of the effects of acidosis on myocardial contractility and ion channel function, no arrhythmogenicity is cited for experiments involving pH above 7.0 [51, 52]. Finally, in a follow-up study of per se lactic and hypercapnic acidoses, no change in cardiac output responsiveness to epinephrine injections was found until the pH was decreased below 6.8. The authors noted an abrupt deterioration in responsiveness below pH 6.6 [53]. Such data counters the common misconception that inotrope responsiveness suffers during much more mild acidemic states (see Fig. 167.4).

Physiologic Effects of Buffering

A clinical discussion of buffering usually focuses on the use of alkali to ameliorate acidemia and generally assumes that the agent given returns the acidemic pH toward normal by lowering arterial $[H^+]$. This may or may not be the case given which agent is chosen and under which circumstances. Stewart has shown that the independent determinants of pH are the strong ion difference (SID), the total concentration of weak acids (Atot), and the $PaCO_2$ [54]. The SID is the difference between the concentration of fully

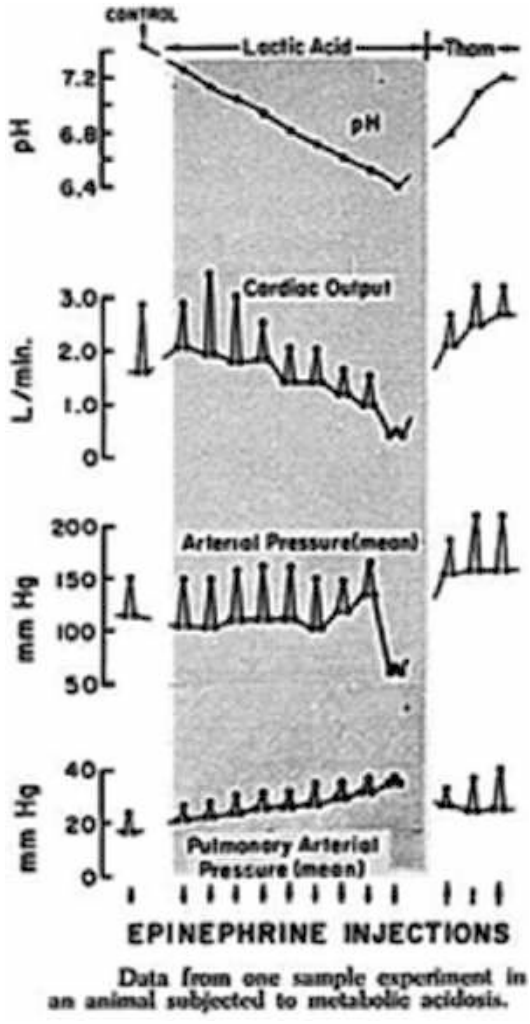

Fig. 167.4 The relationship between responsiveness of cardiac output (CO) to epinephrine injections at different levels of pH. CO has no change in responsiveness to epinephrine injections with progressive academic conditions to a pH of 6.8. At pH 6.6, an abrupt decrement in CO responsiveness to epinephrine injection was seen

dissociated cations, such as Na^+, K^+, and Ca^{++}, and fully dissociated anions, such as Cl^-, SO_4^-, and lactate$^-$. $NaHCO_3$ lowers [H^+] not because of the combination of H^+ and HCO_3^- but because Na^+ is a strong cation. Na^+ will remain dissociated and raise the concentration of strong cations. HCO_3^- will only combine with H^+ to form CO_2 and H_2O through the action of carbonic anhydrase, as at physiologic pH (~7.40) HCO_3^- remains almost completely dissociated from H^+ (pKa ~ 3.57). Only if this increase in CO_2 can be ventilated, driving the combination of H + and HCO_3^- through the law of mass action, will the pH rise. If ventilation is fixed, as has been shown in mechanically ventilated patients with ARDS, then the administration of $NaHCO_3$ will actually further lower arterial pH. In addition, the effect of $NaHCO_3$ administration on intracellular pH is unclear [54]. $NaHCO_3$ may actually lower intracellular pH even in situations where arterial pH is raised due to the rapid diffusion of CO_2 across cell membranes. Other studies have found no effect on intracellular pH or an increase in pH depending on the source of acidosis.

Beyond the cellular effects of the use of buffers, the clinical effects of buffering acidemia are generally noted to be deleterious. While buffering hypercapnia may potentially attenuate increases in PVR by CO_2 [19], there have been no studies indicating a clinically significant hemodynamic benefit with the use of $NaHCO_3$ in the presence of lactic or ketoacidosis. However, there have been associated complications such as volume overload, hyperosmolarity, and hypocalcemia [54]. In addition, buffering hypercapnia abolishes potentially helpful anti-inflammatory effects of CO_2 in acute lung injury models [55]. Alternative buffering agents such as carbicarb and tromethamine do not generate CO_2 as much (carbicarb) or at all (THAM) when administered and may have a role in ameliorating potential disadvantages of acidemia without the attendant complications of $NaHCO_3$ [54], but discussion of their use goes beyond the scope of this chapter.

Cardiopulmonary Interactions in Specific Situations

Pulse Pressure Variation Predicts Fluid Responsiveness

Much of the interest in cardiopulmonary interactions comes from the realization that pulmonary processes can compromise as well as augment CO in critically ill patients. In addition, the cardiovascular manifestations of changing

pulmonary pressures and volumes can be indications of the intravascular volume status of critically ill patients. It is through an understanding of cardiopulmonary interactions that the ubiquitous question in pediatric intensive care units can be better answered: "Would this patient benefit from further fluid resuscitation?"

It is clear that early fluid resuscitation of critically ill patients improves outcomes both in terms of survival and organ dysfunction [56, 57]. It is also known that optimization of preload and cardiac output in adults undergoing surgery improves outcomes [58], while the use of vasopressors in the situation of an under fluid-resuscitated patient will worsen outcome [59].

A recent, excellent review of hemodynamic parameters to guide fluid therapy highlights the utility of pulse pressure variation (PPV), stroke volume variation (SVV), the passive leg raising test, and the end-expiratory occlusion test [60]. The same review stresses the futility of using central venous pressure (CVP) as a guide to therapy, counting over 100 articles that show CVP or change in CVP to have no relation to fluid responsiveness. In fact, only two published articles show "some relationship" between CVP and intravascular volume, both of which involved standing horses. The utility of PPV (and futility of CVP) in predicting fluid responsiveness has recently been replicated in pediatric cardiac surgery patients as well [61, 62].

An important caveat to the use of PPV exists in patients with heart failure. The PPV found in hypovolemia should be distinguished from that in systolic heart failure [63]. In a fluid-responsive patient, PPV from mechanical ventilation will arise from a decrease in SV following a positive pressure insufflation due to a reduction in preload. In a patient with congestive heart failure, who is not preload dependent, PPV from mechanical ventilation may arise from an *increase* in SV following a positive pressure insufflation due to a reduction in afterload. Thus, the PPV response to positive pressure ventilation could be opposite in patients with hypovolemia or heart failure, because hypovolemia is a primarily preload-dependent pathology, whereas heart failure is primarily an afterload-dependent pathology.

An additional important caveat for postoperative cardiac patients should be noted in the use of PPV in patients with an open sternum. When the chest cavity is open, ITP is near atmospheric pressure, and the chest wall is much more compliant. In this situation, cardiopulmonary interactions will be much less pronounced given the ability for previously volume-limited spaces to expand as needed [64]. The pulse pressure variation that is seen will be due to changes in Vt rather than changes in PEEP as PEEP effects on cardiac output will be obviated [65]. Thus, the use of delayed sternal closure will cause reductions in both the beneficial and detrimental cardiopulmonary interactions from positive pressure ventilation. In short, an open sternum will reduce the potentially deleterious effects of decreased preload but will also reduce the potentially helpful effect of decreased LV afterload.

Single Ventricle Physiology/Passive Pulmonary Circulation

Unique considerations of cardiopulmonary interactions exist for patients with single ventricle anatomy due to the increased interrelationship between the pulmonary and systemic circulations. In patients with a complete mixing lesion, in the preoperative state, balancing of pulmonary and systemic circulations will be done via attempted reductions in SVR and prevention of excessively low PVR [66]. For patients with single ventricle physiology and restrictive prosthetic shunts of fixed diameter and resistance, such as the BT shunt, this will be done by minimizing the effects of deleterious cardiopulmonary interactions, utilizing judicious and careful reduction of SVR via vasodilators during the low cardiac output period following cardiopulmonary bypass, and maintaining systemic saturations between 75 % and 85 %, all of which should result in a pulmonary blood flow-to-systemic blood flow ratio (Qp:Qs) of roughly 1:1. In a cautionary report, Li et al. show that the use of hypoventilation to augment systemic blood flow (Qs) in neonates having undergone the Norwood-BT shunt procedure may do so by changing

regional perfusion [67]. A stepwise increase in $PaCO_2$ did not change PVR but did result in decreased pulmonary blood flow (Qp) due to decreases in SVR which increased Qs. The increase in Qs was mostly due to increases in cerebral blood flow (as measured by cerebral NIRS and cerebral arterial blood flow Doppler) and was correlated with a decrease in splanchnic blood flow (as measured by splanchnic NIRS). The authors caution that this decrease in splanchnic flow may be deleterious given the propensity for impaired splanchnic circulation in this patient population. It should be noted, however, that the absolute reduction in splanchnic NIRS (%) (68 ± 10 to 60 ± 7 when $PaCO_2$ (mm Hg) was increased from 40 to 60) does not appear to be as clinically significant as the improvements in cerebral NIRS (%) (56 ± 12 to 68 ± 14), lactate (mmol/L) (1.4 ± 0.4 to 1.0 ± 0.2), or Qs (L/min/m^2) (2.6 ± 1.3 to 4.1 ± 1.5).

For patients with single ventricle anatomy and partial separation of systemic and pulmonary circulations such as that found in the bidirectional cavopulmonary shunt (Glenn), Qp:Qs will be less than 1 and is typically 0.6:1 given the size of the head and upper body of young infants as compared to older children and adults. In this situation, the pulmonary capillary bed is in essence a portal circulation receiving its blood supply from the upstream cerebral vascular bed. Since the trans-cerebral pressure gradient (carotid artery to jugular vein) is typically much higher than the transpulmonary gradient (superior vena cava to left atrium), hypoxemia can be improved by allowing $PaCO_2$ to rise, thus increasing cerebral blood flow and subsequent SVC flow, which in turn increases Qp via the Glenn shunt [68]. Maneuvers to reduce the pulmonary vascular resistance (i.e., hyperventilation) have opposing effects on the upstream cerebral vascular resistance and are generally ineffective in promoting blood flow in Glenn physiology.

For patients with single ventricle anatomy and complete separation of systemic and pulmonary circulations such as the total cavopulmonary shunt (Fontan), the most significant cardiopulmonary interaction is the impairment to pulmonary blood flow due to positive pressure ventilation in the face of an obligatory passive pulmonary circulation. Specific management of patients with these anatomical configurations is discussed below.

Cardiopulmonary Bypass-Related Lung Injury

The lungs of patients with congenital heart disease are abnormal for a number of reasons. Lister and Pitt provided an excellent review of the respiratory complications of uncorrected congenital heart disease including the propensity for large and small airway compression from overdistended pulmonary vasculature and rapid shallow breathing in patients with left-to-right shunts [69]. In addition to anatomic complications present preoperatively, the lung injury associated with cardiopulmonary bypass is a source of significant pathology in the care of postoperative congenital heart patients. Not surprisingly, the magnitude of lung injury preoperatively has been associated with the magnitude of lung injury postoperatively [66]. Many etiologies have been cited for the marked inflammatory response to cardiopulmonary bypass including immunologic cell activation from foreign surface contact of the bypass circuit, mechanical shear stress, tissue ischemia and reperfusion, hypotension, non-pulsatile perfusion, hemodilution and relative anemia, blood product administration, and hypothermia [70]. This manifold activation of the inflammatory system involves virtually all inflammatory systems: cellular and humoral immunity, complement, coagulation, fibrinolysis, endotoxin release, endothelial activation of leukocyte adhesion molecules, platelet and leukocyte activation, and production of oxygen radicals, nitric oxide, arachidonic acid derivatives, and proteolytic enzymes. The use of preoperative corticosteroids and modified ultrafiltration (MUF) has been aiming to mitigate this inflammatory response. Both therapies have resulted in improvement of hemodynamics [71], decreased usage of blood products, decreased length of mechanical ventilation, and decreased length of

ICU stay [72]. However, respiratory dysfunction is still encountered ubiquitously following cardiopulmonary bypass. Observed pathophysiology due to this dysfunction includes increased pulmonary vascular resistance, decreased compliance, decreased functional residual capacity, increased ventilation-perfusion mismatch, interstitial edema, and reduced surfactant activity [70]. The CVICU practitioner must be aware of these potential problems and tailor therapies to ameliorate them accordingly.

Problem-Specific Ventilation Strategies

"Standard" Postoperative Management

Simplifying almost egregiously, the respiratory care of the significant majority of pediatric postoperative cardiac surgery patients can be summed up in one word: extubate. Most patients come into their operations with relatively healthy lungs (notwithstanding the noted respiratory pathophysiology known to coexist with uncorrected or ongoing cardiac disease) [69], and the best thing care providers can do is not damage them with the ventilator. Weaning strategies and approaches to extubation for patients requiring longer-term ventilation are described later in this chapter, but for the majority of patients, getting the tube out of their airway as fast as is safe is the best approach. In fact, many studies document the benefits of operating room or PACU extubation strategies for children after cardiac surgery [73–76]. While practitioners in the CVICU are often subject to the decisions made by the anesthetist at the tail end of the operative case in terms of how quickly patients can be extubated, rapid extubation after return to the ICU should stand as a primary goal for the majority of patients. Various strategies exist for achieving this, including judicious use of dexmedetomidine in some patients [77], but in general, the minimization of sedation and promotion of rapid conversion to spontaneous breathing should be the goal. Inability to achieve this goal may be the first sign of some physiologic, postsurgical, or anesthetic problem.

For patients unable to be extubated rapidly either in the operating room or in the ICU, standardization of the mechanical ventilatory approach initiated upon admission to the CVICU can be of value. While the selection of patients for mechanical ventilation will largely remain at the discretion of the individual physician, or will be determined by the other aspects of the patient's medical need, ventilator management and weaning from the ventilator can clearly be affected through standardization of care. In terms of specific management, for example, it is well accepted that a low tidal volume strategy significantly reduces mortality in acute lung injury [78, 79]. Standardization of ventilator settings for the majority of patients could, then, prevent unwarranted utilization of potentially harmful ventilator strategies and improve outcomes. Repeatedly, it has been shown that the implementation of proven beneficial care strategies does not occur consistently until protocolized or "guided" care is instituted [80, 81]. Each institution should develop its own, evidence-based, and mutually agreed upon guidelines for the respiratory care of the postoperative pediatric cardiac surgical patient.

Most commonly in the modern CVICU, patients are initially placed in some form of volume-targeted, time-cycled, pressure-limited mode [e.g., pressure regulated volume control (Maquet; Servo-i), adaptive pressure regulation (Hamilton; Galileo), or autoflow (Drager; Evita)]. Whichever specific version is used, volume-targeted modes allow for assured ventilation while enjoying the advantages of pressure control breaths (e.g., a decelerating flow wave form and pressure limitation). Tidal volumes of 6–8 cc/kg are acceptable, with ventilation goals of slight hypercapnia to help induce spontaneous ventilation. PEEP is generally low, 4–6 cm H_2O, and FiO_2 is minimized, as extubation is expected. When the patient begins to emerge from anesthesia and spontaneously breathe, they are switched to a spontaneous mode, most commonly pressure or volume support. Standardization of the weaning process is now increasingly

common in the CVICU, with many units operating under protocols that guide the ventilator management for bedside respiratory therapists and nurses, without direct input for each change by the attending physician (Fig. 167.5). Many modern ventilators even have options that allow this transition to be done automatically, switching immediately to a spontaneous support mode upon sensing the first patient-initiated breath. Along with frequent blood gas analysis, monitoring of the mechanically ventilated patient should include continuous capnometry, regional oximetry, and pulse oximetry. Some evidence supports the use of volumetric CO_2 analysis as well [82], but this technique is not as widely used. Once extubation criteria are satisfied (see below), including an assessment of pulmonary compliance, extubation should proceed as rapidly as possible.

Open Sternum

The ventilation of the child with an open sternum after cardiac surgery generally is straightforward. In most cases, sedation and analgesia is maintained, while the chest is open to prevent excessive movement or respiratory effort due to the patient's tenuous hemodynamic state. Any negative intrathoracic pressure can result in inefficient respiratory mechanics and collapse of the chest wall, so ventilation is provided nearly completely with positive pressure, controlled breaths. Clinicians should be aware that total respiratory system compliance will be increased when the sternum is open, and ventilator settings may have to be adjusted accordingly when the chest is closed (i.e., pressures will likely be higher when the chest is closed to achieve equivalent ventilation). Once the chest is closed, rapid weaning of the ventilator is to be encouraged if possible.

While the above strategy is by far the most common, some interest is beginning in earlier initiation of spontaneous breathing, even while the sternum is open. Utilization of modalities such as neurally adjusted ventilatory assist (NAVA) [83] may allow this. In all other modes, patient-initiated breaths are sensed after generation of patient-directed flow or negative respiratory circuit pressure, resulting in negative intrathoracic pressure during the initiation of spontaneous breaths. NAVA triggers through electrical sensing of diaphragmatic neural impulses, allowing spontaneous breaths to be delivered to the patients without generation of negative intrathoracic pressure and with much improved synchrony [84, 85]. This could allow early, positive pressure spontaneous breathing, which could in turn allow faster weaning and extubation once the chest is closed. Further investigation into this potential is warranted.

Pulmonary Overcirculation, CHF, and Left Ventricular Dysfunction

While the specifics of the cardiopulmonary interactions in CHF and related to LV performance during mechanical ventilation were addressed above, the primary pulmonary difficulty in patients with pulmonary overcirculation (due to left-to-right shunt lesions), CHF, and/or left ventricular dysfunction is the decreased pulmonary compliance due to increased total lung water [86, 87] (Fig. 167.6). Obviously, addressing residual intracardiac shunts and ongoing ventricular dysfunction should be first-line interventions. Therapies directed toward reducing extravascular pulmonary water [88], such as diuretics and fluid restriction, can improve pulmonary compliance. For ongoing pulmonary congestion, increased distending pressures will be required for adequate ventilation, and use of a pressure control mode is sometimes necessary to prevent excessive increases in peak pressures. Decreased pulmonary compliance leads to a decrease in end-expiratory lung volume below FRC, and PEEP may need to be increased to maintain adequate lung recruitment and prevent atelectasis. Respiratory resistance may be increased as well, due to airway edema, requiring increased ventilatory pressures and increased expiratory time. Care must be taken

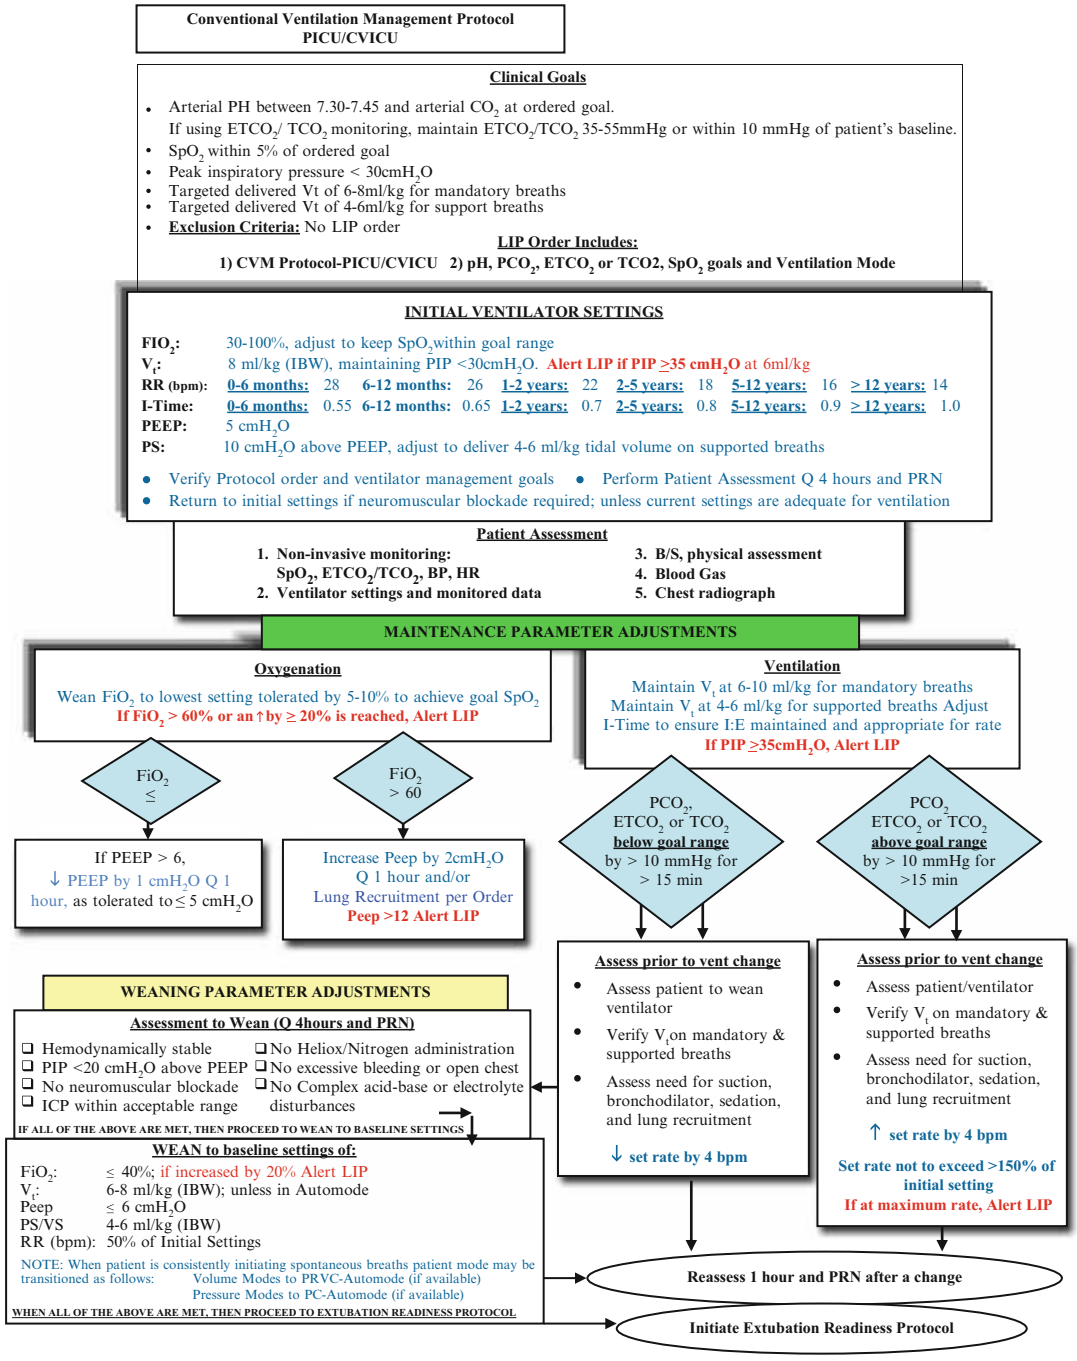

Fig. 167.5 Example of a protocol to facilitate weaning of mechanical ventilation in children. Specific input for each ventilator change is not required from the attending physician. Rather, a blanket order for the protocol is initiated upon admission, and the bedside therapists adjust the ventilator within preset guidelines to achieve therapeutic goals. Management and weaning protocols such as this have repeatedly been demonstrated to shorten the length of ventilation

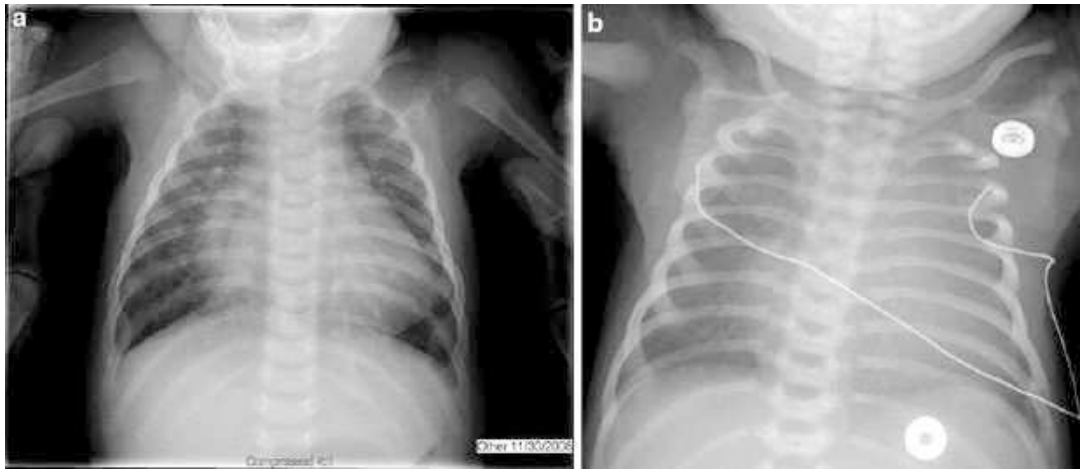

Fig. 167.6 Examples of increased pulmonary lung water leading to decreased pulmonary compliance. (**a**) Increased vascularity due to pulmonary overcirculation in a child with a ventricular septal defect. (**b**) Congestive heart failure in a child with interrupted aortic arch

in the use of beta-agonists in this situation, as their vasodilatory effects can lead to worsening of airways obstruction. Reduction of pulmonary extravascular water should be the primary pulmonary therapeutic goal.

Passive Pulmonary Circulation

The nuances of the complex cardiopulmonary interactions in patients with passive pulmonary circulation [e.g., after a bidirectional caval anastomosis (Glenn) or Fontan procedure] are described above. With these principles in mind, it is clear that in most cases, an early transition from positive pressure to negative pressure ventilation is desirable, resulting in an increase in pulmonary blood flow and improved hemodynamics [89, 90]. Accordingly, extubation in the OR is being more widely advocated [75, 76]. Recently, dexmedetomidine infusions have been described as an adjunct therapy to ease the transition from anesthesia and positive pressure ventilation to extubation [77, 91], if OR extubation is not performed. However, situations arise in which patients cannot be extubated rapidly, due to airway disease, intraparenchymal pulmonary disease, bleeding, or other factors. The long-term management of mechanical ventilation in these patients is challenging.

In general, the goal must be to optimize pulmonary vascular resistance to promote pulmonary blood flow and overall cardiac output. From a pulmonary mechanical perspective, PVR is minimized when end-expiratory lung volume is closest to functional residual capacity, or FRC [1]. Unfortunately, accurate determinations of end-expiratory lung volumes and FRC are difficult and not commonly available at the bedside [1, 92]. However, a decent approximation of matching EELV to FRC can be achieved through the determination of the "PEEP of best compliance" [92]. With this technique, a complete dynamic pressure-volume curve is navigated through a stepwise increase and decrease in PEEP, while a patient is still on the ventilator. Opening and closing pressures are determined, and compliance is monitored throughout. This enables a quick determination of the PEEP level at which compliance is best, which closely approximates the EELV closest to FRC, and the point at which oxygenation will be maximized and PVR will be minimized [93–95] (Fig. 167.7). Clearly, care must be taken in performing maneuvers with increased PEEP in children with passive pulmonary circulation, and hemodynamics must be monitored closely. Once the appropriate level of

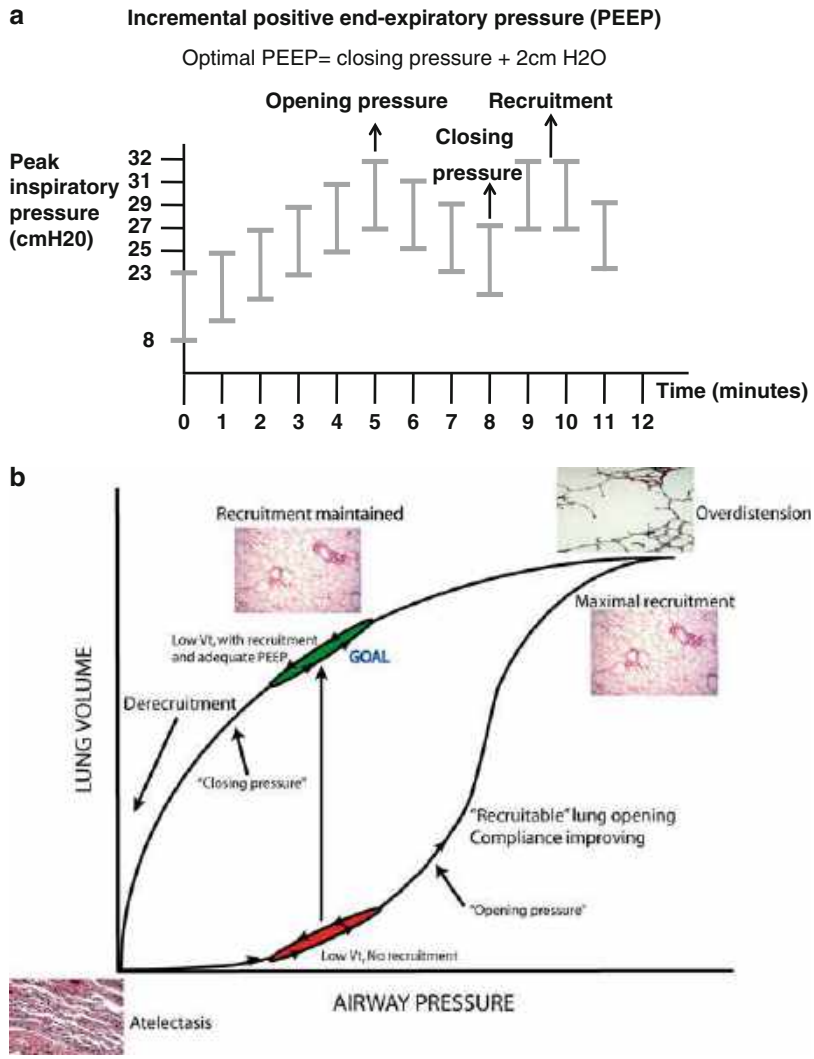

Fig. 167.7 Recruitment maneuver and determination of optimal PEEP. (**a**) With a fixed delta-P in pressure control mode, PEEP is increased in a stepwise fashion until recruitment is achieved. PEEP is then decreased, and opening and closing pressures are defined. Optimal PEEP is set above the closing pressure but below the opening pressure. In this way, end-expiratory lung volume is set as close to functional residual capacity as possible. (Reprinted, with permission, Boriosi et al.) (**b**) Diagram of the changes in pulmonary histology and lung volumes during the performance of a recruitment and optimal PEEP determination

PEEP is selected (and in most patients with relatively healthy lungs, it will be quite low, 3–4 cm H_2O), a general strategy of ventilation that minimizes intrathoracic pressure is usually attempted. Classically, ventilation with lower rates and higher tidal volumes has been the technique of choice, with a goal of a slight respiratory alkalosis. Recently, these ideas have been challenged. A number of studies demonstrated that in patients with bidirectional caval anastomoses, mild hypercapnia (pH $\sim$ 7.35) improves oxygenation and may increase cardiac output [96, 97], likely due to increases in cerebral and superior vena cava flow. Some practitioners now advocate for the use of a primarily spontaneous breathing mode as well (such as pressure support), theorizing that patients will adjust their own minute ventilation parameters (including mean airway pressure) more effectively on their own than what will be set for them.

Utilization of these techniques, along with more standard therapies such as oxygen, inhaled nitric oxide (for patients with proven elevation of pulmonary vascular resistance, e.g., conduit pressure or "CVP" of >15 mmHg and a transpulmonary pressure gradient >8 mmHg [98]), and sedation, generally allows for

acceptable management of intubated patients with passive pulmonary circulation. Despite these optimization techniques, positive pressure ventilation often leads to increased conduit pressures, elevated upstream venous pressures, and the attendant complications of such, including edema, fluid retention, decreased cardiac output, and organ dysfunction. Accordingly, therapy must always be directed toward early safe extubation.

A number of nonstandard ventilatory techniques have been described for patients with passive pulmonary circulation. Negative pressure ventilation is probably the most physiologically sound strategy for postoperative mechanical ventilation in these patients and has been demonstrated to improve pulmonary blood flow, oxygenation, and cardiac output [99]. However, practical considerations in application and a general lack of knowledge about it have limited its use. Airway pressure release ventilation (APRV) has also been described to improve pulmonary blood flow and cardiac output [100] in Fontan and other post-op cardiac surgical patients, but its benefits are largely due to the ability of patients to spontaneously breathe during its application. Use of APRV and its potentially high attendant mean airway pressures without spontaneous breathing is hazardous. For patients who are difficult to ventilate, high-frequency ventilation has been used effectively in patients with passive pulmonary circulation [101]. High-frequency ventilation has also been described in Fontan patients for removal of bronchial casts with plastic bronchitis [102]. However, all of these techniques are reserved for the rare patient who requires prolonged ventilation; the vast majority of these patients should be rapidly "extubatable" after surgery.

Pulmonary Hypertension and Right Ventricular Dysfunction

Mechanical ventilation strategies for patients with pulmonary hypertension and RV dysfunction are very similar to those described above for patients with passive pulmonary circulation. The primary goal is reducing PVR and RV afterload, aiming for the lowest possible intrathoracic pressure and titrating PEEP to closely match EELV to FRC. This is particularly critical in severe RV dysfunction, as patients will be extremely preload dependent. Optimization of RV function is essential, as RV dilation can have profound consequences on overall cardiac function and impact left ventricular function (Fig. 167.8). Of note, in addition, acute hypercapnia is generally not desirable in patients with pulmonary hypertension and RV dysfunction [103], and ventilation goals are generally for normocapnia or slight respiratory alkalosis. Inhaled nitric oxide is a commonly used adjunct in the management of pulmonary hypertension, often begun in the operating suite and continued in the CVICU, and clearly has a role in the management of acute pulmonary hypertension and elevated PVR with RV dysfunction [104]. Adjunctive medications such as inhaled [105] and intravenous prostacyclin preparations and inhaled milrinone [106] have been described and used in refractory cases, but extensive clinical evidence supporting their use is lacking.

Diaphragmatic Injury

Unilateral paralysis or paresis of the diaphragm occurs in 1–2 % of pediatric cardiothoracic surgery patients [107], while bilateral injury occurs in approximately 0.4 % [108], usually due to stretch or severing of the phrenic nerve. The deleterious effects of diaphragmatic paralysis on respiratory mechanics can be severe. Not only is the paralyzed diaphragm unable to initiate a breath, but its lack of tone causes it to move cephalad paradoxically as the rib cage expands, thus compromising the already limited lung volume. Not surprisingly, the observed work of breathing is increased as the patient attempts to maintain ventilation. While sometimes observed during the weaning process, commonly diaphragmatic paralysis is not noticed until after a failed extubation attempt. In suspected cases of diaphragmatic paralysis, chest radiographs may show elevation of the affected side but are often

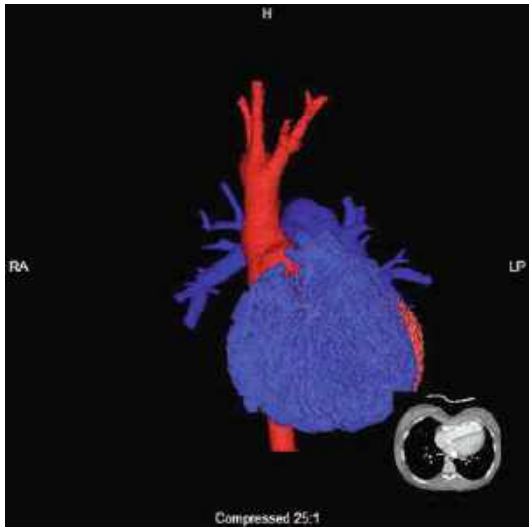

Fig. 167.8 Dilation of the right ventricle in a patient with tetralogy of Fallot resulting in left ventricular compression. *Blue* = RV and venous structures. *Red* = LV and arterial structures

nonspecific (Fig. 167.9). Fluoroscopy and ultrasound are the most specific diagnostic modalities [109], but do require a physician trained in respiratory physiology to interpret adequately, as the patient must be taken off of mandatory ventilation (preferably off of positive pressure altogether) during the examination. Acute therapy for a paralyzed diaphragm can include the application of increased PEEP, which can assist ventilation through "medical splinting," preventing the intrusion of the abdominal contents into the thoracic cavity during attempted inspiration and improving respiratory mechanics with resultant reduced work of breathing [108]. Surgical plication achieves the same goal and is generally the treatment of choice. Patients with unilateral paralysis will often improve with plication and extubate relatively quickly. Patients with bilateral paralysis, however, often require tracheostomy and long-term ventilation as they "learn" to breathe with the intercostal and accessory muscles of respiration [110]. Diaphragmatic function returns in approximately 25 % of patients, usually within 6–7 weeks [107]. Whether or not diaphragmatic function returns, most patients can be extubated eventually.

Tetralogy of Fallot: Absent Pulmonary Valve

Children with the rare condition tetralogy of Fallot with absent pulmonary valve present with a wide range of symptomatology, often with significant pulmonary disease. A common initial presentation of children with this disease, who are not diagnosed prenatally, is respiratory distress and/or recurrent infections as an infant. Symptoms arise due to developmental abnormalities of the bronchial tree, caused by often massive dilatation of the pulmonary arteries due to free pulmonary valvular insufficiency (Fig. 167.10). Instead of single pulmonary arteries, severe cases have tufts of small arteries that surround the bronchi and cause compression [111], possibly explaining why symptomatology does not correlate well with pulmonary artery size [112]. Along with compression, bronchi and even the trachea often have cartilaginous abnormalities beginning in utero [112]. Combined, these abnormalities cause significant large and small airways obstruction, resulting in signs and symptoms of tracheo- and bronchomalacia, including air trapping, hyperinflation, respiratory distress, and hypoventilation. One subgroup tends to present with mild symptoms and are managed medically with bronchodilators, pulmonary hygiene, and heart failure management until surgical correction between 12 and 18 months. These patients often have little difficulty with surgery and are usually able to extubate soon after repair.

A second group of patients comprises children who cannot be medically managed, often progress to respiratory failure in infancy, and require earlier repair. The management of such patients can be challenging to say the least, commonly requiring hospital stays of weeks to months. Air trapping is only minimally responsive to bronchodilators but can be ameliorated somewhat with the application of positive pressure, possibly to stent open collapsible airways. Peak pressure requirements are often high (greater than 30–35 cm H_2O) when control modes are utilized. However, the authors have found that with the appropriate titration of PEEP

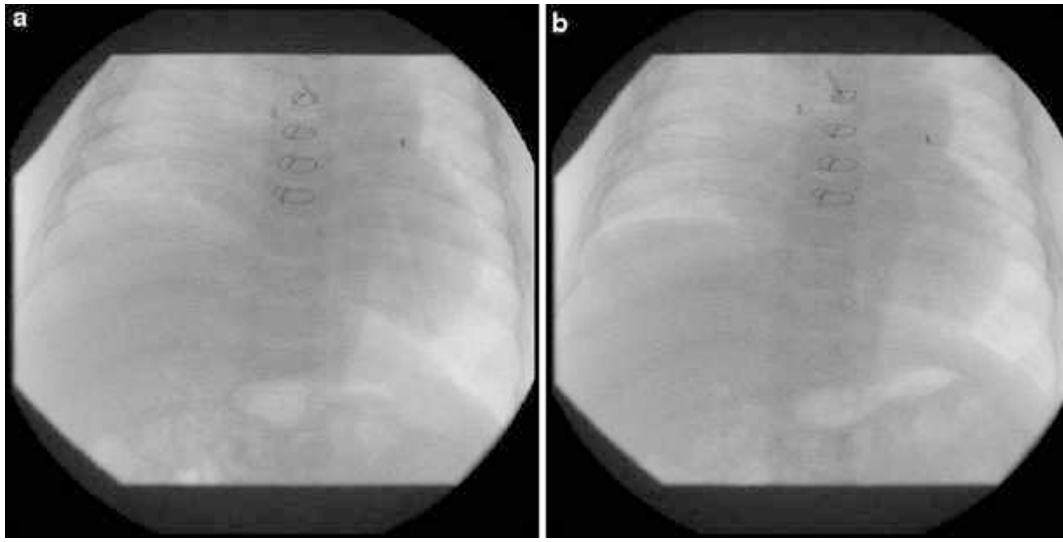

Fig. 167.9 Diaphragmatic injury after pediatric cardiac surgery. Note the elevation of the right hemidiaphragm, as well as the lack of expected drop during inspiration. (**a**) Inhalation. (**b**) Exhalation

(often >10 cm H_2O), and utilization of a spontaneous breathing strategy, as has been described for other subpopulations with small airways disease [113] as well as patients with tracheo- and bronchomalacia [114] from other etiologies, patients can be managed quite effectively with lower peak pressures and somewhat reduced sedation requirements. Other adjunctive therapies for ventilatory crises include heliox and prone positioning. Heliox has been described in the management of children with other airway abnormalities [115] and can be quite effective for short periods of time. Prone positioning cannot be used indefinitely but can be quite dramatically effective in certain cases [116]. Unfortunately, respiratory compromise in this subset of patients is often long term, requiring tracheostomy and long-term positive pressure ventilation in many cases. Trials of extubation are warranted, as some patients can be managed off of positive pressure, or weaned with noninvasive positive pressure modalities after extubation. Despite the attendant problems, however, most children can eventually be weaned from positive pressure as their anatomical airway abnormalities remodel and improve over time after successful surgical repair.

Practical Applications of Nonstandard Modalities

Heated Humidified High-Flow Nasal Cannula Oxygen

Recently, there has been a significant trend toward the utilization of higher-flow, heated humidified oxygen as an adjunct respiratory therapy. A number of different proprietary systems exist, but the basic idea is simple: provide heat and humidification to delivered nasal cannula oxygen and much higher flow rates that can be tolerated for longer periods of time without drying of the nasal and upper airway mucosa. While such systems have been touted as providing a more comfortable type of continuous positive airway pressure [117], the evidence suggests that there is very little oropharyngeal pressure generated in most children. In addition, no pressure is generated when the mouth is open and no consistent relationship between cannula flow rate and oral cavity pressure exists in infants over 1,500 g [118, 119]. Some evidence does suggest, however, that high-flow cannulae may improve ventilation and reduce work of breathing through

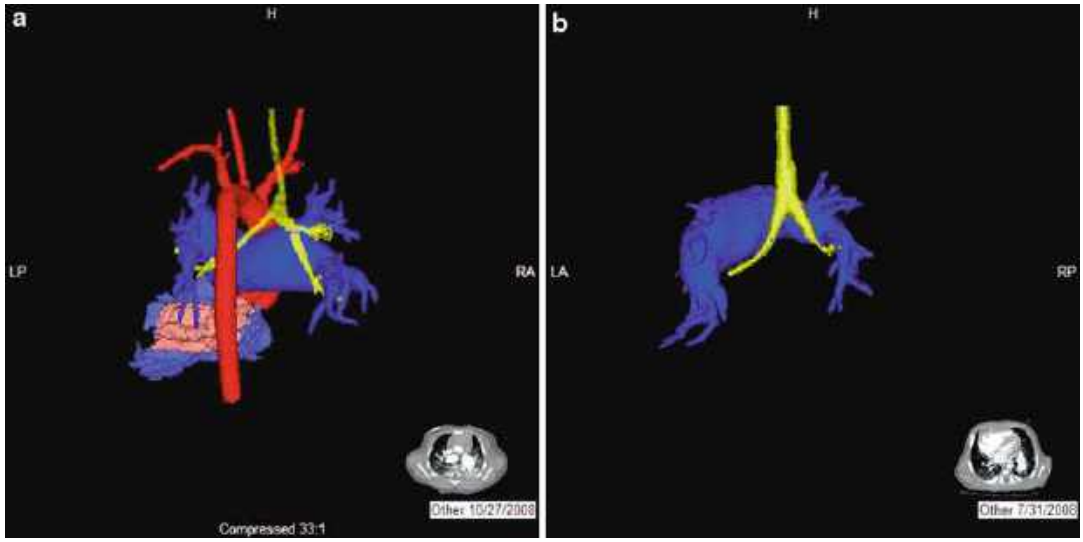

Fig. 167.10 Airway compression in tetralogy of Fallot, absent pulmonary valve. (**a**) 3D reconstruction of cardiac computed tomography scan of a patient with significant airway compression due to massive enlargement of the pulmonary arteries. (**b**) Similar reconstruction of a different patient, with the airway and pulmonary arteries isolated

respiratory dead-space washout and reduction of inspiratory resistance to flow through the upper nasopharynx [120]. The devices are, in addition, widely used, are generally well tolerated by patients, and seem to have very high physician acceptance as a way to provide additional respiratory support following extubation and/or prevent reintubation.

Noninvasive Positive Pressure Ventilation (CPAP and BiPap)

Noninvasive positive pressure ventilation is widely utilized in pediatric respiratory care. It has been repeatedly demonstrated to improve gas exchange, reduce work of breathing, and help to avoid intubation in a significant percentage of pediatric patients with a variety of conditions leading to respiratory failure [121, 122]. Pressure can be applied through nasal prongs, nasal mask, oronasal mask, full facial mask, or helmet, and the choice of interface should be tailored to the individual patient's needs. Modern noninvasive ventilators can provide a wide range of support, from simple CPAP to bi-level support with an IMV rate. The most difficult part of managing patients with noninvasive ventilation is in selecting the appropriate patients for the therapy. Rapid escalation of therapy when utilizing noninvasive support should be a warning sign to the clinician that a switch to an invasive modality may be indicated. In children with critical heart disease, such a decision may need to be made even earlier than in general PICU patients, given the significant deleterious effects of ongoing respiratory distress on a patient's hemodynamics. In general, while noninvasive ventilation can be a significant beneficial therapy, its use must be accompanied by close clinical observation and physiologic monitoring.

Bronchial Hygiene, Airway Clearance, and Strategies for Prevention/ Treatment of Atelectasis

A number of methods are available for airway clearance, bronchial hygiene, and prevention of atelectasis, with varying degrees of evidence and individual passion supporting each one. Generally, the vast majority of pediatric cardiac

surgical patients requiring prolonged ventilation need only standard regimens of routine airway suctioning, airway humidification, routine positioning, early physical mobilization, and assiduous attention to infection prevention [123, 124]. Below a number of maneuvers and techniques that can be used as adjuncts are described, but the reader is encouraged to focus on foundations of basic respiratory care before considering these techniques.

Manual Chest Physiotherapy

Although it is common practice to institute manual percussive chest physiotherapy (CPT) in infants and children in the intensive care unit, there is no evidence that supports the use of CPT in the care of children with critical heart disease. In fact, persuasive evidence suggests that its effects are almost entirely deleterious. A Cochrane review of the utility of manual CPT demonstrated no benefit in clinical outcomes or resolution of atelectasis, worsened hypoxemia, and increased oxygen requirements when CPT was used [125]. Other studies show that manual CPT actually increases atelectasis in children after cardiac surgery [126], does not prevent lobar collapse peri-extubation in neonates [127], increases heart rate, reduces cardiac output, increases intracranial pressure, and has been aptly described as "the most irritating routine intensive care procedure" [128]. Furthermore, this practice has been reported to dislodge indwelling central lines and even inhibit temporary postoperative demand pacing. The routine use of CPT in the pediatric CVICU should be reconsidered with these effects in mind.

Intrapulmonary Percussive Ventilation and Insufflation-Exsufflation

One potentially effective technique for secretion mobilization is intrapulmonary percussive ventilation (IPV). IPV provides high-frequency bursts of gas into the trachea, along with a stable level of CPAP, functioning much like high-frequency jet ventilation [124], and is most widely used in burn patients and patients with cystic fibrosis. IPV can be used in extubated or intubated patients and can help provoke cough responses. Superimposed on spontaneous breathing, it can augment ventilation and may be useful in prevention of extubation failure [129]. Limited evidence supports its use in children [130], including one trial documenting superior resolution of atelectasis when compared with manual CPT [131]. While it is generally well tolerated, it can cause distress and irritation, and so should be used with some degree of circumspection.

Another technique to enhance secretion mobilization and promote cough is mechanical insufflation-exsufflation, more commonly known as a cough assist. With this technique, requiring a specific proprietary device, a significant volume of gas is instilled into the lungs and then rapidly removed by way of a negative pressure active exhalation. Some evidence suggests that this technique improves secretion mobilization in adults and children with neuromuscular disease [132, 133], but its use in pediatric postoperative patients has not been evaluated. However, in certain cases of significant weakness, mechanical insufflation-exsufflation could be considered.

Recruitment Maneuvers

Recruitment maneuvers (RM) are transient increases in distending ventilatory pressures intended to open de-recruited or collapsed alveoli. They have been shown to be safe and well tolerated [94, 134, 135], including in adult patients after cardiac surgery [136] and ventilated pediatric ICU patients [137], and improve a number of physiologic parameters, including pulmonary compliance and oxygenation [94, 136, 137]. RMs also have been shown to improve patient outcomes in some studies [138], but other studies have shown no benefit [139]. RMs may be beneficial at times in addressing problems of pulmonary compliance or oxygenation. A recent excellent investigation supports this view, demonstrating

that RMs are safe and efficacious in critically ill children with acute lung injury [94]. Another study in pediatric cardiac surgery patients showed that RMs dramatically improved oxygenation and pulmonary compliance in pediatric patients undergoing cardiac surgery and did not increase morbidity [140]. Generally, they open atelectatic areas of lung, improve oxygenation, and reduce shunt, but can cause overdistension of previously recruited areas of the lung (Fig. 167.7), with possible attendant reductions in pulmonary blood flow and increased dead space.

Caution must be taken when utilizing recruitment maneuvers in children with critical heart disease. Dramatic or rapid changes in intrathoracic pressure can lead to deleterious effects on cardiac output, pulmonary vascular resistance, and overall hemodynamics [141]. Hemodynamic depressor effects can also occur as a result of the "lung-inflation vasodepressor reflex" described earlier in the chapter [5]. Some evidence exists that slow, gradual increases in PEEP cause less of a disturbance in hemodynamics and lung mechanics [94, 142]. Overall, it does seem that if performed correctly and with appropriate monitoring, recruitment maneuvers can be safely used as part of a respiratory care regimen in the pediatric CVICU.

Incentive Spirometry and Intermittent Bi-level Positive Pressure

For the extubated patient, continuing to maintain lung recruitment is an important goal. Incentive spirometry, in which patients actively but slowly inhale, maintaining inspiratory flow goals, is widely available and quite effective in maintaining end-expiratory lung volume and minimizing atelectasis in the postsurgical patient, including in pediatric cardiac surgery patients [143]. For patients unable to participate actively and perform adequate incentive spirometry, such as young children, participation in the blowing of common toy bubbles can achieve some of the same goals. For patients with more significant atelectasis, or of such young age that they cannot participate with bubbles or incentive spirometry, devices that provide bi-level positive pressure (much like BiPap) through either a mouthpiece or mask can be useful [144].

Inhaled or Instilled Medications

In general, the instillation of any adjunctive substance or medication into the airways is not supported by the evidence during the routine care of the child with critical heart disease. As with the above adjunctive techniques, practitioners are encouraged to focus on the basics of airway management before using any of these medications.

Normal Saline

No evidence supports the routine use of normal saline during suctioning for the enhancement of secretion removal [124]. Moreover, it may significantly increase infection risk, possibly by dislodging bacteria from the biofilm on the ETT. As such, routine use of normal saline during suctioning cannot be recommended [145]. In addition, no evidence supports the use of sodium bicarbonate instillation, and its use should be avoided for similar reasons.

Hypertonic Saline

For the rare patient with extremely thick, tenacious secretions, hypertonic saline installation may be considered. Hypertonic saline (usually administered as 3, 6, or 7 %) increases the osmolarity of the airway surface, enhancing mucociliary clearance [146]. Clinically, it improves lung function and secretion removal in patients with cystic fibrosis and bronchiectasis [147] and has demonstrated some efficacy in patients with bronchiolitis [148]. One study also demonstrated superiority of hypertonic saline to dornase alpha (see below) in the treatment of atelectasis in intubated newborns [149]. No study has examined its use in pediatric cardiac surgical patients, but it stands to reason

that attendant comorbid pulmonary conditions in such patients may warrant its use.

Dornase Alpha (DNAse)

Dornase alpha (recombinant, inhaled DNAse) has demonstrated efficacy in improving the pulmonary function of patients with cystic fibrosis [150]. However, it has repeatedly been demonstrated to be of no benefit in a wide variety of pediatric conditions, including lower respiratory tract infections [151], bronchomalacia, bronchiolitis [152], asthma [153], and other conditions, likely due to its utility primarily in conditions causing purulent secretions. Despite this, one randomized study did demonstrate shorter ventilation times and lower rates of radiographic atelectasis in mechanically ventilated PICU patients treated with DNAse [154], and it is generally tolerated well. Due to its relatively high cost and minimal evidential support, however, dornase alpha should be used only sparingly in the pediatric CVICU.

N-Acetylcysteine

While not uncommonly used as a mucolytic, no evidence supports the routine use of N-acetylcysteine for enhancement of mucociliary clearance or prevention of atelectasis in children [155]. In addition, it is very poorly tolerated in many instances and is quite noxious. While it has been described as being used successfully in the treatment of airway casts in patients with plastic bronchitis (often in combination with inhaled recombinant tissue plasminogen activator and/or dornase alpha) [156], it has not been demonstrated to be of benefit in other cardiac surgical patient populations. As such, its use in the pediatric CVICU cannot be recommended.

Beta-Agonists

The routine use of inhaled beta-agonists in pediatric patients with critical heart disease should be avoided. There is no evidence that beta-agonists enhance secretion clearance [157, 158]. While some evidence demonstrates improved pulmonary extravascular lung water clearance with beta-agonist treatment [159], no clinical outcomes have been demonstrated to be improved in nonreactive airways disease conditions [160]. Given the known effects of beta-agonists on cardiac oxygen consumption and heart rate [161], their use should be limited to patients with obvious episodes of bronchoconstriction.

Weaning from Mechanical Ventilation

Weaning strategies vary widely, but clearly removing patients from mechanical ventilation as soon as is safe clearly improves outcome. Timely weaning and liberation from mechanical ventilation should be a goal at the forefront of every respiratory care practitioner's mind when caring for infants and children. The faster children can be safely extubated, the better. Once a patient is extubated, removal of invasive lines, weaning of sedation, faster initiation of enteral nutrition, and generally faster care progression usually follow suit.

Premature extubation and attendant reintubation result in a high complication and mortality rate for affected patients, both children and adults [162–164]. However, nearly 50 % of "unplanned" extubations end in extubation success [162], without reintubation. This indicates that a significant percentage of patients practitioners deem "not ready" for extubation, in fact, are. As stated above, the focus of all pediatric cardiac critical care providers should be on weaning and liberation from mechanical ventilation at all times. As Dr. Thomas Petty once said, "Intermittent mandatory cerebration (IMC) is the preferred method of mechanical ventilation. Even better, continuous mandatory contemplation (CMC) must emerge as the preferred method used in all forms of respiratory care." To the bedside practitioner, what this means is that at every assessment, they must ask if the current therapy is appropriate, whether the current therapy can be more optimally configured for the

patient, and whether the therapy can be weaned or removed. A very insightful pediatric review of the subject of weaning in pediatric patients concluded that use of a weaning protocol in both children and adults results in a more consistent approach to the process and will result in shorter ventilator times, improved outcomes, and lower costs [165]. Indeed, this conclusion is supported by a variety of studies in pediatrics and adults [166–169]. Whether or not a protocol is employed (Fig. 167.11), a focus on the process of weaning and a drive toward extubation should be primary in the practitioner's mind.

Spontaneous Breathing Trials

Deciding which patients are safe to be extubated is forever vexing to the practicing intensivist. As stated above, reintubation is correlated with a number of poor outcomes; however, a too low reintubation rate could signify that patients are not being extubated rapidly enough; most PICU's average 8 % failed extubations [165], but pediatric CVICU rates are likely somewhat lower. No single test has been proven to perfectly predict successful extubation. While the rapid shallow breathing index is probably the most commonly used index to predict extubation readiness [170], even simple clinical assessments using CPAP trials on an anesthesia bag can be useful [171]. What is clear is that some assessment of extubation readiness should be attempted on every patient fairly frequently, as the simple act of checking for "extubatability" safely reduces the duration of mechanical ventilation [172]. Adult and pediatric studies show that most likely the best way to approximate post-extubation work of breathing is through a CPAP or T-piece trial [165, 173]. The addition of pressure support actually causes an *underestimation* of post-extubation work. A sample protocol for the performance of extubation readiness tests in children is provided in Fig. 167.11. Generally, extubation from mandatory ventilation is to be avoided, as an assessment of the patient's spontaneous effort is desired. Whichever type of extubation readiness test or spontaneous breathing trial is preferred, patients should be extubated as soon as they meet extubation criteria.

Management of Failed Extubation

Causes of failed extubation in pediatric patients are often disease specific [174], and children with cardiac disease can fail extubation trials for myriad reasons. A recent review in children undergoing Norwood procedures revealed most failed extubations are due to ongoing cardiac or respiratory disease (50 %), with airway issues (including airway edema, vocal cord paralysis, and laryngotracheomalacia) and diaphragmatic paralysis causing the remainder [175]. Some failed extubations due to airway edema can be prevented through close attention to endotracheal tube position, well-defined protocols for the securing of tubes, and cuff inflation pressures. Evidence for the use of corticosteroids either before or after extubation to prevent airway edema and stridor is mixed [176], but a recent systematic review demonstrated a moderate effect in preventing reintubation with the use of steroids, with the strongest effect in patients given the medication >12 h prior to extubation [177]. The use of a short course (single dose or four doses over 24 h seem to be the most common regimens) for higher-risk patients would be reasonable. Unfortunately, determining which patients are "high risk" is difficult; the standard "leak test" is highly inaccurate and does not predict extubation success [178]. Inhaled epinephrine and heliox can also be used carefully in select patients.

Any failed extubation deserves careful elucidation of the cause, including an assessment of vocal cord and diaphragmatic function. In addition, pediatric cardiac patients often cannot tolerate respiratory distress and/or upper airway obstruction for very long, due to the abovementioned effects on afterload and cardiac function, and so should be considered for reintubation at an earlier time than a general pediatric ICU patient. Finally, patients with recurrent failed extubations or traumatic intubations may warrant an evaluation by an

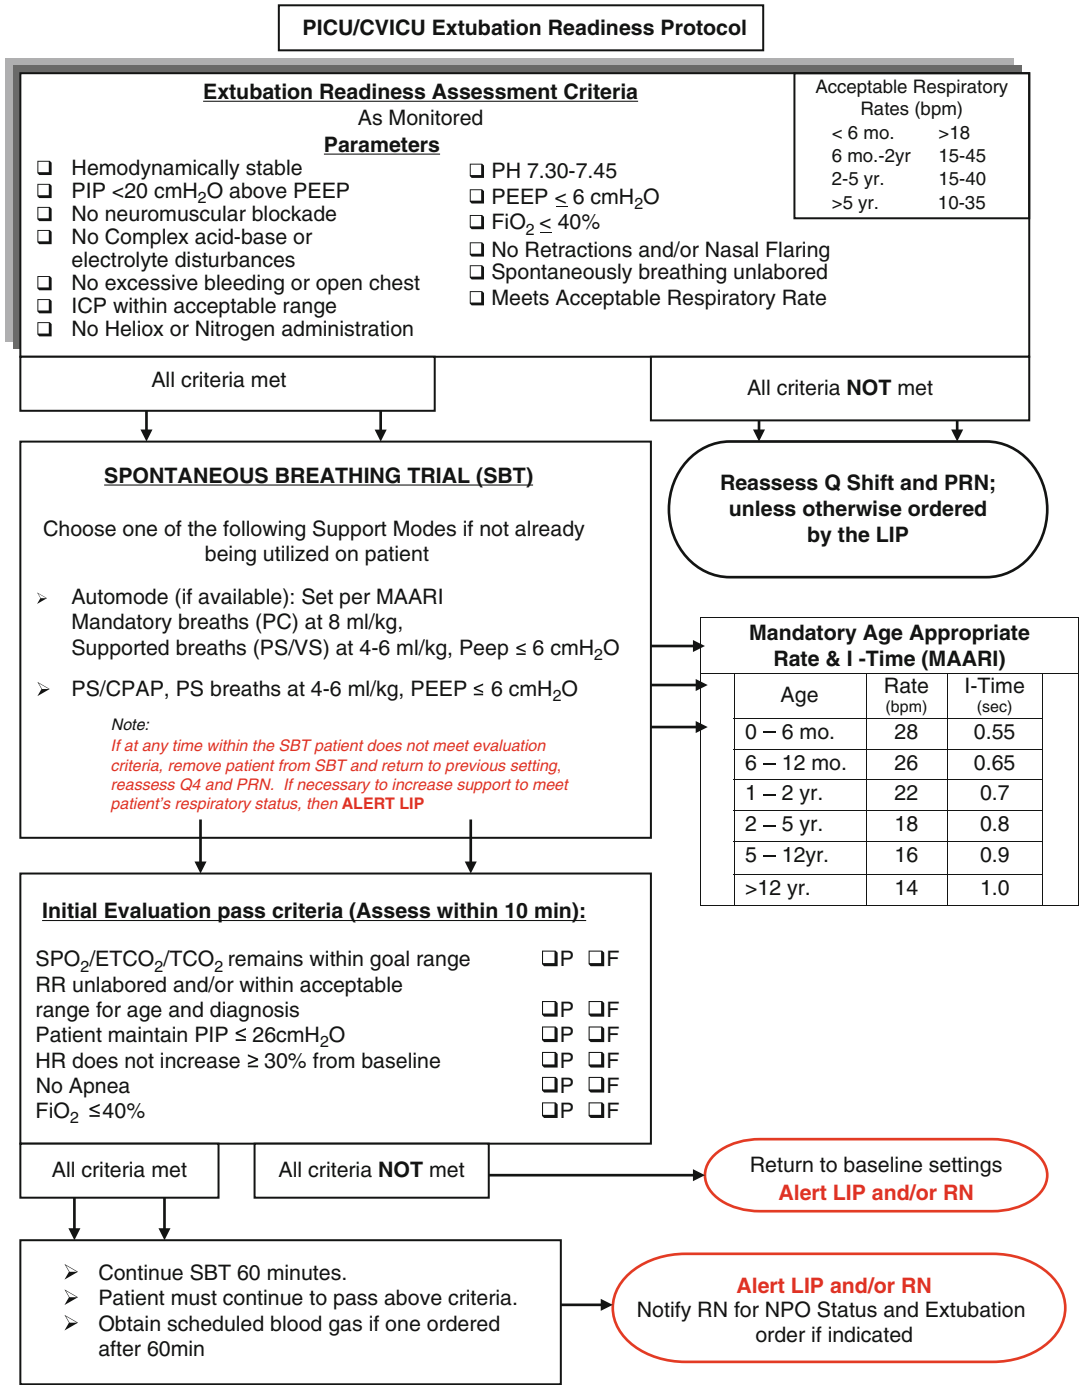

Fig. 167.11 Example of a protocol for the performance of an extubation readiness test in children. The protocol allows for therapist-directed, frequent assessments for extubation readiness. The attending physician is notified when the patient has passed the trial, but does not have to perform each trial

otolaryngologist, as subglottic stenosis and other airway abnormalities can be caused by instrumentation of the airway.

Conclusion

The respiratory care of the child with critical heart disease has profound effects on overall outcome. While often simplified or ignored, a focus on the intricacies and vagaries of pulmonary issues and their management can help pediatric cardiac surgical patients. Implementing strategies for efficient and timely extubation of postsurgical patients, focusing therapies on evidence-based guidelines, and employing physiologically sound strategies in the respiratory care of these patients can result in significant benefits. While a full understanding of the issues presented above would require much more in-depth study and years of practice, it is hoped that this chapter provides a solid foundation in the respiratory and pulmonary issues facing the practitioner caring for children with critical heart disease.

Gastrointestinal Complications in the Perioperative Period

168

James Pierce, Sylvia del Castillo, and Rula Harb

Abstract

Patients with congenital heart disease are prone to various gastrointestinal complications in the perioperative period including necrotizing enterocolitis, gastroesophageal reflux, intestinal perforation, protein-losing enteropathy, and liver dysfunction. The objective of this chapter is to discuss the various perioperative complications that can arise before or after surgical correction or palliation of different types of congenital heart disease. A review of the current literature is performed, and the management of patients from a surgical and intensive care perspective is addressed.

Keywords

Cardiac surgery • Congenital heart disease • Feeding intolerance • Focal intestinal perforation • Gastroesophageal reflux • Gastrointestinal dysfunction • Gastrointestinal • Intestinal ischemia • Intestinal perforation • Liver dysfunction • Necrotizing enterocolitis • Postoperative • Preoperative • Protein-losing enteropathy

Introduction

It is well known that simply eating a meal has a profound effect on the human cardiovascular system [1, 2]. The earliest patients surviving with congenital and acquired cardiovascular disease often suffered with poor feeding and failure to thrive [3]. Indeed, poor feeding remains an independent predictor of congestive heart failure (CHF) even in the modern era [4]. Additionally, with increased survival of children with congenital heart defects, there are now more patients with both heart disease and congenital or acquired abnormalities of the gastrointestinal (GI) tract [5, 6]. GI complications include any acquired disease process arising in either the gastrointestinal tract or to solid organs supplied by the celiac artery (CA), superior mesenteric artery (SMA), or inferior mesenteric artery (IMA). Specifically, the hollow viscera include the esophagus, stomach, duodenum, jejunum, ileum, colon, rectum, and anus. Solid organs supplied by these arteries include the liver, spleen, and pancreas [7]. Every neonatal or pediatric patient with congenital heart disease (CHD) will require some form of medical management related to the gastrointestinal tract. Often, the most critical decision is related to the initiation of feeds. This is particularly true after complex congenital heart surgery. Patients with complicated cyanotic CHD, such as single-ventricle physiology or heterotaxy syndrome, will require multiple steps in their medical management to avoid gastrointestinal morbidity and mortality.

Both GI physiology and pathology are affected by cardiovascular function. Six broad categories of cardiac physiology should be considered when approaching GI pathophysiology: pulmonary overcirculation, left ventricular outflow tract obstruction, tetralogy of Fallot, transposition of the great arteries, obstructed pulmonary veins, and single ventricles (Table 168.1). This chapter will discuss the major decision points that can occur in these patients during the perioperative period.

Table 168.1 Six classes of cardiac physiology influencing gut perfusion

Pulmonary overcirculation
Left ventricular outflow tract obstruction
Tetralogy of Fallot
Transposition of the great arteries
Obstructed pulmonary veins
Single-ventricle physiology

Pulmonary Overcirculation

Pulmonary overcirculation, such as a ventricular septal defect (VSD), is the most common form of cardiac pathophysiology [8]. During the perinatal period, these defects are generally well tolerated due to elevated pulmonary vascular resistances (PVR). Nevertheless, there is a defined subset of patients who develop cardiopulmonary collapse during the transitional period shortly after the placental circulation is removed [9]. The main gastrointestinal morbidity for these neonates is the development of intestinal ischemia, often mistaken for necrotizing enterocolitis [10]. The best studied group in this category concerns premature babies with hemodynamically significant patent ductus arteriosus [11, 12]. These patients are at risk for both global ischemia associated with poor perfusion and focal ischemia related to exogenous administration of cyclooxygenase inhibitors and steroids [13]. The subtle differences between focal intestinal perforation, necrotizing enterocolitis, and intestinal ischemia are discussed below.

For those patients who survive to postnatal circulation, the subsequent weeks and months most commonly manifest as difficulty feeding [15, 16]. PVR drops significantly in the first week of life and can lead to progressive worsening of pulmonary overcirculation. In cases with a nonrestrictive left-to-right shunt, the lungs will become progressively congested resulting in heart failure. While mild to moderate heart failure may be managed with a combination of diuretics and high-density caloric feeds, some patients will continue to experience failure to

thrive. One strategy for managing these patients is early definitive cardiac repair, which generally requires full cardiopulmonary bypass and cardiac arrest. A second strategy is palliative surgery with pulmonary arterial banding to restrict pulmonary blood flow. This avoids both cardiopulmonary bypass surgery and cardiac arrest but has a profound impact on cardiac physiology prior to definitive repair. A third strategy is to postpone surgery and aggressively feed via the enteral route, thus avoiding increased work of oral intake and ensuring adequate caloric support.

Patients with overcirculation who become malnourished fall into two subgroups. The first group includes the patients with no other feeding issues and a significant amount of left-to-right shunt. These patients often have a low-velocity (nonrestrictive) ventricular septal defect or an endocardial cushion defect. The second category includes patients with an associated condition that hinders the ability to feed. The latter include craniofacial abnormalities such as cleft lip/palate or choanal atresia, tracheal abnormalities such as malacia or stenosis, neurologic dysfunction such as intraventricular hemorrhage or seizures, prematurity, and genetic/chromosomal disease. Initial assessment of both groups of patients involves utilizing gavage feedings. Patients who cannot be adequately fed despite high caloric intake should be evaluated for cardiac palliation or repair. The process for this decision is discussed in detail later in this chapter. Patients who can consistently gain weight with supplemental gavage feeds may benefit from placement of a gastrostomy tube (G-tube). This decision to proceed with a G-tube should be carefully balanced with consideration of ongoing feeding difficulties as well as the timing of cardiac surgery. At the authors' institution, patients with no significant comorbidities and a relatively short waiting time to surgery will continue nasogastric feeds. Patients with significant abnormalities that hinder feeding will usually receive a G-tube. Invariably, there are many considerations with this decision, particularly the fact of the family's comfort and ease with an additional invasive procedure. Fortunately, the morbidity and mortality of gastric access is relatively low [17].

The initial postoperative period for these patients may be complicated by pulmonary hypertensive crises which can interfere with feeding secondary to low cardiac output and unstable hemodynamics. However, the postoperative period for this group of patients is usually uneventful, and they are able to resume enteral feeds soon after their repair [7].

Left Ventricular Outflow Tract Obstruction (LVOTO)

Significant left ventricular outflow tract obstruction and congenital abnormalities of the aortic arch comprise the second physiology group in patients with acyanotic congenital heart disease. With the advancement of fetal echocardiography, many of these patients are diagnosed prenatally. Early initiation of prostaglandin maintains fetal circulation, optimizing systemic blood flow and gut perfusion. However, many patients in this category present with either acute left heart failure (true LVOTO) or loss of distal systemic blood flow (aortic arch abnormalities). In these cases, surgical management of the cardiac lesion may be the only option to establish gut perfusion. The acute insult to the GI tract in these patients usually results in ischemic injury. It can lead to gut gangrene in as many as 11 % of patients with coarctation of the aorta [18] but remains an uncommon complication of critical aortic stenosis [19, 20]. Endovascular approaches to aortic valve and arch abnormalities generally do not aggravate gastrointestinal dysfunction. Surgical intervention for aortic valvar and especially for aortic arch defects, however, can be associated with significant postoperative gastrointestinal issues. Recurrent laryngeal nerve injury occurs in approximately 5 % [21] of aortic arch reconstructions and can lead to aspiration and inability to safely feed by mouth. This often requires feeding through a nasogastric or surgical G-tube. Operations within the posterior mediastinum, such as aortic coarctation repair and interrupted aortic arch, can injure both the thoracic duct and the vagus nerve. Thoracic duct injury can result in chylothorax or chylopericardium.

Vagal neuropraxia presents as esophageal dysfunction, delayed gastric emptying, and significant gastroesophageal reflux. In most cases, these are transient processes that can be managed conservatively. In severe cases, interventional radiology, endoscopy, or surgical repair are required.

Tetralogy of Fallot

Tetralogy of Fallot (TOF) is traditionally described as a cyanotic congenital heart lesion associated with decreased pulmonary blood flow. There are several other lesions which have a similar physiology. These include pulmonary stenosis or atresia with an ASD or VSD, double outlet right ventricle (DORV) with pulmonary stenosis, and lesions palliated with a pulmonary artery band such as a large VSD.

During early transition to extrauterine circulation, the patent ductus arteriosus allows left-to-right shunting to increase pulmonary blood flow. Ductal closure is associated with acutely worsening cyanosis which may, in the setting of cardiovascular collapse, lead to ischemic bowel. Thus, while presentation of decreased pulmonary blood flow physiology in the first 2 weeks of life is usually hypercyanosis and shock, presentation in the first several months is usually failure to thrive in patients who have not been repaired or palliated. Other factors contributing to poor feeding include prolonged ventilatory support, need for cardiopulmonary bypass, and prematurity [22, 23]. Patients with TOF or other conotruncal abnormalities have a higher incidence of a right-sided aortic arch or vascular ring which may cause dysphagia. The clinician must therefore have a high index of suspicion in this population when reviewing the echocardiogram in patients who present with dysphagia. Following complete repair, recurrent laryngeal nerve dysfunction can lead to primary aspiration. Contrast studies such as modified barium swallow study (for evaluation of oropharyngeal function) and esophagram (for extrinsic lesions obstructing the foregut) are useful in further dysphagia work-up.

Conotruncal abnormalities are associated with congenital anomalies of the gastrointestinal tract and hepatobiliary system or with heterotaxy syndromes and malrotation.

Parallel Circulation

The second major group of cyanotic congenital heart disease patients presents with increased pulmonary blood flow, but inadequate mixing of saturated and desaturated blood at the atrial or ductal level. The classic example of this type of lesion is *d*-transposition of the great arteries (TGA), although any twisting lesion with streaming dependent parallel circulations can produce transposition-like physiology. In the presence of streaming, double outlet right ventricle (DORV) can result in this physiology, as can truncus arteriosus and nonobstructed total anomalous pulmonary venous return (TAPVR).

Because these lesions are mixing dependent, adequate perfusion is reliant on shunting at multiple levels, and patients lacking this characteristic may present in complete cardiovascular collapse and develop bowel ischemia. Patients with adequate mixing may tolerate extrauterine life but are at higher risk for necrotizing enterocolitis and gastrointestinal dysfunction leading to feeding intolerance. Currently, most surgeons prefer the arterial switch operation for TGA with or without VSD within the first 2 weeks of life to minimize the systemic adverse effects of either congestive heart failure or prolonged cyanosis, both of which can lead to poor GI perfusion and feeding intolerance [24]. These lesions, with complex truncal anatomy, are also at high risk for extrinsic compression of the esophagus (vascular ring) and recurrent laryngeal nerve or vagal nerve injury during definitive repair.

Obstructed Pulmonary Veins

Obstructed total anomalous pulmonary venous return (TAPVR) is one of the true emergent surgical lesions in congenital heart disease. Similar to other repaired physiologies, there are associated feeding issues that go along with neurologic dysfunction from perioperative stroke

or hypothermic arrest, and like other operations posterior to the heart (distal arch reconstruction, the atrial switch procedures now out of favor), there are associated risks of recurrent laryngeal nerve and vagal injury. These situations are unrelated to physiology; instead, they are postoperative complications of the cardiac surgery. Regardless of postsurgical complications, TAPVR has two important effects on the gastrointestinal tract. First, the obstructed veins can lead to significant chronic lung disease, which is a known risk factor for poor feeding [25]. Secondly, TAPVR is more commonly associated with the patterning disorders classified as heterotaxy and abnormalities of hepatobiliary and duodenal development. The initial echocardiogram can help provide the diagnosis of heterotaxy as suggested by bilateral superior vena cava, interrupted inferior vena cava with azygous return, transverse position of the liver, and atrial isomerism or inversion.

Single-Ventricle Physiology

There is a heterogeneous group of complex congenital heart abnormalities which are simply not amenable to either primary or staged biventricular repair. The majority of these patients have either inadequate ventricular mass or multiple VSD; they are only candidates for single-ventricle palliation via the Fontan pathway or heart transplant. Long-term gastrointestinal issues in one and a half ventricle palliation are not yet well described.

Patients with ductal-dependent systemic or pulmonary blood flow who are placed on prostacyclin occasionally need surgery for noncardiac congenital disorders, such as obstructing imperforate anus or tracheoesophageal fistula. There is a growing body of data that suggests that these operations are well tolerated on prostacyclin and these congenital disorders do not affect overall mortality or survival to discharge. Patients who have inadequate systemic blood flow are more likely to develop intestinal ischemia and sometimes necrosis. This is a difficult group of patients, as abdominal catastrophes portend a significant mortality, although if systemic oxygen delivery can be improved after management of the ischemia, postoperative survival increases [9, 26–28].

The impact of single-ventricle physiology on the gastrointestinal tract is based on three aspects: (1) manipulation of the aortic arch, (2) amount of pulmonary blood flow, and (3) the amount of continuous arterial shunt versus oscillatory shunt through the ductus arteriosus.

For patients requiring operation on the ventricular outflow tract to achieve adequate systemic perfusion, the postoperative effects on the gastrointestinal tract are similar to those individuals with biventricular physiology who have LVOTO and require repair. Recurrent laryngeal nerve neuropraxia, occurring in ~5 % [9, 26, 27] of Damus-Kaye-Stansel or Norwood-type procedures, can lead to aspiration and inability to safely take oral intake, mandating need for feeding access. With more posterior operations such as repair of aortic arch or coarctation of the aorta, injury to the thoracic duct or vagus nerve can also occur. Vagal neuropraxia appears to lead to esophageal dysfunction, delayed gastric emptying, and significant gastroesophageal reflux. These issues can be much more significant in the single-ventricle patient as they have significantly less reserve, and chronic reflux or aspiration can prevent pulmonary vascular remodeling and lead to persistently elevated pulmonary vascular resistances (PVR).

Pulmonary blood flow has a delicate relationship with feeding in this population of patients. Those patients who do not require palliation in the neonatal period because of apparently balanced pulmonary blood flow are at higher risk of feeding and growth delays because of progressive high-output congestive heart failure as the PVR decreases. Patients who are palliated with a systemic-to-pulmonary artery shunt in the neonatal period will have a different set of complications to consider. Early following the first stage of palliation, neonates are in severe high-output heart failure because the shunt size is too large relative to their weight, which makes feeding and growing difficult. As these children "grow into" their shunt, the overcirculation

improves and feeding/growing becomes easier. Unfortunately, as they start to "grow out of" their shunt, they will develop progressive hypoxia due to decreased pulmonary blood flow, which will also affect feeding and growing. One of the theoretical advantages to a right ventricle-to-pulmonary artery shunt is lack of diastolic runoff, which theoretically may lead to more uniform systemic-to-pulmonary (Qp:Qs) ratios and lessen the impact on feeding and growing. In all cases, decisions about feeding access must be made with a good understanding of what the pulmonary blood flow is expected to progress as the child grows.

During the interstage period, gastrointestinal infection plays an important role in survival. Acute gastroenteritis, leading to dehydration via significant vomiting and diarrhea, can lead to shunt failure and cardiovascular collapse. Overly aggressive resuscitation can lead to pulmonary edema and congestive heart failure, particularly in patients known to have increased risk factors for interstage mortality, such as those presenting with an intact atrial septum or older age prior to their palliation [29]. Furthermore, many of these events occur very rapidly making interstage patients a fragile population. Given these circumstances, more centers are now using interstage monitoring programs to keep track of the patient's weight and oxygen saturations to help reduce interstage mortality [30].

Patients can become remarkably stable once they undergo stage II palliation with a bidirectional Glenn, which results in ventricular unloading and stabilization of saturations. Following this, it may be the optimal time to accomplish definitive management of associated gastrointestinal congenital anomalies. Patients can undergo, with reasonably safe anesthetic risk, repair of cleft lips and palates, resection and pull through for Hirschsprung's disease, posterior sagittal anorectoplasty for imperforate anus, removal of gastrostomy tubes, and take-down of emergently placed stomas for perforation or obstruction. These patients are relatively resilient when they endure the various acute viral gastroenteritides of childhood. By the time of Fontan completion, the main postoperative issue is related to elevated systemic and mesenteric pressures. Chylothorax, ascites, and protein-losing enteropathy (PLE) are the primary sources of post-Fontan morbidity.

Ductal-Dependent Physiology and Feeding

In neonatal patients with ductal-dependent congenital heart disease (CHD), there is no general agreement among critical care providers regarding the safety or risks of preoperative enteral feeding while on continuous prostaglandin (PGE_1) therapy. It is a common practice by many physicians to refrain from feeding a patient who is awaiting surgical palliation while on PGE_1 because of the concern for the development of necrotizing enterocolitis (NEC) secondary to poor bowel perfusion. In one survey of critical care providers, up to 54 % of those surveyed stated that enteral feeds are never started on patients preoperatively, while 37 % reported either sometimes, always, or frequently starting either oral or nasogastric feeds [31, 32]. One small study of 34 neonates with ductal-dependent CHD found that enteral feeding was well tolerated in all but one of the patients regardless of the cardiac defect or ductal-flow pattern and did not seem to be related to the presence of an umbilical arterial or venous catheter [31].

Whether or not a patient is fed, studies have shown that up to 47 % of neonates with CHD who developed NEC had diastolic runoff in the descending/abdominal aorta regardless of gestational age or anatomic type of CHD [33]. Other studies, however, refute the diastolic steal hypothesis by observation of patients with significant left-to-right shunting through the patent ductus arteriosus (PDA) without an associated higher incidence of NEC [27]. Although not all studies agree on the theory of diastolic steal, most conclude the highest risk factors for mesenteric ischemia are (1) earlier initiation of feeds correlating with earlier diagnosis of NEC [34], (2) hypoperfusion or shock from a closing ductus [35], or (3) apnea and hypotension associated with the use of PGE_1

Table 168.2 Ductal-dependent congenital heart lesions associated with persistent retrograde diastolic aortic flow

TAPVR
Coarctation of the aorta
Aortic stenosis
Truncus arteriosus
Ebstein's anomaly

TAPVR total anomalous pulmonary venous return

preoperatively [10, 27, 33]. Lower fasting SMA Doppler velocities in neonates with CHD compared to neonates without CHD may also increase their risk of mesenteric ischemia [36, 37]. Several varieties of ductal-dependent CHD with retrograde diastolic aortic flow are shown in Table 168.2. Until there are more definitive studies indicating the risks and benefits of feeding preoperative patients with ductal-dependent CHD on PGE_1, the decision to provide enteral nutrition preoperatively remains at the discretion of the team caring for the patient.

Heterotaxy Syndrome

Heterotaxy syndrome refers to any patient with abnormal patterning of left-right symmetry. In early descriptions of patterning and handedness, patients with normal left-right patterning were deemed *situs solitus*, or "usual arrangement." Patients with complete inversion of right and left (i.e., mirror image) were referred to as *situs inversus totalis*, or "completely inverse arrangement." The majority of patients with abnormal patterning failed to be completely reversed. These patients, who often had some organs in *solitus* and others in *inversus*, were named situs ambiguus, or "unclear arrangement."

These patients came to the attention of physicians, particularly Bjorn Ivemark, a Swedish pathologist, who, in 1955, coined the term right atrial isomerism after multiple autopsies he performed revealed abnormalities in the segmental arrangement and patterning of the heart. It became increasingly clear that jumbled viscera, especially intra-abdominal organs, frequently accompanied abnormalities of viscero-atrial arrangement. During the 1950s, a pair of syndromes, now often referred to as "asplenia syndrome" and "polysplenia syndrome," represented around 80 % of these patients with mixed patterning abnormalities. Further work at that time noted that many patients with asplenia had right atrial isomerism and those with polysplenia often had left atrial isomerism. Figure 168.1a demonstrates GI findings in asplenia, and Fig. 168.1b demonstrates findings in polysplenia.

Ciliary Dysfunction in Heterotaxy

In heterotaxy patients, there are often abnormalities of cilia function which can result in ramifications for the gastrointestinal tract such as hepatobiliary and pancreaticoduodenal complications. In addition to increased frequency of annular pancreas, duodenal atresia, and preduodenal portal vein, these patients also have higher rates of inspissated bile syndrome and biliary tract obstruction. Several reports have identified perforated gall bladder following complete obstruction of the biliary duct [38].

Additionally, as many of these patients have intestinal malrotation and undergo a Ladd's procedure, the incidence of adhesive small bowel obstruction is twice that of non-heterotaxy patients and is extremely poorly tolerated, leading to operation and bowel resection in up to 75 % of acute obstructions.

Malrotation and Duodenal Disease

Heterotaxy patients have a number of different potential anatomic arrangements of the stomach, small bowel, and colon. For the gut, situs solitus is a left upper quadrant stomach, duodenal *c*-loop that crosses the spine to the right and returns to turn up to a duodenal-jejunal junction that is posterior to the stomach, jejunum that travels inferiorly and posteriorly to the transverse mesocolon, jejunum and ileum that progress from left upper quadrant to right lower quadrant, and colon that continues clockwise around the

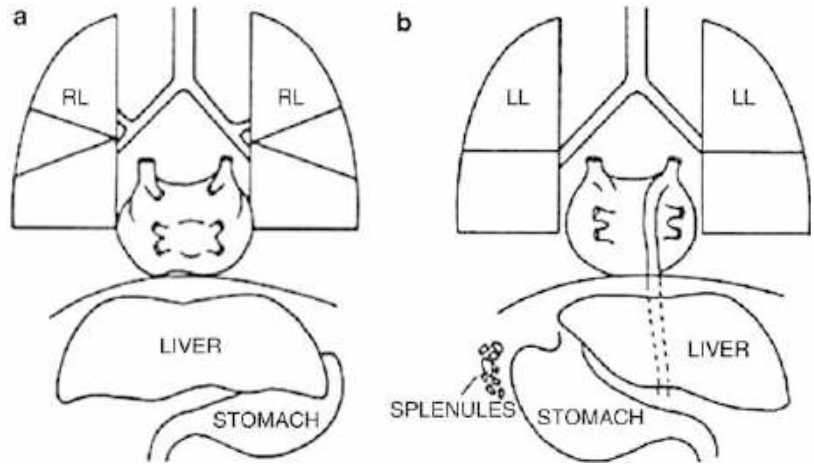

Fig. 168.1 (**a**) Schematic representing the abnormal anatomic features seen with right isomerism (asplenia); *RL* right lung. (**b**) Schematic representing the abnormal anatomic features seen with left isomerism (polysplenia); *LL* left lung

abdomen from right lower quadrant all the way around to the rectum in the pelvis. This arrangement involves a 270° counterclockwise rotation around the superior mesenteric artery. Amazingly, situs inversus totalis is the complete mirror image including the 270° clockwise rotation.

For patients with situs ambiguus, there are several possible anatomic orientations, but most commonly, there are abnormalities of the foregut and midgut. Each of these abnormalities can be screened for by a complete abdominal ultrasound, and if malrotation or other abdominal anomaly is found, a general surgery consult should be considered prior to initiating feeds depending on each institution's preference.

Specific Gastrointestinal Diseases

Necrotizing Enterocolitis and Intestinal Ischemia

Necrotic bowel is a catastrophic situation that occurs as the final common pathway of several distinct disease entities. In all cases, there is clinical deterioration and evidence of an intra-abdominal source. For this reason, these processes are often incorrectly lumped together – both via using denominations interchangeably and also by applying similar treatment plans. It must be emphasized, however, that at the root of these different diseases, there are two main contributing mechanisms. The first is bowel ischemia due to inadequate oxygen delivery which requires emergent intervention to reestablish adequate bowel perfusion, whether by addressing the primary cardiac lesion (LVOTO) or addressing a specific obstructive cause of ischemia (malrotation with volvulus and obstruction of superior mesenteric artery). Conservative therapy will fail because the ischemia will progress to dead bowel. The second main contributing mechanism is not from ischemia but rather inflammation or infection. In these cases, most commonly necrotizing enterocolitis, the inflammation or infection leads to patchy mucosal injury, which may go on to develop congestion, ischemia, full-thickness necrosis, and perforation. In these cases, however, a conservative approach of reducing tissue oxygen demand via bowel rest with gastric drainage and broad spectrum antibiotics to treat infection is often successful. Emergent intervention is only indicated if there is a frank surgical indication: perforation or complete obstruction. Thus, the first step in evaluation of an abdominal catastrophe is to identify ischemic from nonischemic causes [39], which requires a thorough understanding of the underlying cardiac pathology. As discussed above, ischemia can occur following a decrease in systemic blood flow, as occurs at ductal closure in lesions with ductal-dependent systemic blood flow or critical

LVOTO. Ischemia can also occur with adequate blood flow but profound hypoxia, as in *d*-TGA physiology with inadequate mixing. Additionally, ischemia occurs during cardiopulmonary collapse and during periods of cardiogenic shock (from dysrhythmias, cardiac stun, myocardial ischemia, acute valve failure, and other situations). In all of these situations, the bowel ischemia is a symptom, and the primary focus should be on resuscitation and management of the cardiac lesion. Simultaneously, patients should be made nil per os, receive a Salem Sump style gastric drainage tube, have all enteral access (gastrostomy, jejunostomy) placed to gravity, and receive intermittent abdominal films looking for evidence of perforation – specifically, free air. As long as no absolute surgical indication develops (i.e., perforation), continued focus should remain on the cardiac lesion.

In patients without a recent change in cardiac status, acute ischemia is unusual but not impossible. The most common extra-cardiac cause of primary ischemia is acute volvulus. Superior mesenteric artery or aortic thrombosis is rare but can be associated with prolonged use of umbilical arterial lines or primary hypercoagulable states [40–42]. Acute mesenteric ischemia of embolic origin has only been reported in adults. Assessment of the aorta and superior mesenteric artery can be done via Doppler ultrasonography, although without predisposing risk factors, the extremely low pretest probability makes this study unlikely to be useful.

True necrotizing enterocolitis (NEC) is a multifactorial disease process that involves an immature intestinal barrier that is "primed" for mucosal damage by a perinatal or transient hypoxic/ischemic insult. This allows indigenous organisms to breach the damaged mucosa and initiate a cycle of inflammation, worsening mucosal integrity, and increased translocation [43]. Figure 168.2 shows a patient diagnosed with tetralogy of Fallot and pulmonary stenosis who presented with pneumatosis intestinalis after being fed following the closure of the ductus arteriosus. Feeding is a requirement (to facilitate intestinal colonization), and aggressive feeding is a known risk factor for NEC [44]. The timing of NEC is later than ischemia but before a more mature gut flora colonization, suggesting that it is a different group of transient bacteria that may participate in this process. In any event, patients with CHD developing NEC generally are postoperative (palliative or definitive repair), receive an aggressive feeding advancement because they look clinically well, and develop severe sepsis and decompensation with evidence of an abdominal source. This is in stark contrast to primary ischemia as discussed above.

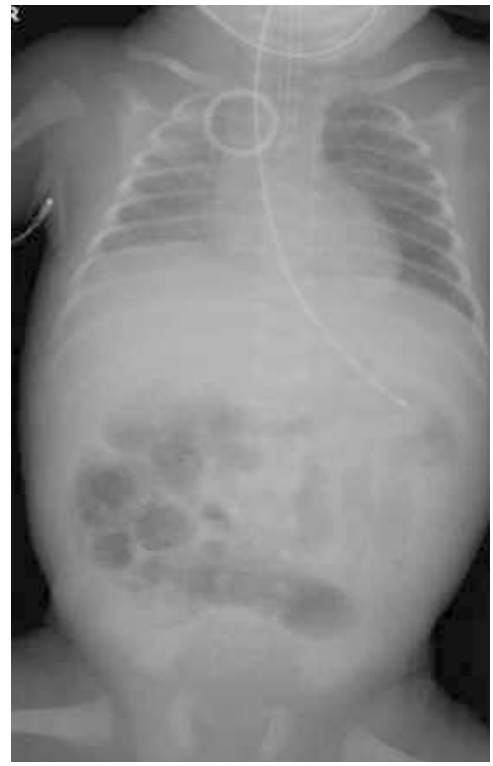

Fig. 168.2 Pneumatosis intestinalis

Necrotizing enterocolitis has a variable clinical picture ranging from very mild to full arrest. Symptoms include feeding intolerance, heme-positive or bloody stools, temperature instability, lethargy, and lability of vitals. Physical exam often shows poor perfusion with mottled skin and central-peripheral temperature gradient. The abdominal exam can range from mild distention to discolored and tense.

Classic laboratory signs include thrombocytopenia, acidosis, and coagulopathy. Plane films of the abdomen in two views are performed looking for evidence of mucosal disease (pneumatosis intestinalis), which can progress to portal venous gas and even perforation (abdominal free air). While a full discussion of the nuances of surgical management is beyond the scope of this chapter, any concern for NEC (or ischemia) should prompt a general surgery consult to determine the frequency of imaging and examination, duration of therapy, and, in the event of perforation or obstruction, the surgical management.

Focal intestinal perforation (FIP, also referred to as single intestinal perforation) generally occurs in a premature newborn with a patent ductus arteriosus. Because of its association with prematurity and perforation, many patients with FIP are classified as one end of the spectrum of NEC. Unlike NEC, however, these patients lack global patchy mucosal disease. Instead, they have a very focal perforation of the terminal ileum, generally a few centimeters from the ileocecal valve. When cases of FIP are selected, independent risk factors for FIP include antenatal steroid administration and cyclooxygenase inhibition for medical closure of PDA. Clinically, patients are usually much more stable with FIP than NEC and lack the intensity of the inflammatory response, and the hallmark finding is massive free air on abdominal film. The current hypothesis is focal dysregulation of distal ileal mucosal blood flow – inhibited by NSAID and steroids, leading to perforation. Like all major abdominal catastrophes, prompt surgical evaluation is mandatory.

Fig. 168.3 Abdominal free air on KUB (kidney, ureter, bladder) radiograph

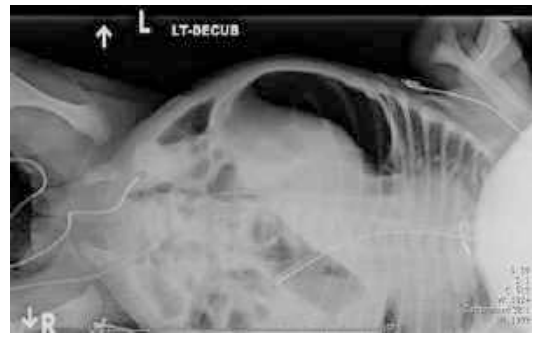

Fig. 168.4 Abdominal free air seen on lateral decubitus radiograph

Abdominal Free Air

Abdominal free air is actually "free gas" as it may not always be the air mixture of 79 % nitrogen and 21 % oxygen. Figures 168.3 and 168.4 demonstrate abdominal free air on kidneys, ureter, and bladder (KUB) and lateral decubitus films.

The most benign source of gas in the abdomen results from a hole in the diaphragm (congenital or iatrogenic). If a congenital diaphragmatic hernia exists without an hernia sac, any open heart operation that violates the pleural space will allow free air to travel through the hernia into the abdominal cavity. Most posterolateral diaphragm hernias (Bochdalek) are identified preoperatively on chest x-ray and, because of

the resulting pulmonary hypoplasia, are considered during operative planning for the cardiac defect. Anterior defects, Morgagni hernias, are usually recognized during operative exposure of the heart. Besides these congenital lesions, because of the limited space in the neonatal costal angle, occasionally mediastinal tubes graze the central tendon and pass through the abdominal cavity. When this occurs, free air can enter the abdomen prior to chest closure. Because these drainage tubes are often placed to suction, most abdominal air will be evacuated reasonably quickly; the remainder will reabsorb over 3–7 days much like free air from laparotomy.

Thoracic operations, particularly reoperations, can be associated with transient air leak from the lung surface. In the event that a congenital or iatrogenic diaphragm hole exists, the leaking air may preferentially drain intra-abdominally. Because of the speed at which postoperative air would be evacuated and the persistence of air in the abdomen in the setting of air leak, the first step in evaluating free abdominal air in the early postoperative period is to evaluate the patient for air leak, ensure all chest drains are unblocked and on suction, and then perform plane films of the chest and abdomen in two views. Generally speaking, in patients with good clinical status, no evidence of ischemia (normal lactate and pH), and an air leak or visible tube traversing the abdomen, there will be minimal suspicion of abdominal catastrophe. Expectant management and utilizing chest tubes to avoid tension physiology will generally allow resolution of the free gas. The late concern of transabdominal mediastinal tube placement is the development of a diaphragmatic or epigastric hernia requiring repair at a later date.

There are times, however, when the clinical status of the patient is questionable or worsening, and it is impossible to discern free gas from the causes above from hollow viscus perforation. In this case, there is generally simultaneous decline in cardiopulmonary function and evidence of abdominal catastrophe. Because these situations can result from both ischemic and nonischemic causes as discussed above, it is imperative that surgeons, cardiologists, and intensivists work together to ensure both cardiac function and abdominal disease are appropriately addressed. An ischemic bowel that perforates can be resected, but unless the cause of the ischemia is addressed, the outcome will be poor. Cardiac function can be supported during an episode of necrotizing enterocolitis, but without broad spectrum antibiotics and bowel rest, patients will succumb to progressive sepsis and disseminated intravascular coagulation.

Gastroesophageal Reflux

Adults and children have physiologic reflux that helps stimulate the esophagus to clear esophageal contents and facilitate evacuation of intragastric (swallowed) air. From birth until approximately 6 months of age, the esophagus has minimal intra-abdominal length, and therefore, neonates have greater reflux than infants who have more than toddlers. Teleologically, this can be explained by the need to evacuate significant gastric air from crying as neonates and infants have greater parasympathetic tone and are less tolerant of acute gastric distention. Severe reflux is associated with failure to thrive, apparent life-threatening events, increased airway reactivity by both reflux-mediated aspiration and parasympathetic reflex, laryngospasm and edema, exacerbation of chronic lung disease, aspiration pneumonias, interstitial pulmonary disease, and persistent pulmonary hypertension.

A number of different methods have been utilized to assess degree of reflux. Upper gastrointestinal fluoroscopy can demonstrate anatomic abnormalities associated with reflux, such as intrathoracic stomach, as well as functional abnormalities like poor esophageal motility and actual episodes of visualized reflux. Unfortunately, this study is limited by its short duration and the unpredictable nature of reflux. Gastric scintigraphy, a longer study, has slightly better predictive value than fluoroscopy but is still limited by averaging during the study. Excessive reflux can lead to an interpretation of delayed gastric emptying, and gastric outlet obstruction can minimize readings of reflux. In adults and

increasingly in children, pH probe is being used to standardize the diagnosis of GER. Although adults have [45, 46] standardized pH probe placement to 5 cm above the manometrically determined gastroesophageal sphincter, it has been difficult to standardize pH placement in children and impossible in infants because of the rapid change in sphincter location, esophageal length, and sphincter function. Different techniques have been tried including radiologic placement using the diaphragm, measurements using crown rump length, and even manometry; however, a pediatric and neonatal gold standard study is still lacking.

Nearly all patients who undergo distal aortic arch manipulation (especially coarctation and hypoplastic arch) vagal dysfunction, likely a neuropraxia due to moving the nerve out of develop at least a transient the way during operation. When significant vagal nerve dysfunction is present, patients manifest not only reflux but poor esophageal motility, proximal reflux, and significant delayed gastric emptying. Fortunately, rates of significant nerve dysfunction are low, estimated in the same range as recurrent laryngeal nerve or phrenic nerve injury, between 1 % and 5 %. In general, this transient reflux can be managed conservatively and resolves in 2–6 weeks.

Patients with single ventricles who require reconstruction of the ventricular outflow tract and arch (i.e., true Norwood procedure) have similar transient vagal dysfunction. In these patients, radiologic reflux is associated with failure to survive to bidirectional Glenn [28]. One hypothesis is that chronic reflux leads to persistently elevated pulmonary vascular resistance due to aspiration pneumonitis and pneumonia with pulmonary sepsis. Fortunately, the majority of these are transient neuropraxia which can be resolved with medical management or low-risk nasojejunal feeding. Several centers have achieved anti-reflux procedural mortality under 5 %; nevertheless, there is not yet a good method to identify which patients will have improved survival with fundoplication.

There is a very unique situation in these patients that deserves mention. Failure to survive to stage II palliation (cavopulmonary shunt/bidirectional Glenn) is increased in patients with severe GER, likely due to a combination of aspiration pneumonitis and elevated PVR which can lead to progressive cyanosis, which may be misinterpreted as shunt obstruction. These patients may undergo many negative evaluations for shunt obstruction via repeated echocardiograms or cardiac catheterization or may be subject to another operation to either upsize or place a second shunt to increase pulmonary blood flow, when in fact, the etiology is severe reflux. Rather than undergoing multiple shunt revisions or early bidirectional Glenn, these patients could benefit from aggressive control of reflux. Attempts to perform anti-reflux surgery after stage II palliation in the authors' institution have had unacceptably high mortality (three of four attempts died), as opposed to early fundoplication which has mortalities from 3 % to 8 % in skilled hands [28].

Protein-Losing Enteropathy After Fontan Operation

Protein-losing enteropathy (PLE) is defined as the abnormal loss of serum proteins into the lumen of the gastrointestinal (GI) tract. It is reported to occur in anywhere from 1 % to 15 % of patients who have received a Fontan operation [47, 48]. The onset of PLE after Fontan is reported to range from 2 months to 16.4 years, with a mean of about 2–3 years [47, 49]. It results in significant morbidity and mortality to the patient, with a reported 5-year survival rate of 50 % after onset of diagnosis [47, 49].

The diagnosis is suspected when patients present with symptoms of diarrhea, weight gain, and increased abdominal girth from peripheral edema and ascites. Often, GI symptoms such as abdominal pain and even diarrhea may not be present and the only symptoms are secondary to fluid accumulation that results from a low intravascular oncotic pressure due to the loss of serum proteins into the GI tract. Other clinical signs and symptoms may include breathing difficulties from pleural/pericardial effusions, failure to

thrive and short stature, and muscle tetany (secondary to low serum calcium). There are reports of acquired immunodeficiency associated with PLE post-Fontan [50, 51] as lymphocytes and immunoglobulins are also lost into the intestine. GI bleeding, where all testing failed to demonstrate GI pathology as a source of the bleeding, has also been reported [52]. Diagnosis is made by demonstrating low levels of serum albumin (<3.5 g/dL) and serum protein (<5.5 g/dL), as well as increased wasting of protein in the GI tract measured by an elevated stool alpha-1-antitrypsin. Primary renal disease (nephrotic syndrome) as well as hepatic disease should be ruled out.

The pathophysiology of PLE after Fontan remains uncertain. PLE is usually seen in primary GI disease, such as Crohn's disease, with an inflammatory component, as well as in primary diseases of the lymphatic system such as intestinal lymphangiectasia. Why it occurs following Fontan operation remains poorly understood although a few studies have been aimed at trying to understand the pathophysiologic mechanisms. The presence of elevated systemic venous pressure leading to lymphatic and vascular engorgement and subsequent protein loss into the GI lumen is the most prevalent theory, although a direct association between elevated systemic venous pressure and PLE has not been found [47]. In their international, multicenter study of PLE after Fontan, Mertens et al. found that although patients with Fontan had elevated systemic venous pressures compared to patients with two-ventricle physiology, it was not significantly different in patients with PLE versus those who did not develop PLE. They did however find that patients after Fontan had low cardiac output, with those with PLE having even lower cardiac output [47]. In 2002, Rychik et al. demonstrated that mesenteric vascular resistance (MVR) was elevated in patients after Fontan and that patients with PLE had increased MVR compared to those without PLE. They postulated that low cardiac output after Fontan leads to elevated MVR and subsequent mesenteric hypoperfusion, contributing to the development of PLE [53]. PLE after Fontan is also thought to have an inflammatory component as it does respond to steroid treatment. In their study of 62 patients post-Fontan, Ostrow et al. found that these patients had elevated C-reactive protein (CRP) and one third had elevated tumor necrosis factor alpha (TNF-a), but these levels were not significantly more elevated in patients with PLE [54]. The authors felt that the number of patients they had with PLE (7 of a total of 62) was too small to see a significant trend. Studies on an in vitro model of PLE by Freeze et al. have shown that there is greater albumin flux across a monolayer of intestinal mucosal cells when it is treated with TNF-a and heparanase (to digest heparan sulfate) and that this increase is additive [55]. So Rychik, in his review article in 2006, postulates that the mechanism for developing PLE post-Fontan involves a low cardiac output that results in increased MVR, causing hypoperfusion of the intestine, subsequent inflammation, and loss of intestinal mucosal integrity, leading to protein loss.

Treatment options of this condition are shown in Table 168.3 and depend upon the severity of hypoalbuminemia and the patient's symptoms. In mild cases, the symptoms can be controlled with a high protein diet, containing medium chain fats (MCT) and diuretics (spironolactone and furosemide). Intermittent intravenous infusions (IV) of 25 % albumin followed by IV furosemide will also control symptoms for a short period of time but do not resolve the underlying problems. Treatment with heparin (5,000 units/m^2 subcutaneously) has been effective in some more moderate to severe cases [56]. Systemic corticosteroids are also effective in moderate to severe disease at a dose of 1–2 mg/kg/day orally [57]. Intravenous administration may be necessary in cases where the intestine is too edematous to be able to absorb oral prednisone, with subsequent transition to oral prednisone once symptoms improve. Sildenafil, at a starting dose of 0.5 mg/kg/dose four times a day, has also been used in patients with satisfactory Fontan pathways and baseline hemodynamics, but when signs of increased pulmonary and mesenteric and vascular resistance are noted [58]. Occasionally, if malabsorption is severe, patients may

Table 168.3 Management options of PLE

Mild	Moderate	Severe
High protein diet with MCT 25 % albumin IV	Heparin (5,000 U/m^2 SQ)	Systemic steroids
IV diuretics	Sildenafil (0.5 mg/kg/dose qid)	Bowel rest/TPN
		Transcatheter Fontan fenestration Surgical revision of Fontan
		Cardiac transplantation

MCT medium chain triglycerides, *IV* intravenous, *SQ* subcutaneous, *mg* milligram, *kg* kilogram, *qid* four times a day, *TPN* total parental nutrition

benefit from bowel rest and total parenteral nutrition (TPN) to replenish the electrolytes and protein that are being lost in the gut. Interventional treatment is reserved for severe cases and usually consists of transcatheter Fontan fenestration or surgical revision. Cardiac transplantation has also been reported to successfully resolve the PLE but is considered a last resort option for treatment [59].

Liver Disease

Ischemic hepatitis, also known as shock liver, results from acute hypoperfusion of the liver [60]. It presents with marked elevation of serum alanine aminotransferase (ALT), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH) and has been reported in children post cardiac surgery [61–63]. These patients may also have hepatomegaly, jaundice/conjugated hyperbilirubinemia, and coagulopathy, consistent with acute liver failure. The pathophysiology is thought to result from a marked reduction in blood pressure, leading to hepatic hypoperfusion and hepatocyte injury. Seeto et al. investigated the pathogenesis of ischemic hepatitis and found that in their series of patients, those who developed the condition all had underlying organic heart disease. They postulate that these patients with underlying cardiac disease had decreased cardiac output leading to hepatic congestion that may predispose the liver to injury precipitated by hypotension [64]. AST and ALT become elevated in the perioperative period after cardiac surgery, usually within the first 48 h. Shteyer et al. retrospectively reviewed the charts of 384 children post cardiac surgery over a 10-year period and found that 11.9 % of them had elevated transaminases, with extreme AST and ALT elevations (>20× normal) found in about 3–5 %. They also found that elevated transaminases were primarily found in those with right-sided heart dysfunction (TOF, DORV) and that there was a significant increase in the overall mortality of patients with extreme transaminase elevation [62]. Despite the fairly classic presentation, it is important to rule out other possible underlying causes of liver disease (infectious, metabolic, toxic, autoimmune). It is also important to rule out other syndromes that may encompass both abnormalities of the heart and the liver such as Alagille syndrome and congenital biliary atresia. Treatment is supportive and is aimed at maximizing cardiac output and improving blood flow to the liver. Prognosis is usually dependent on the severity of the underlying cardiac condition.

Nutrition in Congenital Heart Disease: Challenges, Guidelines and Nutritional Support

169

Piyagarnt E. Vichayavilas, Heather E. Skillman, and Nancy F. Krebs

Abstract

Infants and children with congenital heart disease have high energy requirements and poor intake and are frequently malnourished. Delivering adequate nutrition is challenging and may be difficult due to fluid limitations, feeding intolerance, gut hypoperfusion secondary to low cardiac output and heart failure, hypoxemia, or ductal dependent blood supply. Nutrition intervention, with close tolerance monitoring, is safe, optimizes nutrition status, and reduces morbidity and mortality.

Introduction

Growth failure is a well-known feature among infants and children with congenital heart disease (CHD). Reported prevalence of malnutrition ranges from 27 % to 90 %, with developing countries having a higher prevalence of growth failure [1–6]. Advancements in technology, expertise, and postoperative care have led to a dramatic decline in postoperative mortality [7]. Mortality is reduced for all children with congenital heart disease who undergo repair or palliation but in particular for children with complex anatomy and single-ventricle physiology. Improvement in overall survival, however, has increased morbidity in certain areas. It is no longer adequate to measure success of congenital heart centers in terms of survival alone; reduced morbidity and improved quality of life must also be examined [7, 8]. As growth derangement is a major component in the course of CHD, the arising question regards how nutrients can be best provided in order to optimize

perioperative outcome and support growth in these fragile children. After the acute operative phase subsides, the burden of malnutrition does not cease upon hospital discharge but rather continues to present challenges for optimal outcomes. Early growth failure has been shown to impair cognitive and motor development [9, 10] and increase behavioral problems, such as attention deficit and impulse control, and is related to lower school achievements [9].

Nonetheless, malnutrition in the child with congenital heart disease is not inevitable. With close monitoring, nutrition interventions – via oral intake or nutrition support – may be well tolerated and can promote weight gain [11, 12]. Malnutrition in infants and children with CHD should be prevented rather than expected. Improved nutrition status not only allows infants and children with CHD to reach growth and development potentials but also optimizes surgical outcomes. This chapter will review the nutritional risks associated with CHD, suggest approaches to provide nutrition support and optimize feeding, and discuss the approach to assessment of nutritional status, especially growth.

Energy Requirements, Malnutrition, and Morbidity

The early months of life present a time when energy requirements are dedicated to accrete new tissue. Energy costs for growth are about 35 % of daily energy needs during the first 3 months, fall dramatically to 3 % at 12 months of age, and become negligible in late adolescence [13]. Early infancy is thus a particularly critical time, when compromised energy and nutrient delivery can profoundly impair growth.

Energy Expenditure

The risks of malnutrition and increased energy requirements are dependent on the anatomy and severity of the cardiac defect. Risks are related to the presence or absence of congestive heart failure (CHF), cyanosis, and concurrent pulmonary hypertension. CHF and cyanosis negatively affect both weight gain and linear growth [1, 14–19]. In a study of 150 hospitalized children, acute or chronic malnutrition was present in 70 % of patients with cyanosis and/or CHF, compared to 30 % when neither was present [1]. Pulmonary hypertension exerts an additive effect; the most malnourished have CHF or cyanosis, with pulmonary hypertension [6, 11].

Children with CHF are often smaller and leaner than those without heart disease [1, 16, 19]. Inadequate intake due to fatigue [17] has been reported and may account for some of the observed growth failure. However, those without overtly diminished intake still frequently demonstrate a great degree of malnutrition [14, 16, 20, 21]. This suggests that elevated energy expenditure, increased nutrient loss, or both exert a significant role in the observed malnutrition. Resting energy expenditure (REE) includes myocardial and respiratory work, basic metabolic functions, and the maintenance of thermoregulation. The effort to maintain these functions can be exaggerated with heart failure, contributing to higher REE [22].

While some investigators have implicated elevated REE in growth failure, others have not shown similar results. Menon and Poskitt did not find a significant difference in oxygen consumption between infants with or without CHF, unless pulmonary hypertension was present [11]. In some studies, infants with VSD had no significant difference in REE but rather an elevation in total energy expenditure (TEE), owing to a higher cost of physical activity [14, 16] that was also positively correlated with pulmonary to systemic shunt size [16]. The energy cost of physical activity can be as much as 250 % higher than age-matched healthy infants [14].

In a recent meta-analysis, TEE measured by doubly labeled water – a technique used primarily in research – was 35 % higher in infants with CHD compared to healthy controls [21]. The energy requirement for healthy infants is approximately 90–120 kcal/kg. A 35 % increase from this places energy requirements between 120 and 160 kcal/kg, an intake level that may not be possible to attain without nutrition and feeding intervention.

Growth and Malnutrition

While the etiology of poor growth is multifactorial, one fundamental factor is the discrepancy between energy intake and expenditure. Infants and children with tachypnea and pulmonary overcirculation from large left-to-right shunts may have inadequate intake to match their hypermetabolic state [11, 14, 16, 21, 23–26]. Suboptimal intake due to anorexia, inefficient feeding, and fatigue are also common contributors of inadequate consumption. Malabsorption has also been investigated as a route of energy loss [20, 27, 28], but data have been inconsistent regarding its significance. Sondheimer and Hamilton reported that protein malabsorption was present in 50 % of infants with either CHF or cyanosis, while steatorrhea occurred mostly in cyanotic patients [20]. In contrast, Vaisman reported that fat malabsorption does not play a significant role in this population as the tendency toward steatorrhea is seen only when total body water (TBW) is 20 % in excess of expected, possibly a reflection of bowel edema. Infants and children with 120 % of expected TBW malabsorbed only 8 % of calories ingested. This level of energy loss is out of proportion with the degree of observed growth failure. Further investigation is thus warranted in infants and children with CHD who fail to grow [28].

Infants and children on acute and chronic diuretic therapy experience losses of electrolytes, calcium, and zinc and may require supplementation to correct deficiencies or to restore growth. Hyponatremia, hypochloremia, and a contraction alkalosis are common electrolyte and metabolic disturbances in the Cardiac Intensive Care Unit. Chloride deficiency in particular is common and usually results from acute and chronic diuretic therapy. Low chloride and metabolic alkalosis can manifest with anorexia, poor weight gain, and poor head growth [29]. Manifestations of zinc deficiency include poor growth, anorexia, and impaired wound healing. Premature infants are born with low zinc reserves and are particularly at risk for development of deficiency. Premature infants are at increased risk of the effects of calcium and vitamin D deficiency; cases of rickets have been reported in low birth weight infants receiving furosemide [30].

Providing a more concentrated feed, with fortified human milk or high calorie formula, is a way to deliver more calories and nutrients when fluid intake volume is limited. One report suggested that 150 kcal/kg was required for growth and was only possible via 24-h-continuous nasogastric infusion [17]. For the infant with CHD, the increased energy requirement can lead to growth faltering and malnutrition; however, increased energy density and/or supplemental feedings can improve growth.

Special considerations should be given to infants with hypoplastic left heart syndrome (HLHS) who undergo surgical palliation. Single-ventricle patients are reported to have more feeding and growth challenges [31]. These infants, overall, demonstrate prolonged hospitalization with more tenuous and labile postoperative course. Nutrition support, following the modified Norwood procedure (S1P, stage one palliation), is often inadequate [32]. Diminished weight-for-age z-scores may not resolve by the time of hospital discharge [33, 34] and may persist to the second surgical intervention in the first year of life, the Bidirectional Glenn procedure (BDG). Failure to achieve "catch-up" weight gain at time of BDG is associated with an increased risk for infections and prolonged length of hospital stay [35].

Nutrition Support and Feeding

In the *presurgical* period, concern for systemic hypoperfusion may preclude the initiation of enteral feeding. The policy of some institutions is that infants requiring intravenous prostaglandin (PGE_1) infusions or those with umbilical catheters [36] are not fed, although strong evidence to support this practice is lacking [37]. Natarajan et al. reported that feeding infants on PGE_1 with umbilical catheters is well tolerated. Intake at 100 mL/kg was reached in 75 % of patients and full feeds achieved in 29 % of infants. One case of necrotizing enterocolitis (NEC) was reported in a patient with HLHS.

Willis et al. reported tolerance in enteral feeds in 33 out of 34 patients receiving PGE_1 [38]. Use of feeding algorithms has been shown to improve energy delivery and feeding tolerance and has been associated with reduced incidence of complications [39–41]. Enteral nutrition guidelines or algorithms (Fig. 169.1) should include step-by-step, evidence-based recommendations for initiation and advancement of feedings and customized to the population at risk of complications. Such an algorithm for newborns with CHD, specifically with or without single-ventricle physiology and PGE_1 infusion, could benefit this tenuous population.

Postoperatively, energy expenditure is influenced by many factors specific to interventions employed. Infants who have undergone cardiopulmonary bypass have nearly a 30 % higher REE than those not requiring bypass (74 vs. 58 kcal/kg) [42]. Li et al. investigated energy expenditure and provision from days 0 to 4 following the Norwood procedure via continuous measurement of $\dot{V}_{O_2}$ and $\dot{V}_{CO_2}$ by respiratory mass spectrometer. They reported that the infants were most catabolic in the immediate hours after surgery when they received minimal calories. Energy delivery increased daily; however, it was not until postoperative day 3 that energy provision exceeded expenditure [32]. Petrillo-Albarano et al. reported that it may take up to 9 days to reach full feeds [43]. Fluid limitations and hemodynamic instability are frequent barriers to adequate nutrition support. During this time, nutrient administration is often inadequate to match the catabolic state. This may be critical time lost with the potential to negatively affect wound healing and growth, as well as cardiac, pulmonary, and immune function.

Infants requiring extracorporeal membrane oxygenation (ECMO) are also profoundly catabolic [44]. ECMO replaces pulmonary function, assumes approximately 80 % of cardiac work, and thermoregulation is provided by the circuit. While some studies of infants supported by ECMO have shown an increased mean REE at 89 kcal/kg/day [45], others have demonstrated the average REE of infants requiring ECMO to be the same as age-matched healthy controls at 55 kcal/kg/day [46]. The rate of protein loss is 2.3 g/kg/day [45, 47], representing a greater than 100 % increase in protein requirement compared to healthy neonates. Historically, many providers were reluctant to feed neonates on ECMO due to concern for gut ischemia. Recently, there has been a trend for earlier introduction of enteral feeding: from 67 h after initiation of ECMO in 1997 to 40 h in 2001[48]. Intestinal hormones respond appropriately after initiation of enteral nutrition [49], nutrition support is well tolerated [48, 50], and feeding does not promote deterioration of intestinal integrity [51].

Predictive equations often fail to accurately predict energy expenditure in the critically ill population [52–55]. Failure to adequately match energy and protein delivery to metabolic demand can reduce lean body mass, increase time on the ventilator, and increase length of ICU stay [56]. Overfeeding increases carbon dioxide production and may prolong mechanical ventilation, promote hyperglycemia, hypertriglyceridemia, and increase the risk of hepatic steatosis [57]. Both over and underfeeding carry undesirable consequences; therefore, tailored caloric provision via energy expenditure measurement through indirect calorimetry (IC) should be used when available and feasible. IC is a system that captures the oxygen used and carbon dioxide produced and calculates the amount of heat (energy) generated. This remains the gold standard for measuring energy expenditure in the clinical setting [59].

$$\textbf{Energy Expenditure } (\textit{kcal}) = \left[\left(\dot{V}_{O_2}\ \frac{L}{\min}\right)(3.941) + \left(\dot{V}_{CO_2}\ \frac{L}{\min}\right)(1.11)\right] 1440\ \min$$

$$\dot{V}_{O_2} = Vi(FiO_2) - Ve(FeO_2)$$

$$\dot{V}_{CO_2} = Vi(FiCO_2) - Ve(FeCO_2)$$

It is recommended that IC study be repeated up to a few times per week according to the patient's change in clinical status. This, however, is costly, requires technical expertise, and is not

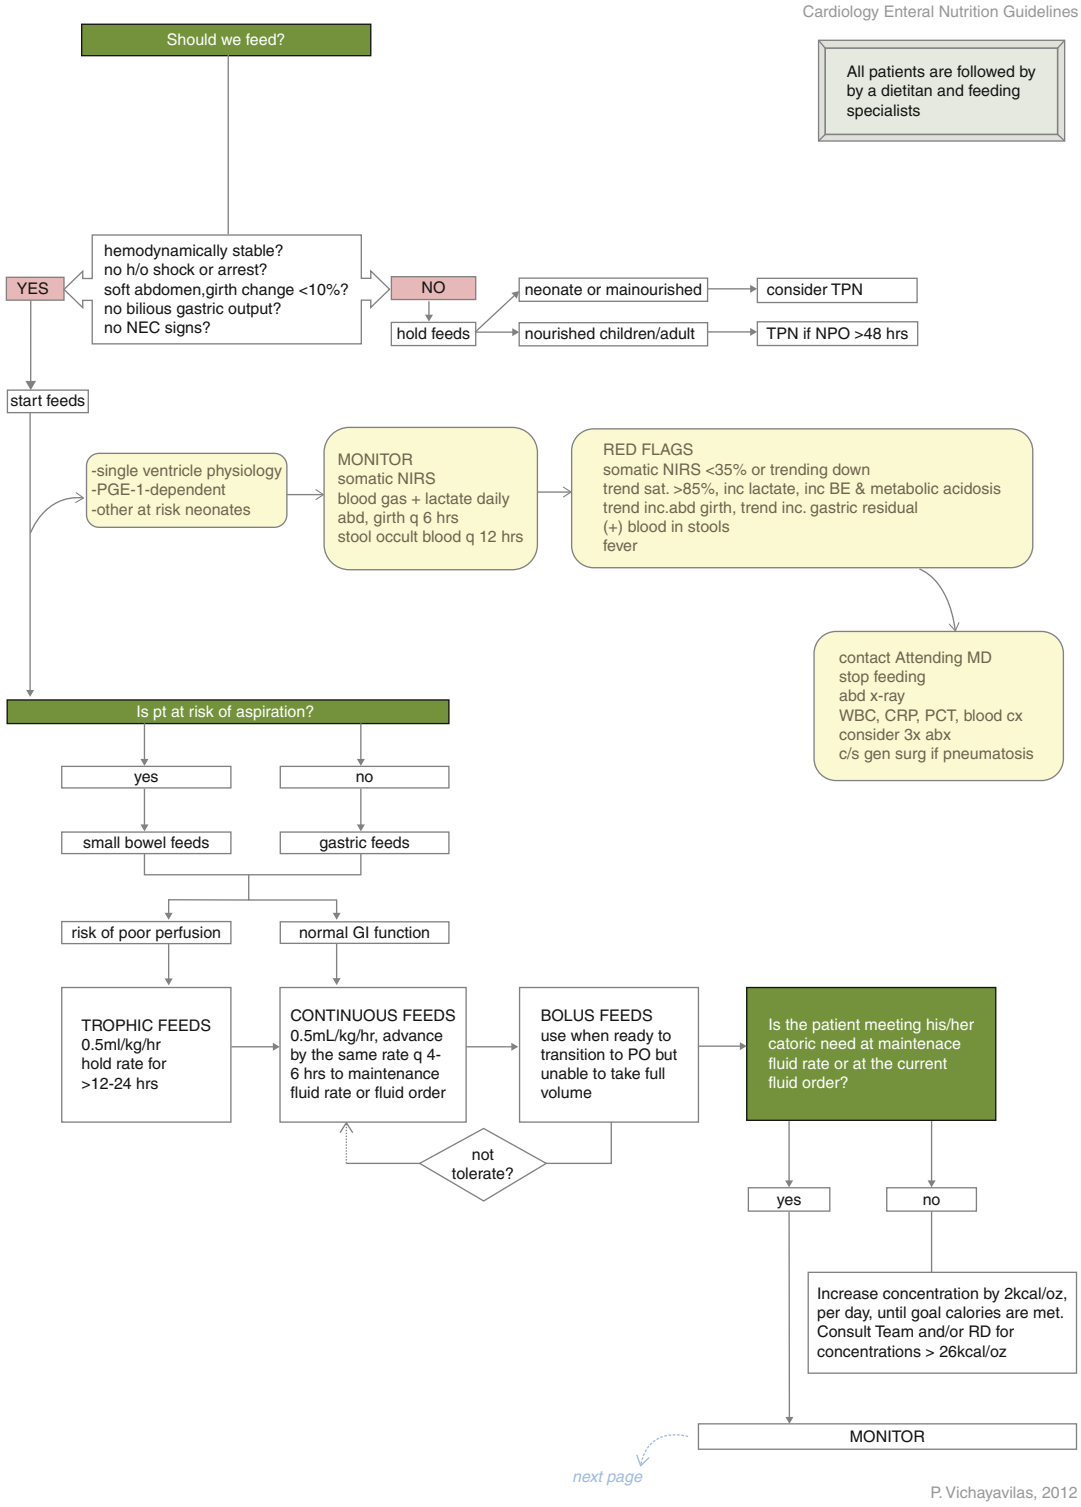

Fig. 169.1 (continued)

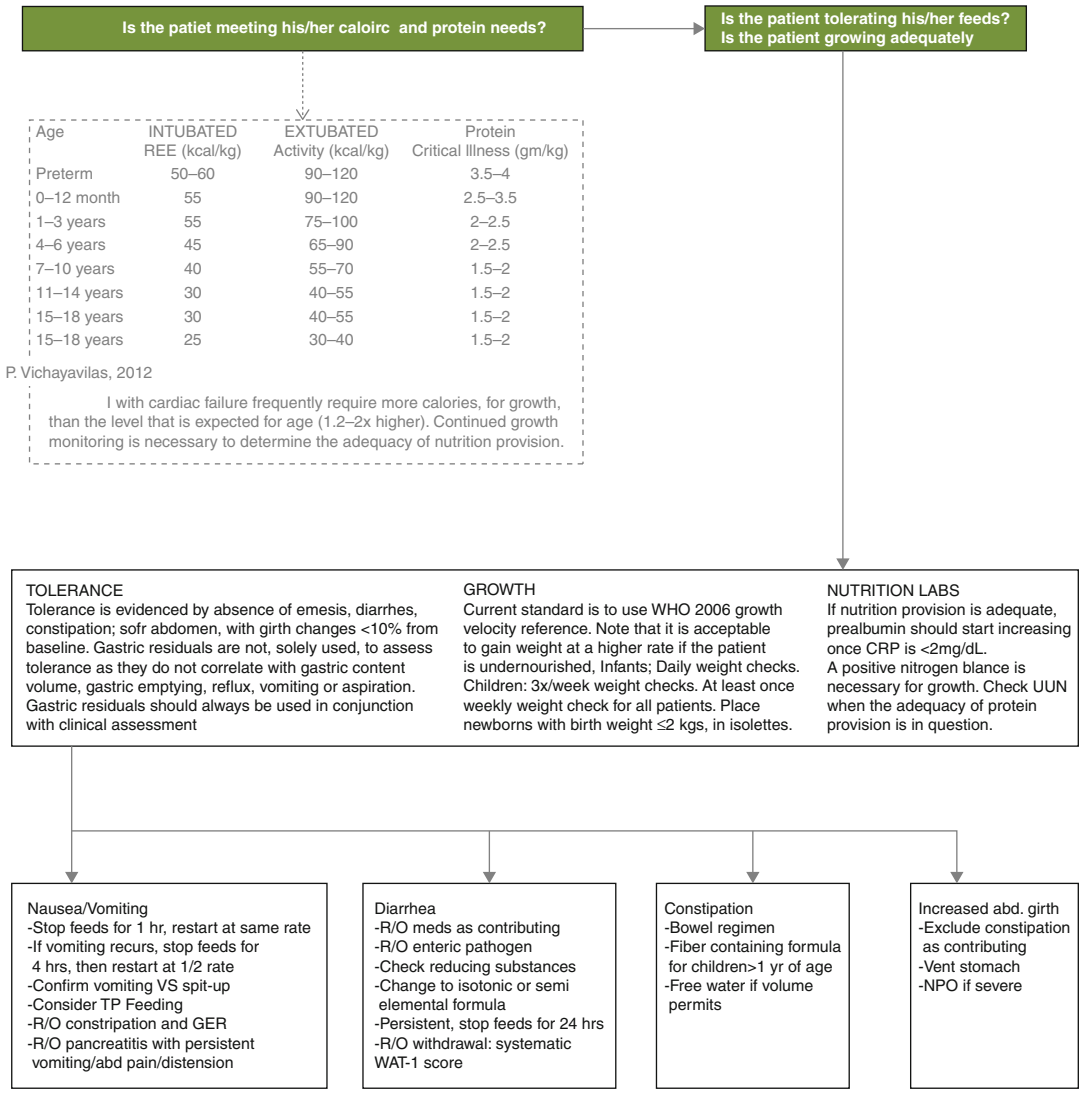

Fig. 169.1 Feeding algorithm

feasible in most centers. There are limitations of IC as well that should be noted. Any clinical intervention that contributes to an incomplete capture of expiration or alters blood gas – e.g., air leak from uncuffed endotracheal tubes, high or unsteady FiO_2, or hemodialysis – will affect the measurement [58, 59].

Feeding difficulty and poor weight gain are vexing complications of surgical repair and palliation. Patients are frequently retained in the hospital until they demonstrate adequate intake and weight gain. Early medical and surgical interventions, and the hospital setting, interfere with an infant's ability to develop his feeding skills. Many infants receive intervention even before feeding has ever been initiated. Lower weight at surgery and surgical procedures that are in close proximity to the aortic arch have been shown to particularly contribute to poor feeding outcomes due to the risk of vocal cord injury [60]. Other factors associated with poorer feeding outcomes are a high Risk Adjustment in Congenital Heart Surgery Scores (RACHS) [43], duration of postoperative intubation [10, 43, 60],

cross-clamp time [10], length of time from surgery to oral feeding and the amount taken at first feeding [10], and single-ventricle physiology [31, 43]. It is well-known that prolonged intubation affects swallowing ability, but it is not well described how RACHS score and cross-clamp time negatively impact feeding outcomes. Perhaps, these sicker patients with prolonged cross-clamp time and high RACHS scores experience impaired early development and oral feeding. Sables-Baus et al. showed that almost half of neonates required tube feeding upon discharge and no infant was solely breast-fed [10]. The authors postulate that as critically ill neonates are intervened upon earlier, critical neurologic, developmental, and social bonding pathways may be disrupted, perhaps irrevocably [10]. Children with HLHS have especially high rates of feeding complications [31, 43]. The Norwood procedure increases risk of vocal cord injury and paralysis which can contribute to poor feeding [31]. Surgery-related complications of the thoracic duct, such as chylothorax, may require the cessation of oral feeds; this further impedes an infant's ability to refine his feeding skills.

If oral alimentation is determined to be unsafe or inadequate, feeding via nasogastric or gastrostomy tube should be pursued. Nasogastric (NG) tubes may be beneficial by providing a route to optimize nutrition and avoid the risks of surgery. However, several potential complications of NG tubes may result in relatively short-term utility. These complications include tube displacement and frequent reinsertion, potential for increased susceptibility to otitis media and/or sinusitis due to obstructed drainage, and possibility for worsened gastroesophageal reflux. Inadvertent nasogastric tube placement into the trachea or main stem bronchus can be fatal. Gastrostomy tubes offer opportunity for normal oral-motor development and while decreasing the risk of reflux [61]. However, the risks of surgical or endoscopic gastrostomy tube placement in fragile neonates and children with CHD are not inconsequential. Careful and vigilant monitoring of these infants in an intensive care unit is recommended after all surgical procedures. It is important that the health-care team identify factors that are associated with feeding failure and involve speech therapists, occupational therapists, and dietitians to optimize feeding and nutrition outcomes. Infants and children with CHD who are unable to receive adequate oral or enteral nutrition should receive parenteral nutrition. Central venous access is typically required to provide adequate energy and protein without excessive fluid administration. Of major concern is the risk of hepatic injury and infection that may be associated with parenteral nutrition [62]. Hence, efforts should be aimed at optimizing enteral nutrition intake, feeding tolerance, and growth to limit dependence on parenteral nutrition in this population. The use of an enteral nutrition protocol has the potential to improve the safety and adequacy of feedings while reducing the reliance and attendant risks of parenteral nutrition. Consultation with specialists in nutrition, feeding and swallowing, lactation, and social work can help to optimize nutrition and subsequent developmental and surgical outcomes of infants and children with CHD.

Nutrition Assessment

For this population that is at high risk of malnutrition, the recognition and anticipation of potential barriers to optimal nutrition and growth are critical first steps in the development of an appropriate nutrition care plan. The nutrition status of all infants and children with CHD must be assessed initially and at regular intervals thereafter; the frequency of follow-up assessments should be determined on the basis of age, clinical status, and nutritional risk. The key areas are the evaluation of growth, intake, and nutrient utilization.

Growth is the best indicator of health in infants and children. "Failure to thrive" is frequently used to denote growth failure; however, this outdated term is not well defined nor does it describe the severity or character of malnutrition. A more appropriate description of growth characterizes the child's linear growth, weight gain, the proportionality of weight and length, and longitudinal growth trajectory. Two of the commonly used childhood growth and nutrition classification systems are the World Health Organization (WHO)

Table 169.1 WHO anthropometric classification

Percentile	Z-score	Classification	Interpretation
Weight for age <3rd percentile	<−2sd	Underweight	Reflects both short- and long-term health/nutrition
Length for age <3rd percentile	<−2sd	Stunting	Reflects chronic suboptimal health/nutrition (and other factors)
Weight for length <3rd percentile	<−2sd	Wasting	Acute and severe malnutrition ± weight loss; concurrent wasting and stunting is possible

Table 169.2 Waterlow's classification of protein energy malnutrition for children under 10 years of age

90	–	100 %	IBW	=	Normal
80	–	90 %	IBW	=	Mild wasting
70	–	80 %	IBW	=	Moderate wasting
	<	70 %	IBW	=	Severe wasting

anthropometric classification and the Waterlow's Criteria (Tables 169.1 and 169.2). Both describe a child's nutritional status as a function of his or her length or stature. Growth velocity (Table 169.3) is another parameter for assessing nutrition adequacy, including the rate of weight gain, length, and head growth compared to norms. A period of accelerated rate of growth is required to correct malnutrition.

Internationally, the WHO 2006 growth standard is recommended for use in all infants/children between 0 and 5 years of age regardless of race or ethnicity [63]. In the United States, the Centers for Disease Control and Prevention (CDC) recommends the use of the WHO 2006 growth standard for infants/children 0–24 months [64]. From ages 2 to 19 years, the CDC growth references are used [64]. Waterlow's Criteria (Table 169.2) is another classification system that describes the degree of malnutrition. The severity of malnutrition is defined by the proportion of a child's weight relative to his or her height or length. The median (50th percentile) weight for height or length is termed "ideal body weight" (IBW). Current weight over IBW is used to determine degree of malnutrition, specifically wasting. Waterlow's Criteria may be used in conjunction with the WHO growth standard and CDC growth reference, in children up to 10 years of age, as IBW is a basic concept common to both. Beyond 10 years of age, describing nutrition status in terms of percent IBW remains a useful concept but is typically no longer based on Waterlow's Criteria.

Dietary Intake history is an important component of nutrition assessment and must be obtained for every infant and child with CHD. Nutrition intervention is contingent upon whether growth inadequacy is caused by suboptimal intake, impaired utilization, or both. While performing a nutrition assessment, the child's social circumstances must be considered. If growth faltering is thought to be due to psychosocial issues, such as financial insecurity, limited resources, or other stressors, a Social Worker should be consulted.

The caloric intake of school-aged children can be particularly challenging to accurately estimate. Questions such as how many meals and snacks per day, the approximate volume, the time required to finish a meal/snack, whether "fighting, bribing, or bargaining" is employed, and whether certain food groups are being underrepresented, can help to determine the adequacy of child's intake. Calculating the energy intake of infants is more straightforward to due to the lack of this variability (see Fig. 169.2). The frequency and duration of feeding should be asked. If an infant is receiving formula or fortified human milk, the preparation method must always be assessed as incorrect mixing can result in serious complications. Over-dilution can result in poor growth, excessive water intake, and electrolyte imbalance. Excessive concentration can result in vomiting, diarrhea, electrolyte imbalance, and dehydration.

Infants with CHD with suboptimal intake or growth faltering often require increased energy

Table 169.3 WHO growth standard for infants

Age	Weight gain velocity in grams/day, for Males and Females, ages 0-6 months				
	3rd%ile (-2SD) M/F	15th%ile (-1SD) M/F	50th%ile (median) M/F	85th%ile (+1SD) M/F	97th%ile (+2SD) M/F
0–4 wks	13 / 14	24 / 22	37 / 31	47 / 42	56 / 51
4wks–2mo	22 / 17	30 / 24	40 / 34	51 / 43	60 / 52
2–3mo	13 / 10	19 / 16	27 / 24	36 / 32	43 / 38
3–4mo	8 / 7	13 / 12	21 / 20	28 / 27	35 / 33
4–5mo	5 / 4	10 / 10	17 / 16	25 / 23	31 / 30
5–6mo	2 / 2	7 / 7	14 / 13	21 / 20	27 / 26

density feedings. The composition of human milk varies throughout the feeding session. A breast-feeding infant who fatigues within minutes may be routinely receiving low calorie feedings. Foremilk of low energy density is received in the first few minutes, and hind milk, of higher caloric concentration, is obtained during the final minutes when the remainder of milk is extracted. Mothers with an adequate breast milk supply may be advised to use a breast pump for a few minutes to remove the foremilk in order to feed the richer hind milk. Lactation specialists have the expertise to assess the adequacy of breast milk transfer, can determine whether this is feasible, and provide appropriate education and support. If the infant is bottle fed, a more concentrated mixture is appropriate to allow for better calorie and nutrient provision in a smaller volume.

If a child is demonstrating apnea, bradycardia, oxygen desaturation, coughing, or choking with feeding, aspiration should be suspected. With severe symptoms, the safety of oral feeding should be evaluated, while an alternate method of enteral nutrition support is provided. A Speech or Occupational Therapist can clinically evaluate swallowing, or a modified barium swallow study can be conducted under fluoroscopy.

Assessment of *nutrient utilization* includes determination of potential losses due to malabsorption or to emesis and to energy expenditure due to physical activity. In young infants, energy expenditure in physical activity is minimal and is generally limited to feeding and crying. Thus, feeding sessions may need to be limited to fewer than 30 min to avoid excessive energy expenditure. Feeding for more than 30 min suggests inefficient extraction and increased energy expended on feeding. Sweating and tachypnea with feeding also reflect increased caloric expenditure.

Stool frequency and character may provide insight on adequacy of intake, digestion, and absorption. For a breast-fed newborn, 6–8 bowel movements per day or one after each feed is normal. See Table 169.4 for general descriptions of infant stool character associated with feeding type and with malabsorption. Great variability in stool character can occur, however, due to different formulas, transit time, and enteral medications. Suspicion for malabsorption should be verified by laboratory analysis of stool for fat or carbohydrate losses. Evidence of fat malabsorption, for example, may prompt use of a formula or supplement containing medium chain triglycerides for improved energy utilization.

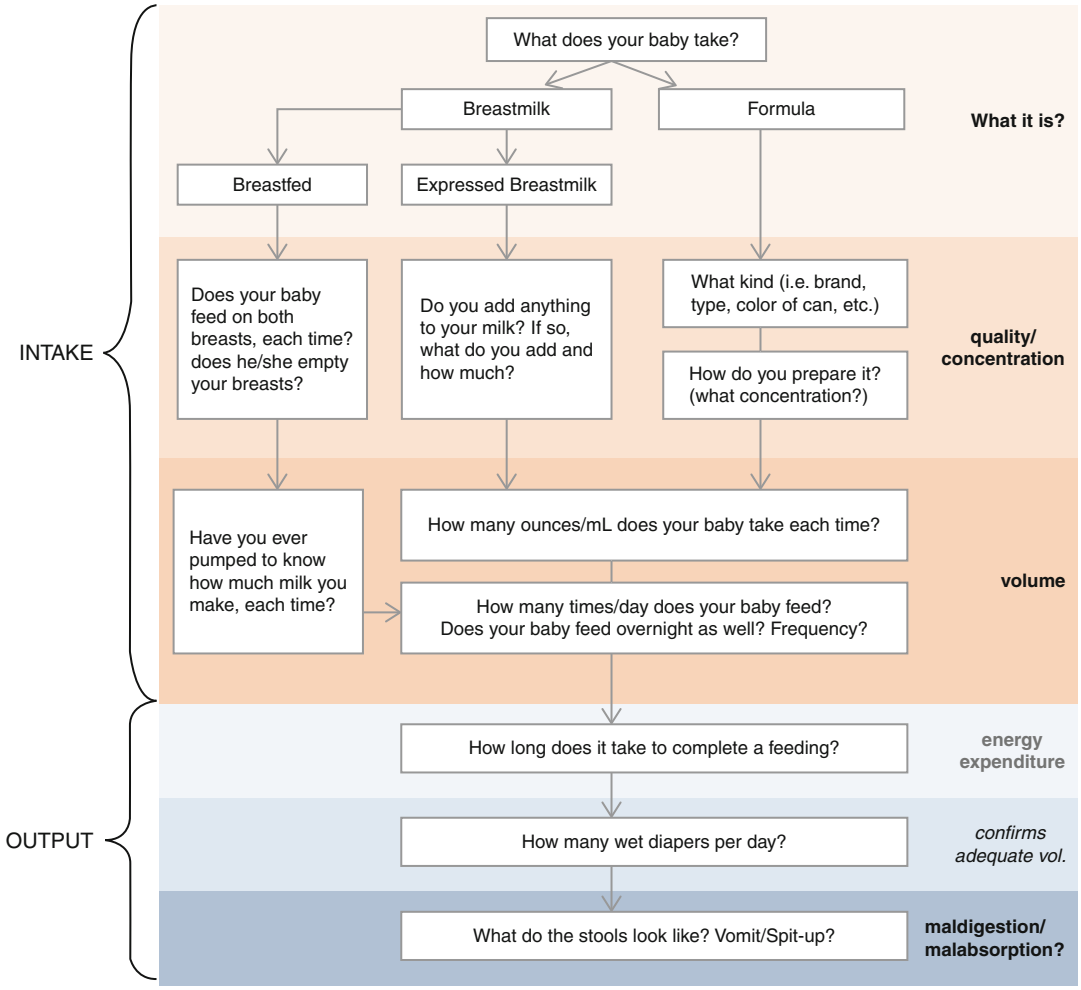

Fig. 169.2 Evaluation of nutrient intake and utilization

Table 169.4 Description of infant stool output patterns

Stools of babies fed breast milk	Yellow, more liquid, more frequent
Stools of babies fed formula	Green, less liquid, less frequent
Stools with possible carbohydrate malabsorption	Water-loss diarrhea
Stools with possible fat malabsorption	Fatty, foamy, frothy, foul smelling

Conclusions

Malnutrition remains prevalent in infants and children with CHD. When oral intake is inadequate to meet growth requirements, nutrition support is an essential intervention. Energy intake and utilization are key factors affecting nutrition status and subsequently can

influence surgical and developmental outcomes, morbidity, and mortality. Having a dedicated multidisciplinary care team of dietitians, nurses, physicians, nurse practitioners, physician assistants, speech and occupational therapists is fundamental in the success of nutrition care in these patients.

Endocrinological Issues

170

Rambod Amirnovin and Grant L. Burton

Abstract

The critically ill pediatric patient with congenital heart disease manifests many derangements of the endocrine system – whether by nature of associated genetic disorders or as a result of their critical illness after bypass surgery. The physiologic background, diagnosis, and treatment of clinically significant endocrinopathies are considered in this chapter. Derangements in the adrenal axis, glycemic control, and thyroid deficiency are among the controversial areas discussed in this chapter. While there is not always consensus on the treatment of these derangements, review of the latest science in these areas is highlighted. The chapter will also review parathyroid metabolism and conclude with implications of the "water hormones" in cardiac patients, namely, vasopressin and the natriuretic peptides.

Introduction

The endocrine system is silent, yet powerful, in patients with critical illness: it represents a system sometimes overlooked in the cardiac intensive care unit, while it is the basis of significant pathology in the critically ill child with congenital heart disease. Patients with congenital heart disease (CHD) are at particular risk for endocrinological issues for two reasons:

1. They represent a population of patients with a high prevalence of genetic and chromosomal anomalies that are associated with *congenital* endocrinopathies.
2. The physiology of these patients, the associated surgical intervention with cardiopulmonary bypass (CPB), and the state of critical illness thereafter place them at risk for *acquired* endocrinopathies.

The goal of this chapter is to review the most relevant endocrinological considerations facing this patient population and to outline the diagnostic and therapeutic options available. Unfortunately, much of what is known about these endocrinopathies is from non-pediatric populations and in those without congenital heart disease; as such, there is speculation about the precise measures to take. This material will review both the options and controversies facing such therapeutic decisions. This chapter is organized with each section covering a specific axis or endocrinological hormone to facilitate rapid acquisition of information.

Adrenal Axis

Background

In 1911, Rupert Waterhouse described a "case of suprarenal apoplexy" in the journal *The Lancet*, in which a patient with disseminated bacteremia had bilateral hemorrhaging into the adrenal glands, causing severe hypotension, hyperkalemia, and cardiovascular collapse. This was one of the first scholarly reports of what has now been termed the Waterhouse-Friderichsen syndrome. This syndrome, most commonly attributed to meningococcemia, highlights the important functions of the adrenal gland and the dramatic results of adrenal insufficiency [1].

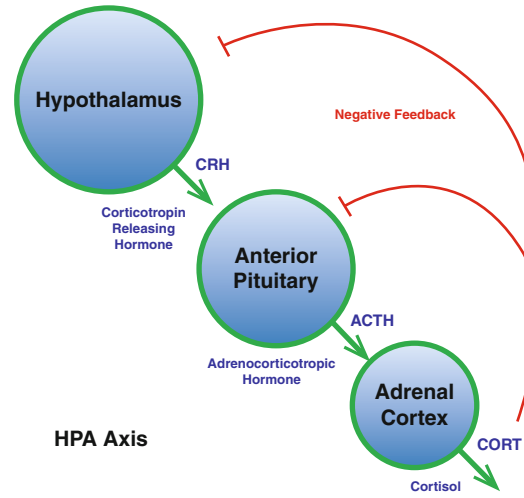

Fig. 170.1 Glucocorticoid release by the hypothalamus/pituitary/adrenal axis (Brian M. Sweis, MD/PhD Candidate, University of Minnesota, sweis001@umn.edu)

The hypothalamic/pituitary/adrenal axis is a complex component of the endocrine system vital in a patient's response to critical illness. The adrenal gland has two major parts: the *medulla*, which produces the sympathetic hormones epinephrine and norepinephrine, and the *cortex*, which produces the mineralocorticoids including aldosterone, weak androgens, and glucocorticoids including cortisol.

The release of *cortisol* by the adrenal gland is stimulated by adrenocorticotropin hormone (ACTH) from the anterior pituitary. ACTH release, in turn, is stimulated by hypothalamic release of corticotropin-releasing hormone (CRH) and arginine vasopressin (AVP, see Fig. 170.1). Inflammatory cytokines, such as interleukin 1 (IL-1), IL-2, and tumor necrosis factor alpha (TNF-α), stimulate both CRH and ACTH release. As such, inflammatory and stress responses result in the release and biosynthesis of cortisol, the main glucocorticoid [2, 3].

Glucocorticoids have a vital role in the cardiovascular system: maintaining vascular integrity,

tone, and permeability and distribution of intravascular volume. They also act to inhibit vasodilators such as nitric oxide and potentiate vasopressor activity of catecholamines. During critical illness, there is normally a rise in cortisol levels and a loss of the normal diurnal variation seen in healthy individuals. In contrast, relative or absolute adrenal insufficiency can lead to hypotension, fluid leak into extravascular spaces, hypovolemic shock, and inadequate response to vasoactive infusions ("vasomotor paralysis"). Glucocorticoids also have important metabolic functions including inhibition of thyroid hormones (see Thyroid Axis) and elevation of serum glucose via gluconeogenesis, glycogenolysis, and insulin resistance [4].

Mineralocorticoid or aldosterone deficiency leads to hypotension, hyperkalemia, hyponatremia, and hypovolemia, the classic findings of an "adrenal crisis" [5]. The dual function of the adrenal gland as both the mineralocorticoid and glucocorticoid organ has led to the assumption that critically ill patients who are glucocorticoid deficient are likely mineralocorticoid deficient as well [4].

Risk factors for adrenal insufficiency include critical illness, severe sepsis, and exposure to bypass surgery, which may relate to a cytokine and humoral response that results in a diminished response of the adrenal axis. Certain medications are also known risk factors for adrenal insufficiency, including ketamine, etomidate, ketoconazole, rifampin, and phenytoin [6–9]. As mentioned above, sepsis with certain organisms, most notably meningococcal infection, can lead to bilateral adrenal infarcts, known as the Waterhouse-Friderichsen syndrome.

Diagnosis

The diagnosis of *adrenal insufficiency* in the critically ill patient, especially in pediatrics, is a controversial topic. Most of the data regarding baseline and expected glucocorticoid levels in critically ill patients come from critically ill adult patients with sepsis [5, 10]. Even in this homogenous population, the baseline levels of cortisol have been estimated from 5 to 30 μg per dL, and prevalence of adrenal insufficiency has been estimated from as low as 15 % to as high as 50 % [11, 12]. Part of the challenge of estimating what is an appropriate basal cortisol response during critical illness is that some patients demonstrate low cortisol levels, but have an appropriate response to low-dose cosyntropin (known as the ACTH or cosyntropin stimulation test). Such concerns regarding diagnosis of adrenal insufficiency are also true in pediatric patients with sepsis and congenital heart surgery [13].

The evaluation of adrenal function requires both knowledge of the patient's baseline cortisol level and an evaluation of the patient's response to a stimulation test. The stimulation test involves checking a cortisol level before, and 30–60 min after, administration of cosyntropin (0.125 mg for children younger than 2 years and 0.25 mg for children older than 2 years). The Multi-Societal Database Committee for Pediatric and Congenital Heart Disease, in its consensus definition in 2008, suggested a set of diagnostic categories for patients evaluated for adrenal function [14, 15]. These categories are based upon a patient's basal cortisol level and response to a cosyntropin stimulation test (see Table 170.1).

Some institutions check basal cortisol levels prior to operative repair and upon return to the intensive care unit after cardiac surgery. However, interpretation of this information is complicated by exogenous administration of steroids such as methylprednisolone in the operating room for patients undergoing bypass surgery or before surgery in patients undergoing deep hypothermic circulatory arrest (DHCA). The diagnosis of adrenal insufficiency is further complicated by a changing adrenal response during the postoperative period: a patient may have an appropriate adrenal response early on, but develop adrenal insufficiency later [15, 16].

Treatment

The most comprehensive studies of corticosteroid treatment in critically ill patients involve adult patients with sepsis. A meta-analysis of

Table 170.1 Diagnostic categories of adrenal function

Category	Basal cortisol level	Response to cosyntropin stimulation test	Glucocorticoid supplementation[a]
Absolute adrenal insufficiency	<16 mcg/dL	Inappropriate – <9 mcg/dL increase	Hydrocortisone 1 mg/kg q6 h for 5–7days, taper
Relative adrenal insufficiency	>16 mcg/dL	Inappropriate – <9 mcg/dL increase	Unclear: use clinical judgment
Insufficient basal cortisol	<16 mcg/dL	Appropriate – >9 mcg/dL increase	Unclear: use clinical judgment
Activated adrenal response	>16 mcg/dL	Appropriate – >9 mcg/dL increase	None

Adapted from the consensus statement of the Multi-Societal Database Committee for Pediatric and Congenital Heart Disease [14]

[a]There is little evidence for the method of treatment of adrenal insufficiency in pediatric cardiac surgical patients – these are suggestions adapted in part from the consensus statement of the Multi-Societal Database Committee for Pediatric and Congenital Heart Disease and currently available literature in septic shock patients [2, 14]

the available data as recently as 2009 indicates that there may be a benefit in short-term mortality (28 days) with the use of long-course (>5 days), low-dose steroids (<300 mg/day) in adult patients with sepsis [17]. However, even in this relatively homogenous population of adults, the data is controversial. The recent prospective randomized controlled Corticosteroid Therapy of Septic Shock (CORTICUS) trial from Europe demonstrated no 28-day mortality benefit in patients receiving hydrocortisone. However, the CORTICUS trial did demonstrate a faster reversal of septic shock in those receiving steroids [18]. Concerns regarding the powering of the study and possible lack of equipoise of critical care units in treatment of their sickest patients with steroids have led to pause before abandoning potential benefits of steroids for patients with septic shock [19].

The benefits of corticosteroid treatment for pediatric patients undergoing cardiac surgery are even less clear. One study of 50 infants undergoing bypass surgery demonstrated no difference in postoperative recovery or suppression of the post-bypass inflammatory response in patients receiving pre-bypass steroids [20]. A different study of neonates receiving both preoperative and intraoperative methylprednisolone also showed no benefits. This included no difference in short-term and long-term mortality and possibly worse renal function in those receiving steroids [21]. A non-randomized retrospective study of 221 patients demonstrated that methylprednisolone administration prior to or during bypass surgery was associated with a risk-adjusted decrease in postoperative morbidity. This included decreased chest tube output, shorter ICU and hospital duration of stay, and shorter duration of mechanical ventilation. There was no evidence of adverse outcomes in this study [22]. In contrast, a large, retrospective, multicentered study evaluating over 46,000 patients undergoing surgery for CHD demonstrated no benefit associated with corticosteroid administration prior to or at the time of bypass surgery. However, there was an association between corticosteroid use and increased morbidity, especially in lower-risk patients. Morbidity included longer hospital and ICU length of stay, increased risk for infection, and greater need for insulin use [23]. A survey in 2005 nicely demonstrated the lack of consensus on the method of preoperative steroid administration: of the 36 cardiac centers surveyed by Checchia et al., 35 used some form of preoperative steroid administration before bypass surgery. However, the exact selection process of steroid use, and the methods of dosing, was extremely variable among these institutions [24].

As with studies of patients with sepsis, studies of pediatric cardiac surgery patients suggest that

the postoperative patient with poor response to ACTH stimulation tests may be the most likely to benefit from steroid treatment. One such study demonstrated that most infants undergoing bypass or deep hypothermic circulatory arrest (DHCA) have an intact intrinsic corticosteroid response *after* their operations [25]. However, a subset of patients may have an inappropriately low cortisol level in response to their intrinsic hypothalamic-pituitary (ACTH) response. There are even fewer data regarding the use of *postoperative* corticosteroids in critically ill pediatric patients with congenital heart disease. As such, therapy is extrapolated from data in patients with septic shock.

Diagnosis and treatment of patients with adrenal insufficiency after cardiac surgery is reserved for patients who exhibit significant cardiac dysfunction or poor response to inotropic support. This is especially true since the benefits of such treatment are unclear and the diagnosis challenging as outlined above. After baseline and postcosyntropin stimulation cortisol levels are sent, therapy with hydrocortisone may be initiated until results are reported [2, 14]. Dosing for children is unclear, with institutions using as little as 1 mg/kg every 6 h to as much as 25 mg/BSA every 6 h, as in an adrenal crisis patient. The addition of fludrocortisone, a mineralocorticoid, is less common; theoretically, evidence of hyponatremia or hyperkalemia may necessitate mineralocorticoid supplementation.

Once cortisol levels return, many institutions will treat a patient with absolute adrenal insufficiency (see Table 170.1). Treatment course is generally 5–7 days and followed by a taper of the dosing interval. Patients with an *activated adrenal response* are generally not treated. However, treatment of patients with either *relative* adrenal insufficiency or *insufficient basal* cortisol levels (but an appropriate response to stimulation) should be based upon the judgment of the clinical team and their suspicion of adrenal insufficiency [2]. Until further data exist regarding these decision algorithms and whether treatment is of any benefit, clinical judgment will drive much of these scenarios.

Insulin and Glycemic Control

Background

The Ebers Papyrus, written in Egypt in 1550 BC, describes a wasting disease characterized by high urine output. The Greek physician Aretaeus (81–131 AD) was the first to use the term "diabetes" in reference to the "running through" of urine. "Mellitus," Latin for honey, was added by British surgeon John Rollo in 1798 to indicate the sweet nature of the urine. It was not until 1875, however, that Claude Bernard recognized the sweet substance in urine was identical to grape sugar. By then, Paul Langerhans had described pancreatic cells in islets unrelated to exocrine function, and it was in 1889 that Oskar Minkowski demonstrated the development of diabetes in dogs following the removal of the pancreas [26]. This work culminated in the isolation of insulin by Frederick Banting and his team in Toronto, Canada, in 1921.

Insulin, a 51-amino acid hormone, is synthesized by pancreatic beta cells in the islets of Langerhans. Insulin begins as preproinsulin, a 110-amino acid protein that is cleaved to form proinsulin, a chain of three connected peptides (A, B, and C). In turn, proinsulin is cleaved again to remove the interconnecting C-peptide chain. Once liberated in this fashion, insulin is stored in secretory granules within the beta cells. The granules then either stay in the cytoplasm, dock to the cell surface and release contents later, or fuse directly to the cell membrane and quickly release insulin into the circulation. Once in the circulation, insulin binds to a tyrosine kinase receptor and ultimately leads to the incorporation of glucose transport receptors to the plasma membrane with resultant intracellular glucose uptake.

The regulation of insulin secretion is a remarkably complex process. Glucose has long been understood to be the primary effector of insulin secretion. In beta cells, glucose metabolism leads to an increase in ATP levels and a subsequent closure of ATP-sensitive potassium channels. This depolarization of the beta cell then allows

for calcium entry that triggers granule fusion and insulin release. Intracellular calcium concentration appears to oscillate in the beta cells, leading to a pulsatile and biphasic release of insulin. The first phase develops rapidly but is of short duration, followed by a long-acting second phase of insulin secretion. Disruption in these phasic patterns is a hallmark of type 2 diabetes [27]. Paracrine signals from neighboring islet alpha cells also affect insulin secretion; mediated via glucagon, a hormone that leads to both insulin secretion and gluconeogenesis from hepatic glycogen stores. More remote augmentation of insulin secretion is caused by a group of intestinal hormones known now as incretins. Two of these hormones, glucose-dependent insulin-releasing polypeptide (GIP) and glucagon-like polypeptide (GLP-1), are secreted by the proximal and distal intestine (respectively) in response to nutrients present in the intestinal lumen. GLP-1 is of particular interest as it seems to increase secretion of insulin, but its effects are entirely inhibited once blood glucose decreases to 80 mg/dL [28]. Finally, there is central nervous system control of insulin secretion as well. The pancreas is innervated by autonomic nerves principally controlled by the hypothalamus. Hypothalamic neurons have the ability to sense glucose and use melanocortin signaling pathways to regulate insulin secretion. There is now growing evidence that other hormones and proteins affect insulin secretion by regulating the hypothalamus; among these are leptin, estrogen, and serotonin [29]. Finally, endogenous and exogenous glucocorticoids are well known to cause insulin resistance in peripheral tissues; hepatic insulin resistance leads to an increase in gluconeogenesis. In higher doses, glucocorticoids actually suppress insulin secretion as well.

Diagnosis: Insulin Deficiency, Insulin Resistance, and Hyperglycemia

Hyperglycemia in a healthy, fasting child is typically agreed to be any plasma glucose greater than 126 mg/dL. Nonetheless, there is more support for a broad diagnostic approach, including hemoglobin A1c, diabetes-related antibody, C-peptide, and an actual insulin level. In this way, a distinction between primary insulin deficiency (type 1 diabetes) and insulin resistance (type 2 diabetes) may be made. While type 2 diabetes is a constellation of insulin resistance, increased hepatic gluconeogenesis, decreased GLP-1, and alterations in insulin secretion, it should be noted that standards are still lacking in young children to assess all of these laboratory tests.

Although the Centers for Disease Control and Prevention has confirmed a rising tide of diabetes in children and adolescents, the cardiovascular effects of both type 1 and type 2 diabetes mellitus are typically relegated to older populations and thus remain beyond the scope of a pediatric cardiology text. Of more relevance is the effect of hyperglycemia in the critically ill child. This topic has been researched extensively over the past decade. Hyperglycemia has been associated with increased mitochondrial superoxide production and subsequently to increased peroxynitrite levels. Peroxynitrite then inhibits mitochondrial respiratory chain enzymes. Hyperglycemia may also lead to vascular endothelial dysfunction and a pro-thrombotic state. At the same time, exogenous insulin therapy appears to have a potent anti-inflammatory role, leading to decreased levels of c-reactive protein in animal models. Given these observations, euglycemia became a natural target for therapeutic intervention in the critically ill.

The most significant study supporting this idea appeared in 2001, when Van den Berghe et al. published a landmark paper demonstrating not merely that hyperglycemia was associated with worse outcomes but that tight glycemic control (targeting 80–110 mg/dL vs. not greater than 214 mg/dL) actually improved outcomes in a postoperative adult population [30]. The absolute reduction in mortality by 3–4 % in this trial's intervention group led to a number of similar trials in other adult population, but of mixed results. Van den Berghe herself conducted an adult medical ICU trial, with similar glucose targets, and found no difference. The largest trial to date, the NICE-SUGAR study, compared 80–108 mg/dL versus less than 180 mg/dL in

6,104 adults in 42 centers. This trial found an increase in the number of hypoglycemic episodes in the treatment group (6.8 % vs. 0.5 %), but no difference in length of stay, mortality, or other parameters [31]. The debate, then, is ongoing, as to whether hyperglycemia is injurious to the critically ill, whether insulin is beneficial, or whether neither of these suppositions is correct. Supporters of tight glycemic control note that hyperglycemia in the critically ill is associated with mitochondrial toxicity, endothelial dysfunction, oxidant injury, and neutrophil dysfunction. Those opposed to tight glycemic control cite a meta-analysis of 26 randomized trials which showed no effect on mortality for critically ill adults (although a possible reduction in mortality for surgical ICU patients) [32]. Adding to the relative confusion is new data on the use of incretins in critically ill adults. Several small studies have now indicated that infusion of GLP-1 in critically ill patients appears to decrease the glycemic response associated with enteral feeds. Further work remains to be done to determine if GLP-1 may provide normoglycemia without the constant threat of hypoglycemia seen with insulin infusions.

Treatment: Pediatric Insulin Resistance/Hyperglycemia

The data for critically ill children are even less clear than for adults, but at best they support an exceedingly cautious approach toward correction of hyperglycemia. There are two randomized controlled trials evaluating insulin therapy in pediatric intensive care patients. The first of these two studies, again by Van den Berghe, was performed on predominantly (75 %) postoperative cardiac patients [33]. This trial randomized to an intensive insulin regimen targeting blood glucoses between 50.4–80 mg/dL (for infants) and 70–101 mg/dL (for children) versus less than 214 mg/dL. The authors enrolled 700 patients and found a decrease in ICU length of stay (5.51 vs. 6.15 days, $p = 0.017$), a decrease in median C-reactive protein from baseline (-6 vs. 0 mg/L, $p = 0.007$), and a decrease in secondary infections (102 vs. 129, $p = 0.034$). They also report a reduction in absolute mortality (2.3 % vs. 5.1 %, $p = 0.043$) at 30 days. However, they also found an increase in hypoglycemia less than 40 mg/dL in the treated group (87 vs. 5 patients, $p < 0.0001$).

More recently, Agus and collaborators from Boston Children's Hospital published a study on 980 children undergoing cardiopulmonary bypass for cardiac surgery. The children were randomized to tight glycemic control (blood glucose levels of 80–110 mg/dL) versus standard care. Patients in the tight glycemic control arm did have normoglycemia earlier and for a greater amount of time than the patients in the standard therapy arm, but there was no other significant difference in terms of infection, mortality, length of stay, or organ failure. Three percent of patients in the tight glycemic arm did have hypoglycemia as defined by a blood glucose of less than 40 mg/dL. Agus et al. concluded that tight glycemic control can be achieved safely, but with no benefit to the patient [34].

The data lacking from both of these trials, unfortunately, is long-term neurodevelopmental outcomes. There are numerous reports of hypoglycemia affecting brain development adversely, and the congenital heart disease population already seems to be at a disadvantage even preoperatively in this sense [35]. This fact, coupled with some published data that suggest hyperglycemia in postoperative pediatric cardiac patients is not associated with worse outcomes, places more bias against aggressively low or "tight" glucose targets in this population [36]. Further studies are clearly needed to define the appropriate therapeutic targets for glucose in infants, children, and adolescents following cardiac surgery.

Thyroid Axis

Background

The thyroid axis begins at the hypothalamus which secretes thyrotropin-releasing hormone (TRH), which in turn stimulates release of thyroid-stimulating hormone (TSH) from the

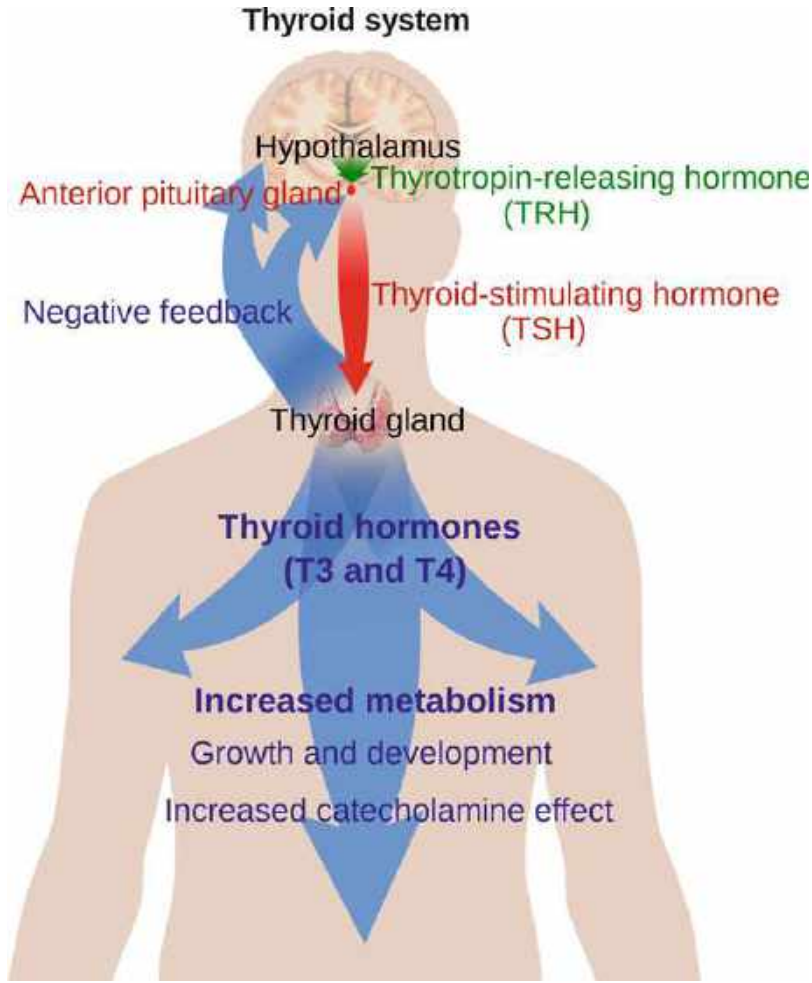

Fig. 170.2 Basic diagram of the hypothalamic/pituitary/thyroid axis (Mikael Häggström. Published in Public Domain)

pituitary. TSH leads to the conversion of thyroglobulin to thyroxin (T4) in the thyroid gland, which is deiodinized to form triiodothyronine (T3), the active thyroid hormone. The T3 hormone is known to increase contractility, improve diastolic function, decrease systemic vascular resistance, and improve ejection fraction and cardiac output [37]. However, it may also lead to increased myocardial oxygen consumption. Thyroid dysfunction, in turn, may lead to bradycardia, hypotension, poor response to catecholamines and inotropic agents, and increased systemic resistance (Fig. 170.2).

Diagnosis

Hypothyroidism is more common in the congenital heart disease patient than hyperthyroidism. In patients with Down syndrome (trisomy 21 chromosomal anomaly) and those with Turner's syndrome (XO chromosomal anomaly), as much as 30 % have hypothyroidism during their lifetime. Patients with Down syndrome typically present earlier in life (as earlier as infancy), while those with Turner's syndrome have autoimmune-associated thyroid dysfunction, most prevalent after the age of 8 years old [38, 39]. As such,

Table 170.2 Common congenital heart disease associated with chromosomal anomalies and endocrinopathies

Congenital heart lesion	Associated chromosomal anomaly	Associated endocrinopathy
Conotruncal malformations (tetralogy of Fallot, IAA, truncus arteriosus)	DiGeorge syndrome (22q11)	Hypoparathyroidism (hypocalcemia, hypomagnesemia)
Endocardial cushion defects (ASD, VSD, AVSD)	Down syndrome (T21)	Hypothyroidism
Aortic arch anomalies (CoA, IAA)	Turner's syndrome (XO)	Hypothyroidism, diabetes mellitus
Stenosis of great vessels (TOF, aortic stenosis, etc.)	Alagille syndrome (JAG1 deletion – 20p12)	Diabetes insipidus (DI)

IAA interrupted aortic arch, *VSD* ventricular septal defect, *ASD* atrial septal defect, *AVSD* atrioventricular septal defect, *CoA* coarctation of the aorta, *TOF* tetralogy of Fallot

phenotypic findings consistent with these chromosomal defects or associated congenital heart lesions should trigger chromosomal testing in addition to testing for thyroid function (Table 170.2).

Such testing will serve at the least as a baseline for the patient in the preoperative period. The most common accepted initial screening tests include a free thyroxine (free T4) level, free triiodothyronine (free T3) level, and thyroid-stimulating hormone (TSH) level. Fluid shifts and low serum protein levels found in critically ill cardiac patients make unbound (free) levels more accurate indicators of endocrine function than total levels [14]. Abnormality in these tests can trigger further testing and consultation with subspecialty endocrinology services.

However, routine interoperative and post-cardiopulmonary bypass (CPB) screening for thyroid dysfunction is controversial. Studies have demonstrated that children undergoing cardiac surgery have a transient *non-thyroid illness syndrome* (*NTIS*, previously known as euthyroid sick syndrome), with decreased levels of TSH, low or normal free T4, and decreased free T3 for as long as 2–7 days [40–42]. Mild forms of this transient state may not exhibit findings consistent with hypothyroidism, or such findings are masked by the patient's critical state (e.g., tachycardia instead of bradycardia).

More severe forms of NTIS may lead to hypotension, bradycardia, decreased cardiac index, increased length of stay, and increased need for inotropic support [14, 42]. Those undergoing bypass surgery and those on infusions of dopamine seem to be at the highest risk. Since dopamine acts as a central inhibitor of thyroid stimulation, this may be a confounding explanation for the prevalence of NTIS in pediatric ICU patients. In fact, the inhibitory effects of dopamine on the anterior pituitary hormones TSH, prolactin, and growth hormone and the resultant rebound of the same hormones once the infusion is stopped have led to concerns about the use of dopamine in critically ill patients. These effects appear to be most exaggerated in neonates and children, although the exact effect on morbidity and mortality is unclear [43]. Regardless of etiology, thyroxine levels below 4 g/dL have been associated with increased risk of death by 50 % in adult patients and even as high as 80 % when levels fall below 2 g/dL [44].

Theories for this transient and *apparent* hypothyroid state include

(a) Stress response secondary to cytokine release that decreases basal metabolic demands during illness via decreased thyroid stimulation and increased glucocorticoid release
(b) Deficiency in T4 to T3 conversion by the body
(c) Thyroxine binding inhibitors or poor binding capacity (and inability to accurately detect free hormone levels due to laboratory limitations)
(d) Central hypothalamic dysfunction or iatrogenic dopamine inhibition of central TSH release leading to hypothyroidism

Routine screening for *non-thyroid illness syndrome* in postoperative patients with congenital

heart disease has not demonstrated improved outcomes in pediatrics, although trials are ongoing [41]. In patients who demonstrate poor hemodynamic function, with evidence of prolonged low cardiac output or poor response to inotropic support, in addition to assessment of their adrenal function (see Adrenal Axis), thyroid testing should be evaluated.

Treatment

As mentioned above, patients with primary hypothyroidism (e.g., Down syndrome) or those with risk for autoimmune associated hypothyroidism (e.g., Turner's syndrome) should be screened for thyroid dysfunction and treated by an endocrinologist if such dysfunction is present. These patients will most commonly be started on levothyroxine (T4) once daily, which they will be on chronically. Postoperative continuation of thyroid repletion can be initiated via parenteral route until it can be given orally or by a feeding tube. The parenteral dosing is 50–75 % of the oral dose and needs to be adjusted as such.

In patients on higher doses and longer infusions of dopamine, testing and treatment should be considered, since this may represent a true *secondary hypothyroidism* (distinct from NTIS) [40]. Treatment of non-thyroid illness syndrome is controversial, especially in pediatric populations. Post-bypass adult patients receive triiodothyronine repletion due to evidence of improved cardiac function and outcomes [41, 45]. Trials are ongoing regarding similar replacement therapy in children with CHD undergoing bypass surgery. Triiodothyronine (T3) repletion has demonstrated improved cardiac function in some studies, with no significant dysrhythmias or elevations in heart rate in pediatric patients [42, 46]. A double-blinded, randomized controlled study by Mackie et al. in 2005 demonstrated that T3 replacement shortened time to a negative fluid balance after arch reconstruction in neonates. The 22 patients who received T3 had no serious adverse effects but also had no improvement in their cardiac index at 48 h [47]. However, in all of these studies, it is unclear whether such T3 supplementation improves morbidity or mortality [14, 41].

Certainly, in patients with prolonged illness, poor response to inotropic support, or very low thyroxine levels (<4 g/dL), thyroid repletion should be seriously considered. Notably, initial therapy should begin with T3 *and* T4 since T4 deiodination by the body may be insufficient. Gradually, the patient can be switched to T4 treatment altogether. This requires close monitoring of T3, T4, and rT3 levels and consultation with an endocrinologist [48].

Parathyroid Axis and Calcium Regulation

Background

The parathyroid gland is a major player in calcium and phosphate metabolism. The release of parathyroid hormone (PTH) from the parathyroid gland leads to osteoclastic function in the bones, releasing both phosphate and calcium into the bloodstream. PTH also stimulates calcium absorption by the intestines and reabsorption by the kidneys, also leading to elevation of serum calcium levels. PTH will inhibit kidney reabsorption of phosphate, which leads to a net decrease of serum phosphate (Fig. 170.3). It also activates vitamin D activation in the kidneys. Calcitonin, produced in the thyroid gland, has antagonistic properties to PTH, leading to net bone absorption of calcium and phosphate by osteoblastic activity, and a net decrease in serum calcium levels. High level of calcium is a negative inhibitor of PTH release and stimulates calcitonin release.

Diagnosis

Patients with conotruncal malformations, in the setting of abnormal facies, hypocalcemia, absence of thymus noted on chest radiographs or during surgery, and/or cleft defects of the lip or

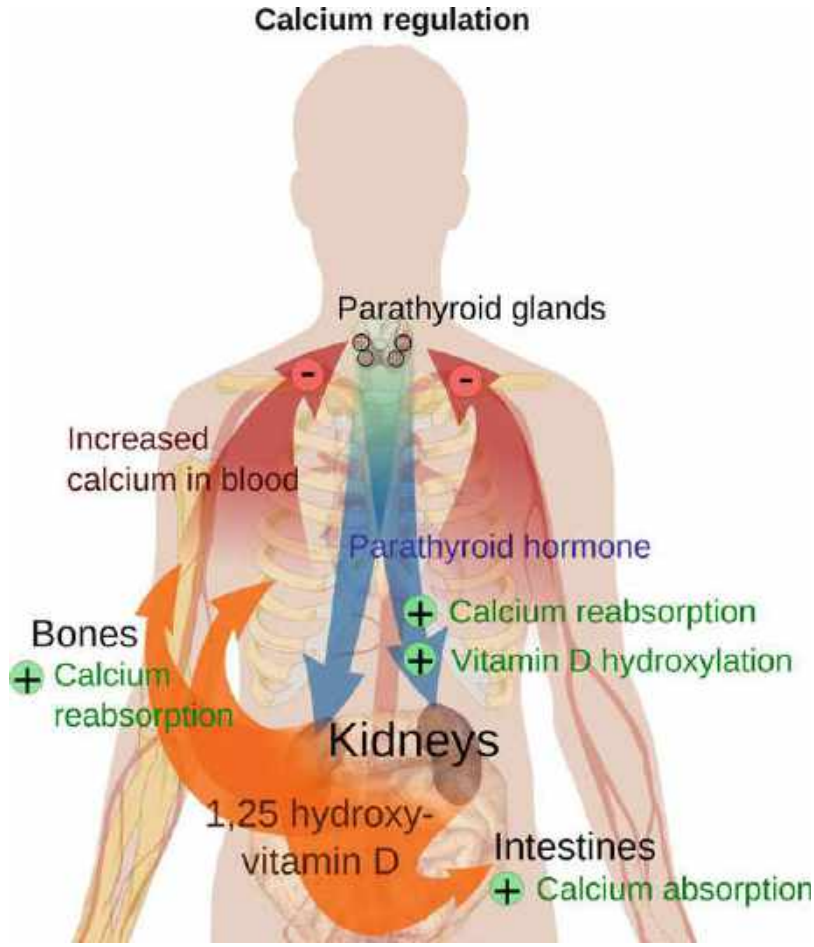

Fig. 170.3 Calcium metabolism by the parathyroid gland (Mikael Häggström. Published in Public Domain)

palate, should trigger testing for DiGeorge syndrome (Table 170.2). This syndrome is a result of a microdeletion of chromosome 22 at q11.2. Testing for DiGeorge syndrome involves sending for fluorescent in situ hybridization (FISH) for the 22q11 microdeletion. As much as 50 % of patients with DiGeorge syndrome have *hypocalcemia* secondary to parathyroid hypoplasia. In practice, DiGeorge syndrome has a highly variable presentation – including normal parathyroid and thymus function or complete absence of both. In addition to testing for DiGeorge syndrome, the patient should have calcium, phosphate, and magnesium levels checked, especially in the postoperative period.

In neonatal patients, but also in other postoperative pediatric CHD patients, checking routine calcium and magnesium levels in the first 24 h after surgery is important. The transfusion of citrate containing blood products and high-dose heparin during bypass surgery and in the intensive care unit places these patients at risk for hypocalcemia [45]. Checking ionized calcium levels is preferable to total calcium levels given that this is the active form of calcium that is unaffected by serum protein levels. Magnesium levels should be checked since hypomagnesemia triggers a decrease in PTH release and resultant hypocalcemia that is unresponsive to calcium repletion. Hypocalcemia can lead to hypotension,

poor response to inotropes, and increased morbidity and mortality in critically ill children [49]. Both hypocalcemia and hypomagnesemia can increase the risk of ventricular ectopy in the postoperative patient.

Treatment

Patients diagnosed with DiGeorge syndrome, microdeletion of 22q11, should have calcium, magnesium, and phosphate levels checked and consultation with an endocrinologist. Only about 50 % of patients with DiGeorge syndrome have clinically significant parathyroid hypoplasia requiring treatment. Perioperatively, these patients may require calcium supplementation, either in the form of intermittent boluses or as an infusion of calcium chloride. The goal of therapy should be normal ionized calcium levels, and if needed, the patients should be converted to long-term oral calcium supplementation. In some patients, simply repleting their magnesium levels will be sufficient to maintain normal calcium homeostasis [14].

Routine postoperative administration of calcium chloride to patients with CHD is controversial. It is known that calcium chloride improves contractility and blood pressure, with little effect on heart rate [50]. However, excessive administration of calcium may lead to cellular apoptosis, and has been associated with morbidity and mortality, as well as increased length of stay and complications in some studies of patients with congenital heart disease [51].

Most institutions will check routine ionized calcium levels postoperatively and administer calcium chloride given via central access to maintain normal levels (calcium gluconate is often used if only peripheral access is available). Patients requiring excessive boluses of calcium chloride may benefit from a continuous infusion or calcium added to the intravenous fluids. A repletion protocol that aims at the lower limits of normal ionized calcium is used at some institutions. Infusions of large amounts of blood products should lead the provider to anticipate hypocalcemia from the citrate in the blood products. Given the possible harms of excessive administration of calcium to postoperative CHD patients, repletion may best benefit those patients with low levels who seem unresponsive to inotropic support or have unremitting hypotension. Further studies of the benefits and harms of postoperative calcium repletion are needed.

Vasopressin

Background

In 1895, Oliver and Shafer first reported the physiologic effects of pituitary gland extract injection, noting a predominant increase in vasoconstriction. Following this discovery, many attempts were made to isolate and purify the pituitary component responsible for this vasopressor action, a process achieved in 1951 by du Vigneaud. He described a nonapeptide structure, similar in content to oxytocin. This peptide has variously been known as antidiuretic hormone, arginine vasopressin (to distinguish it from the porcine form, lysine vasopressin), pitressin, and pituitrin. It is now known that the gene for vasopressin is localized to chromosome 20p13, near the site of the gene for oxytocin. Initial synthesis yields a 166-amino-acid-long prohormone known as preprovasopressin. Further processing removes a carrier protein, neurophysin II, as well as copeptin, a c-terminal protein responsible for the normal folding of vasopressin [52]. Synthesis of the prohormone occurs in magnocellular neurons in the supraoptic and paraventricular nuclei of the hypothalamus; the processing then takes place as vasopressin is transported down the axons of the hypothalamic stalk to the posterior lobe of the pituitary gland.

Vasopressin secretion is regulated by an ever-increasing number of factors. The primary stimulus for secretion is maintenance of appropriate free water balance; this is mediated by hypothalamic osmoreceptors. The system is remarkably sensitive – a 1 % change in serum osmolality

will result in an increase in serum vasopressin levels by 1 pg/mL [53]. A weaker stimulus is intravascular volume as detected by pressure-sensitive receptors in the aorta and carotid sinus. Additional hormones have been implicated in the release of vasopressin, including angiotensin II, tissue plasminogen activator (both stimulators), atrial natriuretic peptide, and glucocorticoids (both inhibitors) [54].

Once secreted, vasopressin acts on several receptors. First, V1 receptor activation in the vasculature results in smooth muscle-mediated vasoconstriction. Additionally, V2 and V3 receptors in the renal collecting duct are stimulated by vasopressin to reabsorb urea, sodium, and water [55]. V2 receptor binding leads to activation of a G protein and then increased cAMP and protein kinase A; the end result is increased synthesis of aquaporin, AQP2, which acts to reabsorb free water from the collecting duct. At higher concentrations, vasopressin also stimulates oxytocin receptors, which have an extracellular domain similar to V1 receptors. Stimulation of cardiac oxytocin receptors, which have been localized in all cardiac chambers, leads to production of atrial natriuretic peptide. Finally, P2 purinergic receptors also bind AVP. Vascular purinergic receptor activation leads to the production of nitric oxide synthase and vasodilation, while in the cardiac endothelium, these same receptors may cause vasoconstriction.

Diagnosis: Vasopressin Excess (Syndrome of Inappropriate Antidiuretic Hormone Secretion)

Vasopressin excess may be associated with CNS disease or infection, pulmonary disease, and even as an adverse effect of certain medications. The classic findings are hyponatremia in the setting of euvolemia with inappropriately concentrated urine. Generally, fluid restriction is the first-line therapy. There are, however, multiple reports of V2 receptor antagonists that allow for secretion of free water and increase serum sodium by 4 days of therapy better than placebo. Six percent of adults in one report had an over-rapid correction of hyponatremia, defined as an increase in serum sodium of more than 12 mmol/L over the first 24 h [56]. Of note, this class of medications, the vaptans, has no published data in pediatrics with the exception of a few case reports.

In the setting of heart failure, however, vasopressin may be secreted despite a lack of osmotic stimulus. This "cardiorenal" syndrome, as it is called, is also associated with fluid overload, renal vein congestion, increased intra-abdominal pressure, and upregulation of the renin-angiotensin-aldosterone system. In the EVEREST trial, tolvaptan was administered to adult patients in heart failure and was associated with a subsequent aquauresis and improvement in dyspnea. However, there was no mortality benefit at 60 days [57].

Diagnosis: Absolute Vasopressin Deficiency

In the normal patient, vasopressin is chiefly responsible for free water balance through the V2 receptor in the renal collecting duct. This role was recognized in 1912 by Alfred Frank whose patient suffered a self-inflicted gunshot wound to the temple and then developed diabetic urine (polyuria) that was not sweet but rather insipid. This diabetes insipidus (DI) is the result of either inadequate vasopressin secretion (central) or dysfunctional V2 receptors in the kidney (nephrogenic). Patients at risk of central diabetes insipidus include those with congenital malformations of the pituitary (e.g., panhypopituitarism and septo-optic dysplasia), patients with gene defects of vasopressin, and patients with injury of any kind to the pituitary. Nephrogenic DI is due to absence or impairment of V2 receptors, which may be X-linked or acquired. Differentiation between these two states may be accomplished with a water deprivation test wherein the patient's serum osmoles are allowed to rise above 295 mOsm/L and then blood and urine may be collected with and without exogenous vasopressin (see Table 170.3). Although DI

Table 170.3 Diagnosis of diabetes insipidus with water deprivation

	Serum osmoles	Urine osmoles	Urine output	Serum vasopressin (if available)	Urine output after DDAVP
Central DI	>295	<300	Inappropriately elevated	<2 pg/mL	Greatly decreased
Nephrogenic DI	>295	<300	Inappropriately elevated	>5 pg/mL	No change

is relatively uncommon in patients with congenital heart disease, it may occur in the setting of Alagille syndrome, with stenosis of the great vessels and moyamoya disease.

Diagnosis: Relative Vasopressin Deficiency

Vasopressin has garnered more interest in recent years as a therapy for critically ill adults and children. Despite numerous studies in adult septic shock, it has not been shown to be more advantageous than alpha adrenergic agonists such as norepinephrine. In cardiac critical care, however, adults have been shown to be vasopressin deficient following cardiac surgery and do improve with exogenous vasopressin. This lack of vasopressin results in vasoplegia, a syndrome of low systemic vascular resistance (SVR) with capillary leak at either the micro- or macrocirculatory level with subsequent impaired oxygen delivery. Colson et al. demonstrated that adults with high copeptin levels preoperatively had low vasopressin levels postoperatively and postulated an exhaustion of endogenous vasopressin as the etiology [58]. An additional population of adults with post-bypass vasoplegia is that group receiving either angiotensin-converting enzyme inhibitors (ACEi) or angiotensinogen II receptor blockers preoperatively. Some adult centers, given the prevalence of ACEi in their populations, routinely start vasopressin following cardiac bypass for this reason. In children, adequate serum levels of vasopressin are not well-defined. Several good studies have attempted to characterize normal pediatric vasopressin levels following bypass, but serum levels do not seem to correlate with clinical vasoplegia [59].

Treatment: Vasopressin Deficiency/ Vasoplegia

Traditionally, the use of vasopressin has been discouraged in children after cardiac surgery, particularly in patients with univentricular physiology. The historical concern with the use of vasopressin has been its promotion of often intense and unopposed vasoconstriction, raising of SVR, and augmentation of afterload on a vulnerable single ventricle with no augmentation of inotropy. Despite this apprehension, several groups have published encouraging retrospective studies on the use of vasopressin in postoperative neonates, including neonates with univentricular physiology following the Norwood procedure [60–62]. The presumed etiology behind vasopressin's usefulness in this population is a redirection of blood flow away from some vascular beds (e.g., skin, muscle) toward others (e.g., renal) due to selective vasodilation. Vasopressin may play a key role in improving urine output due to the presence of V1 receptors on the efferent renal arteriole but not the afferent; this presumably increases pressure at the glomerulus and leads to better urine output [63]. Although some do not advocate the use of vasopressin in all patients, but rather in a select few with evidence of sustained cardiac function and vasoplegia, others are implementing it in the operating room with favorable results. Alten et al. found lower inotrope scores and a quicker time to net negative fluid balance in a retrospective cohort study of neonates undergoing the Norwood or arterial switch procedures and started on vasopressin in the operating room [64].

Although guidelines for vasopressin initiation in the cardiac ICU are lacking, preference should be given to patients with evidence of "good"

contractile cardiac function but with impaired tissue perfusion (e.g., widening arteriovenous oxygen difference, rising lactate) and capillary leak. Once other causes of low SVR are evaluated, vasopressin is initiated at 0.0003 units/kg/min. The dose may then be titrated to 0.007 units/kg/min as a maximum, but rarely is this necessary. Tissue oxygen perfusion is then the guide for alteration in the dosing of vasopressin.

Natriuretic Peptides

Background

In 1988, Sudoh et al. reported the discovery of a new 26-amino acid peptide in porcine brains that had similar but distinct activity to the previously identified atrial natriuretic peptide (ANP). Much like ANP, this new molecule led to increased urine output, salt loss, and decreased blood pressure in rats [65]. They chose to call this new hormone "brain natriuretic peptide" or BNP. Since then, this peptide has been renamed B-type natriuretic peptide, cleverly conserving its acronym (i.e., BNP), while clarifying that in humans, BNP is not found in the brain, but in cardiomyocytes. Furthermore, since the discovery of BNP, it is now known that ANP and BNP are actually part of a family of hormones that act as diuretics, natriuretics, vasodilators, and lusitropic agents among other functions.

The release of atrial natriuretic peptide occurs almost exclusively from the atrial myocytes and increases in the setting of atrial stretch. Also, the release of ANP may occur in a neurohumoral fashion due to increased sympathetic tone as noted in traumatic brain injury. The increased level of ANP in turn acts as a sympathoinhibitory hormone [66]. However, this may imply an initial syndrome of inappropriate antidiuretic hormone (SIADH) followed by atrial stretch, which eventually leads to the so-called cerebral salt-wasting syndrome with associated ANP release. The exact mechanism of natriuretic peptide release during intracranial processes is unclear.

Similarly, BNP is released primarily from the cardiomyocytes of the atria in a normal heart. However, there is evidence that during ventricular failure, there is a disproportionate release of BNP from the ventricular myocytes compared to ANP. This was elegantly demonstrated by Yoshimura et al. in 1993 by comparing patients with mitral stenosis (MS) to those with dilated cardiomyopathy (DCM) [67]. While both DCM and MS patients had similar elevations of ANP, those with DCM had a much higher release of BNP than those with MS correlating to the degree of left ventricular diastolic dysfunction. This implied that ventricular stretch led to increased BNP release, but not ANP release. This distinction has led to the use of BNP as a diagnostic biomarker of congestive ventricular dysfunction in both adult and pediatric patients.

Nonetheless, considerable questions remain about the mechanism of natriuretic peptides, which becomes most relevant when considering the complex anatomic and physiologic derangements seen in pediatric patients with congenital heart disease. Age-dependent variation in BNP levels has been demonstrated in normal pediatric patients, with a peak at birth (~55 pg/mL), rapid decline by 1 week of age, and reaching adult levels by 3 months of age [68]. There is a slightly higher BNP level in postpubescent girls than in boys.

Diagnosis

The natriuretic peptides have gained much attention for their diagnostic utility in a variety of cardiac disease states. The utility of BNP, as well as the cleaved N-terminal of the pro-BNP molecule (NT-pro-BNP), as a diagnostic tool is most evident in the diagnoses of congestive heart failure (CHF) in adult patients. Maisel et al. demonstrated that levels of BNP greater than 80 pg/mL were highly sensitive and specific for the diagnosis of CHF (AUC = 0.97). The biomarker was in fact more sensitive than emergency room physicians' clinical judgment [69]. The availability of a bedside, point-of-care test that uses small volumes of whole blood makes BNP an ideal screening tool. Furthermore, BNP has shown promise as an adjunct biomarker in the setting of myocardial ischemia, prognostication after

coronary bypass surgery, and diagnosis of pulmonary emboli in adult patients. NT-pro-BNP has also been used in the diagnosis of acute kidney injury (AKI), likely due to both the renal clearance of the molecule and increased release during renal failure.

As in adult medicine, BNP has served as a useful biomarker for the diagnosis of heart failure in pediatric patients with chronic syndromes of heart failure, such as dilated cardiomyopathy, post-heart transplant patients, and patients with acquired cardiomyopathy (e.g., viral myocarditis and beta thalassemia) [70]. In one study of 48 adolescent patients with idiopathic dilated cardiomyopathy, an NT-pro-BNP level greater than 250 pg/mL combined with electrocardiographic evidence of left atrial enlargement and an advanced New York Heart Association classification was 100 % sensitive and 77 % specific for an adverse outcome in this population [71]. Another study used blinded serial NT-pro-BPN levels upon admission of pediatric patients with acute decompensated heart failure (ADHF) to demonstrate that the biomarker, while elevated in all patients, was able to predict those who went on to need mechanical circulatory support (MCS) [72].

However, the use of BNP as a diagnostic tool in pediatric patients with congenital heart disease (CHD) is complicated by the age-dependant variation in BNP and the variety of anatomic and physiologic differences between each lesion. Nonetheless, considerable information is accumulating about BNP levels in patients with congenital heart disease. In a recent study, Amirnovin et al. studied 115 patients undergoing repair or palliation of congenital heart disease. They discovered that neonates with single ventricle physiology undergoing a Norwood procedure or those with d-transposition of the great arteries undergoing an arterial switch procedure demonstrated high preoperative BNP levels that dropped rapidly postoperatively. A failure of BNP levels to drop postoperatively was associated with a poor long-term outcome. In contrast, later in infancy, patients with large left-to-right shunts or tetralogy of Fallot demonstrated lower preoperative levels that rose postoperatively. The degree of rise was associated with long-term outcomes [73].

Studies such as this one, as well as others, in total and partial cavopulmonary anastomosis patients (i.e., Fontan and Glenn procedures), patent ductus arteriosus (PDA) patients, and patients with ventricular septal defects highlight the variability of BNP before and after operative intervention. In Fontan patients, the preoperative level was associated with outcomes in one study, while postoperative levels were not. In PDA patients, the rise in BNP can be used to determine the timing for intervention in premature neonates [74]. In contrast to adult patients, or even pediatric patients with anatomically normal hearts who have heart failure, it appears difficult to find exact cutoff values for BNP levels in patients with congenital heart disease. Perioperatively, the use of BNP changes or ratios may be more meaningful given the variability in BNP levels.

Treatment

The basis for the administration of natriuretic peptides stems from the 1981 experimental injection of homogenized rat atria into other rats, leading to natriuresis and diuresis [75]. Since that time, the isolation of individual natriuretic peptides has inevitably led to trials in animals and in humans for a variety of indications but with mixed results. ANP and BNP analogues have received the greatest attention and will be discussed below. CNP and DNP analogues are still in the early stages of testing at this time.

Anaritide, the human recombinant form of ANP, underwent multiple human trials investigating its role in renal protection given its ability to increase GFR. One small but promising trial found that low-dose administration of ANP (50 ng/kg/min) led to increased days of dialysis-free survival in adults following complicated cardiac surgery [76]. Nonetheless, multiple other trials have failed to demonstrate that ANP analogues reduce the need for dialysis or to decrease mortality. As of this publication, there are no pediatric data regarding the use of ANP.

Nesiritide, the recombinant form of BNP, has had greater exposure in both adult and pediatric populations. Again, early work seemed very

promising, indicating an improvement in urine output and reduction in dyspnea scales. Subsequent studies seemed to indicate, however, that nesiritide might be associated with increased renal failure. It was not until 2010 that the Acute Study of Clinical Effectiveness of Nesiritide in Decompensated Heart Failure Trial (ASCEND-HF) confirmed that both conclusions were false [77]. In this adult study of 7,141 patients, 15 % of the nesiritide group and 13.7 % of the placebo group had improved shortness of breath at 24 h. This difference was nonsignificant, much like the 1-month mortality rate for both groups (9.4 % vs. 10.1 %). However, concerns of renal failure with nesiritide were also found to be false. Following this large study, interest in the application of nesiritide in adult heart failure waned significantly.

In pediatric heart failure, several small trials have been published. One open-label study in infants and children with heart failure (including congenital heart disease and following transplant) indicated an improvement in fluid balance with the nesiritide group being more fluid negative [78]. Urine output increased from 1.5 to 2.3 mL/kg/h in the nesiritide group. The only noted complication was hypotension. There have been no large or randomized trials, although there is a current trial comparing nesiritide to milrinone following Fontan completion surgery. Perhaps due to the ASCEND-HF trial, there is less current interest in pursuing nesiritide in pediatric patients.

Conclusion

The endocrine system is extremely powerful and essential in the critically ill cardiac patient. Critical care physicians have begun to pay closer attention to how endocrinological derangements can affect patient outcomes. In excess, the endocrine hormones can be pathologic (e.g., insulin resistance from endogenous and exogenous glucocorticoids with resultant hyperglycemia), and their absence can lead to poor response to critical illness (e.g., hypothyroidism leading to vasomotor paralysis).

For the critically ill child with congenital heart disease, the "appropriate" hormonal state during illness is unclear and yet to be described. As such, this ambiguity often leads to controversy. These patients are especially at risk, however, given the prevalence of genetic defects in this population, their exposure to bypass surgery, and their often-severe critical illness postoperatively. The tautological argument that the "body knows best" is often at odds with the principle of critical illness dysregulation and self-harm. Probably, the truth lies somewhere between these extremes and decisions should be tailored to the individual patient (e.g., a patient who is doing well and weaning off of inotropes may not need cortisol supplementation until there is evidence that routine administration is indicated).

Perhaps more than other fields in pediatric critical care, the field of endocrinology is a growing and exciting one that promises to provide both therapeutic options and continued debate in the care of patients with congenital heart disease.

Venous Thromboembolism

171

Courtney Lyle and Neil Goldenberg

Abstract

Venous thrombotic disease is a serious concern for critically ill children hospitalized in the intensive care and cardiac intensive care units. Children with both innate and acquired conditions, including cardiac disease, a central venous catheter, immobility, a postoperative state, malignancy, an infectious or inflammatory state, traumatic injuries, or a disturbance of the coagulation pathway, may suffer from a venous thromboembolism during their hospitalization. As children suffer from both acute and chronic morbidity as well as a heightened risk of death following venous thromboembolism, it is essential that clinicians consider the latter as a possible complication during an intensive care admission. Treatment of venous thromboembolism in the acute period includes the use of anticoagulants, thrombolytic agents, mechanical and surgical thrombectomy, vena caval filters, and, in rare cases, observation and supportive care alone. In the child with congenital or acquired cardiac disease, the modality of treatment

is dependent upon many considerations. Among these are the severity and location of the venous thromboembolism, the anatomy and physiology of the child, as well as the surgical and intervention history, and the clinical stability of the patient. Chronic therapy is considered to prevent recurrent events and embolization from residual thrombus. Although prevention strategies are imperative to decrease the incidence of venous thromboembolism, there is no consensus in the pediatric literature to inform optimal thromboprophylaxis guidelines. In general, thromboprophylaxis is prescribed for children with cardiac disease requiring palliative or corrective surgery, endovascular stents, bioprosthetic or mechanical valves, cardiac catheterization, or cardiac transplant as they are at greatest risk of developing venous thromboembolism. Further inquiry must be undertaken to determine the safety and benefit of thromboprophylaxis for other critically ill children in the intensive care with multiple risk factors.

Introduction

Venous thrombotic disease is increasingly being recognized as a major concern for critically ill children. The estimated annual incidence of venous thromboembolism in children (VTE) is 0.07–0.14/10,000; however, among hospitalized children, this is estimated at 58/10,000 admissions and is continuing to rise, likely as a result of advancements in the medical support of critically ill children in the intensive care unit (ICU) and cardiac intensive care unit (CICU) in addition to greater awareness of VTE in general [1–3]. Children at highest risk of developing VTE are those with central venous catheters, malignant disease, congenital cardiac disease, postsurgical immobility, infectious or inflammatory conditions, inherited and acquired hypercoagulable states, or those hospitalized following trauma [4]. The overall mortality in children with VTE is 16 % and direct VTE-related mortality in children has been reported as 2.2 % and is likely higher in the ICU and CICU as occlusion of critical stents or central venous catheters delivering life-sustaining medications will significantly impact outcomes [4]. In addition, children diagnosed with VTE are at risk for significant morbidity including recurrent events and post-thrombotic syndrome (PTS), a manifestation of chronic venous insufficiency characterized by pain, swelling, ulceration, and/or functional impairment [5]. It is therefore essential that providers in the critical care setting recognize the signs and symptoms associated with VTE, initiate optimal intervention strategies without delay, and employ prevention strategies to minimize the number of children affected by VTE.

Presentations of VTE

VTE may occur anywhere within the venous system; however, in children, VTE is most frequently identified as a deep venous thrombosis (DVT), pulmonary embolus (PE), cerebral sinovenous thrombosis (CSVT), renal vein thrombosis (RVT), portal vein thrombosis, or intracardiac thrombosis. There is considerable heterogeneity

Table 171.1 Clinical presentation of VTE

VTE	Signs and symptoms
DVT	Painful, unilateral swelling of affected limb
PE	Shortness of breath, pleuritic chest pain, hemoptysis, new/increased oxygen requirement, signs of right heart failure, sudden death
CSVT	Irritability, poor feeding, persistent headache, vision changes, cranial nerve palsies
RVT	Hematuria, oliguria, palpable flank mass
PVT	Hematemesis, splenomegaly, abdominal pain
Intracardiac	Asymptomatic or sudden cardiac collapse

in the presenting symptoms of VTE as the associated symptoms are directly related to the affected organ or vascular location (Table 171.1). DVT in children typically presents as painful, unilateral swelling of the affected limb, including both upper and lower extremities. Sensitivity and specificity of Homan's sign, a palpable cord, for DVT are not well established, particularly in pediatrics. When the upper extremities are involved, initial signs of vessel occlusion may be evidenced by superior vena cava (SVC) syndrome as the venous return to the heart via the SVC is compromised. The presenting symptoms of a PE can vary greatly, from an asymptomatic presentation that is diagnosed on imaging obtained for an unrelated condition to sudden collapse secondary to a proximal PE or saddle embolus. Additional symptoms/signs may include unexplained shortness of breath, hemoptysis, pleuritic chest pain, a new or increasing oxygen requirement, and right heart failure. Presenting symptoms of CSVT are often related to the age and neurologic maturity of the affected patient. In the neonatal population, symptoms are often nonspecific, such as irritability or poor feeding, while older children may complain of severe persistent headache or blurry vision. Children with CSVT may also present with seizures or cranial nerve palsies. RVT, more frequently identified in neonates, is often diagnosed after a work-up is initiated for hematuria, oliguria, thrombocytopenia, or a palpable flank mass. Children undergoing evaluation for splenomegaly, thrombocytopenia, and gastroesophageal varices with bleeding may be diagnosed with a portal venous thrombosis. Intracardiac thromboses may be asymptomatic and diagnosed on routine echocardiography following surgical interventions or may also present as sudden cardiac collapse secondary, for instance, to critical occlusion of a stent. While VTE symptoms may not be considered unique and may be associated with other clinical situations, it is imperative that a clinician considers VTE on the differential diagnosis to minimize delay in initiating appropriate diagnostic modalities.

Risk Factors

VTE risks can be related to Virchow's triad, specifically venous stasis, endothelial damage, and hypercoagulability (Fig. 171.1). The latter disturbance may occur as a result of inherited or acquired risk factors that result in increased thrombin production, enhanced platelet aggregation, endothelial activation, or inhibition of fibrinolysis. In children, an alteration in the hemostatic balance most frequently occurs in the neonatal and adolescent population, representing a bimodal distribution in the incidence of VTE [2]. In the neonatal population, the mechanism is most likely related to perinatal factors and the frequent use of catheters in the central vasculature of premature infants, on a background of a physiologically decreased concentration of inhibitors of the coagulation pathway, with or without superimposed disseminated intravascular coagulation [6]. In the adolescent population, the increase in thrombophilia is likely related to the coagulation system approaching adult parameters with increased thrombin generation in addition to an increase in acquired risk factors such as the use of oral contraception, smoking, and an increase in traumatic injuries resulting in endothelial damage. Unlike the adult population, where many VTE events are considered idiopathic, more than 90 % of VTE events in children have identifiable risk factors, with most children having more than one risk factor [2, 4]. In the critically ill child, specific risk factors that must be recognized include congenital heart disease,

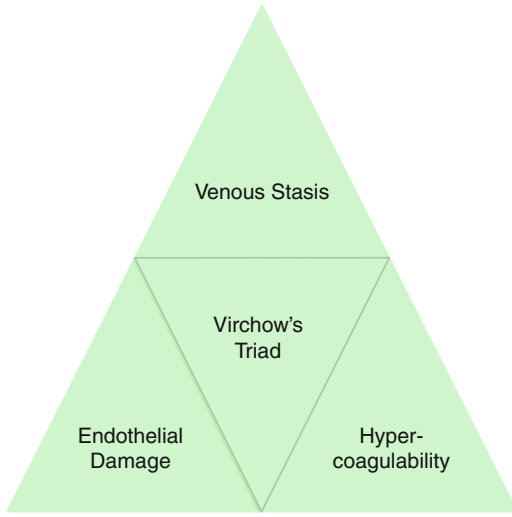

Fig. 171.1 Virchow's triad

immobility or a postsurgical state, malignancy, infection or underlying inflammatory conditions, a traumatic injury, acquired or inherited abnormalities of the coagulation pathway, and the presence of a central venous catheter (Table 171.2).

Cardiac Disease

Children with both congenital and acquired cardiac disease are at risk of developing both extrathoracic and intrathoracic VTE. Due to the presence of intracardiac communications and right side to left side shunts, the children are at increased risk of suffering embolic phenomenon to the lungs, mesenteric, renal and peripheral vasculature, and most importantly to the CNS. Approximately 1/5 of all VTE in children are associated with cardiac pathology [2, 4]. Associated conditions include cyanotic congenital heart disease, presence of a palliative shunt or cavopulmonary anastomosis, endovascular stents, cardiomyopathy or left ventricular dysfunction, valvular dysfunction, the presence of prosthetic heart valves, or following cardiac transplantation (Table 171.3). The mechanism of VTE formation varies depending on the specific cardiac pathology, but may be a result of turbulent flow or venous stasis; polycythemia associated with cyanotic congenital heart disease; or endothelial disruption secondary to central venous lines, surgery, or implanted foreign material [7, 8]. Platelet hyper-reactivity has also been observed in un-operated cyanotic congenital heart disease as well as in children immediately postoperatively, resulting in a pro-thrombotic state [9, 10]. In addition to platelet abnormalities, cardiopulmonary bypass also generates an inflammatory response, resulting in a pro-thrombotic state [11].

Children in the postoperative period with cardiac disease are at an especially high risk of developing VTE, which is associated with considerable morbidity and mortality. In a retrospective review, Manlhiot et al. reported 444 thrombotic events in 1,542 pediatric cardiac surgeries [8]. Presence of thrombosis was associated with longer intensive care stays and an increased risk of cardiac arrest and death. Twenty eight percent of children with a thrombotic event had a serious complication. The incidence of VTE in critically ill children with cardiac disease admitted to the ICU is also concerning, with a reported rate of 3.8 % in an observational study by Hanson et al. [12]. Identified risk factors

of VTE included a younger age at presentation, single-ventricle cardiac lesions, increased illness severity, unscheduled intensive care admission, and a complicated hospital course [12].

Malignancy

Over 25 % of VTE in children are associated with malignancy [4]. As many children diagnosed with malignancy require intensive care at some point during therapy, it is critical to recognize the risk of VTE in this population. The increased risk of VTE may be explained by a hypercoagulable state induced by the malignancy or secondary to treatment and supportive care. Malignancy is often associated with an inflammatory state resulting in increased levels of procoagulant factors, including FVIII, von Willebrand factor, and fibrinogen. Tumor cells also can be associated with an increased expression of tissue factor on the cell surface, thus activating the coagulation cascade [13]. In addition, tumor cells may secrete procoagulant molecules, further exacerbating a hypercoagulable condition. Chemotherapeutic agents also modulate the risk of VTE through direct endothelial damage and by suppressing natural anticoagulants. The majority of children have a CVC placed shortly after diagnosis to administer chemotherapy and supportive medications, which further heightens the risk of thrombosis.

Trauma

Children admitted to the ICU were not historically recognized as a cohort with a significant risk of VTE; however, more recent publications suggest that the prevalence of VTE following a traumatic event has dramatically increased [14]. While the historic incidence of VTE following admission to the ICU for a traumatic injury was less than 0.33 %, Hanson and colleagues reported an incidence of 6.2 % in a recent retrospective study [14, 15]. Identified risk factors for VTE following trauma include increased age, increased injury severity, thoracic or spinal injuries, presence of a CVC, and the use of supportive medications including ionotropic support, TPN, recombinant factor VIIa, and neuromuscular blockades [14–16].

Infection/Inflammation

Children admitted to the ICU with either infectious or inflammatory conditions are at risk for developing acquired thrombotic features in addition to supportive care such as CVCs or immobility with prolonged intensive care stays. Children with bacterial sepsis or disseminated intravascular coagulation (DIC) may suffer from acute deficiencies of anticoagulant proteins resulting in thrombosis. Additionally children with inflammatory or infectious conditions may also develop a pro-thrombotic, pro-inflammatory state [2, 4].

Central Venous Catheter

The presence of a central venous catheter (CVC) is the most frequently identified risk factor for children with VTE. CVCs are associated with more than 80 % of all VTE in newborns and more than 50 % of DVT cases in children [1, 2, 4]. The increased risk of VTE in the presence of a CVC is likely related to endothelial damage caused by the insertion of the CVC, disturbance of flow by the catheter, and the thrombogenic effect of bacterial colonization of the catheter. The overall prevalence of VTE in critically ill children with CVCs has been reported as high as 18–35 % with surveillance imaging [17, 18]. Femoral venous catheters are associated with the highest incidence of VTE. While CVCs are essential to providing optimal care for critically ill children, a provider must weigh the risks and benefits of placing a CVC and be attentive to its removal when no longer necessary.

Laboratory Evaluation

Although still debated, it has been recommended that children diagnosed with VTE, including those in critical care units, undergo a comprehensive

Table 171.4 Laboratory evaluation

Coagulation abnormalities	Laboratory tests
Disseminated intravascular coagulation	CBC, PT, aPTT, fibrinogen, D-dimer
Anticoagulant deficiency/resistance	Protein C activity, free protein S activity, antithrombin, factor V Leiden mutation
Procoagulant excess	Factor VIII, prothrombin 20210 mutation
Antiphospholipid antibodies	dRVVT (lupus anticoagulant), anticardiolipin antibody (IgM, IgG), anti-ß2-glycoprotein-1 antibody (IgM, IgG)
Mediators of endothelial damage	Homocysteine

thrombophilia laboratory evaluation to assist the clinician in determining the etiology of thrombosis, determine if any alternative therapies are indicated, and to potentially guide the length of therapy (Table 171.4) [19]. Initial laboratory testing recommended in the acute setting includes a complete blood count (CBC), prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen. This initial evaluation may uncover signs of associated infection, heparin-induced thrombocytopenia (HIT), or DIC. This initial testing also aids in assessing safety of anticoagulation in a critically ill population, as caution should be exercised in anticoagulating children with thrombocytopenia or hypofibrinogenemia in particular. Fibrinogen testing may also disclose a dysfibrinogenemia, wherein both bleeding and thrombotic complications may be seen. Additional evaluations that should be considered in the acute setting include testing for acquired or genetic deficiencies of natural anticoagulants, including antithrombin, protein C, and protein S. In the setting of acute severe VTE or related disorders such as purpura fulminans, consideration can be given to replacement of protein C, protein S, and antithrombin deficiency with protein C or antithrombin concentrate or with fresh frozen plasma (FFP), as further discussed below. Other pathologic processes encountered in the ICU that may lead to anticoagulant deficiencies include congenital heart disease with a single ventricle, liver disease, nephrotic syndrome, meningococcemia, and asparaginase therapy for acute lymphocytic leukemia.

Additional thrombophilia defects to be assessed that are often acquired but may be genetically modulated include elevated factor VIII activity, hyperhomocysteinemia, and antiphospholipid antibodies (e.g., lupus anticoagulant, anticardiolipin antibodies, and anti-ß2 glycoprotein antibodies). Given that present guidelines (e.g., American College of Chest Physicians) for duration of anticoagulation in pediatric VTE are based on low-quality evidence, the severity and time course of acquired thrombophilic abnormalities may influence clinical judgment on duration of anticoagulation in individualized circumstances [20]. While testing for these acquired defects will likely not alter acute management, the results will inform the duration of anticoagulation. In addition, diagnosis of antiphospholipid antibody syndrome requires testing on two separate occasions, 12 weeks apart; thus, a diagnosis is most easily ascertained when testing is done acutely and 3 months following diagnosis. Genetic testing that should be considered includes testing for Factor V Leiden polymorphism and Prothrombin G20210A polymorphism. Given the minor contribution to incident and recurrent VTE risk conferred by heterozygous states of these polymorphisms, this genetic testing rarely influences acute management, but is important in informing anticipatory guidance toward secondary VTE prevention during future hospitalizations, particularly in the setting of recurrent critical illness. This testing should be performed prior to discontinuation of therapy in order to adequately risk-stratify the patient and determine the appropriate duration of therapy.

Although critically ill children with VTE who require considerable blood product support (either as a result of their underlying condition or related to surgical interventions or cardiac bypass) may develop additional coagulopathies, an acute thrombophilia evaluation as discussed above (including CBC, PT, PTT, fibrinogen and protein C, protein S, and antithrombin activity) can still aid in consideration of therapeutic

options and decision making (e.g., acute interventions as discussed above). Documentation of trend in resolution of a coagulopathy may also aid in the ongoing management of a critically ill patient (e.g., tapering off protein C replacement in a patient with resolving acquired, clinically significant consumptive protein C deficiency, in the absence of recurrent or progressive thromboembolism). Acute testing for thrombophilias will help define any acquired abnormalities impacting therapeutic options and decisions (e.g., acquired antithrombin deficiency as a cause for heparin "resistance" [difficulty achieving targeted therapeutic anticoagulant levels], warranting consideration of antithrombin replacement). *Definitive* diagnosis of inherited conditions should be made on the basis of follow-up testing in the subacute testing, and in the case of plasma-based testing (e.g., deficiencies of intrinsic anticoagulants such as protein C and antithrombin) should be made only after consideration of the individual half-life for a plasma protein that was infused via plasma-derived blood products (e.g., FFP).

Outcomes

Critically ill children suffer from significant morbidity and mortality following an acute VTE event. Complications related to VTE are typically specific to the organ affected in addition to hemorrhagic complications attributed to therapeutic interventions. The most dire presentation secondary to VTE is sudden death following a proximal or massive PE or as a result of a hemodynamically significant intracardiac or extracardiac shunt thrombosis. Overall mortality in children with VTE is reported as 16–20 %, although VTE-specific mortality is less than 2 % [2, 4]. The discrepancy in mortality rates indicates that many children with VTE have severe underlying medical conditions. Among all children with VTE, those with underlying cardiac disease appear to have the greatest risk of death, with a morbidity rate of up to 24 % in children admitted to the ICU with cardiac disease and 25 % with VTE following a Fontan procedure [12, 21].

Other complications that should not be overlooked in the ICU following VTE include early recurrent VTE, cardioembolic stroke, ischemic stroke from paradoxical embolism (i.e., embolism from a DVT to cerebral arterial circulation, via a right-to-left intracardiac shunt), acute renal insufficiency following RVT, SVC syndrome when the upper venous system is affected, and catheter-related sepsis. Recent evidence also suggests that children in the ICU with CVC-related VTE have fewer ventilator-free days and spend more time in the ICU in the first 4 weeks following catheter placement than children in the ICU with a CVC who do not develop VTE [22]. Although causality of VTE resulting in lung impairment and subsequent need for ventilatory support cannot be established with this study, the association emphasizes the importance of removing CVCs as soon as they are no longer needed.

Although the chronic complications of VTE are unlikely to be diagnosed in the critical care setting, they necessitate prompt and effective intervention in the ICU. The most frequent chronic complication following VTE in children is post-thrombotic syndrome (PTS), affecting approximately 1/3 of children with limb DVT [23]. PTS results from venous hypertension and damage to the deep venous valves, which subsequently causes pain, swelling, discoloration of the skin, ulceration of the limb, and/or functional impairment. As treatments for PTS are limited, it is expected that young patients with PTS will suffer from associated symptoms for many decades. Recurrent events are also a frequent phenomenon following VTE in children, affecting nearly 10 % of children [2, 4, 23]. Organ-specific complications are also of great concern affecting children post-VTE. In children diagnosed with CSVT, neurologic complications are frequent, occurring in up to 26 % of neonates and up to 47 % of children [24, 25]. While RVT typically presents in the neonatal population, the long-term effects persist, resulting in renal abnormalities such as a decreased glomerular filtration rate (GFR), hypertension, or renal atrophy [26]. Long-term lung function in children following a PE is yet to be established.

Management

Considerations for VTE treatment include anticoagulants, thrombolytic agents, mechanical and surgical thrombectomy, and in some cases observation and supportive care alone depending on patient characteristics and VTE severity. Intervention must be determined for the initial (acute) phase and the chronic (subacute phase). As there are limited studies evaluating the optimal regimen in children, treatment guidelines are based on adult randomized controlled clinical trials in addition to non-randomized trials, cohort studies, case series, and case reports published in the pediatric literature. The ACCP publishes guidelines for antithrombotic therapy for neonates and children [20]. The American Heart Association also has published a guideline on management of iliofemoral DVT and massive/submassive PE that, while emphasizing adult literature, does address the published pediatric experience [27].

Acute Therapy

The goals of antithrombotic therapy in the acute phase are to diminish hypercoagulability and propagation of the thrombus, to reestablish flow in the affected vessel, and to prevent embolization. It is imperative that diagnosis of VTE occurs in a timely fashion and therapy be started immediately to decrease both morbidity and mortality. The modality of intervention is guided by the severity of the presenting VTE. If the VTE is potentially life-, limb-, or organ-threatening or is considered high risk for long-term complications, then thrombolysis or thrombectomy should be considered, while most other VTEs will be treated with either unfractionated heparin (UFH) or low molecular weight heparin (LMWH) in the acute intensive care setting (or intravenous direct thrombin inhibitors [DTI] in the setting of heparin-induced thrombocytopenia; see section on HIT/T, below and Table 171.5). Heparin-based therapy is given for a minimum of 5 days prior to any transition to oral vitamin K antagonists (e.g., warfarin), based on adult data [20]. Rarely, antithrombotic therapy may not be warranted, particularly when bleeding risk appears to outweigh the prospects for risk reduction in DVT extension/embolism, or as has been advocated by some experts for neonates in the setting of unilateral renal vein thrombosis without renal impairment [20].

Unfractionated Heparin

The anticoagulant properties of unfractionated heparin (UFH) are a result of the augmentation of antithrombin activity, leading to inactivation of key serine proteases in coagulation activation, such as thrombin and factor Xa. Heparin is given as a continuous intravenous infusion and is optimally monitored in children via anti-factor Xa activity. The initial loading dose in non-neonates is 50–75 U/kg followed by a maintenance dose of 15–20 U/kg/hr. The anti-Xa level should be checked 6–8 h after initiating therapy with a goal of 0.3–0.7 anti-Xa activity U/mL. Infants have lower antithrombin levels than older children and a larger volume of distribution, typically necessitating a higher per-kilogram dose of heparin [28]. The starting maintenance dose for neonates is 28 U/kg/h; however, up to 50 U/kg/h may be required to obtain appropriate levels in neonates [29]. While not optimal, if anti-Xa levels are not available, it is possible to follow

Table 171.5 Acute anticoagulant therapy for VTE in children (see text for neonatal dosing)

Therapeutic agent	Loading dose	Maintenance dose	Monitoring	Therapeutic goal
UFH	50–75 U/kg IV	15–20 U/kg/h IV	Anti-Xa activity	0.3–0.7 U/mL (6–8 h after dose)
LMWH		1.0–1.25 mg/kg q 12 h SQ	Anti-Xa activity	0.5–1.0 U/mL (4 h after dose)
Argatroban		0.75 mcg/kg/min IV	aPTT	1.5–2.5 × baseline
Bivalirudin	0.125 mg/kg IV	0.125 mg/kg/h IV	aPTT	1.5–2.5 × baseline

the activated partial thromboplastin time (aPTT) with a goal of 60–85 s or 1.5–2 times the upper limit of the age-appropriate reference value. The frequency of the lupus anticoagulant in children with VTE often renders heparin monitoring by aPTT challenging.

UFH is often the preferred anticoagulant in the intensive care setting for children with labile medical conditions or an increased risk of bleeding as it has a short half-life in comparison to LMWH. UFH is also recommended in children with renal dysfunction when LMWH is not indicated. Disadvantages of UFH, as with all anticoagulants, are the risk of bleeding in addition to the need for frequent monitoring and a heightened risk of heparin-induced thrombocytopenia (HIT). The reported incidence of HIT is <3 % in pediatric intensive care patients who have received heparin for >5 days [30].

Low Molecular Weight Heparin

Low molecular weight heparin (LMWH), including enoxaparin, reviparin, dalteparin, and tinzaparin, is used frequently as a first-line agent in children with VTE who are medically stable, have normal renal function, and who do not have additional risk factors for bleeding. The mechanism of action of LMWH is similar to UFH with the augmentation of antithrombin activity [20]. Recommended dosing of enoxaparin for VTE is 1.0–1.25 mg/kg every 12 h given subcutaneously. Similarly to UFH, a higher dose is often needed in full-term neonates, wherein a typical enoxaparin dose is 1.5 mg/kg. LMWH is monitored with anti-Xa activity with a goal of 0.5–1.0 U/mL. A level should be obtained 4 h post-dose.

Advantages of LMWH in comparison to UFH include a decreased risk of HIT, more predictable pharmacokinetics, and less laboratory monitoring. Disadvantages from the perspective of bleeding risk include a longer half-life of anticoagulant effect [31]. As is well established for UFH, long-term use of LMWH may increase the risk of osteoporosis and liver dysfunction [20].

Following the acute intervention, subacute therapy is initiated, as discussed below.

Alternative Anticoagulants

Alternative anticoagulation is utilized when either UFH or LMWH is contraindicated. The most common indication to use an alternative agent is heparin-induced thrombocytopenia (HIT) which has an incidence of 2.3 % in the pediatric ICU population [30]. HIT is an immune-mediated disorder that occurs after heparin administration. HIT typically occurs after 5 days of heparin therapy; however, if a patient has received heparin within the preceding 100 days, it may occur within 48 h of repeat exposure. Despite a falling platelet level, patients are at risk for developing both venous and arterial thrombosis, necessitating the cessation of heparin and initiation of an alternative therapy. Argatroban, a DTI, is the only agent that has specifically been evaluated in children with HIT [32].

Direct Thrombin Inhibitors

DTI use in children is primarily intravenous with either argatroban or bivalirudin. Oral DTIs (e.g., dabigatran, rivaroxaban) are also available off-label; however, safety and efficacy data are not yet available for children, and are as yet limited in the adult VTE treatment setting. DTIs exert an anticoagulant effect by directly binding to and inactivating thrombin. The advantages of DTIs include more predictable pharmacokinetics than heparin and there is no risk of HIT. There is, however, no specific antidote. Argatroban is considered the first-line agent for children with HIT. The recommended starting dose of argatroban is 0.75 μg/kg/min and should be adjusted to achieve a PTT of 1.5–2.5 times the baseline value [32]. If a child has hepatic dysfunction, bivalirudin may be considered. Bivalirudin is initiated with a bolus dose of 0.125 mg/kg followed by a continuous infusion of 0.125 mg/kg/h with a therapeutic target range of 1.5–2.5 times the baseline PTT [33].

Thrombolysis

Thrombolytic agents are indicated when reestablishment of vascular flow is critical. While it is clear that children with life-, limb-, or organ-threatening VTE may be candidates for

this intervention, treatment guidelines suggesting appropriate patient selection or optimal dosing are not well defined and treatment practices vary significantly [34]. Thrombolytic agents have been used in children for several decades; however, no randomized controlled clinical studies have been performed to determine the efficacy or to determine the optimal dosing or route of administration. Case reports, case series, and cohort studies in the pediatric literature suggest that children with life- or limb-threatening conditions in addition to high-risk clots that have been present for less than 2–4 weeks can experience favorable outcomes, and warrant further study for reducing the risk of PTS.

Thrombolytic agents, including tissue-type plasminogen activator (tPA), urokinase (UK), and streptokinase (SK), are effective in treating VTE by augmenting the fibrinolytic process. These compounds are plasminogen activators that catalyze the conversion of plasminogen to plasmin, which cleaves fibrin fibers. In the USA, tPA has become the preferred agent for the treatment of VTE in children. Urokinase is no longer available in the US market and the use of streptokinase can result in humoral and cellular antibodies, which may lead to decreased efficacy and allergic reactions [35]. Thrombolytic agents may be administered via local, catheter-directed therapy or via a systemic infusion. There are no studies indicating the optimal route of administration; thus, the risks and benefits of either route must be considered for each case. In young children, the small vessel size may preclude the use of catheter-directed therapy. In addition, catheter-directed therapy often requires the use of sedation for line placement unless a preexisting line is present and may require more time to organize compared to systemic therapy [36].

While the optimal dose and route of tPA administration for DVT and/or PE is unclear, it appears that both low-dose systemic tPA and low-dose local catheter-directed tPA are effective in treating VTE while potentially decreasing the risk of treatment-related bleeding relative to historical regimens using higher dose tPA [36]. Low-dose tPA is considered 0.03 mg/kg/h in non-neonates with the option to increase to 0.06 mg/kg/h (maximum 2 mg/h) between 24 and 48 h if there is persistent thrombus. (Higher dosing can be considered in neonates [e.g., initial tPA dose of 0.06 mg/kg/h] [36], given that the substrate for tPA, endogenous plasminogen, in neonates is 50 % that of adult levels [6]; however, systemic tPA should be reserved for life-threatening thrombosis in premature neonates, in whom risk of CNS hemorrhage is considerably increased.) The tPA infusion is discontinued upon complete thrombus resolution and continued for a maximum of 96 h in the event of non-resolution of thrombus. It is suggested that with a longer infusion time with lower doses, the drug is in contact with the target sites for a longer period of time while reducing the risk of treatment-related bleeding [37]. In contrast, ACCP tPA dosing recommendations suggest 0.1–0.6 mg/kg/h for 6 h, when tPA is used [20]. Although not addressed in detail by current ACCP recommendations, salvage therapy with pharmacomechanical thrombolysis may be considered in the event of persistent thrombus at the time systemic tPA is discontinued, or else considered as the principal thrombolytic approach (see below for further discussion) [38, 39].

Additional therapies must be considered during thrombolytic therapy including the use of anticoagulants and plasma transfusions. Thrombolytic agents are effective in lysing existing thrombi; however, these agents are not anticoagulants, and are not presumed to prevent clot propagation. Low-dose heparin therapy is commonly administered while tPA is infused, followed by therapeutic heparinization and warfarinization upon cessation of tPA [36, 38, 40]; however, there are no controlled studied determining safety or efficacy of this approach. Most recently, LMWH has been used for concurrent anticoagulant therapy at half the therapeutic dose [36]. In addition, to maintain therapeutic efficacy of tPA, a sufficient concentration of plasminogen must be present. Thus, the ACCP guidelines recommend supplementation with fresh frozen plasma for physiologic or pathologic deficiencies [20]. Fresh frozen plasma (FFP) may be given at a dose of 10 ml/kg daily for plasma concentrations less than 50 % [37].

There is no established monitored therapeutic range for tPA administration. Efficacy is based on the presence or absence of residual thrombus, as determined radiographically. At a minimum, the thrombus should be imaged prior to initiating thrombolysis and at the conclusion of thrombolytic therapy [37]. In addition, imaging is often done 24 h following the initiation of thrombolytic therapy to determine if additional intervention is necessary such as pharmacomechanical thrombolysis [37, 38]. Prior to beginning therapy, baseline coagulation measurements should be obtained including PT, aPTT, fibrinogen level, plasminogen concentration, and D-dimer or FDP levels. These levels should then be obtained every 24 h to ensure appropriate hemostasis, and supportive care is given as indicated [37, 38]. To maintain hemostasis during systemic tPA administration, the platelet count should be maintained above 100,000 and fibrinogen level should be above 100 mg/dL [20, 38].

The current ACCP guidelines recommend that the use of thrombolytics be employed in children with bilateral renal vein thrombosis in the presence of renal failure and should be considered in children with severe cerebral sinus vein thrombosis who have not improved with initial UFH therapy [20]. Although publications describing the use of thrombolysis in pediatrics are becoming more frequent, the ACCP guidelines indicate that thrombolysis should be used only for life- or limb-threatening thrombosis [20]. Successful outcomes of vessel recanalization have been reported for VTE in various locations, including DVT, PE, CSVT, phlegmasia cerulea dolens, intracardiac thrombi, mechanical valve thrombosis, and aorto-pulmonary shunts [36, 38, 39, 41–43]. Goldenberg et al also suggest that long-term morbidity may also be decreased following the use of thrombolysis [38]. A 98 % relative reduction in the odds of PTS was reported in children with occlusive lower limb DVT treated with a thrombolytic agent compared to those treated with standard anticoagulation in a small cohort study [38]. In addition to life- or limb-threatening clinical scenarios, it is suggested that to achieve optimal outcomes, thrombolytics also be considered for high-risk VTE within 2–4 weeks of symptom onset [38, 44].

The major risk to patients when administering thrombolytic agents is hemorrhage. While the risk of bleeding with thrombolysis is higher than compared with the use of standard anticoagulation, major bleeding is relatively low if appropriate patient selection is observed [36, 38, 41, 45]. To minimize the risk of significant bleeding, it is critical to administer tPA in individuals in whom the expected benefit outweighs the potential risk. While it has not been rigorously studied, it appears that bleeding risks are also lower with local catheter-directed therapy than with systemic therapy. The following are considered relative contraindications for the use of systemic tPA: a known allergy to tPA, active bleeding, major surgery or hemorrhage within the previous 10 days, an asphyxial event within the previous 7 days, an invasive procedure within 3 days of therapy, seizures within the previous 48 h, systemic septicemia, and prematurity <32 weeks gestation [40]. Contraindications that must be considered for local thrombolysis utilizing interventional catheter-directed approach include a known allergy, the size of the involved vessels, and the experience of the interventionalist [37]. While use of systemic thrombolytics has been reported in postoperative cardiac patients with VTE, their use is relatively contraindicated in the postoperative period and consideration for local thrombolytics or thrombectomy should be considered.

Should a patient suffer from bleeding, it is imperative that all coagulation deficits be corrected such as thrombocytopenia (platelet transfusion) or fibrinogen deficiency (cryoprecipitate).

Surgical Thrombectomy and Percutaneous Mechanical Thrombolysis

Children with high-risk VTE, life- or limb-threatening VTE, or contraindications to standard therapy, may warrant surgical thrombectomy in rare circumstances. There are no specific guidelines to guide these interventions; therefore, the risks and benefits must be evaluated in each case. Monagle et al. recognize the following clinical

conditions as situations that may warrant surgical intervention: IVC thrombosis in association with intravascular extension of tumor, acute thrombosis of Blalock-Taussig shunts, thrombosis following cardiac surgery, prosthetic valve thrombosis, septic thrombosis, and severe CSVT [20]. Additional clinical scenarios that have had reported success with surgical thrombectomy include massive DVT and PE [46–48]. While these reports demonstrate successful outcomes, the surgical risk must not be underestimated.

Although surgical thrombectomy has been the historical approach to VTE following cardiac surgery, mechanical thrombolysis with or without pharmacological thrombolytics is being increasingly reported as safe and effective in recanalizing the affected vessel or stent [49, 50]. Fleming et al describe a single-site series with acute recanalization of all vessels that underwent mechanical thrombolysis following cardiac surgery [49]. Vessels involved in this series included pulmonary arteries, systemic veins, and an aorto-pulmonary shunt [49]. Mechanical thrombolysis has also been reported as successful in children with complex congenital heart disease with a remote history of surgery presenting with acute, intracardiac, or shunt thrombosis in addition to children with PE without heart disease [51–53].

Percutaneous mechanical thrombolysis (PMT) and percutaneous pharmacomechanical thrombolysis (PPMT) with adjunctive catheter-directed tPA has also been described as both safe and effective when employed in adolescents with complete veno-occlusion of a proximal limb at high risk for PTS [39]. In a prospective cohort study of 16 children with a median age of 16 years who underwent PMT/PPMT, successful lysis occurred in 94 % without any peri-procedural bleeding. Most significantly, only 13 % of subjects had physically or functionally significant PTS at a median follow-up of 14 months [39]. It is likely that rapid attainment of venous patency diminishes the risk of PTS by decreasing the risk of venous hypertension.

In addition to the risks described for thrombolysis, complications of mechanical thrombectomy also include injury to adjacent vessels, PE, and vessel perforation [54, 55]. With intracardiac or extracardiac thrombi, mechanical thrombolysis also may cause bradycardia, hypotension, and hemolysis [52, 56].

Vena Caval Filter

Vena caval filters may be considered in children >10 kg with lower extremity DVT when anticoagulation is contraindicated, in children with recurrent VTE on therapeutic anticoagulation with persistent pro-thrombotic risk factors, or during periods of heightened risk of PE [20, 37]. It is recommended, however, that IVC filters be removed as soon as possible and anticoagulation be initiated as soon as any contraindications are resolved [20]. It must be noted, however, that the current literature is limited to case series and anecdotal reports; thus, there are no specific guidelines regarding the implementation of IVC filters. The risks and benefits must be evaluated in each case. In addition, cases of non-retrievability of "retrievable" filters have been noted, and hence, the best indication for the use of caval filters may be contraindication to anticoagulation in a patient with PE with significant residual DVT.

Chronic Therapy

The aim of chronic anticoagulant therapy (subacute phase) is to prevent recurrent events and embolization from residual thrombus. Either LMWH or warfarin is used in children (Table 171.6). The duration of therapy is primarily based on data published in the adult literature and is reviewed in the ACCP guidelines [20]. For the first episode of VTE, children without chronic thrombophilia with a reversible risk factor should receive extended anticoagulation for 3–6 months (typically 3 months); however, a national randomized clinical trial (Kids-DOTT) is underway to determine whether 6 weeks is sufficient in such children [57]. For children with idiopathic VTE, anticoagulation should be continued for 6–12 months and for those with chronic risk factors such as poorly controlled systemic lupus erythematosus or profound immobility, indefinite anticoagulation should be considered. Children with recurrent events require consideration for a

Table 171.6 Subacute anticoagulant therapy for VTE in children

Therapeutic agent	Loading dose	Maintenance dose	Monitoring	Therapeutic goal
LMWH		1.0–1.25 mg/kg q 12 h SQ	Anti-Xa activity	0.5–1.0 U/mL (4 h after dose)
Warfarin	(Achieve therapeutic anticoagulation with heparin prior to initiating)	0.1 mg/kg PO q day	INR	2.0–3.0*

*Optimal INR varies with prosthetic cardiac valves

longer duration of therapy than the initial event, and in some cases, an indefinite length of anticoagulation.

LMWH

Dosing, monitoring, and safety concerns of LMWH are discussed above.

Vitamin K Antagonists

Warfarin, a vitamin K antagonist, produces anticoagulant effects by inhibiting gamma-carboxylation of the vitamin K-dependent factors (II, VII, IX, and X) in addition to anticoagulant proteins C and S. It is recommended that warfarin be initiated after anticoagulation is achieved with an initial agent (i.e., UFH or LMWH) as protein C and S levels will decrease prior to the decrease of the coagulant factors (II, VII, IX, and X) resulting in a period of hypercoagulability and risk of warfarin skin necrosis. The typical starting dose of warfarin is 0.1 mg/kg orally once daily. The dose is then adjusted to obtain an international normalized ratio (INR) in the therapeutic range of 2.0–3.0. After determining the optimal dose, the INR should be obtained weekly until the INR is stable and then with decreasing frequency according to the stability of the level, but usually not less frequently than every 6 weeks.

While warfarin is often the preferred agent secondary to its oral route of administration, it has significant food and drug interactions and may thus not be optimal in all patients. It is especially difficult to obtain frequent lab draws and to maintain therapeutic levels in children less than 2 years of age. Warfarin also requires discontinuation 5–7 days prior to any invasive procedure; however, a transition with LMWH ("LMWH bridge") can be used to minimize time without anticoagulation in the preoperative period. Vitamin K and/or FFP is used as anticoagulant reversal agent for children receiving warfarin therapy.

VTE Thromboprophylaxis

As critically ill children are at significant risk for developing VTE, consideration must be given for potential prophylactic interventions. Thromboprophylaxis in the adult population has been well recognized for at-risk adults; however, no consensus has been reached in the pediatric literature regarding optimal thromboprophylaxis. While risk factors of developing in-hospital VTE in children have been described, no definitive randomized controlled trials have been completed in children to determine if thromboprophylaxis would offer more benefit than harm in children. Identified risk factors for in-hospital VTE include severe respiratory, oncologic, or infectious diseases requiring an ICU stay with or without mechanical ventilation [58, 59]. In a single-site, case-control study, mechanical ventilation, systemic infection, and hospitalization >5 days were identified as independent risk factors for the development of in-hospital VTE [59]. In a risk factor model, the combination of these factors appears to confer a significant risk of VTE that may warrant VTE prophylaxis. Further investigation of the safety and efficacy of VTE prophylaxis in high-risk pediatric patients must be undertaken to decrease the overall incidence of in-hospital VTE.

Despite current ACCP guidelines that do not support prophylaxis of CVCs in children, thromboprophylaxis is frequently employed in the pediatric ICU [20, 60]. In a survey of pediatric ICUs in the USA (including medical, surgical, and cardiac units), 45 % of respondents reported using UFH for thromboprophylaxis in children with a CVC at a dose ranging from 5 to 10 IU/kg/h [60]. While there is insufficient evidence to support this practice, clinicians deem the benefits of VTE prevention outweigh the risk of adverse events secondary to heparin. Further research is warranted to determine if this practice confers benefit in critically ill children.

In the neonatal population, the ACCP guidelines do support the use of continuous UFH at 0.5 IU/kg/h to maintain patency of a CVC [20]. In a Cochrane review of three randomized controlled clinical trials comparing the use of heparin to placebo or no intervention, the use of UFH prophylaxis reduced the risk of catheter occlusion; however, there was no statistically significant difference in the risk of thrombosis or catheter-related sepsis [61]. In the CICU, the use of UFH at a dose of 10 IU/kg/h for infants <10 kg is commonly employed to mitigate the risk of VTE. While there are anecdotal reports that the majority of children do not suffer adverse events related to UFH, there are limited data to support or refute this dosing. Clinical studies are warranted to determine which patient population in the CICU warrants more aggressive thromboprophylaxis.

Currently, the decision to offer thromboprophylaxis in the ICU is on an individual basis and led by a referring consultant with broad variability existing across age groups [62]. Despite an absence of clear recommendations for the use of thromboprophylaxis, at minimum ICUs should consider general preventative measures such as maintaining hydration, early mobilization after surgery, and removal of any CVC as soon as practical. In addition, mechanical prophylaxis, in the form of sequential compression devices (SCDs), may be employed in older children and adolescents.

Cardiac Thromboprophylaxis

Children with cardiac abnormalities have a unique set of risk factors that increase the likelihood of developing VTE with an estimated incidence of 3.8 % in children admitted to the ICU with cardiac disease and as high as 6.2 % in children less than 6 months of age with cardiac disease [12]. Not only are children at risk for developing intracardiac thrombi, but they are also at risk for development of CVC-related thrombosis in addition to embolic events including cardioembolic stroke [12]. Prevention strategies rely on the recognition of the patients at greatest risk and implementing the appropriate thromboprophylaxis strategy (Table 171.7).

Children with congenital heart disease requiring palliative or corrective heart surgery are at significant risk for thrombotic events, specifically following the placement of a modified Blalock-Taussig shunt (MBTS). Systemic-pulmonary shunts are a palliative surgical option for many children with cyanotic congenital heart disease. The MBTS is one of the most common forms of palliation and is associated with an incidence of thrombosis as high as 22.7 % following surgery in neonates [63]. Not only does a thrombotic event require urgent intervention, but it is considered an important cause of death and is frequently fatal in single-ventricle physiology secondary to the restriction of blood flow [64]. Although Fenton et al. report a lower incidence of thrombosis following a systemic-pulmonary shunt in children who survived to initial hospital discharge, the associated mortality rate was 33 % [65]. Wells et al. demonstrated that at a median of 8.1 months following shunt placement, more than 21 % had greater than 50 % stenosis of the shunt [66]. An increased risk of thrombosis appears to be related to implantation of foreign material and the size of the shunt, with smaller diameters having the greatest risk [66]. The shunt may also be a conduit for activation of the coagulation system [65]. Unfortunately, there have been no randomized clinical trials demonstrating the strategy that provides optimal prophylactic

Table 171.7 Thromboprophylaxis: palliative cardiac surgery[a]

Intervention	Intraoperative/ postoperative	Primary prophylaxis
MBTS	UFH	Aspirin (1–5 mg/kg/day) or no therapy
Norwood (S1P)	UFH	Aspirin (1–5 mg/kg/day) or no therapy
Glenn	UFH	Aspirin (1–5 mg/kg/day), VKA, or no therapy
Fontan	UFH	Aspirin (1–5 mg/kg/day) or VKA

[a]Recommendations in accordance with ACCP 2012 guidelines

anticoagulation. It does appear that the rates of shunt failure are increased without intraoperative heparin [67]. The benefit of providing antiplatelet therapy with aspirin or clopidogrel following surgery is still unclear, but typically prescribed to offer any theoretical benefit with limited side effects from the medication itself. Current ACCP guidelines recommend intraoperative unfractionated heparin followed by aspirin (1–5 mg/kg/day) or no further antithrombotic therapy [20].

The Norwood procedure, or Stage 1 Palliation (S1P) for hypoplastic left heart syndrome, is undertaken to provide definitive pulmonary and systemic blood supply. An aspect of the S1P is that pulmonary blood supply is ensured either through a modified Blalock-Taussig shunt described previously, or via a right ventricular to pulmonary artery conduit, also known as a Sano shunt. Postoperative mortality has fallen in the last 10 years for infants undergoing these procedures; nevertheless, thrombotic events still are a concern and are associated with increased morbidity [20, 68]. It is important to note that there are no current studies evaluating the use of postoperative interventions or medical therapy designed to mediate coagulation or platelet aggregation following S1P. Nevertheless, these infants are typically treated with heparin infusions postoperatively followed by aspirin prophylaxis, according to the guidelines for the MBTS [20]. It is also important to note the paucity of data on perioperative management of heparin infusions in terms of achieving, or not, therapeutic anticoagulation.

The second stage palliation for infants who have undergone the Norwood procedure is the Glenn procedure. In certain circumstances, this intervention may in fact be the first surgical procedure that children with hypoplastic right heart variants undergo. The Glenn shunt provides pulmonary blood supply via a connection between the superior vena cava and (usually) the right pulmonary artery. It ensures bidirectional blood flow to the lungs. As this is a connection between exclusively venous structures, and there is an absolute dependence on maintaining unobstructed and unimpeded passive pulmonary blood flow through the surgical anastomosis, the standard of practice is to maintain some kind of systemic anticoagulation therapy until changing over to antiplatelet therapy. Although there are no studies to determine optimal postoperative practices, the ACCP guidelines recommend postoperative UFH followed by either no anticoagulation, antiplatelet therapy, or anticoagulation with VKA [20].

The Fontan procedure is often the final (and often the third) palliative surgery for many congenital univentricular heart lesions. As with the first two palliations, the Fontan procedure carries significant morbidity and mortality attributed to thromboembolism. The Fontan procedure ensures venous blood from below the diaphragm (usually all IVC drained venous blood) returns to the pulmonary circulation via some venous connection. Often there is a fenestration placed in the Fontan circuit, in fact in the conduit, in order to facilitate shunting in times of high pulmonary artery pressure, or elevated end-diastolic ventricular pressure. This fenestration may be prone to platelet aggregation and premature closure. In addition to fenestration closure, thrombotic events, including intracardiac thrombosis, intravascular thrombosis, cerebrovascular thrombosis, and other embolic phenomena, may occur in the early postoperative period as well several years following the procedure [69–72]. Thromboembolism after a Fontan may be attributed to low flow states, stasis in venous pathways, right-to-left shunts, blind cul-de-sacs, prosthetic material, atrial arrhythmias, and hypercoagulable states [73]. An additional hypercoagulable state in these children, which

consists of albumin and coagulation protein wasting, is protein-losing enteropathy.

Neither the true incidence of VTE following the Fontan, nor the optimal thromboprophylaxis strategies are known [21]. A systematic review of studies evaluating VTE following an extracardiac conduit Fontan reported a rate of 5.2 % with a mean follow-up ranging from 2 to 144 months while a recent multicenter, multinational prospective RCT reported a cumulative thrombosis rate of 23 % in the first 2 years following a Fontan [71, 74]. The significant difference in reported rates is likely related to varying surgical approaches, differences in patient attributes, and varying surveillance.

The optimal strategy for thromboprophylaxis following a Fontan procedure is still unclear [69, 72]. In an international, multicenter RCT, there was no significant difference between the use of ASA or warfarin as primary prophylaxis; however, despite the use of primary prophylaxis, thrombosis occurred in 21 % of children who were given aspirin prophylaxis and in 24 % of children who received warfarin [71]. In a secondary analysis of this RCT, it was noted that children who received ASA or those who received warfarin, and had a consistently therapeutic international normalized ratio (INR) level, had a decreased risk of thrombosis compared to children receiving sub-therapeutic warfarin [75]. However, despite the use of either agent, the incidence of thrombosis is still significant with considerable mortality. Thus, it is imperative that additional prophylaxis regimens be evaluated to improve the morbidity and mortality following a Fontan procedure [21]. In the absence of any further studies, the current guidelines recommend either therapeutic UFH followed by anticoagulation with vitamin K antagonists or aspirin (1–5 mg/kg/day) [20].

In addition to the risk of VTE related to the cardiac surgery/shunt, it appears that children with single-ventricle physiology may also have inherent coagulopathies that are present prior to any palliative repair, which may also contribute to the overall risk of thrombosis. In a prospective study comparing children with single-ventricle anatomy to age-matched controls, Odegard and colleagues noted decreased concentrations of both procoagulant and anticoagulant factors (factors II, V, VII, IX, X; plasminogen; fibrinogen; antithrombin; and protein C) in the children with single-ventricle physiology just prior to undergoing a bidirectional Glenn procedure [76]. Furthermore, Cholette et al. noted similar abnormalities in a prospective study of children with single-ventricle physiology just prior to undergoing an initial palliative cardiac surgery. In this study, subjects had decreased concentrations of factors II, V, VII, VIII, X; antithrombin; fibrinogen; and protein C when compared with age-appropriate reference ranges [68]. It is unknown if these coagulation defects are secondary to the abnormal cardiovascular physiology or if there is a genetic predisposition for these coagulation defects associated with the cardiac anomaly. As both of these studies recognize abnormalities in both the procoagulant proteins as well as the anticoagulant factors, it is unclear if the net effect results in a balanced hemostatic state or if there is a trend toward a hypercoagulable state. Further studies utilizing global assays to determine overall coagulative and fibrinolytic capacities would be beneficial.

Additional cardiac conditions that also warrant consideration for thromboembolic prophylaxis include the presence of endovascular stents, cardiomyopathy, the presence of bioprosthetic or mechanical valves, or following cardiac catheterization (Table 171.8). Endovascular stents are often placed in the management of congenital heart lesions; however, no studies have evaluated the role of anticoagulation or antiplatelet therapy in minimizing the risk of stent occlusion. Current ACCP guidelines recommend the administration of unfractionated heparin perioperatively [20].

While there have also been no studies evaluating the use of anticoagulation in children with cardiomyopathy, the incidence of VTE is substantial and may result in complications in children awaiting heart transplant. In a cross-sectional study, 31 % of children with cardiomyopathy had PE confirmed either by V/Q scan or angiography [77]. In addition, these children are also at significant risk for cerebrovascular events [78]. Up to 43 % of children with dilated cardiomyopathy had clinically significant emboli and

Table 171.8 Thromboprophylaxis: interventional cardiology/cardiac disease[a]

Intervention/disease	Prophylaxis
Endovascular stent	UFH perioperatively
Cardiomyopathy/left ventricular dysfunction	VKA no later than activation on a cardiac transplant list
Bioprosthetic valve	Aspirin (if no further hypercoagulable risk factors)
Mechanical valve	VKA (no optimal pediatric guidelines)
Cardiac catheterization	UFH 100 U/kg bolus followed by 20 U/kg/h
Central line	Neonates: 0.5 IU/kg/h to maintain catheter patency
	Children: prophylaxis not recommended

[a]Recommendations in accordance with 2012 guidelines

43 % had mural thrombi [79]. These thrombotic events are likely related to blood stasis and poorly functioning ventricles with low cardiac output, left ventricular dysfunction, and dilatation [77, 80]. Current recommendations suggest children with cardiomyopathy be prescribed VKAs no later than activation on a cardiac transplant list [20].

Although mechanical prosthetic heart valves confer a significant risk of VTE, appropriate anticoagulation drastically improves this risk [81]. In a retrospective, single-site study of 54 children who received warfarin anticoagulation following mitral valve replacement, only one patient developed a thromboembolism during the median follow-up period of 9.2 years [81]. There are, however, no RCT in pediatrics to inform the guidelines for optimal prophylaxis. Adult guidelines recommend warfarin anticoagulation with variances based on specific patient scenarios [82]. Although bioprosthetic valves have a lesser risk of thrombotic events, prophylaxis is still warranted. Recommendations, including anticoagulation and/or antiplatelet therapy, vary depending on valve location and presence of any additional risk factors for hypercoaguability [82].

While thromboprophylaxis following cardiac catheterization has drastically reduced the incidence of both arterial and venous thrombosis, there is still considerable controversy in the optimal dosing of anticoagulation. Without thromboprophylaxis, the incidence of arterial thrombosis is as high as 40 %; yet, with UFH prophylaxis, the incidence ranges from 3 % to 8 % [83, 84]. Current guidelines recommend that UFH be given as a 100 U/kg bolus dose following catheterization with subsequent doses for prolonged procedures [20]. However, a recent RCT comparing high-dose UFH (100 U/kg bolus followed by 20 U/kg/h continuous infusion) vs. low-dose UFH (50U/kg bolus followed by 50 U/kg bolus every 2 h during the procedure) suggests that low-dose UFH may be sufficient in the prevention of thrombotic events [84]. In this study, there were no differences in the incidence of thrombotic or bleeding events between the high- and low-dose UFH treatment arms; however, the study was underpowered. The aforementioned literature may inform general patient dosing; however, further consideration of appropriate dosing should be given to patients with additional thrombotic or bleeding risks.

Conclusion

Critically ill children, particularly those with congenital or acquired heart disease, are at increasing risk for developing VTE as a result of their underlying medical disorders and anatomy, multiple and repeated surgical interventions such as cardiac catheterization and intervention, central venous line placement, and cardiac surgery. Other comorbid states and specific risk factors include merely the presence of a central venous catheter, immobility or a postsurgical static state, malignancy, infection or underlying inflammatory conditions, a traumatic injury, and acquired or inherited abnormalities of the coagulation pathway. Associated conditions in the cardiac patient include cyanotic congenital heart disease, presence of a palliative shunt or cavopulmonary anastomosis, endovascular stents, cardiomyopathy or left ventricular dysfunction, valvular dysfunction, the presence of prosthetic heart valves, or following cardiac transplantation. There is some evidence that single-ventricle patients demonstrate an altered, and procoagulant coagulation profile as well. Clinicians in the ICU must

recognize presenting signs/symptoms of VTE in order to facilitate early diagnosis and initiation of appropriate therapy. Heparinization is an appropriate and common acute therapy in the pediatric ICU setting, although thrombolytic approaches may be warranted acutely in select circumstances. Heparin-induced thrombocytopenia is an important complication of prior heparin exposure in pediatric populations with cardiac intensive care patients, for which direct thrombin inhibitors such as argatroban are given. General preventive strategies against the occurrence of VTE in the critically ill pediatric population include the removal of central lines when possible, early mobilization, and use of SCDs in older children. In addition, thromboprophylaxis is reasonable in children with severe cardiomyopathy, following the implantation of stents or prosthetic valves, and perioprocedurally with cardiac catheterization. Whether critically ill children in the ICU who have multiple thrombotic risk factors may safely benefit from prophylactic anticoagulation will require devoted future study.

Acute Kidney Injury

172

Scott Aydin, Samriti Dogra, and Marcela Del Rio

Abstract

Acute kidney injury is a well-known risk factor for increased morbidity and mortality in hospitalized adults and children. Understanding the interaction between the heart and the kidneys is paramount in order to successfully manage the pediatric patient in the perioperative period. Acute kidney injury can be due to a broad range of causes, and the differential diagnosis must be considered in a systemic fashion to avoid missing multiple factors that may be contributing to the condition. Traditionally, acute kidney injury is divided into prerenal, renal, and postrenal causes. Prerenal acute kidney injury is secondary to any disease process that results in intravascular volume depletion. If the injury is severe, prerenal acute kidney injury can evolve into acute tubular necrosis. Although renal ischemia is the most common etiology for acute kidney injury, patients with congenital heart disease often have multiple causes for renal injury. These include sepsis, altered autoregulation, use of cardiopulmonary bypass, and various patient-specific risk factors. In addition, reperfusion injury may play a prominent role in the development of acute kidney injury in this patient population. In the postoperative period, the degree of cardiac performance is critical for the preservation of kidney function after cardiac surgery. Ultimately, invasive therapies such as renal placement therapy

Introduction

Acute kidney injury (AKI) is a well-known risk factor for increased morbidity and mortality in hospitalized adults and children. In adults who undergo cardiac surgery, postoperative AKI is associated with long-term mortality, independent of other complications or comorbidities. Even a modest postoperative increase in the serum creatinine level may predict a poor postoperative outcome. However, this relationship may be less evident in pediatrics likely due to the heterogeneous nature of congenital heart disease. Thus, understanding the fundamentals of renal physiology and interaction between the heart and kidneys is crucial when managing a critically ill child.

Pathophysiology

Renal Blood Flow

Physiology of the neonatal kidney is important in understanding acute kidney injury in congenital heart disease. Blood flow to the kidneys is determined by cardiac output and the ratio of renal to systemic vascular resistance. After birth, an increase in cardiac output and a decrease in renal vascular resistance increase renal blood flow. Renal vascular resistance is controlled by an intricate balance between vasoconstricting and vasodilating agents. The glomerular filtration rate (GFR), which is the sum of the filtration rates of the volume of fluid through all of the functioning nephrons, of a full-term infant is 10 % of the adult level [1–3]. However, within 2 weeks the GFR doubles and increases to the adult level by 2 years of age [4, 5]. A variety of mechanisms are important to maintain GFR. The tubuloglomerular feedback system adjusts GFR based on the rate of distal tubular flow and the chloride concentration of the tubular fluid sensed by specialized cells in the macula densa. A large chloride concentration sensed by the cells of the macula densa is interpreted as an elevated GFR, while a low chloride concentration is interpreted as a low GFR. This is transmitted primarily to the afferent arteriole and glomerular capillaries to adjust the rate of filtration. The myogenic reflex regulates GFR based on perfusion pressure to the kidney. Decreased perfusion pressure to the kidney will dilate the afferent arteriole and vasoconstrict the efferent arteriole to maintain GFR.

Diminished renal perfusion as a result of impaired cardiac output is a common cause of renal dysfunction. An individual's intravascular volume is regulated by the kidneys ability to augment salt and water retention and excretion. Normally, the heart provides approximately 25 % of its cardiac output to the kidney. However, in the context of cardiac dysfunction, this can be greatly reduced and subsequently lead to undesirable effects on a patient's homeostasis. The kidneys generally are the primary organ affected when cardiac output is compromised. In addition, renal perfusion may be impaired despite normal or increased intravascular volumes. GFR is maintained by an increase in the filtration fraction in the context of diminished cardiac output and renal blood flow. This compensatory mechanism

of the afferent and efferent arterioles is adequate initially, but as cardiac function continues to deteriorate, it no longer can maintain an acceptable GFR. Subsequently, GFR is decreased secondary to diminished renal perfusion which leads to accumulation of water and solutes via multiple sodium-retaining systems. The kidneys exhibit these water- and salt-retaining mechanisms to return cardiac output and arterial pressure to normal. Depending on the nature and degree of the diminished cardiac output, this may lead to a vicious cycle of worsening edema and congestion. However, a drastic reduction in renal perfusion may overwhelm the kidney's ability to autoregulate and result in a dramatic decrease in the GFR. When speaking about less drastic renal perfusion compromise, GFR may be maintained via various mechanisms that act on the afferent (vasodilatory prostaglandins) and efferent (angiotensin II) arteriolar systems, which will be discussed further. However, any aggravation of this system by exogenous factors (ACE inhibitors and/or NSAIDS) may produce a dramatic fall in the GFR.

Vasoconstriction

Sympathetic activation causes arterial vasoconstriction resulting in increased afterload which is mediated by adrenergic α-receptors. Venoconstriction is also activated leading to increased preload. The renin-angiotensin-aldosterone system (RAAS) is activated via this pathway by secretion of norepinephrine in the peripheral vasculature. This leads to intrarenal vasoconstriction and subsequently diminished renal blood flow and increased sodium retention [6–8]. Renin secretion is enhanced by stimulation of baroreceptors of the renal vessels secondary to diminished renal blood flow. Renin is produced in the juxtaglomerular cells of the afferent renal arteriole. The release of renin promotes production of angiotensin II. Renal-derived renin cleaves hepatic-derived angiotensinogen to form angiotensin I, which is converted by angiotensin-converting enzyme in the lungs to angiotensin II. Angiotensin II is a potent vasoconstrictor of the efferent and afferent renal arterioles. The effects of angiotensin II are mainly mediated through plasma membrane receptors AT1 and AT2. The effects of angiotensin II is greatest on the efferent arteriole which subsequently leads to an increase in the filtration fraction resulting in water and sodium retention [9–11] (Fig. 172.1). With the release of angiotensin II, the production and secretion of aldosterone is stimulated from the zona glomerulosa of the adrenal gland. The sites of action of aldosterone are mineralocorticoid receptors located in the kidney, heart, brain, colon, and vessel walls. Aldosterone stimulates sodium retention via activation of mineralocorticoid receptors which eventually leads to retention of water [12].

Both AT1 and AT2 receptor expression increase dramatically after birth [13]. These all contribute to vasoconstriction of the neonatal kidney. Likewise, there is increased production of angiotensinogen, renin, and angiotensin-converting enzyme in the postnatal kidney. These effects are counteracted by the postnatal increase in prostaglandins, nitric oxide, and kinins which promote vasodilation and contribute to the maturational increase in renal blood flow [14]. In the setting of compromised cardiac function, the normal homeostasis and natriuresis observed is no longer present, and continued sodium retention persists with subsequent accumulation of extracellular water.

Regulatory mechanisms to maintain GFR may not be fully mature in the young kidney. This may predispose infants to acute kidney injury. In adult rats, decreasing the renal perfusion pressure by 30 % from baseline caused only a mild decline in GFR. However, in young rats, GFR decreased by 80 % [15]. Micropuncture experiments revealed that the young rats had decreased glomerular capillary pressure due to incompetence of the angiotensin II-mediated vasoconstriction of the efferent vessels. The young rats may not be able to activate angiotensin II, and the immature efferent arteriole may not respond to angiotensin II the same way as in adult rats. This is not due to receptor and angiotensin availability but instead to immature post-receptor processes [15].

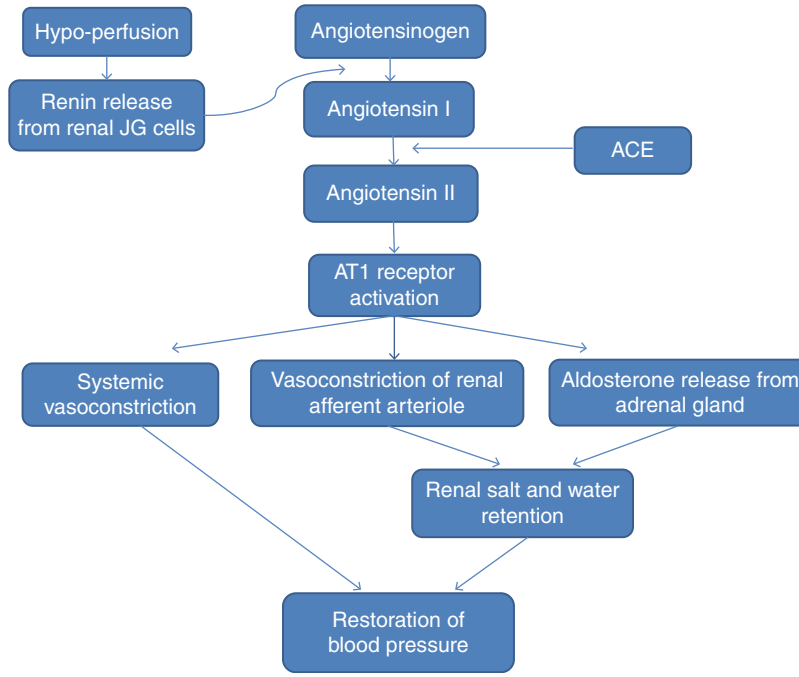

Fig. 172.1 Pathophysiology of the renin-angiotensin-aldosterone system (RAAS)

It is well known that infants with poor cardiac function secondary to congenital heart disease are at risk for acute kidney injury. Mechanoreceptors in the aortic arch, left ventricle, and renal afferent arterioles sense systemic arterial pressure and regulate body fluid volume. Arterial underfilling activates the sympathetic nervous system to increase myocardial contractility, heart rate, and vasoconstriction of the peripheral vasculature and renal arteries. Stimulation of the RAAS also contributes to systemic vasoconstriction as well as vasoconstriction of the efferent and afferent arterioles mediated by angiotensin II. Alpha adrenergic stimulation and angiotensin II increase sodium transport in the proximal tubule and deliver less sodium to the distal tubule. This leads to persistent aldosterone-mediated sodium retention in the collecting duct. Arginine vasopressin (AVP) is secreted from the posterior pituitary in response to arterial underfilling. Stimulation of the V2 receptors initiates a cascade of intracellular signaling events by means of the adenylyl cyclase pathway. This leads to translocation of aquaporin-2 water channels from cytoplasmic vesicles to the apical surface of the collecting duct and results in increased water reabsorption. These adaptive mechanisms can become maladaptive with persistent activation, leading to fluid overload, worsening heart failure, and decreased renal perfusion [16, 17]. RAAS activation can have deleterious effects on the heart. Aldosterone increases myocardial fibrosis, collagen deposition, inflammation, and remodeling of the heart and blood vessels [18]. Angiotensin II via its interaction with the AT1 receptor additionally contributes to left ventricular hypertrophy as well as remodeling [19].

Vasodilation

Atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) plasma levels are known to be elevated in patients with heart failure [20]. Atrial natriuretic peptide (ANP) is stored in the perinuclear granulocytes in cardiac atria and released in response to atrial stretch mechanisms. ANP increases GFR by dilatation of the afferent arteriole and constriction of efferent arteriole.

ANP promotes natriuresis by inhibiting tubular sodium reabsorption. BNP is produced mostly in the ventricular myocardium and has similar effects to ANP. ANP and BNP counteract the effects of the RAAS and sympathetic activation seen in acute cardiac dysfunction. Studies have shown BNP secretion to increase in response to left ventricular dysfunction [21, 22]. Afferent arteriolar vasodilation is promoted by ANP as well as efferent arteriolar vasoconstriction, these effects act to increase glomerular capillary pressure and GFR [23]. In addition, ANP acts to counteract the effects of angiotensin II on the proximal tubule in regard to sodium and water retention [24]. Renin and aldosterone secretion is also inhibited by the presence of ANP [25]. BNP's effect is similar to those of ANP.

Prostaglandins are potent renal vasodilators produced by arachidonic acid in many cells throughout the body [26]. Nitric oxide is an endothelium-derived gas synthesized from the amino acid L-arginine by nitric oxide synthase. Nitric oxide diffuses across the endothelial cellular membrane and enters vascular smooth muscle cells and induces vasodilation through second messenger pathways guanylate cyclase and cGMP.

Acute Kidney Injury

The term acute kidney injury was introduced in 2005 and has replaced the term "acute renal failure." Acute kidney injury is defined as a sudden loss of renal function. This is usually reversible. There are multiple classification systems that standardize the definition of acute kidney injury in adults. The RIFLE (risk, injury, failure, loss, and end-stage) criterion was developed by the Acute Dialysis Quality Initiative (ADQI) workgroup in 2004 to classify acute kidney injury in critically ill adult patients [27] (Table 172.1). It is based on absolute values and changes in serum creatinine from baseline, estimated glomerular filtration rates, and/or decrease in urine output. There is a reasonable correlation between stage of acute kidney injury based on RIFLE criteria and mortality. The criteria have been validated as predictive of mortality in studies including different adult patient populations, including cardiac surgical patients [28]. A modified pediatric version of this classification system, pRIFLE, has also been developed and validated [29]. The pRIFLE criterion was proposed in 2007 to classify acute kidney injury in pediatrics. It uses the same stages of acute kidney injury as the RIFLE criteria; patients are classified based on estimated creatinine clearance and/or urine output (Table 172.2), whichever is worse. pRIFLE criteria has been validated by various single-center studies and found to be predictive of outcomes, specifically mortality [30].

The Acute Kidney Injury Network (AKIN) has established a separate system that classifies AKI into stages I–III on the basis of small (>/0.3 mg/dL) increases in serum creatinine levels or oliguria in 48 h [31] (Table 172.3). Comparison of the AKIN and RIFLE criteria for efficacy in predicting morbidity and mortality in critically ill patients has not found any statistically significant differences in outcome [32].

Table 172.1 Acute Dialysis Quality Initiative (ADQI) workgroup RIFLE criteria

AKI stage	Serum creatinine	GFR	Urine output
R (risk)	Absolute increase ≥0.3 mg/dL or 1.5 × baseline value	Decrease by ≥25 %	<0.5 mL/kg/h for >6 h
I (injury)	2 × baseline value	Decrease by ≥50 %	<0.5 mL/kg/h for >12 h
F (failure)	3 × baseline value or value ≥4 mg/dL with absolute increase ≥0.5 mg/dL	Decrease by ≥75 %	<0.3 mL/kg/h for >24 h or anuric for 12 h
L (loss)	Persistent AKI = complete loss of renal function for >4 weeks		
E (ESRD)	End-stage renal disease defined as persistent failure >3 months		

Adapted from [27]
AKI acute kidney injury, *GFR* glomerular filtration rate

Table 172.2 Pediatric RIFLE (pRIFLE) criteria

AKI stage	Estimated creatinine clearance (eCcl)	Urine output
R (risk)	Decrease by ≥25 %	<0.5 ml/kg/h for >8 h
I (injury)	Decrease by ≥50 %	<0.5 ml/kg/h for >16 h
F (failure)	Decrease by ≥75 % or eCcl < 35 ml/min/1.73 m^2	<0.3 ml/kg/h for >24 h or anuric for 12 h
L (loss)	Persistent AKI = complete loss of renal function for >4 weeks	
E (ESRD)	End stage renal disease defined as persistent failure >3 months	

Adapted from [28]
AKI acute kidney injury

Table 172.3 Acute kidney injury network AKI classification

AKI stage	Serum creatinine	Urine output
1	Absolute increase ≥0.3 mg/dL or 1.5x baseline value	<0.5 ml/kg/h for >6 h
2	2x baseline	<0.5 ml/kg/h for >12 h
3	≥4 mg/dl (with acute rise of ≥0.5 mg/dl) or 3x baseline	<0.3 ml/kg/h for >24 h or anuric for 12 h

Patients receiving RRT classified as stage 3 irrespective of stage prior to initiating RRT

AKI acute kidney injury

Epidemiology

Renal impairment remains among the most serious complication of post-cardiac surgery. In adult postoperative cardiac patients, it has been demonstrated that AKI has an incidence of 7.2–48 % with a mortality of 14–80 % [33–36] depending on the definition used and the population studied. It has been demonstrated that AKI is the strongest independent risk factor of mortality [37] following adult cardiac surgery with an odds ratio of 27 [38].

Several studies in adults have demonstrated certain risk factors associated with AKI, such as length of cardiopulmonary bypass (CPB), cross-clamp time, off-pump versus on-pump procedures, congestive heart failure, and elevated preoperative serum creatinine [39–41]. In the pediatric population undergoing congenital heart surgery, there have been several reports demonstrating AKI in the postoperative period with an incidence of 3–61 % and a mortality of 20–79 % [42–51]. There have been various studies that evaluated AKI in pediatric patients after congenital heart surgery. Li et al. [50] performed a prospective study enrolling pediatric patients undergoing cardiac surgery with cardiopulmonary bypass. They utilized the AKIN staging system [31] to define AKI. Three hundred and eleven children were enrolled in the study, and there was a 42 % incidence of AKI in children who had undergone heart surgery. Fifty-three percent developed AKI within the first 24 h, and 98 % developed AKI within 48 h. Risk factors associated with AKI were lower mean age and longer cardiopulmonary bypass time. They also found that AKI was independently associated with longer length of hospital stay and greater odds of requiring mechanical ventilation for >2 days. Similarly, Zapitelli and colleagues [52] examined children undergoing open chest surgery to identify AKI based on pRIFLE criteria. Within 4 days of surgery, the incidence of AKI was 36 %. In addition, AKI was independently associated with longer hospital stay and duration of mechanical ventilation. Risk factors for AKI include longer cardiopulmonary bypass time. Finally, Aydin and colleagues [51] examined 458 children, using the RIFLE criteria, undergoing surgery for congenital heart disease including neonates. Using the RIFLE criteria, the authors demonstrated an overall AKI incidence of 51 % in these children. The vast majority recovered within 48-h. Younger age, higher RACHS-1 category, and longer cardiopulmonary bypass (CPB) time were associated with development of AKI.

The incidence of AKI in patients 1 month of age or younger was 60.9 %, of which more than half required >72 h to recover. In patients 1 month of age or younger, use of CPB, lower preoperative serum creatinine, and higher preoperative blood urea nitrogen were associated with AKI. AKI was the only factor associated with longer length ICU and hospital stay.

There have also been studies that have linked worsening renal function with acute decompensated heart failure. Price and colleagues [53] looked at the incidence of worsening renal function, which was defined as an increase in serum creatinine >0.3 mg/dL at any time during their hospitalization. The incidence of worsening renal function occurred in 48 % of patient hospitalizations for acute decompensated heart failure and was associated with in-hospital death or need for mechanical circulatory support.

Etiology

The etiology of acute kidney injury can be divided into prerenal, intrinsic, and postrenal causes. Prerenal acute kidney injury is secondary to any disease process that results in intravascular volume depletion. Dehydration due to gastrointestinal or renal losses, third space losses in nephrotic syndrome and sepsis result in true volume contraction. The decreased effective blood volume that occurs in congestive heart failure also decreases renal perfusion pressure and results in prerenal acute kidney injury. The kidney responds with compensatory mechanisms to restore renal perfusion pressure. Decreased vascular tone of the afferent arteriole maintains renal blood flow. Prostaglandin production in the kidney also mediates vasodilation of the renal microvasculature as mentioned earlier. Prerenal injury is often reversible once blood volume and hemodynamic conditions have been restored. Urinalysis, urine osmolality, urine sodium concentration, and the fractional excretion of sodium help to distinguish prerenal from intrinsic renal acute kidney injury. With prerenal AKI, the renal tubules respond to decreased renal perfusion pressure by avid sodium and water retention. This results in urine osmolality greater than 400–500 mOsm/L, urine sodium less than 10–20 meq/L, and fractional excretion of sodium less than 1 %. These values will differ in newborns and premature infants who have relatively immature renal tubules compared to older infants and children [1–3].

If the injury is severe, prerenal acute kidney injury can evolve into acute tubular necrosis. With persistent hypoperfusion, vasoconstriction of the efferent arteriole helps to maintain adequate glomerular perfusion pressure. Persistent renal vasoconstriction becomes unopposed as vascular relaxation mechanisms become ineffective. This can decrease renal blood flow, glomerular filtration, and urine output resulting in oliguria. Although renal ischemia is the most common etiology for AKI in children, patients with congenital heart disease have multiple factors that attribute to development of AKI sepsis, and nephrotoxic agents are often contributory factors in this population.

Renal tubules are dependent on polarity for transport. The sodium gradient along the apical membrane is maintained by Na/K-ATPase-dependent transport channels on the basolateral membrane, providing this polarity. Ischemic injury causes blebbing, loss, and internalization of brush border membranes. As a result, basolateral Na/K-ATPase migrate to apical membranes leading to loss of polarity and reduction of transepithelial sodium reabsorption [54]. This corresponds with increased fractional excretion of sodium (FENa) consistent with intrinsic renal disease. As ischemia ensues, medullary vascular congestion, tubular injury, and death of tubular cells cause cellular debris to slough and enter the tubular lumen. These injuries ultimately lead to intratubular obstruction, increases in intraluminal pressure, and backflow of ultrafiltrate into the interstitium [55].

Renal ischemia also impairs normal ATP metabolism and triggers pathways that lead to further epithelial injury and damage. The production of reactive oxygen molecules damages cellular components and the extracellular matrix. ATP depletion reduces the activity of calcium

ATPase which normally functions to keep intracellular calcium concentrations low. Increased intracellular calcium concentration increases uptake to mitochondria and may activate mechanisms that contribute to lethal cell injury [56]. ATP depletion also activates endogenous phospholipases that causes breakdown of membrane phospholipids into products that disrupt membranes and tubule cell architecture [57]. Finally, the activation of an inflammatory cascade initiated by endothelial cell dysfunction produces proinflammatory cytokines in ischemic renal injury. Leukocyte infiltration has been identified in injured kidneys, although the significance of this is still unknown [58].

In addition, the preoperative state of the congenital heart disease patient may also affect the incidence and evolution of acute kidney injury [59]. Normal infants have a lower GFR due to a low mean arterial pressure and high renovascular resistance. GFR is maintained by postglomerular, efferent arteriolar vasoconstriction, which is predominantly dependent on a higher angiotensin II activity. Therefore, neonates have a higher sensitivity to the administration of angiotensin-converting enzyme inhibitors compared with adults [60]. In addition, prostaglandin synthase inhibitors (e.g., indomethacin) used to promote the closure of patent ductus arteriosi may blunt the vasodilation of afferent arterioles needed to maintain adequate perfusion of the newborn kidney. Cyanotic patients with resultant hypoxemia have reduced renal blood flow and GFR, which may induce hypotension, hypervolemia, and activation of the RAAS [60]. Hypothermia may also be associated with renal vasoconstriction and a decrease in GFR. Preoperative patients undergoing positive pressure ventilation experience decreases in venous return and cardiac output. Subsequently, there is an increase in renal sympathetic nervous activity and serum vasopressin levels [60].

All of these mechanisms contribute to cell death, which can result in necrosis and/or apoptosis of cells and even patient death. Patchy tubular necrosis can be seen on biopsy. Urinalysis will likely demonstrate casts and renal tubular epithelial cells. Urine sodium greater than 40 meq/L and FENa greater than 2–3 % reflect an impaired ability to conserve salt and water. Recovery of renal function after acute tubular necrosis is variable.

Cardiopulmonary Bypass

The etiology of acute kidney injury is multifactorial and related to the presence of diminished renal perfusion, ischemia, and altered autoregulation. Some of these factors that play into the development of kidney injury include the use of cardiopulmonary bypass, the associated systemic inflammatory response, and various patient-specific factors. Fluid accumulation after CPB is frequently encountered during the postoperative period, which typically is more prominent in neonates [61, 62]. The associated fluid overload can adversely affect other organ systems as well as exacerbate myocardial dysfunction and impaired pulmonary compliance. Patients with congenital heart disease undergoing surgery with CPB also demonstrate large volume and blood component shifts which may also have a deleterious effect on renal function [63]. The subsequent hemodilution encountered after initiation of CPB, as a result of the large circuit priming volumes, may be associated with vital organ dysfunction and tissue edema [64]. Furthermore, non-pulsatile flow during CPB has been implicated in the genesis of acute kidney injury secondary to renal vasoconstriction and ischemic renal injury [65]. Additionally, since blood components are exposed to the foreign surface of the CPB circuit, multiple studies have investigated this relationship and the subsequent inflammatory response that is triggered [65–67]. Studies have shown that renal function may be better preserved in preserved in patients undergoing cardiac surgery without CPB as compared to those requiring CPB. Non-CPB cardiac procedures also elicit a milder systemic inflammatory response [68]. Of concern is that these relationships may be more evident in younger patients, especially neonates, due to their small body surface area. In addition, several studies [49–52] have demonstrated an association of

progressively longer CPB times and a greater likelihood of developing AKI postoperatively. The systemic inflammatory response observed postoperatively is responsible for various degrees of cellular and cytotoxic injuries. However, it is important to note that paramount to the initiation of an inflammatory response is the inciting insult, whether it be mechanical or ischemic. Cardiopulmonary bypass is responsible for activation of the complement system and promotion of secretion of various proinflammatory cytokines such as interleukin-8 (IL-8), interleukin-10 (IL-10), and tumor necrosis factor-α (TNF-α) [65–67]. Renal hypoxia induces epithelial cells to produce some of these mediators. Activation of the complement system may also cause direct injury to the renal tubular epithelial cells which in turn promotes secretion of cytokines. In addition, cardiopulmonary bypass has been shown to increase the activation of neutrophils, monocytes, and endothelial cells which have also been implicated in the development of kidney injury. Furthermore, oxygen free radicals are released which may contribute to end-organ damage. A recent animal study [69] using piglet kidneys attempted to look at the effects of CPB on the neonatal kidney. The histological examination of the piglet kidneys exposed to CPB demonstrated significantly higher incidence of tubular dilation, vacuole formation, leukocyte infiltration, and epithelial destruction as compared to the control group. Though this study is purely a histological study and does not speak to the renal function of the kidneys examined, it does demonstrate the global nature of the changes seen in neonatal kidneys.

Further implicated in the development of acute kidney injury is the presence of hypoperfusion which is present in the perioperative period. Reperfusion injury may play a prominent role in the evolution of this injury. Prolonged ischemia followed by reperfusion induces apoptosis and inflammation, which leads to tissue damage and eventually organ dysfunction. This cycle leads to the activation of the angiotensin I-renin system. There is also an inherent risk of micro-embolization of particulate and non-particulate matter during cardiopulmonary bypass [70]. Particulate matter may be related to inadequate anticoagulation during the course of cardiopulmonary bypass or a result of surgical manipulation and instrumentation.

Modified Ultrafiltration

Modified ultrafiltration (MUF) is a process where water and low-molecular-weight substances are removed with the use of hydrostatic forces following completion of CPB. This technique was initially described by Naik and colleagues [71]. MUF has become the preferred method for preventing total body edema and subsequent inflammatory response after CPB. The increase in total body water may lead to vital organ dysfunction and tissue edema. Some of this increase in total body water can be controlled by decreasing the volume of crystalloid solutions administered while on CPB as well as removing the excess fluid during weaning from CPB or shortly after. Generally, blood is removed from the arterial cannula and passed through a hemoconcentrator. Blood remaining in the venous reservoir is ultrafiltrated, hemoconcentrated, and then returned to the right atrium. A roller pump maintains a flow rate of approximately 200 mL/min with a filtration rate of 150 mL/min. Hemodynamics are monitored with direct pressure measurements of the left- or right-sided filling pressures. Typically, the duration of ultrafiltration is approximately 20–30 min, but has a high institutional variability. Typically, hemoconcentration is carried out until a hematocrit value of 40 % is achieved. The benefit of performing the ultrafiltration after cessation of CPB is reaching a greater degree of hemoconcentration by ultrafiltrating just the patient's extracellular volume without the volume in the CPB circuit.

Studies have demonstrated that the accumulation of total body water is decreased in those patients undergoing MUF as compared to controls or patients undergoing conventional ultrafiltration [72]. In addition to the reduction in total body water, there may also be hemodynamic benefits related to MUF. Hemoconcentration

seen after ultrafiltration may lead to greater oxygen carrying capacity in the postoperative period. Studies have demonstrated improvements in various markers of hemodynamics after MUF [72]. Improvements have been seen in heart rate, cardiac index, systemic vascular resistance, and pulmonary vascular resistance [72]. The benefits seen in the hemodynamic parameters have been theorized to be a result of reductions in myocardial water content, pulmonary vascular resistance, and myocardial cross-sectional area after MUF [73, 74]. In relation to the, MUF has had mixed results with regard to reducing the systemic inflammatory response or clearing inflammatory markers from the serum post-CPB [75–77].

Postoperative Events

The degree of cardiac performance plays a central role in the preservation of kidney function after cardiac surgery. Persistence of cardiac failure with reduced cardiac output increases the risk for AKI. Systemic hypotension, residual heart defects, failed surgical corrections, and neuroendocrine reflexes have all been implicated as risk factors [78]. Oliguria in these patients is initially related to reduced GFR, which may lead to increased salt and water retention. Subsequent renal ischemia, which may initially be reversible, can lead to accumulation of nephrotoxins in the renal tubules leading to tubular injury, sustained renal impairment, cell death, and delayed renal recovery requiring tissue regeneration [79–81]. Fluid administration in this setting is aimed at reversing renal ischemia. The distinction between prerenal failure and tubular injury is based on clinical assessment along with biochemical and microscopic analysis of the urine. The role that renal ischemia plays in the initiation and continuation of AKI is debatable. Acute tubular necrosis (ATN) in the postoperative period continues to be challenging and continues to promote the use of intravenous fluids in patients with evidence of AKI. Episodes of oliguria and/or hypotension prompt intravenous fluid challenges and maintenance fluids to promote diuresis, to maintain cardiac output, and to maintain adequate volume status. Adequate fluid resuscitation is essential to restore cardiac output, systemic blood pressure, and renal perfusion in patients with shock secondary to low cardiac output. From a renal standpoint, fluid therapy is used to restore GFR and thus increase urine output. Fluid therapy is aimed at restoring systemic blood pressure (a major determinant of renal perfusion pressure) and cardiac output (a prerequisite for adequate renal blood flow). Fluid administration aimed at restoring systemic blood pressure works mechanistically by increasing preload and stroke volume. Fluid responsiveness of cardiac output is dependent on the volume of the central venous reservoirs and venous tone.

In hypovolemia, restoration of right ventricular end-diastolic volume remains the primary goal of fluid resuscitation. This restoration of blood pressure, central venous pressure, and/or urine output are only indirect measures of cardiac output and may be much less indicative of the restoration of adequate organ perfusion [82, 83]. The effects of critical illness, preexisting chronic disease, and pharmacotherapy can unpredictably alter determinants of fluid responsiveness such as myocardial compliance and contractility, systemic vascular resistance, regional blood flow distribution, venous capacitance, and capillary permeability. Importantly, fluids do not correct vasodilatation. The use of invasive monitoring becomes very important as a guide treatment, not only to ensure adequate volume expansion but also to prevent excessive fluid administration. Indiscriminate use of intravenous fluids and other vasoactive therapies to maximize cardiac output may not be beneficial and even deleterious.

Colloid solutions are frequently used for resuscitation despite limited evidence to justify their use. Most fluids administered as iso-oncotic solutions are likely to leak into the extravascular compartment and have a limited theoretical advantage over crystalloids in preventing tissue edema and lead to only a small decrease in the total quantity of fluid administered. Hyperoncotic starches might be more efficacious as fluid-sparing volume expanders, but they are associated with an increased risk of AKI [84, 85].

The administration of exogenous crystalloid solution expands the extracellular compartment and, over time, will leave the circulation and distribute in the extracellular volume. This is particularly true in critically ill patients with increased capillary leak. Renal excretion of exogenous sodium is slow and is further impaired in acute illness. The presumed clinical benefit of fluid therapy is being challenged by increasing evidence that positive fluid balances in the order of 5–10 % of body weight are associated with worsening organ dysfunction in the critically ill and with worse postoperative outcomes after surgery. At the same time, there is no evidence of beneficial effects on renal function. Net fluid removal requires a refilling of the circulation along a colloid osmotic gradient. During acute illness and/or postoperatively, the plasma colloid osmotic pressure is impaired by the increased capillary permeability. Slow vascular refilling may contribute to diuretic resistance or hemodynamic instability during fluid removal in these patients, either on conventional or intermittent dialysis. Gross fluid overload may result in visceral edema. Renal interstitial edema alone might impair renal function.

The adverse effects of fluid overload are even more evident in the lungs, where overzealous fluid resuscitation can lead to acute pulmonary edema. In patients with established acute lung injury (ALI), retrospective and prospective multicenter randomized controlled trials have provided evidence correlating increased positive-fluid balances with worse pulmonary outcomes, such as fewer ventilator free days and impaired oxygenation [86–88]. On the other hand, recent randomized studies [88, 89] examining restrictive fluid strategies in the ICU demonstrated clinically significant deterioration of renal function with fluid restriction. When managing fluid resuscitation, the best strategy may be to ensure that preload is sufficient to generate adequate cardiac output rather than simply responding to hypotension. This approach may help determine when fluid resuscitation can safely be stopped. Such an approach may require earlier initiation of vasopressor therapy and judicious use of intravenous fluid boluses. For example, epinephrine at lower dose will increase ventricular contractility, reduce systemic vascular resistance, and increase renal blood with subsequent improvement in urine output. However, with escalating doses, more vasoconstriction ensues resulting in decreased renal blood flow.

Historically, medical management of AKI included therapy with low-dose or "renal-dose" dopamine in the attempt to increase renal blood flow and enhance urine output. However, multiple studies and meta-analyses have demonstrated that renal-dose dopamine is ineffective in AKI in adult patients [90].

Another agent, fenoldopam mesylate, a selective dopamine-1 agonist, has been used to increase renal blood flow. It has no effect on dopamine-2 or α-1 receptors. When compared with dopamine, fenoldopam has a sixfold greater vasodilatory effect on the renal vasculature, and its natriuretic and diuretic effects are independent of renal vasodilation. Several studies have demonstrated that fenoldopam decreases the need for RRT in adults with AKI. The use of fenoldopam in pediatrics has been limited. However, the largest reported pediatric experience is in neonates after cardiac surgery and CPB, which demonstrated a possible improvement in urine output, in addition to lower inotrope scores [91]. In a retrospective review of selected critically ill pediatric patients with AKI who did not require mechanical circulatory support, fenoldopam increased urine output without requiring escalation of inotropic support and with no adverse hemodynamic effects or alterations in serum creatinine [92].

Once patients achieve hemodynamic stability, their sodium and water balance should be neutral or even negative. Achieving this balance postoperatively may be difficult, and loop diuretics are frequently employed. However, their use can be complicated by electrolyte abnormalities, worsening of renal function, and progressive diuretic resistance. Resistance can be overcome by the administration of diuretics that target the distal tubule and collecting ducts. Furosemide is the most widely used diuretic in children undergoing cardiac surgery. Dosage and administration vary from boluses (1 mg/kg every 6–24 h) to continuous infusion (up to 10–20 mg/kg/d). Continuous

furosemide infusion may be preferred because it yields comparable urinary output with a much lower dose, fewer hourly fluctuations, and less urinary sodium and chloride wasting. The suggested starting dose is 0.1–0.2 mg/kg/h. The prevention and treatment of edema remains particularly difficult in patients with AKI as diuretic therapy may worsen renal function induce hypernatremia or fail to induce sufficient diuresis. The indication for more invasive therapies may be warranted in those patients with fluid overload unresponsive to conventional diuretic therapies. Initiation of renal placement therapy (RRT) may be required to successfully maintain neutral fluid balance, avoid progressive lung injury, and treat life-threatening electrolyte disturbances.

Renal Replacement Therapy

Renal replacement therapy (RRT) should be initiated early if fluid balance cannot be adequately controlled with diuretic therapy. This will limit the extent of fluid overload and allow for adequate nutritional support without worsening fluid balance. It is suggested that RRT should be initiated within the first 48 h of ICU admission in critically ill AKI patients [93]. It is well documented that fluid overload is associated with increased mortality in patients treated with CRRT [93]. Although there are no clear recommendations for RRT in patients without AKI, it is widely accepted that RRT can favorably affect the clinical course of multiple organ system failure. It is estimated that up to 20 % of cases of pediatric multiple organ dysfunction syndrome (MODS) occur in children who have undergone cardiac surgery. Multiple single-center and multicenter pediatric studies demonstrate that increasing degrees of relative fluid accumulation or percent fluid overload at the time of RRT initiation in children with AKI is independently associated with mortality [94]. Percent of fluid overload was calculated by totaling fluid volumes from ICU admission to RRT initiation using the following equation: % Fluid Overload = [(Fluid input – Fluid output)]/Patient ICU admission weight (kg). Analysis of different percent thresholds from these studies suggests mortality increases from 40 % to 60 % in children with >10–20 % fluid overload at CRRT initiation, independent of patient's severity of illness.

Continuous Renal Replacement Therapy

Continuous renal replacement therapy (CRRT) allows for removal of fluid, urea, toxins, and/or potential inflammatory mediators from critically ill patients. Because it is continuous, it avoids rapid volume and solute shifts that can occur in standard hemodialysis treatments and is an ideal therapy for hemodynamically unstable patients with AKI and fluid overload. Veno-venous therapies involve the active drainage of a patient's blood from one lumen of a double lumen central venous cannula, passage through a motorized roller pump, through a filtration membrane, and then return of the blood to the patient via a second lumen of the central venous cannula. During ultrafiltration, a pressure gradient along a filter cartridge removes an ultrafiltrate of plasma. In continuous veno-venous hemofiltration (CVVH), a replacement fluid is added to the circuit before (pre-dilution) or after (post-dilution) the filter to augment convection of large molecules (and fluid) across the filter membrane. In continuous veno-venous hemodialysis (CVVHD), a dialysate fluid is infused through the outer chamber of the filter in a countercurrent direction to that of the blood flow. This allows removal of small solutes by diffusion. Continuous veno-venous hemodiafiltration (CVVHDF) utilizes replacement fluid and dialysate fluid to provide efficient removal of small, middle, and large molecules by both diffusion and convection (Fig. 172.2).

The principles of CRRT are similar for adults and children. However, there are special considerations to make when prescribing therapy to smaller patients. CRRT was first performed in the 1960s in critically ill adults in whom hemodialysis or peritoneal dialysis was contraindicated. It was not until 1981 that it was first successfully performed in a neonate [95].

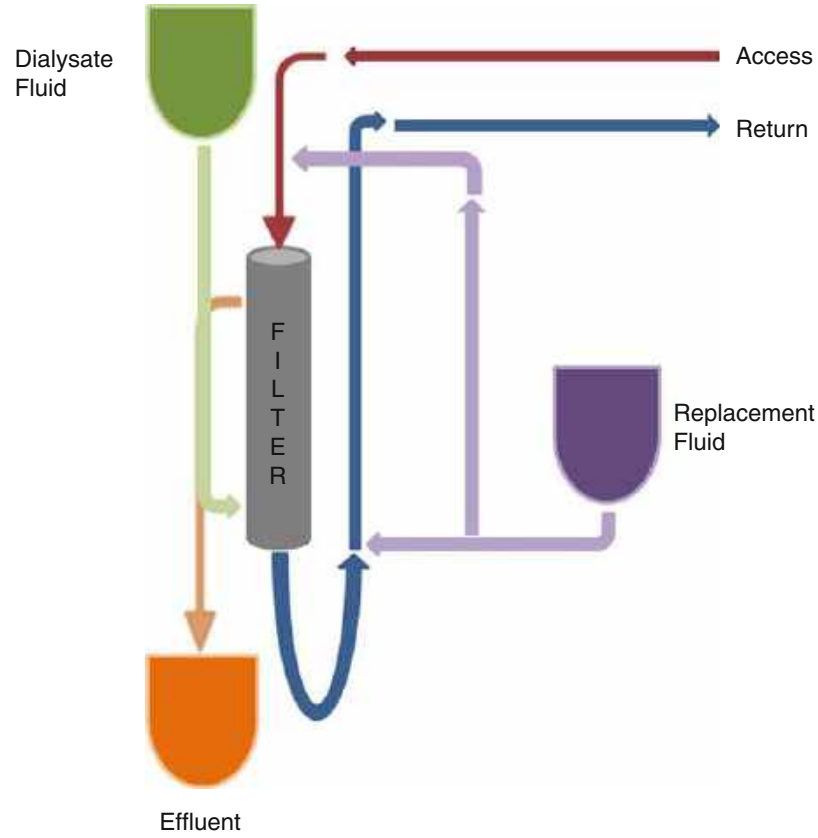

Fig. 172.2 TIF Schematic of continuous veno-venous hemodiafiltration (CVVHDF)

Since that time, the development of filters and extracorporeal circuits specifically adapted for pediatric patients in addition to precise ultrafiltration control systems has made CRRT a safe and effective method of fluid and solute removal.

The choice of machine is specific to the institution and also based on the preference and knowledge of the nephrologists and intensivists prescribing therapy. There is no machine that has been found to be well suited for children. More precise ultrafiltration pumps and controls minimize errors in fluid removal, which is crucial in infants who have smaller blood volumes and therefore are more sensitive to blood volume changes. Children's Hospital at Montefiore uses the Prismaflex™ CRRT machine manufactured by GAMBRO. Having functional vascular access is critical for the success of all modalities of renal replacement therapy. Patient size can make placement of vascular access challenging. Ideally, a seven French double lumen hemodialysis catheter is short and wide enough in diameter to obtain adequate blood flows for dialysis while minimizing clots formation in the extracorporeal circuit. Typical locations for placement include the internal jugular, subclavian, or femoral veins. The internal jugular vein is preferred, as access in the subclavian vein increases the risk for subclavian stenosis and may compromise placement of an AV fistula in the future. The femoral vein is not ideal because increased abdominal pressure could affect blood flow rates. Femoral cannulation can also compromise the patient's vasculature for future kidney transplants.

The extracorporeal circuit is comprised of the bloodline from the patient, the hemofilter, and the bloodline back to the patient. It is important to consider the priming volume of the extracorporeal circuit. Extracorporeal circuit volumes that comprise more than 10–15 % of the patient's blood volume should be primed with whole blood. There are a variety of hemofilter

membranes available for use with CRRT. The appropriate hemofilter for pediatric patients should be designed to have a low priming volume and low resistance. The filters customized for the Prismaflex™ machine are made of AN-69 polyacrilonitrile membrane. In regard to solutions utilized to perform RRT, bicarbonate-based replacement fluid and dialysate solutions are the standard of care for CRRT. CRRT solutions are composed primarily of physiologic concentrations of the electrolytes in plasma. Our institution uses PrismaSATE™ as the dialysate formula with the GAMBRO Prismaflex™ machine. There are six PrismaSATE™ dialysate formulas that vary primarily in the concentrations of calcium and potassium (Table 172.4).

Anticoagulation remains an area of intense research regarding the use of RRT. Activation of the clotting cascade occurs in CRRT because of contact of circulating blood with artificial surfaces. Protocols have been standardized for both heparin and regional citrate anticoagulation. Both have been shown to achieve comparable filter survival [96]. Citrate functions by binding free calcium, a necessary cofactor in both intrinsic and extrinsic coagulation pathways. Citrate is infused in the arterial limb (blood return to the machine) of the CRRT circuit to inhibit regional coagulation in the circuit. A calcium chloride drip is infused in the venous limb back to the patient to prevent citrate-induced hypocalcemia. The regional citrate protocol requires frequent monitoring of ionized calcium, with the goal to maintain the patient's ionized calcium in the physiologic range. Heparin is infused prefilter in the CRRT circuit. Frequent monitoring of PTT is necessary, with the goal to achieve a PTT level two times that of normal, between 45 and 60 s. Typically, a heparin bolus of 20–30 units/kg is given, followed by a continuous infusion of 10–20 units/kg/h.

RRT prescriptions typically initiate blood flow rates range from 4 to 5 ml/kg/min. Although the optimal dose of renal replacement therapy is not known, recommended dialysate or replacement fluid rate (or the sum of both in CVVHDF) is typically 2,000–3,000 ml/1.73 m^2/h. Ultrafiltration rates typically start at 1–2 ml/kg/h.

Complications associated with pediatric CRRT are usually related to the limitations of the equipment serving the smallest patients. Although CRRT

prevents less hemodynamic instability than intermittent hemodialysis, close monitoring of CRRT machines is necessary in infants because even small rate adjustments can result in significant changes to blood volume and hemodynamic status. Working with slower blood flow rates in pediatric patients or a poorly functioning vascular access increases the risk for circuit clotting and subsequent blood loss to the patient. Anticoagulation regimens are often essential to increase the life span of the hemofilter. Repeated changes of the hemofilter result in loss of blood for the patient. Although the dose of heparin typically given in CRRT was devised to cause minimal systemic effects, the risk of bleeding does exist. Because citrate is metabolized in the liver, patients with liver dysfunction may develop citrate toxicity. Finally, electrolyte abnormalities may occur after initiation of CRRT, and it is necessary to monitor electrolytes closely and to make regular adjustments to the composition of the replacement fluid.

Peritoneal Dialysis

Peritoneal dialysis (PD) is another form of renal replacement therapy in children. Peritoneal dialysis solution is infused into the peritoneal cavity through a PD catheter, and the peritoneal membrane is the barrier through which solutes and water must cross during dialysis. The peritoneal membrane lines the inner surface of the abdominal and pelvic walls, covers the intraperitoneal organs, forms the omentum, and connects loops of bowel. The peritoneal membrane is vascularized with peritoneal capillaries. Blood flow has been suggested to vary between 50 and 100 ml/min in these capillaries. Diffusion occurs by movement of solutes across a concentration gradient between the blood and the dialysis solution. It is also dependent on the molecular size of the solute and the effective surface area and permeability of the peritoneal membrane. Ultrafiltration of water across the peritoneal membrane occurs primarily due to the osmotic gradient generated by the glucose concentration in the dialysis fluid.

There are numerous types of permanent peritoneal dialysis catheters available. The type used varies by institution. However, national registry data collected by the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) in 2008 identified the curled Tenckhoff® catheter as being the most commonly used pediatric peritoneal dialysis catheter. A double-cuffed catheter is recommended because data suggests a lower incidence of peritonitis. In addition, the use of a swan neck subcutaneous tunnel with a downward exit site is associated with longer time to first peritonitis episode [97]. Experienced surgeons should place permanent peritoneal dialysis catheters surgically. Prophylactic antibiotics are usually given at the time of insertion of the catheter. In addition, an omentectomy at the time of catheter placement is routinely performed at some institutions to decrease the risk of peritoneal dialysis catheter occlusion. Peritoneal dialysis catheters can be placed by an open or laparoscopic technique. There is no consensus about a rest period prior to catheter use. There is some data to suggest that early usage of a peritoneal dialysis catheter increases the risk for dialysate leakage, but it is unclear whether this increases risk of infection [98].

Glucose is the standard osmotic agent that drives the ultrafiltration of fluid in peritoneal dialysis. Commercially available peritoneal dialysis solutions have supraphysiologic glucose concentrations that range from 1,500 to 4,250 mg/dL. Choosing the appropriate peritoneal fluid glucose concentration can depend on the degree of fluid overload in the patient. Generation of glucose degeneration products occurs over time in glucose-based fluids and can cause inflammation and fibrosis of the peritoneal membrane. Because of these deleterious effects, alternative peritoneal dialysis fluids with icodextrin and amino acids have been developed. Lactate is the standard buffer available for peritoneal dialysis fluids. The supraphysiologic concentration of lactate is rapidly absorbed via the peritoneal membrane and metabolized to bicarbonate in the liver. In patients with lactic acidosis

Table 172.5 Dianeal™peritoneal dialysis solutions

	Glucose (%)	Sodium (meq/L)	Chloride (meq/L)	Calcium (meq/L)	Magnesium (meq/L)	Lactate (meq/L)	Osmolarity (mosmol/L)
Dianeal™ low calcium peritoneal dialysis solution with 1.5 % dextrose	1.5	132	95	2.5	0.5	40	344
Dianeal™ low calcium peritoneal dialysis solution with 2.5 % dextrose	2.5	132	95	2.5	0.5	40	395
Dianeal™ low calcium peritoneal dialysis solution with 4.25 % dextrose	4.25	132	95	2.5	0.5	40	483
Dianeal™ PD-2 peritoneal dialysis solution with 1.5 % dextrose	1.5	132	95	3.5	0.5	40	344
Dianeal™ PD-2 peritoneal dialysis solution with 2.5 % dextrose	2.5	132	95	3.5	0.5	40	395
Dianeal™ PD-2 peritoneal dialysis solution with 4.25 % dextrose	4.25	132	95	3.5	0.5	40	483

secondary to shock, bicarbonate-based peritoneal dialysis solutions may be a better option. Sodium, chloride, calcium, and magnesium are also added to peritoneal dialysis solutions to maintain mineral homeostasis. Peritoneal dialysis solutions are available as low calcium (1.25 mmol/L) or normal calcium (1.75 mmol/L) (Table 172.5).

Peritoneal dialysis regimens can be continuous or intermittent. Continuous peritoneal dialysis is typically employed in patients who require emergent dialysis. Dialysis solution is infused in hourly exchanges continuously over 24 h. The volume of dialysis solution infused in the abdomen is based on weight and body surface area. A typically starting volume is 10 ml/kg with a dwell time of 30–50 min. It is recommended to maintain low fill volumes when starting dialysis immediately after catheter placement to prevent dialysate fluid leakage. When the wounds have healed, the fill volume can be gradually increased. The target fill volume for adequate dialysis is 30–40 ml/kg.

Acute manual peritoneal dialysis sets are typically employed in children starting peritoneal dialysis because it can be performed with fill volumes less than 100 ml. Peritoneal dialysis fluid is drawn up into a burette marked in milliliter increments. The peritoneal dialysis fluid is then gradually instilled into the peritoneal cavity, allowed to dwell, and then drained by gravity into a drainage bag. Automated cyclers can be utilized when performing peritoneal dialysis with fill volumes greater than 100–150 ml. The cycler delivers the fill volume, and after an appropriate dwell time programmed into the cycler, the drain phase occurs. The ultrafiltrate volume is the difference between the drain and fill volumes at each cycle. Pumps aid in the movement of fluid into and out of the patient.

Peritoneal dialysis can be complicated by obstruction of the peritoneal dialysis catheter. Drainage from the peritoneal dialysis can be disrupted due to catheter kinking, fibrin clots, or omental wrapping. Also, it may be difficult to optimize ultrafiltration in peritoneal dialysis. Increasing dwell volumes may not be tolerated in a critically ill infant with respiratory insufficiency. Finally, peritoneal dialysis does not provide efficient removal of molecules and may not be the optimum modality in cases of severe electrolyte abnormalities.

Future Directions and Biomarkers

The presence of renal disease in children always raises the question of diagnosis as well as the prognosis following acute kidney injury. To that effect, research in acute kidney injury has progressed into the search to define and identify this injury earlier. Traditional markers of kidney injury such as serum creatinine, estimated glomerular filtration rate, casts, fractional excretion of sodium, filtered high-molecular-weight proteins, and tubular proteins or enzymes have significant delay in the timely diagnosis and subsequent management of AKI. The current biochemical gold standard to estimate GFR and diagnose AKI is an increased serum creatinine level above baseline. However, creatinine is an imperfect biomarker for AKI. The serum creatinine may not rise for several days after an episode of AKI. In AKI, an acute drop in GFR will lead to an elevation in serum creatinine, but the rate of rise may be difficult to predict due to variation in body habitus as well as nutritional and clinical status. In addition, it takes days for serum creatinine to equilibrate. A true rise in creatinine or nadir in estimated GFR is not immediately apparent, decreasing the chances of making an early diagnosis of AKI and implementing treatment.

Current research is focused on identifying new potential biomarkers that may hasten the diagnosis and management of acute kidney injury. The approach taken has been similar to the development of cardiac biomarkers of myocardial ischemia after infarction. AKI biomarkers were discovered using genomic and proteomic studies in animal models and result from upregulation or downregulation of genes or proteins in the kidney by different mechanisms of renal tubular cell damage and death. This includes ischemia-reperfusion or nephrotoxic injury. The current group of markers being investigated include interleukin-18 (IL-18), neutrophil gelatinase-associated lipocalin (NGAL), kidney injury molecule-1 (KIM-1), and liver-type fatty acid-binding protein (L-FABP). In addition to earlier detection of acute kidney injury, biomarkers may also shed some light into the possible location of the injury, possible subtype of renal injury, etiology of injury, outcomes associated with injury, and ability to monitor the injury itself. Krawczerki and colleagues [99] have provided an excellent foray into this area of ongoing research in patients who undergo CPB and develop AKI, demonstrating a correlation of AKI biomarkers and disease severity and clinical outcomes after pediatric CPB.

The search for early detection and treatment of acute kidney injury has many parallels to that for acute myocardial infarction. Just as there are limitations to using troponins in acute myocardial infarctions, there is no single biomarker that specifically indicates the presence of acute kidney injury. Due to the heterogeneous etiology of acute kidney injury, there needs to be a panel of multiple markers, each providing critical information about AKI. The ability to have early detection and prediction of acute kidney injury will be a major innovation in how we approach and treat our critically ill patients.

Abstract

Stroke is being increasingly recognized as an important cause of childhood disability. Congenital heart disease (CHD) has been identified as a major risk factor for the development of childhood stroke. The most common types of stroke seen in children with CHD are arterial ischemic stroke (AIS) and white matter injury or periventricular leukomalacia (WMI/PVL). This chapter is a review of the existing literature on AIS and WMI/PVL in patients with CHD and summarizes the mechanisms of injury, diagnosis, and management of the critically ill child with CHD and stroke.

Keywords

Congenital heart disease • Pediatrics • Periventricular leukomalacia • Stroke • White matter injury

Introduction

Stroke is being increasingly recognized as an important cause of childhood disability. While congenital heart disease (CHD) has been identified to be a major risk factor for the development of childhood stroke, there is a paucity of literature on stroke in patients with CHD. The most common types of stroke seen in children with CHD are arterial ischemic stroke (AIS), which is cerebral infarction in the territory of arterial occlusion or hypoperfusion, and hypoxic-ischemic injury to the white matter of the brain that is referred to as white matter injury or periventricular leukomalacia (WMI/PVL). This chapter will review AIS and WMI/PVL in patients with CHD summarizing existing literature on epidemiology and mechanisms of injury and discuss management strategies for the critically ill child with CHD and stroke.

Epidemiology

The incidence of AIS in children ranges between 0.58 and 10.7 per 100,000 children [1–6]. One of the major identifiable risk factors for developing AIS in childhood is CHD, which includes children with a spectrum of disease ranging from an atrial septal defect to complex cyanotic CHD and includes children with congenital cardiomyopathies [5–14]. Single-center and regional reviews from the United Kingdom and the United States (USA) have found that 18–25 % of children presenting with AIS have cardiac disease, which includes children with CHD and acquired cardiac diseases such as myocarditis and endocarditis [6, 15]. Recently, the International Pediatric Stroke Study reported a frequency of cardiac disease of 31 % in 676 patients with AIS from 10 countries [16, 17]. Of the 204 patients with cardiac disease, 59 % had congenital anatomic defects, 20 % had acquired heart disease, 15 % had a patent foramen ovale, and a smaller number of patients had arrhythmias. In another recent regional study in the USA, the majority of cardiac patients diagnosed with AIS had a single ventricle (33 %), with a smaller number of patients with arrhythmias, atrial septal defects, Ebstein anomaly, atrioventricular canal defect, aortic arch obstruction, dextro-transposition of the great arteries, and double-outlet left ventricle [6].

While a large proportion of infants and children with AIS have CHD, the proportion of infants and children with CHD that have stroke is relatively small. The prevalence of stroke with focal ischemic injury in infants with CHD undergoing postoperative brain magnetic resonance imaging (MRI) was recently reported to be 10 % (12 of 122), including seven patients with watershed ischemia [17]. Thus, the prevalence of AIS was 5 of 122 or only 4 %. Other studies in infants with transposition of the great arteries (TGA) have found the prevalence of stroke to be as high as 21 % [18], though this has not been seen in other centers [19, 20]. Hypoxic-ischemic brain injury seen in children with CHD in the form of WMI/PVL has been widely reported [7, 21–23]. Perioperative brain imaging studies with MRI in neonates and infants with complex CHD have reported an incidence of WMI/PVL ranging from 16 % to 38 % before surgery and up to 50 % after surgery [18, 20–22, 24–26]. The prevalence of WMI/PVL is highly dependent on CHD type and is as high as 89 % in postoperative infants with HLHS [18].

Mechanism of Injury

Numerous mechanisms including hypoperfusion, hypoxemia, thromboembolism, and an underlying cerebral vasculopathy have been implicated as mechanisms of stroke in children with CHD. Though the literature is not always consistent, WMI/PVL is primarily associated with hypoxic-ischemic mechanisms, and AIS occurs primarily secondary to thrombosis and embolism.

White Matter Injury/Periventricular Leukomalacia

WMI/PVL arises from hypoxic-ischemic injury to immature pre-myelinating oligodendrocytes in the watershed white matter regions adjacent to the lateral ventricles (Fig. 173.1). Recent investigations in WMI/PVL have demonstrated that the brains of children with complex CHD are immature at the time of birth with significantly altered metabolism [26–28], making them selectively vulnerable to ischemic insults. Hemodynamic factors during the fetal phase have been implicated in development of these abnormalities [28]. Brain immaturity as measured by the Total Maturation Scale (TMS), an observational rating metric of preoperative brain MRIs [27, 29], has been found to be a leading risk factor for both pre- and postoperative WMI/PVL [26]. Other risk factors for development of WMI/PVL in the preoperative period include hypoxemia [19] and decreased cerebral blood flow [22]. In the postoperative period, identified risk factors include hypoxemia, diastolic hypotension, cardiopulmonary bypass (CBP) with regional cerebral perfusion, and decreased hemoglobin during bypass [18, 30].

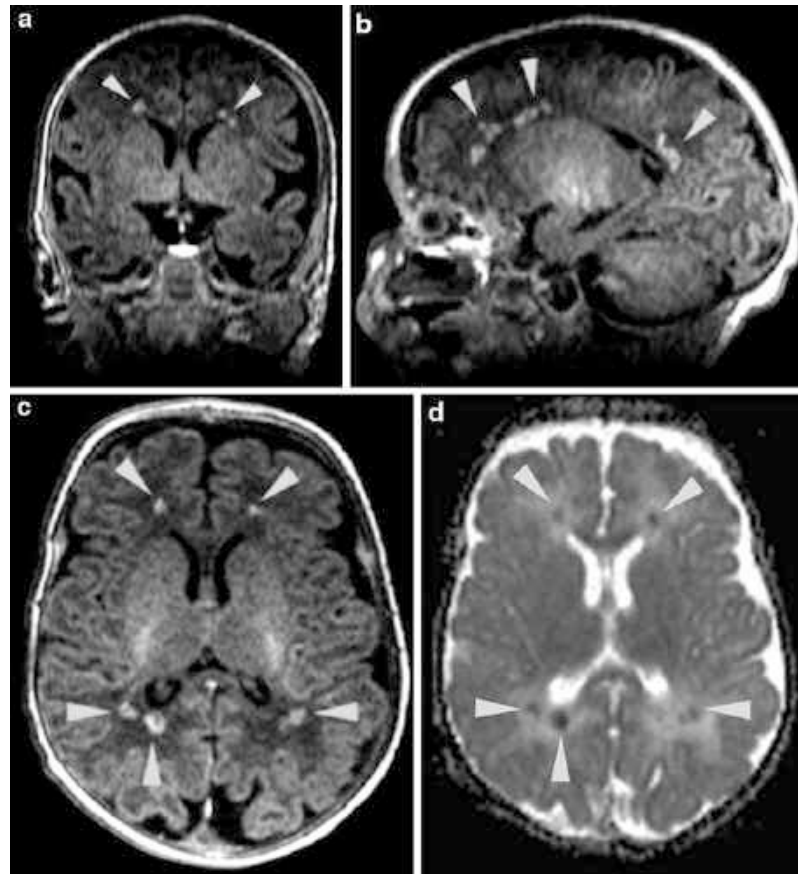

Fig. 173.1 White matter injury/periventricular leukomalacia (WMI/PVL) is demonstrated in an 11-day-old male with HLHS on postoperative day 7. MRI images are T1 sequences in the coronal (**a**), sagittal (**b**), and axial (**c**) planes. Areas of acute WMI/PVL (*arrowheads*) are seen as hyperintense lesions. Apparent diffusion coefficient sequence (**d**) shows restriction of water diffusions consistent with acute ischemia

Arterial Ischemic Injury

Numerous mechanisms for thromboembolism in CHD exist. These include ventricular dysfunction, mechanical valves, paradoxical embolization of a venous thrombus through and right-to-left shunt, or underlying cerebral vasculopathy associated with genetic forms of CHD.

Perhaps the most common source for AIS is a right-to-left shunt [17, 31]. Systemic venous thrombi can occur from prolonged immobilization following surgery, catheter-related thrombosis, and other prothombotic conditions including polycythemia, infection, and dehydration secondary to illness or diuretics. One quarter of AIS associated with cardiac disease in the International Pediatric Stroke Study occurred in association with a cardiac procedure or catheterization [16, 17]. Embolism has also been reported to be the mechanism for focal ischemic brain injury in neonates with transposition of the great arteries (TGA) undergoing balloon atrial septostomy for preoperative hypoxemia [24, 25, 32], though other groups have not seen this association [19, 20]. Embolic stroke has also been seen in hypoplastic left heart syndrome (HLHS) before the Norwood stage 1 operation [20]. Interestingly, all the preoperative strokes seen in HLHS were in patients with aortic atresia (no antegrade blood flow in the ascending aorta), and all strokes were in the right hemisphere (Goff et al. in preparation) (Fig. 173.2). Embolic events have also been widely reported in the Glenn [6] and Fontan population [6, 7, 12–14, 33] and have been associated with thrombi on both the systemic venous and arterial sides [34], residual right-to-left shunts [12], and prolonged immobilization [33]. In the largest report to date on patients who have undergone the Fontan operation by the pediatric heart network, stroke and/or thrombosis

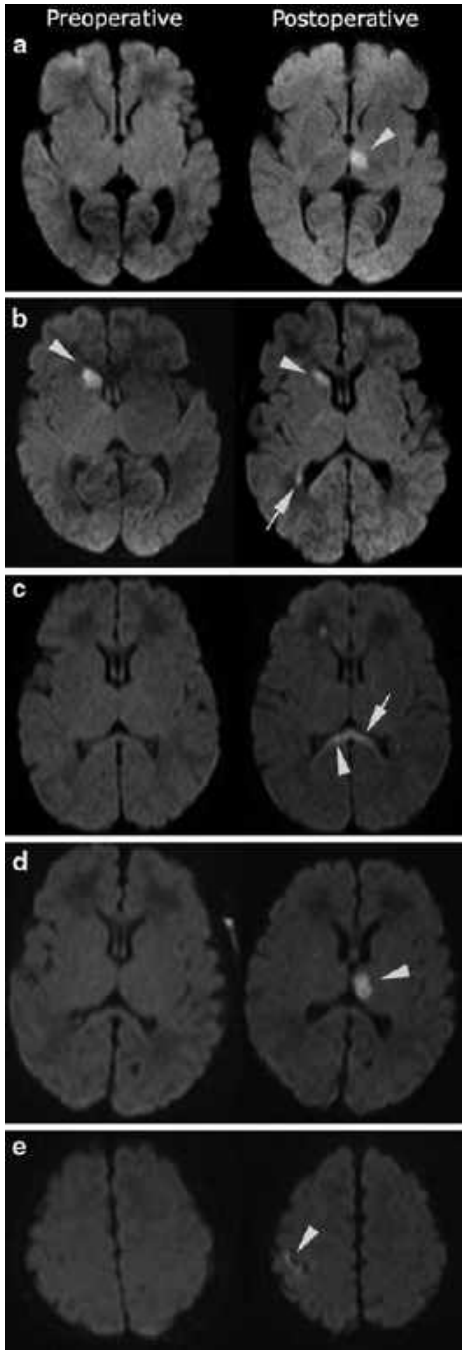

Fig. 173.2 Acute ischemic stroke is demonstrated on diffusion-weighted image (DWI) in 5 neonates (**a**–**e**) with HLHS, imaged before and after surgery (*right and left columns*, respectively). Patient A – new postoperative left thalamic stroke (*arrowhead*). Patient B – demonstrates preoperative stroke (*arrowhead*), with expected changes postoperatively, and new postoperative PVL in right periatrial white matter (*arrow*). Patient C – demonstrates complex combination of Wallerian diffusion restriction from parietal PVL (*out of plane*) and an acute stroke in the splenium of the corpus callosum (*arrowhead*). There is also acute PVL in the right frontal white matter. Patient D – new postoperative left thalamic stroke (*arrowhead*). Patient E – small area of postoperative cortical infarction in the right central sulcus (*arrowhead*)

was seen in 8 % of 546 children [35, 36]. While initial reports suggested that the risk of thromboembolism decreased with time [33, 34], a recent report from the Children's Hospital of Boston showed a sharp increase in thromboembolic events at 15 years following Fontan completion, which were responsible for late deaths in 8 % of the cohort of 261 patients [37].

Systemic arterial thrombi can occur with mechanical aortic and mitral valves on the aortic cannula during venoarterial extracorporeal membrane oxygenation and CBP. They can also occur within a left ventricular assist device and within the systemic ventricular cavity with severe ventricular dysfunction occurring with congenital and acquired cardiomyopathies [37] and myocarditis. In non-compaction cardiomyopathy, it is unclear if thrombi form because of ventricular dysfunction or form in situ within the clefts in the ventricular wall [38].

Stroke associated with CBP has been reported to occur in 5.4 cases per 1000 children [39] undergoing cardiac surgery. In a study of brain specimens on 36 patients that died within 3 weeks after undergoing CBP, thousands of microemboli were found in brains of patients soon after CBP, and an increased duration of CBP was associated with an increased embolic load [40]. In another study looking at brain specimens of children with HLHS with brain injury, CBP with deep hypothermic circulatory arrest greater than 40 min was associated with a higher incidence of neuropathology with hypoperfusion and altered glucose and oxygen delivery as proposed mechanisms [41].

Patients with CHD have also been found to have genetic risk factors for thromboembolism including lipoprotein A, protein C deficiency, and anticardiolipin antibody at a greater frequency than controls [42].

Another increasingly recognized phenomenon is the cerebral vasculopathy moyamoya disease in association with CHD. Moyamoya disease is characterized by chronic progressive stenosis of the distal internal carotid artery (occasionally the anterior cerebral artery and middle cerebral artery, the basilar artery, and the posterior cerebral arteries) The term "moyamoya" is a Japanese word meaning "hazy, like a cloud of smoke drifting through the air," referring to the appearance of the distal collateral network on angiography. Moyamoya was first reported in 5 children with CHD; 3 with coarctation of the aorta (one with ventricular septal defect), 1 with tetralogy of Fallot, and 1 with aortic and mitral valve disease, of which 3 patients presented with stroke and 2 with seizures [43]. There have been subsequent reports of moyamoya disease in other syndromes associated with CHD including Noonan syndrome [44], Down syndrome [45], neurofibromatosis type 1 [46], and Alagille [47] syndrome, implicating a genetic basis for development of cerebral vasculopathy with predisposition to ischemic stroke and CHD. The authors suggest that in a patient with CHD and one of these genetic diagnoses, consideration should be given to performing a brain MRI with MR angiography.

Diagnosis

Strokes commonly present with focal neurological deficits including hemiparesis and speech or visual disturbance. In neonates and infants with CHD, the majority of strokes are asymptomatic [17, 24] but should be suspected in this population if a child has seizures [48] or altered mental status. The detection of stroke in critically ill children is confounded by the use of sedating medications. As the majority of strokes in the perioperative neonate present with seizures, the use of continuous closed circuit video-electroencephalography monitoring in critically ill newborns and infants has been suggested [49].

Critically ill neonates and infants often have cranial ultrasonography as their initial diagnostic study, as it is easily accessible and portable to the patient; however, this modality is insensitive for stroke detection [48]. Computerized tomography (CT) is also used for detection of strokes; however, this modality exposes the patient to radiation and is less sensitive for diagnosing small strokes or strokes less than 6 h after occurrence. The current gold standard imaging modality is MRI with MR angiography coupled with diffusion-weighted (DWI) and perfusion imaging which play a critical role in evaluation of the pathophysiology of stroke including assessment for an underlying vasculopathy [50]. Perfusion-weighted imaging with arterial spin labeling (ASL) is a relatively new sequence that may be helpful in assessing brain territory at risk for extension of ischemic injury (Fig. 173.3).

The cardiac evaluation of a child with an acute stroke includes a 12-lead electrocardiogram to assess for an underlying arrhythmia as well as a transthoracic echocardiogram to assess for ventricular function. The echocardiogram should be performed with agitated saline contrast to rule out a right-to-left shunt. To assess for an intracardiac thrombus, transesophageal echocardiography should be considered. In addition, in patients with AIS and right-to-left shunts, imaging of the systemic veins with ultrasonography should be performed, especially if the patient has a central line to assess for a catheter-related thrombus.

A thorough hematological evaluation should also be requested which should include assessment of anemia, polycythmia, thrombocytosis, and a comprehensive evaluation for an inherited or acquired prothrombotic disorder (Table 173.1).

Treatment

Unlike in adults, thrombolytic therapy is currently not approved for use in children with stroke and should only be considered in very special cases with very close attention to adult guidelines (Table 173.2) [51]. The national rates of thrombolysis in pediatric stroke in the USA between 2000 and 2003 were reported to be only 1.6 % [52] but did not include any patients with CHD.

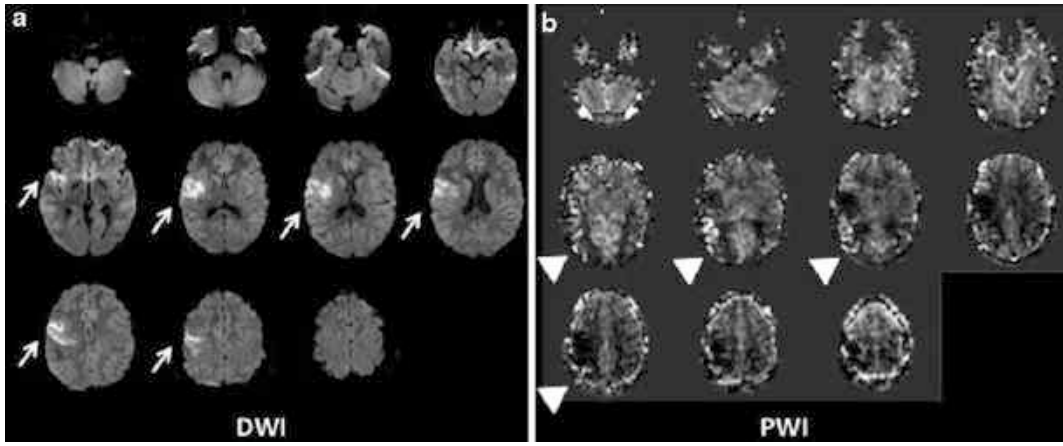

Fig. 173.3 16-year-old boy with paradoxical embolism to the right middle cerebral artery. (**a**). Diffusion-weighted imaging (*DWI*) – a moderate-sized area of ischemia is demonstrated (*arrows*). (**b**). Perfusion-weighted imaging (*PWI*) – arterial spin-labeled perfusion MRI, a larger area of hypoperfused brain parenchyma, is demonstrated (*arrowheads*). Hyperintense signal lateral to the area of hypoperfusion represents collateral blood flow with delayed transit

Anticardiolipin antibody Anti-beta-2-glycoprotein antibody dRVVT	

The use of intra-arterial thrombolytic therapy has been reported from Japan CHD in a 16-year-old with palliated complex cyanotic heart disease with AIS [53].

Once a stroke has been identified, cerebral neuroprotection to prevent secondary brain injury is critical. This includes prevention of hyperthermia, glucose control (not recommended in infants and newborns), aggressive treatment of secondary seizures, and maximizing cerebral perfusion with IV fluids and keeping the head of bed flat (at zero degrees). Optimization of cardiac output, ventilation, and oxygenation and prevention of secondary injury associated with hypotension are the cornerstones of stroke management.

Anticoagulation or antiplatelet therapy is recommended for secondary stroke prevention, in cases where there is a high risk for future strokes (i.e., thrombophilia, arterial stenosis, arterial dissection, venous congestion). Anticoagulation should be used with caution as hemorrhagic transformation can occur, and clinical deterioration after anticoagulation should have a low threshold for reimaging with head CT. Safety of anticoagulation in AIS has been established in

Table 173.2 Inclusion criteria for tissue plasminogen activator (t-PA) administration in children. *NIHSS* National Institutes of Health Stroke Scale, *mmHg* millimeters of mercury, *aPTT* activated partial thromboplastin time, %ile, percentile

Inclusion criteria for t-PA administration 2007 AHA guidelines with ECASS modifications (Del Zoppo Stroke 2009)	
Criteria	Comment
Symptom onset no more than 4.5 h prior to treatment	*Onset* – is defined as the time patient was last seen well
Diagnosis of ischemic stroke causing measurable neurologic deficit, NIHSS > 5	Can use PedNIHSS[a]
Baseline NIHSS score must be < 25	Can use PedNIHSS[a]
Neurologic signs do not diminish spontaneously	Reexamine patient prior to administration of t-PA
No major surgery in the previous 14 days	
No use of oral anticoagulants or INR ≤1.7 if anticoagulant therapy is being used	aPTT within normal range, if heparin was administered in previous 48 h
Platelet count ≥100,000 mm^3	
Nonelevated blood pressure (systolic <185 mmHg and diastolic <110 mmHg)	Or < 95th%ile for age[b]
No evidence of active bleeding or acute trauma upon examination	
Potential risks and benefits of treatment are understood by patient or family members

[b]The Harriet lane handbook 19e, 2011

children (including children with CHD) [54]. A recent study of pediatric stroke concluded that the greatest risk for hemorrhagic transformation occurred with large strokes (stroke volume > 5 % of total brain volume) [55]. The authors reported an increased risk of hemorrhagic transformation in children with CHD, though this failed to reach statistical significance.

The mainstay of treatment is anticoagulation for prevention of stroke in high-risk patients. Recommendations have been published by the American Heart Association for optimal diagnosis and treatment of children with cerebrovascular disease [56], which includes recommendations for the use of low-molecular-weight heparin or warfarin in children with a risk of cardiac embolism. In the Fontan population in whom thromboembolism has been widely reported, anticoagulation with aspirin [14, 33] and warfarin [33] has been shown to be effective in preventing strokes, although there is no consensus on long-term use of anticoagulation. A recent report on Fontan patients from the Pediatric Heart Network on Fontan patients showed that 32 % of patients were taking no antithrombotics [36]. At the authors' institution, it is common practice to introduce antiplatelet therapy in any child undergoing staged palliation for single ventricle CHD.

Outcomes and Long-Term Follow-Up

There is limited data on the outcome of children with stroke and CHD. One of the main concerns of children with CHD with ischemic strokes is hemorrhagic transformation with anticoagulation with CBP. In a study of 92 patients with CHD, brain injury was identified in 43 % of neonates on preoperative MRI, which included AIS and WMI/PVL; on postoperative brain MRI, none of the lesions showed extension [24]. However, this experience is not universal; in another study looking at late postoperative (at age 3–6 months) MRIs in neonates with brain injury including infarcts and WMI/PVL, the majority (58 %) of lesions had resolved [26], though this may be a limitation of the resolution of conventional MRI. Diffusion tensor imaging (DTI) may be required to identify occult lesions.

The literature on functional outcome of children with CHD and AIS is limited. One single-center study looked at in children with AIS and cerebral sinus venous thrombosis following cardiopulmonary bypass. In this study only 14 % reported normal neurologic outcome [39]. This is contrary to reports on mixed populations with AIS where about half of children have normal

neurologic outcomes [57, 58]. Many children have impairments that interfere with daily life [57] and include secondary epilepsy, severe mental retardation, dystonia, and dyskinesia [58]. Mean intelligence quotient falls significantly below population mean but still in average range [59]. Poor prognosis has been associated with altered consciousness, seizures, and a completed or cortical completed middle cerebral artery ischemic stroke [60].

Another important concern is stroke reoccurrence which has been reported to occur in up to 19 % of children with childhood AIS in a mixed population [61]. The Canadian Pediatric Ischemic Stroke Registry has recently reported a recurrence rate of 27 % in children with CHD; significant risk factors associated with recurrence included the presence of a mechanical valve and prothrombotic condition or the presence of an acute infection at the time of the sentinel stroke [62].

Future Directions

There is paucity of literature on stroke in children with CHD. Further investigation is needed to delineate patterns of injury and correlate them with functional outcome. Multicenter trials are needed to investigate potential therapies including thrombolysis in highly selected populations. In addition, more studies are needed for identification of modifiable risk factors to prevent disability from childhood stroke.

Intracranial Hemorrhage

174

Dusty M. Richardson and Todd C. Hankinson

Abstract

Intracranial hemorrhage is a rare but serious complication in pediatric patients who require intervention for cardiovascular disease. These children are at risk for intracranial hemorrhage not only as a result of their primary vascular illnesses but also because the treatment of their diseases often requires anticoagulants and antiplatelet agents. This chapter discusses the anatomy of various types of intracranial hemorrhage and reviews the current literature addressing intracranial hemorrhage in pediatric patients undergoing cardiac procedures. This chapter also discusses management of intracranial hemorrhage in the acute, subacute, and chronic settings.

Keywords

Angiography • Anticoagulation • Antiplatelet • Brain • Endoscopic third ventriculostomy • Epidural • Extracorporeal membrane oxygenation (ECMO) • Hemorrhage • Hydrocephalus • Intraparenchymal • Intraventricular • Neurologic deficit • Neurosurgery • Shunt • Subarachnoid • Subdural

Intracranial Hemorrhage After Cardiac Intervention

Intracranial hemorrhage (ICH) can be a devastating complication following cardiac surgery or intervention. In patients who present with intracranial hemorrhage as the chief complaint, the 1-month mortality rate has been reported to be as high as 42–48 % with a 10-year survival rate of approximately 18 % [1]. Clinical outcomes studies invariably describe ICH among the "major bleeding events." Patients who suffer a major bleeding event after a cardiac procedure have significantly worse outcomes compared with those who do not have a major bleeding event [2]. This may result from the fact that these patients often require anticoagulation as part of the standard treatment for their cardiac disease yet acutely require therapies to correct platelet and coagulation abnormalities in an effort to minimize hemorrhage-associated injury.

This chapter describes the neuroanatomical characteristics of the various types of ICH and reviews the most recent literature regarding incidence and management of pediatric patients who have suffered an ICH in the setting of cardiac disease and/or having undergone a cardiac procedure.

Defining Characteristics of Intracranial Hemorrhages

Intracranial hemorrhage can be divided into categories based on the anatomic location of the hemorrhage. A vessel that ruptures within the parenchyma of the brain (see Fig. 174.1) results in intracerebral (or intraparenchymal) hemorrhage. Intraparenchymal hemorrhages range in severity from small focal lesions that are detected incidentally to catastrophic hemispheric hematomas.

Immediately surrounding the surface of the brain are the leptomeninges (pia mater and arachnoid mater). The subarachnoid space contains cerebrospinal fluid (CSF) and is the plane in which the major intracranial arteries are located. Spontaneous subarachnoid hemorrhage (SAH) merits investigation of the cerebral vasculature via angiography, whether virtual (in the form of CT or MR angiography) or through formal catheter angiography. This is certainly true in patients with underlying systemic vascular disease.

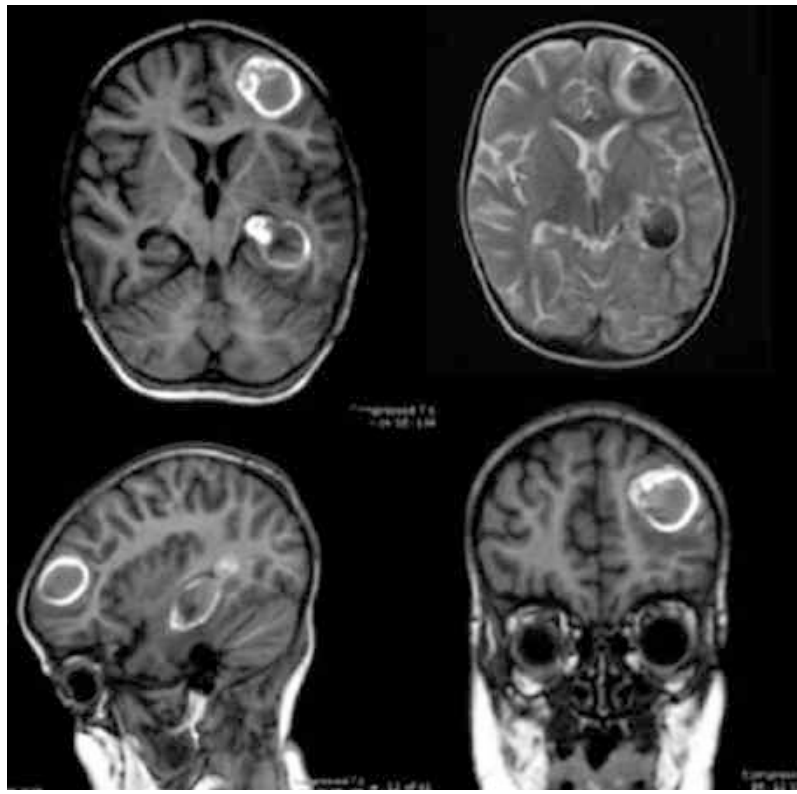

Fig. 174.1 Non-contrast axial T1-weighted MRI of the brain (*upper left*) demonstrating intense signal in the left frontal and medial temporal lobe representing intracerebral hemorrhage in a 22mo who presented with ARDS and metapneumovirus pneumonia which ultimately required ECMO. The *upper right* image is an axial T2-weighted MRI of the brain showing the blood to be hypointense. The *bottom* images are T1 sagittal and coronal (*left* and *right*, respectively) views of the same hemorrhages. The signal characteristics of intracranial blood change with evolution of the blood products; in this case, the T1 images demonstrate hyperintensity, while T2 imaging demonstrates hypointensity, indicating an acute hemorrhage

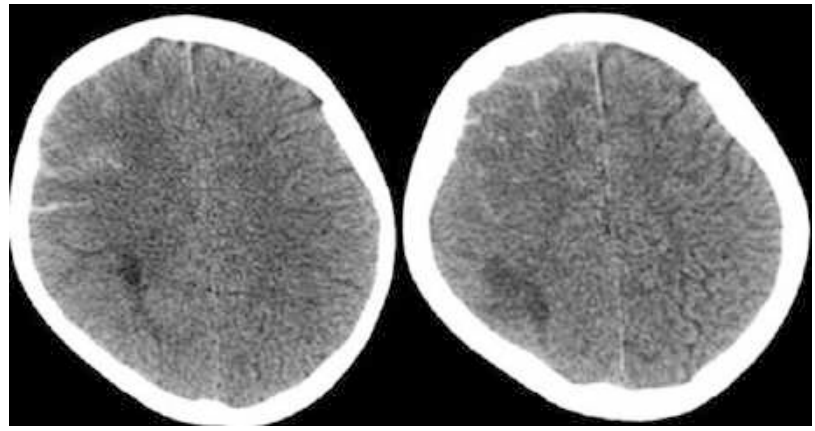

Fig. 174.2 Axial non-contrast CT scan demonstrating a right frontal subarachnoid hemorrhage in a 5 year old on aspirin with a history of multiple cardiovascular anomalies including a remotely repaired total anomalous pulmonary venous return and double outlet right ventricle. This patient did not require neurosurgical intervention

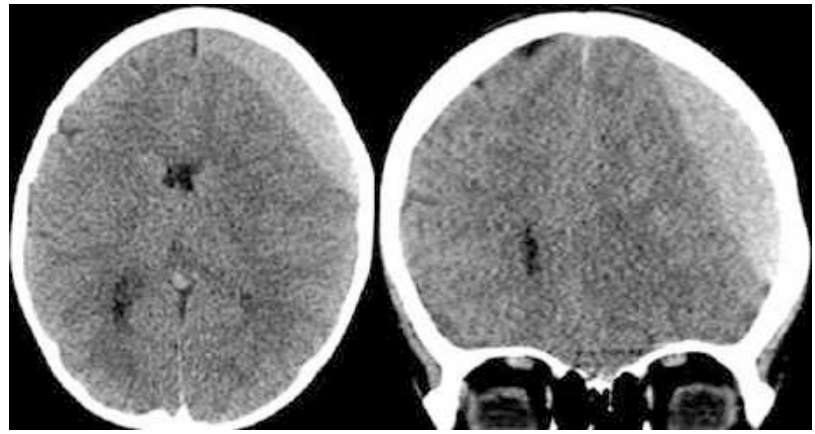

Fig. 174.3 Axial and coronal non-contrast CT of the brain demonstrating a left frontal subdural hemorrhage in a 3 year-old child on aspirin therapy who suffered a minor head trauma

Generally, if the etiology of subarachnoid hemorrhage is not apparent on CT or MR angiogram, a formal angiogram is warranted. Subarachnoid hemorrhage (see Fig. 174.2) is associated with transient cardiac dysfunction in the absence of primary cardiac disease, complicating its management in patients who do harbor underlying cardiac dysfunction.

Superficial to the arachnoid layer is the dura mater and potential subdural space. Bridging veins (veins that cross the subarachnoid space to connect with the dural venous sinuses) travel in this space. In the setting of cerebral atrophy, relatively little force is required to stretch bridging veins sufficiently to cause rupture and hemorrhage into the subdural space. The sequelae of subdural hemorrhage (SDH, see Fig. 174.3) range from asymptomatic to catastrophic. Anticoagulated patients are at a higher than normal risk of spontaneous or non-traumatic subdural hematomas [3]. Patients who are taking anticoagulation are additionally at a significantly higher risk of increased mortality from SDH [4].

The epidural space is a potential space between the inner table of the skull and the dura mater. Most frequently, epidural hematomas within the cranial vault occur in the setting of trauma with a resultant skull fracture that traverses one of the meningeal arteries, classically, the middle meningeal artery. Nevertheless, venous bleeding and bleeding from unidentified sources are not uncommon [5]. Epidural hematomas (see Fig. 174.4) are very rare in a non-traumatic setting. Patients are generally managed in an emergent fashion with close follow-up for nonsurgical cases and surgical evacuation when indicated.

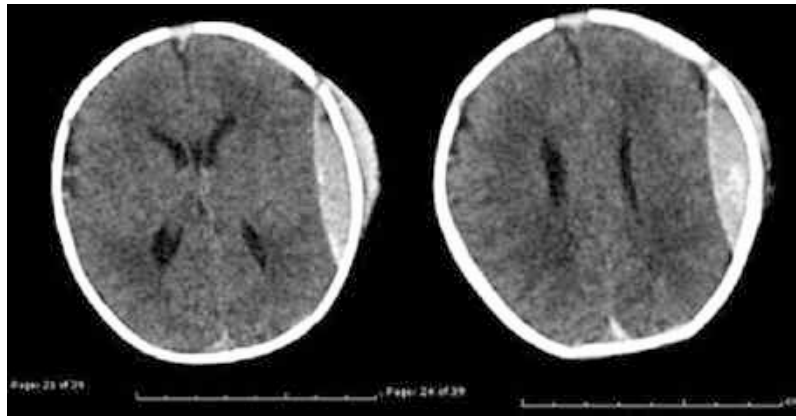

Fig. 174.4 Axial non-contrast CT scan of a newborn with a ventricular septal defect (VSD), coarctation of the aorta and mitral stenosis whose delivery required vacuum assist and was complicated by an epidural hematoma (EDH). The coarctation was repaired but VSD repair was deferred due to concerns regarding anti-coagulation with the EDH, which did not require surgery. Her VSD was repaired at 3 months of age

Incidence of Hemorrhage

Open Surgery Versus Endovascular

In the setting of intervention for cardiovascular disease, the incidence of intracranial hemorrhage varies by type of procedure performed, reason for intervention, and existing comorbidities. The majority of the literature regarding the incidence of hemorrhagic complications exists in adult patients, so this review will focus on the studies performed in children, although some of the data described is derived from adult populations.

A postmortem pathologic study of children who had undergone cardiac transplantation showed that 87 % of this population had an intracranial abnormality. Of those abnormalities, extra-parenchymal (subarachnoid, subdural, or epidural) hemorrhage was found in 16 % of children. Extra-parenchymal hemorrhage, as well as other intracranial abnormalities, was plotted against the indication for orthotopic cardiac transplantation (cyanotic, hypoplastic left heart syndrome, restrictive, obstructive, and intracardiac shunt). No etiology demonstrated a significantly increased rate of intracranial hemorrhage relative to other etiologies, although only 82 brain examinations were performed.

In pediatric transplant populations, the incidence of intracranial bleeding identified at autopsy is considerably higher than the clinically significant rate of intracranial hemorrhage. In a study of 43 pediatric heart transplant patients over 20 years, no early or late mortality due to a neurologic complication was reported [6]. In another study of 47 pediatric patients who underwent 50 orthotopic transplantations, there was one late mortality from intracranial hemorrhage. No other morbidity or mortality due to intracranial bleeding was reported [7].

The data on pediatric endovascular cardiac interventions and/or diagnostic procedures and intracranial hemorrhage is quite limited due to the low incidence of intracranial hemorrhage. One study reviewed 2,953 diagnostic angiograms and 695 interventional procedures and found two patients who suffered an intracranial hemorrhage. Thrombotic complications outnumbered hemorrhagic complications seven to one. Interventional procedures were significantly more likely to be associated with a neurologic complication than diagnostic procedures [8].

Patients Requiring Mechanical Cardiac Support (ECMO, Ventricular Assist)

Children who are placed on extracorporeal membrane oxygenation (ECMO) as a life-saving maneuver are at especially high risk of intracranial hemorrhage due to the systemic anticoagulation required for the procedure as well as the associated medical comorbidities. A retrospective study of the Extracorporeal Life Support Organization (ELSO) Registry, which reviewed 33,100 patients over the course of 20 years (31,335 patients were under 18 years of age), reported a 7.6 % rate of intracranial hemorrhage in the pediatric age group. Overall survival to discharge or transfer after being placed on ECMO was 63 %. In the patient group that suffered an intracranial hemorrhage, only 36 % survived to hospital discharge. There was a statistically significant difference in the incidence of intracranial hemorrhage between children and adults (7.6 % and 2.9 %, respectively). It was also found that children who were younger than 30 days old had an 8.2 % incidence of intracranial hemorrhage, while those who were older than 30 days old had an incidence of 5.4 %. There is also a significantly increased risk of intracerebral hemorrhage for patients undergoing ECMO for cardiac indications (8.4 %) versus pulmonary indications (7.0 %). Among patients from their home institution, the authors reported that 81 were found to have intracranial hemorrhage, three (3.7 %) of which underwent craniotomy. One of those patients died, one has cerebral palsy but was in high school at the time of the paper's publication, and one is neurologically normal [9].

Hemorrhage in Patients Undergoing Antiplatelet and Anticoagulation Therapy

The use of anticoagulants and antiplatelet agents during and after cardiac surgery and interventional procedures is required in many cases. In adult populations, oral anticoagulant use is among the most common causes of fatal intracranial bleeding [10]. The current literature regarding this topic primarily describes adult populations. In adults, it is estimated that between 5 % and 12 % of all intracerebral hemorrhage is secondary to oral anticoagulant use. The risk of intracranial hemorrhage also varies based on the indication for oral anticoagulant therapy [10]. Pooled analysis of all patients undergoing oral anticoagulation has shown that the risk of suffering an intracranial hemorrhage in well-controlled patients is around 0.4 % per year. Age-matched controls who are not on oral anticoagulants have an approximately 0.23 % per year risk of intracranial hemorrhage, yielding an absolute risk increase of 0.2 % per year for patients on oral anticoagulants [11]. Regardless of the indication for anticoagulation, there is a significantly increased risk of intracranial hemorrhage in patients with an international normalized ratio (INR) greater than 4.0–5.0. In a case-control study, Hylek and Singer demonstrated an odds ratio for intracerebral hemorrhage of 2.1 for each 0.5-point increase in prothrombin time ratio [12].

Timing of Anticoagulation or Antiplatelet Agents in Patients with Intracranial Bleeding After Cardiac Intervention

For patients who have suffered a spontaneous intracranial hemorrhage but require chronic anticoagulant or antiplatelet therapy, the optimal timing of therapy resumption has not been well defined. A systematic review of published studies on the subject of patients with mechanical heart valves and intracranial hemorrhage revealed only case series and case reports with no randomized controlled trials [13]. A pooled statistical analysis of the data from these studies was not possible due to the heterogeneity of the data. The authors concluded, however, that withholding vitamin K antagonists entailed an approximately 0.06 % per day risk of thromboembolism. As such, they concluded that a period of 7–14 days off therapy following spontaneous ICH to be reasonable.

The largest and most comprehensive study on the subject of intracranial hemorrhage in the setting of oral anticoagulant therapy to date [14] reviewed 2,869 consecutive intracranial hemorrhages. This study was not specific to pediatric patients and represents a heterogeneous group of adult patients. Of these, 234 patients were found to be taking oral anticoagulation for a wide variety of reasons, including mechanical heart valves, atrial fibrillation, and other cardiac indications. Statistical analysis of this group of patients demonstrated that the risk of restarting oral anticoagulation versus the risk of suffering an ischemic stroke while not taking anticoagulation resulted in an optimal restart time of 10–30 weeks following the initial hemorrhage.

Acute Management

Timing of Neurosurgical Consultation

Intracranial bleeding in the setting of a cardiac intervention or cardiac surgery should prompt neurosurgical consultation. In many circumstances, hemorrhage is discovered incidentally or does not result in neurological impairment. Nevertheless, even small intracranial hemorrhages have the potential for significant expansion with resultant neurological deterioration. Current evidence does not provide guidelines for the management of pediatric patients with complex cardiovascular illness that has been further complicated by intracranial hemorrhage. As such, an individualized multidisciplinary approach is indicated. In general, this includes contributions from pediatric cardiology, cardiac surgery, critical care, and neurosurgery.

Correction of Coagulopathy and Acute Systemic Management

In the setting of an acute hemorrhage, rapid reversal of coagulopathy, iatrogenic or otherwise, is almost universally recommended. Traditionally, fresh frozen plasma has been used as the primary agent for correction of coagulopathy associated with oral anticoagulation. Administration and correction of coagulopathy with FFP can be slow and put patients at risk of worsening hemorrhage. In recent years, administration of prothrombin complex concentrates (PCC) has been advocated, and evidence is accumulating regarding the risk of causing thrombotic complication balanced by correction of life-threatening coagulopathy [15]. Patients who are taking oral vitamin K antagonists should also receive IV vitamin K.

Patients who suffer an intracranial hemorrhage often suffer from elevations in blood pressure, especially in the acute term. The elevation in blood pressure may be a result of numerous causes, including the brain's attempt at autoregulation when hypoperfusion exists as a result of intracranial hemorrhage, activation and/or dysregulation of an autonomic nervous system response, or a combination of these or other factors. Patients who suffer ischemic strokes often benefit from allowing blood pressure to remain elevated above normal parameters, but only recently have data demonstrating that aggressive blood pressure management, defined as maintaining systolic blood pressure less than 140 mmHg, in patients with intraparenchymal hematomas may lower risk of death and disability [16].

Hyperglycemia is common among patients with intracranial injury, and many studies have shown that poor glycemic control correlates with poor outcome in patients with neurosurgical emergencies. Current recommendations from the AHA/ASA state that hypoglycemia should be strictly avoided but that optimal glycemic goals have not been clarified by the literature to date, though normoglycemia is recommended [15].

Fever has been correlated with poor outcome in animal models of intracerebral hemorrhage. Potential mechanisms include increasing intracranial pressure, aggravating cerebral edema worse, and magnifying ischemic injury. There is also a correlation between worsened outcome and fever in patients with subarachnoid hemorrhage. Though fever control is recommended, various strategies can lead to shivering, which could

theoretically decrease oxygen delivery to the brain [17].

Patients who suffer any brain injury are more susceptible to seizure activity. Current guidelines from the AHA/ASA recommend treatment of clinical seizures with antiepileptic medications and that prophylactic agents should not be used in the setting of intracerebral hemorrhage [15].

Many patients who suffer intracranial hemorrhage are candidates for surgical evacuation of a hematoma, external drainage of cerebrospinal fluid, and/or placement of an intracranial monitoring device. The large spectrum of types, locations, surgical accessibility, and benefit that might be achieved through surgery should prompt neurosurgical consultation in all instances of intracranial hemorrhage. Patients who appear to potentially have intracranial hypertension on imaging of the brain and have a neurologic exam that cannot be consistently followed (usually defined as a GCS less than or equal to 8) generally are candidates for placement of either an external ventricular drain (EVD) or intracranial pressure monitor in order to guide medical treatment for intracranial hypertension. In some instances, medical management is insufficient to control intracranial pressure, and EVD placement, decompressive craniectomy, and/or evacuation of an intracerebral hematoma are indicated.

Subacute Management

Timing of Cardiac Intervention in Neonates with Intracranial Hemorrhage (IVH, SDH)

Current evidence does not provide guidelines with respect to the timing of cardiac surgery in patients who have suffered an intracranial hemorrhage. Block and colleagues [18] prospectively obtained MRIs of the brain in 92 neonates with congenital heart disease prior to cardiac intervention and again following cardiopulmonary bypass. Preoperative "brain injury" (stroke, white matter injury, or intraventricular hemorrhage) was present in 40 (43 %) subjects. The authors found that the preoperative injury did not progress in any patients following surgery. However, a new lesion was noted in 32/78(40 %) neonates who had a postoperative MRI. In addition to this, there were also 12 new subdural hematomas noted on postoperative imaging. None of these required surgical intervention.

An additional study of infants with cardiac defects obtained MRIs following birth and post-cardiac surgery [19]. Preoperative imaging demonstrated that 13/21 (62 %) of infants who were born vaginally had evidence of intracerebral hemorrhage in the form of subdural hemorrhage. The majority of the hemorrhages were along the tentorium cerebelli, but there were hemorrhages identified within the choroid plexus, intraventricular hemorrhage, and one intraparenchymal hemorrhage. Postoperative MRI showed that 43 % of the hemorrhages had increased in size, 30 % were unchanged, and 26 % were smaller. All infants were neurologically asymptomatic both prior and following cardiac surgery.

Although many cases of intracranial hemorrhage in the anticoagulated population do not require surgical intervention, there are multiple studies that describe more clinically consequential hemorrhages [20–23]. Although these reports describe adult patients, the risk is likely similar in the pediatric population. As such, neurosurgical consultation is recommended in any case where intracranial hemorrhage is identified.

Chronic Management

Hydrocephalus and Neurological Deficits

Many infants who suffer from intracranial hemorrhage go on to develop other conditions that require neurosurgical intervention. The primary complication is hydrocephalus, which occurs most frequently in patients who suffer from intraventricular hemorrhage. In this group, the incidence of hydrocephalus is 30–40 % [20, 24]. Cerebrospinal fluid (CSF) diversion in the form of a ventriculo-peritoneal shunt is the most common therapeutic procedure. Other methods of

CSF diversion include external ventricular drainage, ventriculo-subgaleal shunting, and endoscopic third ventriculostomy. The appropriate procedure should be selected on an individual basis.

In many cases, a significant intracranial hemorrhage results in a chronic neurological deficit. Although this spectrum of resultant disability is extraordinarily broad, children often make significant improvements following an initial neurological insult. Following recovery from the acute event, a multidisciplinary team that includes neurosurgeons, neurologists, neuropsychologists, and/or physical medicine and rehabilitation physicians will generally provide long-term care in the hope of maximizing the patient's neurological recovery.

Conclusions

Children with significant cardiovascular illness are at elevated risk of intracranial hemorrhage both due to the underlying disease process and the procedures that may be required to treat their primary disease. There are multiple intracranial compartments in which hemorrhage can occur, each with a unique risk of neurological injury and need for surgical intervention. Fortunately, most cases of intracranial hemorrhage in this setting do not require surgical intervention. Nevertheless, neurosurgical consultation is recommended in any patient in whom intracranial hemorrhage is identified.

Neurologic Complications and Neuromonitoring in Pediatric Congenital Heart Disease

175

Philip Overby

Abstract

Congenital anomalies are the most common cause for infant mortality in the USA, and congenital cardiac anomalies are the most common type of anomaly. Children with congenital heart disease are at increased risk for adverse neurologic outcomes from a range of causes, both congenital and acquired. Neurological injury can result from recognized acute. The goal of neuromonitoring is to detect neurological events early or even before it occurs to minimize or prevent injury. This chapter will provide an overview of the types of neurological pathologies associated with congenital heart disease, as well as forms of neuromonitoring available perioperatively and postoperatively, the aims of which are maximizing neurological outcomes.

Keywords

Acquired brain insult • Brain plasticity • Congenital heart disease • Congenital brain malformation • Neurologic injury • Neurologic outcomes • Neuromonitoring • Perioperative • Periventricular leukoencephalomalacia • Postoperative • Seizures • Stroke

Introduction

Congenital anomalies are the most common cause for infant mortality in the USA, and congenital cardiac anomalies are the most common type of anomaly [1, 2]. Approximately 40,000 children are born in the USA with congenital heart disease (CHD), half of whom will require corrective or palliative intervention in the first year of life and the majority of whom will survive, often to adulthood [3]. Children with CHD are at increased risk for adverse neurologic outcomes from a range of causes, both congenital and acquired. Neurological injury can result from recognized acute insults such as hemorrhagic strokes, ischemic strokes, seizures, or infections. In addition, this population is at increased risk for learning disabilities and behavioral disturbances [4–6]. The goal of neuromonitoring is to detect neurological events early or even before it occurs to minimize or prevent injury. This chapter will provide an

overview of the types of neurological pathologies associated with CHD, as well as forms of neuromonitoring available perioperatively and postoperatively, the aims of which are maximizing neurological outcomes.

Types of Neurological Injury

Congenital Insults

Approximately one third of children with CHD have noncardiac congenital anomalies. Some genetic conditions are known to be associated with CHD, such as trisomy 13, 18, or 21, Williams syndrome, CHARGE and VACTERL associations, and the 22q11 deletion syndromes (e.g., DiGeorge). Children with CHD, particularly hypoplastic left heart syndrome, have also been found to have a higher incidence of congenital brain malformations [7].

Acquired Insults

Unstable CHD can result in hypoxia and ischemia from inadequate cerebral perfusion pressure. Cerebral perfusion pressure is equal to mean arterial pressure minus intracranial pressure. That is, CPP = MAP-ICP. Decreased cardiac output, left-to-right shunting, or unstable cardiac rhythms can lower CPP beneath critical thresholds. Alternatively, elevated right atrial pressures can diminish cerebral venous return, increase ICP, and ultimately lead to decreased CPP. Management of critically ill patients with high central venous pressures should take into consideration the possibility of compromised CPP.

Both intrauterine and perinatal insults in patients with CHD have been described. White matter injury such as periventricular leukomalacia (PVL) is illustrative of how injury can occur. PVL has typically been associated with premature infants and is thought to reflect vulnerability of developing oligodendrocytes to hypoxia, ischemia, and inflammation. Oligodendrocytes are the glial cells responsible for central myelination. Premature infants have immature, limited cerebral autoregulation. This, in combination with the vulnerability of developing oligodendrocytes, can result in PVL [8]. Patients with transposition of the great arteries (TGA) in particular have been found to have similar MR spectroscopy profiles to children with PVL, in part due to altered cerebral perfusion [9, 10]. In utero, brain injury in children with CHD is multifactorial and has recently been reviewed. Abnormal prenatal imaging was noted in 33–59 % of the studies reviewed, which included a wide range of congenital cardiac anomalies. Findings similar to PVL have also been seen in infants following cardiac surgery [9, 11]. While the mechanism of injury in term infants is likely not identical to preterm infants, in both cases PVL on neuroimaging is associated with impaired neurologic outcomes [12].

Strokes

When evaluated prospectively, ¼ of children with strokes have cardiac disease [13]. The incidence of acute ischemic stroke in patients less than 18 years of age with congenital heart disease was 0.13 % (132/100,000) [13]. The incidence of stroke in the general population of children <18 years of age in the same study was 0.01 % (10.7/100,000). Similarly, the incidence of stroke in adult patients with CHD is 10–100 times higher than controlled populations [14].

Established risk factors for ischemic stroke in the general pediatric population are congenital heart disease, sickle cell disease, thrombophilic states, preceding viral infections, and arterial dissection [15]. Cardiac-specific risk factors include cardiac catheterization, cardiac surgery, extracorporeal membrane oxygenation, cardiomyopathy, cardiac arrhythmia, and valvular disease. The mechanism is typically cardio-embolic. Hemorrhagic strokes can result from reperfusion of an ischemic insult, vascular malformations, and thrombocytopenia or in the setting of anticoagulation. Posterior reversible encephalopathy syndrome or PRES with seizures and/or ischemic and hemorrhagic strokes, typically in the setting of immune suppression, is an entity well described in the transplant literature [16].

In all children with a history of stroke, the largest study reports 74 % of children had a neurologic deficit upon hospital discharge [17]. Childhood stroke is also associated with an increased risk of seizures, learning disabilities, and behavioral abnormalities [18, 19].

Despite the high incidence and associated morbidity of stroke in pediatric cardiac disease, basic questions about optimal management of prevention and treatment remain. The optimal regimen for anticoagulation as primary prevention remains at the level of expert opinion. No randomized controlled trials have been published except in sickle cell disease. Once ischemic stroke has been diagnosed, recommendations on acute anticoagulation vary. The American College of Chest Physicians (ACCP) guidelines call for anticoagulation with low molecular weight heparin (LMWH) until a source for embolism: cardiac or arterial dissection is excluded. The Royal College of Physicians (RCP) recommends aspirin therapy 1–3 mg/kg until a cardio-embolic source has been identified. The American Heart Association (AHA) guidelines allow for either approach [20–22]. For secondary stroke prevention in instances of pediatric cardio-embolic disease, anticoagulation with warfarin or LMWH is recommended by the RCP and ACCP guidelines.

Seizures

The incidence of clinical postoperative seizures ranges from 6 % to 20 % [23, 24]. In the case of strokes due to ischemia or hemorrhage, seizures are a marker of neurological injury. Seizures themselves can cause neuronal cell loss and synaptic reorganization (i.e., brain injury) as is discussed in more detail below.

Brain Plasticity and Neurologic Outcomes

Brain insults range in severity and can be focal or diffuse and isolated or comorbid with other conditions. They occur at different stages of brain development, in children with different underlying capacities, and in different socioeconomic conditions. These factors among many others make providing neurologic prognosis in the setting of CHD challenging, to say the least [4].

While the developing brain is capable of plasticity, there is also evidence of increased vulnerability to insult. This has resulted in competing outlooks on prognosis. On the one hand, young children demonstrate remarkable plasticity. For example, perinatal stroke in the left hemisphere where language is typically dominant or early removal of the dominant hemisphere in children less than 4 years of age can nevertheless be followed by the development of language in the unaffected hemisphere. This provides evidence for plasticity: synaptic formation and dendritic connection into functional networks to a degree not seen later in normal development. On the other hand, it has been argued that because young developing neural networks are immature, they are more vulnerable to injury and worse neurologic outcomes at early stages of development. Since cognition is dependent on the integrated functioning of multiple separate structures and networks, early injury results in dysfunctional networks.

Outcome studies for children with acquired brain injuries have mixed results. A recent prospective study of children with unilateral (focal) perinatal strokes demonstrated that these children began with lower IQs from age-matched controls, but their cognitive development progressed at the same rate [25]. This suggests that the developing brain can adapt to acquired insults. The exception to this in the study was patients with seizures, in whom there was a decline in cognitive functioning over time. How much of this decline was due to seizure medications vs. uncontrolled seizures was not addressed in the study. However, the association of poor cognitive outcomes with uncontrolled seizures has long been recognized [26, 27]. Recent studies have also shown that early brain injuries are associated with worse cognitive outcomes in multiple domains and that vulnerability in different domains may be linked to different stages of brain development [28, 29]. Patients from the Boston Circulatory Arrest Study Group with transposition of the

great arteries act as evidence for plasticity in the young. Compared to controls, these patients at initial follow-up had more seizures, worse motor outcomes, and lower IQ scores (93) [30]. However, at 8 years of age, their average IQ had improved to near normal (98). The improvement in IQ in the Boston Circulatory Arrest suggests that plasticity allows for improvements many years after the insult. Despite their recovery in IQ, the same patients continued to have difficulties with higher levels of functioning, such as sustained attention and language skills. This reflects a more general trend in children with CHD, namely, that learning disabilities and behavioral issues are more prevalent than strokes and seizures [4–6]. This indicates a neurological vulnerability in patients with CHD that cannot simply be attributed to the more readily recognizable insults that strokes and seizures represent.

Ethical Questions

Pediatric neurologists are commonly consulted regarding the neurologic prognosis of a patient with CHD, before and after their surgical repair or following a perceived neurologic injury. In particular, one of the most challenging clinical situations is when an acquired neurologic insult potentially alters a patient's candidacy for a heart transplant. In adults, mental retardation is considered a relative contraindication to cardiac transplant, a practice that recently has been called into question [31]. An IQ of <70 (the definition of MR) has been reported in more than 50 % of children with CHD <6 years old undergoing transplant [32]. While the child with acquired brain injury will often perform worse than controls, the outcomes are variable and predictions for individual patients lack precision.

Pediatric hearts available for transplant represent a limited resource. In addition, children with neurological impairments incur significant cost to the healthcare system. Nonetheless, there are many children born with neurological impairments who do not have routine medical care and often have extraordinary care, particularly rescue therapy, withheld from them on this basis. In young children with CHD in particular, the question of when not to proceed with transplant is illustrative of a larger question, namely, when is neurologic injury sufficient to impact ongoing medical care and/or further surgical intervention? This question extends well beyond CHD and this review. The approach to this dilemma will vary widely based on the individual providers, the institutions, and the culture and environment of the individual healthcare delivery system. This includes influences of religion, politics, and national standards.

Neuromonitoring

In the intensive care unit (ICU), numerous devices exist for continuous or intermittent monitoring of vital signs as well as functioning of end organs such as blood pressure, pulmonary function, blood gas composition, and urine output to name a few. At the current time, however, there is limited monitoring of the brain.

The purpose of monitoring is to track trends of the clinical course in an effort to anticipate clinical worsening and improve outcomes. Monitoring of the brain is an important part of ICU care, because insults to the brain are often associated with poor outcomes and irreversible injury. Injury to the brain can happen quickly, and the brains' capacity to repair itself is limited. Preventing and avoiding injury are much more effective at producing better neurological outcomes than any other therapeutic options following injury. Traditionally and currently, brain monitoring takes the form of the bedside neurological exam. In addition, imaging modalities such as MRI and CT provide information on brain structure. To an increasing degree, however, innovations in monitoring, invasive and noninvasive, are being employed throughout ICUs around the world.

Types of Neuromonitoring

The most familiar form of neuromonitoring beyond the clinical exam is the measurement of intracranial pressure (ICP). This has been

employed since the 1970s. ICP monitoring generally takes one of two forms. For example, a catheter can be placed in the subarachnoid space. This type of device measures ICP but offers no means of intervention. Alternatively, an externalized ventricular drain (or EVD) can be placed. This requires placement of a burr hole and threading of the catheter through the brain parenchyma into the lateral ventricle. The advantage of the EVD is that it allows both measurement and intervention. That is, cerebral spinal fluid (CSF) can be drained to maintain a goal intracranial pressure (ICP). Cerebral perfusion pressure (CPP) is affected by elevated ICP. CPP is equivalent to mean arterial pressure minus intracranial pressure, i.e., CPP = MAP – ICP. Therefore, ICP measurements along with blood pressure measurements allow goals to be set to maintain CPP levels. Adequate CPP has been shown to affect neurologic outcomes in particular populations such as traumatic brain injury.

Other forms of invasive neuromonitoring are sometimes combined with an EVD and electroencephalography (EEG) for "multimodality monitoring" or "bundles." A typical invasive "bundle" is an EVD, with an adjacent device to measure the partial pressure of oxygen in brain tissue (usually a "Licox" monitor), and microdialysate monitors, also placed in the brain parenchyma. This latter methodology is used to measure lactate and pyruvate levels or lactate/pyruvate ratios. An elevated lactate can be seen with ischemia and a depressed pyruvate represents increased metabolic demand, e.g., with a seizure. Both are sampled intermittently. They offer a view of the metabolic milieu of the brain, as a means of following clinical status and measuring the efficacy of interventions. To date, these devices have had limited use in the pediatric population.

One limitation of these devices is that the ideal location for placement is uncertain. That is, in a patient with a stroke should the unaffected area far from the injury be monitored in order to monitor for further injury, or should an immediately adjacent region to the injury that is more likely to suffer further injury be the site of device placement. Current practice varies from placing the devices in the area of "penumbral" tissue, i.e., the tissue surrounding the insult, to placing bilateral devices in affected and unaffected tissue. The devices need to be sampled intermittently and are then recorded. Another limitation is that the devices are invasive and therefore carry the inherent risk of bleeding, infection, and potentially aggravating further injury with placement and insertion. Currently, the state of the art in adult neurocritical care units is that multiple devices are employed simultaneously, and data is synthesized at the bedside to assist in treatment decisions.

Two additional types of monitoring are noninvasive: continuous video EEG (cEEG) and near-infrared spectroscopy (NIRS).

NIRS

NIRS is an old technology that is being used increasingly in adult and pediatric ICUs [33]. Near-infrared spectroscopy is a noninvasive technology used to follow trends in regional tissue oxygenation. In particular, NIRS predominantly measures oxygenation of blood in the venules, in a much higher proportion than that of the arteries and capillaries. Cerebral blood is typically 25 % in the arterial compartment and 75 % in the venous compartment. The measure of blood oxygen saturation is influenced by brain oxygen delivery, consumption, extraction, and the ratio of arterial to venous blood. While it cannot provide a precise measurement of tissue oxygenation, NIRS is a well-validated means of following trends and is currently employed in the operating room for many congenital heart surgeries. NIRS values have been shown to correlate well with other measures of systemic perfusion such as venous saturation of the jugular bulb (SjO2) and central SvO2 from the superior caval vein during cardiac surgery [34]. Utilizing principles similar to those utilized for pulse oximetry, NIRS devices express numeric values as a percentage from 15 % to 95 %, known as the regional cerebral saturation index (rScO2) [35]. In healthy neonates, infants, children, and animal models, rScO2 ranges from 60 % to 80 %. In piglet

models, EEG deteriorates at 45 % and neurologic injury increases by the hour at levels less than 40 % [36, 37]. This suggests that there is at least a 20 % buffer between normal levels and dangerous levels of hypoxia/ischemia. How this applies in cyanotic congenital heart disease, however, where adaptations to chronic hypoxemia are present, is uncertain. However, even in this setting, a worsening rScO2 may help clinicians at the bedside anticipate worsening cerebral perfusion. A study employing NIRS, EEG, and transcranial Doppler in the OR found that 70 % of patients who suffered adverse neurological outcomes had a significant change in at least one of these variables. While EEG detected 5 % of these abnormalities, TCD detected 37 % and NIRS 58 % [38].

NIRS has the advantage of being noninvasive. One of its limitations is that it monitors a limited area of the brain. Typically it is placed bifrontally, though some practitioners are using it over the vertex to be closer to the sagittal sinus to reflect more global venous drainage. Like other forms of neuromonitoring, or monitoring in general, it does not provide a full reflection of injured, healthy, or threatened brain. Like any monitoring device, NIRS values must be interpreted in their clinical context. The expectation is that addressing a sustained rScO2 decrease from baseline may provide clinicians at the bedside the opportunity to improve cerebral oxygenation and perfusion and improve neurologic outcomes [39].

cEEG

Continuous EEG is now used regularly in critical care units, particularly in the setting of encephalopathy, status epilepticus, or repetitive seizures [40]. Its technical advantages are that it provides excellent temporal and spatial brain monitoring. That is, data is gathered continuously and reflects a broad area of cerebral cortex. The first application for cEEG in the ICU remains its primary one, which is to detect seizures. As part of a seminal prospective study on status epilepticus by Delorenzo in 1998 in patients, it was observed that adults who presented in *convulsive* status epilepticus (CSE) went on to have *nonconvulsive* seizures (NCS) in 48 % of cases with nonconvulsive status epilepticus (NCSE) in 14 % [41]. These were patients in whom the visible, convulsive seizures had stopped but who were monitored with continuous EEG for the first 24 h after presenting in CSE. That is, their seizures were detected only on EEG. Since then, numerous studies on the incidence of nonconvulsive seizures (NCS) and nonconvulsive status epilepticus (NCSE) have been performed. Depending on the particular subpopulation of patients, the incidence of nonconvulsive seizures and nonconvulsive status epilepticus in comatose ICU patients ranges from 8 % to 48 % [42, 43].

The significance of nonconvulsive seizures in terms of outcome remains controversial. While it is well accepted that prolonged convulsive seizures are associated with neuronal injury, the degree to which this is the case for nonconvulsive seizures is still uncertain. In humans and animal models, convulsive status epilepticus resulting in cell loss and synaptic reorganization is well established [44, 45]. Whether this is true at all, or to the same degree, in nonconvulsive seizures is uncertain. Nevertheless, a prospective randomized trial will likely never be performed due to obvious ethical concerns about leaving electrographic seizures untreated.

Literature on the incidence of NCS in the pediatric population is limited, but increasing. When all patients undergoing cEEG monitoring are included, the incidence of NCS ranges from 23 % to 44 % in critically ill children who are monitored [46, 47]. Of course, the patients selected for cEEG monitoring vary among themselves. The pediatric diagnoses with the highest incidence of NCS are epilepsy, stroke, and hypoxic-ischemic encephalopathy [48]. In studies from 1973 to 1984, the quoted incidence of postoperative *clinical* seizures in patients undergoing congenital heart surgery is 4–10 % [49]. In the Boston Circulatory Arrest study evaluating two techniques for bypass in patients undergoing surgical repair of transposition of the great arteries, 20 % of 136 patients had *electrographic* seizures within 48 h of surgery [49]. Moreover, the electrographic seizures preceded clinical seizures

anywhere from a few hours to up to 20 h. This finding suggests that early use and application of cEEG should be considered when evaluating a critically ill patient who may be having nonclinical seizures. Upon neurological follow-up at 1 year, based on structured examination of motor outcomes and structural changes on MRI, there was a trend towards worse neurological outcomes, with definite neurological abnormalities in 33 % of patients who had seizures vs. 17 % in those who did not. However, this discrepancy did not reach statistical significance ($p = .10$).

More recently, in infants undergoing congenital heart surgery at the Children's Hospital of Philadelphia (CHOP), the incidence of nonconvulsive seizures postoperatively was 11.5 % within a group of 183 patients [50]. A follow-up study of this cohort at 1 year did not show a difference in developmental outcomes at 1 year between the patients with and without electrographic seizures. However, as the authors note, it is not at all clear that it can therefore be concluded that the seizures were inconsequential. First, the study was not adequately powered to detect a difference in outcome between the patients with and without seizures. Second, neurological injury may not be fully apparent at 1 year of life. Furthermore, more subtle impairments may only be discovered with subsequent testing. Future studies with longer follow-up and more extensive diagnostic evaluation may demonstrate a difference in the outcomes. One final consideration is that, unlike the Boston Circulatory Arrest Study, the patients in the CHOP study were in fact treated with seizure medications, potentially altering their outcomes.

Conclusions

As outcomes from surgery for congenital heart disease improve, neurologic outcomes in CHD have gained growing attention, particularly in the past decade. With decreased perioperative morbidity and mortality, long-term neurologic outcomes impact the ability of our patients to function as independent adults in society. Acute complications of surgery for CHD include strokes, infections, and seizures and provide opportunities for aggressive and early intervention. However, more subtle impairments in learning, attention, and behavior are becoming more prevalent in those who have experienced acute neurologic injuries following cardiac surgery. In each instance, questions arise as to what modifiable risk factors affect neurologic outcome, what are the mechanisms of injury, and what means are available to detect neurologic insults. Along with other forms of cardiovascular monitoring and continuous EEG, the goal of neuromonitoring is to provide early warning signs of impending neurological injury. This may provide an opportunity for clinicians, who are caring for these vulnerable patients, to act with timely interventions that diminish or even avert poor neurological outcomes.

Therapeutic Hypothermia After Cardiac Arrest

176

Emily L. Dobyns

Abstract

Therapeutic hypothermia after cardiac arrest, in adults and neonates, has been associated with improved survival and neurologic outcome. This approach has its roots in induced hypothermia for cardiopulmonary bypass, though historically, the temperatures targeted during bypass are much lower than in therapeutic hypothermia. Techniques used in therapeutic mild hypothermia range from whole-body cooling to selective head cooling. Overall, this appears to be a relatively low risk and well-tolerated endeavor. Evidence would also support that a slow and methodical rewarming phase is at least as important as the cooling phase. To date there have been no prospective studies in pediatric patients that agree with the benefit of mild hypothermia, as has been seen in adults and neonates. A large, prospective, and multicenter pediatric study is currently in progress.

Keywords

Hypothermia • Hypoxic-ischemic encephalopathy • Induced mild hypothermia • Pediatric cardiac arrest • Rewarming • Selective head cooling • Targeted temperature management • THAPCA • Trial of therapeutic hypothermia after pediatric cardiac arrest • Whole-body cooling

Introduction

Approximately 16,000 children in the USA suffer a cardiac arrest each year [1]. Sixty percent or more of these children will achieve return of circulation; however, the 1-year survival rate is less than 35 %, many with significant neurological sequela [2, 3]. Hypoxic-ischemic encephalopathy is the major cause of this post-resuscitation morbidity and mortality.

Mild, induced hypothermia improves survival and neurologic outcome after cardiac arrest in adult patients [4, 5]. Selective head cooling in birth-asphyxiated newborns has been associated with improved outcomes [6]. Induced hypothermia has been used in cardiac surgery

since 1952 [7]. Minimal neurological injury is seen with deep hypothermic arrest times of 30 min in neonates cooled to 18–20 °C [8]. However, the effects of therapeutic hypothermia in comatose pediatric patients post-cardiac arrest are not well known.

In the 1970s, Conn described neurologically intact survivors following ice water near drowning [9]. Comatose, near-drowning victims treated with hypothermia and barbiturates appeared to have a better outcome. However, the use of this combined therapy was abandoned when it was found to be associated with an increased risk of neutropenia, sepsis, and death [9, 10]. The complications of this earlier therapy may have been related to the use of more intense hypothermia (30–33 °C), prolonged duration of hypothermia, and the concomitant use of barbiturate coma. Induced mild hypothermia is reemerging in the management of comatose survivors post-cardiac arrest.

The depth of hypothermia in recent studies is not as intense as reported by Conn et al., but no generally accepted terminology for the grading of hypothermia currently exists. Mild hypothermia has been used for temperature range between 32 °C and 34 °C by the American Heart Association and European Resuscitation Council [11]. More recently, a jury convened by the American Thoracic Society, European Respiratory Society, European Society of Intensive Care Medicine, Society of Critical Care Medicine, and Société de Réanimation de Langue Française has recommended that the term *targeted temperature management* replace *therapeutic hypothermia* and that descriptors such as *mild* be replaced with explicit targeted temperature management profiles [12].

Pathophysiology

Global hypoxic-ischemic encephalopathy in children most commonly results from asphyxial cardiac arrest. Respiratory failure leads to hypoxemia, hypercarbia, and acidosis. Hypotension, pulseless electrical activity, and asystole follow. The patient becomes unconscious within seconds of cessation of cerebral circulation and the neuronal oxygen stores become depleted. Complete cerebral anoxia with loss of brain glucose and ATP stores occur within 5 min [13]. This energy failure results in uncontrolled release of excitatory amino acid compounds leading to depolarization and release of calcium stores. Increases in cytosolic calcium lead to the formation of membrane transport pores in the mitochondrial membrane [14]. The leakage of cytosolic compounds into the mitochondria destroys the respiratory chain and mitochondria itself, ultimately leading to cell death.

The return of spontaneous circulation (ROSC) results in reperfusion and restoration of oxygen delivery to the injured brain. Oxygen and nitrogen free radicals are formed in excess of free radical scavengers [15, 16]. These free radicals cause further cell damage by lipid peroxidation, DNA damage, and induction of apoptosis. Additional oxidative injury results from inflammation and the formation of cerebral eicosanoids.

Post-ischemic cerebral hemodynamic disturbances result from release of vasoactive agents (endothelin-1, nitric oxide). A transient, reactive global hyperemia related to vasoparalysis occurs immediately after cerebral anoxia. This is followed by a prolonged global, multifocal hypoperfusion. The blood–brain barrier is disrupted and cerebral edema occurs.

Neuroprotection

Therapeutic hypothermia involves multiple processes that lead to neuronal protection [15–17]. Hypothermia reduces cerebral metabolism as reflected by depression of electrical activity on EEG, oxygen demand, and carbon dioxide production. Metabolism is reduced by 5–8 % per degree Celsius fall in core temperature [15]. Hypothermia inhibits the release of glutamate and dopamine attenuating excitotoxicity. Additionally, mild hypothermia induces brain-derived neurotrophic factor reducing glutamate and infarct size in an animal model of stroke [18]. Hypothermia also acts as an

immunomodulator by reducing neutrophil function and infiltration, lipid peroxidation, and leukotriene production [19, 20]. Hypothermia inhibits the induction of programmed cell death seen after ischemia by preventing calcium influx/overload, glutamate release, and translocation of cytochrome C into the cytosol.

Clinical Studies in *Adults*

Two landmark studies comparing mild hypothermia with normothermia in comatose adult survivors of out-of-hospital cardiac arrest were published in 2002 and have greatly influenced the treatment of patients post-cardiac arrest [4, 5].

The Hypothermia After Cardiac Arrest (HACA) Study Group included nine centers in five European countries [4]. This was a randomized, controlled trial with blinded assessment of the outcome. Patients were eligible if they were between 18 and 75 years of age, they had a witnessed cardiac arrest, presenting rhythm was ventricular fibrillation or ventricular tachycardia, only 5–15 min elapsed before initiation of cardiopulmonary resuscitation (CPR), and they experienced return of spontaneous circulation (ROSC) within 60 min.

Patients randomly assigned to the hypothermia group were cooled to 32–34 °C using a cooling mattress. The goal was to reach the target temperature within 4 h of ROSC, maintain it for 24 h, and then passively rewarm them.

Two hundred seventy-five patients were enrolled, 137 randomized to the hypothermia group, and 138 randomized to the normothermia group. The target temperature could not be achieved in 19 patients in the hypothermia group. Both groups were similar at enrollment. Primary outcome was defined using the Pittsburgh Cerebral Performance Scale at 6 months. Seventy-five of the 136 (55 %) patients in the hypothermia group had a favorable outcome defined as being able to live independently and work at least part-time at 6 months, compared to 54 of 138 (39 %) in the normothermia group (RR 1.40, 95 % CI 1.08–1.81, NNT = 6). The rate of death at 6 months after cardiac arrest was 14 percentage points lower in the hypothermia group. There were 56 deaths in 137 (41 %) patients in the hypothermia group versus 76 of 138 (55 %) in the normothermia group (RR 0.74, 95 % CI 0.58–0.95, NNT = 7).

The total number of complications was not significantly different in the hypothermia compared to the normothermia groups. However, there were 22 % more complications in the hypothermia group, particularly pneumonia (number needed to harm = 12), bleeding (NNH = 14), and sepsis (NNH = 16).

Bernard's group conducted their study in four hospitals in Melbourne, Australia [5]. Patients were enrolled if they had an initial rhythm of ventricular fibrillation at the time of arrival of the ambulance, successful ROSC, and persistent coma after ROSC and were being transferred to a participating hospital. Exclusion criteria included age less than 18 years for men, age less than 50 years for women, cardiogenic shock, and noncardiac causes for coma. Eligible patients were assigned to hypothermia or normothermia according to the day of the month. Paramedics initiated hypothermia in the field by removing the patient's clothing and applying cold packs to the head and torso. Cold packs were continued in the hospital until core temperature reached 33 °C. Cooling was maintained for 12 h following arrival to the hospital after which patients were actively rewarmed. Target temperature for the normothermia group was 37 °C.

Seventy-seven patients were enrolled, 43 into the hypothermia group and 34 to the normothermia group. Baseline characteristics were similar for both groups. Primary outcome was discharge from the hospital, with discharge home or to a rehabilitation facility considered a good outcome. Twenty-one of 43 (49 %) patients in the hypothermia group were considered to have a good outcome compared to 9 of 34 (26 %) in the normothermia group (RR 1.85, 95 % CI 0.97–3.49, NNT = 4). Mortality at discharge was 22 of 43 (51 %) in the hypothermia group and 23 of 34 (68 %) in the normothermia group (RR 0.76, 95 % CI 0.52–1.10, NNT = 6).

Although none of the adverse events reached statistical significance, the hypothermia group did have lower cardiac index, higher systemic vascular resistance, and more hyperglycemia than those in the normothermia group.

Clinical Studies in *Pediatrics*

Selective head cooling has been used to treat newborn infants with birth asphyxia. Several randomized trials have shown that term infants with moderate to severe encephalopathy cooled to rectal temperature of 34.5 °C for 72 h have an improved survival and less disability at 18 months compared to conventional care [6, 21, 22].

Doherty et al. in 2009 presented a 2-year retrospective study from five centers to determine the effect of hypothermia therapy in pediatric patients with cardiac arrest on mortality and functional outcome [23]. Two hundred twenty-two pediatric patients with cardiac arrest were identified. Seventy-nine patients met eligibility criteria: between 40 weeks post-gestational age and 18 years, 3 min or more of cardiac arrest, survived at least 12 h post-ROSC, and intensive care unit admission. Twenty-nine patients were treated with hypothermia (33.7 ± 1.3 °C) for 20.8 ± 11.9 h. The cause of arrest was cardiac in 55 patients, respiratory in 16, cardiorespiratory in seven, and unknown in one patient. The majority of the 79 patients (45/50 normothermia vs. 22/29 hypothermia) had a chronic illness before the cardiac arrest. All but four (three normothermia vs. one hypothermia) of these cardiac arrests occurred in the in-hospital setting. Hypothermia therapy was associated with higher mortality and worse functional outcome than normothermia. However, hypothermia therapy no longer had a statistically significant adverse impact on survival or functional outcome when regression modeling was used to adjust for duration of cardiac arrest, use of ECMO, and propensity scores.

Fink et al. in 2010 reported a single-center retrospective cohort study of hypothermia after pediatric cardiac arrest [24]. One hundred eighty-one pediatric patients suffered a cardiac arrest. Ninety-one percent of these arrests were asphyxia in origin and 52 % occurred in the in-hospital setting. Forty patients received therapeutic hypothermia (33.5–34.8 °C) for 16–48 h. There was no difference in hospital mortality (55 % hypothermia vs. 55.3 % standard therapy) between the two cohorts. In multivariate analysis, mortality was independently associated with initial hypoglycemia or hyperglycemia, number of doses of epinephrine during resuscitation, asphyxial etiology, and longer duration of cardiopulmonary resuscitation.

Topjian et al. in 2011 presented a feasibility study of surface cooling protocol of 12 pediatric patients post-arrest [25]. Using a standardized approach, the investigators were able to achieve hypothermia (32–34 °C) in 6 h and maintain it for 24 h. Half of the patients survived. Adverse events included hypokalemia in 67 % and bradycardia in 58 %, and there were no significant bleeding events or ventricular tachyarrhythmias.

Three multicenter cohort studies of pediatric cardiac arrest have been reported and have been used to help design a multicenter, interventional trial of hypothermia after pediatric cardiac arrest [26–28]. Four hundred ninety-one patients between the ages of 24 h to 18 years who achieved return of spontaneous circulation following either in- (353) or out-of-hospital (138) cardiac arrest were reviewed to determine whether significant differences existed between groups. Use of hypothermia post-arrest was less than 5 % in each cohort. Mortality was greater in the out-of-hospital cohort and more often attributable to a neurological indication than in the in-hospital cohort [26]. The 353 pediatric patients who suffered an in-hospital cardiac arrest and identified in the above study were reviewed to identify factors associated with hospital mortality [27]. Preexisting hematologic, oncologic, or immunologic disorders, genetic or metabolic disorders, presence of an endotracheal tube before the arrest, and the use of sodium bicarbonate during the arrest were associated with increased in hospital mortality. Postoperative cardiopulmonary resuscitation was associated with decreased mortality in this population. The 138 patients with out-of-hospital pediatric cardiac arrest were reviewed for characteristics associated

with increased survival [28]. Using multivariate logistic model of variables available at the time of arrest found the administration of atropine and epinephrine to be associated with mortality. A second model using information available up to 12 h after return of spontaneous circulation found preexisting lung or airway disease, drowning or asphyxia as etiology, higher pH, and bilateral reactive pupils to be associated with lower mortality. More than three doses of epinephrine were associated with poor outcome in 44/46 cases. A multicenter, randomized, controlled trial of therapeutic hypothermia after pediatric cardiac arrest (THAPCA) is enrolling patients within 6 h of achieving ROSC after either in- or out-of-hospital arrest (clinicaltrials.gov). An 18-month vanguard report of the THAPCA trial confirmed study feasibility and patient safety [29].

Data from the use of therapeutic hypothermia in adults post-cardiac arrest is already being extrapolated to the treatment of pediatric patients post-arrest. However, data specific to pediatric patients are needed from multicenter randomized pediatric trial(s) to evaluate the benefits and potential harms of therapeutic hypothermia after pediatric cardiac arrests since this population is clearly different. The majority of adult studies have described a fairly homogeneous population with approximately 60 % of adult cardiac arrests resulting from ventricular arrhythmias (ventricular fibrillation or ventricular tachycardia) [3]. Similarly, the neonatal studies have described infants with birth asphyxia. Pediatric patients with cardiac arrest are a much more heterogeneous population. Hypoxia and shock are the most common causes of pediatric arrest [3]. In-hospital pediatric cardiac arrest patients often have underlying conditions that may lead to insidious deterioration and arrest [23]. The developing brain of pediatric patients may respond differently to hypoxic ischemia and reperfusion [14]. Hypothermic protection may be more pronounced in younger gerbils but the animal data is somewhat conflicting [30, 31]. Additionally, there is a developmental change in neuronal vulnerability to hypoxic-ischemic injury with infants less than 1 year of age showing a relative sparing of the cortex and cerebellum compared to older children and adults [14].

Cooling Techniques and Monitoring

A variety of cooling methods exist; however, which is best remains under investigation. However, early implementation of hypothermia appears to be important. In a canine model of ventricular fibrillation cardiac arrest, the application of hypothermia early in resuscitation was associated with increased intact survival [32, 33]. In 49 consecutive adult patients who had been successfully resuscitated from cardiac arrest, early achievement of mild therapeutic hypothermia appeared to reduce hypoxic injury and favor good neurological outcome [34]. Furthermore, the time needed to achieve the target temperature of 33 °C was an independent predictor for good outcome, and with every hour delay, the chance of favorable neurological recovery was reduced by 31 %.

Surface Cooling

To date, most clinical trials have used surface cooling. Surface cooling devices are noninvasive and range from simple ice packs to machines with automatic feedback controls. Although the ease of application is appealing, simple cooling methods often depend on intensive nursing care, may overshoot the temperature range, rewarm unintentionally, and are relatively slow to reach the core temperature [35]. Ice packs applied to the head, neck, and body have a fairly slow rate of cooling-0.9 °C/h [5]. Other commonly used surface methods include cooling blankets, fan with lukewarm bath, reducing the temperature of the room and ventilator humidification system [4, 5, 36].

Several novel surface cooling methods are in early clinical trials. Ice water immersion provides a rapid method for cooling in hyperthermic healthy volunteers and is able to cool anesthetized healthy normothermic volunteers to 34 °C in 20 min [37, 38]. This principle is used by a novel surface cooling device (ThermoSuit System, Life Recovery Systems, Kinnelon, NJ) which was used in a feasibility multicenter trial of 24 post-cardiac

arrest adults [39]. Rapid cooling to the target temperature (32–34 °C) was achieved at a median rate of 3 °C/h. Six-month survival was 68 %, with 87 % of survivors living independently.

Another novel cooling method is a pad composed of graphite and water (EMCOOLS Pads, Emcools, Vienna, Austria). These pads were precooled and applied after admission to the hospital to post-cardiac arrest adults [40]. Patients were cooled to 32–34 °C at a cooling rate of 3.4 °C/h. An advantage of this device is that no power supply is required, so it can be used by EMS in the prehospital setting to rapidly cool out-of-hospital patients post-cardiac arrest [41].

Another novel cooling device that is independent of an external energy source and may prove useful in the prehospital setting is the RhinoChill device (BeneChill, Inc., San Diego, USA). This surface cooling technique sprays a convective coolant via a catheter into the nasal cavity at flow rates of 40–50 L/min [42]. Nasopharyngeal cooling was used for 1 hour in 84 patients who had been successfully resuscitated from cardiac arrest. Tympanic temperature was reduced by a median of 2.3 °C then controlled with systemic cooling at 33 °C. There were minor adverse events; 34/84 patients survived with 26/34 with favorable neurological outcomes (Cerebral Performance Categories 1–2) at discharge.

Invasive Cooling

Central venous infusion of 40 ml/kg normal saline over 30 min in healthy adults achieved a temperature reduction of 2.5 °C [43]. Similarly the infusion of 30 ml/kg cold Ringer's lactate over 30 min in 22 comatose cardiac arrest survivors resulted in median core temperature from 35.5 °C to 33.8 °C [44]. These patients also demonstrated significant improvements in mean arterial blood pressure, renal function, and acid–base balance. Additionally, none of the patients developed pulmonary edema. Fink et al. induced hypothermia in 18 pediatric patients with brain injury or post-cardiac arrest with 18 ± 10 ml/kg iced normal saline over 10–15 min [45]. Temperature decreased from 37 °C to 35 °C 1 hour post-infusion. Mean arterial blood pressure and oxygenation parameters were unchanged. Serum sodium and international normalized ratio were significantly increased after infusion.

Choice of fluids for infusion does not appear to effect safety or effectiveness. Although a bolus of cold fluid can induce hypothermia, it cannot maintain mild therapeutic hypothermia [46]. Infusion of cold fluids can be combined with other methods of cooling to speed and maintain therapeutic hypothermia. One hundred thirty-four adults with a variety of neurological injuries were cooled using cooling blankets and the infusion of ice-cold fluids [47]. Core temperature decreased by a rate of 4 °C/h, mean arterial pressure increased, but no patient developed pulmonary edema.

Endovascular cooling is an investigational method of invasive cooling. A catheter (CoolGard, Alsius, Irvine, CA) containing circulating saline at a controlled temperature is placed in a large central vein [48, 49]. Fluid is then pumped through this catheter by a bedside heat exchanger with temperature feedback from the patient to control core temperature. Two feasibility trials have used this technology to successfully cool adult patients post-cardiac arrest [48, 49]. Al-Senani et al. terminated the study due to bleeding from the insertion site in two patients. There are several drawbacks to this technique (placement into a large vessel, expense of equipment, and need for specialized training to place catheters), and its use will likely be restricted to the hospital setting [49].

Other invasive methods that have been shown to be effective in animal models of cardiac arrest include total liquid ventilation with perfluorocarbons and drugs, such as an analogue of neurotensin given intravenously [50, 51].

Rewarming

The optimal duration of cooling remains uncertain. Duration in the above trials ranged from 12 to 72 h. Longer duration of cooling may be beneficial. Adult patients with traumatic brain injury

cooled for two days had significant increase in intracranial pressure and poorer outcomes at 6 months when compared to those cooled for 5 days [52].

The rate of rewarming after hypothermia is controversial, but rapid rewarming (15–20 min) in rodent models of traumatic brain injury appears to reverse the protective effects of hypothermia [53]. "Slow" rewarming (120 min) decreased markers of axonal injury and infarct size in these same rodent models [54, 55].

One hundred sixty-five otherwise healthy adults requiring coronary artery bypass grafting using cardiopulmonary bypass and hypothermia to 28–32 °C were randomized to fast (100 patients) versus slow (65 patients) rewarming. Those patients who were rewarmed slowly had significantly better neurocognitive function at 6 weeks compared to those in the fast rewarming group [56].

Fink et al. recommend that rewarming occur no faster than 0.5 °C every 2 h due to the risk of cerebral hyperperfusion and vasogenic edema [35, 51]. This is the same rate of rewarming used in the current THAPCA trials. Continuous temperature monitoring has been recommended for 48 h post-rewarming to maintain normothermia and to recognize and treat fever.

Monitoring and Adverse Effects

No serious adverse events associated with therapeutic hypothermia have been noted in the major randomized trials in either adults or neonates.

Cardiovascular and Hemodynamics

Therapeutic hypothermia can lead to bradycardia and increased vascular resistance [5]. A subset of 70 adult patients from a multicenter trial of hypothermia post-cardiac arrest followed with Holter monitors for 24 h showed that the risk of serious arrhythmias remains low at 33 °C but increases with temperatures below 30 °C [57]. Despite these reassuring data, invasive monitoring of heart rate and blood pressure is recommended.

Temperature Control

As stated above, the risk of arrhythmia increases with temperatures below 30 °C; therefore, it is important to monitor core and surface temperatures continuously. Some centers use both esophageal and rectal thermometers, one for monitor display and the other to drive the cooling blanket [36].

Sedation, Analgesia, and Neuromuscular Blockade

Use of short-acting narcotics (remifentanil, fentanyl) and intermittent benzodiazepines (lorazepam, midazolam) provides pain and sedation control while still permitting frequent neurological exams.

Once cooled to goal temperature, few patients shiver; however, shivering raises energy and oxygen demands potentially counteracting the beneficial effects of therapeutic hypothermia [58]. Muscle relaxation may be required during the maintenance phase of therapeutic hypothermia to sustain target temperature [4, 5, 23, 36]. Short-acting agents such as vecuronium and cisatracurium may be used with cisatracurium preferred in patients with liver dysfunction. The use of muscle relaxation may conceal seizures; therefore, monitoring continuous EEG should be considered.

Hypothermia affects drug levels, drug metabolism, and duration of action. Furthermore, the clearance of many drugs routinely used in critical care settings is altered by hypothermia [59]. The changes in drug metabolism seen during cooling may be reversed during rewarming, enhancing the risk of over- or underdosing drugs.

Risk of Infection

In addition to the effects on inflammation and immune function, hypothermia may delay the

detection of infection by suppressing the appearance of fever. Increased risk of sepsis and pneumonia has been reported in adults treated with hypothermia [4, 60]. However, neither Fink nor Doherty reported an increased rate of infection in the cohort of children treated with hypothermia [24, 36]. Irrespective, it seems prudent to remove vascular and urinary catheters as soon as possible and to obtain daily surveillance cultures.

Electrolytes

Metabolic, pancreatic, and renal abnormalities have been reported in patients with head injury who were treated with hypothermia [61, 62]. Fink et al. reported that the hypothermia patients received more frequent electrolyte supplementation [24]. In the HACA trial, no significant electrolyte abnormalities were seen [4]. Since it is unclear which factors (etiology of injury and/or age) impact electrolyte balance, close attention should be paid to fluid and electrolyte balance.

Hematology and Clotting

Coagulation abnormalities have been described at increased depths of hypothermia; therefore, preexisting coagulopathy has been included as an exclusion criterion for many of the clinical trials of hypothermia [63]. None of the clinical trials have reported major bleeding complications attributable to hypothermia. Several smaller trials have reported bleeding at the site of catheter placement while the patient was being actively cooled [53, 63].

Conclusions

Therapeutic hypothermia appears to be safe with rare adverse events. There are multiple techniques available to cool patients, but the best method and timing of application post-arrest remain uncertain. The duration of cooling and method of rewarming have varied and require additional study.

Use in comatose adults post-cardiac arrest and in neonates with birth asphyxia has been associated with improved survival and neurological outcomes. Retrospective, cohort studies of the use of hypothermia in pediatric patients post-cardiac arrest have not been associated with the same improvement in outcomes. A large, multicenter, randomized, controlled trial of therapeutic hypothermia post-cardiac arrest in pediatrics is in progress.

However, based on the published evidence available in 2003, the Advanced Life Support Task Force of the International Liaison Committee on Resuscitation [64] made the following recommendations:

1. Cool to 32–34 °C for 12–24 h an unconscious adult patient with SROC following an out-of-hospital cardiac arrest where the initial rhythm was ventricular fibrillation.
2. Cooling may also be beneficial for other rhythms or in-hospital cardiac arrests.

Sepsis and the Cardiac Patient: Diagnosis and Management

177

Jennifer Exo

Abstract

Sepsis and septic shock may occur in the child with underlying heart disease and require rapid recognition and institution of appropriate therapy to achieve best outcomes. Treatment includes judicious fluid resuscitation, identification of the infection nidus, and treatment with effective antibiotic therapy. The application of cardiovascular therapies (including inotropes and vasopressors) will be dictated by the patient's clinical exam and underlying cardiac pathology and anatomy.

Keywords

Acute renal failure • Adrenal insufficiency • Antibiotic therapy • Catecholamine-resistant shock • Continuous veno-venous hemofiltration/dialysis • Dopamine-resistant shock • Extracorporeal membrane oxygenation • Fluid overload • Fluid-refractory shock • Inotropes • Invasive hemodynamic monitoring • Resuscitation • Sepsis • Sepsis-induced myocardial depression • Septic shock • Vasopressors

Introduction

Sepsis is a major cause of morbidity and mortality in children, and the pathophysiology of sepsis and septic shock is complex and incompletely understood. The shock state in sepsis is the culmination of multiple problems, including infection and the patient's inflammatory response to infection, myocardial depression, and pathologic alterations in blood flow to vital organs. The prevalence of pediatric sepsis, particularly in patients with chronic illness, makes it an important disease state for health-care providers to rapidly identify and effectively treat. Patients with underlying cardiac pathologies, both congenital and acquired, are particularly complex to treat and require an understanding of the effects of sepsis and its treatment on the diseased heart.

Definitions

Several useful definitions have been developed to describe the spectrum of conditions associated with infection and infection-related shock [1].

Table 177.1 Consensus definitions for pediatric SIRS, infection, sepsis, severe sepsis, and septic shock (Adapted from Goldstein et al. [1] and Wheeler et al. [44])

Systemic inflammatory response syndrome (SIRS)
The presence of at least two of the following criteria, of which one must be abnormal temperature or leukocyte count:
Core temperature > 38.5 °C or < 36 °C (by rectal, bladder, oral, or central catheter probe)
Tachycardia, defined as mean heart rate > 2 SD for age (in the absence of pain, fever, drug therapy) or otherwise persistent elevation over a 0.5–4 h time period
Bradycardia, defined as mean heart rate < 10th percentile for age in the absence of drug therapy or presence of congenital heart disease over 0.5 h time period (criterion applies to children < 1 year of age)
Mean respiratory rate > 2 SD above normal for age or mechanical ventilation (not for underlying neuromuscular disease or receipt of general anesthesia)
Leukocyte count elevated or depressed for age (not due to chemotherapy = induced leukopenia) or >10 % immature neutrophils
Infection
Suspected or proven infection caused by any pathogen or a clinical syndrome associated with a high probability of infection (e.g., presence of white blood cells in a normally sterile body fluid, chest radiograph consistent with pneumonia, petechial or purpuric rash)
Sepsis
SIRS + infection
Severe sepsis
Sepsis plus either cardiovascular dysfunction or acute respiratory distress syndrome (ARDS) or two or more other organ dysfunctions
Septic shock
Sepsis and cardiovascular organ dysfunction

An *infection* is characterized by the presence of organisms in normally sterile host tissue or the inflammatory response to the presence of those organisms. The *systemic inflammatory response* (*SIRS*) is indicated by the presence of two or more of the following: temperature >38°C or <36°C, heart rate greater than two standard deviations above normal for age, respiratory rate greater than two standard deviations above normal for age or need for mechanical ventilation not related to neuromuscular weakness or administration of anesthesia, and white blood cell count >12,000 cells/ml^3 or less than 4,000 cells/ml^3 or >10 % band forms [1]. *Sepsis* is defined as the presence of SIRS in the context of infection, and severe sepsis is uniformly defined as sepsis and organ failure determined by various organ failure scores (Tables 177.1 and 177.2) [1]. *Septic shock* has been defined as infection with hypothermia or hyperthermia, tachycardia (may be absent if with hypothermia), and altered mental status, in the presence of one or more of the following: decreased peripheral pulses compared with central pulses, capillary refill prolonged more than 2 s (cold shock) or flash capillary refill (warm shock), mottled or cool extremities (cold shock), and decreased urine output (<1 ml/kg/h). In 2002, the American College of Critical Care Medicine provided several other hemodynamic definitions of shock, including fluid-refractory/dopamine-resistant shock (shock persisting despite ≥60 ml/kg of fluid resuscitation and dopamine infusion to 10 μg/kg/min), catecholamine-resistant shock (shock persisting despite using direct-acting catecholamines, such as epinephrine and norepinephrine), and refractory shock (shock persisting despite goal-directed use of inotropic agents, vasopressor, vasodilators, and maintenance of metabolic and hormonal homeostasis) [2]. Importantly, hypotension (systolic blood pressure less than the fifth percentile for age) is frequently observed late in the progression of septic shock and may herald impending cardiovascular collapse. Severe sepsis and septic shock often lead to the development of multiple organ failure, particularly in the context

Table 177.2 Consensus definitions for pediatric organ dysfunction (Adapted from Goldstein et al. [1] and Wheeler et al. [44])

Cardiovascular dysfunction
Despite administration of isotonic intravenous fluid bolus $\geq$ 40 ml/kg in 1 h:
Decrease in BP (hypotension) $<$ 5th percentile for age or systolic BP $<$ 2 SD below normal for age, or
Need for vasoactive drug to maintain BP in normal range (dopamine $\geq$ 5 μg/kg/min or dobutamine, epinephrine, norepinephrine, or vasopressin at any dose, or
Two of the following:
Unexplained metabolic acidosis (base deficit $>$ 5.0 mEq/l)
Increased arterial lactate $>$2 times upper limit of normal
Oliguria (urine output $<$ 0.5 ml/kg/h)
Prolonged capillary refill ($>$5 s)
Core to peripheral temperature gap $>$ 3 °C
Respiratory dysfunction
One of the following criteria:
$Pa_{O2}/Fi_{O2} < 300$ in the absence of cyanotic congenital heart disease or preexisting lung disease
$Pa_{CO2} > 65$ Torr or 20 mmHg over baseline Pa_{CO2}
Proven need or $>$ 50 % FI_{O2} to maintain saturation $\geq$ 92 %
Need for nonelective invasive or noninvasive mechanical ventilation
Neurologic dysfunction
One of the following criteria:
Glasgow Coma Score $\leq$ 11
Acute change in mental status with a decrease in Glasgow Coma Score $\geq$ 3 points from abnormal baseline
Hematologic dysfunction
One of the following criteria:
Platelet count $<$ 80,000/mm^3 or a decline of 50 % in platelet count from highest value recorded over past 3 days (for chronic hematology/oncology patients)
International normalized ratio $\geq$ 2
Renal dysfunction
Serum creatinine $\geq$ 2 times upper limit of normal for age or twofold increase in baseline level
Hepatic dysfunction
One of the following criteria:
Total bilirubin $\geq$ 4 mg/dl (not applicable for newborns)
ALT two times upper limit of normal for age

of delayed resuscitation or inadequate source control (ineffective nidus removal or antibiotic regimen). Risk of mortality rises in proportion to the number of concomitant organ failures [3].

Burden of Pediatric Sepsis

The mortality rate attributed to septic shock in children in the USA has steadily improved over the last five decades with the development of neonatal and pediatric intensive care (from 97 % to 9 %) [4–7]. The Children's National Medical Center reported a 57 % mortality rate in children with septic shock in 1985, which significantly improved to 12 % following the adoption of aggressive fluid resuscitation therapy for these patients [8]. In 2002, the American College of Critical Care Medicine (ACCM) published the Clinical Practice Parameters for Hemodynamic Support of Pediatric and Neonatal Shock [2], in part, to provide a framework of "best clinical practices" for the management of children with sepsis. Subsequent to this publication, two centers have reported improved outcomes (overall mortality between 6 % and 10 %)

in children with septic shock following the implementation of the 2002 ACCM guidelines [3, 9]. In addition, analysis of an inpatient database (Kids' Inpatient Database) in 2003 found that hospital mortality from severe sepsis was estimated to be 4.2 % (2.3 % in previously healthy children, 7.8 % in children with chronic illness) [10].

Despite improvements in mortality, the financial and long-term care burdens of newborn and pediatric sepsis in the USA are increasing [7]. More children die in association with severe sepsis (sepsis with associated organ failure) than from cancer, and the estimated annual health-care cost of pediatric sepsis in the USA is four billion dollars [7]. One half of the children with sepsis are neonates, and the majority of the pediatric populations with severe sepsis have an underlying chronic illness. Chronic cardiovascular and neurologic illness are most common in infants less than 1 year old with severe sepsis, while cancer and immunodeficiency are most common in children (1–18 years old) with severe sepsis [7].

It is therefore likely that a health-care provider treating pediatric patients with chronic cardiac disease will encounter a child with heart disease and concomitant septic shock, and it is critical that he or she understands the effects of sepsis and its treatment on the heart and other organ systems.

There are relatively few studies describing the epidemiology of sepsis in critically ill children with congenital heart disease [11–13], and generally these describe patients who develop sepsis secondary to hospital-acquired infections (e.g., catheter-associated bloodstream infections and ventilator-associated respiratory infections) [13–16] which are associated with increased mortality and length of hospital stay [13].

Sepsis-Induced Myocardial and Hemodynamic Dysfunction

While it has been established that vasomotor paralysis is a primary cause of hemodynamic dysfunction in adult patients with septic shock, pediatric patients most often suffer from low cardiac output leading to impaired oxygen delivery and cardiovascular collapse [17–19]. Sepsis-induced myocardial dysfunction in adults appears to be linked to changes in their systemic vascular resistance. In contrast, the cardiovascular collapse identified in children with sepsis appears intrinsic to the myocardium and unrelated to changes in systemic vascular tone [20].

The mechanisms of sepsis-induced myocardial dysfunction in children remain unclear and cannot be explained by hypoperfusion-induced damage to cardiomyocytes alone. Pro-inflammatory cytokines (particularly TNF-α and IL-1β) have been shown to impair cardiomyocyte function, although the intracellular mechanisms by which they affect these cells have not been elucidated [21, 22]. Several other mechanisms of sepsis-induced myocardial dysfunction in adult patients have been proposed, including autonomic dysregulation, alterations in microcirculation and myofibrillar function, mitochondrial failure, and pathologic calcium trafficking [23–25], but their relevance to the pediatric experience is unknown. Interestingly, these changes in myocardial performance appear to be reversible in the majority of patients, with cardiac function in survivors returning to normal within 7–10 days [25–27]. However, organ failure, due in some proportion to sepsis-induced myocardial dysfunction, may still lead to significant morbidity and mortality [28].

Echocardiography is frequently used to evaluate for sepsis-related myocardial depression. In adults with septic shock, echocardiography has identified significantly decreased ejection fraction and ventricular dilation in the context of normal or increased cardiac output [26]. Few studies have used echocardiography to examine myocardial function in septic children. Feltes and colleagues found an impaired ventricular contractility frequency rate of 40 % that resolved in all affected patients within 3–6 days [27]. Basu et al. [29] demonstrated that speckle tracking imaging could be used to identify impairments in the myocardial performance of children with sepsis that were not found by

standard echocardiographic measurements (e.g., ejection fraction and fractional shortening), which are influenced by myocardial preload and afterload and significantly altered by volume status and vascular resistance in the context of sepsis. Cardiac serum biomarkers also indicate the presence of direct myocardial injury in sepsis. Troponin I, the inhibitory subunit of the troponin complex of the cardiomyocyte contractile apparatus, is released upon disruption of the cardiomyocyte cell membrane and can be detected within minutes to hours in serum and lymphatics [30]. In adults with sepsis and septic shock, 50–80 % of patients have increased troponin I levels [31–33]. Studies in children with meningococcal sepsis have demonstrated increased serum levels of troponin I, but a portion of the patients with the highest levels also had EKG findings consistent with myocardial ischemia [34]. In a study of children with generalized septic shock not attributed to meningococcal infection, Fenton and colleagues showed that troponin I levels were significantly increased in half of the patients early in their disease course and were associated with decreased ejection fraction and fractional shortening by echocardiography [35]. B-type natriuretic peptide (BNP), the cleavage product of the precursor molecule pro-BNP, is synthesized by the atrial and ventricular myocardium and has natriuretic and vasodilatory effects [36]. Myocardial stress resulting in increased left ventricular wall stress and/or end-diastolic pressure is believed to increase production of BNP [37], and serum BNP levels have been validated as a diagnostic marker for congestive heart failure in children [38, 39]. Several studies have established that adults with septic shock have increased BNP measurements [40–42]. In one of the few studies examining BNP levels in pediatric sepsis, Domico et al. [43] found that children with septic shock had significantly elevated BNP levels. Interestingly, BNP levels measured 12 h after admission correlated directly with Pediatric Risk of Mortality III scores and inversely with shortening fraction measured by echocardiogram.

Risk and Severity of Sepsis in Children with Underlying Heart Disease

In their recent review of sepsis in the pediatric cardiac intensive care unit, Wheeler and colleagues [44] provide a comprehensive discussion of the additional factors increasing the risk of sepsis in children with underlying heart disease. In addition to the well-known risk factors of extremes of age [6, 7, 45], male gender [46, 47], malnutrition and obesity [48–50], and chronic illness [6, 7], several other conditions make the child with congenital heart disease particularly vulnerable. Trisomy 21 and 22q11 deletion or DiGeorge sequence is associated with congenital heart abnormalities and immunologic defects. Chronic hypoxia in children with cyanotic heart disease may affect both innate and adaptive immunity [51]. The palliative and corrective procedures undergone by children with heart disease often require invasive monitoring, increasing their risk of hospital-acquired infection, including catheter-associated bloodstream and ventilator-associated respiratory infections. Cardiopulmonary bypass elicits a systemic inflammatory response that activates leukocytes, endothelium, and the complement cascade and induces the release of pro-inflammatory cytokines [52–54]. This condition can result in a transient state of immune paralysis, increasing the risk of sepsis [14, 55].

Infection and the Immune Response

Endotoxins, components of the cell walls of yeast and fungus, and toxins associated with some gram-positive bacteria, mycobacteria, and viruses activate the polymorphonuclear neutrophils (PMNs), monocytes, and macrophages of the innate immune system. These cells phagocytose and kill these microorganisms, and monocytes and macrophages present antigens from these killed microorganisms to circulating T lymphocytes. These circulating T lymphocytes coordinate the adaptive immune response, which includes the generation of

cytotoxic T cells and natural killer cells. Antibodies are produced by B lymphocytes, and opsonization with antibodies allows more efficient recognition, killing, and clearing of microorganisms by the reticulo-endothelial system.

The activated inflammatory cells also initiate cytokine release. The pro-inflammatory cytokines IL-8 and interferon-gamma promote immune cell-mediated killing, and anti-inflammatory cytokines IL-4, IL-10, and soluble TNF receptor turn off the immune response when the infection has been cleared. They also stimulate nitric oxide (NO) production, which leads to vasodilation and formation of peroxynitrite (ONOO–), which participates in killing microorganisms. Cytokines increase expression of adhesion molecules that facilitate white blood cell rolling and adhesion, guiding activated inflammatory cells to the site of infection. The cytokines also induce a change in the endothelium to a prothrombotic and antifibrinolytic state, and the thrombus isolates the infection and allows vascular remodeling.

If the immune response is unable to clear the infection, inflammation becomes uncontrolled, and systemic organ injury ensues [56] (Fig. 177.1). Pro-inflammatory cytokines can contribute to cardiovascular dysfunction, and peroxynitrite can cause DNA damage and energy failure leading to cell death. Thrombosis and antifibrinolysis become systemic, and persistent consumption of procoagulant factors can lead to simultaneous thrombosis and bleeding. The anti-inflammatory response also becomes deranged, when interleukin-10 reduces the ability of immune cells to kill microorganisms.

Treatment of Sepsis and Septic Shock

While the 2002 ACCM Clinical Practice Parameters for Hemodynamic Support of Pediatric and Neonatal Septic Shock [2] and the 2007 update [57] (Fig. 177.2) were published as a set of "best clinical practices" for the management of these critically ill patients, they do not address modifications in treatment and monitoring that may be necessary in children with underlying heart disease and septic shock. In fact, indiscreet application of these recommendations to such patients may adversely impact their care, and a "one-size-fits-all" approach to treatment is not likely to be successful [44]. Instead, it is critical that monitoring modalities, treatment, and therapeutic endpoints be determined within the context of the individual patient's underlying cardiac anatomy and physiology.

Goal-Directed Therapy in Sepsis and Septic Shock

Early recognition and resuscitation of shock has improved outcome in critically ill infants and children with septic shock [58, 59]. Han and colleagues [58] found that every hour that passed with hypotension or capillary refill longer than 2 s was associated with increased mortality in children with community-acquired septic shock. A Brazilian trial showed that management implementing the 2002 ACCM Clinical Practice Parameters for Hemodynamic Support of Pediatric and Neonatal Septic Shock and targeting superior vena cava saturations of >70 % resulted in improved mortality and reduced organ dysfunction [59]. Good outcomes in children with septic shock are associated with a cardiac index between 3.3 and 6.0 l/min/m^2 [18], and a sustained cardiac index below 2 l/min/m^2 is associated with death in neonates after cardiac surgery [60]. As such, the 2002 ACCM Clinical Practice Parameters for Hemodynamic Support of Pediatric and Neonatal Septic Shock emphasizes early use of therapies to attain several time-sensitive goals, specifically: (1) first-hour fluid resuscitation and inotrope therapy directed to goals of threshold heart rates, normal blood pressure, and capillary refill ≤ 2 s and (2) subsequent hemodynamic support directed to goals of central venous oxygen saturation >70 % and cardiac index 3.3–6.0 l/min/m^2 [2].

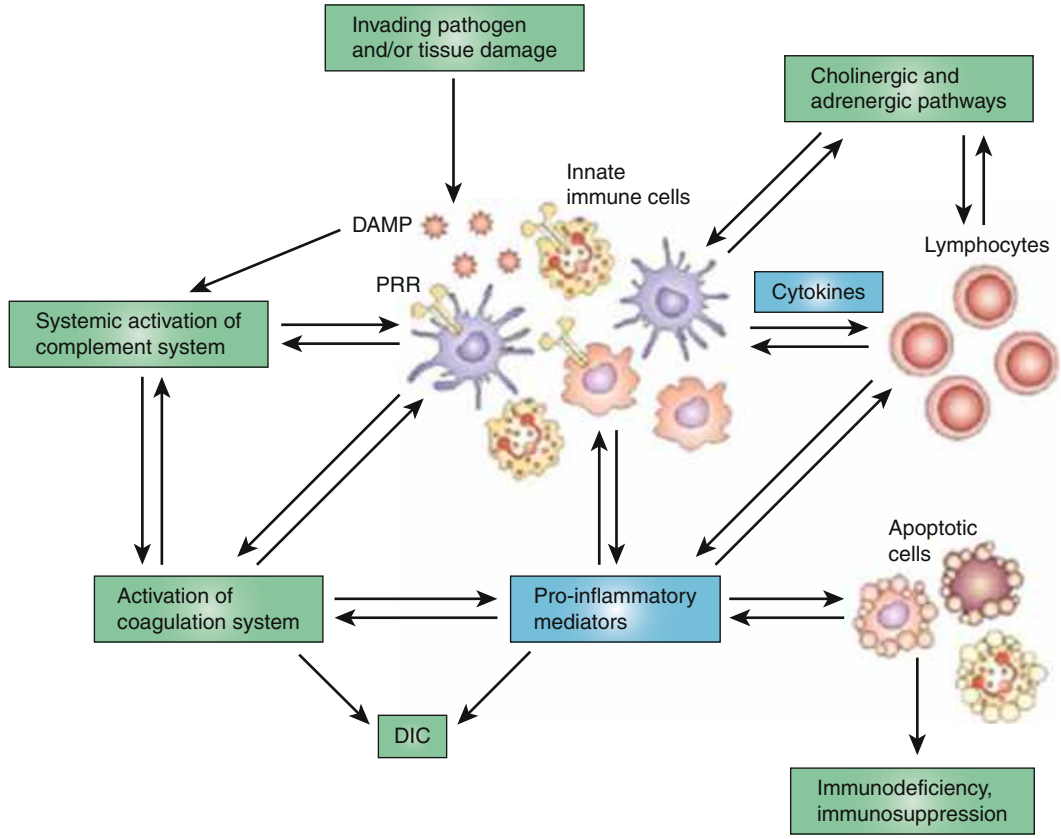

Fig. 177.1 The sepsis cascade [56]. During sepsis, homeostasis between the various biological systems is lost. Early in sepsis, invading organisms or damaged host tissue releases damage-associated molecular patterns (DAMP), resulting in overstimulation of pattern-recognition receptors (PRR) on immune cells. These cells produce excessive amounts of pro-inflammatory mediators, free radicals, and enzymes that convert the normally beneficial effects of inflammation into an excessive, deleterious response. Increased activation of the adrenergic branch of the autonomic nervous system, coupled with a reduction in the activity of the anti-inflammatory effects of parasympathetic nervous system activation, amplifies the pro-inflammatory response of immune cells. Simultaneous activation of the coagulation system and inhibition of normal fibrinolysis in the context of damaged endothelium and a pro-inflammatory environment can result in disseminated intravascular coagulation (DIC). This sustained inflammatory state affects the functional state of immune cells and eventually leads to leukocyte apoptosis and immune paralysis

Because children with underlying cyanotic cardiac disease may have significantly lower baseline arterial and superior vena cava oxygen saturations, therapy can be targeted to normalization of the difference between the two saturations to <30 %. In addition, normalization of lactate levels and acid–base status also signal that relative cardiovascular hemostasis has been achieved.

Airway, Breathing, and Mechanical Ventilation

Persistent hemodynamic instability, respiratory insufficiency manifested as hypoxemia and/or hypercarbia, and altered mental status resulting in the inability to maintain a patent and protected airway may occur in sepsis and septic shock,

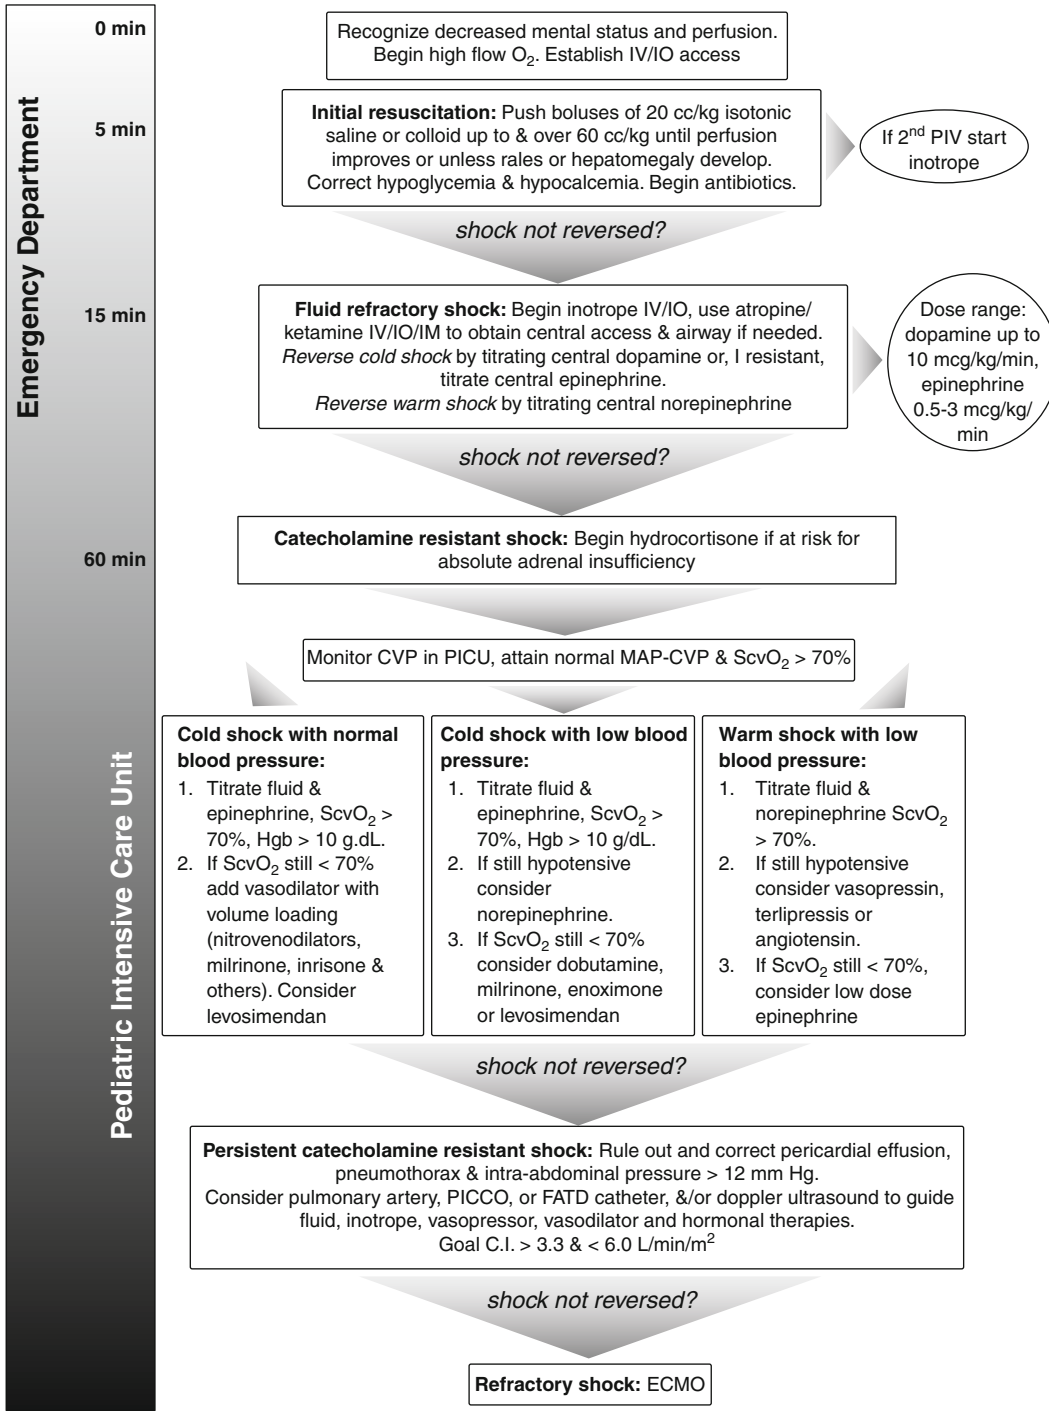

Fig. 177.2 Algorithm for management of infants and children with septic shock from the American College of Critical Care Medicine 2007 clinical practice parameters for hemodynamic support of pediatric septic shock [57]. *MAP* mean arterial pressure, *CVP* central venous pressure, *Scvo2* central venous oxygen saturation, *Hbg* hemoglobin, *PICCO* pulse contour cardiac output, *FATD* femoral arterial thermodilution, *ECMO* extracorporeal membrane oxygenation, *CI* cardiac index, *CRRT* continuous renal replacement therapy, *IV*: intravenous, *IO* intraosseous, *IM* intramuscular

and mechanical ventilation is required in up to 80 % of these children [3]. Infusion of large amounts of fluid for resuscitation, coupled with ongoing capillary leak, often results in the development of pulmonary edema. As pulmonary edema worsens, lung compliance decreases and the work of breathing substantially increases, and up to 40 % of cardiac output may be needed to support respirations. Mechanical ventilation in patients with septic shock reduces the metabolic cost of breathing, thereby decreasing oxygen consumption. In patients with impaired left ventricular function, positive-pressure ventilation can assist in unloading the left ventricular and improving cardiac output. Intubation should be performed according to Pediatric Advanced Life Support (PALS) and Neonatal Resuscitation Program (NRP) guidelines. Judicious volume resuscitation prior to and during initiation of mechanical ventilation may be necessary to maintain adequate preload in the severely dehydrated or vasodilated patient transitioning from negative- to positive-pressure ventilation. The choice of an induction agent to facilitate intubation or allow performance of invasive procedures is particularly delicate in the child with myocardial depression and/or structural heart disease. Many commonly used agents, including inhalational anesthetics, propofol, and benzodiazepines, increase the risk of worsening hypotension from their direct myocardial depressant or vasodilatory effects or by indirectly blunting endogenous catecholamine release. Etomidate is another popular induction agent because it maintains cardiovascular stability through blockade of vascular potassium channels. However, the 2007 guidelines [57] recommend against the use of etomidate because of its independent association with increased mortality in adults and children with septic shock, possibly secondary to inhibition of adrenal corticoid biosynthesis [61, 62]. This effect may be overcome by supplementation with high-dose hydrocortisone. Ketamine is a central NMDA-receptor blocker and has been recommended for sedation and intubation in septic shock [57, 63, 64] because of its sympathomimetic effects. In patients with intact autonomic nervous systems, ketamine administration induces increases in heart rate, cardiac output, myocardial oxygen consumption, and systemic and pulmonary blood pressure [65–68]. However, these effects may be undesirable in patients with ischemic heart disease, cardiomyopathy, pulmonary hypertension, and mitral stenosis. Ketamine has also been shown to have direct inotropic depressant effects in experimental models [69, 70]. Overdistension of alveoli during positive-pressure ventilation is associated with the release of inflammatory cytokines [71] and concomitant acute respiratory distress syndrome (ARDS) and commonly complicates the ventilator management of septic shock patients. Effective tidal volumes of 6–8 ml/kg can reasonably ventilate children with sepsis and ARDS while reducing volutrauma. Selecting an appropriate peak end-expiratory pressure (PEEP) in the cardiac patient with sepsis should aim for a balance between the maintenance of functional residual capacity (FRC) and anatomic and/or functional abnormalities that increase left ventricular end-diastolic and atrial pressures and predispose the patient to development of pulmonary edema and/or hemorrhage.

Fluid Resuscitation

Virtually all children with shock require some degree of volume resuscitation. Many had poor oral intake prior to development of sepsis, and development of increased intravascular permeability leads to intravascular volume losses. Vasodilation related to excessive nitric oxide production also increases vascular capacitance, reducing the effective fluid volume. A suspicion for sepsis should accompany rapid obtainment of safe vascular access and initiation of fluid resuscitation. Fluid requirements are usually determined by clinical parameters, including heart rate, blood pressure, peripheral perfusion, level of consciousness, and urine output. Patients who do not respond rapidly to initial fluid boluses or those with insufficient physiologic reserve should be considered for invasive hemodynamic monitoring of arterial and central venous pressures.

For patients with underlying cardiac disease, even subtle changes in fluid volume status can profoundly influence their cardiovascular physiology. Volume resuscitation should be tailored to physical signs of fluid status and heart function, and the effects of fluid resuscitation should be understood in the context of the underlying cardiac pathology and anatomy.

Fluid resuscitation is traditionally administered as rapidly infused 20 ml/kg boluses of normal saline or colloid to a total of 60 ml/kg. In cardiac patients, boluses of 10 ml/kg or even 5 ml/kg can be given. If the liver edge descends significantly, rales are heard, pulse pressure (SBP-DBP) narrows, or central venous pressure (CVP) dramatically rises, additional fluid administration is not advised. Large volumes of fluid for resuscitation have not been shown to increase the incidence of respiratory distress syndrome [8, 72] or cerebral edema [8, 73], but may adversely impact the condition of children with underlying cardiac disease. Increased fluid requirements may persist for several days secondary to ongoing capillary leak resulting in decreased intravascular volume.

The choice of fluid for resuscitation is the subject of ongoing debate, but crystalloids (normal saline or lactated Ringers') and colloids (dextran, hetastarch, or 5 % human serum albumin) are routinely used. Colloids have been posited as a superior resuscitation fluid because of the likelihood they will remain in the intravascular compartment and not contribute to capillary leakage, but this theory has not been clearly borne out in clinical studies. Few large, properly controlled studies of the differences between various resuscitation fluids have been performed in children with septic shock, but normal saline or 5 % human serum albumin infusions are generally considered as reasonable choices for the initial resuscitation of septic shock. Fresh frozen plasma may be used to correct prolonged prothrombin and partial thromboplastin times. Blood replacement is not usually required in the septic patient without underlying cardiac disease, but should be considered in patients whose cardiac physiology requires a higher hemoglobin concentration. Septic patients, with or without underlying cardiac disease, may experience decreased cardiac contractility and relative anemia and may benefit from a blood transfusion to improve oxygen delivery to peripheral organs.

Cardiovascular Stabilization

A study by Ceneviva and colleagues found that children with fluid-refractory or dopamine-resistant shock have varied hemodynamic states, including low cardiac output/high systemic vascular resistance (60 %), low cardiac output/low vascular resistance (20 %), and high cardiac output/low vascular resistance (20 %), and that these states can change over the course of illness [74]. Cardiovascular instability secondary to septic shock is further complicated by the presence of underlying cardiac dysfunction, although the goals of therapy remain the same. The first "golden hour" of resuscitation is directed at restoring normal perfusion pressure and peripheral oxygen and nutrient delivery. Once intravascular volume has been restored, or it becomes apparent that the cardiovascular system will not tolerate continued fluid resuscitation to achieve normotension, it is appropriate to begin treatment with inotropes and/or vasopressors. The most commonly chosen initial agent is dopamine, which provides inotropic support at lower concentrations and exhibits vasopressor effects at higher concentrations. If shock persists despite escalating doses of dopamine, an addition of a second agent should be considered. Dopamine, particularly in higher doses, may have several undesirable side effects in septic patients with underlying cardiac disease, including increasing arrhythmia risk and myocardial oxygen consumption [75–77]. In addition, dopamine has been shown to inhibit anterior pituitary function (decreasing prolactin, growth hormone, and thyroid-stimulating hormone release) [78–80], lymphocyte proliferation, immunoglobulin synthesis, and cytokine production and promotes lymphocyte apoptosis [81–83]. The agent

selected should be tailored to the pathophysiology underlying the persistent shock. If the ongoing shock is due to direct myocardial depression and reduced cardiac output, an agent increasing inotropy (e.g., dobutamine, epinephrine) should be used; in the context of persistently decreased vascular tone, an agent that increases vasoconstriction is helpful (e.g., norepinephrine, epinephrine, vasopressin). Like dopamine, vasopressin exerts its effects through various receptors [84, 85] and therefore has extracardiac and vasomotor effects, including stimulation of ACTH and prolactin release and promotion of platelet aggregation [86]. For the patient with impaired heart function secondary to excessive vasoconstriction and afterload, a vasodilator (e.g., milrinone, sodium nitroprusside) should be considered.

Refractory shock in neonates and children is usually secondary to cardiac, not vascular failure, and extracardiac support through the acute phase of sepsis may improve outcome. Extracorporeal membrane oxygenation (ECMO) has been shown to be an effective therapy in refractory neonatal shock and should be considered a viable therapy with 50 % survival in refractory pediatric shock [87–91].

Antibiotic Therapy

Ample evidence suggests that early administration of appropriate antibiotic therapy reduces mortality in critically ill patients with sepsis and septic shock and is one of the most important interventions for improving morbidity and mortality [92–96]. The pathogens that cause sepsis and septic shock vary by age, but across all age groups, gram-positive bacteria, particularly Streptococcus and Staphylococcus species, are the most prevalent. In addition, geographic location and host immunologic status importantly influence the etiologies of sepsis and should be taken into consideration when formulating a treatment regimen. Early in the course of disease, the treatment regimen should cover all likely pathogens. Once the infectious cause has been identified and patterns of susceptibility ascertained, antibiotic coverage can be tailored to treat the causative organism(s). The emergence of resistant organisms has resulted in recommendations to restrict the use of antibiotics in the broad community setting. In critically ill children with sepsis and septic shock, failure to rapidly and adequately treat the cause of infection can have devastating consequences, and for this reason, such patients should initially be treated with broad-spectrum antibiotics therapy. Although infection eradication is important for survival from sepsis and septic shock, administration of antibiotics should never supersede or postpone volume and cardiovascular resuscitation.

Metabolic and Hormonal Support

The support and maintenance of metabolic and hormonal homeostasis in infants and children with sepsis and septic shock is important for reducing morbidity and mortality. Unidentified hypoglycemia can cause neurologic damage and must be rapidly diagnosed and treated. Necessary glucose infusion rates are age dependent and can be met with 10 % glucose-containing solutions infused at maintenance rates (8 mg/kg/min glucose in infants, 5 mg/kg/min glucose in children, 2 mg/kg/min glucose in adolescents) [57]. Patients with concomitant liver failure also require higher glucose infusion rates, even up to 16 mg/kg/min. Hyperglycemia is also a risk factor for mortality. Lin and Carcillo [97] reported that children with septic shock and hyperglycemia (glucose >140 mg/dl) and an elevated anion gap demonstrated resolution of this gap and reversal of metabolic catabolism following initiation of an insulin infusion. Infusions of insulin and glucose are also effective inotropes.

Replacement with thyroid hormone and/or hydrocortisone can be lifesaving in children with thyroid or adrenal insufficiency and catecholamine-resistant shock [98–101]. Triiodothyronine infusion therapy has been beneficial in postoperative congenital heart disease patients, but has not been rigorously evaluated in children with septic shock [102].

Children are more likely to have absolute adrenal insufficiency defined by a basal cortisol

level <18 μg/dl and a peak adrenocorticotropic hormone (ACTH)-stimulated cortisol concentration <18 μg/dl [57]. Patients at risk of inadequate cortisol production in the setting of shock include children with purpura fulminans and Waterhouse-Friderichsen syndrome, those who previously received steroid therapies for chronic illness, and children with underlying pituitary or adrenal abnormalities. The 2007 American College of Critical Care Medicine (ACCM) update of the clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock [57] recommends hydrocortisone treatment for patients with absolute adrenal insufficiency (peak cortisol concentration after ACTH stimulation <18 μg/dl) or adrenal-pituitary axis failure and catecholamine-resistant shock, and the recommended dosage remains under debate. It is generally recommended that doses between 500 mg/m^2 or 2 mg/kg/day and 50 mg/kg/day, administered intermittently or as a 24-h infusion, can be used until the resolution of shock and/or a reduction in inotropic or vasopressor requirements.

Renal Failure and Fluid Overload

Renal insufficiency and failure is a frequent occurrence in septic shock and occurs in the context of prolonged ischemia (>60 min), thrombosis preventing adequate renal perfusion, or obstruction of tubular flow by myoglobin or uric acid deposits. Prolonged ischemia prompts the neurohormonal system to release aldosterone, angiotensin, and antidiuretic hormone (vasopressin), which prevents natriuresis and diuresis, and manifests clinically as oliguria. Acute kidney injury, in particular, appears to be an independent risk factor for mortality in patients with sepsis and septic shock [103–105].

The large fluid volumes used to resuscitate septic shock frequently result in significant fluid overload, which has been associated with worse outcome in the setting of critical illness [106]. Goldstein et al. [107] evaluated the use of continuous veno-venous hemofiltration/dialysis (CVVH/D) in critically ill children with volume overload and found that after adjusting for severity of illness, a greater degree of fluid overload was associated with worse outcome. Based on their observations, they proposed that earlier initiation of CVVH/D (at 10 % fluid overload vs. 25 % fluid overload) might prevent morbidity and potentially improve survival in critically ill children. The 2007 ACCM clinical practice parameters for management of neonatal and pediatric septic shock [57] recommend that fluid removal, using diuretics, peritoneal dialysis, and/or continuous renal replacement therapy (CRRT) (including CVVH/D), is indicated in patients who have been adequately fluid resuscitated but cannot maintain an even-fluid balance through native urine output.

Conclusions

Sepsis is an important cause of morbidity and mortality in the pediatric population, including those children with concomitant cardiac disease. Successful treatment includes early recognition, administration of appropriate antibiotic therapy, and cardiorespiratory support that takes into consideration the individual patient's underlying cardiac abnormalities.

End of Life: Ethical and Legal Considerations

178

Denis Devictor, Mostafa Mokhtari, and Pierre Tissières

Abstract

This chapter addresses some ethically challenging situations related to end of life (EOL) that can occur especially in pediatric intensive care units (PICUs) and pediatric cardiac intensive care units (PCICUs). It begins with some considerations regarding principles of medical ethics. It continues with a discussion on EOL in PICUs. Finally, it broaches the difficult question of the decision-making. This chapter aims at helping pediatric cardiac intensivists and other caregivers to resolve moral dilemmas.

Keywords

Autonomy • Competency • Death • Decision-making process • Decision • Deliberation • End of life • Ethics • Evaluation • Family-centered care • Information • Law • Life-sustaining treatments • Moral dilemma • Palliative care • Philosophy • Principlism • Spirituality

Introduction

Today's practicing pediatric intensivists are likely to face ethical dilemmas with regularity. Knowledge of ethical theories is necessary to construct coherent justifications to resolve these challenging situations. While severity of illness of hospitalized children has progressively increased over the past decades, advanced techniques have allowed such patients to survive. At the same time, it is increasingly accepted that continued aggressive care may not always be beneficial. It is this notion that has given rise to frequent limitation of life-sustaining treatments. Decision-making is one of the most challenging issues in intensive care because it confronts the values of patients, families, health-care professionals, and the society. The decision-making process could be divided into three steps: the deliberation leading to the decision, the implementation of the decision, and the evaluation of the decision and its application. During the deliberation, caregivers and family consider the pros and cons of medical interventions. Then, they come to a decision: in this case to continue or forgo life-sustaining treatment. Finally, the decision is implemented and its consequences are evaluated.

This chapter begins with some considerations regarding principles of medical ethics. It continues with a discussion on EOL in PICUs. Finally, it broaches the difficult question of the decision-making. It aims at helping pediatric cardiac intensivists and multidisciplinary caregivers to resolve moral dilemmas.

Definition

The word *ethics* is used in a number of related senses, which have to be distinguished to avoid confusion. Normative ethics is a rational inquiry into, or a theory of, the standards of right and wrong, good and bad, in respect of character and conduct, which ought to be accepted by a class of individuals. Its main aim is to formulate valid norms of conduct. The study of what general norms and standards are to be applied in actual problem situations is called applied ethics. Medical ethics is the discipline devoted to the identification, analysis, and resolution of value-based problems that arise in the care of patients. It relates to the peculiar problems dilemmas that arise in medicine. The term "bioethics" is often used interchangeably with medical ethics. The words "ethics" and "morality" are often used interchangeably. Morality consists of social norms of behavior and consequently often varies dramatically between cultures.

Principles of Medical Ethics

There are several ethical theories that are useful in resolving moral dilemmas. Broadly speaking, two theories have dominated Western philosophical tradition: utilitarianism based on J Bentham's philosophy and deontology based on I Kant's philosophy [1]. Both theories attempt to provide a set of "fundamental principles" for approaching ethical conflict. Utilitarianism is a moral theory according to which an action is right if (and only if) it conforms to the principle of utility. This theory is rooted in the thesis that an action or practice is right if it leads to the greatest possible balance of good consequences or the least balance of bad consequences. According to this view, moral codes are designated to promote humane welfare by maximizing benefits and minimizing harm. According to the deontology theory, consequences are rejected as the first principle. Actions should be guided by universal moral obligations, duties, or codes. More recently, a number of alternative theories have emerged as useful tools for analyzing complex ethical decisions. Perhaps the best known is called *principlism*. In a classic textbook on modern medical ethics, Tom Beauchamp and James Childress advocate four principles on which to base ethical analysis: respect of autonomy, beneficence, non-maleficence, and justice [2]. When faced with a moral dilemma, one's task is to identify the relevant ethical principles that bear on the medical case, which will suggest a set of rules that are pertinent to the situation. From these rules, one should be able to discern the proper judgment regarding the particular medical case.

- *Beneficence*: This principle refers to a moral obligation to act for the benefit of the patient. This may seem self-evident, but the experience has shown that conflicts of interest can influence medical decisions. For example, caregivers might have the temptation to test new treatments or procedures as rescue therapies, even if their expected benefits have not been proved so far.
- *Non-maleficence*: According to this notion, doctors have the duty to avoid harming patients. Again, this idea may seem obvious, but in practice, it is highly complex. When considering which treatment will best help the patient, doctors must balance benefits against harm. For example, when deciding whether to use ventricular assist device for a desperately ill infant suffering with cardiogenic shock, caregivers must consider the possibility that technology will extend the infant's life only by several days, without long-term benefit.
- *Respect for autonomy*: This principle suggests the obligation to respect the decision-making capacities of autonomous persons. In pediatrics, this obligation raises difficult dilemmas. For instance, neonates and small children cannot be considered as autonomous persons.

Therefore, parents are often considered as their surrogates. However, the fact that parents must give legal consent for medical treatments does not mean that the opinion of the children and adolescents should be considered irrelevant or ignored and that parents know what the best is for their child.

– *Justice*: This principle raises the most challenging dilemmas for modern medical care. Namely, this principle exhorts caregivers to use medical services fairly to avoid decisions that accept or reject candidates for therapies based on factors that are irrelevant to their medical situation (such as their religion, origins, and social conditions).

It can be safely stated that *principlism* is an overly simplistic theory to resolve many ethical dilemmas that arise in clinical practice [1]. The problem is that, because more than one principle may have bearing on any given case, conflicting rules and judgments may be the first fruit of deliberation. As *principlism* does not rank the four principles in order of priority, this approach falls short of comprehensively resolving many ethical dilemmas that arise in clinical practice. Nevertheless, the *principlism* has the virtue of being clear, useful, and educational. A number of alternative more or less complex theories exist. One of them is the "case-based reasoning" or casuistic analysis. This pragmatic approach may be particularly valuable when conflicts among principles arise; moral virtues can play a role in guiding the balancing of principles and arriving at morally acceptable solutions.

End of Life in PICUs

Advances in pediatric critical care medicine have led to ethical issues of profound concern to all pediatric intensivists and nurses. One of the most striking changes is that now most children admitted to a PICU will die following a decision to withhold or withdraw life-sustaining treatments. While severity of illness of hospitalized children has progressively increased over the past decades, advanced techniques have allowed such patients to survive. At the same time, it is increasingly accepted that continued aggressive care may not always be beneficial. It is this notion that has given rise to frequent limitation of life-sustaining treatments. Consequently, the mission of pediatric intensive care also includes provision of the best possible care to dying children and their families. It is important, therefore, that all health-care professionals in pediatric intensive care should be competent in both end-of-life decision-making and palliative care.

The decision to forgo life-sustaining treatment is made for 20 % to 55 % of terminally ill children in North American as well as European PICUs [3–10]. There is a large variability, however, in the modes of death among countries [11–14]. Diverse cultural, religious, philosophic, legal, and professional attitudes may be involved to explain this variability [13–18]. Differences have been documented in all aspects of decision-making, including the practices, the decision-makers, and the frequencies of limitations of life-sustaining therapies. For example, in a study from North America, the time elapsed from decision to withdraw life-sustaining treatment to actual withdrawal was a median of 30 min as compared to 2 days in Europe [10, 19].

Actually, the most salient international difference touches upon the question of who should be responsible for decision-making. In North America, parents are the main decision-makers, in contrast to some European and South American countries where the doctors fulfill this role [13, 20, 21]. This latter paternalistic attitude is firmly contested, however, by North American intensivists [22, 23]. Nevertheless, the review of the literature shows that the ethical climate is rapidly evolving and that a convergence of opinion about good practice appears to be developing among professional societies in Europe and in the United States [24, 25].

Essential Elements of Medical Decision-Making

Decision-making is one of the most challenging issues in intensive care because it confronts the values of patients, families, health-care

professionals, and the society. A major shift in patient–families–doctors–society relations has occurred in recent years. As previously mentioned, doctors now have less freedom to make paternalistic decisions about treatment according to their own beliefs. They must take into consideration the patient's and family's perspectives. This shift has embodied in the doctrine of informed consent. The doctrine of informed consent assumes the right of a reasonable person to accept or refuse offered treatment. To make a valid choice, the patient or his/her surrogate needs understandable information regarding the medical situation, so any choice will reflect the range of alternatives and their consequences. This choice should occur voluntarily, that is, free of any undue pressure, especially from health-care providers. Informed consent must satisfy at least three requirements: competency, information, and understanding, requirements which are especially meaningful in PICUs and PCICUs.

Competency

– A competent individual has the capacity to understand the medical situation, consider the risks and benefits, make a choice among the alternatives, decide upon a course of action, and appreciate the consequences of the choice. In most circumstances, minors are legally incompetent, and their parents give legal consent for medical treatments as surrogates. This does not mean that the opinions of the children should be considered irrelevant or ignored. Children as young as 6 or 7 years of age are often able to have reasoned opinions about certain aspects of their care. Moreover, physicians must assess the decision-making capacity of the parents.

Information

– The concept of information remains a central component of informed consent. Assuming a patient or his/her surrogate has an appropriate decision-making capacity, the decision-maker needs information about patient's condition, prognosis, and alternative treatments. Ethical and legal considerations require that the information is understandable. The information must allow the decision-maker to weigh the pros and cons of the therapeutic alternative. One can easily imagine situations in which understanding does not occur despite a competent decision-maker and full information.

Understanding

– Understanding is unlikely if the physician uses excessive medical jargon or the patient is ignorant of basic medical concept. This is particularly true in cardiology and PCICUs because of the complexity of the medical situations. Research suggests that physicians routinely overestimate what patients and family members understand. Similarly, parents may not hear what is said because of the stress induced by their child's illness. Moreover, in some cases, parents may not have enough time to consider alternatives. Time limitations might influence the decision and might invalidate full consent.

The Decision-Making Process

The decision-making process could be divided into three steps: the deliberation leading to the decision, the implementation of the decision, and the evaluation of the decision and its application. During the deliberation, the caregivers and family consider the pros and cons of medical interventions. Then they come to a decision: in this case to continue or forgo life-sustaining treatment. Finally, the decision is implemented and its consequences are evaluated. Several guidelines have been published on these different steps [26–31]. In the following sections, relevant issues pertaining to these steps are elaborated.

The Deliberation Leading to the Decision

During the deliberation phase, the decision-makers weigh the benefits and burdens of medical treatments, taking into account numerous factors. Some of them are medical such as factors influencing the prognosis, like the cause of the

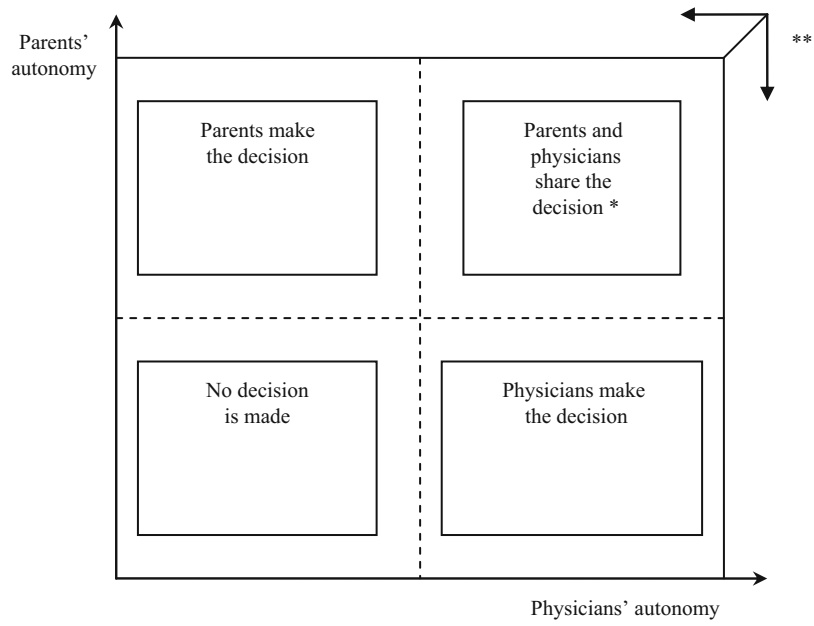

Fig. 178.1 The shared decision model (*This square represents the ideal model, **In practice, for each individual case, there is an oscillation between both parents' and physicians' autonomy)

disease. Others are organizational such as professional guidelines, training of the staff, and communication within the staff, with the patient, and his/her family. Then there are factors with regard to patient's and family's wishes, their religion, and social insertion. Finally, societal factors may interfere, such as cultural background or legal framework. This non-exhaustive list shows that the decision is multifactorial, the relative importance of each factor being weighed in each individual case.

The Decision-Makers

A controversy persists regarding the roles of parents and physicians in the decision-making process. Schematically, two extreme scenarios are opposed. The first emphasizes that parents – as surrogates of their child – should be the main decision-makers [31, 32]. The second scenario argues that parents may not have full decision-making capacities when, for example, under pressure as a result of the child's critical illness. In this case, the physicians bear the sole responsibility of the final decision. Between these extremes, many countries have adopted the concept of shared decision (Fig. 178.1). The purpose is to reach consensus on a process that is in accordance with family's values and to build a collaborative relationship with the family. The shared decision paradigm allows for variations in family's wishes regarding participation in the decision-making process. This feature points out the crucial role of communication – within the health-care team itself and with the family. In fact, the concept of information and communication remains a central component of the shared decision model. To make decisions for their children, parents must acquire process and organize information. Assuming they have appropriate decision-making capacity, parents need clear information from the doctors about their child's condition, prognosis, and alternative treatments. Ethical and legal considerations require that the information is understandable and transparent. Regrettably, research suggests that physicians routinely overestimate what patients and family members understand [33, 34]. Should the physician use excessive medical jargon, or the child or

his/her family be ignorant of basic medical concepts, good understanding is quite unlikely. Similarly, parents may not fully comprehend what is said when struck by the realization that their child is severely ill. Moreover, there may be only limited time to consider alternatives. Time limitations might influence the decision and might invalidate full consent.

Parents' Perspectives

Factors influencing the parents' decision are their possible previous experiences with death and end-of-life decision-making for others, their personal observations of their child's suffering, their perceptions of their child's will to survive, their need to protect and advocate for their child, and the family's financial resources and concerns regarding lifelong care [35]. Meyer et al. likewise have shown that parents place the highest priorities on quality of life, likelihood of improvement, and perception of their child's pain when considering withdrawal of life support [36]. The recommendations of physicians, the nature of the illness, the expected neurological recovery, and quality of life are also important to parents when making end-of-life decisions for their child [37]. All these reports underline that establishing trust is crucial in guiding parents through the decision-making process.

Physicians' Perspectives

Factors influencing physicians' perspectives mainly regard outcome prediction, the balance between burdens and benefits, and the concept of futility [38–40].

Predicting Outcomes

Two scores are available to predict the risk of death for children receiving intensive care: the Pediatric Risk of Mortality (PRISM) and the Pediatric Index of Mortality (PIM) [41, 42].

Regrettably, both have several drawbacks. First, they make predictions based on hospital outcomes at the time of their creation. It would seem that they need to be updated as medical treatments improve. Then, they derive their predictions from factors present at admission and do not provide updated mortality estimates as the patient's condition changes. But perhaps the most obvious problem is that they say nothing about morbidity, disability, quality of life, or survival after hospitalization.

The use of published data – an essential tool for clinicians in predicting the course of illness – has drawbacks as well. One is that the population studied for a particular illness may not have the same characteristics as an individual patient. Another issue is the rapidity with which therapies can change and improve.

The Balance Between Burdens and Benefits

One of the most commonly used justifications for withholding "high-tech" therapy from patients is the belief that "extraordinary" treatments are not ethically justified. However, clinicians should understand that the distinction between ordinary and extraordinary treatments is not considered to be helpful when attempting to reason through the ethical aspects of difficult decisions [43]. A much more legitimate and useful approach to deliberating about whether a procedure is ethically required is to inquire about the benefit–burden balance for a particular procedure in a particular patient. In other words, rather than relying on such terminology as ordinary and extraordinary to decide whether a treatment should be offered, it should be considered whether the proposed benefits outweigh the burdens. For example, a child's family may accept a 30 % chance of survival if it were followed by high quality of life, but not accept a 70 % chance of survival if it were likely to entail poor quality of life.

The Concept of Futility

Who should determine that treatment is futile? This question remains largely unresolved for several reasons. First, the concept of futility is difficult to define. Schneiderman and colleagues in 1990 provided the following definition: "when physicians conclude (either through personal experience, experiences shared with colleagues, or consideration of published empiric data) that

in the last 100 cases a medical treatment has been useless, they should regard that treatment as futile. If a treatment merely preserves permanent unconsciousness or cannot end dependence on intensive care, the treatment should be considered futile" [44]. This definition is highly arguable, however, since each patient's situation is unique and cannot be compared with the 100 previous cases. Moreover, opinions on the value of life may differ. For instance, while some may value the preservation of life at all costs, other may conclude that the foreseeable quality of life is so poor that death is the preferred outcome. Or some may see hope in an extremely small chance of success ("hoping for a miracle"), whereas others see a prolongation of the dying process. Another definition was provided by the Society for Critical Care Medicine. It states that treatments should be defined as futile only when the will "not accomplished their intended goal" [45]. This definition seems to be more pragmatic and useful.

Nurses' Perspectives

The involvement of nurses in end-of-life decisions is crucial [46]. The role of nurses can be described as managing the process and care of the dying child and guiding the parents in these difficult times. Besides the caring components of care, nurses usually build up a close relationship with the parents. Having not only expertise but also knowledge of the child's and parents' background, nurses nevertheless are still not always involved in multidisciplinary end-of-life discussions. In a qualitative study using group interviews, 14 critical care nurses unveiled discrepancies between nursing and medical perspectives and their interactions [47]. The nurses felt that the physicians were more interested in their colleagues' view rather than the nurses' holistic knowledge.

It is recognized that physicians usually take the ultimate decision on life and death in the ICU. Such a decision should always be based, however, on the complete overview of the patient's status and the family perspectives. In this respect, it seems logical that nurses should take part in any end-of-life care discussion, even from the first discussion session onwards. Unfortunately, this collaborative practice is often a far cry from reality. For example, a recent survey among nurses and physicians in the adult ICU revealed that nurses reported lower collaboration with physicians, resulting in higher moral distress and less satisfaction with care [48]. And in a study from New Zealand among adult, pediatric, and neonatal critical care nurses, 88 % of the 611 participating nurses felt that nurses should always be involved in end-of-life decisions [49]. Nevertheless, only 292 (48 %) nurses reported that they were always or most of the time involved in the decision-making process. Regardless of who has to make the ultimate end-of-life decision, interdisciplinary collaboration is a must in any preliminary and ongoing discussions towards an end-of-life care decision. Giving all the PICU staff a role in this process can eventually improve the competencies of all professionals and thus safeguard judicious end-of-life decisions. Consequently, this collaboration benefits the complex care of the dying child and parents.

The Implementation of the Decision

The second step in the end-of-life decision-making process concerns the actions that are taken once decision has been made to forgo life-sustaining treatments. This issue raises different ethical questions and moral dilemmas.

Withholding and Withdrawing Life Support: Are They Ethically Different?

Is there a difference between stopping a treatment once it is started and not starting it in the first place? In a survey including 110 physicians and 92 nurses from 31 pediatric hospitals in the United States, the statement that withholding and withdrawing life support are unethical was not endorsed by any of the physicians or nurses [46]. More physicians (78 %) than nurses (58 %) agreed or strongly agreed that withholding and

withdrawing are ethically the same. Nevertheless, this survey shows that physicians are much more comfortable in withholding treatments than in withdrawing those [46]. The underlying reasoning is clearly psychological in part. Physicians will feel more responsible for the death of a patient when it results from the withdrawal of a therapy than they do when it results from the withholding of a therapy.

Nutrition and Hydration: Are They Natural or Artificial?

Should techniques for providing medical nutrition and hydration be considered as medical treatments? In other words, if it is ethically acceptable to withdraw a ventilator from a terminally ill child, would it also be ethically acceptable to withdraw medically provided nutrition and hydration? A gradually emerging consensus answers these questions in the affirmative [50]. However, many clinicians have been reluctant to accept the withdrawal of medical nutrition and hydration, at least in part because "feeding" seems to be such a basic and fundamental aspect of the care they provide. Pediatricians have been more particularly reluctant to acknowledge this emerging consensus for several reasons [51]. First, prognoses are often more uncertain in children, given their remarkable ability to recover from injury. Second, even healthy newborns need assistance with feedings, so pediatricians are less likely to see artificial feedings as a "medical" treatment. Third, while the hospice experience shows that elderly patients who are dying a natural death often refuse food and water, the death of a child is never a "natural" event, and caregivers are reluctant to accept it with apparent passivity.

Sedatives and Analgesics: What Is the Real Intention?

One crucial issue is the doctrine of double effect. This doctrine states that when an action has two effects – one of which is inherently good and the other inherently bad – it can be justified if certain conditions are met. For example, the administration of morphine to a dying patient produces both a good effect (relief of pain and suffering) and the potential for a bad effect (hastening the patient's death through respiratory depression). Despite the beliefs of many clinicians, no moral, legal, or religious reasons justify withholding adequate pain relief from dying patients. Pain and suffering should always be adequately treated, even if the treatment results in a foreseen but unintended hastening of death. The key difference between this practice and euthanasia lies in the *intention* of the physician. When the physician's intention is to hasten the patient's death, then the line between accepted practice and euthanasia is crossed.

The Goals of Care: Where Is the Border Between Curative and Palliative Care?

The clinician's responsibility to the child and his/her family does not end with a decision to forgo life-sustaining treatment but continues throughout the dying process. The emerging perspective is that palliative care and intensive care are not mutually exclusive options but rather should be coexistent [29]. When physicians focus solely on extending the duration of life, as opposed to maximizing the quality of life, their goal can drive futile interventions which prohibit the patient from receiving optimal comfort care. This is especially true when the institution of palliative care is viewed as an abrupt all-or-nothing change from life-prolonging to symptom-oriented care [29, 46]. Thinking in terms of the goals of care for an individual patient can aid the physician in discussions with the health-care team and the family when making or revising a management plan [23, 46]. The question then becomes how to best manage the patient during the dying process. Recommendations on this issue have been published by the Ethics Committee of the Society of Critical Care Medicine [29].

Needs of the Dying Child and Family

Preparation of the patient and the family is based on the knowledge of their needs. One can easily imagine the fundamental needs of a dying child, such as to be with his/her parents and family, to have no pain, to have tender loving care, to respect his/her body, and to respect his/her parents' wishes.

Meyer et al. recently reported on the specific needs of parents whose children had died after the forgoing of life-sustaining treatment [38]. It appears that in practice pediatric intensivists do not always satisfy these needs. As an example, 86.5 % of parents ($n = 52$) of a dying child agreed or strongly agreed they had obtained information regarding their child's condition, but only 48.1 % agreed to have been informed about the persons they could go to with their questions [36]. Clearly, the child and his/her family should know the identity of the attending physician, understand that this individual is ultimately responsible for the care, and be assured of his/her involvement. In fact, most families consider clinicians' communication skill as equally or more important than clinical skill. On that note, the critical care nurse plays a central role in addressing families' needs: she/he is able to explain various treatments the patient is receiving and to assess the family's spiritual and cultural needs. Eventually, it is the multidisciplinary team that should consider their jointly communications towards the parents. Strategies to improve communication with the family have been studied in the adult ICU. A French study implemented an intervention by which ICU staff took more time to converse with the family and also provided a bereavement brochure [34]. The intervention group (n = 56) was compared to a control group (n = 52) approached in the customary way. Persons in the control group experienced less stress, anxiety, and depression three months after the death of their beloved relative. Similarly, meeting the parental needs and giving enough time to parents to express their emotions might indeed help them cope with the loss of their child.

Family-Centered Care

Family-centered care is an approach to the planning, delivery, and evaluation of health care that is grounded in mutually beneficial partnerships among health-care providers, patients, and families [52, 53].

Family is acknowledged as expert in the care of their child, and the perspectives and information provided by the family are important to clinical decision-making. This concept is demanding since it imposes to recognize the family as a constant in the child's life, to facilitate parents–professionals collaboration, to share complete and unbiased information with families, and to satisfy child's and family's needs. Parents should be viewed as partners in care rather than visitors [53]. Parents are better able to cope when their roles as caregivers are recognized. Still, providing care can be alienating for parents who feel incompetent or too stressed. Parents may feel frightened by their child's appearance or overwhelmed by the technology. Staff, especially nurses, can help delineate the kind of care the parents can provide. The critical care nurse plays an essential role in providing and facilitating the communication between health-care workers and the family [54]. Parents' participation may be as simple as holding the child's hand. They can participate more actively as well, such as assisting with bathing, positioning, or massage.

The parental presence during medical rounds is encouraged in some institutions. On the other hand, many institutions are concerned that this practice will significantly increase the time spent rounding and disrupt the usual workflow. There are also concerns that rounds may not be the best avenue to convey information and solicit family input in decision-making. Conversely, there is a fear that the presence of parents might inhibit open discussion among staff [55, 56].

The presence of family members during cardiopulmonary resuscitation is also a controversial issue. Concerns in the literature are mainly focused on three points. The first is the potential for family members' presence to affect the performance of resuscitation staff. The second is that witnessing a traumatic event may have negative emotional and

psychological consequences. Third, many studies have identified that members of the public would like to be given the choice whether or not to be present. The ethical principle is that all patients have the right to have family members present and that the patients' family members should have the opportunity to be present during resuscitation of a relative [57].

The philosophy of family-centered care reflects the nature of the concept of multidisciplinary care for parents in the PICU. A complete overview of related issues of family-centered care, including clinical practice guidelines, was recently published by the American College of Critical Care Task Force [58]. The Task Force reviewed the literature of the past two decades. The work was divided in 10 subheadings related to the care of the family in the intensive care unit [58]:

1. Decision-making
2. Family coping
3. Staff stress related to family visitation
4. Cultural support
5. Spiritual/religious support
6. Family visitation
7. Family presence on rounds
8. Family presence at resuscitation
9. Family environment of care
10. Palliative care

Among these subheadings were also the issues of decision-making processes and palliative care. Basically the guidelines address partnership of family and the health-care team. Six of the 43 recommendations are directed towards staff training and education – specifically towards communication, assessment of family's needs and stress levels, cultural care, religious issues, family presence during resuscitation, and also palliative care. Indeed, continuing education is needed to improve the clinical competency of the health-care workers to provide patient-driven care based on their needs [59].

Palliative Care

In the curative model, the benefits of care are related to the degree to which the procedure will contribute to the patient's recovery from illness. In the palliative model, the benefits are related to whether the intervention will improve symptom relief, improve functional status, or ameliorate emotional, psychological, or spiritual concerns [29]. The goal is to achieve the best possible quality of life for patients and their families [60, 61]. As previously mentioned, palliative care and curative care are not mutually exclusive options but rather should be coexistent. The palliative care objectives have the most relevance for those patients whose goals of care have been redirected from life-sustaining curative goals to palliative goals. These are usually children with terminal illnesses or other conditions for which the benefits of further life-sustaining therapy are in question. Implicit in the phrase "redirecting the goals of care" is that care – apart from life-sustaining treatment – is never withdrawn. The objectives of palliative care are to provide relief from pain and other distressing symptoms, to intend neither to hasten nor to postpone death, to affirm life and regard dying as a normal process, to integrate the psychological and spiritual aspects of care for the patient and his/or family, to offer a support system to help patients live as actively as possible until death, and to offer a support system to help family cope during the patient's illness and in their bereavement.

The Evaluation

Quality improvement procedures are important for evaluating the process of dying, just as they are for other hospital procedures. The concept of a "good" death has received substantial consideration. The Institute of Medicine defines a good death as "one that is free from avoidable distress and suffering for patients, families, and caregivers; in general accord with patients' and families' wishes; and reasonably consistent with clinical, cultural and ethical standards" [62]. Initially focused on adults, the Institute of Medicine later also focused the concept on children, with a publication called "When Children Die: Improving Palliative and End of Life Care for Children and their Families" [63]. Interventions to improve end-of-life care in the PICU setting have been little researched.

Two recent publications are available, based on a conference hosted by the Robert Wood Johnson Foundation and the Society of Critical Care Medicine "Improving the Quality of End-of-Life Care in the ICU: Interventions That Work" [64, 65]. At least six relevant domains were identified:

1. Strong interdisciplinary collaboration and communication within the critical care team and with the palliative care specialists
2. Good communication skills of the team members
3. Excellence in symptom assessment and management, including pain, dyspnea, delirium, anxiety, and a host of other symptoms
4. Patient-centered care focusing on patients' values and treatment preferences
5. Family-centered care, including regular communication; psychological, spiritual, and social support; and open visiting hours
6. Regular interdisciplinary family meetings focused on shared decision-making, as well as support for family members

Bereaved parents are in a unique position to comment on current practice in end-of-life care. Indeed, gaining an understanding of the perspectives of the family on the dying process is an essential step in understanding the quality of care provided.

Legal Issues

The legal issues involved in discontinuation of life-sustaining treatment are highly dependent upon the legislation of the country. In many Western countries, there is consensus in the law that parents have the authority to determine the best interest of their children and to make decisions in accord with their own values. However, pediatric intensivists must be thoroughly familiar with their legal duties to their pediatric patients, independent of parental viewpoints about life-sustaining treatments.

Conclusion

Advances in pediatric intensive and critical care have led to ethical and legal issues of profound concern to all critical care providers. One of the most striking changes is that the majority of deaths in the PICUs occur following the decision to withdraw or withhold life-sustaining treatments. This fact heightens the importance of competence n EOL decision-making and palliative management by all practitioners working in PICUs and PCICUs.

Quality and Performance Improvement: Challenges for the Congenital Heart Center

179

Steven Choi and Jonathan Kaufman

Abstract

A commitment to quality improvement is mandatory for pediatric centers dedicated to caring for the child and adult with congenital and acquired heart disease. This is particularly true as pediatric cardiac surgery and critical care moves far beyond mortality, as the defining outcome measure of success of a heart center, and as health care, nationally and internationally, undergoes transformative change. The coming years will likely see a premium placed on health care that is cost-effective and health care that is judged to be of good value. As members of multidisciplinary teams of providers caring for children with critical and chronic cardiac disease, congenital heart centers are uniquely positioned to drive process change in delivery of both general and highly specialized care.

Cardiac intensive care unit • Congenital heart disease • Multidisciplinary • Outcomes • Pediatrics • Quality improvement

Introduction

Quality improvement in health care has undergone the most extensive transformation in the past decade. Today, it is arguably the single largest focus for the entire health-care system in the United States as well as the global community [1]. With hundreds of agency-endorsed practice guidelines and quality measures, health-care providers and institutions are now required to assure that their delivery systems produce a set of outcomes aimed at improving the overall quality of the patient and their care experience. In addition, there is now a much greater effort to reduce cost to deliver this high-quality care and ultimately provide the best value for population health [2].

Context of Quality Improvement in Congenital Heart Disease

With the complexity and significant resources needed to care for patients with congenital heart disease, Pediatric Heart Centers have a particularly challenging population with which to achieve these goals. Universally, this evolution in health care has created a tremendous demand for resources, education, and time from providers to meet the standards for improvement. It is within this context that we present the overall landscape for health-care quality improvement and provide some insight into a successful delivery system for patients and their families. Specifically, this chapter will discuss the evolution of quality improvement concepts, quality improvement tools and methodologies, an overview of health-care quality improvement, and a framework for creating quality improvement systems in the health-care environment. The field of congenital heart disease is such a unique opportunity for so many different medical services to align their goals and coordinate their care processes for the ultimate quality improvement effort. In fact, congenital heart disease arguably is the best example of how a team of providers from so many different specialties, at so many different sites, can coordinate the care for a patient population over an entire lifetime – from gestation to adulthood. This is the ultimate model for a safe, efficient, high-quality delivery system.

History of Quality Improvement

The Manufacturing Industry

Quality improvement as a science is most notably cited as product of the manufacturing industry. It is from their experiences and successes that quality improvement in health care has emerged as a discipline and a systematic initiative. Throughout the early- to mid-twentieth century, there was a tremendous demand from factory plants in America to supply parts and materials for the increasing demand in telephone communication, automobiles, and military products for World War II. This increased demand occurred during a period where mass production and management was based on factory line workers performing at a very high-paced, high-volume rate, not necessarily a high-quality rate. This management philosophy was known as Taylorism, coined after its creator Fred W. Taylor who described the concept in "The Principles of Scientific Management" [3]. Taylor believed that production would be most efficient through a breakdown of the production process into simple repetitive tasks that were assigned to individual groups of laborers. Although there was initial success with this management strategy, it quickly became clear that quality improvement needed to be incorporated into production efficiency. It was during this time that Walter A. Shewhart developed and described one of the first revolutionary concepts for quality improvement [4]. Shewhart believed that quality management and process improvement needed to focus on reduction of variability and continuous monitoring of production outcomes. This theory is now better known as statistical process control (SPC). Using SPC charts, he was able to determine when defects ("waste") in a manufacturing process were a result of normal expected variation versus a result of a process error that required an intervention change. By addressing these true process errors, Shewhart demonstrated that early detection with continuous monitoring could eliminate most, if not all, defects while only addressing "out-of-control" variation in production and accepting those that occurred due to the intrinsic nature of the industry (i.e., expected number of defects).

Throughout the remainder of the twentieth century, W. Edwards Deming further developed the concepts of quality control by emphasizing the "Shewhart cycle," better known as the PDSA ("Plan, Do, Study, Act") cycle. The PDSA cycle today is widely accepted as the standard methodology for quality improvement, where repeated executions of this four-step quality management plan are used to improve and sustain the success of particular process. PDSA will be detailed later in this chapter. Deming's teachings were adopted by

the Japanese manufacturing industry to improve quality control and management in their production plants. He is recognized as one of the most influential leaders contributing to the rebirth of the Japanese economy following World War II [5].

As the twentieth century came to a close, one of the foremost leaders to emerge in quality improvement was Joseph Juran. He is widely noted for being the first of his generation to add the human element to process improvement. He coined the term "cultural resistance" as the major stumbling block for all quality improvement efforts. Today, industry management has devoted much of the process improvement efforts toward "culture change" to achieve goals for success. Juran emphasized the need for process changes to occur, even at an initial cost, in order to sustain long-term success and viability. He encouraged managerial training at all levels, not just the top executives, and demonstrated that such investment produced great returns in profit and reduction in waste. Perhaps his greatest contribution to modern-day quality improvement, Juran published "The Quality Trilogy." In this landmark piece, he described the three basic steps for quality management: quality planning, quality control, and quality improvement. This concept is now widely used throughout many industries as the framework for quality management.

Quality Improvement in Health Care

Institute of Medicine Report: To Err Is Human and Crossing the Quality Chasm

While the manufacturing industries were fine-tuning its production lines and developing new management strategies, the Institute of Medicine (IOM) published an unprecedented report on the rates of human errors leading to patient deaths in US hospitals [6]. The IOM functions as one of the leading authorities on health care for both the government and private sectors. Their hallmark report, titled "To Err Is Human: Building a Safer Health System," was published in November 1999 and was one of the first communications of its kind, informing the American public that health care in the United States was facing an epidemic of patient injuries. The report estimated that close to 98,000 deaths occurred every year as result of preventable medical errors in the health-care system. Many experts feel that this publication was the pivotal event that catapulted patient safety as a priority for all US hospitals. Within the report, the IOM highlighted the most common avoidable medical errors occurring in hospitals. These included adverse drug events, blood transfusions, wrong-site surgery, patient falls, pressure ulcers, and incorrect patient identification. The most serious patient injuries were noted to occur in the intensive care units, operating rooms, and emergency departments. One of the most important conclusions that the report made was that the large majority of medical errors resulted from poorly designed systems rather than from a particular individual or group of providers. It was within these delivery systems that certain processes and conditions created an environment for human error. While the most alarming consequence of medical errors is the cost of human lives, the estimated cumulative financial toll that results from preventable patient injuries was astronomical. The IOM estimated that nearly $30 billion of US dollars were lost each year for the cost of avoidable errors. These costs were endured by the health-care providers, institutions, payers, patients, and their families.

Less than 2 years following the release of "To Err Is Human," the IOM released a follow-up report "Crossing the Quality Chasm: A New Health System for the 21st Century." The report highlights the figurative chasm that lies between the health-care system that currently exists in America and one that could be designed with the proper application of knowledge and technology. The health-care delivery system was identified as "poorly organized" and "uncoordinated," allowing for multiple opportunities, major "unsafe acts," and "human error." Of note, patient transitions (between different providers and hospital units) were found to have a very negative impact on the efficiency as well as the safety of patient care. Crossing the Quality Chasm provided a strategy for "reinventing the system" with six redesign imperatives:

1. Reengineered care processes
2. Effective use of information technologies
3. Knowledge and skills management
4. Development of effective teams
5. Coordination of care across patient conditions, services, and sites of care over time
6. Making change possible

Within the same report, the IOM also asked that all stakeholders share a vision for the specific aims of health-care quality improvement. These aims were identified as the core elements for our health-care delivery system:

1. Safe
2. Effective
3. Patient-centered
4. Timely
5. Efficient
6. Equitable

Recognizing the need to respond immediately to these reports, Congress (under the Clinton administration) issued a motion for federal agencies to create an initiative aimed at reducing medical errors. (To date, almost a billion US dollars has been appropriated for these efforts by the federal government.) The private sector also responded with endorsement of similar efforts directed toward patient safety, urging providers to demonstrate their commitment to quality improvement. The new era of quality improvement in health care had finally arrived.

Patient Safety and Regulations

Since the release of the IOM reports, hospitals across the United States and other countries have placed a tremendous amount of resources dedicated to patient safety and reduction of patient injuries. Today, many of these efforts are aimed at specific categories of medical errors. The Joint Commission endorses an annual list of National Patient Safety Goals for hospitals worldwide. The list includes efforts aimed at improving the following:

1. Identify patients correctly
2. Improve staff communication
3. Use medicine safely
4. Prevent infection
5. Identify patient safety risks
6. Prevent mistakes in surgery

Although there are potentially an infinite number of areas for health-care improvement, many health agencies have now developed a growing set of defined safety measures for hospitals and providers to comply with. In particular, the Agency for Healthcare Research and Quality (AHRQ), a division of Health and Human Services (HHS), has endorsed a panel of quality indicators for hospitals to identify potential safety and quality concerns as well as monitor trends in care over a period of time. The current AHRQ quality indicators are categorized in four modules, each representing a different aspect of health-care quality [7].

AHRQ QI Modules

1. Prevention Quality Indicators
2. Inpatient Quality Indicators
3. Patient Safety Indicators
4. Pediatric Quality Indicators

Individual indicators can be found on the AHRQ website. Each of the modules has undergone multiple investigations for clarification, and revisions have been made since the initial release of the quality indicators. Although the federal, state, and local government have not mandated hospitals to report their performance within these modules, many private payers and other agencies have now endorsed many of the same quality indicators. Likewise, the rate of mandatory state reporting for hospital outcomes has been increased significantly over the past decade. Depending on the individual state, many hospitals today are required to publicly report these rates of hospital-acquired infections, surgical mortality, and outcomes for specific diseases such as heart attacks and pneumonia.

There are now hundreds of accepted patient safety and health-care quality measures that are endorsed by governmental and nongovernmental agencies. In addition to the Joint Commission and the AHRQ, the National Quality Forum (NQF) and the Centers for Medicaid and

Medicare Services (CMS) have provided a very extensive battery of standards for health-care organizations and their providers. These include measures such as childhood dental screening, wrong-site surgery, patient falls, and disease management for asthma. In more recent years, many local and state agencies have adopted these same standards for public reporting and have encouraged hospitals and their providers to develop an internal infrastructure for tracking and monitoring.

Defining Quality Improvement

Quality Assurance Versus Quality Improvement

Historically, quality and patient safety efforts in medicine have been predominantly based on quality assurance (QA). This process was almost always a reactive and retrospective approach to medical events and errors which occurred throughout the hospital. These trigger events would initiate an investigation through a peer review process and individual interventions would often take place. In many ways, quality assurance became a punitive process, ultimately aimed at identifying a person or group of people who performed poorly and deviated from what was deemed "standard of care." Expectedly, many providers became reluctant with reporting medical errors to their QA department from fear of being perceived as accusatory of their colleagues. Likewise, individuals who were being questioned about their errors or their involvement with adverse events developed an aversion with the QA process and became very defensive with case investigations. Today, most institutions have moved past this approach and now focus on identifying opportunities through system redesign and process changes. Many centers have coined this new approach as "Just Culture" and have avoided assigning blame to the specific actions of individual providers. This new methodology, however, is still predominately a retrospective process. Although it is an absolutely critical element to a successful quality improvement program at any institution or health-care delivery system, it is largely dependent of the self-reporting of a medical event. Most of these events are notable errors that have resulted in some form of patient harm. Of equal and arguably greater importance may be the events that did not result in patient harm but had the potential of such injury. These "near-misses" can only be measured consistently with a prospective monitoring of ongoing clinical activity that can capture such events. An example of this type of triggering system is tracking orders for the medication naloxone ("Narcan®"). This is a common strategy that hospitals will use to track potential narcotic overdoses and/or adverse effects of narcotic use on inpatients.

Quality improvement requires a comprehensive system that includes all the elements and activities of a quality assurance program as described above. However, modern-day quality improvement is a prospective process that incorporates lessons learned from retrospective case reviews as well as targeting clearly defined goals for future performance. Improvements in health care are no longer based on simply avoiding egregious medical errors. The delivery system must now demonstrate a capability to provide safe and effective care for their patients while performing with high efficiency and low cost. This is the aim for progressive quality improvement models in health care. Value-based purchasing and the Pioneer Accountable Care Organization (ACO) model, two individual programs designed by CMS, have used this as the premise for providers and buyers to optimize the performance and outcomes of their delivery system [8, 9]. Both programs incentivize hospitals and delivery systems to develop process measures to improve the management of specific areas in their hospitals as well as their ambulatory centers. Some of the major disease categories include diabetes, obesity, heart failure, pneumonia, and hospital-acquired infections. While both programs are in their initial phases, experts and advocates in health-care policy believe that this will be a central focus for the future of health-care reimbursement.

Creating a System for QI

Building a Team

No single provider, administrator, or health-care advocate can successfully create a quality improvement program without starting with a multidisciplinary team of stakeholders. This team should not be exclusive to just physicians, nurses, and hospital directors but should also include allied health personnel, social workers, case managers, health information technology specialists, hospital finance, and any other areas that involve the patient care experience and service delivery. Furthermore, involving patients and their families in quality improvement efforts has always proven to be beneficial. The best quality improvement efforts have come from collaboration with members from each of these areas. This not only provides for an effective means of communication between all the involved services but also creates an environment for strategic alignment and pooling of resources for the necessary steps in a quality initiative.

For individual projects, functional roles and leaders should be appointed within the multidisciplinary team. These include a clinical leader, administrative leader, technical leader, and a project manager. Each of these leaders should then be responsible for completion and compliance of each process within the project. The team leaders need to meet regularly to update and support each other with the progress of the project.

When developing these smaller project teams, it is crucial to involve frontline personnel (i.e., bedside nurses, residents, fellows, receptionists) as part of the team effort and assigning appropriate leadership roles to these individuals. One of the most common obstacles to successfully implementing change and improvement is not involving the frontline workers. Without their involvement, it is nearly impossible to create any effective and sustainable change within a delivery system.

Defining Goals and Aims

Defining goals for a quality improvement program begins with an understanding of the local delivery system as well as the consumers (population) that it is serving. It is with this understanding that we can then begin to define individual goals and create projects to meet the necessary outcomes. There are several key points when choosing and identifying a quality improvement goal.

The first, and arguably the most important, element of the goal should be the importance of the condition (i.e., an illness) or service (i.e., mental health counseling) that the project is aiming to improve. The importance is defined as the degree to which the consumer (patient/population) will be affected, both by severity and by prevalence. In other words, improving a serious condition that affects a large population (or subpopulation) within a delivery system is a fairly safe start.

Second, the potential for improvement should be evaluated and analyzed prior to committing further resources to the individual project. If the process (an individual clinical service) has already met the expected standards and particularly if it has exceeded the expected standards, then there may be little or no room for improvement. An example would be attempting to create a new process to improve the outcomes from a 98 % success rate to a 100 % success rate. While some conditions, such as patient falls, may be appropriate for this approach, others (i.e., medication errors) may never reach this goal. Certainly, many hospitals today would be very proud to boast a 98 % error-free rate for medication errors.

While most processes can be changed and improved in any delivery system, some are limited to the structure that the system is operating under. This may be the only obstacle to a well-designed quality improvement project, but it may also be an obstacle that can potentially limit any progress, even with the best efforts of a well-organized team. For example, a busy pediatric emergency room may find it nearly impossible

to provide privacy for their patients when being treated due to the space capacity of their facilities. While they may find alternatives which may improve privacy and even secure more physical space, other services and clinical areas may be compromised as a result. Consequently, one solution to a problem may create another challenge within the same structure or delivery system. For instance, the emergency department may create new space for individual patients to receive treatment, but this may result in a smaller space where patients are registered and triaged by the emergency department nursing staff.

Improvement Outcomes

Traditionally, quality improvement in health care has focused on physical outcomes such as mortality, morbidity, length of stay, and readmission rates. For congenital heart centers and intensive care units in particular, these outcomes may include length of intubation or ICU stay after surgery, incidence of heart block after a particular procedure, survival rate after heart transplant or post-Norwood death, post-cardiotomy cardiac arrests, incidence of neurologic injury, need for reintubation, catheter-related infections, and pressure ulcers. Physical outcomes tend to be the most common outcome measures for most clinical research projects. While medicine and health care is aimed at improving the life of patients and populations, it is understandable why these physical outcomes have become the major focus for both quality improvement and medical research.

More recently, both service outcomes and cost outcomes have played a larger role in health-care quality improvement. Service outcomes focus on patient satisfaction and the patient (family) experience with the health-care delivery system. For a family, this can be a routine follow-up visit with a child's primary cardiologist or their entire experience during an extensive hospital admission during which their child underwent complex open heart surgery. Access to health-care and individual providers is now a major service outcome that is being endorsed by many agencies. As a result, many institutions have adopted new strategies and innovations to create changes that will facilitate patient access.

As health-care resources and affordability continue to challenge the economy worldwide, cost outcomes become increasingly more significant. The cost(s) of any process is not necessarily the financial cost. It also includes the cost of time, human and technical resources, space utilization, variation in care, medical errors, and excess waste. Quality improvement for almost every health-care process should involve a detailed analysis of the various resources required to deliver the best outcomes at the lowest cost. This defines the value of any clinical service, whether it is a successful cardiac catheter ablation of a fatal arrhythmia or a protocol to manage anticoagulation for mechanical valves.

These three categories of outcomes (physical, service, and cost outcomes) are also used as the framework for the Institute for Healthcare Improvement (IHI) Triple Aim Measures [10]. The three dimensions of the Triple Aim approach include:

1. Improving the health of populations (physical outcome)
2. Improving the patient experience of care (service outcome)
3. Reducing the per capita cost of health care (cost outcome)

Many organizations now use this approach to address the growing challenges of maintaining a successful and viable health-care delivery system while providing the best care for their patient population. This approach can also be readily applied to any individual process improvement project.

First Steps

Quality improvement initiatives in congenital heart centers may, and in fact should, be situated within all of the clinical subsections. This includes the outpatient and satellite clinics, the adult congenital practice, the cardiac catheterization laboratory, the cardiovascular operating

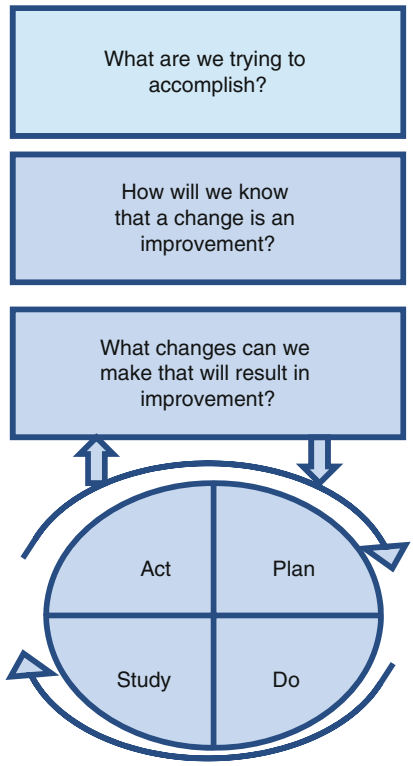

Fig. 179.1 Plan-Do-Study-Act model

room, the cardiac intensive care unit, the inpatient services, the echocardiography laboratory, and the exercise laboratory. In short, it should include any of the sections and disciplines that make up a comprehensive care center for children and adults with heart disease. *Quality improvement* and *patient safety* are closely linked, may comprise two identities of a single department, and may even be considered interchangeable terms. However, this is inaccurate and may weaken initiatives designed to strengthen both areas. While the two may comprise similar efforts with the broader heading of improvement in patient outcomes, they should not be used as interchangeable disciplines. The focus of the second section of this chapter is presenting specific examples of quality improvement initiatives located within the cardiac intensive care unit, but whose success depends upon and enjoys the support of multiple disciplines. These are programs, policies, procedures, and efforts that seek to alter and improve delivery of effective therapies.

A fundamental component and first step of quality improvement is accurate measurement of performance through data collection and aggregation and analysis of the data. The research dictum of "bad data in leads to bad data out" holds true in quality improvement as well. The first step toward improving delivery of care and a successful quality improvement initiative is a comprehensive and accurate understanding of the existing practice. Questions to be answered may include:

"What constitutes and characterizes our practice in a certain realm?"

"What are our outcomes for a particular procedure or disease state?

"What is our experience with a particular medication, device, or intervention?"

"What is the incidence of a particular critical illness complication?"

In order to drive change and improvements in delivery of care, accurately answering questions such as these are paramount, though not always easy. Among the clinical staff, anecdotal "evidence" that rationalizes practice may be a powerful element to combat. Most nurses and physicians vividly recall that one dramatic case with a poor outcome or good result and from this extrapolate to all subsequent others. Perceptions of clinical staff are often not based on fact, or the best evidence, and these false perceptions may need to be addressed forcefully. The benefit of accurately characterizing clinical practices can be impressive and this will likely lead to identifying some aspect of care or communication in need of improvement. This maybe the first designed target of a quality improvement process.

The information from accurate data collection and data analysis should lead to identification of opportunities for improvement. A particular tool that is useful in structuring an effort, once a question or problem is identified, is the Institute of Health Care Improvement's Plan-Do-Study-Act model.

The PDSA tool (Fig. 179.1) provides a simple and fluid framework for assessment of particular steps in a quality improvement project. Frequently, successful QI initiatives may go through

multiple PDSA cycles before success is achieved. Each phase's titles are relatively self-explanatory: the *Plan* phase identifies both the task at hand, defines the environment and the key participants, as well as attempts to anticipate challenges. The *Do* phase includes the initial actions and may be the period of time before practice change or intervention occurs, when baseline data is compiled. The *Study* phase is that of the identifiable intervention or practice change. The final phase, the *Act* phase is characterized by assessment and outcome of intervention. Many times, this cycle will be repeated or specific phases noted to demand more attention and time. Although these phases are linked in execution, a successful initiative will reflect the distinctive demands of each phase as well.

Multicenter Collaboration Versus Single-Center Experience

Although congenital heart disease is the most common human birth defect, the incidence of all the lesions taken together remains relatively low. Since congenital heart lesions are relatively rare, standardization of practice across multiple centers is challenging. This is particularly the case for infants born with the most challenging lesions such as hypoplastic left heart syndrome. These neonates are among the most complex and critically ill patients, and as such, their clinical outcomes would seem to be a natural target for improvement strategies. The National Pediatric Cardiology Quality Improvement Collaborative (NPC-QIC) represents one of the first organized efforts to incorporate quality improvement methods to pediatric cardiology. The NPC-QIC included participation from multiple sites from around the United States. The initial QI project that was identified was the reduction of mortality among the single-ventricle patients with hypoplastic left heart syndrome after the first palliative stage and before the second stage. The NPC-QIC has endeavored to determine best practice guidelines for these fragile patients by characterizing perioperative and postoperative care, as well as interstage outpatient care [11–16].

Multidisciplinarity and Interdisciplinarity

Multidisciplinarity is a model for organizational structure for quality improvement initiatives. Multidisciplinarity is a nonintegrative mixture of disciplines in that each discipline retains its methodologies and assumptions without change or development from other disciplines within the multidisciplinary relationship. Care teams need to be educated to interact as interdisciplinary by blending the practices and assumptions of each discipline involved, which meant that the team was able to work collaboratively, mixing the different scopes of practice and areas of competence [17]. *Multidisciplinarity* is distinguished from *interdisciplinarity* by the latter blending the practices and assumptions of each discipline involved.

These two concepts have been important to the success of efforts aimed at reduction of preventable harm and mitigating human error at The Heart Institute of the Children's Hospital Colorado. As there are many approaches toward quality as well as performance and outcomes improvement, it is important to recognize the particulars that pediatric cardiology, cardiac surgery, cardiac anesthesia, and intensive care entail. The reader may be directed to previously published pieces that discuss the susceptibility of cardiac surgery in particular and pediatric critical illness specifically, to the occurrence of adverse events as well as initiatives aimed at improvement [16, 18–20]. The final part of this chapter details specific examples of quality improvement initiatives efforts whose success and failures rest on the backbone of multidisciplinary collaboration.

Checklists

Checklists in the intensive care unit are employed in order to reduce errors of omission. The complexities of routine procedures and their propensity for risk and adverse events are incredible. It is impressive that so many critically ill patients do well in spite of the wide practice variation among care providers.

The utility of the checklist has been described and lauded in the academic medical literature as well as the lay public. Extolling the virtues of the "simple checklist" is commonplace in the adult and pediatric intensive care unit; however, the benefit of checklist use is less certain. Use of checklists to monitor a single intervention has been demonstrated, but clear and repetitious demonstration of usefulness on a more global use remains somewhat subjective and without consistent evidence of efficacy. Authors have identified many problems surrounding checklist efficacy to be in the implementation phase [21]. Merely "adopting a checklist" is no guarantee of efficacy and compliance. Checklists may benefit from accountability strategy and repetitive prompting. For a checklist to be used to its maximum potential, active prompting should be promoted rather than simply having the checklist available for use [22]. Examples of the most successful implementation of checklists have been coincident with changes of behavior, which also involved empowerment of ancillary staff to participate and, in some circumstances, enforce use of the checklist. It is critical that with roll out of checklists, the clinical team also details a strategy for monitoring compliance. This may be performed with observational audits by observers familiar with the process, as well as by surveying data completion via the electronic medical chart. Not surprisingly, as with most quality improvement interventions, the success of the intervention is dependent upon an adherence strategy.

In the cardiac intensive care unit in Children's Hospital Colorado, the use of a checklist as a registered nurse (RN) rounding tool has proved very useful (Fig. 179.2). This is used during medical rounds and allows the bedside nurse to methodically and succinctly update the team, as well as review the care plan and interventions planned for the day.

Protocols

Evidence-based protocols may improve the quality of care delivery provided that they often can also account for practice variation. In adult critical care, protocols may exist for many interventions and policies, including ventilator-weaning, insulin administration, and patient sedation practices. Protocol use is widespread in adult critical care. This is less the case in pediatric critical care and perhaps even less in pediatric cardiac critical care. Disease-specific care bundles have demonstrated to improve some disease processes including ventilator-associated pneumonia (VAP), catheter-associated bloodstream infections (CABSIs), ventilator-weaning protocols, and protocols that guide sedation administration as well as sedation tapering. This lack of application in pediatric critical care and cardiac critical care may be attributed, once again to the relatively smaller numbers of patients an individual center may encounter, as well as the overall lack of development of multicenter cooperation.

Communication and Patient Handovers

The cardiac intensive care unit (CICU) is a place of increasingly complex patient care. It is not uncommon for there to be in excess of double digit care team members per day involved in decisions and discussions regarding the daily care plan for routing patients in the units. It becomes even more challenging when different patients within the same CICU have different providers such as transplant/heart failure patients, adult congenital patients, and patients undergoing complex interventional catheterization procedures. Throughout their hospitalization, patients are admitted and transferred between various units. It is fairly common for a pediatric CICU patient to travel between the cardiovascular operating room (CVOR), the non-acute inpatient service, the radiology suite for procedures and imaging, and the cardiac catheterization laboratory. The destinations and the number of staff involved are almost too numerous to identify. This all occurs in the setting of the myriad number of monitors with their alarms, lights and buzzers. It is easy to see how

misunderstandings and miscommunications are ripe for the occurrence, with multiple conversations occurring simultaneously and at times with multiple leaders.

Improvements in handover communication have their roots in some nonmedical fields such as Formula 1 motor racing and the aviation industry [18]. The idea, taken from these

industries, is that a multidisciplinary team can come together as a cohesive unit to perform complex and often simultaneous procedures or skills, in a manner that is efficient, timely, and above all safe for the patient. Actually it is a time of particular vulnerability as in the process of the transfer the patient undergoes a break in continuous monitoring as the cables and devices are disconnected from the patient in order to settle them into the intensive care unit [19, 20, 23]. Figure 179.3 illustrates the breadth and depth of what is expected to be covered during cardiovascular operating room to cardiac intensive care handover at Children's Hospital Colorado Heart Institute.

Examples of Successful Collaborative Efforts to Reduce Preventable Harm

Catheter-Associated Central Line Infection Reduction

Catheter-associated bloodstream infections (CABSIs) in children with critical illness are costly and cause a significant morbidity. Efforts to reduce catheter-associated bloodstream infections have been recognized as an important preventable event for many years, but only recently have a concerted and coordinated efforts to reduce the incidence of CABSIs have yielded impressive results. The National Association of Children's Hospitals and Related Institutions (NACHRI) identified CABSIs as a target for reduction of preventable harm, in 2006. Since then, a multi-institutional and collaborative effort in the USA has been ongoing in pediatric intensive care units and CICUs, designed to test and reform catheter care practices and identify best practices. Pediatric-specific central line insertion and maintenance bundles have resulted in a sustained decrement in overall PICU and CICU CABSI rates [24, 25].

Nevertheless, even within a single institution, there are substantial challenges to achieving sustained zero events. Figure 179.4 illustrates the experience of Children's Hospital Colorado's CICU from January 2011 through December 2012. During this time, this program has been able to significantly reduce the incidence of overall CABSI events, but the unit continues to experience variability in rates, usually bouncing off of zero, but not yet able to sustain zero incidences for more than 6 months.

Code Reduction

The implementation of pediatric rapid response teams and early warning systems have been two strategies designed to reduce codes from occurring outside of the intensive care units. This initiative has its roots in multiple studies across many institutions and patient demographics. Consistently these studies conclude that patient survival is worse if the patient experiences a cardiorespiratory code outside of an intensive care environment. With this in mind, The Children's Health Corporation of America (CHCA, Shawnee Mission, KS) formed a multicenter collaborative designed to reduce the rate of pediatric codes outside ICUs. Twenty hospitals participated in the collaborative, the focus of which was elimination of failure to escalation and improvement in prevention, detection, and correction of specific high-risk units in each member institution and their patients contained within.

This collaborative was able to demonstrate a reduction in pediatric codes outside the ICUs, although this reduction was variable and in some cases modest: 3 % reduction for the entire collaborative, but a 24 % reduction of reported codes in selected hospitals after the collaborative ended. The collaborative was able to demonstrate an improvement in the Agency for Healthcare Research and Quality's Hospital Survey on Patient Safety Culture (AHRQ HSOPS) patient safety culture scores. The authors conclude that a complex quality indicator such as survival from a code (a relatively rare event) and overall code reduction is an ongoing process that requires dedication and sufficient time. Nevertheless, a collaborative model may be able to accelerate such improvements [26].

CVOR to CICU TRANSFER PROTOCOL

The transfer of critically ill patients from the CVOR to the CICU should follow a systematic approach. The ANESTHESIOLOGIST is responsible for the care of the patient until the report process below is complete. The CICU nurses assessment of the patient must occur AFTER the repot process is complete so that there are no distractions during the process below.

Staff to be present for the transfer of care in the CICU: SURGEON, ANESTHESIOLOGIST, NURSE, RT

BEFORE LEAVING CVOR

- PUMP Check
  - With CICU nurse
  - Check programming
  - Correct labels
- PACEMAKER
  - Check thresholds
- ORGANIZE
  - Arterial, central and peripheral lines color labels etc
- PREPARE for transport:
  - Airway equipment
  - Pacemaker and cables
  - Drugs
  - Correct bed
  - Transport monitor working and cables organized
  - Oxygen or Blender

TRANSFER OF CARE IN THE CICU

- PARK & BRAKE the patient's bed on arrival in the CICU
- VENTILATOR
  - Check initial ventilator settings
  - Transfer patient to CICU ventilator and check for bilateral breath sounds
- CHEST TUBES
  - CICU nursing staff attach to wall suction and check correct functioning
- MONITORING
  - Transfer brick from the monitor
  - Check that all parameters are displayed, lines are zeroed etc
- COMMUNICATION
  - SURGEON gives report on surgery performed
  - ANESTHESIOLOGIST gives report
    - Patient Information
      - Name, age, weight, allergies and relevant H & P
    - Operative Course
      - Anesthetic problems
      - ETT size and position
      - Line locations, size and any problems
      - Epidural if present - location, drugs used during case and infusion ordered
      - Times: CPB, XC, DHCA
      - Weaning from CPB and any issues
      - ECHO findings post-CPB
      - Pacemaker settings
      - Inotrope infusions
      - Blood products given and transferred with patient
      - Last Antibiotic time
- Q & As
  - ONE person speaks at a time
  - Discuss anticipated course for the patient

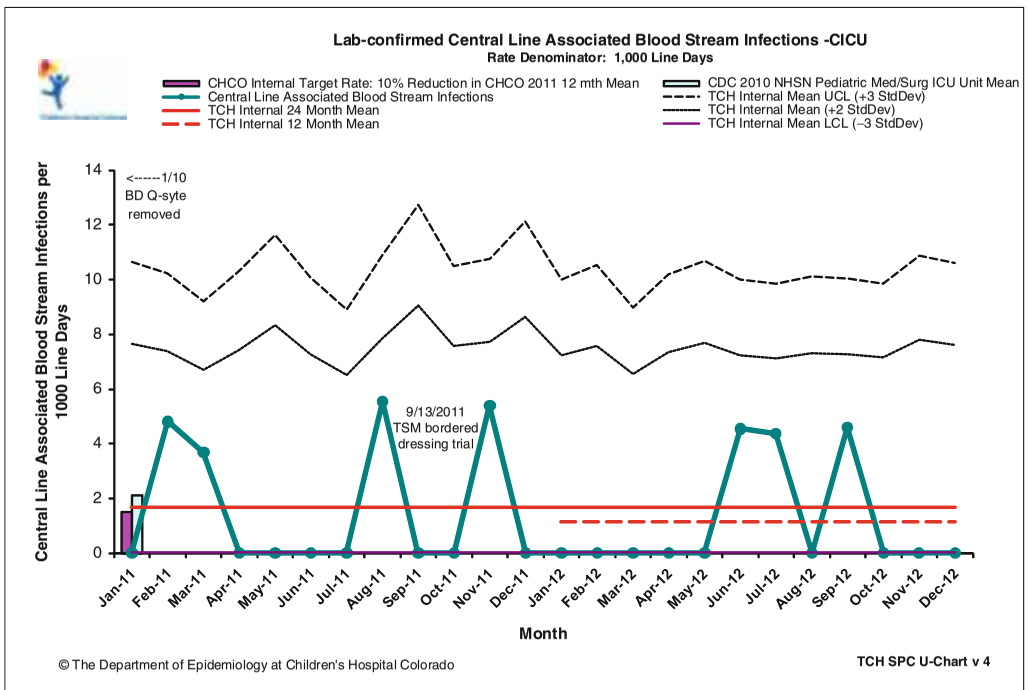

Fig. 179.4 Statistical process control chart for catheter-associated bloodstream infections in the CICU

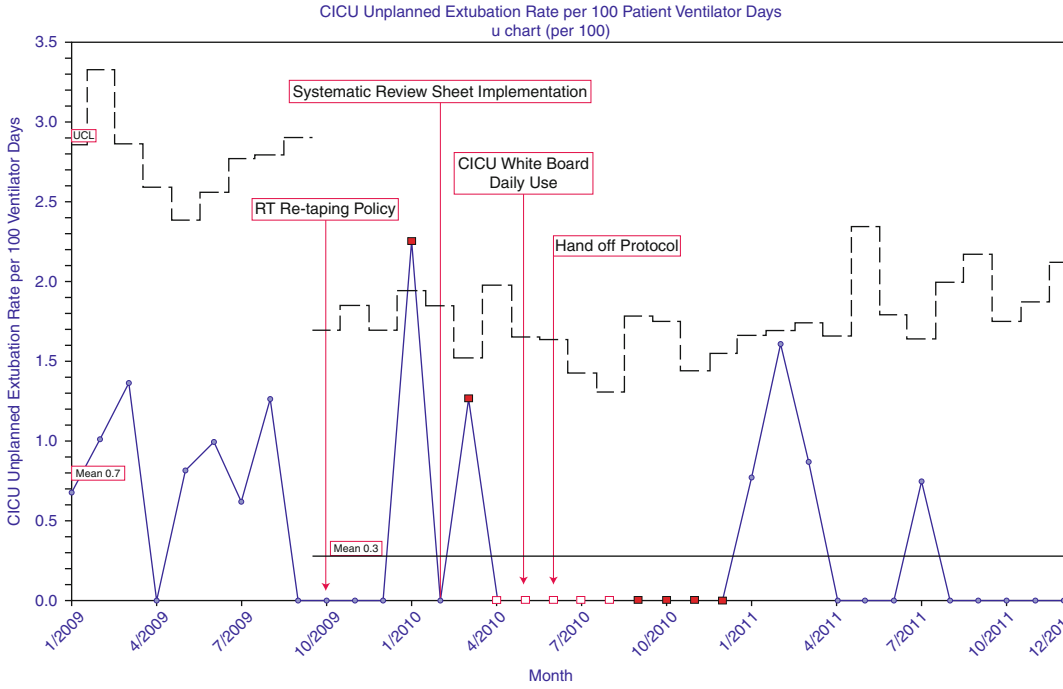

Fig. 179.5 Statistical process control chart for unplanned extubation events in the CICU

Unplanned Extubations in Critical Care Units

Unplanned extubations in pediatric critical care units can result in mortality, increased ventilator time and ICU length of stay, as well as increased risk of adverse events during reintubation. The CICU at Children's Hospital Colorado did not have an accurate way to track these preventable events prior to 2009. Unplanned extubations were deemed an area of concern by both the CICU and the PICU in this institution due to (1) unreliable data tracking, (2) a subjective awareness that the incidence of these events was on the rise, (3) the aforementioned risk of adverse events, and (4) lack of awareness among the staff of the importance of these events. The leadership team of both units organized an interdisciplinary quality initiative which relied upon multiple PDSA cycles and was able to significantly reduce the incidence of unplanned events in both units. Improvements and interventions carried out included those in data collection as well as in clinical practices and systematic data review. Figure 179.5 demonstrates the statistical process control (SPC) "u" chart of monthly unplanned events per 100 ventilator days for the CICU over a 2-year period (2009–2011). Average rates are calculated separately for baseline, intervention, and post-intervention periods, and the relative effect of the various intervention may be gauged as well [27].

Conclusions

In summary, it is no longer sufficient to characterize a congenital program's health as dependent on surgical survival or survival to discharge. The clinical correlate is that we cannot just reassure the parent of an infant undergoing an arterial switch that the baby will survive to discharge. We now must achieve a new quality standard where parents are told that their child will have a successful and uncomplicated procedure with great long-term outcomes. Mortality for all lesions including the most complicated and complex has

fallen so dramatically that survival is often expected in most patients. Patients and families should expect the congenital heart center, where they seek care, to be a place wherein the highest perioperative, outpatient, and subspecialty care is delivered, and delivered safely, by a multidisciplinary staff committed to continuous process improvement. As congenital heart centers are correctly now turning attention to reduction in morbidity and ensuring acceptable longer-term neurocognitive neurobehavioral and functional quality of life outcomes, quality improvement is an engine driving this endeavor.

Complexity of Caring for Complex Pediatric Congenital Heart Disease

180

Samuel D. Yanofsky, Randall M. Schell, and Roberta Williams

Abstract

The optimal care of pediatric patients with complex congenital heart disease requires collaboration and a multidisciplinary team approach from surgery, cardiology, anesthesiology, critical care, and other medical subspecialties. It is essential that an effectively functioning cardiac team be established in the care of complex congenital heart disease patients to reduce their morbidity and mortality. The vital components of a highly effective team not only include clinical excellence throughout all disciplines but must include excellence in leadership, trust, accountability, respect, and a shared mental model of the heart center's mission and values. If these components are maximized, the quality of patient care excels, optimizing the lives of children with congenital heart disease.

Introduction

Medical and surgical advances have allowed many complex, and formerly life-ending, congenital heart defects to be managed as a chronic illness. Examples of recent innovations in the care of complex congenital heart diseases (CHD) include (1) definitive repair in very low birth-weight neonates, (2) new surgical techniques (e.g., hybrid techniques, minimally invasive techniques), (3) improvement in infant and pediatric perfusion equipment and mechanical support devices (i.e., extracorporeal membrane oxygenation(ECMO) to manage refractory cardiorespiratory failure and aid cardiopulmonary resuscitation), (4) newer pharmacologic therapies (e.g., inhaled nitric oxide, natriuretic peptide, vasopressin, milrinone), (5) advances in imaging technology (e.g., cardiac MRI, transesophageal echocardiogram(TEE)), and (6) "state-of-the-art" monitoring modalities (e.g., cerebral oximetry) [1].

In the neonatal period, patients with CHD frequently require interventions and perioperative care that is highly complex and there is little physiologic tolerance for error. Moreover, there is a vast array of congenital and postsurgical anatomic variations and numerous possible palliative or reparative options to consider.

The optimal care of pediatric patients with complex congenital heart disease requires collaboration and a multidisciplinary team approach from surgery, cardiology, anesthesiology, critical care, other medical subspecialties, and multiple other professionals. Pediatric cardiac professionals greatly enhance functionality as a team and are limited as individual members. To obtain the greatest benefit for the child with CHD, all members of a pediatric cardiac team must be provided the opportunity to contribute their knowledge and skills and share the common vision of excellence in outcomes.

Decreasing mortality across institutions has led to the increased use of in-hospital morbidity and functional status as a relevant outcome measure following cardiac surgery for congenital heart disease. Functional, collaborative, and multidisciplinary teams work to further reduce mortality and morbidity for pediatric patients undergoing complex congenital heart surgery.

Multidisciplinary Nature of Care

A search of the websites of congenital heart disease programs in the United States frequently cite "team approach," "multidisciplinary approach," "integrated," "collaborative," "multiple experts," and "specialized knowledge" to describe the local pediatric cardiac team. Moreover, many programs state "management of the pediatric patient for congenital heart disease requires a multidisciplinary team approach." Such indications stress the importance of multidisciplinary care, yet do not always state why it is so valuable.

Patients with complex CHD are frequently very sick and require complex interventions while they are still in the fragile neonatal period. Collaboration, defined as professionals with different skill sets sharing knowledge and expertise in a positive working environment as they deliver health care, is required. Maternal-fetal specialists, neonatologists, pediatric cardiologists, pediatric cardiac surgeons, and others may be consulted to make an in utero diagnosis of CHD, prepare for delivery, and plan early palliative or corrective intervention. Preoperatively, palliative interventions may be undertaken by pediatric cardiologists and specialized imaging used by radiologists (i.e., cardiac MRI and MRA) and pediatric cardiologists (i.e., TEE, cardiac catheterization), often requiring the involvement of pediatric cardiac anesthesiologists.

In addition, multidisciplinary meetings are used to plan the necessary palliation or definitive repair with the pediatric cardiac surgeon and/or pediatric cardiology interventionalist. Newer techniques, such as the hybrid palliative strategy of pulmonary artery banding and ductal stenting for neonates with hypoplastic left heart syndrome (HLHS), involve multiple disciplines working seamlessly together. The cardiac surgeon, cardiac anesthesiologist, cardiologist, perfusionist, and specialized nurses and technicians work

together as a multidisciplinary team during the intraoperative period. A "handoff" or transition of care is required as the patient is transferred from the operating room to the intensive care unit (ICU). In the ICU, a team mainly composed of cardiac intensivists, cardiologists, cardiac surgeons, nurse practitioners, bedside nurses, and many others including pediatricians, pharmacists, respiratory therapists, nutritional therapists, occupational therapists, physical therapists, social workers, child life experts, and multiple support staff provide care for the patient. Residual problems following corrected CHD (e.g., arrhythmias, ventricular dysfunction, arterial-pulmonary or veno-caval shunts, valve stenosis or regurgitation, pulmonary hypertension) may require further interventions and collaborative team efforts.

Good outcomes depend on well developed and mature collaborative teams working together and many complex systems functioning smoothly. However, the contribution of each member of the multidisciplinary team on outcomes has not been well evaluated in the realm of pediatric cardiac care. Most research has focused on surgeon performance and mortality as a single outcome. However, in some cases, mortality may be strongly influenced by patient and postoperative management factors, rather than technical outcomes of the procedure itself. The contribution of other team members (e.g., anesthesiology, cardiology, intensive care teams) towards errors in diagnosis, decision-making, and communication has not been well investigated. Recently, the relationship of nurse staffing, skill mix, and Magnet recognition to institutional volume and mortality for congenital heart surgery was examined in almost 20,000 cases and at 38 children's hospitals. Interestingly, none of the nursing characteristics was associated with mortality. The authors postulated the outcome variable of mortality might be insensitive to nursing characteristics in children's hospitals, as long as certain staffing thresholds have been met [2].

More patients with congenital heart disease are reaching adulthood, resulting in a changing profile of congenital heart disease. In 2000, the number of adult congenital heart disease patients was approximately equal to the number of pediatric congenital heart patients. In 2020, adult pediatric CHD patient population is projected to far exceed the pediatric CHD patient population [3, 4]. Multidisciplinary teams with specialized knowledge and training in adult CHD management will be needed, as residua and sequelae frequently complicate reparative surgery and require long-term surveillance and further intervention. The care of individuals with complex heart defects must be continuous through life and provided by multidisciplinary teams.

The Pressures of a Rapidly Evolving Health Care: Outcomes, Quality, and Economics

Outcomes

Although mortality is the ultimate outcome variable, analysis of this variable is limited to only approximately 4 % of the total pediatric congenital heart surgery population [5]. Current published estimates of mortality rates for children and infants undergoing cardiac surgery vary from 3.7 % to 4.3 %, while mortality rates for individual cardiac procedures based on type and procedural complexity range from 0 % to 30 % [6, 7]. The use of in-hospital morbidity, rather than mortality alone, and functional status as an appropriate outcome measure following cardiac surgery for congenital heart disease is in its infancy [8, 9].

There is significant inter-institutional variation in mortality after congenital heart surgery, and there are limitations of using in-hospital mortality rates as a basis for quality measurement or comparison. Mortality rates are "too low," and pediatric cardiac surgery is performed too infrequently and with a high number of operation types, to allow valid quality comparisons between programs based on in-hospital mortality [5, 10]. There also appears to be racial and ethnic disparity in mortality rates. Racial/ethnic minority groups have greater risks than white children for death after congenital heart defect surgery and an earlier median age at death for those with

congenital heart defects [11]. Hence, mortality rate alone is not a valid indicator of quality differences between pediatric cardiac surgical programs.

Case Complexity

Mortality increases as complexity of the pediatric cardiac surgical procedure performed increases. An institution or program that does predominantly atrial septal defect (ASD) repairs would not be expected to have a similar mortality rate as a program or institution that performs predominantly complex congenital heart surgical procedures or interventions including Norwood staged procedures. Therefore, using raw data such as measurements of mortality without adjustment for complexity is inadequate. Quality of care and outcome evaluations must take into account variations in case complexity or "case mix" [5, 12].

Comparing mortality rates between institutions/programs that have varied case mixes requires the use of complexity-based "risk adjustment" methods. Two common ways of performing risk adjustment in congenital heart surgery include the RACHS-1 (Risk Adjustment in Congenital Heart Surgery-1) and Aristotle methods [13, 14]. As complexity increases in both the RACHS-1 and Aristotle methods of assessing complexity, discharge mortality increases. Both RACHS-1 and Aristotle risk adjustment methods are used to facilitate complexity stratification in databases such as the Society of Thoracic Surgeons (STS) Congenital Heart Surgery Database. Risk adjustment may perhaps be used in assessing local risk-adjusted results for CHD lesions and using evidence-based referral to other centers with lower risk-adjusted mortality for specific CHD pathology [15].

Case Volume

Most studies of the volume-outcome relationship have reported significant associations between higher case volume and better health outcomes for many types of surgical procedures. However, the relationship between pediatric cardiac surgical volume and mortality is not straightforward. Larger case volumes cannot automatically be equated with better quality of care. With adjustment for patient-level risk factors and surgical case mix, there appears to be an inverse association between pediatric cardiac surgical volume and mortality that becomes increasingly important as case complexity increases. When comparing mortality for low-complexity cases, volume was not associated with mortality; however, when case complexity increased, lower-volume programs underperformed larger volume programs. Small was defined as yearly pediatric cardiac surgical volume <150; medium, 150–249; large, 250–349; and very large, ≥ 350 cases [16].

Evidence-Based Practice, Variability, and Quality

As clinical outcomes in CHD have improved in recent years and mortality rates have decreased, measurements of quality and outcome have moved away from mortality alone towards reducing morbidity and improving functional outcomes. Quality improvement science has demonstrated that standardization of practices is associated with cost savings and improved operating efficiency. Reducing process variation through the standardization of common practices results in more favorable outcomes. However, there still remains considerable institutional and individual variation in the management of pediatric patients with complex CHD.

Although practice should be driven by evidence, there currently exists a large gap in knowledge on the impact that everyday decisions have on the surgical management and outcome of patients with CHD [17]. There is great variability in the patients, as well as many aspects of the management of patients with CHD, that makes standardized assessment and comparison of outcomes between programs or institutions difficult. There are multiple possible types of interventional/surgical procedures that vary in complexity and mortality rates, multiple anatomic variants of specific CHD lesions, and multiple associated abnormalities that increase morbidity or mortality that might be present in some patients

but not others. Moreover, there is considerable individual practitioner and institutional variability as well as inter-institutional variation in the post-operative course and management of patients based on specific CHD pathology, whether post-operative care is provided in a dedicated pediatric cardiac ICU, whether a pediatric cardiac intensivist is present in house 24/7, among other patient-care variables [17–20].

The National Heart, Lung, and Blood Institute established the Pediatric Heart Network in 2001 to provide a collaborative network for conducting clinical studies in an attempt to provide the evidence needed to drive evidence-based practice. Recent advances include the formation of working groups to help identify and define the areas in which clinical studies might have the greatest impact, clinical registries and databases (i.e., STS Congenital Heart Surgery Database) for researching outcomes, and large multi-institutional research and quality improvement collaborations to assist in reducing clinical process variation and improving patient outcomes [17, 18]. Quality improvement projects could include multidisciplinary site visits between institutions to discover both variability and commonality in practice, allow sharing of information about successes, and compilation of successful practice changes as a route to better outcomes [21].

Cost/Economics

Across the world, approximately one million children per year are born with congenital heart disease, but approximately 90 % of these receive suboptimal care or no care at all. Childhood CHD mortality is very high in low-income countries, and only a small number benefit from surgical treatment. Problems with care of those with CHD in developing countries include (1) a large number of children with congenital heart defects, (2) delay in diagnosis and late presentation, (3) prioritizing patients with congenital cardiac malformations for cardiac surgical procedures when resources are limited, (4) difficulty maintaining quality care, including training caregivers, (5) and determining the best procedure to achieve maximum palliation at lower cost, as less than 5 % can afford surgery [22–25].

Congenital heart disease affects nearly 1 % of all live births and consumes an estimated six billion dollars annually in acute care costs alone. Although the incidence of CHD has remained stable during the last 50 years, the natural history of most lesions has changed quite dramatically [26]. In developed countries of the world, approximately 90 % of infants with CHD survive into adulthood, and the focus has changed from an emphasis on reducing perioperative mortality to improving quality of life and reducing morbidity [27]. Those with CHD are living longer. These patients will require interventions, have complications, and may need more than one operation. As the life expectancy for adults with CHD increases and diagnostic and therapeutic options continue to evolve, significant resources will be required to care for this patient population [4].

There is limited data regarding factors impacting resource utilization for patients undergoing congenital heart surgery. Hospital discharge data from the year 2000 including 10,569 cases of congenital heart surgery in patients <18 years of age from 27 states identified median total hospital *charges* per patient of $53,828. Those patients with charges in the uppermost decile for total hospital charges (i.e., exceeding $192,272) were designated as high resource users. Independent predictors of a higher odds of high-cost cases included risk adjustment for congenital heart surgery risk category, age, prematurity, the presence of other major non-cardiac structural anomalies, Medicaid insurance, and admission during a weekend. Gender, race, bed size, teaching and children's hospital status, hospital ownership, and hospital volume of cardiac cases were not independently associated with greater odds of high resource utilization. There was some geographic variation in resource utilization between states [28].

In a more recent investigation, patients 0–18 years of age undergoing congenital heart surgery and surviving to hospital discharge ($n = 2124$) between 2001 and 2007 at a large number of

hospitals utilizing a specific database system were studied. The median unadjusted total hospital *cost* per patient for four specific CHD lesions was as follows: ASD repair ($12,761), VSD repair ($18,834), tetralogy of Fallot repair ($28,223), and arterial switch operation ($55,430). For each of the four surgeries, room and board accounted for the largest proportion of total costs (≈33–40 %). Interestingly, total hospital costs varied significantly by center for all congenital heart surgeries evaluated, even after adjustment for patient and center characteristics and length of stay. The differences among centers were most prominent for lower-complexity procedures, suggesting that strategies to reduce cost variation may be best focused on lower-complexity, common CHD operations [29]. However, most would agree that higher complexity justifies higher reimbursement. There is a known positive correlation between in-hospital costs and Aristotle scores, and the Aristotle score or complexity score could be used to match reimbursement with the clinical complexity of the disease or condition [30].

Evidence should be used to drive change when attempting to reduce costs and improve quality in the care of children with CHD. Several areas that have been investigated for which there is at least some data to help guide therapy include (1) evidence-based referral of patients to the most appropriate centers for care, (2) cost-effective use of salvage cardiac ECMO in children with CHD, (3) cost-effective use of TEE during pediatric cardiac surgery, and (4) appropriate use of "fast-tracking" defined as the concept of early extubation, mobilization, and hospital discharge, in an attempt to improve outcome [15, 31–33].

Complications (e.g., postoperative infection, hemorrhage complicating a procedure, iatrogenic pneumothorax) are associated with higher resource utilization. In one study, those with complications were three times more likely to exceed $192,272 in total charges (uppermost decile of charges), despite adjusting for known risk factors for high resource use [34]. Complication reduction is likely to result in economic benefit. If a health-care system permits institutions to charge for each hospital day, postoperative procedure, and complication that prolongs hospital stay, it is paradoxically financially rewarding institutions with poor outcomes. Reimbursement in the future should be designed to reward institutions with better "surgical performance" for equal or greater complexity care.

In reality, medicine may be able to provide more care than society can afford. A discussion of financial cost should include long-term psychosocial and societal economic "costs" [9, 35]. Future discussions of cost need to move beyond the costs of in-hospital care [36]. Maintaining cost-effective care requires (1) evidence-based and timely referral, (2) early surgical correction, (3) adequate postoperative care provided in an evidence-based manner, and (4) reduction of complications. Innovation and effective team building are also necessary to cut costs and improve the quality of care.

The Importance of Teamwork in the Care of the Complex and Fragile Child

> The major benefits of a team concept occur only when all involved have a chance to exert their skills, knowledge, and influence.
> –Gregory E. Huszco (Tools for Team Leadership 2004)

> Perhaps the most significant requirement for creation of a cohesive team is in creating a collective sense of responsibility towards the patient.
> –PK Kumar (Ann Pediatr Cardiol 2009)

> The patient is the star, not you.
> –R Schell, M.D.

Multidisciplinary Teams

Minimizing the financial costs of providing care to children with CHD that is innovative and effective, yet efficient and cost-effective, will require teams whose individual members are allowed – and encouraged – to contribute their individual discipline-specific expertise. Innovations in technology, growth in knowledge, and improved interdisciplinary collaboration have contributed to improved outcomes in CHD.

The development of pediatric cardiac subspecialties in cardiology, surgery, anesthesiology, and intensive care, among others, has increased the number of highly trained professionals with unique knowledge and skills. In the optimal setting, these subspecialists work as a cohesive team that effectively communicates, collaborates, and cooperates. In this multidisciplinary team approach, each member of the team has both an opportunity and obligation to exert their skills, knowledge, and influence towards a common vision of excellence in outcomes. A model based on one professional being the "captain of the ship" and other professionals following orders is antiquated and suboptimal for managing patients with complex CHD.

In the past, roles have been quite compartmentalized. The pediatric cardiologist made a diagnosis and referred the child with CHD to a cardiac surgeon who performed the requested surgery, and the patient was cared for by the cardiac surgeon in a pediatric intensive care unit, not specifically dedicated to pediatric cardiac patients, and followed up by pediatric cardiology.

There has been a blurring of the distinction between individual specialties and defined specialty roles and increased recognition that pediatric cardiac care thrives on teamwork. Innovations in technology, increased complexity of disease, and evolving therapeutic strategies have driven this change. Examples include (1) increased available choices for methods of correction or palliation (i.e., surgical or catheter interventions, hybrid heart procedures) with individualized treatment plan determined by a multidisciplinary team; (2) requirement for correction in the newborn period or infancy; (3) newer imaging modalities, such as TEE, that contribute to the team approach when anesthesiologists and pediatric cardiologists provide insights that the pediatric cardiac surgeon seeks, including immediate postoperative assessment of repair; and (4) pediatric cardiac intensive care management by a multidisciplinary team in a dedicated pediatric cardiac intensive care unit [1, 19, 37, 38].

Although cardiac surgical skill deficiencies may be more immediately visible to those evaluating overall program quality and outcomes, deficiencies in other members, though often more subtle, may become apparent over time. Significant incompetence in one area of the multidisciplinary team can result in the whole team becoming dysfunctional and ultimately compromising patient care.

Characteristics of Functional Teams

By definition, a team is "a number of persons associated in some joint action," while functional refers to that team's ability to perform a regular function. When referring to teamwork in pediatric heart care, Kumar states, "Establishment of a cohesive team requires organization of a group of team members with diverse skills to come together through good mutual understanding, under a leadership that actively promotes team harmony" [39].

The Accreditation Council for Graduate Medical Education's (ACGME) six general competencies can be incorporated into the definition of a well-functioning team. Members of a functional team would, individually and collectively, provide excellent patient care and have an in-depth knowledge of pediatric congenital heart disease as it relates to their subspecialty as well as that of others. In addition, they would have excellent interpersonal and communication skills, exhibit professionalism, have a good understanding of the system they work in (systems-based practice), and continuously try to improve individual as well as collective knowledge, skills, and attitudes (practice-based learning and improvement).

Huszczo describes seven components of excellent teams in organizations. He follows in a later publication adding the X-factor in whether a team succeeds, that being leadership.

Components of Excellent Teams
- Clear goals and sense of direction
- Identification of talent
- Clear roles and responsibilities
- Agreed-upon procedures
- Constructive interpersonal relations
- Active reinforcement of team-oriented behaviors

- Diplomatic external ties
- Effective Leadership

Clear goals and objectives allow the team, and the organization, to know why it exists and what it is to accomplish. Individuals that are skilled and talented are needed in key team positions (i.e., pediatric cardiology, pediatric cardiac surgery, pediatric cardiac anesthesiology, pediatric cardiac intensive care, pediatric cardiac nursing). All members should have clear understanding of each team member's role and responsibilities. One way to improve the process of understanding each team member is to develop an interest in each other's specialty. For example, the pediatric cardiac anesthesiologist who attends pediatric cardiology conferences and learns more about echocardiographic imaging in CHD will better understand the role of the pediatric cardiologist. The pediatric cardiologist who spends time in the operating room observing the pediatric cardiac surgeon operate and the process of separating from cardiopulmonary bypass will have a better understanding of the role of the surgeon, perfusionist, and anesthesiologist. Teams that have agreed-upon procedures and who have worked together to establish patient-care protocols and standardization of perioperative management in an attempt to reduce variability would be expected to have better outcomes. As well, constructive interpersonal relations are fostered by good communication. Disagreements, which are inevitable, should not be left to fester but be resolved quickly, in an open, transparent manner and in an environment of trust and mutual respect. Team-oriented behaviors are reinforced when all members of the team have the opportunity to exert their skills and knowledge. One example of this is a weekly team meeting for preoperative collective decision-making and planning of specific strategy and to anticipate and prepare for perioperative issues. Diplomatic "external ties" are required for the team to effectively work within an organization and also to maintain an active referral system. Moreover, team leadership is a key component of functional teams. It is often necessary to have many individual leaders in different areas working together to help the team move forward, but there is usually a single key leader. Team leaders should encourage harmony, influence but not control team members, help the team make an accurate assessment of its actions (i.e., sharing patient outcomes) and structure, facilitate consensus decisions, and push the team to operationalize the ideas they generate.

Team Building

Team building can be defined as "a continuous process to apply some systematic approach to getting people to work together successfully." This definition implies that team building in pediatric cardiac surgery is much more than one or several events designed to develop camaraderie but rather is a continuous, intentional, and systematic process.

Important aspects of teams and teambuilding in pediatric cardiac surgery teams have recently been reviewed [39].

1. *Understand Each Other's Role*
   As mentioned above, it is important that each member of the team has an understanding of each other's role in the team and this should be encouraged. The pediatric cardiologist spending time in the operating room observing the technical process and decision-making of the pediatric cardiac surgeon serves such a purpose.
2. *Maintain Clear Communication*
   Clear communication between team members at all times, and especially at critical junctures in patient care such as "handoffs" or transition in care, is essential. Forms of communication include verbal between team members, written documentation on records, group meetings where outcomes are reviewed, and family meetings where family members are kept informed of all aspects of patient care.
3. *Address and Resolve Disagreements*
   It is inevitable that a team of highly educated and diversely trained caregivers will have occasional disagreements. A team made up of individuals who trust each other, communicate well, and have mutual respect will resolve disagreements rapidly, transparently, and amicably. Disagreements that are not resolved this

way may lead to fractured relationships, dysfunctional teams, and negative impacts on patient outcome.

4. *Encourage Collective Decision-Making*
   Forums such as multidisciplinary patient rounds, monthly quality improvement meetings, and pre-intervention patient management meetings provide the opportunity for each team member to exert their skills, knowledge, and influence so that decisions are made collectively and in the patient's best interest.
5. *Recognize Individual Team Member Roles*
   Cohesive and functional teams have a collective sense of responsibility towards the patient. While individual roles may vary in their importance to overall program success, leadership must recognize the contributions of individual members of the team. This includes the nursing staff at the bedside, resident physicians, catheterization laboratory technicians, and others, as well as the more highly visible team members. Leadership that privately and publicly recognizes individual members will more likely have a motivated team that is working in harmony towards the common goal of excellent patient outcomes.
6. *Regular Review of Team Performance*
   It is relatively easy to collect annual mortality data as a measure of performance and focus the review of team performance on the highly visible members, such as the pediatric cardiac surgeon. However, a functional team will perform collective introspection at regular specified intervals. These responsibilities should be performed within each discipline in formal performance improvement programs and reporting to an oversight committee of heart center leaders. These reviews examine morbidities as well as mortality to correct substandard systems processes.

Team Best Practices and Team Training

Examples of best practices in pediatric cardiac teams and training include regular multidisciplinary planning conferences, multidisciplinary cardiac surgery rounds, a dedicated pediatric cardiac intensive care unit, integrated clinical pathways, effective and safe transitions in care, ongoing continuous evaluation and review, and the use of simulation and crew resource team training.

1. *Regular Multidisciplinary Planning Conferences*
   There is a wide variability in congenital cardiac disease anatomic variation and presentation. Moreover, there are multiple palliative or definitive interventions to consider. Utilization of multidisciplinary planning conferences where input from all members of the multidisciplinary pediatric cardiac team is obtained prior to intervention is an example of a best practice.
2. *Multidisciplinary Pediatric Cardiac Surgery Rounds*
   The American College of Critical Care Medicine recommends the availability of a multidisciplinary team and a full-time intensivist as a way to "improve outcomes as measured by reduced mortality, improved efficiency, decreased length of stay or decreased cost of care" [40]. Multidisciplinary rounds in the critical care environment have demonstrated a reduction in medical errors, cost savings, and increased communication [37, 41]. Members of the multidisciplinary cardiac surgery rounds include the pediatric cardiac surgeon, pediatric cardiac intensivist, acute care pediatric nurse practitioners, pediatric cardiac nursing staff, clinical pharmacist, and clinical respiratory technician, among others [38, 42]. One study of multidisciplinary rounds of cardiac patients in a pediatric intensive care emphasized the need for more evidence regarding the effectiveness of this approach and the need to shorten data retrieval and presentation time and focus more on decision-making, discussion, and teaching [37].
3. *Dedicated Pediatric Cardiac Intensive Care Unit*
   Most high-volume centers (>350 surgical cases/year) have dedicated pediatric cardiac intensive care units. In France, pediatric cardiac surgery programs approved by the French Health Ministry must perform at least

"150 major operations per year in children" and must provide a "specialized pediatric intensive care unit." In one study, a dedicated pediatric cardiac intensive care unit was associated with a decrease in morbidity (i.e., wound infections, need for chest re-exploration) and less need for resuscitation as well as decreased mortality [19]. Dedicated pediatric cardiac intensive care units have shown better outcomes in terms of earlier extubation, de-intensification, and discharge from the ICU. Bloodstream infections are also reduced [43].

Optimally, pediatric cardiac intensive care programs should have patients (preoperative and postoperative) grouped together geographically and in close proximity to the operating room, catheterization laboratory, radiology department, and regular ward. Also important are dedicated age-appropriate equipment and strategies [20].

4. *Integrated Clinical Pathways*
Marked institutional and individual variability exists in the care of pediatric cardiac patients [17, 44]. The concept of integrated clinical pathways refers to development and attempts to utilize evidence-based standardized care throughout the pediatric heart patient's intervention and hospitalization especially for the more complex anomalies (i.e., hypoplastic left heart syndrome and staged repairs).
5. *Effective and Safe Transitions in Care*
Transitions in care, or "handoffs," may require physical movement of equipment and technology, sharing of patient information, and transfer of responsibility for care of the patient. The ACGME recently recognized the importance of transitions in patient care and made training and documentation of such a residency training a requirement.

The care of infants after complex congenital heart surgery and "handoff" of care from the surgical team to the intensive care team after intervention is an especially vulnerable period for errors. Components identified as critical to the successful handover of a patient to the ICU include (1) efficient transfer of monitors and equipment, (2) limiting discussions to those related to the patient, (3) face-to-face sharing of patient information, (4) discussion of care plan with all providers involved, and (5) limiting interruptions during the information handoff. A formal standardized multidisciplinary protocol handover process for pediatric cardiac patients transitioning to the intensive care unit after cardiac surgery can mitigate human error, help prevent patient harm, and improve teamwork among caregivers [45].

Standardized multidisciplinary handover protocols, including ones that utilize Formula 1 pit-stop and aviation models, have improved the safety and quality of the handover process [46]. In this model, the anesthesiologist is given overall responsibility for coordinating the team, and this is transferred to the pediatric cardiac intensivist at the completion of the handover. The anesthesiologist completes a standardized transfer form at least 30 min before transfer of the patient to the pediatric cardiac intensive care. The handover includes three major components: (1) equipment and technology, (2) information, and (3) discussion and plan with allocated tasks for each caregiver, including nurse and respiratory technician. Communication is limited to essential conversations during handoff where the anesthesiologist and surgeon speak uninterrupted. This is followed by a printed handover protocol process and a task sequence and checklist with task allocation known and observed by team members. Although the anesthesiologist and intensivist have responsibility for situational awareness at handover and regularly step back and make safety checks, all "crew members" are encouraged and trained to speak up if issues are identified.

6. *Ongoing Continuous Evaluation and Review*
The pediatric cardiac program should make every attempt to study and improve all aspects of patient care. This should include a multidisciplinary quality improvement process and a mechanism for longitudinal follow-up of patients and outcomes.
7. *Work and Train Together as a Team*
Effective multidisciplinary teams often work and train together. Resuscitation of pediatric

cardiac patients requires multidisciplinary collaboration and teamwork. Simulation-based Crisis Resource Management (CRM) training has been utilized to improve preparedness and decrease anxiety among multidisciplinary resuscitation teams [47]. Situations in which team training utilizing simulation might be helpful include crisis resource management, failure to separate from cardiopulmonary bypass, rapid deployment or emergent ECMO, and transitions in care. Simulation might also be utilized to reinforce training and evaluate performance. However, whether participation in a pediatric cardiac intensive care CRM training program improves team function during real resuscitation is unproven.

Examples of Pediatric Cardiac Team "Best Practices"

1. Utilize regular multidisciplinary planning conferences.
2. Utilize multidisciplinary pediatric cardiac surgery rounds.
3. Provide a dedicated pediatric cardiac intensive care unit.
4. Develop and follow evidence-based integrated clinical pathways.
5. Provide effective and safe transitions in care.
6. Perform ongoing continuous evaluation and review of program.
7. Work and train together as a team.

Team Performance

Team performance improvement should focus on issues rather than on individuals and reporting of morbidity encouraged with review of morbidity and mortality accomplished in a nonjudgmental manner. Although at times specific contributors (e.g., providers or systems issues) to morbidity and mortality need to be identified precisely, the focus should be on collective team performance, reducing variability, and improving outcomes.

Factors that might impede team performance include (1) ego of individuals often evidenced by the attitude "I am right and all others are not"; (2) serious inequities in recognition, salaries, and rewards; (3) inability to "find time" to accomplish multidisciplinary meetings where all are encouraged to contribute to the team effort; and (4) leadership that does not encourage all team members to be involved in decision-making processes, protocols, and change management [39].

Quality improvement processes should be used to reduce clinical process variation and expand clinical networks, using data for research and improvement (i.e., STS Congenital Heart Surgery Database), resulting in better outcomes and generating new knowledge [17, 44, 48]. Both internal and external peer review of the program may provide insights and examples of how to improve care [42].

Leadership in a High-Stakes Service Line

181

Lara P. Nelson, Barry P. Markovitz, and Cynthia Herrington

Abstract

Healthcare has undergone a substantial evolution over the past decade. It has evolved to a system increasingly focused on an outcomes-based market economy. It is also evolving to include a wide spectrum of healthcare professionals beyond the physician with the realization that patient care is provided by multidisciplinary teams. Clinicians can no longer afford to be passive bystanders in this process and must step in as leaders in determining the course for the future. The current era requires a new definition of the healthcare leader and an understanding of the necessary skill set to move healthcare forward while assuring safe delivery of patient care. Nowhere is this more important than in the high-stakes environment of congenital cardiothoracic medicine.

Introduction

Healthcare has undergone a substantial evolution over the past decade. It has evolved from a relatively stagnant industry operating on unquestioned third-payer reimbursement to a system increasingly focused on an outcomes-based market economy. Additionally, medicine historically has focused on physicians as the sole care provider, but is now evolving to include a wide spectrum of healthcare professionals beyond the physician with the realization that patient care is provided by multidisciplinary teams.

Clinicians in general and physicians in particular can no longer afford to be passive bystanders in this process and must step in as leaders in determining the course for the future. The previous model of the service line leader (in academic medicine) was largely predicated on the practitioner's performance as a researcher with publications and grants as a tangible measure of success and was grounded in a strongly hierarchical model. The current era requires a new definition of the healthcare leader and an understanding of the necessary skill set to move healthcare forward while assuring safe delivery of patient care. Nowhere is this more important than in the high-stakes environment of congenital cardiothoracic medicine.

Leadership as a Team

The traditional medical approach to leadership has been through the utilization of strong hierarchical models, a structure based mainly on power by achievement where individuals along the hierarchy have their power assigned by title accumulation, such as "cardiac surgeon" or "medical director," and the premise that technical expertise and clinical knowledge serves as the primary basis for promotion [8]. In congenital cardiothoracic medicine this has functioned through the focus on the cardiothoracic surgeon as the "leader." The success or failure of the patient's treatment was directly attributed to the individual leader/surgeon with perfunctory acknowledgement of the rest of the care team.

Newer approaches to healthcare delivery have shifted to team-based medical models as represented by the development of service lines, such as a "heart institute." The shift is based on the recognition that with the explosion of medical knowledge and technologies leading to improved outcomes for complex medical problems, it takes more than one person or single group of specialists to provide effective care for a patient; traditional care areas were organized around what was most convenient for the physician; now complex patients seeing multiple specialists have changed this focus to the patient rather than the healthcare providers. Service lines provide multidisciplinary care for patients and create an environment with greater breadth and depth of expertise, which is especially crucial in high-stakes medical situations. Congenital cardiac service lines require the active participation of congenital cardiothoracic surgeons, pediatric cardiologists, pediatric intensivists, cardiac anesthesia, skilled nurses, respiratory care practitioners, pharmacists, nutritionists, and others. It is also important to include administrative support, as the health of our hospitals and health systems requires financial stability and program development of the service line for viability.

While successful teams require motivated and skilled members, they still need sound oversight and direction. Physicians are well positioned to serve this role, but it requires a shift in the paradigm from the traditional role of the physician-leader. What are the components necessary for physicians to fulfill this leadership role?

Leadership Versus Management

In order to begin to redefine physician leaders, it is important to first have a common definition of leadership. Traditionally, leadership referred to hierarchical (or positional) power. A physician with an administrative title was by definition a

leader. Having a title, at best, puts this person in a management position. Leadership and management, once regarded as interchangeable concepts, have evolved into different but complementary realms in organizations. As stated by Kotter, management involves coping with complexity, while leadership deals with coping with change [12]. Management includes making budgets, organizing staffing, and problem solving. Leadership then requires development of a vision, aligning people with that vision, and motivating them to action by empowerment and supplying their needs.

Management can best be understood as the organization and coordination of the activities of an enterprise in accordance with certain policies and with the purpose of achieving clearly defined objectives. Functions of a manager include planning, controlling, staffing, directing, and organizing. Alternatively, leadership can be defined as a teaching and serving process that envisions, influences, shapes, and enhances to the end that the leader and followers realize their goals are for change within the community [16]. Warren Bennis characterized the difference as: "Leaders are people who do the right things. Managers are people who do things right. There's a profound difference. When one thinks about doing the right things, the mind immediately goes toward thinking about the future, thinking about dreams, missions, visions, strategic intent and purpose. But when you think about doing things right, you think of control mechanisms. You think about how-to. Leaders ask the what and why question, not the how question" [2].

The roles of leaders and managers are both important to the success of an institution, and successful institutions recognize and support both.

Characteristics of a Leader

Leaders in today's healthcare environment must build for themselves a toolbox of personal skill sets that will allow them to use their character traits and managerial skills to create reality from vision.

Emotional Intelligence

Accomplished leaders must have self-awareness and a highly integrated level of emotional intelligence; these two characteristics are intimately related. Emotional intelligence was originally defined by Salovey and Mayer as the "ability to assess one's own and others' emotional states, and then utilize this information in subsequent decision-making" [18]. More specifically, they proposed four branches of emotional intelligence: perceiving emotion, reasoning with emotions, understanding emotions, and, finally the most complex branch, managing emotions. Having the ability to understand one's emotions and to read the verbal and nonverbal emotions of others is of paramount importance. Regulating one's own emotions and successfully managing the emotions of others is the hallmark of an experienced leader. Gone are the days when the support was given to the leader who shouted the loudest. The ability to perceive, understand, and modify one's own emotional response requires an abundance of self-awareness. An experienced leader demonstrates this skill by his capacity to show the emotional state he wants to display and nothing more. This skill is essential in times of change and crisis, where the team is reading every glance and intonation, and especially in the high-stakes environment of a cardiothoracic operating room or intensive care unit.

Communication Skills

Effective communication is an essential component of successful interactions. While many focus on good communication being about the effective use of the English language, that is, good speaking skills, Stephen Covey proposes that one needs to "seek first to understand, then to be understood" [6]. There are several forms of listening. Covey prioritizes what he labels empathic listening. He differentiates this level of listening from those of ignoring, pretending, selective listening, and attentive listening. Empathic listening focuses on truly understanding the other person in the moment, listening to not just the words

being said but also the emotion behind them and the nonverbal communication. In doing so, individuals have more accurate "data" in the sense that it is not tainted by their projection of their own feelings, thoughts, and past experiences. Empathic listening involves a series of logical steps: first the listener mimics the content heard, then rephrases it, reflects the feeling of content, and then rephrase the content with the appropriate feeling. He juxtaposes this to the usual responses of the following: evaluate, probe, advise, and interpret. In the latter, the listener is more focused on his reaction to what is being said and results in these prescriptive responses. Alternatively, in empathic listening the goal is to understand, so the objective of the listener's responses is to fully elicit the other's position and secondarily express comprehension.

This level of listening requires significant concentration from the listener and attention to one's colleague. Oftentimes while someone is "listening" to a colleague, he/she is also doing tending to other business – checking email, texting, and entering orders. It is difficult to change this pattern, especially in the context of a high-intensity, busy environment, and develop this new skill. Individuals must turn off all of the internal noise, stop multitasking, and not think of how to respond to what is being said in order to fully hear the message being delivered. It is important not to make decisions or profound statements until there is all the available information on a topic. Effective leaders listen. While listening is important, the role of a leader is to implement change and provide guidance so eventually he must also speak. When leaders speak they must realize their words carry weight and meaning. Nobody can minimize the influence a leader's communication has, and thoughtless glib responses can be quite damaging. The communication style of a leader needs to be clear, decisive, well informed, and frequently inspiring.

Conflict Management

A group without conflict is a group without vision and is likely to be dysfunctional and ineffective. Healthy conflict – where individuals differ openly on data interpretation and decisions – is vital to build programs and in our sphere, care properly for patients. Unhealthy conflict involves attacks on individuals, rather than their ideas. Managing healthy conflict flows naturally from emotional intelligence and team building. Four types of negotiating conflict approaches have been described: avoidance, adversarial, compromising, and collaborative [4]. Avoidance and adversarial approaches are self-explanatory and rarely achieve results. Compromising involves each party giving up to some degree to arrive at a shared position. Collaborating, on the other hand, represents a synergistic position, where together the parties arrive at a solution that is stronger and larger than the sum of the two individual ideas, the proverbial win-win situation.

Team Building

A highly functional medical team is a group of talented individuals committed to common goals, accountable to each other, and results-driven. Patrick Lencioni presents these concepts in the negative as *The Five Dysfunctions of a Team* [13]. At the base of his model, or the first dysfunction, is absence of trust. If there is no trust, the second dysfunction emerges, fear of conflict. This leads a team to avoid helpful debates about different ideas and instead have backroom conversations. If the team does not openly discuss their opinions, then there is a lack of commitment to decisions made, the third dysfunction. The fourth dysfunction is an avoidance of accountability; teams that are not committed to their goals will not point out people with counterproductive behaviors. Finally, this culminates in the fifth dysfunction of inattention to results, putting individuals' goals ahead of those of the team.

An effective team is built on a foundation of trust and is capable of managing and growing from internal conflict and disparate ideas. To create a foundation of trust, medical leaders must first show vulnerability. When the leadership demonstrates their personal comfort by being

vulnerable with the team, they will influence the behavior of others. Through their vulnerability, such as looking for advice, direction, or assistance, leaders demonstrate they can trust the other members of the team and set the model for the group. This foundation supports the further healthy development of the team and allows for the necessary natural conflict to arise for someone to challenge the status quo and bring a new intervention or plan to the table for discussion. In this environment of trust and mutual respect, conflicts will naturally play out in a healthy fashion, and the team will manage the debate to a result that is in line with the goals of the team.

Rapid advances in healthcare – technical, demographic, and economic – require nimble organizations that can adapt to change quickly. Only a trusting team that values healthy conflict can openly discuss the advantages and disadvantages of adoption of particular changes. In an environment where fear of conflict rules, so does the status quo, and everyone shuns change because of how it will affect their sphere of influence, mediocrity will be the norm.

Once a healthy foundation has been established and all members of the team are committed to the goals of the team, the team must be able to hold one another accountable. A high-functioning team achieves results greater than those achievable by individual team members on their own. Each member of the team needs clear definition of his responsibilities and how these contribute to the goals and faith that teammates are functioning similarly. A healthcare team whose members understand organizational goals, trust each other, engage in healthy debate, and hold themselves and one another accountable will move projects through to completion and deliver the most effective care to their patients.

Culture/Program Development

Culture, with respect to an organization, can be simply defined as "the way we do things around here." Effective leadership cannot grow and thrive without a deep understanding of the local culture, for the culture must be supportive of the leaders' visions, or the culture must be transformed to do so. Another common adage is that "culture eats strategy every day for lunch." So, for example, if the culture is one of sarcasm, negativity, and resistance to change, even the most effective leadership will struggle to move such a group forward.

Many academic institutions were built with a "silo" mentality. Departments and divisions fought over power, prestige, and resources, with little sharing and certainly rarely sharing of an institutional vision. Several organizations, for example, Senn Delaney and the Studer Group, now are working with healthcare institutions in "cultural transformation" programs, designed to break down these "silos" and literally change the organization's culture. Ravasi and Schultz have defined organizational culture as a "set of shared assumptions that guide interpretation and action in organizations by defining appropriate behavior" [15]. An organization's culture is not overtly stated or described, but it is reflected in its mission statement, values, language, habits, and systems. While an organization may have one culture, it is also common for departments within the organization to have different subcultures. This lack of unity in a hospital is what drives the "us versus them" mentality seen between different work areas or specialties. Although the methods and programs may differ between the organizational transformation projects, they all strive to break through the subcultures to reorient all to the unified goal of excellent medical care and promotion of the institution's mission.

Changing Paradigms of Leadership

Just as there is not one defining characteristic of a leader, there is not a singular leadership style. Leadership is a dynamic relationship between the leader and his followers and is also influenced by the context of the interaction [3]. Successful leaders are able to assess the culture and landscape and apply different leadership styles as the situation dictates.

Transactional Leadership

Transactional leadership has historically been the most common form utilized in healthcare organizations and academic medical centers. This model is based upon leaders and followers defining goals or objectives to be met, and leaders allocate appropriate rewards for success in meeting the goals or performance criteria [9]. This is a practical approach to leadership and utilizes established hierarchy such that followers achieve the established goals because it is in their best interest. Its strength is in supporting adherence to practice standards. Successful transactional leaders are able to identify the accomplishments of their followers and apply positive reinforcement and rewards in a timely fashion. Limitations of transactional leadership include a potential lack of innovation and creativity, since followers are often judged on rigid predetermined criteria [11]. Employees working under this style of leadership are at higher risk to experience decreased work satisfaction and motivation, with limited loyalty to the common goals of the organization [17].

Transformational Leadership

Leadership expert James Burns introduced the concept of transformational leadership. He stated, "transformational leadership can be seen when leaders and followers make each other advance to a higher level of moral and motivation" [5]. Bass then built on this concept to include transformational leaders garner the trust, respect, and admiration of their followers [1]. He suggested that transformational leadership was made up of four components – intellectual stimulation, individualized consideration, inspirational motivation, and ideal influence. As opposed to a basis on a reward system, transformational leaders inspire, energize, and intellectually stimulate their followers. For this reason, many associate this style with "visionary" leadership and erroneously believe it to be based on the leader's "charisma." In fact, transformational leadership means getting people to want to change, improve, and be guided. It includes valuing people's motives, meeting their needs, and truly valuing their contributions [14]. This model is more of an individualized approach and works better in closer, supervisory relationships. It differs in that the leader encourages novel thinking in his followers and challenges to the status quo.

Servant Leadership

The concept of servant leadership, first proposed by Robert Greenleaf in the 1970s, envisages a leader as servant [7]. In the classic American, military, top-down definition of leadership, as is also commonly seen in medicine, the leader/physician is often seen at the top of a pyramid delivering orders to subordinates, with the consumer or patient at the bottom. James Hunter describes the theory of servant leadership by inverting this pyramid [10]. In his model the frontline workers are at the top, and the pyramid moves down through varying levels of supervisors until ultimately the leader or chief executive officer (CEO) supports its base. This results in (1) a focus toward employees and customers rather than the leader and (2) moves the ultimate goal away from satisfying the leader to focusing on the job at hand and the mission of the organization. This is especially important when introducing the customer, or patient, into this model. The customer is on the top of this inverted pyramid, and the employees look "up" to serve the customer, and not "down" to serve the CEO.

Also important to this model is the difference between power and authority. Power, as Hunter describes, represents the ability to force or coerce people to do one's will based on position which erodes relationships; alternatively, authority moves people to do your will because they want to, because of your personal influence with them. Genuine authority outside the traditional definition of organizational power can be seen in the lives and following of Gandhi, Martin Luther King Jr., and Mother Theresa. None had (positional) power in the classic definition of the word, but each of these individuals wielded great influence with large numbers of people. If leadership

is the skill of influencing people to enthusiastically work toward the common good, enduring leadership is based on authority built on relationships and sacrifice.

Why Does It Matter?

Leadership matters in a high-stakes service line because of the very nature of the work, caring for the lives of children. In a typical operative procedure – and ensuing care – of an infant with congenital heart disease, a multitude of steps must be followed in the right order, in the correct way by qualified professionals (often dozens for each patient) at precisely specified intervals. The myriad of opportunities for error – from diagnosis through anesthesia, surgery, cardiopulmonary bypass, postoperative recovery, and appropriate follow-up – is daunting. Because of the life or death nature of the work, errors at any point along this trajectory carry the potential for serious consequences, for both patient and caregiver. It is clear that organizational and team culture, created by what we have defined as leadership, is the glue that holds this process together, every day, for every patient.

Analogies between aviation and medicine have grown popular over time. Indeed, from simulation to team training to checklists, we still have much to learn from an industry that offers a safety record today second to no other industry. No one would dispute that the airline industry is also a high-stakes enterprise, and the leadership shown by the industry as a whole, as well as that shown by every crew on every flight, remains exemplary.

Who Are the Leaders?

Just as leadership can be found at any and all levels of a large organization, such as an academic medical center, the same is true for a service line, such as a heart center. Since leadership is not defined herein as strictly hierarchical or by organizational structure, every member of the pediatric cardiac program should be considered a leader and should be expected to develop their leadership as well as clinical skills. While understanding the realities that some individuals have more organizational leadership responsibilities than others, every member of the team must exhibit the qualities and characteristics of leadership as we have defined them here. The bedside intensive care unit nurse, the perfusionist, the cardiac surgeon, and all team members must demonstrate emotional intelligence and excellent communication skills, and they must be fully integrated team players and part of the positive organizational culture.

The Future

It is interesting that clinicians in general, and physicians in particular, are frequently called upon to lead, whether it is at the bedside or the boardroom, and yet, few have been formally trained in leadership or management. It is true that some have independently taken courses, perhaps attended a retreat, or even gone on to formal education, such as a master of business administration (MBA) or master of health administration (MHA). These individuals are few and are still not the norm in the medical community today. A decade ago there were less than five MD/MBA programs, currently there are 54 programs graduating 500 dual degree professionals annually. For our clinical peers who have furthered their professional development, it is not uncommon for them to experience some degree of professional hazing. They are "going to the dark side," "getting all touchy feely on us," or "more kumbaya, less work" are statements made with some regularity. Nevertheless, as clinicians have long understood excellent care requires strong relationships with patients, so too must leaders have healthy relationships with colleagues.

A change of this magnitude may not occur until the current leadership paradigm is shattered. In using the field of cardiac surgery as an example, the collective leadership style is hierarchical and power-based. This military-like paradigm is the same in cardiothoracic residency programs. The surgical apprenticeship model is likened to a military style with an "only the best survive,"

"I lived through it so you have to live through it," or intern boot camp mentality. It is no surprise that the specialty faced – and still faces – a significant reduction in the number of residents in cardiac surgery training programs. The quality of residents also diminished, and long-established training programs are closing due to positions being unfilled. This crisis situation was the tipping point for cardiothoracic surgical educators to reevaluate how surgeons are educated and open up possibilities for new more efficient and effective ways to educate the cardiac surgeon of the future. It seems a complete meltdown of the educational system was required to precipitate this change. Now, new 6-year programs are approved and being developed to streamline the resident educational experience, simulation is becoming an active educational tool, and educating our young colleagues has received the attention it has deserved. This change was not easy; it was not even welcome, but it was necessary. Likewise, changing leadership strategies to produce cogent, effective leadership teams is crucial. . .before another crisis within our field our pediatric heart care drives it.

Intersection of Leadership, Organizational Culture, and Clinical Performance

182

Niurka Rivero, Beth Zemetra, and Cynde Herman

Abstract

Errors in healthcare occur every day. The Joint Commission challenges organizations to produce a "safety culture" characterized by a continual drive toward the goal of maximum attainable safety, one in which errors and events are not only reported, but are evaluated transparently [1]. In taking a systematic approach to quality improvement, visible clues/outcomes are focused on, and in doing so, the underlying beliefs and behaviors that drive the performance are missed. Overlooked is the effect of culture which is the backbone of daily performance. Rarely is a cultural analysis performed to determine if the underlying issue is, in reality, a dysfunctional culture. There must be reflection and conscious consideration to culture dysfunction as a critical effect contributing to the areas of quality, risk management, outcomes management, patient and staff satisfaction, and cost-effective medicine. Organizations exist in an interactive relationship between the subcultures and the overall organization itself. Subcultures influence other subcultures as well as the organization and vice versa. Healthy culture behaviors include collaboration, appreciation, and supportive and accountable behaviors, as well as selflessness to the greater good of the organization. Examples of dysfunctional culture barriers include internal competition, lack of ability to

adapt or change, hierarchical leadership, a critical mindset that staunches new ideas, lack of accountability trust issues, and hidden agendas, to name a few. It follows that most organizations would want to treat their dysfunction or cultural barriers to achieve greater effectiveness and meet the challenge posed by The Joint Commission. Large, transformational change begins with the vision and resolve of individuals who want to improve performance outcomes. The ability for leaders to create or shape culture begins on the inside. Most received no formal training in developing the skill set required to transform culture. All were likely too busy, learning specific trades within medicine. When was there focus on developing leaders in medicine? Leaders shape, and hence lead cultures, by choosing to do the right things day to day, hour to hour, choice by choice, until they become habits that drive quality, patient safety, and organizational financial health.

Introduction

It seemed like things were moving along at the usual intensive care unit (ICU) hum when the focus of the unit changed abruptly. The alarms sounded in room 312. A patient was asystolic. A finely tuned machine emerged as everyone seemed to know their role. Instructions were easily heard. If you did not happen to know there was a crisis situation on that end of the unit, you would miss the gravity of the event occurring only two beds away. Within minutes, the patient had a perfusing rhythm. Blood pressure was stable. The attending physician thanked the staff for a "code well done."

To an untrained observer, the scene appeared to be a success. Prior to this event, all seemed normal in the unit. The staff and physicians were polite and cordial. Some staff in the ICU were sharing stories about their weekend. Others were focused on administering medications to their patients in the timely manner expected. To a leader aware of the significance of organizational culture and his role in shaping it, there may have been clues to possible dysfunction in the unit. He might have been able to perceive tension in the ICU before the young patient coded. Perhaps the tension was due to the frustration and fear of the bedside nurse who had tried unsuccessfully to get the attending physician's attention when the patient was deteriorating. Perhaps the tension was from the charge nurse, busy with bed allocation and admission priorities for the day, worried about the unstable patient in room 312. Even though the patient seemed to be successfully resuscitated, the attending physician was visibly angry and preoccupied wondering who was at fault. "What did they miss?" he would think to himself. The leader might also notice that the charge nurse was so focused on patient acuity and bed staffing that she was distracted. The child's risk for morbidity and mortality stemmed not only from his underlying clinical state, but also from the lack of effective communication and teamwork secondary to the dysfunctional culture of this ICU. Indeed, this

team likely has little recognition that every child admitted to their ICU is placed at risk for adverse events due to barriers toward effective teamwork and communication.

On the surface, one saw a critically ill child successfully resuscitated. A leader understanding the intersection of leadership, culture, and clinical performance saw that this team got lucky.

Signs, Symptoms, and Diagnostics

Performance of the Individual or the Team?

Clinical teams in medicine make quick decisions that carry the weight of a patient's life. The individual responsibility to provide outstanding care is both self-evident and enormous. Physicians and nurses are educated and trained in preparation for highly specialized work, then socialized to provide outstanding error-free cognitive and technical care. The training of physicians and nurses is oriented toward the achievement of clinical autonomy, but patient care requires interdependence with other members of the team. For example, the team depends upon the bedside nurse to identify undesirable changes in clinical parameters. The dependence within the team to understand bleeding in the postoperative patient, resulting from intraoperative events, and how this was communicated by the surgeon is another example. The clinician's individual sense of responsibility and accountability to provide quality care competes with the growing knowledge that interdependent caregivers' expertise is needed for optimal patient care. The more individuals involved in providing care, the greater the dependence on and necessity to trust the skill and performance of the team.

To become a top notch unit in a first rate organization, the drive to be a high-performing team is essential. It requires data to evaluate the success. This data is collected through various tools and systems that measure organizational and individual performance by examining clinical outcomes of patients, staff satisfaction, patient satisfaction, and the organization's financial health. Many of these quality measures are available to the public. Medication errors, central line-associated blood stream infections, high nursing turnover, and loss of physician referrals, all demand intervention. Process improvement provides a mechanism to examine structures and processes of care, and enhances one's ability to design sound interventions. In fact, The Joint Commission challenges organizations to produce a "safety culture" with a continual drive toward the maximum attainable safety, with all errors reported transparently [1]. An important focus in attaining a culture of safety is the emphasis on behaviors of individuals and the team, through the development and implementation of evidence-based protocols, the standardization of routine work, and the use of hourly rounding, to name just a few.

With these standards in place, why is it that teams often have a difficult time in implementing change? Why do most quality improvement projects fail to result in measureable or sustained improvements? Patient satisfaction scores are mediocre; nursing turnover rates are high, but within the national average; the care provided is good, but not great. While the team was able to resuscitate the child in the above scenario, should they have been able to prevent the code from happening in the first place?

While quality improvement efforts are usually focused on easily visible behaviors of the physician or nurse, the underlying beliefs and behavioral norms that drive the performance or context can be missed. "When we look at a situation. . .we *see* individuals – individuals acting, making decisions, doing great or awful things. The *context* in which this happens is less obvious and vivid. We over-attribute actions and consequences to individuals, rather than the constraints under which they operate" [2]. Individuals are recognized for "making a good catch" or performing the difficult procedure. Likewise, when errors are made, individuals are often blamed. When this occurs, the opportunity to address and correct future errors is lost. It is the *behaviors* within the team, including those of leadership, that keep patients safe or put them at risk. These behaviors, both healthy and unhealthy, are a summary manifestation of

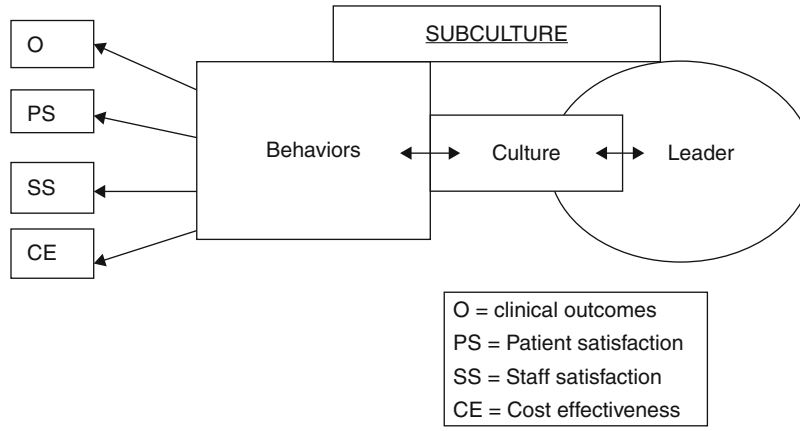

Fig. 182.1 The leader in each subculture influences the norms and values of culture that, in turn, drive the behaviors that produce the visible outcomes of clinical care, patient satisfaction, staff satisfaction, and the organizations financial health

values, beliefs, and behavioral norms, and are a reflection of the team's culture. It is this balance between accountability for behaviors of the individual and the structure of the system that creates a healthy culture.

Underlying Values, Beliefs, and Team Behaviors

Culture can be defined as the sum of the shared values, beliefs, and norms of behavior among a group of people [3]. These norms of behavior are common ways of acting (as a result of underlying values and beliefs) that are fostered in a group because of rewards and socialization. Norms of group behavior are somewhat visible – such as fellows present on rounds or families being asked to leave the bedside during a code. Shared values are concerns and goals that shape group behavior and persist over time. The underlying shared values of the culture are deeply embedded, such as family centered care, utilization of state-of-the-art technology, service to the community.

The behavioral patterns of a team within a strong organizational culture are very predictable, and in large part, a product of these underlying values, beliefs, and thoughts. In turn, these behaviors and communication drive the conscious decisions that dictate the manner in which clinical care is delivered and ultimately patient outcomes. This daily performance is an expression of the underlying beliefs and values of this team, comprised of individual behaviors. It is by how one speaks to a new nurse or intern; whether or not one holds each other accountable for hand hygiene; how one behaves in a crisis (Fig. 182.1). Some studies described below suggest that the health of that culture determines patient outcomes.

Culture Is Formed

Shared values and beliefs of the team create normative behaviors that influence the actions of individuals. By routine interactions on bedside rounds, hand-off communication, meetings with families, the team culture is formed and strengthened. Through promotions, training, and reinforcement with rewards, culture operates outside of people's awareness, and exerts its influence on individual actions, team actions, and patient outcomes. When the attending physician externally values the fellow's suggestion on bedside rounds, his behavior encourages the team to share ideas and collaborate to do what is best for the patient at this encounter and in the future.

Despite a unit or team's desire to provide outstanding care, disruptive behavior and poor communication often impedes this goal. Why is disruptive behavior and poor communication tolerated, especially when it is not conducive to

promoting the health of children? "Avoiding potential conflict means making it through the day in a hectic system where the lives of people are at stake. For many, that means that they direct all of their psychological energy to performing daily tasks, while inflicting as little harm on patients as possible" [4]. Many healthcare providers relate to this perspective. While making it through the day in the middle of this type of behavior often seems sufficient enough, tolerating this unprofessional behavior (for any reason such as fear of retaliation or lack of courage) actually promotes it. Psychological safety is imperative to creating an environment that provides high quality and safe care. Yet, disruptive behavior is tolerated at all levels of the organization, including the charge nurse ignoring the bedside nurse behaving unprofessional to a family or the administrator that heeds to the demands of a surgeon yelling in the hall. Approximately 40 % of physicians agreed that "physicians in my organization who generate high amounts of revenue are treated more leniently when it comes to behavior problems than those who bring in less revenue" [5].

Teams facing insidious intimidation issues and disruptive behavior typically have enabled the problem to thrive for years in two principal ways. First, the presence of a long-standing dysfunctional culture discourages open and honest interpersonal communication. Second, individuals habitually ignore and, therefore, accept dysfunctional and ineffective behaviors [4]. One allowance of a disruptive event leads to another, which leads to another, which leads to the cultural norm and a dysfunctional work environment. This lack of accountability to professional behavior undoubtedly transforms into a patient safety issue. The Joint commission attributes inadequate leadership as a contributing factor in 50 % of reported sentinel events [5].

As will be discussed later, a leader has the opportunity to focus on halting disruptive behavior, promoting teamwork, and encouraging collaboration in order to positively drive performance outcomes and ultimately improve quality of care, staff and patient satisfaction. The leader must step away and take a self-reflective approach to *consciously* drive the *unconscious* norms and values of the department in which he leads. If the leader chooses not to diagnose, create, and manage the culture of the department, then the behaviors and leadership of others in the department will ultimately manage him.

Cultural Transformation: Awareness, Diagnosis, and Change

Awareness Versus Tolerance

As mentioned previously, most healthcare leaders today are aware that errors, events, and patient service failures of varying magnitude occur every day in an organization. With new public reporting requirements, the awareness of events is intensifying through internal and external scrutiny [6]. With this increasing awareness, organizations are conducting root-cause analyses to determine system, rather than individual, causation [7, 8]. Cultural analyses are seldom performed to determine if the underlying issue following a serious event is, in reality, a dysfunctional culture. Nevertheless, quality and safety leaders are beginning to realize the profound impact of an organization's culture on the success of quality improvement efforts.

The challenge is to give serious consideration to organizational culture as a central factor in quality and safety efforts, risk management, patient and staff satisfaction, and financial performance. At a minimum, examining events through the lens of culture provides a view into areas of strength or opportunity when planning a new quality improvement project.

Culture: The History of Awareness and Diagnosis

How does one begin to reflect and consider organizational culture as a contributing factor to

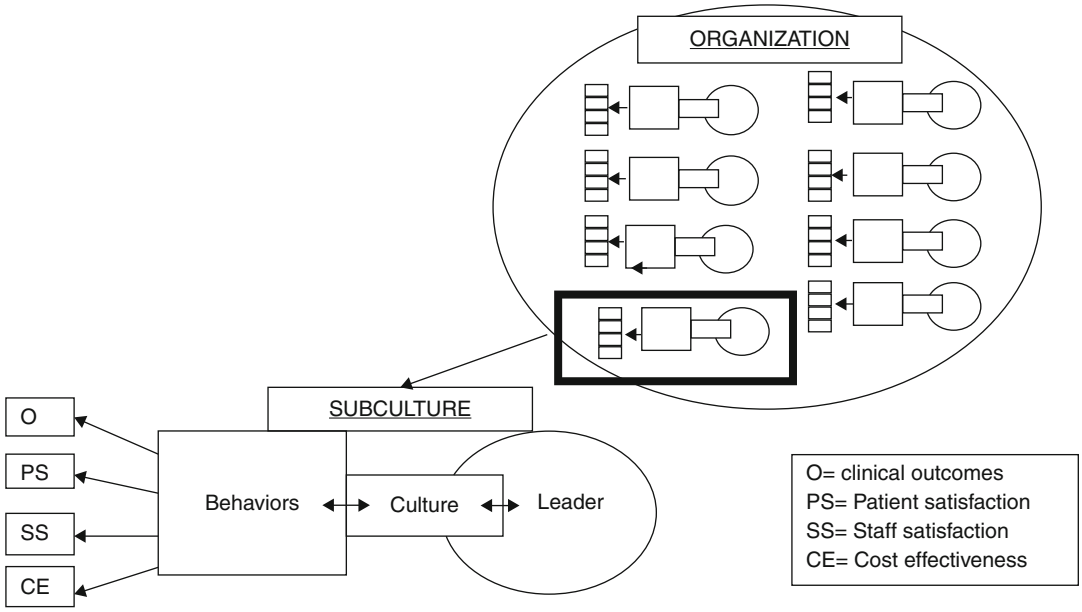

Fig. 182.2 Organizations exist in an interactive relationship between the subcultures and the overall organization itself. Subcultures influence other subcultures as well as the organization and vice versa. The end results of these interactions are demonstrated in the outcomes of clinical care, patient satisfaction, staff satisfaction, and financial performance

failures and successes within an organization? An interesting question since culture is likened to the air one breathes – a seeming invisible force often unarticulated in one's life and a blind spot for many [9]. Yet upon reflection, most intuitively understand that organizational culture exists and is unique to each organization.

Culture research in the 1960s was the initial step toward understanding this invisible force. Researchers from three primary philosophies and perspectives – psychological, sociological, and anthropological – led research efforts and focus until they were later joined by researchers in business [10–12]. Given the foundation of culture research, it seems logical to recognize that "organizational culture is socially constructed, arising from group interactions" [11, 13]. Culture resides in group interactions that occur in teams or units, also called subcultures. Organizational subcultures are a microcosm reflective of the culture as a whole, each contributing to overall organizational culture either positively or negatively [14]. The subculture and the leadership is different in different units and, thus, experienced differently just as staff report different levels of job satisfaction and organizational commitment in different units [15] (Fig. 182.2).

Over time, common understanding, models, or frames of culture were developed by leading researchers such as Schein and Hofstede [16, 17]. Schein developed his model on a sociological frame, defining culture on three levels – artifacts and observed behaviors, espoused beliefs and values, and basic underlying assumptions, similar to the behavioral norms, values, and beliefs previously mentioned by Kotter [3, 16]. Artifacts are all around one as, for example, an intensive care unit might display a white board in every room with the names of caregivers for that day as they value communication (artifact and observed behavior). Schein not only defined culture (at three levels), he also acknowledged the role of leaders as creators, managers, or destroyers of culture [16].

Similar to Schein, Hofstede focused on the dimensions of culture and cultural differences within organizations from a sociologic and

cultural anthropology perspective. His research in organizational culture and cultural dimensions extended into cross-cultural communication and leadership, which are important considerations for an individual leader's effectiveness within an organization [17].

Researchers developed culture diagnostics in the 1970s to deepen their research efforts and understanding. Qualitative research methods such as focus groups or employee interviews were used to gather information about the culture. This information was studied for recurrent themes and patterns that were then used to define the culture [12]. In the late 1990s, quantitative validated instruments were developed to classify and change organizations [18]. Two more frequently cited and scientifically rigorous instruments are the Organizational Culture Assessment Instrument (OCAI) [18] and the Organizational Culture Inventor (OCI) [19].

Aside from culture specific diagnostics, other surveys have been used to diagnose culture such as staff or customer service satisfaction surveys. Staff satisfaction surveys elicit perceptions about different cultural indicators such as teamwork and communication. Typically, human resource departments host these types of surveys. Recently, organizations are using staff satisfaction in their surveys [20]. Customer satisfaction surveys are also used to diagnosis culture – albeit from an external rather than internal perspective.

Over time, cultural diagnostic methods have evolved to integrate quantitative and qualitative methods to triangulate data for a more comprehensive view of culture [9]. Consulting companies such as Senn Delaney Leadership, LLC [21], and the Studer Group [22] specialize in culture, culture diagnostics, and culture transformation. Senn Delaney, for example, focuses on communication and teamwork, while providing education and development at the individual, team, and organizational levels. The concepts taught to physicians, nurses, and staff provide a common language that is to be used to facilitate issue discussions, resolve conflict, and promote collaboration.

Culture in Healthcare: Growing Awareness and Diagnosis

In many respects, healthcare has been catapulted into mandatory cultural awareness through the patient safety requirements of many regulatory or accrediting agencies such as The Joint Commission, Magnet, National Quality Forum Safe Practices, the Agency for Healthcare Research and Quality (AHRQ), and Leapfrog Group [5, 23–26]. The impetus for this requirement is an espoused belief that "the culture of the healthcare industry is regarded as a potential risk factor threatening the patients for whom it provides care" [9]. This belief has fueled the advocacy for and prevalence of patient safety efforts that is evidenced by the number of organizations involved.

Due to the importance of this cause and growing advocacy for patient safety efforts, it is expected that hospitals and physician practices will increasingly be evaluated by agency standards and requirements. These agencies and their requirements are outside influences designed to improve healthcare quality and safety, specifically, and subsequently, to change healthcare culture. While results are now becoming public knowledge, it is expected that future public opinion, patient referrals, and even payor contracting ability will be increasingly impacted by these publicly reported data. The future implications are tremendous for future financial health and viability of physician practices and healthcare organizations financial health.

At the subculture level, diagnostics of leadership and culture occur through root-cause analyses performed when a patient injury or a sentinel event occurs. With public reporting and the understanding that these types of occurrences may result in inspections by regulatory agencies such as the Department of Health Services, these diagnostics will be held to greater scrutiny. During these investigations and analyses, best practices and problems, so-called positive and negative deviance, respectively, within a subculture should be used for future improvement opportunities.

Regarding individual level assessment and diagnostics, physician evaluations in academic medical institutions are evolving from a primary focus on clinical, education, and research productivity to include professional behavior assessments. In a similar fashion, the Accreditation Council of Graduate Medical Education (ACGME) in 2002 completed a 3-year extensive review process to identify and require program compliance to teach six general competencies, three of which expanded beyond patient care, medical knowledge, and practice-based learning. These three requirements, professionalism, interpersonal and communication skills, and systems-based practice support the growing emphasis on and need for leadership and teamwork development to provide high-quality safe care [27, 28].

As with other industries, the customers of industry are regularly surveyed regarding the quality of service. In healthcare, patient satisfaction surveys are being used to drive behavioral changes and improve the service and safety of healthcare organizations. Some measures included in these types of surveys include feedback about service received, perceptions about the care team collaboration, and respect from caregivers. Interestingly, there is a positive association between patient satisfaction and healthy cultures identified through empirical research which found that organizations that value teamwork, cohesion, and employee involvement tend to outperform organizations that do not have these values [29].

With any diagnostics, the information obtained can be used to create a change or treatment plan and it should be no different when one is dealing with culture. Many failed change initiatives have occurred because diagnostics were not performed or available data was not used effectively in the change initiative. Take, for example, a small change such as the presentation of data during bedside rounds. If this change is not driven by or accepted by senior physicians, the change attempt will fail if there is no reason or data supporting the need for the change. Hence, understanding the diagnostics available, choosing appropriate diagnostics for gap areas, and triangulating the data to support change initiative become a critical component of success.

Appropriate and comprehensive diagnostics are essential to change efforts in addition to focusing on three areas important for any culture transformation: (1) *Senior leadership aligned as role models leading the change*, (2) *organizational leadership alignment and accountability for the change throughout, and* (3) *accountability to the change efforts at the subculture levels* [21, 22, 30, 31]. For example, senior leadership behaviors provide the model for change throughout the organization when a department chair supports a promotion or probation incorporating considerations of professional behaviors. Along with senior leadership commitment, leadership selection and development also demonstrates the organization's commitment to change [22]. These types of leadership actions, accompanied by relevant diagnostics, will form the foundation for anchoring organizational values and communicate the importance of the change desired.

Change and accountability at the subculture levels require diagnostic data and root-cause analyses of events to focus on systems improvements. Specifically, identifying negative deviance and "work-arounds" are two key areas of opportunity for process improvement to support patient safety. Positive deviance, or subculture best practices, can be emulated to create and build success in other areas [32–34]. For example, using the best practices from a unit with the lowest morbidity, mortality, or infection rates to train others in the organization is an example of using positive deviance for change. Data from the "work-arounds" can be used to solve system weaknesses and redirect innovation to other needs. This direction is especially important since the "work-arounds" themselves, if not corrected, will often lead to long-term issues such as increased errors, wasted resources, and cynicism [35].

With this emerging awareness of organizational culture's effect on patient safety, it is helpful to understand the behavioral differences observed in healthy versus unhealthy cultures. Recognizing these behaviors can be an important first step toward culture change.

Healthy Cultures

Ultimately, the health (or dysfunction) of a culture can be seen through performance at the organizational as well as the subculture levels. A healthy culture can be recognized by positive mindsets, behaviors, attitudes, and beliefs. Behaviors characteristic of healthy cultures include collaboration, appreciation, graceful responses to change and feedback, supportive and accountable behaviors as well as selflessness to the greater good of the organization. Appreciation, for example, will be recognized when a nurse thanks a respiratory therapist for his help with transporting a patient. Effective listening and communication will be prevalent. Most will assume best intentions of one another – a foundation for trust. Leadership within subcultures and throughout the organization, including senior leadership, is aligned and modeling these behaviors. Leaders will lead from the organization's values to guide and create synergy. Individuals will feel valued, respected, and rewarded for their contributions [21] (Table 182.1).

Table 182.1 Cultural behaviors, attitudes, mindsets of healthy and dysfunctional cultures [8, 10, 16, 21, 28]

Healthy culture	Dysfunctional culture
Collaboration	Dissonance; internal competition between units and functions
Communication – open and honest	Communication – failures, or lack of, disruptive behaviors
Appreciation	Lack of appreciation or unexpressed appreciation
Trust, assuming best intentions	Trust issues, hidden agendas, assuming mal-intent, disruptive behaviors
Individuals feel valued, appreciated, respected, and rewarded for their contributions	Individuals feel disrespected, disregarded
Accountable behavior	Lack of accountability with excessive blaming and excuses
Selflessness to greater good of the organizations	Entitlement mindsets with poor empowerment
Effective listening and communication	Inability to listen deeply
Aligned leadership	Silos; lack of alignment
Emotional intelligence	Lack of self-awareness, self-management
Innovation and creativity	Bureaucratic tendencies and critical mindset that stifles or kills new and innovative ideas
Ability to adapt and change	Lack of ability to adapt or change
Transformational leadership	Hierarchical leadership and structures
Healthy conflict management	Conflict avoidance with passive-aggressive behaviors, disruptive behaviors
Cultural diversity	Inability to foster and support diversity of ideas or people

Dysfunctional Cultures

A dysfunctional culture will be recognized by an organization, despite repeated efforts, when unable to achieve intended results, goals, or strategies. These inabilities are due to barriers or a "cluster of habits and ways of thinking that are destructive to effectiveness" [28]. These clusters of behavior or thought habits are characterized by internal competition between units and functions, an inability to adapt or change, hierarchical leadership and structures, bureaucratic tendencies with little to no innovation, a critical mindset that staunches new and innovative ideas, entitlement mindsets with poor empowerment, lack of accountability with excessive blaming and excuses, hidden agendas, inability to foster and support diversity of ideas or people, tolerance of disruptive behavior, ineffective communication, and conflict avoidance [21].

As discussed previously, there has been recent emphasis on disruptive behaviors by the American Medical Association [23] and The Joint Commission [5] because of the identified causal link to compromised patient safety [5, 23, 36, 37]. The American Medical Association defines disruptive behavior as any abusive conduct that harms or intimidates others to the extent that quality of care or patient safety could be compromised [23]. The Joint Commission reports that approximately 40 % of clinicians

have kept quiet or remained passive during patient care events rather than question the known intimidator [5]. Disruptive behavior can be as obvious as throwing a chart across the room or as passive as not returning a page, all contributing to a hostile work environment with intimidation and fear. This can be a situation as simple as a nurse not speaking up to remind a physician that he did not perform hand hygiene. Other impacts of disruptive physician behavior are increased medical malpractice risk, job dissatisfaction, and decreased team collaboration and communication [36, 38, 39].

Due to the intimidation factor and passivity when dealing with events, leadership is now called to address disruptive behaviors through educating physicians and the healthcare organization. Knowing that "disruptive behaviors are often reinforced within the clinical microsystem," a systems approach to change is required for sustainable change [37].

Culture Change

Healthcare organizations continually work to improve patient safety and outcomes, effective and efficient use of technologies, as well as financial health. Indeed, "professional and organizational cultures in healthcare must undergo a transformation in the interests of promoting safer patient care" [9]. To change holds great promise for patients, their families, and healthcare organizations. To not change will result in wasted resources and the inability to capitalize on human talent and technology. Enhancing an organization's culture hand in hand with change implementation is critical to success.

How will the culture change be implemented? Will the change initiative be targeted at transformation at the individual, subculture, and organizational levels that is embraced and role-modeled by all leaders from senior leaders to front-line leaders? Will the organization leverage the positive deviant subcultures to catapult the organization to successful change initiatives?

The Leader's Role in Creating and Shaping Culture, and Ergo Quality and Patient Safety

Leadership is integral to culture, culture change, and patient safety. As mentioned previously, leaders are the creators, managers, or destroyers of culture [16]. There are numerous dimensions to culture and the culture analysis will confirm areas of strength, and uncover areas of culture that are out of alignment with the organization's values, goals, and strategies. Leaders must address the aspects of their culture that will impede their ability to drive quality, safety, and financial health. These areas of opportunity for improvement define the "gap" between the current culture and the desired state.

Large, transformational change begins with the vision and resolve of individuals – usually leaders – who want to improve performance in clinical care, staff satisfaction, patient satisfaction, and financial health. In order for an existing culture to change, leaders at both the organizational and subculture levels must first consider themselves as the nidus of change. Effective leadership begins with leaders who know themselves, and understand their environment. Thus, the ability of leaders to create or shape culture begins on the inside. Leaders who align themselves with explicit values, goals, and strategies of the organization through their behaviors and daily decisions contribute to narrowing the gap between the current and desired culture and vision they have for their team and organization.

Leadership influence is not to be underestimated. One study based on data collected from over 17,000 patients across 42 adult ICU's revealed that caregiver behaviors that reflect a healthy culture through effective leadership, communication, and conflict management were significantly associated with lower risk-adjusted length of stay, lower nursing turnover, higher evaluated technical quality of care, and greater evaluated ability to meet family member needs [40]. In another study, Baggs demonstrated medical ICU nurses' reported level of collaboration was a positive predictive value of patient

outcome (decreased death/readmission to the ICU) after controlling for disease severity. For each increase of one point in the collaboration instrument (Collaboration and Satisfaction about Care Decisions (CSACD)), the odds of a negative patient outcome were reduced by 4 % (odds ratio, 0.96; 95 % confidence interval, 0.926, 0.998) [41].

Leaders with high levels of communication skills, social awareness, conflict skills, and team dynamics skills are likely to be more adept at using resources (technology) to decrease patient morbidity. Covey refers to these skills as character growth from the "inside-out" [42]. That is exactly where cultural transformation begins. A leader's ability to affect change an organization does not begin by focusing change on the surrounding environment, but change within himself.

But how often does medicine give its doctors, nurses, administrators, and health care providers the luxury to develop this most crucial component of cultural transformation – the leader? Most physicians had no formal leadership training during their years of preparation for medical practice. At some point, it was understood that they would lead a team, but they did not likely have a full understanding of what that would entail. Most received no focused training in developing the skill set required to transform culture through leading teams. Healthcare providers, particularly physicians, are socialized in their training to work independently and autonomously. Historically, there has been a hierarchy to the model of healthcare delivery. This model has been passed on through generations of trainees and accepted as the prevailing culture of medical education. There is a paucity of attention on the collaborative model of a flattened hierarchy within teams and the role leaders play in creating it. The focus during training years, regardless of the discipline in medicine, was learning the trade. When did healthcare providers have time to learn about themselves? Where was the focus on individuals becoming leaders in medicine? How often was the focus on the shaping the primary role model – the physician leader – who would set the tone for the collaboration responsible to improve quality, safety, caregiver health, and financial health in the cultures they serve?

Leaders and Cultural Analysis

Leaders must diagnose culture. They must become experts at diagnosing the current reality and eventually linking it to a future vision. Acknowledging culture as "how we do things around here," is a good first step in cultural analysis and diagnosis. Usually, the visible elements of culture developed as a solution to a problem solved by a previous leader or group. It is deeply ingrained around every leader. Leaders can be part of an existing culture themselves over a long period of time, or walk right into what is a new culture for them and still be expected to make the culture effective. "If a leader is imposed from the outside, he or she must have the skill to diagnose accurately what the culture of the organization is, which elements are well adapted, which elements are problematic for future adaptation, and how to change what needs changing" [16]. Culture diagnostics, described above, will provide valuable information to the leader to help with understanding the current cultures and defining how to reach the future vision.

In the diagnosis, the leader must interpret hidden meaning to how things are done, often with very few clues and use the diagnostic data available. Just as in medicine, if one does not make the correct cultural diagnosis, one cannot prescribe the correct therapy for changing it. Leaders must become a cultural anthropologist, in a sense. They study the science of humans and how they work within the culture they exist. As mentioned previously, instruments such as the OCAI and the OCI can be used for the diagnosis of culture. Survey tools are also useful. On a much smaller scale, leaders who wish to change culture can begin with asking open-ended questions to aid in their diagnosis. "What works well in the organization? Tell me about the team. What does the unit value? What changes would improve the team?" Asking and then listening to not only the superficial answer, but the deeper hidden answer, can provide the springboard for what ails a culture and also what makes it effective.

Following diagnostics, the leader's understanding of "how things are done around here" is not as easy as it sounds. The original reasons

behind the culture are not always outwardly visible. As explained above, culture is an intricate web that involves what not only what people think and do today, but also what others before them thought and did. How does a leader come to understand what has been shared, learned, transmitted cross-generationally, adapted and integrated? [43] Those who reside in the current culture may have become embedded over time to even the maladies of the culture and propagate the "unspoken rules." They become part of the culture of which they complain. Most of the buried rules are not spoken of. Only the external behaviors that represent them are evident. The format of reporting procedures, the layout of a unit, or even the actions of the different roles within the team seem to move along with little or no questions posed to their origin in most work areas. As will be described later, leadership and its role in shaping culture is clearly not a passive one. A leader begins to understand culture by seeing the way people interact, seeking out the expressed values of the group or organization, trying to uncover "the rules of the game," and watching group norms of behavior, to name a few. He then can also begin to focus on his role within that culture.

Leadership, Personal Growth, and Development

Personal transformation through leadership growth can be an exciting journey of self-discovery with focus and intentionality. Make no mistake, though, this journey is not for the faint of heart. With this journey of self-discovery comes awareness not only of self but eventually of the surrounding culture. This self-discovery requires an inner analysis that allows reflection of behaviors such as integrity. Understanding one's mental habits and patterns from the past is essential to change.

Leadership growth is a heart-opening experience as only the leader who knows his own heart will be able to encourage the heart of others. It is an eye-opening experience to uncover the blind spots that subvert one's credibility. Kouzes and Posner write that, "if we don't believe the messenger, we will not believe the message" [44]. Credibility builds trust and leaders are followed through the severity of change. They are authentic. Their words and deeds match. Their yes means yes and their no means no. Their behavior is the brightest billboard for the cause they promote. That billboard not only has the cultural values of the organization and their subculture written on it, but they are displayed in the leader's actions. They state, "The truest test of credible leadership is what leaders pay attention to and what they do. Leaders are measured by the consistency of deeds with words." The art of creating trust requires vision, courage to see things differently, and willingness to recreate – even when what is being recreated is the leader himself.

Leaders that transform organizational culture and their subcultures are highly emotionally intelligent (EI). Finding shared meaning and moving the heart of those who exist in a subculture is about emotion. Leaders are skilled at working emotion. Great leaders transform culture by moving us. The "I have a dream" speech by Martin Luther King is one such example. Goleman writes, "The fundamental task of leaders, we argue, is to prime good feelings in those they lead. . . at its root, then, the primal job of leadership is emotional. We believe this primal dimension of leadership, though often invisible or ignored entirely, determines whether everything else a leader does will work as well as it could" [45]. Leaders compel emotion and create resonance. Only then can culture shift willingly. For true cultural transformation to occur, leaders are required to become personally and socially competent in EI (Table 182.2). Senn Delaney calls it "the shadow we cast" [21]. Cloud refers to the concept of EI as "the wake" one leaves behind [46]. EI competency is like any other competency in medicine. It is built with practice and feedback.

Leadership development programs appear to be evolving and felt to be essential by many. These programs can be found in varying institutions and organizational bodies, and can be composed of multiple pedagogies. Hospitals may

Table 182.2 Emotional intelligence domains and associated competencies

Personal competence (capabilities of how self is managed)		Social competence (capabilities of how relationships are managed)	
Self-awareness	Self-management	Social awareness	Relationship management
Reading ones emotions: recognizing their impact; using "gut sense" to guide decisions	Emotional self-control: keeping disruptive emotions and impulses controlled	Empathy: sensing the emotions of others, understanding their perspective, and taking active interest in their concerns	Inspirational leadership: guiding with a compelling vision
Accurate self-assessment: knowing personal strengths and challenges	Transparency: displaying honesty and integrity; being trustworthy	Organizational awareness: perceiving the currents, networks, and politics at the organizational level	Influence: having a wide range of tools for persuasion
Self-confidence: a realistic sense of self-worth and capabilities	Adaptability: flexibility in adapting to changing situations	Service: recognizing and meeting the needs of others	Developing others: empowering others' abilities through feedback and guidance
	Achievement: motivation for performance improvement while meeting inner standards of excellence		Change catalyst: initiating, managing, and leading in novel directions
	Initiative: readiness to act when opportunities arise		Conflict management: resolving disagreements
	Optimism: seeing the upside in events		Building bonds: cultivating and maintaining a network of relationships
			Teamwork and Collaboration: cooperation and team building

Adapted from Goleman D. *Primal Leadership* [45]

seek professional consultation from transformational/leadership development experts such as Senn Delaney or consult with other healthcare organizations who have driven internal change and development such as Columbus Children's Hospital with their "Medical Leadership Program" [47]. Individual departments have also chosen to expand the ACGME's professionalism competency training requirements mentioned previously to include leadership with well-defined education programs and curricula. In some cases, individual departments have also chosen to train faculty in the areas of leadership and professionalism development as was mentioned previously. The University of Southern California offers extensive training in personal development in its Masters of Academic Medicine program. Others, such as The Greenleaf Society for Servant Leadership, The American College of Physician Executives, the Pediatric Academic Societies, the Society or Pediatric Anesthesiology also provide workshops and education in the development of leadership skills, to name a few. The Department of Veteran's Affairs has become one of the nation's leaders in the delivery of quality healthcare and education. They foster patient safety through their Medical Team Training program. Their program requires a commitment to behavioral change from the participating medical center and offers long-term follow-up, coaching, support, and feedback of data analysis of their individual participants.

The Leaders Role in Transforming Culture

As leaders diagnose and understand the current reality of their culture, another difficult question arises. "What role do they themselves play in the

dysfunctionality (or functionality) of the culture they are trying to lead?" Leaders must then take time again to look at not just who they are, but *how they think* and *what they do* within their own culture. How do they navigate the concepts of change, power, and conflict in teams to transform culture? Do they understand what those concepts have to do with culture? Are they skilled in "using" these concepts?

It may sound simple, but leaders understand that transformation is essentially about change. Change provides an opportunity for growth, an invaluable process for future hope. Leaders should not only anticipate change, monitor change, and adapt to change, but create change itself. It is said that leadership and change are two sides of the same coin. When it comes to change in a culture, one watches the leaders. One watches what they do. Kotter writes, "People change what they do less because they are given analysis that shifts their thinking than because they are *shown* a truth that influences their feelings" [48]. How do leaders think internally and behave externally about change, realizing it impacts their culture? If they are not comfortable with change and embody its role in cultural transformation, they then feed the dysfunctionality of the culture they lead.

How leaders model themselves as change agents may affect the teams they lead and hence the cultures they attempt to transform. A study of how surgical teams at 16 major medical centers implemented a difficult, new procedure for performing cardiac surgery revealed that the teams that adapted most quickly to the new procedure had some unexpected things in common. The teams that best adjusted to the change occurring in their operating rooms were not necessarily the teams with the most experienced surgeons or the most highly supportive hospital administration. The "fast factors" they isolated included leaders that "framed the challenge in such a way that team members were highly motivated" [49]. They also found that the design of the team to include members that were willing to deal with new and ambiguous situations was important. They created an environment where their teams were made to feel like they were "part of something new." Leaders understand that in order to improve performance outcomes in clinical care, staff satisfaction, patient satisfaction, and financial health, they must navigate both personal and team change to transform their culture.

Leaders who transform must also set the same microscope on themselves as it relates to their understanding of power in general, and the power of community in their subcultures. Hagberg defines power in this way, "personal power is the extent to which one is able to link the outer capacity for action (external power) with the inner capacity for reflection (inner power)" [50]. How a leader sees and uses his/her own power will dictate how followers will follow. When they know themselves and are aligned with their core values (inner power), how they act (external power) is clear, sound, and easily followed. Leaders transform the cultures within which they exist as they win the hearts of their followers. Although not apparent at first glance, Hunter defines authority similarly to how Hagberg defines power. He writes, "authority: the skill of getting people to *willingly* do your will because of your personal influence" [51]. Both definitions, although for different words, have the same shared meaning. Leaders transform the cultures they exist within by bringing the hearts of the people they are leading along the path they envision for the subculture or the organization. Power as it relates to leadership is not about coercion, manipulation, or politics. Sure, those tactics may work in the short term, but it will not allow transformation to stick. The political power of culture and community is highly embedded and can only be softened by a leader of integrity who influences to a vision larger than himself. Followers must know that what they are following is so deeply and fundamentally sound, that it will (and should) continue long after they, and their leaders, have stepped aside. Leaders create that belief within culture that allows it to be sustained by deeply held convictions within that culture, not by coercion.

Healthcare and its subcultures have special challenges with change. Flattening the hierarchy of medicine, medical administration, and the

unbalanced use of power need ongoing attention. When using a survey tool in assessing the status and significance of disruptive behavior around perioperative areas, Rosenstein et al. that disruptive behaviors were common [52]. They reported comments, such as some doctors "seem to believe that they have the right to be rude, verbally abusive, and disrespectful to non-physicians. It makes it very difficult to perform at a high level when one is constantly in fear of being screamed at." Their work supported a growing body of literature that inappropriate use of power manifesting itself in disruptive behavior has a significant impact on perceived team dynamics and communication which can have a negative impact on patient care. Leaders cultivate an understanding of power and use their own to positively change behaviors that do not support the vision mentioned above – improved quality, patient safety, and financial health.

To transform culture a leader must navigate internally and externally with conflict. Healthy conflict is at the root of moving from one step to the next in transforming culture and ultimately providing safe patient care and promoting patient satisfaction. When a leader or member of the group cannot disagree openly about issues that at one point or another will translate to how one safely provides medications, a procedure, or other intervention to the patient, the patient will suffer. Strong leaders trying to transform culture understand that conflict is a natural part of their interactions with others. They are comfortable with it being present in the room. They create healthy conflict when appropriate. Cultural transformation requires leaders who are highly adaptable in the different modes of conflict management such as collaboration, compromise, avoidance, competing, and accommodation as identified in the Thomas-Kilman Conflict MODE Instrument [53]. They create a culture of transparency and seek the input of others even if that opinion is different from their own.

In the previously mentioned study by Edmonson, the authors also reported that one of the "fast factors" in implementing change (a new procedure) was the ability of the leader to create "an environment of psychological safety that fostered communication and innovation." Team members were confident in bringing up suggestions to others within the team of higher status [49]. Leaders see conflict as an opportunity for change and their personal conflict management skills as the vehicle to navigate the change required to maximize their current cultural strengths and minimize its negative components.

The behaviors of leaders as they relate to conflict and other skillsets of leadership are watched and emulated as they propose changes within culture. When leaders are self-aware, self-managed, socially aware, and carry strong social skills (highly emotionally intelligent), they are in their best position to shift culture. Leaders display *how they think and what they value* by *what they do* within their own culture. Much of medicine is learned by watching role models and then emulating their behavior. "The informal curriculum, which consists of unscripted, unplanned, and highly interpersonal forms of teaching and learning, is very powerful teaching tool for passing on the knowledge, skills, and values of the medical profession" [54]. One would argue that this is also the most significant way in which culture is learned. Leadership behavior is not exempt from this type of pedagogy. In a single center study by Schneider et al., the authors were able to show that hand hygiene (HH) of junior practitioners (nursing and fellows) improved under the supervision of adherent role models even when these role models presented no verbal cues toward HH compliance. HH adherence by junior practitioners at baseline was 22 % of possible opportunities and improved to 56 % as a result of role modeling [55]. Leaders can portray the positive behaviors mentioned previously that are characteristic of healthy cultures such as honesty, selflessness, and collaboration – they can display EI. They can also portray the polar opposites – lack of appreciation, ineffective listening, and competitiveness. In distinguishing top-performing hospitals in acute myocardial infarction (AMI) mortality rates, Curry et al. reported on in-depth interviews conducted in 11 US hospitals ranked either in the top or the bottom 5 % in risk-standardized mortality rates (RSMRs). They discovered that the

high-performing and low-performing groups differed in several key themes. These included shared values, sustained physician champions, empowered nurses, groups that recognized interdependencies, and groups that saw adverse events as opportunities to learn [30]. Leaders need to be the role models for these behaviors. Leaders set the tone of their subculture with their behavior.

The Courage of Leaders

As mentioned previously, leading and shaping culture was not for the faint of heart and requires intentionality. Leaders who transform culture must utilize courage to get it done. The efforts required to shift an organization's culture is an arduous and long-term commitment, requiring years to change and then anchor. "Usually the organization can be renewed, energized, or made effective only if some leader is willing to take some big risks by stepping outside the well-defined boundaries. When this happens, the organization is lured, pushed, or pulled into unknown territory" [56]. Whether this is at a team level, a unit level, or organizational level, the interplay of fear, risk, and courage always exists because excellence in shaping culture is a high-risk endeavor with the possibility of great rewards.

Leaders courageous enough to embrace change, live with ambiguity, and commit to personal growth will drive quality, safety, and financial health. Leaders find courage to reinvent themselves, walk with integrity, and become flexible by putting the status quo at risk. A vision of excellence is essential to staying courageous despite fears. Johnson asks, "what would I do if I wasn't afraid?" [57]. Leaders move their cultures by staying focused on the vision while acknowledging the fears, while capitalizing on the strengths of the team as they relate to patient morbidity and mortality. The leader envisions something better and reminds others often of the vision. Leaders envision something far beyond the ordinary, far beyond what others may think possible for the cultures in which they exist. They know that here is a tangible tension that exists between their current reality and their vision, and they are ready to overcome that gap. In filling that gap, they find collaboration, coalition, less dysfunction, and buy-in within their teams. In bringing their current culture to their future vision, leaders may also find improved patient/staff satisfaction, patient health, and organizational financial health.

Summary

Everyone knows him/her: The amazing doctor who is highly skilled in his craft. He has well-honed hand skills and his knowledge base is breathtaking. Yet no one wants to work with him. They all cringe as he walks into the work unit or operating room. He creates angst and not harmony. He leaves a wake of gloom and anxiety wherever he goes. The tone of the room is clearly worse when he exits than when he entered. Yet one hears those around him say: "Yes, but he is so good at what he does." The question that arises is: "Is he really good at what he does"? Does he lead his patients and team to improved health? Do those who work with him feel satisfied? Do his patients have better outcomes and less morbidity? If one could make a list of the qualities that would make up the kind of physician one would want to entrust their care to, would he be a picture of that physician? Is he truly effective in moving his team along for organizational and patient health? As presented in previous chapters, technical skills and knowledge base are listed as important, but one would also see that his ability to use his skills and knowledge base, to be effective in creating and shaping culture, requires so much more. Schein wrote "In fact, one could argue that the only thing of real importance that leaders do is create and manage culture and that the unique talent of leaders is their ability to understand and work culture" [16]. This importance is magnified in medicine because the stakes are so high, patient morbidity and possible mortality. No one in healthcare wants to gamble with a patient as the chip, but as unaware leaders who do not understand how to navigate culture, one gambles with patient lives every day unless one becomes skilled at understanding culture, their role in

cultural transformation, and the role those play in quality, patient safety, and patient health.

Performance Management in a Multidisciplinary Service Line

183

Jeannine Acantilado, Jacqueline N. Hood, and David Moromisato

Abstract

Performance management is the process of creating a work environment or system in which people are enabled to perform to the best of their abilities. Performance management is a whole work system that begins when a job is defined and ends when an employee leaves your organization.

Recruiting and retaining top performers is the most important leadership function of an efficient, quality cardiac service line. To attract, recognize, and successfully recruit employees who possess the competencies required to provide excellent service and make vital contributions to the overall effectiveness of the team is the first step in building a premier service. Aligning individual values and performance with the organizational goals and service line mission is the core basics of a successful team working toward a common vision. By encouraging employees to their highest potential and empowering them to assume responsibility over their work processes as a valued member of the team, leaders will receive the highest performances from their physicians and staff. Although considered the soft skills in managing a complex service line, an effective leader will

not minimize the importance of developing their leadership as well as their managerial skills in receiving the highest performance from their service line staff.

This chapter provides the basic principles of recruiting strong, talented individuals to serve within the service line and outlines the necessary skills to manage their performance. The ability to inspire and maximize every individual's contribution to the team regardless of the role or function within the service line will be the leader's greatest challenge, and it starts with people management skills.

Introduction

Performance management is one of the most difficult aspects of leadership and crucial to the successful growth and quality of a service line. Strategically, leaders can come together and agree on a vision, mission, and values; but it is how this is integrated into the daily operations that ultimately impacts the quality of the service line. Day-to-day management of individual performance from the perspective of employee engagement, clinical competence, and contribution to the team can be a challenging aspect of leadership. Yet performance management molds the organizational culture. The frontline clinician-to-patient/family interactions within a framework of systems and processes are the greatest reflection of the organizational culture. The vision, mission, values, and goals of the service line would otherwise be meaningless and intangible [1]. Leaders can set up successful performance management and support a strong organizational culture by turning their attention to some foundational principles. Performance management is the process of creating a work environment or setting in which people are enabled to perform to the best of their abilities. Performance management is a whole work system that begins when a job is defined and ends when an employee leaves your organization.

Important aspects of performance management that high-performing leaders must master were most likely not an integral part of their education and training, especially if their entry into healthcare was clinically focused. These leaders must accept personal accountability for their leadership and therefore build on their skills with the same dedication they apply to increasing their clinical competence in their area of expertise. This requires self-reflection and an honest evaluation with regard to their leadership strengths and weaknesses [2]. With self-knowledge, leaders are able to build skills sets as leaders to address their gaps and maximize their contribution.

Operational skills include both relational as well as organizational skills needed to achieve results through leading others. These skills are the nuts and bolts of execution and the development of efficient and effective work processes. Strong service line leaders with honed operational and leadership skills can simultaneously envision the big picture and focus on clinical strategies. They make complex strategic decisions with multiple factors at play and are comfortable with taking risks to develop new and

innovative programs. They function with the confidence to manage downstream decisions in order to arrive at better strategic decisions. To achieve superior service line results and consistently execute a strategic plan, these leaders work through people to optimize their strengths and mitigate the impact of their weaknesses. Operational effectiveness and strategic execution of a service line hinges on the leader's ability to manage performance and inspire people. Thus, the important aspects of performance management for service line leaders include relational, strategic and systems thinking and organizational skills.

In this chapter, the authors will describe several key elements of managing performance. First, performance management requires learned leadership. Emotional maturity and thoughtful judgment are required in complex systems such as a multidisciplinary service line. Second, recognizing and hiring for talent and values is critical. Skills, for the most part, can be imparted through training and experience. However, talent and values are difficult to inculcate and are important for shaping a culture intended for high performance and accountability. Third, professional development and advancement of the staff and physicians is required to continuously improve quality and safety, in general, and the ever-evolving field of congenital heart care, specifically.

The Value of Leadership Skills

Leadership skills are necessary in performance management in order to recognize and hire for talent, coach and manage staff and physicians, and manage individual performance. Leaders with strong personal and interpersonal skills manage their emotions and are able to shape and manage how they are perceived by others [3]. They are guided by a moral compass that allows them to act with integrity even during highly charged emotional situations so employees can place trust in them. This type of mindful leader with the ability to self-regulate and self-manage garners respect and loyalty for the long haul. Service line leaders – including clinicians – must constantly develop their administrative skills with the same rigor and discipline surgeons would invest in learning a new skill in the clinical arenas where technical expertise and knowledge have traditionally reigned supreme [4, 5].

Performance management is greatly dependent on personal and interpersonal skills because strong, talented employees will not follow a leader who does not model competence, integrity, vision, purpose on inspire confidence in the future [6]. These skills are critical in keeping top performers engaged. Interpersonal skills are traditionally seen as the "soft skills" of managing and leading people. They involve the ability to be empathetic, listen effectively, manage diverse relationships, inspire the people they serve, and build trust. Interpersonal skills are closely tied to personal skills, which are generally the ability to honor commitments and make decisions firmly aligned with the organization's espoused values. Without a strong foundation in this set of skills, effectively leading and managing a multidisciplinary service line is almost impossible to achieve. Yet this can be the area where leaders receive the least amount of training and therefore focus the least amount of their attention. When a service line finds significant weaknesses in key portions of the provided services, as signified by weak clinical outcomes, poor customer satisfaction, or financial instability, leadership effectiveness should be the first area examined. Unfortunately, it is often the last area of consideration or completely overlooked as a contributing factor during a root cause investigation in many organizations.

Service lines need a clearly defined strategic plan with regard to quality and patient safety, growth, finance, customer satisfaction, and employee satisfaction. The direction of the service line provides a context upon which important decisions are made and builds a framework leaders use to guide performance management. Any time the strategic plan, mission, vision, and

values are not clear to the entire team, individual interpretations of the service line's purpose and personal agendas begin to build and sustain a culture that is not easily reshaped. Senior service line leaders must place immediate decisions about growth, quality and patient safety, customer satisfaction, and referrals in the context of the larger strategic plan. Then well-designed communication plans keep everyone focused in the same direction, using a common language and understanding.

Recognizing and Hiring for Talent and Values

> If we didn't spend four hours on placing a man and placing him right, we'd spend four hundred hours on cleaning up after our mistake. Alfred Sloane, CEO. GM

Performance management with regard to individuals is a daily responsibility. It starts with choosing the best candidates with the right skills, education, training, and work ethic. Healthcare is a service, and the quality of a pediatric heart center will be defined by its outcomes. The outcomes of the center are, in turn, determined by the collective skills and knowledge of its people. The importance and primacy of the technical skills and knowledge of the center's clinicians is self-evident. Nevertheless, there is ample literature and evidence that the collective team – rather than a single superstar – determines the quality and safety of the care delivered to its patients [7].

The more rigorous the selection process is upfront, the easier performance management will be long term. The initial investment that leaders make in understanding the people they lead and with whom they interact impacts their ability to choose the right participants and lead a team. Developing these skills allows a leader to position people on the right projects or in areas or work groups where they can excel. The employees are then more likely to experience success developing their expertise and remain highly engaged. A cardiac service line requires significant levels of engagement and specialty knowledge. Therefore, most service lines thrive when there is high engagement and low turnover in all areas of clinical services. A leader's skill in placing people in the right work environment performing the functions suited to their skills and talents is vital to service line success.

A systematic approach to hiring may be the most important aspect a service line implements in the development and sustainability of a quality program. The most successful organizations in industries outside of healthcare focus most intensely on their selection of people [8]. Indeed, there is a strong business case for why one would want to make this a priority in a clinical service line as well.

First, the cost of a bad hire is expensive to an organization [9]. The higher-level positions cost money from a recruitment, training, and onboarding standpoint. The frontline employee whose employment costs are considered low by superstar physician standards has several costs that – in the face of high staff turnover – are enormous. There are the obvious, tangible costs. The investments made on upfront expenses include such items as advertising; human resources time in screening, interviews, reference checks, background checks, employee physicals, and orientation to the hospital; and standard hospital competencies related to infection control, HIPAA, fire safety, etc. For some positions, there are travel expenses related to having the employee come from out of town for the interviews, recruitment fees if a firm has been retained to fill the position, relocation expenses, benefits package, short-term housing, and new employee costs such as phones, computers, and office space. For physician positions, there are malpractice premiums and licensure fees. The most notable is the expense of hiring an individual who is a poor fit for your service line, and the time and money spent managing poor performance. The hours of training and performance management to support and supervise a poor-performing employee are financially and emotionally expensive.

The second consideration for developing a standardized approach is the volume of recruitment that institutions will be facing over the next decade as baby boomers leave healthcare and

take their expertise and leadership skills with them. Sustainable programs designed by current leaders must be implemented and hardwired in order to transition a robust, effective program to younger leaders who will be tasked with learning to work more efficiently with less experience in leadership and management. Program design, leadership skills, and a strong vision with clear expectations and direction will mitigate the impact of the retiring workforce. A clear, intentional means of bolstering the next generation of leaders and clinicians is paramount. A robust hiring process is just one of those processes that need attention to secure top talent individuals for the future of the service line.

Finally, one must also consider the more immediate and intangible costs. These intangibles include misaligned values and behaviors that impact patient safety, customer satisfaction, employee morale, quality standards, and the loss of expertise and experience secondary to increased staff and physician turnover surrounding a hiring mistake; the impact is magnified when these poor hiring decisions happen frequently. With administrators and physician leaders, there is the impact on quality, regulatory readiness, and morale, but one must also consider the loss of market share or referrals and reputational and brand injury to the program. Indeed, these intangibles are more costly to the growth and financial stability of a service line than statistics can quantify [9].

A standardized approach using behavioral-based interviewing allows the hiring team to compare and contrast the skills, strengths, and fit of every candidate in a consistent fashion [10, 11]. There are several steps in developing this approach to recruitment. First, every team member must know the specific job expectations and required set of skills candidates will need to possess for every position for which they are interviewing. The team must also have a clear understanding of the values and behaviors expected of colleagues and a vision of the culture desired within the service line. Second, leaders should not build a job around a particular individual. This is common in healthcare settings especially if the individual is an outstanding clinician. It is a costly error that healthcare leaders repeatedly make. A position should be created to fill a gap in services, and leaders should hire the individual who best meets the criteria for success in the vacant position. For frontline positions, there are extensive specialty education needs that cannot be gleaned from generic education such as those finishing a nursing or residency program, and the high demands placed on employees to perform at a high level in a complex work environment require careful selection. Although it is important that top-performing employees recommend candidates they can endorse without reservation, every candidate regardless of who they know should go through the same rigorous hiring process. Members of the team have the influence to secure an interview for a candidate and can pull them through the human resources process but they cannot guarantee an offer. The candidate must earn the position like everyone else. This ensures a fair process and communicates to candidates to take the process seriously because there is no "shoe in."

Although leaders should be hiring for a candidate's ability to critically think and manage patients, they should also be hiring for attitude, motivation, and values. A provider can be trained to care for sick patients with expertise and competence; it is more difficult to instill values and intrinsic qualities such as work ethic, emotional intelligence, and stewardship [12]. Those are qualities leaders must learn to screen for in conjunction with a candidate's clinical skills or prior work experience. Past performance is the best predictor of future success. Therefore, the interview process should be geared toward knowing as much as possible about that candidate's past experiences, choices, and value judgments.

Service line leaders must partner with the human resources department and determine what tools they have available to prescreen candidates. The hiring manager should narrow the candidate pool through a prescreening process. Oftentimes, they have an online survey that can give the employer insight into a candidate's values and work habits. Based on these insights into a candidate's responses, these tools generate individualized behaviorally based interview

questions to allow further probing for a candidate's organizational fit. However, the interviewers should not put candidates through to the formal peer interview stage unless they can see the candidates as a potential hire. The process should also eliminate anyone who does not meet the basic qualifications for the position.

It is common for individuals in a leadership position to interview several candidates individually and not participate in a formal peer interview group process. However, having several team members interview a candidate can provide additional information on the suitability of the interviewee for the position, insight into the individual's ability to integrate into the team, and it can ensure that current employees are committed to the hiring decision. At a minimum, these individuals should be trained in behavioral-based interviewing techniques. Partner with human resources to determine if there exists a structure for training service line-based teams to perform behavioral-based interviews. Conducting interviews requires a set of skills for which people should be formally trained. If one does not currently exist, enlist the help of human resources and central education to develop a training course to establish common understanding of the objectives and skills required to perform effective interviews. Not only are there legal aspects of the hiring process that must be learned by everyone involved, but it is important that stakeholders have had some input into designing a predictable process for choosing new team members. Some organizations require that a minimum number of behavioral-based interview questions be asked by each interviewer and then recorded for submission to human resources prior to selection.

Creating a formal interview team for the front-line positions within a service line such as nurses, charge nurses, respiratory therapists, social workers, dietitians, secretaries, or administrative assistants has enormous benefit [13]. Those involved in the interview process will be comfortable with the new employee and have confidence in his or her abilities. Also, involvement in peer interviewing provides a sense of cohesiveness for existing employees. Finally, the peer interviewers are likely to have a desire for the new hire to succeed.

In creating a formal peer interview team for most positions, choose team members who demonstrate high levels of engagement in the work environment and who want to learn the skills necessary to hire effectively. Although there will be a variety of people on the team from various areas and disciplines within the service line, they should all be top-performing individuals. Top performers like to work on projects with other top performers and are more likely to recognize a fellow top performer [13]. Develop an understanding of how many interviews the team will perform to stay competent and decide how new members will be added and trained. In choosing the right candidates for the interview team, the leader is communicating the value in these employees' opinions. It is one of the most crucial aspects of employee engagement in which employees play a powerful role in influencing the work culture. Participation should be viewed as an honor and taken very seriously. These team members who give their stamp of approval on candidates in whom they believe will aggressively onboard new hires, welcome them onto the team, and ensure an early successful transition.

Based on the interview and a standardized tool, the team makes a recommendation to make an offer or to decline the candidate. Typically, the interview team could categorize candidates into three groups. Hire, they are the perfect fit for the team and there are no reservations about this candidate. Do not hire, there are too many red flags and believe this candidate will not be successful. Both of these indicate what should happen next with little debate.

If there is disagreement or uncertainty regarding a candidate's fit, he/she is placed in a "maybe" category. Candidates may be categorized as a "maybe" because of concerns regarding work ethic, skills, abilities, integrity, commitment, enthusiasm, flexibility, or conflict-style based on whatever behavioral questions the team had decided was important for the position. If the candidate lands in the "maybe" category, he/she is a "do not hire." The team should not

recommend hire if they are not convinced without reservation of the candidate's success. The goal is to hire top performers, not average ones who may get there. If the candidate is interviewing for a position where the final selection is being made at a higher level, then a recommendation with a detailed summary of the team's reservations should be part of the feedback to the decision makers. Once the candidates move to the next step, the hiring manager should make every effort to honor the selection recommendations of the peer interview team.

The candidate must make it through the screening process in human resources and be selected by the interview committee as a potential new hire before moving on in the hiring process. The next step is a job shadow experience. The job shadow experience is meant to provide a candidate with a realistic picture of what the work environment is really like and what challenges and opportunities for professional growth exist for the person selected for the position. This is also the time when the team sets the stage for clear expectations and values that exist in the work environment. The job shadow usually lasts a minimum of an hour but more typically 2–4 h. The candidate gets an accurate picture of the role and can do her own analysis of whether she will be a good fit. The team gets to know the individual and welcome her. Skipping this aspect of the hiring process is a common mistake because it takes extra coordination. However, the benefit should not be overlooked. Indeed, this aspect of the onboarding of a possible staff member is believed to be a key element in decreasing early turnover [14].

Coaching Versus Managing

With high performers, leaders are in the position to coach, rather than manage, employee behavior. The way in which leaders interact with new employees will set the course for the employees' performance early. In *First Break All the Rules*, Marcus Buckingham challenges leaders to focus their attention on maximizing the strengths of their top performers rather than spending time managing their lowest performers [15]. Leaders should not spend 80 % of their time managing the lower-performing employees. This seems obvious on the surface but difficult to implement when a leader devotes too much time managing crises that generally do not occur with higher-functioning individuals.

Studer describes a similar concept applied to healthcare environments [13]. He outlines a prescriptive way to lead and manage employees in order to harness the insight of the top performers while ultimately managing low performers to either rise to the expectations and standards of performance or leave the organization. Although these principles are difficult to initiate for an existing team, the culture shift in accountability and performance can be remarkable if done consistently and well. The goal is to minimize the impact of a low-functioning employee so that over time the gap between medium performers and high performers is minimized, and there are rare or no low performers in the work environment. Once the proper performance management processes are in place, leaders are free to coach more and manage less.

The appropriate management of low performers impacts quality, finance, and service outcomes across the service line continuum. If low performers are not managed, top performers often attempt to implement work-arounds to compensate for poor performance. These work-arounds are costly, inefficient, demoralizing, and preventable. However, it is important for leaders to differentiate between low performance and poor processes. Inefficient, poorly executed processes can make it seem that employees are low performers. When the right processes are implemented, these same employees demonstrate significant improvement. On the other hand, if processes are well defined but poorly executed related to individual accountability, leaders are required to act. So before performance management is considered, less than expected outcomes should be evaluated with regard to process as well as individual performance.

Clear communication and enforcement of consistent standards can address most

performance issues. Top performers generally work above and beyond the level of expectations required. If the leader has engaged the right employees, those employees will value excellence in their own performance as well as in the outcomes of their team. Well-communicated group norms and performance standards are the first steps in managing all employees. For example, if one values people's time, then everyone should be on time to a meeting, on time to receive sign out, on time to the operating room, or on time to patient/family care conferences. If people in the service line value timeliness, it should be a consistent standard for everyone. Therefore, providing information of evolving performance expectations is facilitated by a well-defined communication plan.

Another vital skill in performance management is the ability to initiate difficult conversations or manage conflict. Ideally, the majority of crucial conversations would be averted by having regular, transparent, effective communication before the conversations become difficult. Leaders should offer timely encouragement, support, and guidance when teaching moments happen for employees who could have handled decisions or performance more effectively. If the leader inspires employees to their best while helping them see and own what they could have done differently, the conversation is easier, less emotional, and more effective for everyone involved. The employee perceives support rather than criticism and generally strives to improve performance immediately.

There are several resources available that guide leaders through effective conversations to achieve results. In the book *Crucial Conversations*, Patterson, Grenny, and McMillan emphasize the importance of initiating difficult conversations from the right perspective [16]. The leader must be emotionally in check, set forth clear expectations or behavioral standards, and have specific examples of the deficiencies in performance related to these standards. These types of conversations generally take preparation and therefore should not be spontaneous or impromptu. Informal conversations that are meant to lead employees to a change in behavior may not be as effective as a planned, intentional, deliberate conversation that has a clear, well-articulated message.

When the leader communicates the expectations and gives clear examples of deficiency to the employee, the leader is listening for their ownership and accountability. Employees who offer excessive excuses, blame others, or deny involvement and responsibility for the outcomes lack personal accountability for the performance. These employees generally demonstrate little improvement over time. High-performing employees accept responsibility and ask for guidance or suggestions on how to improve their performance. Signs of improved performance and ongoing requests for feedback ensue.

Individual Performance Management

There are three types individual performance management approaches, based on the level of employee performance, that are important to the development of a strong team. And taking the time to know each direct report with an assessment of their communication style, motivation, clinical expertise, teamwork, adaptability, and others' perception of their performance will guide the management of their performance.

The first approach addresses the highly functioning, best performers on the team. An employee who is highly functioning in all aspects of their performance, not just in their clinical abilities, would fall into this category. If they are excellent clinicians, but poor team players, they are not the best performers on the team. The best performers are the employees that everyone on the team holds in high regard because all aspects of their performance contribute to the vision, mission, and values of the service line. This group comprises only 10–20 % of a typical large team. This percentage may increase over time with the right hiring, performance management, and strong leadership.

High performers demonstrate the greatest contribution to the team but are often the most overlooked on a day-to-day operational basis. It is not that their contribution is not valued or

appreciated. The team just assumes they will continue to do their job well and they will consistently deliver the highest quality outcomes. However, the best performers may have answers to perplexing problems and leaders need to ensure that they are included as a valued resource. A strong leader will weave these employees into a variety of teams and harness their energy and expertise. The processes they use to perform their jobs, how they use their influence with the rest of the team, and their ideas for process improvement must have an avenue for expression and close consideration. These high performers give leaders the template for success.

In addition, leaders should check in with the best performers and make a point to interact with them often, even if it is just a quick check in by phone. If it is an issue of schedule, scheduling a calendar appointment to touch base by phone should be planned and consistent. This gives leaders access to constant feedback on how changes and new processes are functioning at the front line and also gives the opportunity for these high performers to provide rapid feedback if processes need fine-tuning. It also gives the leader an opportunity to connect daily operations and recent decisions to the larger vision for a frontline employee. The leader has an opportunity to reframe the employee's thinking into a larger context. Over time, trust is built. If the employee needs feedback in terms of leadership, communication, or clinical competence, it is easily given in the context of coaching and support. A consistent check-in with top performers also gives the best employees validation of their value to the team. The leader has an understanding of the employees' interest and motivations and can plug them into projects that keep them working in their areas of strength.

Top performers are sometimes the most difficult group of employees for an inexperienced or average leader to manage and lead. They are often vocal in their continuous push for improvement. They are highly energetic and have credibility with the rest of the team. They have garnered everyone's respect because of their expertise and emotional intelligence and therefore can influence and mold the culture of the work environment. Inexperienced or new leaders will derive greater success by engaging this group and unleashing their strengths through collaboration rather than corralling them in or trying to hold them back.

Middle performers are employees who can be relied upon to perform their jobs well, are highly valued members of the team, but may have some areas of improvement that require coaching and ongoing education and training. All teams need the middle performers who come in and get the job done even if they have competing priorities that do not allow them to be highly energetic and fully engaged. The leader's challenge is to maximize their performance when they are at work and help them develop strong clinical and interpersonal skills to enhance the team's performance.

One way to accomplish this is through regular, timely feedback that supports, coaches, and mentors individuals to their best performance. With direct, transparent, specific feedback, most employees will improve their performance. If they see the vision for the service line and understand the performance standards required of them to do their part, they will move in the right direction. The amount of time, attention, and willingness to coach and support the middle performers is directly proportional to the value a leader places on leading them. Often times, with coaching, individuals in this group improve and join rank with top performers. If the top performers are led well, they serve as the role models for the rest of the team demonstrating exemplary performance and inspiring others to their best. With coaching and inspiration from the leader, the middle performers will soon adopt the work habits and performance standards of the best performers on the team.

Low performers are the leaders' biggest challenge and usurp the most emotional energy. However, strong values, a well-defined vision, and specific performance standards guide and facilitate performance management for this group. First, a leader must understand that low-performing individuals are generally managed and not led. Leaders will not inspire low performers to their best performance until they

have managed their areas of poor performance and helped them cross over into the same standard of performance as the middle performers. Strong leaders will force this group to improve and meet the expectations of the team without excuses and without lowering the standards. In high-performing organizations, there are only three positive outcomes for low performers. They raise their performance to meet and sustain clearly defined performance standards in a clearly defined period of time through consistent feedback. They will become so uncomfortable in the work environment; they recognize they are not a good fit for the team and seek employment elsewhere. Some will continue to perform poorly in spite of ongoing feedback and learning opportunities and be managed out of the work environment. One negative outcome remains for low performers; the leaders fail to set the standard and hold them accountable, and thus, low performers remain a drain on resources while negatively impacting service line success. Leaders who are in service to their best performers, and who embrace a clearly defined vision of the service line, will not allow low performers to affect quality, teamwork, or forward movement. To do so would be leadership malpractice.

Managing Misaligned Behaviors

Disruptive clinician behavior – or behaviors not aligned with the organization's mission and values – is believed by some to be the major cause of patient safety lapses and patient injury [17]. While classically described and attributed to physicians, disruptive behaviors are manifested by any of the disciplines of a service line, including nurses and administrators. The culture and tone of the service line will be determined by the conduct of its leaders and the behaviors tolerated by the service line's leadership. Managing misaligned behaviors is vital to the development of the character and culture of the service line and organization. The strength and integrity of the service line's leaders will be measured by their tolerance for disrespectful behaviors that are not aligned with espoused values.

Defining and recognizing disruptive behavior is a challenge for some leaders. Many believe yelling, loud nonverbal gesturing, and foul or abusive language are the only examples of disruptive behaviors. However, failure to communicate, refusal to collaborate, not intervening on behalf of the best interest of another, and undermining, blaming, or scapegoating are also forms of disruptive behavior, and these oftentimes go unaddressed. They are silent forms of misaligned behavior that insidiously erode the culture and the team's ability to function. Astute leaders will rapidly address individuals who display these behaviors in an effort to guard a safe, supportive, transparent culture.

The most important aspect of addressing and managing these behaviors is to maintain the individual's contributions to the service line and to patient care while protecting quality, safety, and service excellence. There are strategies for managing disruptive behavior that all the senior leaders must uniformly adhere to in order to guard the integrity of the culture. First, it is important to remember to condemn the behavior and not the person. A strong leader will listen for what triggers the behavior and guide the individuals toward appropriate channels to address their frustrations. Second, zero tolerance must be communicated without exception, regardless of position or circumstances. One of the most common, detrimental responses to disruptive behavior is that somehow the behavior was justified. There was a good reason or excuse either because the situation was highly stressful, the patients were so sick, a staff member was too new and inexperienced, or someone failed to communicate in a timely fashion. Regardless of the excuses, disruptive behavior is never justifiable. The service line leaders must believe it first before the disruptors can own and change their behavior, and the other team members can feel safe from it. Minimizing the behavior or perceived tolerance of these behaviors will destroy the credibility of the senior leadership and create cynicism and low morale among staff and physicians. From the perspective of the individual team members within the service line, silence from leadership is tantamount to consent. What is

permitted is promoted. Finally, management of disruptive behaviors must be proactive and timely. Specific examples of unacceptable behaviors must be explicit. Clearly defined acceptable behavior is sometimes just as important in helping employees to find effective ways to communicate. Leaders must coach an employee to use communication strategies that will allow him/her to be heard without intimidating others into avoidance or silence. If the communication with regard to disruptive behaviors is not interrupted in the moment, or addressed soon thereafter, the likelihood of the offender owning their behavior and recognizing the need for change lessens. The time lapse implies lack of importance or urgency for change.

Conclusion

In closing, performance management is largely dependent on personal and interpersonal skills. Strong, talented employees will neither join nor ultimately follow a leader who does not possess them. The best performers will expect their leaders to demonstrate strength in these skills. They will expect leaders to hire and inspire team members who possess the competencies of other high performers on the team. The effective leader must recognize the importance in coaching high performers to build capacity and strength of the service line. The character and integrity of a service line is at stake when members exhibit behaviors inconsistent with it mission and values. The leaders are responsible for managing low performers who inhibit the forward movement of their team in achieving superior results to maintain credibility with the rest of the team.

Common Mistakes in Hiring/Promotion Practices Prevalent in Healthcare

Myth #1- "She is a great bedside nurse and understands the patient care issues; she'll make a great manager (charge nurse, administrator, nurse practitioner, discharge planner, researcher, etc.)."

Not true. A team must listen for and screen an internal candidate with the same rigor they would an external candidate. A failed hiring process is a double loss for the service line; not only has the organization lost an outstanding bedside nurse, it has gained a low-performing manager that must be managed out of the position. If the values and skills for what the position requires are clearly defined, a team is less likely to make this mistake. This applies to promoting individuals from within the organization as well as someone who comes highly recommended from another program.

Myth #2- "Bless her heart" or "that's just the way he is, you'll get used to it."

Work environments must have strong professional boundaries that are sometimes difficult to apply to long-standing work relationships. Families and friends generally have to tolerate some degree of occasional bad behavior to maintain peaceful coexistence. In the work environment, no one should get a pass for "meaning well," "having their heart in the right place," or "just being the way they are" if it means that the rest of the team has to justify and tolerate bad behavior. Promoting these individuals or moving them laterally to make the work flow smoother for them does not work. In addition, it is disrespectful to the individual who deserves honest feedback for an opportunity to improve or to move on to a position in which they can thrive if they had a better fit. If the behavior is unacceptable and every opportunity for improvement has been granted, not only is promotion out of the question, demotion is too. There should be no room in a high-functioning service line environment for bad behavior.

Myth #3- Creating a position to get a job done, because the person doing the job is not capable of doing it right. One solution to a poor-performing employee is to add

another position because no one wants to manage the low performer who is close to retirement, very likable, or has competing priorities. This impacts labor costs and is not a sustainable long-term solution. Leaders must build the job description for the work needed for the service line to thrive and then choose from the candidates who can best perform in the role rather than tailoring the job for the individual currently in it. The service line culture suffers every time an unnecessary layer of work force is added to compensate for one not meeting the demands of the job. This applies to all levels within the hierarchy of the service line.

Myth #4- "I acted that way in my last job because I was frustrated. The administration (board of directors, manager, etc.) couldn't give me what I needed to take excellent care of the patients."

If they pouted, threw temper tantrums, were disrespectful, or have a reputation for that type of behavior in the professional community, chances are they earned that reputation. You would be wise to listen objectively and then state very clearly in the interview process several times from several different sources what the behavioral expectations and values are within the service line and the consequences should they not be met. A sustainable, quality program can't be built with even one toxic individual in a key role regardless of their talents in other areas of their professional life. There isn't anyone on the leadership team who wants to discipline a new employee nor does anyone have the time. A service line needs highly functioning professionals and should not take on the risk of providing rehabilitation for someone's intolerable performance elsewhere.

Myth #5- "I know this person and he is fabulous. We don't have to put him through the paces of a formal interview. Let's just do what we legally have to and then offer him the position."

This mistake undermines the credibility of the entire selection process and denigrates the confidence of the team. No one individual should have the power or influence to alter the process. Once exceptions are made, team members perceive the inconsistencies and no longer believe in the integrity of the process or the senior leadership. Often times, participation starts to wane and it becomes difficult to re-engage the top performers in this process or other important projects that impact the service line.

Seven Practices of Highly Resonant Teams

184

Jamie Dickey Ungerleider and Ross M. Ungerleider

Abstract

This chapter evaluates how substantial improvement in quality and outcomes can be achieved by attention to intra- and interpersonal factors that create teamwork. Together, these factors influence learning, growth, and innovation, as well as safety for team members and the patients they care for. It is difficult to quantify the improvement in outcome in terms of lives saved, errors prevented, and morbidity reduced, but the literature on this topic as well as the experience of numerous providers suggest that it will be real and substantial. Medical knowledge, skills, and judgment are not enough to reach high standards of quality and safety, and high performance requires much more than clinical skill. This chapter provides a framed construction for how good teams work and incorporate those important principles into *Seven Practices of Highly Resonant Teams*.

Introduction

This chapter evaluates how substantial improvement in quality and outcomes can be achieved by attention to intra- and interpersonal factors that create teamwork. Together, these factors influence learning, growth, and innovation, as well as safety for team members and the patients they care for. It is difficult to quantify the improvement in outcome in terms of lives saved, errors prevented, and morbidity reduced, but the literature on this topic as well as the experience of numerous providers suggest that it will be real and substantial.

When providing talks and workshops to groups of cardiac surgeons, cardiologists, intensivists, nurses, and perfusionists, experts in the field invariably encounter an individual who comments: "The only thing that matters is the patient and the outcome. That is our job – to provide good outcomes." Some have even said: "We don't really care about teamwork or how people take care of themselves. We don't even care if they get along. Our job is to get good results." The literature and experience are consistent on this fact (and these authors can reiterate; this *FACT*): Good outcomes *require* teamwork, leadership (the kind that will be discussed below), and *engagement* by team members who are committed to supporting and working with each other. Good outcomes *require* excellence in medical knowledge, skills, and judgment. That is indisputable. It is the obligation of all providers of children's heart care that they continually develop their knowledge, skill, and judgment. But medical knowledge, skills, and judgment are not enough. As this chapter will document, high performance requires much more than clinical skill.

In 2003, the IOM published their report on Health Professionals Education [51] and emphasized the importance of teamwork and communication in achieving *patient safety*. (In fact, patient safety is the title of their next report published in 2004 [52].) This concept had resounding implications in the field of healthcare. The Accreditation Council for Graduate medical Education (ACGME) introduced the "outcomes project" in which they emphasized the importance of competence in six areas which included, besides patient care and medical knowledge, interpersonal and communication skills, professionalism, practice-based learning (the importance of information and experience), and systems-based practice (appreciation for the interconnected relationships across the entire field of healthcare). The "outcomes project" forced education systems to begin teaching skills that many of the faculty had never (formally) received training to perform. For the first time, physicians were being held accountable for teaching (and learning) new ways of thinking, interacting, and leading.

Fortunately, emerging research into the neurobiology of relationships has provided a guide for how to create a culture that enhances the ability of people to work together. The astounding results achieved by the FAA (Federal Aviation Association) in reducing commercial airline crashes by introducing a protocoled form of team communication (crew resource management) provide testimony to the extraordinary power of creating highly functioning teams [107]. This chapter provides a framed construction for how good teams work and incorporate those important principles into *Seven Practices of Highly Resonant Teams*.

Foundations and Domains of Teamwork

Figure 184.1 depicts the foundations and domains of teams. Many of the books and articles on teamwork focus primarily on the three components (domains) of the wheel on the top – *who* (the people on the team), *what* (the reason the team is assembled – their identity), and *how* (the ways the team members go about working together). While each of these is important and will be addressed by the seven practices, the foundational blocks cannot be ignored, for without them, no recipe for teamwork will be effective. At the very base of good teamwork is *safety*. Without safety (within between and among), no teamwork is possible. No technique, tool, or process can create a sense

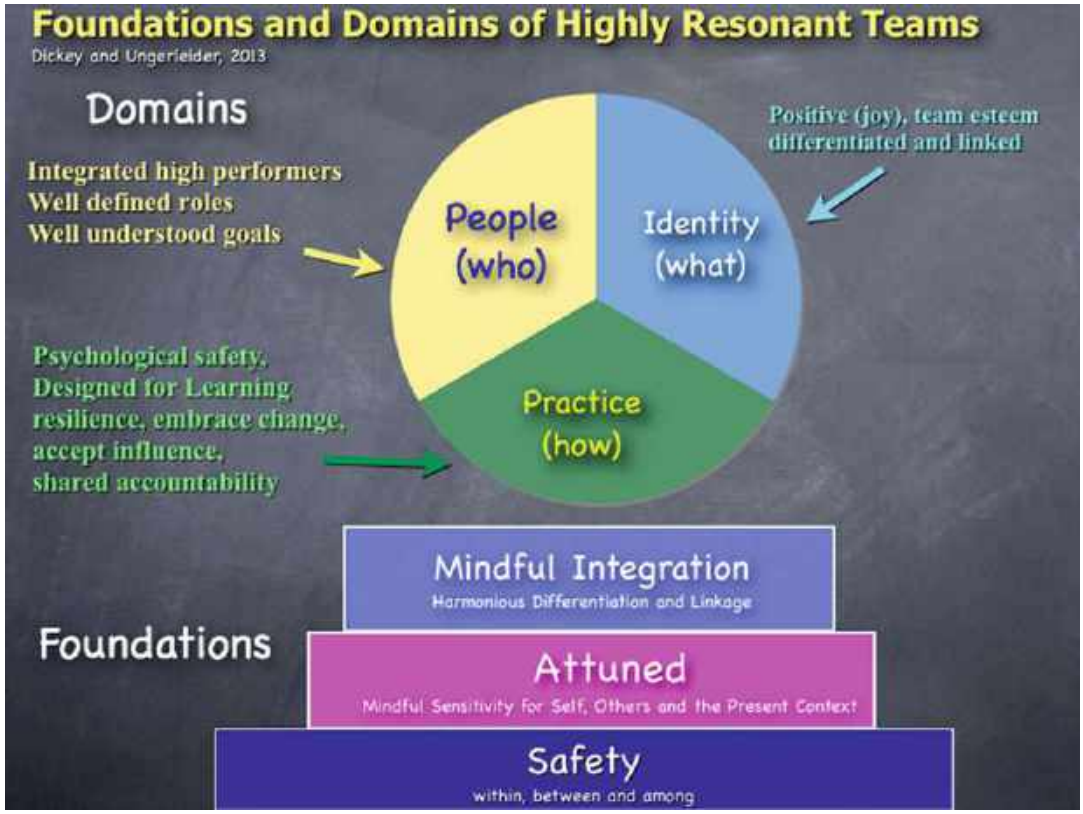

Fig. 184.1 Foundations and domains of highly resonant teams (Dickey and Ungerleider in press)

of team if members don't feel safe. In medicine, this is usually not *physical* safety as much as it is *psychological* safety – freedom from harassment, intimidation, ridicule, or contempt (all of which will be discussed in some of the practices outlined below). Safety stems from the ability of the team leaders to encourage the members to embrace and practice five freedoms:

1. *To see and hear what is here as opposed to what ought to be*
2. *To say what they feel and think and not just what is expected*
3. *To feel what they feel*
4. *To ask for what they want*
5. *To take risks on their own behalf to express themselves for the betterment of the team*

Great team leaders find ways to constantly encourage and reinforce these practices.

Creation of an environment in which it is safe for members to contribute and to engage is essential and invites the next foundational building block: *attunement*. Attunement manifests as mindful sensitivity for the individual's self, for the others on the team, and for the context of the present situation. Attunement is a reflective quality, although it may function at an unconscious level. Dan Siegel, the eminent neurobiologist who has studied how people create secure attachments, has termed this *mindsight* [88] and it is a critical component for healthy relationships. When attunement is used to describe medical teams, it should be emphasized that it can be reflected with words that demonstrate an empathic connection to another (or a compassionate connection to one's self) or it can be reflected nonverbally, by actions or behaviors that demonstrate awareness of and responsiveness to another or to a situation. In his book, *The Empathic Civilization*, Jeremy Rifkin [78] indicates that the desire to connect is

basic and inherent in most humans. The ability to attune is in itself not sufficient to create good team function. In fact, attunement without conscience and compassion for how a person's thoughts or behaviors affect others can present as manipulation – a destructive interpersonal style that is characteristic of sociopaths – and can have devastating impact on how a team performs [4, 14, 16, 17, 41, 77, 95]. Without attunement, safety can be destroyed or eroded. Attunement carries empathic and compassionate understanding for others or for situations and what they require from people, and is essential to creating team resonance. It creates an essential foundation for teamwork and, as will be described later, in the *seven practices*, it manifests in the way team members work together.

Once members of a team are invited to and become able to attune, then it is necessary that they communicate. A lot has been written on communication styles and used by groups teaching teamwork to physicians [45, 58, 72, 79], and they are all useful tools. However, without intra- and interpersonal integration [81], these tools are simply tools and, like any tool, are only as valuable as the skills of the person using them. For this reason, *mindful integration* is also at the foundational level of how resonant team members interact and work together. The ability to communicate with integration (emanating from genuine *attunement*) is so important that it is the *first practice* of highly resonant teams.

The Seven Practices of Highly Resonant Teams

Practice One: Mindful Integration

Integration has been described in previous articles [20, 21] and chapters [22]. The nature of integration was first introduced by Virginia Satir (which she called "congruence") [81] and is as relevant today as when she explained it in the 1970s. Based on the many recent contributions to the literature on how people act and react during times of safety and comfort as well as during times of anxiety or stress, many of which will be discussed in this chapter, mindful integration must exist at a foundational level for achieving team resonance. Integration refers to people's ability to value and to honor their own needs (*self*), the needs of *others*, and the demands of *context* in making individual choices. Integration is first an individual process that begins at the level of emotions and thoughts. This blending of emotions and thoughts can be described as feelings (this sensing is named as feelings because people actually feel them with their bodies). Others [39, 41] have referred to this awareness and ability to manage self, others, and context as *emotional intelligence*. Mindful integration expands these concepts to describe a level of awareness, engagement, and inclusiveness that is required of team members as they attempt to understand and respond to the complex challenges that present in medical systems. Integration is secondly a relational process – one that we have with ourselves, with others, and with our context or environment. Integration is, quite simply, a system requirement and an essential component for members of interdisciplinary teams to communicate and collaborate in a manner that is best suited to harness the collective wisdom of the team and result in best outcomes [99].

Integration requires attunement to self, to others, and to the current situation (context) that is placing demands on the team. Therefore, integration demands that team members be consistently aware of the competing demands of these three elements and find a way to value, *without judgment*, the inescapable and undeniable presence of each of these within the system. Integrated communication arises from this awareness and expresses itself with nonjudgmental acceptance that in all situations the (sometime competing) needs of self, others, and context create challenges. Since the needs of self, others, and context are all equally important and valuable, integrated communication acknowledges with compassion that all of these exist. Integrated communication does not demean or discount any of these elements. Choices or decisions can be made as an "and," not a "but," for example, "I know it is your son's birthday *and* I would really value your help with this case." which might feel

a lot more valuing of someone's needs than "I know it is your son's birthday *but* I need you to stay and help with this case."

The current system of pediatric cardiac care provides limitless examples. A manuscript related to professionalism, which appeared in a surgical journal in 2004 [20], told the story of a young, hardworking cardiac surgeon who is asked by his senior partner to return from a vacation (that he had finally taken with his wife), to assist with an important operation. The story is related as a narrative and many surgeons have commented that it poignantly captured the anguish they commonly feel as they try to balance the competing demands in their lives. The point of these familiar scenarios is not that there is a correct answer. The response may differ in various circumstances. The importance is *consciousness* that the solution is dynamic and not simple and in fact, might have different solutions depending on the unique and changing needs of the *self*, *others*, or the *context*. When team members constantly select a consistent response to challenges, discounting one of the triadic elements as less important (*self*, *other*, or *context)*, they risk creation of a system that feels *non-integrated*. Depending on which element is consistently and repeatedly discounted (not valued as important), this can lead to cultures of (1) *blame* (in which the needs of others are not valued by or considered important. This can result in discounting or not listening to others – for example, blame – as people in the system try to protect themselves at other's expense; (2) *placating* (in which one constantly diminishes their own needs to attend to others or to the context, with a huge risk for depression and burnout); (3) *super reasonable* (in which no needs for people in the system are valued – the only "important" need is the context, which risks developing a system that has no room for joy, and this also can result in burnout or dropout); or 4) *irrelevance* (when the stress has become so great that people just want to disengage and no longer participate in helping the team. This is seen particularly in exceptionally stressful or toxic circumstances, and it is an invitation to suboptimal patient care and possibly destructive behavior – substance abuse and suicide – by team members who have lost the safety and support needed for them to remain engaged) [22].

What is important for team resonance is not that members all be consistently congruent – that is likely not possible – but rather that they have awareness of (and attunement to) the dynamics of integrated systems and a willingness to constantly engage with one another and make it a value to honor the difficult and challenging (and often unspoken) needs of *self, others*, and *context*. Integrated communication is nonviolent [79] and seeks to explore in order to understand and connect rather than to harshly interrogate, judge, and fix.

The concept of congruence can be expanded to include both concordance and coherence (see Appendix 1). In fact, learning to behave and communicate with mindful intergration of all system parts is crucial for teams to function with trust and shared understanding.

Mindful integration is a foundation for team resonance because it constantly grounds team members to the need to attune, engage, and be present to one another. Once team members can begin to communicate with mindful intergration, it is possible to engage in the next practice for highly resonant teams.

Practice Two: Invite Learning

It is ironic that most healthcare professionals learned at *teaching hospitals*. A professor at one such hospital once exclaimed, in exasperation: "There is a lot more teaching going on here than learning!" Teaching evolves from knowing and a desire to share with others what you know. In 1998, Parker Palmer published "The Courage to Teach" and each year, the ACGME bestows a *Courage to Teach* award on one of the nation's great teachers. All health practitioners recall their most influential and inspiring teachers with fondness, admiration, and gratitude. We can also recall some of those teachers who made our ignorance feel painful, shameful, and frightening. A "teacher" who contemptuously reprimands a student for "not knowing" or, worse, for being

"stupid, lazy, and insulting their time" does more damage than they likely can imagine. In her work on learning, Carol Dweck [25] describes the kind of attitudes that best correlate with performance excellence, and not surprisingly, they are not related to knowing the answers, but rather to asking the questions, even when the answers seem most elusive. This is why it takes more courage to learn than it does to teach [100]. Learning requires accepting the vulnerability [8] that accompanies "not knowing" and then embracing a willingness to struggle – and possibly fail – while trying to challenge ourselves to think differently or to do things we have never done. Everybody walks because their parents likely created an environment that *invited learning*. You likely don't remember for yourself, but think of how babies learn to walk. When babies fall, nobody criticizes them for being a failure or tells them that they will never be successful at walking. It is not likely that they will be compared to a sibling who was walking sooner and admonished that they should try to be more like that person. No. They are applauded and encouraged to try again. Until they learn. And adults share their joy in accomplishment. What happens when caregivers and teachers forget how to do that in their teaching institutions? Have they become so fearful of "not knowing" – that it might expose them as charlatans? The rationale can be heard: "we deal with a serious business – life and death stuff. We can't afford to tolerate those who don't know or who can't be perfect. There is too much at stake." Some individuals actually believe that "it is a good thing that they 'know' because what would happen to our patients if it weren't for them?" An inviting reframe of that last statement is "what 'could' happen for our patients if we could let go of knowing and, instead, keep wondering?"

It is unfortunate that a culture that demands perfection has been created, because, in the words of noted historian, Arthur Toynbee, "nothing fails like success." It is regrettable that most health professionals have been taught that "if you want a job done right, do it yourself," because this form of contempt for how other's might complete a task is a powerful way to diminish innovation and progress. (The statement instead should be "if you want a job done your way, do it yourself.") One of the babies learning how to walk today will likely set the future record for the 100-yard dash. One of our struggling young students of today may be a future leader in his or her field, but only if we find a way to invite him or her to learn, which means teachers have to tolerate the students' struggles, encourage them to continue to think differently, and carefully craft an environment that is safe and free from premature judgment.

The demand for perfection stems from the high stakes of what we do – taking care of patients with life-threatening illnesses – and from our hope that all patients will survive to have a normal life [99]. For some, this intent gets entangled with their own sense of worth and esteem – more important than the patient doing well is how they are thought of by their peers, and therefore, they can only be valued if all their patients survive and their peers (many of whom barely know them and have likely never worked with them) believe they are exceptional. The concept that there is a "solution set" that will always create a successful outcome is not realistic in complex biological systems, in which no two patients or defects are exactly alike. Although mechanical systems are expected to perform in a consistently reliable and predictable fashion [50], biologic systems do not behave this way. That is why there is an occasional mortality after ASD closure or why some patients develop early pulmonary hypertension from lesions that should be safe to follow. In his presidential address to the American Association of Thoracic Surgeons, Tom Spray lamented over the impossibility (and inappropriateness) of perfectionism, stating "What we do is hard" [92]. Unfortunately, when perfection is not possible, the delusion that it is achievable can lead to dashed expectations, disappointment, and a "culture of blame" [19].

Another unintended consequence of the striving for perfection is the lack of forgiveness for oneself and for others when the results

aren't perfect. The research on self-compassion [59, 65–67] has been impressive. The ability to have compassion for oneself is directly and positively linked to the ability to learn [25] and to the ability to be resilient and cope with difficulties. When contrasting high self-esteem with or without self-compassion, there is a distinct difference. Self-esteem without self-awareness and self-compassion (recognition and acceptance that we all have experiences of disappointment and failure – that the self is imperfect and still deserves kindness) is often associated with grandiosity and failure to acknowledge what is "real" – a potentially dangerous trait in a healthcare professional [59, 66]. When self-esteem is tempered by awareness of limitations, and associated with the ability to be compassionate toward oneself, this can lead to more genuine (less grandiose) self-esteem that is more appropriate because it is related to the ability to hear feedback (without defensiveness) while still maintaining kindness toward oneself as a *learner* [59]. This is the challenge for us as lifelong learners – to accept that we are learners, meaning there will be times we "don't know" and have to "struggle" as we try to do new things or think in new ways [100]. A system that insists on perfection makes it very dangerous to be a learner and, ultimately, limits our ability to provide best practice.

Carol Dweck is a psychologist from Stanford who has spent decades studying the learning process and has arrived at the conclusion that one of the crucial ingredients of success is the ability to learn from mistakes. Her work is thoughtfully cited by Jonah Lehrer in his book *How we Decide* [60] in explaining the neurobiology of learning.

Lehrer tells a story [25, 60] about Dweck's most famous and for many, most poignant study. It was conducted in 12 different New York City schools and involved more than 400 fifth graders. One at a time, the kids were removed from class and given a relatively easy test consisting of nonverbal puzzles. After the child finished the test, Dr. Dweck and her researchers told the student his or her score and provided a single sentence of praise. Half the kids were praised for their *intelligence*: "You must be smart at this." The other students were praised for their *effort*: "You must have worked really hard."

The students were then allowed to choose between two different subsequent tests. The first choice was described as a more difficult set of puzzles, but the kids were told that they'd learn a lot from attempting it. The other option was an easy test, similar to the test they'd just taken.

When Dweck was designing this experiment, she'd expected the different forms of praise to have a rather modest effect. After all, it was just one sentence. The results of her intervention are described below. Imagine, if a single sentence has the power to create these outcomes, what might result from a pervasive attitude in a system where the sentence is expressed as the organizational value?

Of the group of kids that had been praised for their efforts, 90 % chose the harder set of puzzles. However, of the kids that were praised for their intelligence, most went for the easier test. If we do what works because we think it makes us look good – if we aren't willing to risk failure or struggle as the condition of learning, then we are doomed to stop learning, growing, and improving. We get stuck. There are surgeons who tout themselves as experts, yet they are reluctant to offer new procedures to their patients and simply state: "I don't do that operation." I myself (RMU) used to say that about the Ross procedure in the 1980s. I rationalized that it was a bad operation ("risk for two-valve disease, etc.") and encouraged patients to avoid it. What I really meant was that "I didn't know how to do the operation and it scared me to try it," so I had to find a way to rationalize why I didn't offer it. Fortunately, at the time, I was also learning about fixed versus growth mind-sets [25] and beginning to understand how to find the courage to try and master new things. This is similar to the transition that occurred in pediatric cardiac surgery when transitioning from the atrial switch to the arterial switch procedures. Surgeons had to be courageous enough to learn a new technique, because there was a likelihood that the new

technique might be better even though the previous one seemed to work well. Learners recognize that they need to continue to invite the "discomfort" of not knowing and of having to adopt something new if they are to keep current. The arterial switch is now a standard procedure for infants with transposition of the great arteries, and the Ross operation seems to have considerable benefits compared to other valve replacement procedures for children [1, 54, 69]. Without "inviting learning," we won't have progress, whether it is new technology or new solutions (such as new operations or strategies). We are unlikely to develop the skills and experience necessary to deal with challenging new problems if we continually choose the "solutions" that are comfortable in order to feel better about ourselves.

When we are taught to fear failure, we suppress learning. How does your organization handle failure? What happens to people who fail? Are they applauded for their efforts and encouraged to learn what they need to succeed, or are they admonished, punished, dismissed, or ridiculed? Which kind of team do you think would bring out the best in you?

Dweck went on to study this further. She gave the same fifth graders yet another test. This test was designed to be extremely difficult – it was originally written for eighth graders – but Dweck wanted to see how the kids would respond to the challenge. The students who had been praised for their efforts in the initial test worked hard at figuring out the puzzles. "They got very involved," Dweck says. "Many of them remarked, unprovoked, 'this is my favorite test.'" Kids that had initially been praised for their smarts, on the other hand, were easily discouraged. They viewed their inevitable mistakes as signs of failure: perhaps they really weren't smart after all. After taking this difficult test, the two groups of students were asked to choose between looking at the exams of kids who did worse than them and looking at the exams of those who did better. Students praised for their intelligence almost invariably chose to bolster their self-esteem by comparing themselves with students who had performed worse on the test. In contrast, kids praised for their hard work were more interested in the higher-scoring exams. They wanted to understand their mistakes, to learn from their errors, to figure out how to do better.

The final round of tests was the same difficulty level as the initial test. Nevertheless, students who'd been praised for their efforts exhibited significant improvement, raising their average score by 30 %. Because these kids were willing to challenge themselves, even if it meant failing at first, they ended up performing at a much higher level. This result was even more impressive when compared with students who'd been randomly assigned to the "smart" group; they saw their scores drop by an average of nearly 20 %. The experience of failure had been so discouraging for the "smart" kids that they actually regressed.

The problem with emphasizing "smart" is that it misrepresents the neural reality of education [60]. It encourages avoidance of the most useful learning activities, which is learning from mistakes. In medicine, this may be avoidance of doing the procedure we are uncertain of – staying safe doing what we know – even when the more risky procedure may be better for the long-term benefit of the patient. It may manifest, as it did in the group of "smart" kids, by choosing to compare our programs to those that are worse, perhaps using a nonvalid criterion that favors us, in order to make us feel better. Perhaps this is accomplished by avoiding difficult cases (complex puzzles) or by doing less risky, although possibly less optimal procedures. "Anything to convince ourselves and those who might judge us that we are smart." Leaders for organizations that will find solutions to rare and unusual problems MUST create an environment where it is safe to struggle as we try new things, even if there is the price of occasional failure. In systems where leaders respond like the fifth graders who wanted to be validated, failure is feared and the eventual outcome is regression. There is no shortcut for this painstaking process.

In order to create a learning environment, leaders have to have enormous courage and vision. Short-term appearances give way to long-term investment. Driven by fear that something might or could go wrong, the prevailing styles of leadership in medical organizations have been

(a) *commanding*, which, used consistently, over time, is a dissonant leadership style (it eventually drives people away) that will produce resentment or disengagement of team members who will eventually try to find a more inviting atmosphere, or (b) *pacesetting* (doing everything and not delegating through a conviction that others cannot be trusted to do things right), which also deters some of the best people in an organization from wanting to participate, since their contributions or suggestions will be rejected. New, more resonant leadership styles invite the knowledge and experience of others [6]. More exceptional organizations are creating leadership programs or sending potential leaders to national programs for leadership training to learn skills of engaging the entire workforce as a process that leads to best care [42, 63, 70, 71, 75, 82, 93, 94, 96, 108]. As leadership styles change from dissonant to resonant, all members of the healthcare team will be reengaged into a more collaborative framework that harnesses the collective skills and experience of the entire team, making individual weaknesses less relevant. These teams also embrace a shared accountability that favors the type of systemic change and awareness required for growth and learning in complex endeavors. In order for leaders to encourage the transformation from knowing organizations to learning organizations [83], their operative *mantra* needs to invite a *courage to learn.*

These leaders have faith in best outcomes as a by-product or "indicator" of processes [53] that encourage creativity, innovation, and growth. It is manifest by open invitation to questions, even when the answers are not apparent, and especially when the answer is apparent. This valuing of genuine curiosity and safety in "not knowing" becomes a value that all the members of the team are invited to practice. Failure is viewed as an opportunity to explore and discover, not as an event to be ashamed of [8]. Each member can be challenged to learn. What don't you know that you would like to know more about? What can't you do that you would like to learn how to do? How can a team support, encourage, and wonder more about learning what they don't know?

The answer, in part, is in the *third practice*.

Practice Three: Push the Up Button

There has been a lot of research [33, 35, 44, 46, 61] examining successful (high performing) compared to unsuccessful (low performing) relationships and work teams. In fact, recent research on creating great teams has indicated that *how* we communicate is far more important than *what* we communicate. [73] The result of all this research is astonishingly similar. There are ratios that can be measured and that seem to consistently distinguish high performance from low performance. The most important of these ratios is the one between *positive* (P) and *negative* (N). The ratio always finds P greater than N and ranges between 3:1 and 5.8:1, depending on whether the relationship being studied is between two individuals (3:1–5:1) [33–35, 44, 45] versus a work team (5.8:1) [61]. The important point is that positive has to outweigh negative. (Stated differently, the negative is a more powerful influence than the positive and it therefore takes more positive to counterbalance the negative.) The other important point is that negative is never zero. There has to be permission and space for conflict or imperfection. Negative elements contain valuable information and can contribute to highly functioning relationships as long as they are outweighed by a lot of positive emotions. Resonant leaders [6, 39] understand this and strive to create environments that promote positivity. We call this "pushing the up button."

There are many ways to enhance this on teams. In his book, *Results that Last*, Quint Studer [96] describes a behavior that he terms "*managing up*." This behavior is an easy and powerful way for a team to push the "up button" and to suppress a "we/they" phenomenon (making oneself look good at the expense of others – a core element of blaming) that can create polarization and dysfunction on a team. As discussed above, this blaming phenomenon is particularly common in healthcare because the stakes of what we do, life and death, are so high. We have learned to be critical. So, when something is not going well, it is common to "blame" the administration for not being responsive to our needs, or the trainees who just

don't know what they are doing, or the nurses, or the surgeons, or the intensive care staff, and so on. Managing up is an organizational commitment to describe what people on the team are doing to make things work well. It requires a trust that everyone in the organization is committed to doing "good" and finding examples to demonstrate that. For example, a cardiologist might say to his or her catheterization team: "I know this case is difficult and that is not lost on our administrators. They want to know what we need to help us work better." Or an administrator might come to the ICU and tell a nurse: "Shannon, our chief surgeon tells me what an outstanding job you are doing with his most critical patients and I want you to know how much your work is appreciated." Or perhaps as one intensivist is signing off to another, they might tell a family: "Dr. Logan is now taking over for me. She trained here and is one of the best doctors to come through here in years. She is going to take wonderful care of your daughter." (Contrast this to the more damaging comments: "Our administrators don't care at all about how much we struggle – it's amazing we do as well as we do." Or an administrator walks through the unit and just misses a chance to manage up. Or, instead of the sign out described, the intensivist comes back to work in the morning and makes a comment during rounds – overheard by the family: "Logan had no clue what she was doing last night. It's a wonder this girl is still alive.") We versus they. The contrast between how these two types of teams function is extraordinary.

In the past decade, much has been written about the pressures inherent to the demands of becoming and practicing as a professional [21]. Some have described it as a lifestyle choice in which the professional demands leave little room for the balancing of relationships with one's self and others. The prevailing cultural value has been that physicians must, of necessity, sacrifice thoughts of their own needs or the needs of their family in order to place all attention on the primacy of the needs of their patients. This has created the belief that *we* (the healthcare providers) don't matter – the only one who matters is the patient. Unfortunately, this disregard to one's own needs leads to an insidious inability to connect to the needs of others. Without the ability to find a way to genuinely honor and value our own needs, our attention to others (whether they be team members or patients) becomes artificial and obligatory – rarely driven by genuine compassion and concern. In the previous section, we described this as a form of *non-integration* (super reasonable) that, over time, feels dehumanizing. An important way to push the up button is to emphasize and encourage work-life balance (or what we term work-life integration, since balance suggests an equal allocation of time to work and to other life's needs, and that is rarely achievable or even desirable). Instead, we believe that emotional health requires the ability to make choices that consider the needs of one's self and others (e.g., team members, family members) and the demands of what we do (context) in a dynamic system that allows for flexibility. This is what was referred to above as integration [20–22, 99, 100].

The problem with a culture of personal denial is it is not sustainable. Over time, the physician who embraces the belief that he or she has no personal needs is at risk for burnout, depression, anxiety, chronic fatigue, substance abuse, divorce, or suicide [3, 5, 9, 14, 15, 20, 21, 24, 27, 28, 32, 48, 55, 68, 84, 89, 91]. Not only is it irresponsible to encourage people to enter a career that risks these outcomes, but *lack of self-care, with its attendant consequences, has been definitively linked to errors and other forms of impaired outcomes for our patients* [7, 21, 24, 26, 49, 85, 102, 106].

It is ironic that we have inadvertently created a culture that emphasizes denial of the personal needs that make us truly human while simultaneously requiring that we cater to the very real needs and demands of the humans we serve, work alongside, and seek to heal. The link between physician wellness and quality [85, 102] is becoming more apparent and increasingly more important. Although held in disdain by some, encouraging work-life balance for healthcare providers is emerging as a major factor in improving outcomes [21, 55]. One of the preeminent leaders of business transformation and

growth, Peter Drucker, addressed this in his classic article on Managing Oneself [23] which is consistently reprinted by Harvard Business Review in their annual issues on leadership. Self-awareness, self-management, and self-regulation comprise the cornerstone of emotional intelligence [10, 39] and are being linked to quality in every professional enterprise, including the practice of medicine and surgery. The journey to the self is an essential path to leadership [100] and may be the core work that can help us achieve the type of outcomes that are possible in our field. Stated succinctly, you cannot manage others if you cannot manage yourself; you cannot genuinely care for others if you do not find a way to genuinely care for yourself; and you generally can only give away to others what you yourself have to give – so if you have disdain for yourself and your needs, then you will likely give disdain to others for their needs. And who would ever want to work with or try to perform their best for someone like that? Unless they have to.

Pushing the up button involves all the things that leaders and team members can do to elevate the excitement, support, and camaraderie shared among team members. Sarcastic, teasing humor is eliminated and replaced by genuine caring about how to help all members of the team be the best they can be. Pushing the up button is an antidote to medical errors that result from burnout. Unfortunately, not all medical errors come from burnout, which is why there is another practice.

Practice Four: Create Systems with the Outcome in Mind

Paul Bataldan wrote that "every system is perfectly designed to give you the results that you get." So if you don't like the results you are getting, then you had best look at your system (not the people) and design it to provide more of what you want. In his work with High Reliability Organizations and High Consequence Industries (and the field of children's heart care would certainly qualify as one of those), Karl Weick [103] emphasizes the importance of systems that harness the collective wisdom of the team. In high-reliability organizations, the most valuable person on the team is the person with the most relevant information at each moment in time, and therefore, the system needs to provide safety for each team member to speak up and share.

Have you ever played the game where everyone in a group selects a playing card and without looking at it, places it facing out in a headband on their head? They then spend several minutes relating to one another according to the hierarchy of the cards, so that the person with an ace (ace is high) or a face card is treated differently than someone with a 2, 3, or 4. Seems ridiculous since it discounts all the unique talents and skills that each person might otherwise contribute to the team, yet this is how our organizations sometimes act. Harnessing all the members of the team is the basis for cockpit resource management (CRM) [107] – the process created by the FAA to reduce fatalities from airline crashes. Prior to the institution of CRM, the hierarchical system of the cockpit, with the pilot in command having complete charge over the first officer and anyone else on the plane, could lead to fatal mistakes (termed by the FAA as pilot error – or the human factor). Malcolm Gladwell writes about the consequences of mitigated speech [38] in dysfunctional airline teams where the hierarchical relationships override permission for someone with important information to speak up. As a plane approaches a mountain, instead of demanding the pilot to "ascend," a subordinate without permission to speak up might say "that mountain sure looks pretty when we get this close to it" and just hope their message gets across in time. In an effort to improve outcomes and reduce errors, methods of cockpit resource management (CRM) [107] and checklists [36] have begun to invade our practices, especially our operating rooms. They are undeniably helpful and useful. But they will not function optimally if they aren't utilized in an environment that permits open and noncritical communication [62]. The risk to patient safety and best outcomes in hierarchical organizations is the suppression of bottom-up and horizontal communication that is necessary to

prevent errors or to introduce new ideas. In one particularly toxic organization, a surgeon "fired" an experienced operating room nurse for "insubordination" because she told him, prior to the case, that the family who he had not yet met – the consent for surgery was obtained by a junior team member – wished to speak to him before he made the incision. This nurse "spoke up" without being asked and with the intent of helping the surgeon and the family establish an important relationship that, while it might not change the operative procedure, would change the comfort level of the family as they anxiously waited for the outcome. The nurse later confided that it was a relief to no longer be a member of that team that didn't value her input and that she felt that she had witnessed numerous patient safety issues. The tragedy is that our profession "lost" the future contributions of an experienced and very capable team member. How will this loss be manifested for that team in the future? Of course, a surgeon like that won't even bother to read this chapter – he is already convinced that he is gifted and none of the team members can contribute to his skills! The extreme side of poor communication is the reluctance of healthcare workers to speak up when the risk to them for doing so is admonishment, ridicule, or dismissal (being *waved off* or *waved out*) [2, 18, 37, 64, 101]. In the airline industry, the reluctance of a team member, such as a first officer, to speak up, or the use of "mitigated speech" (language that is non-direct but less risky), has been shown to result in fatal crashes [38]. A system that encourages speaking up when a team member is concerned will only work when there is experience in the system that speaking up is safe. The risk of hierarchical relationships is the inhibition of some team members to speak up when they see or know something that might be important, and this can have devastating consequences. It is incumbent on the team leader to create an atmosphere of psychological safety (it is permissible to "not know" or to say something to anyone that might be important information). In her work with cardiac surgical teams, Amy Edmondson from Harvard cites the need for psychological safety [29] for all team members so that they can speak up without fear of reprimand, ridicule, or repercussion. In fact, in tracking the kind of outcomes desired by surgical teams, the presence of psychological safety – the permission for team members to speak up freely when they have a concern becomes more important than efficacy – the ability of team members to perform their stated jobs. None of us is as good as all of us.

An excellent example of this occurs in the movie, *Master and Commander*. Russell Crowe is called to the deck because the lieutenant on watch thinks he sees an enemy frigate through the fog. But the lieutenant is not sure and appears a bit intimidated that he is being asked by his captain to stand by his claim. Crowe looks at another of the men on watch and asks: "Did you see it." After hearing the second man's reply of "No, Sir," Crowe could choose to admonish the first lieutenant, but instead he says: "Very well. You did the right thing. Go back to your station." In actuality, there is an enemy ship out there beyond the shroud of fog, and by checking out this information, Crowe is able to save numerous lives on his ship. But imagine if instead, he rebuked or ridiculed (such as with the use of sarcasm, as we often see in medical settings) the person on watch. Even if there were not an enemy ship, would that person have felt safe speaking up the next time? How do you treat your teammates when they make a suggestion? Especially a suggestion you disagree with? And how do you reject those suggestions? Do you do so in a way that invites future participation? Research has shown several ways of improving relations among members of a team, and perhaps one of the most effective is to "accept influence" (as Russell Crowe did in the example above) from others. In a hierarchical organizational structure, it is easy to fall into a pattern of top-down decisions, even though vital information may be trying to burst up from below – and is available to the trained leader who listens, invites engagement, and accepts influence so that all team members feel invested [46].

Even in systems designed to permit open expression of concerns or observations, the human factor can result in unanticipated errors

from omissions or oversight. In the past few years, this has led to a resurgence of checklists and time-outs to enable team members to go through a regulated process that helps prevent errors from mistakes. Atul Gawande provides an outstanding overview for the power of this type of process in his recent book, *The Checklist Manifesto* [36, 37]. Simply stopping prior to a planned procedure to review for critical (he calls them the "killer") oversights can prevent errors. "Are the antibiotics in?" "Is blood in the room?" "Any allergies?" Introductions by team members to help improve communication. A review by the lead surgeon or cardiologist of the procedural steps (to make sure all the necessary equipment and supplies are available and at hand). And finally, the most important sentence of all: an invitation – in fact, a mandate – for anyone to speak up at any time *if they have any concerns*. As Edmondson states in her work, this usually only happens when the team leaders have made it safe to speak up. This is why our processes for creating better teams have to integrate with our understanding of how to make these processes effective. A checklist might help us avoid an error of omission (the blood not being in the room for a redo sternotomy; an allergy to contrast dye in a patient about to receive an angiogram), but it won't always prevent us from making judgment errors, technical errors, or errors of commission. However, someone's courage to speak up with suggestions or concerns might help us reduce the latter. A checklist can create consistency of process, but it might inhibit us from deviating to seize an innovative opportunity. A checklist might provide a forum for conversation, but it won't create attunement. And although we can require team members to speak up if they have a concern during the case, they may not do so if they are chastised or sarcastically ridiculed once they do.

There are other important elements to this fourth practice of highly resonant teams. In order to create processes with the outcome in mind, we have to generate clarity about the outcomes we desire. Outcomes should be measureable and they should reflect precisely on the quality of the work being performed. Since outcomes are indicators of what is being done, they are the result of processes or *drivers* that can be controlled. A properly selected *driver* will be intimately connected to the desired outcome. If we want speed, we step on the gas pedal. If we want a certain result from our cardiac team, we have to do something. Identifying that something is the challenge for highly resonant teams. Kaplan and Norton provide an intriguing method for creating this with the concept of the *balanced scorecard* [53]. Their "strategy-focused" organizations were designed to engage all the members of the organizational team in a commitment to identify and contribute to *drivers* that created the outcomes (*indicators*) that were desired. Drivers were usually related to education and learning and to tools that could be developed as a part of the internal business plan. The result of putting energy into the correct drivers is to see *eventual* improvement in the outcome indicators to which they are linked. If you are able to know what you want to see, and if you can identify the drivers that will lead to that, then all you need to do is keep fueling the drivers. This is difficult in the field of congenital heart care where outcome parameters are difficult to define and oftentimes are influenced by variables in complexity and sample size so that they are difficult to interpret [99, 104, 105]. If the team isn't careful, it can become so focused on the outcome that it loses connection to the drivers and begins reacting to the last case or to the last set of experiences rather than staying steadily connected to the processes that are important. It is also possible to create unclear outcomes. For example, if the team wants a low morality rate, then they simply have to avoid high-risk cases or do lower risk (but possibly suboptimal procedures) for their high-risk patients, such as staging patients to a Fontan when a two-ventricle repair, although feasible, seems too risky. In this manner, the patients may survive to be discharged from the hospital (if that is how the good outcome is measured), but that team hasn't really created value for the patient, who might not have the best long-term outcome.

The ability to identify the correct drivers – the ones that will ultimately result in desirable outcome – is made even more challenging by the fact that we work in complex adaptive systems as opposed to mechanical systems. Mechanical systems are easier to understand and control. An elevator is a mechanical system. So is a heart lung machine or an airplane. When you push the button in an elevator to go to the 5th floor, the elevator is supposed to take you there. Likewise, when you turn up the flow on a pump head of a heart lung machine or pull back on the throttle of an airplane, you are supposed to get a predictable response. Mechanical systems are characterized by predictability. They lend themselves to checklists and task orientation. Emergent (creative, innovative, unconventional) behavior is discouraged in mechanical systems, since they are supposed to be routine, repeatable, and predictable. These systems support linear (if this, then that) thinking where there is one correct answer and that correct answer is the previously experienced outcome that is expected from the action applied. When a different outcome occurs (e.g., the elevator keeps stopping on the 3rd floor when the button for 5 is pushed), then someone is assigned to interrogate, judge, and fix the problem. Complex adaptive systems (e.g., biologic, human relationship) are unpredictable and variable. By nature, each system is different and does not lend itself to checklists. In fact, these systems can vary day to day and do not respond to a task orientation as much as to a relationship orientation – a collaborative, connecting inquisitiveness designed to enhance change and growth. (We once had to remind a surgeon that his wife was not a checklist!) Because of the unique challenges of complex systems, emergent (creative) thinking can provide outstanding solutions and problems often have multiple possible solutions. The key to managing complex adaptive systems is to explore with genuine curiosity in order to understand more about what is happening. People don't like to be treated like mechanical systems – they don't like to be "interrogated, judged, and fixed." They do like being understood and joined. In order to be successful in healthcare of systems, leaders of teams need to develop both left brain (logic, pattern recognition, strategic thinking, knowledge, and past awareness) and right brain (big picture orientation, identification of possibilities, spatial perception, risk-taking, future focus, and imagination) functions.

Creating processes with the outcomes in mind is a complex adaptive challenge. Our outcomes are difficult to measure and although every team wants to be excellent, careful questioning of team members often demonstrates that there are numerous definitions of what is meant by excellent. For some it might be the way the team functions – how it feels to be a member of the team. For others it might be the measureable outcomes (mortality and morbidity). And for others it might be how much they are challenged to learn and to grow. For some it might be an intuitive sense of safety and that patients are being well cared for. For others excellence might be simply related to volume and market share. In his book, *Good to Great* [13], Jim Collins describes the *hedgehog* principle – the thing a company can do to distinguish itself as great. It is different for each organization, *and* there is something for every organization that can help them achieve this level of excellence. But identifying this distinguishing characteristic is difficult and elusive and takes careful, agonizing thought. It can take years to identify. Our job, in our own complex adaptive organizations, is to determine what excellence means to each members and how to acknowledge the individual definitions (dreams) while crafting the overall organizational vision and mission.

As we move our teams toward those performances that can distinguish them as great, we need to be mindful of a pitfall created by our medical culture, and that is the basis of the next practice.

Practice Five: Be Flexible and Stable

When Moses received a revelation from God called the Ten Commandments, they were given

to him carved in stone. Carving in stone left little option for discussion, exceptions, or modifications. They were indelible.

We are accustomed to being governed by rules. When we were young, rules were created to protect us. "Don't cross the street without holding a grown-up's hand." "Don't put your hand in fire." "Wash your hands before eating." Some rules were created to protect others as well. "Thou shalt not kill." "Treat others the way you would like to be treated yourself." "Don't speed or go through red lights." The problem with rules is that they can become rigid and inflexible (indelible), even though the context might change. At what age did you realize you could safely cross the street without holding the hand of a grown-up? Are there times when you have driven through an intersection even though the light was red (perhaps at 3 in the morning when there was no traffic and you just wanted to get home from the hospital)? In his lifelong work on creating healthy attachments and integrated minds [86–88], Dan Siegel has written about the importance of a balanced approach to rules, which he terms *FACES:* **f**lexible, **a**daptive, **c**oherent, **e**nergized, and **s**table.

Flexible and stable are not mutually exclusive and, in fact, are necessary for healthy growth. The two elements found as "brackets" for FACES work perfectly when balanced, but become distorted at either extreme – where flexibility can become *chaos* (complete lack of consistency) or stability can become rigidity (indelible without ability to consider other options).

The question that healthcare providers must consider is what are the rules under which they operate? Are they indelible, or are they open to modification as situations and technology change? For example, if a cardiologist was trained to always look at the ECG when evaluating a new patient, that might be a very important part of their ability to understand the nature of a heart defect. But what happens to that cardiologist when a patient presents in critical condition with an echocardiogram diagnosis that suggests immediate institution of PGE1? A flexible approach, governed by a stable commitment to patient welfare, would be to begin an IV and start PGE1 – and get the ECG later. A rigid approach would be to insist on an ordered sequence of diagnostic information and withhold PGE1 until ALL the information is complete. On the other hand, suppose a surgeon has a "rule" that cardiologists can't be trusted and that it is better to just explore the anatomy at the time of surgery? In the 1960s, when cardiologists were certainly trustworthy, but had limited ability to make diagnoses, this rule might have been useful in some circumstances. Some surgical trainers passed this rule down to their trainees (and in some cases, also passed along the contempt for their cardiology colleagues). A surgeon in the modern era who operates inflexibly according to this rule would likely have problems planning an appropriate approach to some patients, especially since modern diagnostic information from echocardiography and other imaging modalities, including MRI and catheterization, can help enormously in operative planning. However, the surgeon who demands multiple, expensive, and time-consuming tests when a specific patient has had adequate diagnosis and requires surgery is creating an opposite kind of inflexibility. Stability comes from conscious adaptation to each situation, coherent intra- and interpersonal communication to understand better the experiences and thoughts of others as well as what might be operating internally that is driving behavior or choice making, and a sense of being energized about the process that each patient invites for us as we formulate their best care plans.

Our rules also invade our expectations for ourselves and for others and can create conflict when others don't share our rules or have conflicting rules of their own. Can you imagine the dynamic between two people who learned different rules to govern their relationships with others – one learned that in order to be successful, they should always treat others with respectful consideration, while the other learned that it is a "dog eat dog world" and to annibilate and to not to give in to anyone if you want to succeed? We work in a culture governed by the rules that we have invented – in fact, aren't all rules

"invented?" In general, ours is a culture that values work, but not always time away – how many times are you asked at a meeting: "Are you busy?" Are you ever asked: "Are you getting enough time to live the life you want?" We have a rule that leadership should set the "example" and demand perfection – meaning you should only follow their example and do it their way – leaving little space for the emergent behavior that can help complex adaptive and human systems prosper. In our invented culture, people are expected to behave like machines – indefatigable. To admit exhaustion, such as canceling a case because we were awake all night tending to another problem (in the hospital or out), is considered a sign of weakness. We are supposed to be experts, so asking for help might also be considered a sign of weakness. Multitasking and not admitting to being affected by stress – both forms of self-neglect – are applauded and considered to be the attributes we should embrace.

Many of us have gotten inoculated with "hurry up" disease [90]. You may recognize the symptoms: You are in an elevator bay and the "down" button is already lighted, but you push it repeatedly anyhow. You believe that every stoplight is turning red out of sequence just to make you stop at every intersection. You get impatient with the recorded options being given to you on the phone call you have just made and you begin to push the "0" button repeatedly or yell at the recorded operator expressing your frustration. You are having a conversation with someone (a spouse) and you walk away in the middle of their comments to you (or worse, yours to them) because you are trying to do something else simultaneously. You find yourself getting angry because the person in the grocery line in front of you is stopping to chat with the clerk. It goes on and on. Why do we choose to live like this? Yet, we have an operational "norm" in our work that states: "I handle stress well." What we need is education on how to live life on life's terms.

How many of us have actually been trained to recognize when we are stressed, much less ways to manage it? The implication of this for quality and outcomes is that none of us can offer our best once we have gotten swept up in the amygdala hijacking of stress [43]. We fall into time-worn patterns and often these are ones of blaming others, placating to try and make everyone happy (an impossible task), trying to outthink the problem (super reasonable), or just extracting ourselves from meaningful involvement (disengagement, which then makes us irrelevant). Learning to recognize and manage our stress is a lifelong challenge. In the process, we move from *unconscious incompetence* (we don't even see how ineffective or out of control we are), to *conscious incompetence* (self-awareness – which is the first important step for change), to *conscious competence* (we begin to learn and practice skills to manage ourselves), and eventually to *unconscious competence* (we have integrated new skills in a way that we have changed). This process is circular and repetitive as we continue to learn.

Our field of pediatric cardiac care will never be devoid of stressful circumstances. Most teams perform just fine when there is no stress, but their ability to function well when there is stress can mean the difference between outstanding and simply average outcomes. Recognizing and managing stressful situations require enormous practice, especially by the team leader, but there are numerous techniques available that can be learned [11, 12, 31, 43].

If we don't force ourselves to consciously examine our rules and transform them into guidelines, we run the risk of being overrun by inventions of the mind and missing opportunities for change, growth, and learning. On the other hand, if we fail to create basic guidelines, connected by core values and principles, we run an equal risk of chaotic, unreliable, and inconsistent decision-making that can be just as confusing, disruptive, and damaging to our patients and to the individuals on our teams. We recommend that team members carefully examine their "rules" – and that they openly discuss the drivers of their individual actions and behaviors. This type of open forum (often led initially by a skilled facilitator) can help team members recognize and become aware of differences between each other, as well as their similarities. As stated above, teams are

complex adaptive systems and require curious exploration aimed at creating understanding and shared meanings. If teams are managed as mechanical systems that should be constantly told what and how to do things, and interrogated and "fixed" when something goes wrong, that team is doomed to fail – in fact, they already have and are just not recognizing or admitting it. Virginia Satir once wrote that it is "in our similarities that we connect, and it is in our differences that we grow." Teams, or organizations, that are committed to only seeing things one way won't grow, and the danger of rigid adherence to rules is the prohibition of the kind of creative thinking that can lead to desirable, disruptive change. [74] Automatic or reactive thinking – the type that comes from rigid adherence to a rule – can obscure subtle and meaningful deviations in patterns that, if recognized, could lead to innovative actions and improved outcomes. This is how errors occur. We fit circumstances to our rules – it is why it is so difficult to be an editor – we can easily miss the duplicated word (unless it is underlined in green thanks to grammar check) because our brain automatically tells us what the sentence is supposed to say. We encourage mindfulness to assess each situation as unique and not to try and make them fit our rule. Look for the exceptions. Dan Siegel has termed this YODA – "you observe to decouple automaticity" [88]. Once the members of a team can identify their basic core values and principles, then they can transform their rules into guidelines and understand the exceptions to their rules that can create energy and growth, consistency without rigidity, flexibility with stability. The team begins to adopt an understanding of what they are, which is why the next practice becomes so important.

Practice Six: Share Accountability

On October 14, 2003, the Chicago Cubs major league baseball team lost to the Florida Marlins (who eventually went on to win the major league baseball world series) in the sixth game of the National League Championship Series. The loss by the Cubs was blamed on Steve Bartman, a Cubs fan sitting in a row of seats near the left-field foul line. In the eighth inning of the game, the Cubs were leading 3–0. The Marlins already had one out and when the Marlin's batter, Luis Castillo, hit a fly ball toward the left-field foul line, Bartman (as fans are allowed to do) reached over to catch it. Actually, replays confirm that the bell was actually going to and in the seats and not in the field of play. He deflected it and it fell to the field inches away from the glove of Cubs outfielder, Moises Alou. Had Bartman not deflected the ball, Alou could likely have caught it (or so he claimed later), resulting in the second out of the inning and putting the Cubs 4 outs away from qualifying for their first world series since 1945. The Cubs pitcher, Mark Prior, was pitching well and it seemed that the Cubs were on the verge of making important team history. Important history was made, but not what was hoped for by Cubs fans. The dropped ball was considered just a strike and Castillo went on to walk when Prior was unable to get him out on subsequent pitches. The next batter for the Marlins singled, and the next hit a ground ball to short which could have been a potential inning-ending double play, but it ended up going under the glove of the Cubs shortstop and all base runners were safe. The Marlins went on to score 8 runs in the inning, handing the Cubs a crushing defeat from which they never recovered (the Cubs lost the decisive game the next day, giving up a lead late in the game, and have not won a play-off game since that time). The debacle was termed the "Bartman incident" and Steve Bartman required police protection and suffered for years from criticism and blame for costing the Cubs their chance at the World Series.

Does any of this sound familiar? There is a bad outcome and the members of the team decide who to blame. We know of two pediatric cardiac programs that have actually constructed committees that are designed to assign blame when there is a bad outcome – under the auspices of quality improvement and learning. Who would want to work in an organization like that – unless they were on the committee and committed to deflecting the blame from themselves?

In 2001, a team of very skilled, qualified, and exceptional individuals at one of this country's leading hospitals transplanted an ABO incompatible heart into a 13-year-old girl, who subsequently died. This incident boiled on national television until the blame was given to one individual who accepted accountability in what was, to us, one of the most disturbing and poignant examples of public team destruction that we have ever witnessed [19].

What really happened in these and other similar incidents? Some experts on error theory have described the Swiss-cheese model, where the unfortunate oversights or mistakes made at several levels conspire to get past all the checkpoints designed to prevent those errors. The problem is that there is someone at the end of those aligned holes who gets the blame. Look at the famous Bartman incident. Mark Prior walked the batter who could have been out. He then gave up a base hit to the next batter. Then there was an error by the Cubs shortstop that should have ended the inning with the Cubs still in the lead. Subsequently, the Cubs pitchers gave up more hits and more walks, and the Cubs outfielders made more errors (that led to more runs). Bartman was a spectator. A fan who was caught up in a moment of thrill that he might catch a foul ball during a championship game – a ball that was close enough to the foul line that he might be able to catch it. Where was the accountability by the players, many of whom subsequently failed to do their jobs well? And what about the incident of the "botched" heart transplant? There were numerous people who could have, perhaps should have, caught the type mismatch and said something. But they didn't. Why? Perhaps there was no psychological safety to speak up when the locomotive of impending transplant was barreling down the track. Or was the mismatch simply unrecognized by numerous people? And why didn't the leaders of the institution acknowledge this as a systems error – and find a way to still commend the excellence of their team members (who truly were excellent and still are despite this unfortunate occurrence) instead of allowing the blame to fall on one member of the team? More importantly, what happens to us when someone, who is not we, but who is on our team gets blamed? Do we feel relieved that at least it isn't us? Or do we feel sad because there was a bad outcome that we might have been able to help avert?

Regardless of whom we choose to blame, a bystander or a team member, the outcome doesn't change. The team loses the game, even an important game. Or worse, in our profession, we might fail to save a patient from their disease. It feels bad. We wish it didn't happen. We might wish that we could do it all again in the hopes of achieving a better outcome. In golf, this kind of "do over" is termed a Mulligan. Many people who play golf always wonder why that second shot is so much better. But, our field doesn't give Mulligans. And occasional shots, despite our best efforts, go awry. Great teams find a way to recover from adversity – they develop a team resilience that is important to identify and to understand. How do they do this? How can they avoid being dragged down by adversity and find a way to succeed again, often in remarkable fashion?

The answer lies in acceptance of the outcome *and* recognition that it belongs to the entire team. We term this shared accountability. The team wins or loses together. Many studies on errors have demonstrated that it is often the culmination of a lot of minor errors by multiple people that led to one, final, critical mistake. These minor errors are occasionally termed near misses. Some of the practices described in this chapter can help to reduce errors, but will not eliminate them. In complex adaptive systems, errors will happen. How we manage ourselves and learn from these experiences is what distinguishes the great teams from the average or poor teams. A technique that can be helpful is to use the team QI (quality improvement) sessions as an opportunity to improve team cohesiveness. Instead of trying to determine who (or what) was at the end of the error sequence (root cause) and therefore responsible, try having each member of the team express what they might wish to do differently the next time. What did they do, or didn't they do and wish they could have done, that might have contributed to the undesirable outcome? We did this

once with a team and a team member ducked their accountability by stating "Well, I wasn't there that day." We pointed out that this was a perfect example of the fragile and important interconnectedness of a team. The simple loss of the potential contributions from that member on that day was an important deficit to the team. Although none of us can be there all the time, we should appreciate, value, and honor the important reliance we have on one another. None of us is indispensable or more (or less) important than anyone else. As team members begin to share accountability, they take on a unique understanding of the complex nature of congenital heart problems and the importance of all team members to the outcomes. More recently, we were asked to work with a team that encountered an unfortunate occurrence. When we asked each person to discuss what they would like to have done differently, one individual kept insisting that they wouldn't have done anything differently – that they didn't do anything wrong – had done everything "by the book" and would not have changed a thing. We wondered out loud to this person how many of these sessions they would be able to tolerate coming to if the same actions produced the same results before they might be able to reflect on something they would like to try differently. In their book on *Mistakes were Made (but not by me)*, Tavris and Aronson [98] emphasize the human capacity to create schemas that continually support their beliefs. We see what we choose to see and hear what we want to hear. How often do perfusionists worry about the neurological outcomes or the postoperative convalescence of patients? Or how often does an OR nurse come to the ward (or even be granted time to do so) to see a child a few days after surgery so that they can gain appreciation for the life of the patients who they generally only see in the OR? How often does a cardiologist come to the operating room to *encourage* the surgeon during a challenging repair? How common is it in your program for a surgeon to go, unsolicited, to the echo or cath lab to simply see how his or her colleagues are doing, offer morale support, or discuss a challenging patient? At the completion of a surgical case, how often have you heard the surgeon ask the anesthesiologist: "Is there anything I can do to help you?" How often do we "manage up" our colleagues? We see all of this on great teams. Is there a palpable sense of esprit de corps? Or is the palpable sense one of the people staying under the radar? Great teams rally together when there is difficulty. They openly discuss their experiences as shared, team experiences and try to explore ways to help one another.

In his seminal work on relationships, John Gottman [44, 46] found that there were four behaviors that destroyed relationships and teams: stonewalling, defensiveness, criticism, and contempt. We see all of these on low-performing teams. Stonewalling is an avoidant behavior by leaders to acknowledge problems. Their common statement, if you could even engage them, is "I don't want to talk about it." Important topics become off-limits, and if you try to bring them up, these leaders will either change the subject or withdraw and ignore the issue. When there is stonewalling on a medical team, it is difficult to solve problems because the problems aren't allowed to exist. The antidote is for team members to support one another when there is a difficult issue. Make it safe to struggle and encourage learning. Teach stonewallers how to self-soothe – how to disengage constructively; find a way to breathe and accept the difficulty of the circumstance so that they can reenter with a positive attitude aimed at contributing to solution, not ignoring a real concern. Defensiveness is the "flip side" of blame. When someone says "I didn't do it," it is tantamount to saying "She did it." Defensiveness occurs when it is dangerous to take accountability. On these teams, excuses abound and the common statements that you hear are "Yes, but. . .." The antidote to this is teaching the courage to fail and to learn by accepting some accountability (notice, we didn't say all accountability) for a poor outcome. In organizations or on teams that transform defensiveness into shared accountability, it is safe to accept accountability for one's part in an outcome, and when the self-accountability of all team members is counted, there is a *shared*

accountability that is healthy and life giving for teams. Criticism is common on medical teams. It seems to be a part of the medical training culture, and the common phrases associated with it include personal attack with rampant generalization: "You (personal) never (or always – general)..." It is difficult to create an environment where it is safe to take and to share accountability when there is risk to being attacked and criticized. This can be imagined as taking a soccer ball and putting it inside someone and kicking them around. The antidote is to take the soccer ball out of the person and let everyone on the team kick it (the problem) around. It is no longer personal. It belongs to the team. "We aren't getting good results with such and such disease. What can we do so that we might all get better at this?" This is very different than putting the responsibility into one person: "You need to get better at this because you never seem to get this right." Ouch! Finally, there is contempt. Perhaps the most destructive of all the four behaviors, contempt doesn't even require a common phrase. Surgeons, unfortunately, have learned it well. A simple roll of the eyes or a sneer may be all that is necessary to show disdain for someone else or for their ideas. Contemptuous behaviors include insults and sarcasm. There is no role for biting sarcasm on a high-performing team. The antidote to contempt is the exploring and appreciation for differences among team members that comes from *attuning*. Great leaders and great teams appreciate and value the unique attributes of each member, and each member of a team has something uniquely valuable to offer, as long as the team members can recognize it, appreciate it, and harness it. This requires the ability to listen to others and to honor and try to understand their perspectives, even when they are different than yours.

Shared accountability is an attribute that is unique to successful teams, whether they are medical, business, sports, or families. It prospers in an environment that cultivates psychological safety [29] and is prominent in great organizations and in great leaders [13]. It is not likely that a team will sustain greatness if individuals on the team are unable to simultaneously explore their own self-accountability and encourage others to share the same. Ironically, the ability to be accept one's own accountability (with self-compassion) while inviting others to do the same may be the single driving factor that can help teams move from good to great. In more recent research [47], Gottman has emphasized that the most important element in relationships that succeed is that the partners feel that the other one has his or her "back." What stands in the way? That is why there is one final practice that is important in order to achieve resonance as a team.

Practice Seven: Be an Upstander

Unfortunately, not all people belong on a team. The research is clear that there are some individuals who are incapable of the kind of self-awareness, self-accountability, honesty, and compassion for others [4, 95] essential for attunement and congruence. These individuals are often characterized by lack of conscience for the impact of their behaviors on others. They have a notable lack of self-awareness, manifested as deceit, grandiosity, extreme self-focus, and inability to learn from or to be accountable for their actions. When we have given our talks around the country, someone invariably asks how to deal with these types of team member, and we have received so many requests related to this topic that it finally became apparent that we needed to include this final, essential practice for creating team resonance.

Cultivate the willingness to stand up to bullies as both an individual and a team attribute. This is not an easy task. Albert Einstein once stated: "The world is a dangerous place, not because of those who do evil, but because of those who look on and do nothing." When a team member witnesses acts of "violence" against another team member (and this can be nonphysical, verbal, or relational), it is imperative that the system allows for and encourages them to speak up or the disregard will continue and eventually have the potential to harm patients who depend on the team function, as well as the individuals themselves who no longer feel valued and

included by the team or worse, safety as a member of the team. In the words of Hannah Arendt, "the problem. . ...after all, was not what our enemies did, but what our friends did." Or in some cases, didn't do. On resonant teams, the health of the team is paramount and people on the team have each other's "backs" and are encouraged to stand up for one another. Resonant leaders encourage this, model this, and acknowledge with gratitude the team members who are courageous enough to be upstanders.

Without this final practice, a team can go astray, often following the lead of someone whose interests are more personal and less connected to the important practices outlined above that will ultimately contribute to best outcomes. When teams slide down this path, they lose resonance. It is a palpable shift for members who have experienced the pure joy and productivity of highly attuned and resonant teams.

We often see this manifest, not only as low morale, but by an unfortunate occurrence that has received substantial press in the past year – bullying and mobbing. In these instances, organizations, or the poor leaders who have gained control of the team, try to find a scapegoat for problems. Oftentimes these are deep-seated institutional deficiencies, but an individual is selected (usually by a dysfunctional few who are able to gain traction from leaders who are not able to truly look at a problem), and this individual is singled out as the "problem." The literature on mobbing, and some of the forces behind it, is chilling [4, 17, 30, 57]. We have encountered increasing examples of this in the field of pediatric cardiac care, and the stories that some have approached us with are heart wrenching. The reason this is important in a *chapter* related to teamwork, outcomes, and quality is that mobbing almost invariably robs a workplace of their most dedicated, diligent, and competent performers [17]. Because it is becoming, unfortunately, so prevalent, it is pertinent to list the ten key factors that define mobbing. If you find yourself experiencing or witnessing these in your workplace, then not only will you be at risk for poor performance (in fact, that has likely already occurred and is often the "trigger" that incites mobbing), but you may need to find a way to protect someone (including your patients) from harm.

Ten key factors of mobbing [17]

1. Assaults on the dignity, integrity, credibility, and professional competence of an employee
2. Negative, humiliating, intimidating, abusive, malevolent, and controlling communication
3. Committed directly, or indirectly, in subtle or obvious ways
4. Perpetrated by one of more staff members –"vulturing"
5. Occurring in a continual, multiple, and systematic fashion, over some time
6. Portraying the victimized person as being at fault
7. Engineered to discredit, confuse, intimidate, isolate, and force the person into submission
8. Committed with the intent to force the person out
9. Representing the removal from the workplace as the victim's choice
10. Not recognized, misinterpreted, ignored, tolerated, encouraged, or even instigated by the management of the organization

It is easy to discern that these factors violate virtually all the practices discussed above that contribute to team resonance, high performance, and better outcomes.

The result of mobbing is always injury. Although the literature is explicit that this is injury to the victim, in a field like pediatric cardiac care, there will also be injury to our patients. Organizations that tolerate or allow mobbing will not be centers of excellence. The people in the organization have gotten too out of control (usually from lack of leadership) to function as a safe team. In our opinion, organizations that permit this behavior by a member or a few members of a team should recognize the serious lack of leadership, dismiss the offending parties, and provide leadership training for people with leadership roles. Bullies only succeed because the "adults" allow them to. In organizations, mobbing (which is sophisticated bullying) can only exist when there is poor organizational leadership. Most important is the huge impact that this behavior has on quality and outcomes [57]. It should be clarified that

bullying and mobbing are an extreme dysfunction along the spectrum of not counting others and valuing their contribution to a team. It won't be permitted to occur in organizations or on teams where there is resonant leadership [6, 98, 109] and in particular, where team members are encouraged to be *upstanders* and to speak up when they see other members of the team being treated unfairly or contemptuously.

The permission and encouragement to "upstand" is similar to the expectation in crew resource management programs developed by the Federal Aviation Association that if anyone on the crew sees something concerning, they will speak up. Even more important is the support by leadership that the concerns are taken seriously and evaluated objectively, irrespective of the "role" of the person on the team. This is what makes high-reliability organizations (HRO) [103] highly reliable. It is equally important that leadership remain connected to important core values developed by the entire team, so that concerns are handled as complaints (not criticisms) where all team members are encouraged to participate in solving the problem (and not focused on "solving a person") and that the team approaches this problem solving with all of the requirements of evaluating complex adaptive problems – explore to understand (rather than coerce and tell), share accountability (rather than defensive blaming of another), appreciation for the collective talents of the team (rather than contemptuous diminishment of a victim), and the courage to address difficult dilemmas with acknowledgement of numerous perspectives (the truth is the consensus of perspectives).

Upstanding has had an important role throughout history. It is a mechanism for standing up to bullies who might use their position, authority, or persuasions to further self-interests rather than the interest of the greater good.

Conclusion

This chapter has summarized the practices of highly resonant teams. These practices are supported by considerable research in the neurobiology of relationships, business, psychology, medicine, and sports. The relationship of these practices to best outcomes has been clearly documented. The final question is simply a personal one: "You have a fleeting professional life. This professional life can add energy and joy to your world, as you work with others toward a noble shared goal. Or it can slowly erode away at your happiness, satisfaction, and health. The practices can be learned and embraced by any team that is willing to establish them as a core mission and value. You can go to work and try to survive, or you can go to work and thrive. Which do you choose?"

Appendix 1

We can define three kinds of interpersonal interactions, all of which we include under the general term *integration*, which is meant to be inclusive of:

- Congruent [22, 80] – which defines the *decision-making* process between yourself, others, and the current context in a way that integrates all the competing needs in a manner that honors them and has them contribute to the choices that are made.
- Concordant – which defines the *relationship* between two or more members of the team such that they are completely "in sync." This can also be called attunement or resonance.
- Coherent – which defines the *communication* process between yourself, others, and the current context. It requires *simultaneous states of differentiation and linkage* to self, others, and contexts. In coherent communication, an individual has a knowing and stable core from which he or she feels available to be influenced and receptive to the opinions of others without disintegrating into chaos or needing to operate/communicate from a rigid status quo. Coherent communication is based on personal insight and interpersonal empathy, and it allows for flexible, adaptive, and creative outcomes.

High-performing (resonant) teams require congruent, concordant, and coherent

communication. Without attunement, this kind of communication is not likely to occur. Attunement-driven integration entails the following ten functions that must be practiced and mastered [10, 12, 31, 40, 56, 76, 88, 100]. For experts, these functions can be performed in less than a second. The following is a definition of each and a concrete example of an experience you can incorporate in support of each function:

1. *Interoception*. This is your ability to be aware of the sensation the current situation creates in you in a way that you can sense that it just doesn't feel right [60]. Sensation is created in our nervous system from implicit and explicit memories. It is important that you be able to observe with all of your senses in the operating room, cath lab, or clinic, not just your eyes, ears, and hands but also with your important sixth sense.
   (a) What happens inside of you when something unexpected occurs? Do your hands shake, does your heart race, does your breathing become shallow, or do you feel weak and shaky? Try to recognize and tune into these feelings. They will be your clues that you need to get off automatic pilot and tap into a greater wisdom for response.
   (b) Take a deep breath(s) and connect to your internal sensations. Check-in with yourself. What images or experiences from the past are creating or contributing to this present physiological experience? Do I have someone else's "hat" on a person in the room? Does this situation remind me of a specific time (explicit memory) or a feeling that I can't quite explain (implicit memory) that I had an unpleasant experience? Remind yourself that you don't have to continue to be shaped by the past.
   (c) Learn to take a deep breath(s) and be aware that something inside you says "danger."
   (d) Understand that this is happening *inside you* and not necessarily out there for others to be aware of, before you formulate your verbal commentary.
2. *Emotional Balance*. This state is controlled by the prefrontal cortex and enables you to use both your brakes and your accelerator. If you lack this internal emotional balance, you will either find yourself panicking or not reacting appropriately to the current circumstance. In order to communicate coherently with team members, you first need to find your emotional balance. You can't allow the circumstance to knock you off your feet or bounce you off the walls.
   (a) Practice reflection/relaxation. Take a deep breath(s).
   (b) Moderate energy and ask yourself: Do I need more energy? Do I need to slow my energy down? Is my nervous system sending both messages simultaneously so that I need to practice self-soothing? Should I provide more energy? Can I sense the energy of my teammates?
   (c) Check with team to gauge their energy levels.
   (d) Step back from the surgical table (metaphorically), take a deep breath(s), and connect to your internal sensations. Check-in with team.
3. *Attunement*. As you are assessing your own response, you are aware that something is also happening with others. When we are attuned to ourselves, we experience nonjudgmental compassion for ourselves [66, 67] and others feel felt by us in much the same way. When you are attuned to others, you can resonate with them. This is an essential component for high-performing teams and is required for coherent communication.
   (a) Practice compassion and genuine caring for yourself and others.
   (b) Spend time and energy learning more about the other members on your team. The more you can learn about them, the easier it will be to attune to them and value (congruence) what might be happening for them.
4. *Response Flexibility*. This is a leadership trait that is developed by resonant leaders [22] who have learned to break away from patterned reactions and create responses that

are flexible and adapt to the current situation. (We will describe this further in our *fifth practice* of highly resonant teams.) Response flexibility provides you with an openness to be able to consider a variety of options for communicating, including some you rarely use.

(a) When you encounter a problem, try to think of three more options. Then ask members of your team what they might do. See if they think of options that you hadn't considered.

(b) Spend time learning about your typical response patterns. There are numerous tools for this kind of learning, including the Thomas-Kilmann Conflict Resolution Index (TKI), the Myers-Briggs Temperament Indicator (MBTI), and the Strength Deployment Index (SDI). Then consider how you would respond if you adopted other patterns.

(c) Practice COAL – *c*uriosity, *o*penness, *a*cceptance with *l*ove (nonjudgment) [88].

5. *Focused Energy*. Integration requires attentiveness to the present moment. The present moment becomes your consciousness. Imagine having this dialog with yourself:

"Where are you?"
Here
"What time is it?"
Now
"What matters?"
The moment

Your mind becomes clear and you have an experience of consciousness about consciousness. You have an awareness of the possibility to choose where to direct your focus. This experience was described beautifully by Captain Sullenberger as he prepared to try and land his powerless plane in the Hudson River [97]:

(a) Practice mindfulness, reflection, and relaxation.

(b) Stop and notice where you are focusing. Does the focus make it more or less intense? Can you observe yourself observing? Observe yourself and what you are choosing to think and feel. Have curiosity and experiment with focusing on a variety of experiences.

6. *Self-Regulation and Self-Soothing*. You find a way to control your impulses and to modulate your fear. You acknowledge your "fear" but you don't allow yourself to be overcome by it. You know how to bring your heart rate and your fear back under control. This is taught by heart math [11, 12] and can be learned as a tool for stress management. You won't be able to communicate with others if you can't control and communicate with yourself:

(a) Practice reflection/relaxation.

(b) Take calming breaths. Notice the fear without trying to control it. Speak gently to yourself.

(c) If a colleague is fearful, angry, upset, don't respond in kind. Take a deep breath(s) to suppress a reaction and to maintain your stability. From this position, you can communicate with a sense of compassion and empathy.

7. *Insight*. This is where you perform mental time travel to tap into your wisdom of the current situation and link past with present and future. This is termed self-knowing awareness. You have awareness of your choices. You have awareness of what you have learned and how the future can be influenced by the past.

(a) Internally articulate your understanding of the present experience to yourself as well as what you want to do with your understanding. Try it on with yourself and then share it with your team, not as a fact, but rather as a speculation. Ask for feedback from others. Do they share your insight? Allow influence.

8. *Empathy*. The cognitive ability to put yourself in the shoes of another and understand the world through their eyes. In order to do this, you need to learn how to practice

"self-empathy." What is the part of you that is reacting or feeling? Does it tap into a past experience (an explicit memory) or are you unable to pinpoint the experience? You only know that the event that is happening has created somehow in your forgotten past a response of anxiety (implicit memory – olfactory memory is an example of the power of implicit memory, when a certain smell can conjure up a very strong emotional association from our past; or perhaps when you hear a certain song, it arouse intense feelings in you related to a past event). Try to identify the part of you that is reacting and have empathy for that part of you – perhaps a part that you have outgrown, like your fear that you might be thought of as not capable, even though you have proven yourself capable many times over many years. It requires the cognitive capacity to move from the concrete to the abstract. Use your knowledge of your colleague to try and understand how they may be having an internal experience based on their memories and tune into what they might be experiencing. Using what you have learned about them, can you understand the experience from their perspective?

(a) Think of what you know about another team member. What are their hopes, beliefs, values, and goals? Has your team taken time to learn this about the team members? If you were in their shoes as if you were he or she, ask yourself, "What would I be experiencing?"
(b) When appropriate, check out your experience of another to discover if you are accurate. Revise your picture of them to include new information.

9. *Morality*. As you consider the current situation, you also tap into your moral code of what is important to you and you hold the intent to function with the greater good for the whole in mind. As you choose your response, you want to ensure that it is consistent with who you are and who you want to be, as well as being a choice that considers the impact on others:
   (a) Get clear on your personal values and goals as well as the goals and values of others. Try to write down your values as words or sentences and then ask yourself, "how important is this value to me?" "Would I rather leave this job than sacrifice on this value?" Take your own welfare into account as well as the welfare of others.
   (b) As a team, articulate and define your values, goals, and mission. Create a vision statement for your team, but in order to do this, you must first be clear on your own values.
10. *Intuition*. Your anterior cingulate cortex has spent years gathering information for you about experiences [60]: If this, then that. The dopamine receptors in your brain have been trained to teach you because they have been responding to patterns your entire life. You have wisdom collected from years of experience and your intuition is more than a random guess. Learn to be aware of what your intuition has learned:
    (a) Check out hunches with others and tap into the collective wisdom of your team.
    (b) Keep a record of times you had an intuition. What was the outcome? Were you right? How would you modify your intuition for the next time something similar happens?

As you master these foundation functions, you will develop the ability to attune (to yourself, to others, and to situations) and to communicate from a place of mindful integration. You will exhibit personal insight and the ability to have empathy for others. This is a dynamic, evolving, and expanding process that feeds off energy and information available within yourself and from the members of your team. *Mindful integration* (as defined by the steps listed above) is the first, and essential,

practice for teams to function with the kind of attunement that leads to high performance. It is mandatory for leaders of teams to understand the complexity of integration and to model it for the team.

Animal Research in Pediatric Cardiology and Cardiac Surgery

185

Suzanne Osorio-da Cruz, Paul Flecknell, and Claire Richardson

Abstract

Experimental animal models are often part of the process to develop new methods, devices, or discoveries in modern medical science, and choosing the right model is key to the success of any project. The object of animal models is to reproduce human diseases, metabolically and pathophysiologically, to help provide answers of disease pathogenesis, prevention, and treatment. When carrying out any experimental surgical procedure, appropriate anesthesia and effective analgesia (pain control) are essential to minimize the likelihood of pain or distress in the animals being studied. This chapter aims at providing basic tools for the nonanimal specialist in order to make the right choice, to learn the introductory principles of laboratory animal anesthesia, and to appreciate factors that can affect the data obtained, while understanding the social and ethical issues involved in the use of animals in biomedical research.

Introduction

Experimental animal models are often part of the process to develop new methods, devices, or discoveries in modern medical science, and choosing the right model is key to the success of any project. This chapter aims at providing basic tools for the nonanimal specialist in order to make the right choice and appreciate factors that can affect the data obtained, while understanding the social and ethical issues involved in the use of animals in biomedical research.

The object of animal models is to reproduce human diseases, metabolically and pathophysiologically, to help provide answers of disease pathogenesis, prevention, and treatment. It is worth to mention that veterinary medicine has also directly benefitted from discoveries related to biomedical research, which are now part of everyday clinical veterinary practice. When planning an animal study, two types of models should be considered, in vivo and in vitro, and the pros and cons of each type taken into consideration. Because of the nature of pediatric pathologies, this chapter will mainly consider in vivo models for surgical correction of congenital heart disease. The model should be chosen for the specific pathology; however, technical ability, infrastructure, costs, and animal husbandry and physiology must be part of the assessment. The decision to use animals in research should not be rushed; before considering it for any experiment, all alternative methods of research have to be considered, and this should include a thorough literature review, assessment of in vitro and in silico studies. If an approach involving animal models is required, then studies should be carefully planned to minimize animal use and refine procedures so that they cause a minimum of pain and distress. The study design should also include determination of the methods that will be used for statistical analysis, and power calculations to determine sample sizes should be undertaken. Consulting other professionals to include a multidisciplinary aspect to the study is often essential for good results. More information on alternative methods can be found in www.caat.jfsph.edu/. Last but not least, published articles often summarize materials and methods used, abbreviating technical details, and omitting important facts, like breed, sex, age, and origin of the animals. A thorough description of the materials and methods is not only useful for other researches to the set up of their own experiments but also for comparisons between studies. When publishing results, the ARRIVE guidelines should be followed [1].

Alternative Methods, 3R, Welfare, and Ethics

Animals have been used in scientific experimentation for many centuries; however, methods have thankfully changed dramatically, from experiments involving surgery in conscious animals to the use of appropriate anesthetic and analgesic techniques. The animal species used has expanded, and the majority of animals used are now housed and reared in carefully standardized conditions. These developments and the introduction of genetically modified strains have expanded the range of studies that can be conducted, reduced unwanted variation, and reduced animal stress and distress.

In 1959, two English scientists, William Russell and Rex Burch, presented a philosophically motivated but scientifically

based study on ethical aspects and humane techniques in the laboratory [2]. Although they proposed that true humanity should make researchers naturally inclined to respect and act compassionately toward other species, they determined that some studies are inherently inhumane. By presenting the 3 R principles of *replacement*, *reduction*, *and refinement*, they hoped to establish a basis for more humane experiments, reducing the fear and suffering inflicted on animals. *Replacement*, the most radical principle, proposes the use of nonsentient organisms (plants, cells) and in vitro techniques as possible alternatives to higher animals. *Reduction* proposes that use of good experimental design and optimized techniques (particularly statistical analysis and sample size calculations) can enable the required data to be obtained with the use of a minimum number of animals. The third principle, *refinement*, refers to changes in protocols in order to minimize any pain and distress caused to animals – both directly by research procedures and indirectly, for example, by housing and husbandry. The 3Rs have been adopted as a fundamental cornerstone of laboratory animal science and are integral to legislation in numerous countries. Organizations such as the National Centre for the Replacement, Refinement and Reduction of Animals in Research [http://www.nc3rs.org.uk] or the 3R Research Foundation [www.forschung3r.ch] exist to fund research and disseminate information about the 3Rs.

Any scientist considering the use of animals for research should keep these three principles in mind, trying to respect them, not only for the good of the animal, but because they will generate "good science," benefiting their experiments, by reducing biases related to physiological and environmental stress produced in the animal, as well as respecting social and welfare issues. All nonanimal alternatives have to be exhausted, for example, computer simulations and mathematical models, leaving the animal experimentation as a last resource. When the use of animals becomes necessary, the experiments should be carried under strict ethical principles, respecting all aspects of the animal physiology, health, environment, and behavior.

Housing and Scientific Biases

Detailed information on the housing and husbandry of laboratory animals is outside the scope of this book. Good sources of information are the Guide for the Care and Use of Laboratory Animals [3] and the www.FELASA.eu, website of the Federation of European Laboratory Animal Science Associations. Before planning an experiment, housing and husbandry advice can be obtained from the institution's veterinarian to confirm infrastructure, technical help, and materials available.

Laboratory animals are usually confined in limited spaces, and the appropriate type of housing will not only benefit their well-being and physiological parameters but it will prevent infections and other illnesses and decrease stress, a potential confounding factor in many types of study. Housing conditions can affect sanitary, reproductive, and growth parameters and have a direct effect on the experimental results. Environmental factors, such as light, humidity, noise, and temperature; the number of animals per cage, feeding, water supply, handling, and infrastructure facilities; medical requirements; and type and dosage of drugs, anesthesia, pain control, and euthanasia, all should be taken into consideration when planning a study, and they all vary according to the specie, duration, and aim of the study.

Animals should be assessed by a laboratory animal veterinarian and allowed time to habituate to their surroundings, handler, and procedures, before any animal is assigned to an experiment. If animals originated from a nonspecialized breeder, a quarantine period is also likely to be required (Fig. 185.1). These procedures will help to maintain the health status of other animals in the laboratory. Acclimatization will also allow baseline parameters for the animals to be obtained, as although normal ranges for different parameters can be found in the literature, these should be taken only as a general guide, since they will vary with the environment, breed, age, size, and other factors.

Enrichment such as wood blocks, chains, bedding, or commercially purchased items should

Fig. 185.1 Thorough health assessment at arrival and gentle but firm handling will help the acclimatization of the animal to the new environment. Wood blocks and chains constitute a good enrichment factor for swine

always be provided, as this can both improve animal welfare and produce a more "normal" animal [4] (Fig. 185.1).

Animal Handling and Restraint

Handling animals takes experience and is one more factor that can introduce bias in a research study. Poor handling can provoke high levels of stress, affecting the outcome and result of the experiment. Each species has specific handling requirements, depending amongst other factors on size, age, and health status of the animal; however, general principles can be used for all of them. The handler should remain calm and should approach the animal confidently. Loud noises or sudden movements should be avoided, and each movement must be gentle but firm. Each species has specific sites for collection of blood, urine, bone marrow, or other samples, and the researcher must understand and apply proper techniques. If repeated samples need to be obtained from an awake animal, the handler must first make sure that the animal is used to the procedure, since sudden changes or rough treatment can affect not only the well-being of the animal but also the outcome of the study. Guides to handling small rodents and methods of conducting different procedures can be found at www.procedureswithcare.co.uk, www.nc3rs.org.uk, and www.aalas.org.

Animal Models

A very wide range of animal models, of many different species, have been described. This chapter focuses on how to choose a particular model and why one species might be useful or not for a particular purpose.

It is useful to divide animal models in three main groups:

Induced: The pathological process is experimentally induced in a healthy animal. This is a type of model particularly relevant for pediatric cardiology, since many models of congenital heart defects have been developed. Some transgenic animals can be included in this category and are particularly valuable when a genetic mutation can help mimic human diseases.

Spontaneous: The pathological process occurs spontaneously in the animal. Genetically modified strains can also be considered in this group. The opposite situation, when a disease does not appear in a particular species or breed, is called a negative model.

Orphan: When a disease present in animals is studied in view of a future appearance of the process in humans.

Before planning any protocol, a thorough study of the literature should be performed [5]. The model should be based on comparative studies and scientific validity and not simply on convenience or familiarity. It therefore follows that developing and validating a new model can be expensive and time consuming. Unless an obvious anatomical or physiological reason exists, the ideal course is to start with the simplest model, usually including less expensive smaller species and, for higher or secondary projects, proceed with a more developed one: as a general rule, aim to study the species with the lowest neurophysiological sensitivity, which current scientific evidence suggests may be less likely to experience pain, suffering, and distress, for example, an invertebrate rather than a vertebrate species.

Further information on species selection can be obtained online at www.threers.ccac.ca/en/alternatives/species-selection-especes.html.

Many factors influence the choice of an animal model:

- A physiological and anatomical similarity between the chosen animal species and humans may be essential for a good reproduction of the entire disease process; however, specific aspects of a disease can be modeled in very simple systems. Although most mammals have similar anatomy to man, specific anatomical features may be essential for certain experiments. This is directly related with an essential point: the similarity of the process being studied between animals and humans. An animal model will never be identical to a human condition (as humans would be the best animal species for this model); it should however reproduce the specific pathology/technique to be studied as closely as possible, allowing the extrapolation of the results to humans and providing a scientific benefit important enough to compensate the use of animals. As with any scientific process, to guarantee consistent results, the model should also be reproducible and reliable.
- Ease of handling and sampling in the animal: a full-grown farm pig can be challenging to handle, but performing complex surgery in a mouse can be equally difficult.
- Availability, financial feasibility, and infrastructure are key not only for the successful development of the experiment but also for the well-being of the animal, which will equally influence the outcome of the results. Specialized laboratory animal breeders should be chosen over ordinary farm breeders, as they will provide a more stable genetic lineage and a guaranteed health status. The health status of laboratory animals can be classified according to their microbiological qualities: *conventional* (unknown or questionable microbiological status), *gnotobiotic* (germ-free animals reconstituted with a defined microflora), and *specific pathogen free* (SPF, free from specified pathogens) [6].
- Survival of the animal and length of the experiment, an acute cardiac implantation of a heart device can be performed in a calf without much difficulty; however, long-term survival can be difficult because the animal will soon attain a size that would challenge not only the device itself but also the handling and housing facilities in many establishments and thus influence the outcome of the experiment.
- Last but not least, ethical and social considerations are equally significant. There was a time when animals were not considered sentient beings; it is now known that they can feel not only pain but stress too. Every experiment should be planned with the minimum discomfort for the animal, respecting its natural environment, nutrition, and other needs. In modern society (particularly in the Western world), humans have developed a close relationship with certain species, like dogs, rabbits, and others, which make it socially challenging to use them.

Animal Species

Many species can be used as research models, with mice and rats being the most commonly used [7, 8]. Fish, although not developed in this chapter, are becoming more popular for many types of research, particularly *Brachydanio rerio* (zebra fish) and should not be neglected when choosing a model [9–11]. Each species has positive and negative points depending on the hypothesis and outcome desired. Some of these points will be discussed, and husbandry and management aspects for various species will be briefly described, relevant when planning an experiment. As mentioned earlier, an extensive literature review is necessary for the researcher to become familiar with the physiological, anatomical, and pharmacological particularities and differences. A list of references is provided, as well as examples that can be used as a starting point for more in-depth research.

Rodents

Order: Rodentia; Family: Muridae

Table 185.1 General physiological parameters of species used in the laboratory

Physiological parameters		Mice	Rats	Rabbit
Adult weight	Female	25–40 g	250–300	2–6 kg
	Male	18–40 g	300–500	2–5 kg
Life span (years)		1–3	2–3	5–7
Heart rate (/min)		285–800	300–500	150–300
Respiratory rate(/min)		100–200	80–110	30–60
Body temperature (°C)		36.5–37.5	37.5–38.5	38.5–39.5

Rodents include mice, rats, guinea pigs, and hamsters. They have one pair of continually growing incisors in the upper and lower jaw that need even wearing by gnawing to maintain a functional occlusion.

Mice

Genus: *Mus*

Most widely used laboratory mammal, relatively easy to breed and house and useful for the researcher due to its genetic malleability, as single or multiple genes can be manipulated to enhance or minimize a trait, creating different inbred strains with diverse susceptibilities to pathological processes. An inbred strain is obtained by mating brother x sister for 20 or more generations (extensive information on mouse genomics can be consulted in www.informatics.jax.org) [12]. The low genetic variability obtained by using mice inbred strains reduces the number of animals per experiment, leading to an obvious ethical, scientific, and financial benefit. Mice are social, nocturnal, and very active animals; however, activity patterns can be strain specific and laboratory strains can adapt to experimental conditions. As a guide, Table 185.1 indicates some of their main physiological parameters, although these might vary amongst breeds and with stress, gender, age, and other factors. Water should be supplied ad libitum, unless restriction is specifically required by the experiment, in which case their minimum intake should be 15 ml/100 g/day. They are susceptible to environmental changes, so temperature and humidity have to be carefully monitored. Mice are polyestrous with a spontaneous ovulation and can breed several times a year, with an average littler size of ten. Clean bedding in each cage is necessary, taking into consideration the natural needs of the animals, for example, their nesting behavior (for which they can be provided with shredded paper, paper rolls, or a commercially acquired material) [12, 13].

From a surgical perspective, the use of mice for cardiovascular surgery can be challenging. Good expertise in microsurgery is needed, and not all models are viable in such a small animal. However, there are many models established, and a growing proficiency in the surgical field has permitted an increasing precision and perfection of techniques. Tarnavski provides a good surgical guide, and a variety of models can be found in Qingbo's Handbook of Mouse Models of Cardiovascular Disease [14–16]. Allogenic heterotopic heart transplantation has been performed by several authors to study heart transplant rejection [17–19]. Bartelds et al. used a murine model for the study of right ventricular (RV) dysfunction in congenital heart disease [20]. This model includes banding of the pulmonary artery through lateral thoracotomy, aortocaval shunt and sham surgery for control animals. This technically challenging model allowed the authors to study the changes suffered by the RV by modifying pressure and volume loads. Cardiac studies in mice have also been favored by advances in diagnostic methods, like ultrasound biomicroscopy, Doppler analysis [21], echocardiography [22], and refined electrocardiography models [23], making precise measurements possible.

Rats

Genus: *Rattus*

Rats are the second most frequently used animal in biomedical research [7, 8]. Although genetic modifications are less common than in the mouse, there are hundreds of inbred strains and tenths of outbred strains available (for more information on commercial strains, consult www.harlan.com and www.criver.com). The larger

Fig. 185.2 Excess of porphyrin around eye socket in a rat

size and weight makes surgery and monitoring easier than in the mouse. Most strains are less aggressive and active than mice; they are vulnerable to temperature and ventilation changes, which can lead to respiratory distress. Like in the mouse, luminosity is important for physiologic regulation, but rats are also prone to retinal damage, so it is important to maintain a good control of the lighting intensity. Harderian glands present within the eye socket secrete a brown/purple substance that rats will normally groom, and the presence of this secretion represents an excess of porphyrin and may be a sign of distress, which should be addressed (Fig. 185.2). Unlike higher mammals, blood supply to the atria is mainly extra-coronary, from branches of the internal mammary and subclavian arteries [24]. They are polyestrous animals with spontaneous ovulation and can breed several times a year, with an average littler size of 8–12. Water should be supplied ad libitum and cages kept clean, with enrichment objects such as wood blocks, paper rolls, or commercially purchased material. Table 185.1 describes some general physiological parameters of rats that can be used as a guideline.

Examples of cardiac studies in rat include heterotopic heart transplantation for rejection studies [25], atrial fibrillation, and remodeling [26]. Faber et al. [27] published a study of the changes in right and left ventricular function after 6 weeks of pulmonary artery banding, with complete hemodynamic studies in 15 animals, obtaining relevant information in cases of corrections of congenital heart disease [27].

Rabbits

Order: *Lagomorph*; Family: *Leporidae*; Genera (amongst others): *Oryctolagus* (European rabbit), *Sylvilagus* (North American rabbit).

These lagomorphs are small, but big enough to allow surgical techniques to be performed with more ease. The most common breeds used in biomedical research have a body weight of 2–5 kg (New Zealand white, Dutch, Californian) [13, 28, 29]. Rabbits have two pairs of upper incisors and one pair in the lower jaw that require proper wearing to keep a physiological occlusion. They are herbivorous and produce during the night a soft type of droppings rich in proteins and vitamins B and K (caecotrophs) that the animals eat directly from the anus as a source of nutrients (caecotrophy). Rabbits are induced ovulators, without a defined estrus cycle; litter sizes vary between 4 and10 kits. Table 185.1 presents other physiological parameters that can be used as a reference. Rabbits cannot sweat, and thermoregulation occurs mainly by heat exchange in the ears and by inspiring moistened air; environmental temperature should be kept between 15 °C and 21 °C for optimal conditions. They are very sensible to stress, pain, unfamiliar surroundings, overcrowding, and poor handling, which can have extreme consequences, even leading to heart failure, reduction in gut motility, decreased urine flow, and gastric ulceration. To reduce stress, rabbits can be wrapped in a towel for examination, and avoiding loud sounds, abrupt environmental changes, providing clean

and enriching bedding material, and administering analgesics when performing painful procedures can reduce these negative effects [30].

Rabbits are important in the production of polyclonal antibodies, cancer studies, and cardiovascular diseases, particularly atherosclerosis [28, 31]. Covering other aspects of the cardiovascular field, Brunner et al. worked on long QT syndrome (LQTS) to study cardiac arrhythmias and sudden death in a transgenic model of rabbit, performing telemetric and electrophysiological studies, and the results proved the successful use of a rabbit model to identify mechanisms of sudden death [32]. Postoperative pericardial adhesions [33, 34], as well as myocardial repolarization in chronic heart failure, are also examples of rabbit models recently published [35].

Swine

Order: *Artiodactyla*; Family: *Suidae*; Genus: *Sus*

Several breeds of domestic swine are used in biomedical research: Landrace, Yorkshire, Duroc, as well as purpose-bred miniature breeds (Yucatan, Gottingen, Hanford), which might show different physiological parameters than farm breeds [36]. Although less frequently used than rodents, physiological similarities and a comparable heart size to humans make swine a good cardiovascular model, and perhaps because of its use in farming, it is better accepted by the public than other species like the dog. Swine can be housed individually or grouped in pens or stalls; however, they are social animals, so visual or direct contact with other pigs will improve their well-being. When group housing is provided, the groups have to be established as early as possible to avoid hierarchical conflicts. Pens should have adequate bedding (e.g., straw), enrichment factors, water ad libitum, and an environmental temperature between 17 °C and 24 °C. Swine are omnivorous. Most acute or short-term studies use young animals, 3–4 months of age, with a body weight of 30–35 kg. The body weight of farm breeds will become a major handling issue if used in long-term studies, since an older animal can reach 90–100 kg by 5 or 6 months of age. Mini-pig strains are a good alternative, as their adult body weight will fluctuate around 30–60 kg. They are more expensive to purchase, but much more manageable when reaching adult sizes and with a guaranteed health status. Sinclair Research developed a Yucatan mini-pig born with ventricular septal defect (VSD), ideal to study the condition in humans, and their website provides a thorough compilation of technical bulletins (www.sinclairbioresources.com). Gottingen mini-pigs are recommended by their producer Ellegard as good models for cardiovascular safety pharmacology studies, and their website constitutes a good source of technical information (www.minipigs.dk).

Certain strains of pigs (lean muscular breeds like Landrace and Duroc) may present a fatal genetic condition, malignant hyperthermia, which can be induced by stress and/or volatile anesthetics. Rectal temperature will rise up to 45 °C, with muscle rigidity, tachycardia, tachypnea, leading to a quick death. Animals from identified strains should be avoided, but if the condition appears during surgery, stop the anesthetic at once, and treat immediately with dantrolene sodium (5 mg/kg) and cooling, which may save the animal [37].

Suematsu et al. [38] described three methods of closure in a beating heart of an experimentally created atrial septal defect, under 3D echocardiographic guidance [38]. This acute swine study was performed in animals weighing 73.7 + 5.8 kg, under isoflurane anesthesia and continuous electrocardiogram monitoring. Besides their use in traditional experimental models, swine are also utilized to assess the feasibility of new techniques [39] and in teaching, either with relatively new equipment like the da Vinci® Surgical System [40] or traditional surgical methods, like mitral valve surgery [41].

Dogs

Order: *Carnivora*; Family: *Canidae*; Genus: *Canis*

Dogs have been used in the cardiovascular research, since the 1600s with Harvey's studies

Table 185.2 General physiological parameters of species used in the laboratory[a]

Physiological parameters		Dog	Swine (farm breeds)	Small ruminants	Cattle
Adult weight (Kg)	Female	6–60	50–60	150–250	700–1,100
	Male	6–80	50–70	200–300	
Life span (years)		8–15	14–18	8–15	20–25
Heart rate (/min)		80–150	60–90	40–85	60–120
Respiratory rate(/min)		20–30	8–18	20–50	20–60
Body temperature (°C)		38–39	38–40	38.5–40	38–40.5

[a]Data will vary with age and breed

on cardiac movement. In the twentieth century, Beagles (because of their docile temperament) and mongrels have been popular, from early studies of the effect of hypothermia in cardiac surgery [42, 43] to stem cells [44]. Although they present good anatomical and physiological characteristics for cardiovascular models, their use in biomedical research has decreased. Increased costs and stricter regulations could be partially the cause, but their place in society has also created social concerns, discouraging their use in many countries. Physiological parameters, body weight, and size vary significantly with the breed, and these variations may introduce significant biases in scientific results [45]. Table 185.2 shows an average of these parameters. Dogs are social animals, and while they can be housed in individual cages if necessary, it is preferable to house them in groups, which will establish a hierarchy; male dogs will be more aggressive and will mark their surroundings with urine, and when fed, it is important to ensure that all the animals have access to food. Indoor and outdoor housing should be provided. Dogs are carnivores, a balanced diet is necessary for good scientific results; water should be supplied ad libitum. Canines need to get well acquainted with their handler and the experimental procedures, as well as been socialized at an early age (sexual maturity is attained between 5 and 10 months depending on the breed, but social maturity is attained much later, between 18 and 36 months), they usually respond well to food rewards [46]. Pain relief, as with any other species, should be provided at all times, and a good and rigorous vaccination protocol is necessary to maintain healthy animals. Meunier presents good information on how to best prepare dogs for animal experimentation, including training and acclimation [47].

Examples of recent publications on experimental procedures in dogs include mechanical studies of valve velocities, with echocardiographic and sonometric measurements [48], tissue-engineered valve implantations [49], and pilot studies on intracardiac device implantations [50].

Ruminants and Small Ruminants

Order: *Artiodactyla*; Family: *Bovidae*; Genus: *Ovis* (sheep), *Capra* (goat), *Bos* (bovine)

The number of ruminants used in experimental research is limited. These herbivorous mammals have a four compartment stomach (rumen, omasum, reticulum, and abomasum or true stomach), necessary to complete their digestive process. They spend several hours a day ruminating (mechanism through which the ingested bolus is regurgitated and chewed again) and should be fed with good quality hay and water supplied ad libitum. Indoor or outdoor group housing is preferred, with an adequate flooring to allow easy movement and hoof maintenance. A good habituation to the handler and the surroundings is necessary, hooves and horns may need trimming, and a regular vaccination schedule is needed. Progeny is usually 1–2 depending on the breed. Conventionally acquired animals are common; however, health monitoring and adequate reproductive techniques can lead to SPF animals, more suitable for biomedical studies. The 2000 report from the Federation of European Laboratory Animal Science Associations (FELASA) is a good source for health monitoring considerations [51].

In cardiovascular research, they have been used, amongst others, as models of valve repair and transplant [52, 53]. Another example comes

from a team of researchers at Penn State College of Medicine, who developed a small ruminant model (sheep) to test a pediatric ventricular assist device, including anticoagulation and implantation protocols [54, 55].

Nonhuman Primates

It is necessary to mention nonhuman primates, used in biomedical research because of their close phylogenetic characteristics compared to humans. They are a highly sentient group, and their use should be restricted and extremely controlled [56]. Although nonhuman primate models are necessary under certain circumstances, for example, AIDS, malaria, tuberculosis, hepatitis, and immune-based diseases [57], their use should be considered only when indispensible and on final stages of research projects.

Anesthesia and Analgesia

When carrying out any experimental surgical procedure, appropriate anesthesia and effective analgesia (pain control) are essential to minimize the likelihood of pain or distress in the animals being studied. A wide range of both anesthetics and analgesics are available for the most frequently used laboratory animals. Introductory principles of laboratory animal anesthesia are discussed herein. For more information, there are several detailed references available: Laboratory Animal Anaesthesia [58], Lumb & Jones Veterinary Anesthesia and Analgesia [59], and an increasing number of online resources which may also be useful (e.g., http://www.procedures-withcare.org.uk/, http://www.ahwla.org.uk/site/tutorials/BVA/BVA01-Title.html). On-site support from experienced laboratory animal veterinarians and animal health technicians should always be sought when carrying out an unfamiliar anesthetic protocol or working with an unfamiliar species.

The anesthetic/analgesic protocol should be carefully considered prior to carrying out any surgical procedure to minimize the potentially confounding effect of the anesthetic and/or analgesic on the research being carried out. Similarly, the regimen with the fewest adverse effects on the animals being studied should also be used in accordance with Russell and Burch's 3Rs principle [2]. Note that drug metabolism varies greatly between species; therefore, it is rarely appropriate to simply extrapolate a drug dosage from one species to another. Similarly, significant differences in response to anesthetics exist between strains in some species, for example, mice [60]; therefore, it may be advisable to carry out pilot studies prior to anesthetizing an unfamiliar strain. Finally, the anesthetic/analgesic protocols reported in the literature for the specific research procedure that will be carried are not necessarily the most refined or appropriate techniques, and therefore, it is not advisable to simply repeat what has been used previously but to carefully weigh the costs and benefits of all anesthetic/analgesic options.

Preexisting conditions including obesity, dental disease, and chronic illness can greatly increase anesthetic risk, and it is always preferable to use healthy animals for scientific procedures. In addition to carrying out a physical examination when an animal arrives at the animal unit, an examination should also be carried out prior to the induction of anesthesia. The type of physical examination carried out will vary with the species studied – a thorough visual examination should be carried out on all animals and in larger species such as dogs the heart and lungs should be auscultated.

The animal should also be habituated to routine handling (as previously described) prior to any surgical procedure to minimize any effect of handling stress during anesthetic induction. Food should be withheld in the preanesthetic period in some species, like in the dog, pig, and ferret, to reduce the risk of aspiration, but it is unnecessary to withhold food and water prior to anesthesia in rabbits and rodents as these animals do not vomit. Finally, animals should be weighed daily for several days prior to carrying out any surgical procedure (Fig. 185.3). An accurate preoperative body weight will ensure that the correct dose of anesthetic/analgesic is administered, and body

Fig. 185.3 Weighting of an animal with adequate equipment is necessary before any surgical procedure

weight is likely to be one of the objective parameters evaluated during the postoperative assessment period.

General anesthesia of laboratory animals can be carried out using an injectable anesthetic agent, an inhaled anesthetic agent, or a combination of agents. Preanesthetic medications and local anesthetics are frequently useful components of many protocols.

Legislation

Both national and institutional guidelines should be strictly adhered to. In the United States, the National Welfare Act (AWA) (www.aphis.usda.gov/animal_welfare/awa_info.shtml) passed by Congress in 1966 and amended several times since is enforced by the United States Department of Agriculture (USDA). It requires each research facility to establish an Institutional Animal Care and Use Committee (IACUC) to approve and monitor all research protocols. The "Guide for the Care and Use of Laboratory Animals" published by the Institute of Laboratory Animal Research [3] provides more information on the regulatory framework within the USA. In Europe, Directive 2010/63/EU will take full effect in 2013 as legislation protecting animals used in scientific procedures. Individual member states are required to introduce legislation that enforces the requirements of this directive, for example, the Animals (Scientific Procedures) Act, 1986 [61], in the United Kingdom. Additional legislation regulating the provision and use of veterinary medicines also exists and should also be adhered to (e.g., the Veterinary Surgeons Act in the United Kingdom). Finally, it is preferable to use drugs that are licensed for the animal species that will be anesthetized or that local guidelines regarding extra-label use of anesthetics or analgesics are followed.

Preanesthetic Medication

It is often appropriate to administer some form of preanesthetic medication (typically a sedative combined with an analgesic) prior to anesthetic induction. The use of a preoperative sedative minimizes stress at induction of anesthesia and typically reduces the anesthetic requirement for surgery. Sedatives are therefore frequently a useful component of *balanced anesthesia* which refers to the use of different classes of anesthetics together to provide more effective anesthesia with fewer adverse effects (because lower doses of each individual drug is used). The administration of an analgesic prior to anesthesia, *preventive analgesia*, can reduce both peripheral inflammation and noxious stimuli reaching the central nervous system [58].

Preanesthetic medication is a particularly useful technique in larger laboratory animal species such as the rabbit, dog, pig, sheep, and nonhuman primate. Sedative dose rates are presented in Table 185.3.

Local Anesthesia

Local anesthetics such as lidocaine may be (1) applied topically (e.g., through the use of a cream preparation such as EMLA (APP Pharmaceuticals, IL)), (2) infiltrated into

Table 185.3 Suggested sedative drugs and dose rates

Sedative drugs	Mouse	Rat	Rabbit	Pig	Sheep	Dog	Rhesus macaque
Acepromazine	2–5 mg/kg sc or ip	2.5 mg/kg im or ip	1 mg/kg im	0.2 mg/kg im	0.05–0.1 mg/kg im	0.1–0.25 mg/kg im	0.2 mg/kg im
Diazepam	5 mg/kg im or ip	2.5–5 mg/kg im or ip	0.5–2 mg/kg im, ip, or iv	1–2 mg/kg im	1–2 mg/kg im	0.2–0.4 mg/kg im or iv	1 mg/kg im
Ketamine	100–200 mg/kg im	50–100 mg/kg im or ip	25–50 mg/kg im	10–15 mg/kg im	20 mg/kg	NR	5–25 mg/kg im

sc subcutaneously, *im* intramuscularly, *iv* intravenously, *ip* intraperitoneally
NR = not recommended as a sole agent in dogs

a surgical site, (3) used to carry out peripheral nerve blocks, or (4) used to carry out spinal/epidural anesthesia. They may be used on their own/combined with sedation for minor procedures or combined with other agents as a component of balanced general anesthesia. More information is available from Tranquilli et al. [59].

General Anesthesia

General anesthesia involves loss of consciousness. There are three stages to general anesthesia: (i) *induction*, (ii) *surgical anesthesia*, and (iii) *recovery*. In both the induction and recovery stages, the aim should be to have a smooth and rapid transition between conscious and anesthetized states. The goal for surgical anesthesia is typically to use the lightest plane of anesthesia that will immobilize the animal, produce a lack of awareness, and eliminate pain.

Supportive Care and Anesthetic Monitoring

Supportive care is always required for general anesthesia regardless of the protocol used. Supplementary oxygen is essential as most anesthetic agents depress the respiratory system and can be provided via a simple face mask when injectable anesthetics are used (Fig. 185.4). It is also important to keep the animal warm as most anesthetics depress thermoregulatory mechanisms. Loss of body heat during anesthesia is particularly critical for small animals such as rodents as they lose heat quickly due to a high surface area to volume ratio. Homeothermic blanket systems (Harvard Apparatus, UK), warmed intravenous fluids, and veterinary bedding such as Drybed® (William Daniels, UK) may be used together during anesthesia to keep animals warm. It is also advisable to minimize surgical times and the use of excessive surgical disinfectants which may contribute to evaporative heat loss. The core

Fig. 185.4 Face masks can be used for oxygen supplementation when injectable anesthetics are used

body temperature should be monitored throughout the duration of the anesthetic (with a rectal/esophageal temperature probe). Finally, as many anesthetics abolish the blink reflex, ophthalmic ointment should be placed in the animals' eyes to prevent corneal damage.

Monitoring should also be carried out throughout the anesthetic to ensure that the depth of anesthesia is appropriate and that cardiac and respiratory function is not adversely affected by the anesthetic. Simple tests of anesthetic depth for routine use in rodents include the pedal withdrawal test in which the anesthetist pinches the animal's toe, and reflex withdrawal of the leg indicates that anesthesia is inadequate for surgery to be carried out. Other techniques of examining anesthetic depth have been described in detail [59].

One of the simplest ways to monitor respiratory function is to observe thoracic respiratory movements throughout the anesthetic procedure. Unfortunately observation of the chest can be difficult in small animals particularly when surgical drapes impede visualization of the chest and distraction of the anesthetist may also occur. It is therefore advisable to use anesthetic monitoring equipment in addition to clinical monitoring. A range of monitoring equipment such as pulse oximetry, capnography, electrocardiogram (ECG), and blood pressure monitoring (invasive and noninvasive) are available with an increasing number being appropriate for use in small laboratory species [62]. More complex anesthetic techniques, such as endotracheal intubation and intermittent positive pressure ventilation, are relatively easy to apply to both small and large laboratory animals [58].

Injectable Anesthetics

A wide number of injectable anesthetics are available [58], and some of the most frequently used agents are listed in Table 185.4. In addition to considering potential drug effects on the research to be carried out and on the welfare of the animals, other factors to consider when choosing an injectable anesthetic agent include duration of anesthetic action and whether a specific antagonist (anesthetic reversing agent) exists. The route of drug administration (e.g., orally, subcutaneous, intramuscular, or

Table 185.4 Anesthetic drugs for use: (a) in rodents and rabbits and (b) in larger laboratory animals. Note that considerable variation in effect exists between individual animals (e.g., strain and sex differences); therefore, concentrations will need to be adjusted

(i) Mouse, rat, and rabbit

Anesthetic drugs	Mouse	Rat	Rabbit
Fentanyl/fluanisone and diazepam	0.4 ml/kg ip + 5 mg/kg ip	0.6 ml/kg ip + 2.5 mg/kg ip	0.3 ml/kg + 1–2 mg/kg iv, im, or ip
Fentanyl/fluanisone and midazolam	10 ml/kg ip[a]	2.7 ml/kg ip[a]	0.3 ml/kg + 1–2 mg/kg iv or ip
Ketamine and medetomidine	75 mg/kg + 1 mg/kg ip	75 mg/kg + 0.5 mg/kg ip	15 mg/kg im + 0.25 mg/kg sc or im
Propofol	26 mg/kg iv	10 mg/kg iv	10 mg/kg iv

(ii) Pig, sheep, dog, and rhesus macaque

Anesthetic drugs	Pig	Sheep	Dog	Rhesus macaque
Ketamine/medetomidine	10 mg/kg + 80 μg/kg im	1 mg/kg iv + 25 μg/kg iv	2.5–7.5 mg/kg im + 40 μg/kg im	5 mg/kg im + 0.05 mg/kg im
Propofol	2.5–3.5 mg/kg iv	4–5 mg/kg iv	5–7.5 mg/kg iv	7–8 mg/kg iv

[a]This dose refers to a mixture of fentanyl/fluanisone and midazolam made up by combining 1 ml "Hypnorm" (0.315 mg fentanyl/ml; 10 mg fluanisone/ml) with 1 ml midazolam (5 mg) and 2 ml water for injection. Note that the water for injection should be added to the "Hypnorm" before adding midazolam

sc subcutaneously, *im* intramuscularly, *iv* intravenously, *ip* intraperitoneally

intravenous) should also be considered. An advantage of the intravenous route is that anesthetic dose can be administered to effect, but intravenous access may be difficult particularly in the smaller species.

Inhaled/Gaseous Anesthesia

Although injectable anesthetic regimens are often used to anesthetize laboratory animals particularly rodents [63], inhaled anesthetics/volatile anesthetics have the advantages that it is relatively easy to administer them to effect and also to quickly reduce the depth of anesthesia should complications arise. Inhaled anesthetic agents include isoflurane, sevoflurane, and desflurane with isoflurane being the most frequently used in laboratory rodents [63]. An anesthetic machine is required to carry out inhaled anesthesia – these may be available secondhand from local hospitals and can be used to anesthetize laboratory animals as long as they are carefully maintained and routinely serviced.

In rodents, anesthetic induction is frequently carried out using an induction chamber (Fig. 185.5). The mouse or rat is placed into the empty chamber which is then filled from the bottom with anesthetic gas while waste anesthetic gases are scavenged from the top. Following rapid anesthetic induction in a chamber (e.g., with 5 % isoflurane), a simple anesthetic facemask can be used to maintain anesthesia throughout surgery. In the larger species such as rabbits and pigs as discussed, preanesthetic medication is typically administered prior to anesthetic induction. A short-acting intravenous anesthetic agent such propofol can then be administered to allow intubation with an endotracheal tube to be carried out.

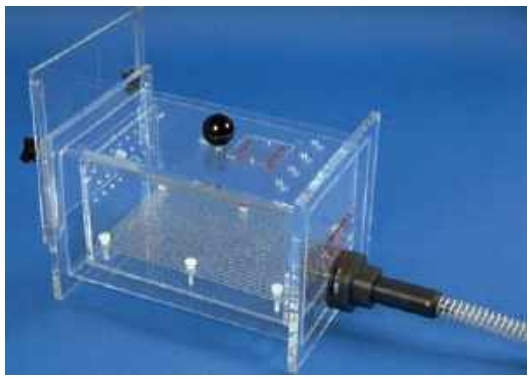

Fig. 185.5 Induction chamber used for anesthetic induction in rodents

Analgesia and Postoperative Care

Following any surgical procedure, the animal should be carefully monitored to ensure that anesthetic recovery is uneventful, that no surgical complications have arisen, and that there are no indications of postoperative pain. A video link can be useful for postoperative monitoring, particularly when the animals will be monitored by unfamiliar individuals. Thermoregulatory mechanisms will continue to be depressed in the immediate postoperative period; therefore, the animal should be kept warm. Provision of warmth can be achieved using an incubator for the smaller species such as rodents or by a warm postoperative room for the larger species such as pigs. Nesting material and/or bedding should also be provided for additional warmth. Water and palatable foods should be available postoperatively, and the animals' fluid and food consumption along with their body weight should be carefully monitored.

It is particularly critical to carefully monitor animals for evidence for pain postoperatively. Clinical signs including a hunched posture, lack of grooming, and changes in normal behavior are frequently indicative of postoperative pain [64, 65]. Recognition of clinical signs of pain however is dependent on the person assessing the animal being familiar with the normal behavior and appearance of both the species and the animal. Rather than relying on clinical impression alone, it is preferable to use a species-specific behavior-based pain scoring system to objectively study the animals for the presence of pain [58]. Unfortunately even with the careful use of behavior-based pain scoring systems, evidence of pain in laboratory animals can be very subtle and easily missed [66]. It is therefore advisable to (1) always administer at least one dose of

Table 185.5 Suggested analgesic agents and dose rates

	Mouse	Rat	Rabbit	Pig	Sheep	Dog	Rhesus macaque
Carprofen	5 mg/kg sc	5 mg/kg sc	4 mg/kg sc	2–4 mg/kg iv or sc	2–4 mg/kg sc or iv	4 mg/kg iv or sc	3–4 mg/kg sc
Meloxicam	5 mg/kg sc	1 mg/kg sc or po	0.6–1 mg/kg sc	0.4 mg/kg sc	0.5 mg/kg iv	0.2 mg/kg sc or po	0.1–0.2 mg/kg sc or po
Buprenorphine	0.05–0.1 mg/kg sc	0.01–0.05 mg/kg sc or iv	0.01–0.05 mg/kg sc or iv	0.01–0.05 mg/kg im or iv	0.005–0.01 mg/kg im or iv	0.005–0.02 mg/kg sc, im, or iv	0.005–0.01 mg/kg im or iv

po per os (orally), *sc* subcutaneously, *im* intramuscularly, *iv* intravenously

systemic analgesia to all animals undergoing surgical procedures that are likely to be painful, (2) consider the use of preventive analgesia and/or multimodal analgesia, and (3) attempt to match analgesic administration to the severity of the procedure [63].

There are two broad classes of systemic analgesics that are typically used to provide systemic analgesia: nonsteroidal antiinflammatory drugs (NSAIDs) and opioids. The most frequently used agents are carprofen and meloxicam (NSAIDs) and buprenorphine (opioid), and dose rates are presented in Table 185.5. These widely used analgesics typically have a wide safety margin in most laboratory animals.

Patient-Specific Imaging-Based Techniques for Optimization of Pediatric Cardiovascular Surgery

186

Kiran Dyamenahalli and Robin Shandas

Abstract

Advances in tomographic imaging techniques and computer processing power in recent decades have made it possible to artificially simulate surgical procedures using reconstructed patient-specific data. This ability lends itself well to the field of pediatric cardiology, in which complex congenital malformations and highly compensated circulations make it difficult to plan interventions or predict their physiological outcomes. At the moment, efforts to model septal defects, tetralogy of Fallot, congenital single-ventricle defects, valve disease, and other structural cardiovascular pathologies, pre- and post-repair, are limited to the research setting. This is because many necessary steps, including the development of virtual anatomical "meshes," application of equations governing fluid and tissue behavior, and incorporation of clinical hemodynamic data, have yet to be automated. Nonetheless, computational simulation of pediatric cardiovascular surgeries represents an intense area of study and may 1 day revolutionize the field.

Introduction

Historically, technological innovation in the operating room has often been driven by surgeons themselves, with assessment of new surgical techniques and devices undertaken initially in animal models. Precedent, rather than quantitative simulation, was used to predict outcomes and improvements were made through trial and error. More recently, increased collaboration with engineers, physicists, and mathematicians, and the growth of interdisciplinary fields such as biomedical engineering, has led to a surge of a priori design and prediction in surgery. Image-assisted interventions, in which fundamental advancements in imaging are tailored for specific medical applications, are some of the best examples of this growing collaboration. Pediatric cardiology in particular relies heavily on imaging data for surgical planning.

Image-guided intervention in pediatric cardiology has evolved to include patient-specific computational models and simulations designed to optimize cardiovascular surgeries. This involves reconstructing the anatomy of interest into a discretized geometric model and then applying equations governing three-dimensional (3D) fluid flow, cardiovascular soft-tissue mechanics, and fluid–structure interactions. While not yet adopted on a large or routinely useable scale, this technique has seen rapid growth during the last decade. Certainly, the confluence of technological factors has been critical; these include improvements in the spatial and temporal resolution of three-dimensional imaging modalities, the development of advanced reconstruction and simulation algorithms for medical imaging datasets, and the ubiquity of fast, multi-core processors necessary to render detailed mesh-based heart models and multiparameter simulations.

As with many other technologies, efforts to model the progression and treatment of congenital heart disease (CHD) in children have drawn heavily from computational work in adult studies. To name just a few applications, computational simulations have been used to visualize blood flow and pressure in the adult coronary arteries [1], predict blood flow changes following coronary artery bypass grafts [2] and peripheral arterial anastomoses [3], assess the risk of rupture of abdominal aortic aneurysms [4], model dyssynchronous heart failure [5], and optimize surgical replacement of the pulmonary valve [6]. While predictive adult models of the heart, pulmonary circulation, and peripheral vessels can be adapted to children to an extent, the pediatric cardiovascular system offers both unique opportunities and challenges. Congenital single-ventricle defects, tetralogy of Fallot, valvular

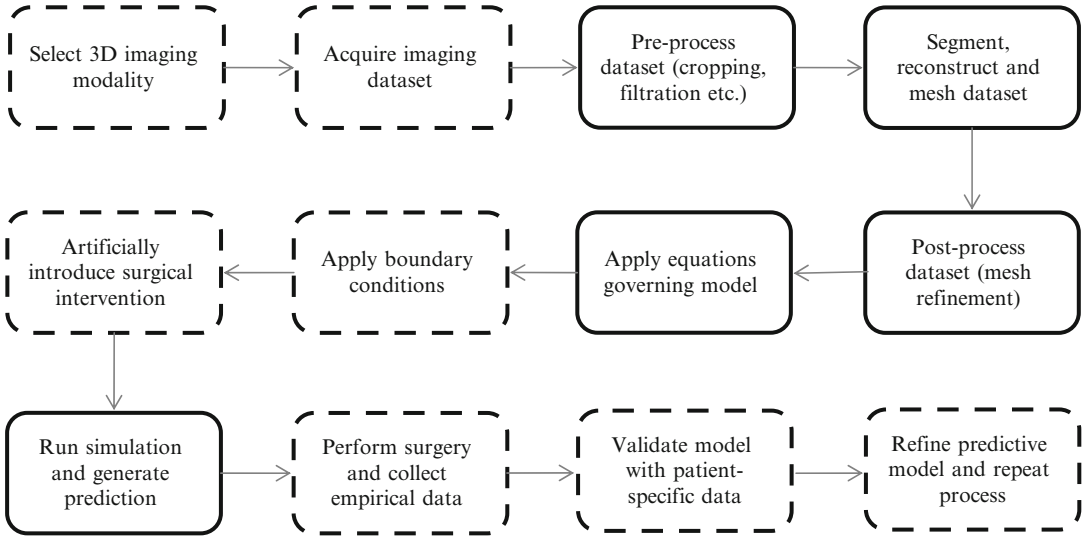

Fig. 186.1 Flow diagram illustrating the creation of an iterative computational model for simulation and prediction of surgical interventions in pediatric cardiology. Perforated boxes indicate steps at which input from a physician or technician is required

stenosis, septal defects, and aortic coarctation are all prime candidates for computational modeling. Simulations can help better visualize the anatomical region of interest and identify structural and hemodynamic pathologies. Moreover, they can help define the best surgical approach by rapidly predicting the biomechanical and physiological effects of intervention. Undoubtedly, the ability to simulate total cavopulmonary connection surgery in patients with single-ventricle physiology, the placement of ventricular assist devices, patch closure of septal defects, or pacemaker implantation would be invaluable. Challenges specific to pediatric cardiology relate to the wide range in physiologies associated with congenital anomalies and changes linked to normal or abnormal growth and development. Potential patients include fetuses weighing a few hundred grams to fully grown adults. This high degree of variation makes patient-specific imaging in the pediatric population very important.

The advantages of image-based computational models over in vivo and in vitro techniques to assess and optimize surgical interventions are numerous. Once created and validated, they can reduce the high cost and complexity associated with animal studies, minimize the speculation that accompanies surgical manipulation of highly compensated and sensitive circulations, and lessen the need for repeat procedures. Patient-specific simulations also allow for much greater spatial and temporal resolution of hemodynamic parameters and rapid variation of inlet and outlet (boundary) conditions. Moreover, computational simulations can provide predictive functional information over much longer timescales than traditional studies, taking normative or pathological growth models into account. As noted earlier, this is particularly relevant in developing children. Lastly, perhaps the greatest benefit of computational models is the ease in which they are refined. Through constant feedback of clinical data, the predictive power of simulations can be optimized. This establishes an elegant loop in which the model is used to improve surgical outcomes, and surgical outcomes are used to improve the model.

A framework for the development of an image-based, patient-specific, predictive computational model for improving pediatric cardiovascular surgeries is shown in Fig. 186.1. Fully realized systems will require minimal input from physicians, pertaining mostly to the

intervention being simulated. This chapter reviews foundational concepts in the growing area of image-based, patient-specific modeling in pediatric cardiovascular surgery and highlights emerging trends that promise to dramatically alter diagnostics and treatment in pediatric cardiology.

Imaging Techniques for Modeling and Simulation

The first stages of computational simulation include selection of an appropriate imaging modality and acquisition of a 3D dataset. By their nature, numerical simulations of biological phenomena are simply approximations. In addition to the analytical equations underlying the simulation, the accuracy of these approximations is highly dependent on constraints introduced by the dimensions of the model and the conditions at the boundaries of the model, such as blood velocity or resistance/impedance. Both components are pulled directly from imaging data. Accordingly, an ideal imaging modality for reconstruction and simulation purposes would combine high spatial resolution, excellent soft-tissue contrast, and the ability to measure blood pool velocity, pressure gradients, and vascular resistance. It would also be amenable to patient-specific validation of the computational results (more on this later).

The principal options for noninvasive cardiovascular imaging include echocardiography, magnetic resonance imaging (MRI), computed tomography (CT), and nuclear imaging. These technologies differ significantly in their relative abilities to visualize intra- and extracardiac anatomy and provide functional information. However, differences in performance and utility only partially account for the dominance of certain imaging modalities in pediatric cardiology. Clinicians routinely take practical issues into account, including availability, cost, and safety, while evaluating CHD in children. The same considerations must be made when selecting the best modality for computational modeling and simulation.

Cardiac catheterization and nuclear imaging have important roles in cardiac imaging, but are employed sparingly relative to echocardiography. Catheterization can provide direct measurements of blood flow and pressure, which can be used to assign boundary conditions to patient-specific computational models. Moreover, when paired with angiographic CT imaging, it can provide contrast-enhanced, pseudo real-time volumetric datasets [7]. However, due to its invasive nature, cardiac catheterization has essentially been replaced by transthoracic and transesophageal echocardiography in the initial assessment of "simple" structural heart defects, including atrial and ventricular septal defects (VSDs) and straightforward cases of tetralogy of Fallot [8]. Doppler ultrasound and MRI-based flow visualization and quantification techniques have also contributed to the decline in its use. Cardiac catheterization is now mainly employed in cases involving complex congenital malformations, such as functionally univentricular hearts, and other conditions where detailed perfusion and hemodynamic assessments are critical [9]. Nuclear scintigraphy also has the potential to provide valuable information for patient-specific cardiovascular modeling. In general, nuclear imaging techniques use radioisotope-labeled compounds to measure metabolism, blood flow, cardiac chamber function, and myocardial perfusion. Serial-gated acquisitions of ^{99m}Tc-labeled red blood cells or albumin can be used to quantify cardiac chamber volumes, ejection fraction, regurgitant fraction, and cardiac output [9]. Even so, nuclear imaging has a restricted role in children due to its relatively poor spatial resolution, the risk of ionizing radiation exposure, and the availability of superior alternatives. Consequently, in this chapter, detailed discussion of the relative merits of cardiac imaging modalities for modeling purposes will be limited to echocardiography, MRI, and CT. A comparison of these modalities in light of the structural and functional information they provide, as well as practical considerations, is shown in Table 186.1.

Table 186.1 Comparison of the most common cardiac imaging modalities

	Echo	CT	MRI
Structure			
Spatial resolution	<1 mm	<1 mm	1–2 mm
Cardiac chamber size and wall thickness	+++	++++	++++
Valve structure	++++	++	++
Coronary arteries	++	++++	+++
Extracardiac morphology	++	++++	++++
Tracheobronchial tree	–	++++	+++
Function			
Temporal resolution	5–20 ms	60 ms (gated)	25–100 ms
Valve function	++++	+	++
Diastolic function	+++	–	++
Systolic function	++++	–	++++
Pressure gradients	++++	–	+
Flow quantification	+	–	++++
Myocardial perfusion	+	+	++++
Practicality and safety			
Availability	++++	+++	++
Portability	++++	–	–
Radiation risk	–	++++	–
Patient sedation necessity	++	+++	++++
Fetal imaging	++++	–	+
Cost	$	$$$$	$$$$

Echocardiography

Role in Current Practice

Due in part to its availability, low cost, and ability to provide real-time imaging, echocardiography has become the workhorse of pediatric cardiology. Almost all patients referred to a specialty clinic for suspected CHD will undergo echocardiographic examination. Early technological developments in this field, including M-mode, Doppler and color flow imaging, dramatically expanded the diagnostic range of echocardiography, allowing for excellent temporal resolution of tissue motion patterns and facile visualization of blood velocity. Pulsed Doppler and tissue Doppler modes can be used to assess fetal arrhythmias. More recently, the development of strain rate imaging and real-time 3D echocardiography has extended the ability of ultrasound to study anatomy and physiology in CHD patients. The availability of 3D high-frequency transesophageal echocardiography probes has had a particularly significant impact since the restriction on viewing angles has been one of the primary drawbacks of this modality. It is now possible to obtain real-time tomographic images and volumetric datasets that can be reformatted and viewed in any arbitrary plane [10]. The portability of ultrasound equipment has also been an important factor in the adoption of this imaging modality in the operating room and for transcatheter procedures. In some centers, transesophageal echocardiography is routinely used to evaluate the results of complex congenital heart surgery before the patient is disconnected from cardiopulmonary bypass. 3D transesophageal echocardiography can be particularly helpful in assessing the mechanism of valve regurgitation or stenosis prior to surgical valve repair. In addition, percutaneous closure of atrial septal defects (ASDs) can be successfully performed under the guidance of transesophageal or intracardiac 2D or 3D echocardiography [11]. Lastly, echocardiography is the only traditional option for fetal and newborn imaging, due mainly to its high spatial resolution, the known risks of ionizing radiation exposure associated with CT imaging in young patients, and the poorly characterized bio-effects of MRI in this age group.

Ultrasound contrast agents have found significant use in vascular and perfusion imaging, though their use in children is still limited to the research setting. These agents traditionally consist of 3–6 μm microbubbles of air, nitrogen or perfluorocarbons encapsulated in human albumin, lipid layers, or other materials. Contrast agents take advantage of the large difference in acoustic impedance and compressibility between fluids/tissues and gases. Their compressibility produces expansion and contraction of the bubble in response to the ultrasound wave, which causes the bubble to behave as an active point-source emitter of ultrasound [12–14].

Utility for 3D Modeling and Simulation

Doppler ultrasound imaging is likely the most common technique for measuring blood flow velocities in the clinical setting. As such, it provides an inexpensive and safe method to gather boundary condition data for computational models. However, it is important to note that ultrasound can only provide the velocity component parallel to the direction of the ultrasound beam. This constitutes a significant limitation given the spatial complexity of many vascular flows in children. Not only is this true for the pulsed and continuous modalities but also for the 2D and 3D color Doppler modalities. The latter provide velocity data in planar or volumetric sections, but these data only consist of one velocity component. In comparison, phase-contrast MRI provides all three velocity components.

For image reconstruction and model building, 3D ultrasound can provide detailed volumetric datasets. Several studies have shown that, regardless of the acquisition technique, left ventricular volume measurements from 3D scans are more accurate and reproducible than those from 2D ultrasound and comparable to those from MRI [15–18]. Recently, gated transesophageal echocardiography methods and new reconstruction techniques have allowed for the superimposition of 3D color flow jets on grayscale data, producing quantifiable 3D color flow imaging [19]. However, this technology is still in its infancy and has several drawbacks related to the long time required for data acquisition (resulting in temporal and spatial misregistration) and the high computational load. Lastly, a new technique termed *echo particle image velocimetry* has shown significant promise in the ability to measure multicomponent blood velocity vectors through a combination of high-frame-rate B-mode imaging and contrast imaging, although the method has yet to be used in pediatrics [57].

Magnetic Resonance Imaging

Role in Current Practice

In view of the ubiquity of ultrasound imaging, MRI and CT have played complimentary, rather than central, roles in the evaluation of CHD during the past decade. However, the growing flexibility of MR pulse sequences and cardiac gating techniques have markedly widened the utility of this modality in pediatric cardiology. Today, applications include peri-surgical assessment of structural cardiovascular abnormalities, quantification of biventricular function and valve regurgitation, magnetic resonance angiography, measurement of systemic and pulmonary blood flow, identification of myocardial ischemia and fibrosis, and tissue characterization (through magnetization transfer contrast) [9]. One clear advantage of cardiac MRI over traditional echocardiography is that it is a volumetric technique, allowing for the display of complex intracardiac anatomy and reconstruction of large spatial windows. Secondly, flow-related enhancement provides visualization and quantification of blood velocity in any direction. On the other hand, cardiac MRI faces significant technical challenges in pediatric patients. For instance, sedation or anesthesia is often required, which demands additional time and monitoring equipment. The limited temporal and spatial resolution of MRI when compared to echocardiography also limits its applicability in small patients. Fetal imaging is especially challenging due to the lack of safety data and fetal movement during scanning. Like 3D ultrasound, real-time 3D MRI, also called 4D or interventional MRI, is still in its infancy, but preliminary studies have demonstrated the feasibility of placing endovascular stents and ASD closure devices under 4D MRI guidance. Difficulties relate to the low temporal resolution relative to ultrasound and the limited availability of MR-compatible instruments and catheters.

Utility for 3D Modeling and Simulation

The main advantage of MRI over traditional ultrasound techniques is its ability to provide volumetric datasets that can easily be reconstructed for computational simulations. Moreover, the only mainstream imaging technique that is capable of providing time-resolved 3D blood velocity maps is phase-contrast MRI (4D PC-MRI). Pilot work using 4D PC-MRI has been instrumental in describing the highly

complex flow patterns that appear in branched vessels and in congenitally malformed hearts [20–22]. Real-time MRI is typically gated by the cardiac cycle, so a respiratory velocity component must be added after the fact to avoid inaccurate flow velocity calculations in certain vessels.

Computed Tomography

Role in Current Practice

In general, CT systems capable of cardiac gating are more readily available than comparable MRI systems. CT imaging also provides greater contrast and spatial resolution than MRI and echocardiography for certain extracardiac structures. For instance, the value of cardiac CT in evaluating the trachea, bronchial tree, and thoracic vasculature is widely recognized. Moreover, recent advances in multi-detector instruments have significantly improved spatial and temporal resolution, allowing for detailed coronary artery imaging and gated cine imaging for evaluation of ventricular function [9]. However, unlike echocardiography, which uses mechanical energy, and MRI, which employs electromagnetic radiation in the radiofrequency energy range, CT requires significant exposure to ionizing radiation. This is particularly concerning in children, since the greater number of remaining years in their lifetime compounds the effects of DNA damage. It has been shown that even very low doses of ionizing radiation can increase the lifetime risk of developing solid cancers [23]. Most centers use CT in pediatric populations only when other imaging modalities are inconclusive, unavailable, or contraindicated (as in the case of pacemaker dependence).

Utility for 3D Modeling and Simulation

Like MRI, cardiac CT imaging yields volumetric datasets that are appropriate for reconstruction and computational methods. In some situations, CT may be preferable due to its higher spatial resolution or when MRI is contraindicated. Additionally, CT is valuable for computational models that incorporate thoracic vasculature or airway structures, which are difficult to visualize with MRI or echocardiography. Even so, in most scenarios, the equivalence of MRI in structural imaging and paucity of functional information provided by CT reduce this modality's utility in computational studies.

Image Reconstruction and Model Building

Patient-specific cardiovascular simulation requires the development of a mesh of repeating geometric entities (often triangles) that represents the surfaces of the heart and/or blood vessels in question. This process can be divided into three main steps, including the following: (1) preprocessing of the raw imaging dataset, (2) surface or volumetric reconstruction, and (3) post-processing/refinement. Before these steps can be described in detail, it is vital to understand the properties of the original dataset. Medical imaging datasets intended for modeling and simulation usually take the form of a series of stacked grayscale images, wherein slice thickness determines resolution along the z-axis and each slice consists of a matrix of pixels in the x-y plane. Typically, there are an equal number of pixels in the x and y directions (e.g., 512×512), and each pixel has 2^n possible intensity values (e.g., $2^8 = 256$ values). The 3D unit volume defined by the x, y, and z dimensions of each pixel is called a voxel. While the in-plane dimensions of each voxel tend to be equal, the slice thickness often differs, leading to non-cubic voxels. Most tomographic datasets are acquired as transverse sections, so that the z-axis runs in the cranial-caudal direction.

Preprocessing

Image preprocessing is a general term describing operations performed on images at the lowest degree of abstraction. Preprocessing operations cannot add information to images; rather, they modify or decrease the existing information. The goal is to subdue distortions, such as noise

and some artifacts, and enhance features that improve the performance of further processing and analysis tasks, such as segmentation. Some preprocessing operations also serve to reduce the computation time required for the reconstruction.

Cropping

Cropping is always the first step in preprocessing. It involves removal of irrelevant outer parts of an image in order to focus attention on the anatomical structures of interest and reduce the computational load associated with subsequent filters and automatic segmentation techniques. In some cases, the user may also want to change the aspect ratio of the image. Cropping can be performed in the through-plane dimension by removing slices at either end of the imaging stack.

Interpolation

In general, interpolation occurs whenever the image is resized or remapped from one voxel grid to another. It works by using known data (voxel intensities) to estimate values at unknown points and is most often employed to improve the performance of automatic segmentation. If the voxel size is too large for optimal detection of sharp boundaries/edges in an image, interpolation can be used to decrease the in-plane voxel size and thereby artificially increase the image resolution. Less commonly, interpolation can be used to rotate an image. However, rotations (outside of 90°) generally deteriorate image detail. 3D interpolation can be a computationally intensive task.

Windowing

Windowing is the process of selecting a limited segment of the total range in voxel intensity values (as defined by the dynamic range of the imager) and mapping that segment to the full brightness scale (from black to white). After windowing, voxel intensities outside the selected segment will appear black or white, with no contrast. The selected segment is defined by both a center and a width. If a high window is chosen, regions that appear lighter in the original image will have good contrast. The purpose of windowing is to enhance the contrast in a particular segment of the total voxel intensity range. This is useful when two adjacent tissues are displayed with similar brightness in the original image and need to be distinguished. Figure 186.2 illustrates the process of image windowing.

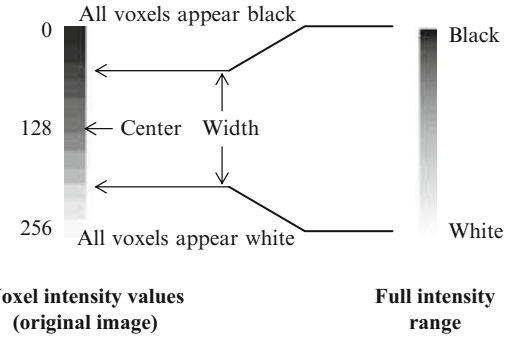

Fig. 186.2 Digital image windowing. After windowing, no contrast is detected in regions of the image occupied by voxels having intensities below or above the window boundaries

Filtering

The goal of filtering is to improve image quality and the performance of segmentation algorithms by removing noise and enhancing contrast or sharpness. In general, filtering is performed by defining a small matrix of numbers called a kernel, which is convolved with the image matrix. Convolution is a process that evaluates the sum of products of elements from two 2D functions as one function (kernel) moves over each element of the other function (image matrix). While there are too many filters to review here, it is useful to cover one example: the median filter. Median filters replace a given voxel with the median value of all of the voxels in the filter window. The larger the window, the greater the smoothing effect. Median filters are an effective method of minimizing noise, but excessive filtering can modify high-contrast edges and blur the image.

Volumetric Reconstruction

In order to extract pertinent anatomical information from 3D imaging datasets, boundaries separating different tissues have to be identified. This is most often accomplished through a process of

segmentation, which groups compartments that fall within a particular range of voxel intensities and separates them by identifying large intensity gradients. Through this method of brightness thresholding, multiple independent 3D structures can be identified within the same dataset. When applied to multiple image slices, segmentation yields a volume defining the tissue or compartment of interest (e.g., intravascular space). It is important to note that not all 3D reconstructions are suitable for computational modeling. In fact, only surface reconstructions, not volumetric reconstructions, are useful, since they establish precise physical boundaries for the model, which are required by most software packages. However, volumetric cardiovascular reconstruction via segmentation is often the first step in producing surfaces, since they allow for extraction of centerline vessel geometry and luminal diameters. It can also produce striking visual representations of the model.

Segmentation techniques can be classified as either manual, semiautomatic, or automatic. *Manual* segmentation is the simplest, but most time-consuming technique. Essentially, the user labels all voxels to be included in the reconstruction by hand. This method requires excellent knowledge of the anatomy and is time intensive, but often produces the highest-quality reconstructions with fewer post-processing requirements. *Semiautomatic* segmentation techniques require basic input from the user. One popular example is the seeded-threshold technique, in which the user selects a "seed voxel" within the compartment of interest and defines a range of voxel intensities that specifies membership in that compartment. The program then moves to neighboring voxels in an iterative manner, determining which belong with the original seed. Semiautomatic segmentation techniques generally involve some trial and error before the optimal threshold is identified. Though no segmentation technique is fully computerized, many require minimal input from the user and are termed *automatic*. For instance, the user may have to select the total number of compartments in an image, but will not directly determine compartment boundaries. In automatic segmentation, edges are assigned at voxels where the intensity function changes abruptly. Mathematically, an edge is simply a vector variable with a magnitude and direction. The magnitude reflects the degree of change in voxel intensity, while the direction indicates the path of maximum growth or decline in the intensity function. The boundary runs perpendicular to this direction.

Surface Reconstruction

While volumetric reconstructions produce closed 3D volumes, surface reconstructions yield open 2D surfaces. They are considered open because the fluid inlets and outlets of the model are uncovered. As discussed earlier, many reconstructions generate surfaces indirectly using the 3D volumes resulting from image segmentation. However, it is possible to generate surfaces directly. Most often, this is achieved by skeletonizing the vasculature of interest. Vascular skeletons store centerline vessel geometry and branching point information as a series of Cartesian coordinates. Lumen diameters at multiple locations are then extracted from the imaging dataset, allowing a surface model to be constructed. In simple models, it may be assumed that blood vessels have circular cross sections that are positioned perpendicular to the centerline curve at each coordinate.

When modeling the heart and blood vessels as rigid structures, it is sufficient to ignore vessel or chamber wall thickness. However, rigid wall assumptions drastically oversimplify cardiovascular simulations and may only be useful for educational purposes in modern practice. In order to account for the elastic and capacitive properties of the cardiovascular system, wall thickness information must also be extracted from the imaging dataset and incorporated into the model. The anisotropic material properties of myocardium, vascular smooth muscle, and fibrous tissue are well documented and also need to be defined before running simulations [24, 25].

Since computational simulations are numerical/iterative in nature, they cannot be applied to continuous 2D or 3D structures. As a result, the reconstructed vessel surfaces must be discretized

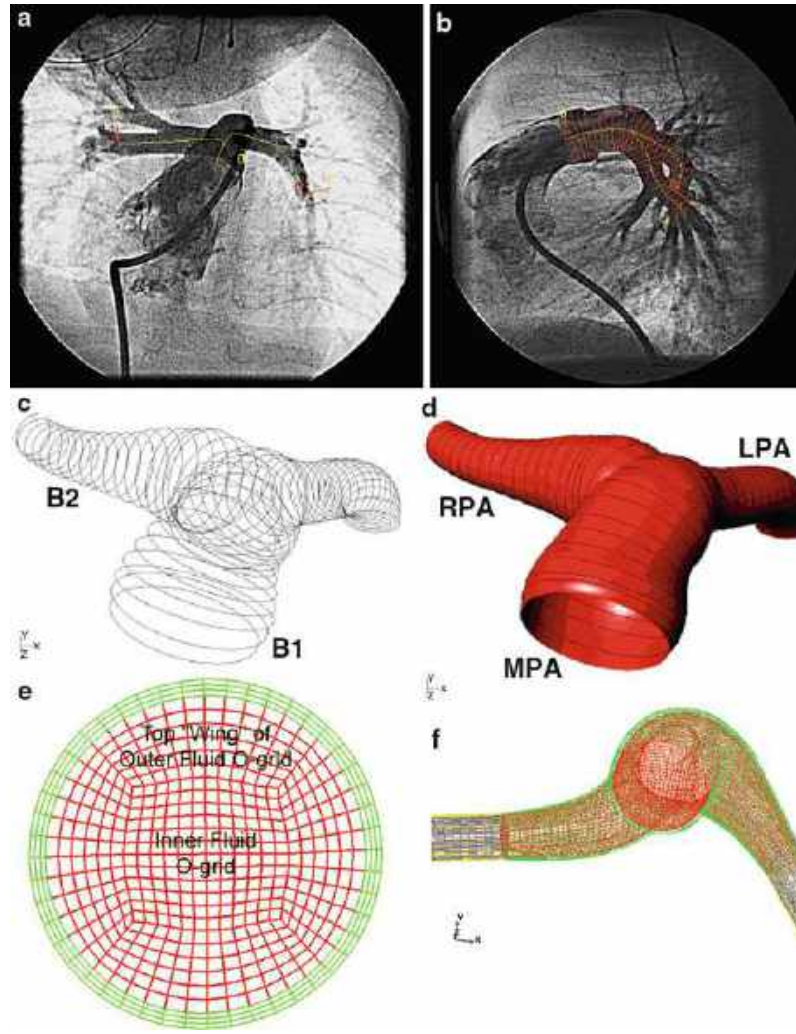

Fig. 186.3 Production of a patient-specific computational model of the pulmonary artery. (**a**) AP and (**b**) lateral pulmonary biplane angiogram images showing centerline vessel geometry and diameter information, respectively. (**c**) Vascular skeleton in solid modeling environment and (**d**) resulting surfaces. Note that the MPA and LPA are represented by one surface (B1) and the RPA by a second surface. (**e**) Complete mesh with fluid domains is shown in *red* and structure domains shown in *green*. (**f**) Typical mesh cross section

into a mesh of finite geometric elements. Smaller elements lead to greater computational complexity, but generally replicate the original surface more faithfully. Meshing is an automated process and is supported by many commercial and open-source modeling packages. Figure 186.3 demonstrates the creation of a patient-specific model of the left and right pulmonary arteries.

Post-processing

Post-processing is a critical step in computational model building. It is the practice of cleaning and refining the initial mesh that results from image reconstruction. Spurious entities, such as floating faces or artifactual holes, must also be removed from the mesh. An optimal mesh should be "watertight," should consist of equilateral triangles with similar areas, should be devoid of discontinuities that do not reflect the original anatomy, and should minimize the total number of triangular faces. Like preprocessing, post-processing can be divided into multiple steps, including mesh cleaning, re-meshing, and interactive refinement.

Mesh Cleaning

Occasionally, the reconstruction process will result in faces or vertices that do not contribute

to the model or present logical inconsistencies. These include faces or vertices that appear to be floating in the nearby 3D volume, zero-area or self-intersecting faces, duplicate or unreferenced entities, and spikes that originate from pixelation errors. Mesh cleaning entails removal of unwanted faces, vertices, and holes that are not part of the actual vascular tree. Meshes constructed from manually segmented images rarely need extensive cleaning. Spurious entities usually result from automatic segmentation or when 3D optical scanners are used to construct a mesh from a physical model.

Re-meshing

Re-meshing introduces more fundamental changes to the mesh than simple cleaning/repairing operations. The goal here is to ensure that the mesh consists of roughly congruent equilateral triangles and that it is not over-defined, without altering the overall shape, volume, or boundaries. Accordingly, the re-meshing process often involves decimation (limiting the surface feature density), edge simplification (iteratively replacing an edge separating two triangles having very small angles with a single vertex), and smoothing. A common smoothing function is the Laplacian filter, which repositions each vertex in a polygonal mesh based on the average position of its neighbors. It is vital to remember that re-meshing functions alter the actual mesh geometry; care should be taken to avoid over-filtering the mesh and removing relevant detail.

Computational Simulation

Once a 3D cardiovascular model has been discretized into mesh elements, the behavior of each component tissue or compartment can be specified. This is accomplished by establishing fluid and tissue domains within the model and applying time-dependent equations to each one. Since the model itself is composed of finite elements, the equations are simply time- and space-discretized counterparts of fundamental energy conservation laws. A numerical solver then calculates the solution to these equations at each node in the mesh over multiple iterations. This section covers basic models used to describe the behavior of blood (hemodynamics) or heart and vascular wall tissue (tissue biomechanics), and the complex ways in which these two elements interact (fluid–structure interactions). Special terms, such as *boundary conditions*, *convergence*, and *validation*, which are central concepts in computational simulation, are also defined.

Cardiovascular Hemodynamics

Imaging and diagnostic modalities are used routinely in the clinic to obtain information about the hemodynamic status of the pediatric patient. They are by nature "sparse" modalities, in that they provide time-limited and/or space-limited data. For example, pulsed wave Doppler provides velocity along the ultrasound beam as a function of time but within a small spatial volume. PC-MRI allows measurement of a larger number of dimensional parameters, including velocity vectors at various points in space and as a function of time. However, even MRI is highly limited in its capacity to capture the entirety of the hemodynamic field. Within this context, patient-specific computational fluid dynamics (CFD) simulation has great promise since it can fill in the gaps and thereby provide the most comprehensive hemodynamic measurements available for a particular patient. A very brief overview of the underlying process is provided below; readers are referred elsewhere for excellent reviews and books regarding CFD simulation in the cardiovascular system.

CFD involves the evaluation of the fundamental equations of fluid dynamics using computers. Since most real-world problems are far too complex for the relevant physics to be described using analytical solutions, numerical methods are used to provide estimates of the solution. These methods involve the discretization of the underlying *nonlinear* equations into sufficiently small intervals of space and time and subsequent simultaneous solution of the multiple (now-linearized) equations using high-performance computers. The fundamental equations of fluid dynamics represent elegant mathematics and are highly

complex. Practically, however, it is useful to think of them as variations of Newton's second law (Force = mass × acceleration), also known as the *Navier–Stokes* equations, and the principle of mass conservation, also known as the *continuity* equation. In cardiovascular hemodynamics, the "Force" side of the Navier–Stokes equations comprises the forces that propel blood forward minus the forces that impede blood flow. In general, the primary force that propels blood flow is the pressure gradient between the upstream (cardiac) side and the downstream (venous) side; gravitational gradients are usually ignored. The forces that impede blood flow involve fluid resistance (dominated by blood viscosity) and, under certain conditions, turbulence, which increases dissipation of useful fluid energy into heat. The non-Newtonian nature (shear thinning) of blood rheology complicates the situation further, since viscosity (and hence resistance) may vary substantially within different regions of the cardiovascular system. These terms are equated to the "mass × acceleration" side, which involves both temporal (change in velocity as a function of time) and convective (change in velocity as a function of space) acceleration, multiplied by blood density (a constant). Various simplifications of this formula can be generated if one assumes minimal or no temporal acceleration (i.e., steady flow) and minimal or no change in convective acceleration (i.e., no change in blood vessel diameter). However, for most conditions, such simplifications cannot be made and all components of the Navier–Stokes equations need to be considered. In light of the underlying nonlinearity, this removes any hope of achieving a closed-form analytical solution and requires computational methods for the solution. The basic equation of incompressible fluid flow is shown below, where u is the velocity of an arbitrary portion of the fluid, t is time, P is pressure, ρ is fluid density, V is kinematic viscosity, and ∇ and ∂ are the del and differential operators, respectively. This form ignores gravitational and turbulence forces:

$$\frac{\partial u}{\partial t} + u \cdot \nabla u = -\frac{\nabla P}{\rho} + V\nabla^2 u$$

As with all computational simulations, the computer simply crunches through the equations with the parameters provided and does not care whether it is solving the correct problem or indeed whether the problem is within the bounds of physical reality. Therefore, it is imperative that correct boundary conditions be applied to ensure the computer is solving the correct problem.

Boundary Conditions

Just as patient-specific imaging data are used to establish model geometry, patient-specific clinical data are incorporated into boundary conditions. Boundary conditions are simply the defining parameters or constraints placed on the ends of the computational model. In other words, they are the input and output states of the process being simulated. They can take several forms, such as blood velocity, pressure, or resistance/impedance, and strategies concerning their acquisition and application differ between inlets and outlets. Those familiar with generic numerical simulations are aware that boundary conditions are necessary to achieve an explicit (non-generalized) solution and that the accuracy of the solution is often very sensitive to the accuracy of the boundary conditions. In general, the further the boundaries are from the primary area of interest in the model, the less influence they will have on the local results of a simulation. Then again, it is practically impossible to create a computational model of the entire cardiovascular system, due both to the spatial resolution limitations of imaging systems and the excess computational load introduced by large models. Because of this, the selection of cutoffs for a model can significantly impact its ultimate value and involves a compromise between accuracy and computation time.

Inlet Conditions

Incorporation of inlet conditions is usually straightforward since there are rarely more than two inlets in a model and they are generally large enough to allow for accurate measurement of blood velocity by ultrasound or PC-MRI techniques. That said, in some cases, standard

institutional practices involving flow measurement for various congenital defects will have to be modified. It is also important to remember that due to resolution issues, especially in pediatric patients, the measured velocity fields are rarely applied directly. Instead, they are integrated to calculate flow rate and subsequently mapped to a prototypical flat, parabolic, or Womersley theory-based velocity profile [26]. Examples of single inlets include the pulmonary artery for tetralogy studies, the aorta for coarctation simulations, and the superior vena cava for Glenn procedures. In simulated Fontan repairs, the superior and inferior venae cavae are typically both used as inlets. While some studies set a uniform blood flow at the inlets for the sake of simplicity, others have shown that accounting for cardiac [27] or respiratory [28] pulsatility significantly changes the predicted energy dissipation in simulations of total cavopulmonary connection procedures.

Outlet Conditions

In models that include multiple branching points, outlets are greater in number and smaller in diameter than inlets. As a result, it is usually difficult to acquire time-dependent flow rates for outlets directly from clinical data. Moreover, when constant pressure values are used as outflow boundary conditions, the calculated energy losses and flow/pressure divisions are generally inaccurate unless the model extends to the level of capillaries [29]. Outlet conditions that describe the ratio between pressure and flow, such as resistance and impedance, are thus preferred. A pure resistance boundary condition can overpredict both the pressure pulse and rate of decay and thus overpredict vessel wall displacements [30]. Instead, researchers can employ a three-element (resistor-capacitor-resistor) Windkessel model to relate pressure and flow at outlets. Such models evaluate impedance, in the frequency domain, and can be formulated with the assumption of either periodic or fully transient solutions. When clinical measurements are not available for small branches, assumptions can be made to approximate outlet conditions. For instance, Murray's law relates the luminal radii of daughter branches to the radius of a parent vessel. Some researchers assume that the relative resistances of small branches are proportional to their cross-sectional area.

Cardiovascular Tissue Biomechanics and Fluid–Structure Interaction

In addition to the Navier–Stokes and continuity equations, most cardiovascular simulations also solve the equations governing the mechanical behavior of blood vessels. Such solutions take into account the dynamic behavior of blood vessels that can distend and contract in relationship to the cardiac cycle. Indeed, in many diseases, particularly those that involve changes to structural protein configurations (Marfan's syndrome, scleroderma, pulmonary hypertension, etc.), altered blood vessel mechanical properties may change hemodynamics to significant degree. Thus, "fluid–structure interaction (FSI)" models have become increasingly popular in simulating the cardiovascular system, and multiple methodologies have been proposed describing how such models can be applied to study the pediatric cardiovascular system in health and disease.

Before robust FSI methods were developed, cardiovascular simulations modeled blood vessels as rigid walls which did not deform as a function of transmural pressure gradients. Accurate quantification of wall motion due to blood flow or muscle/soft-tissue effects requires information about vessel wall properties and comes with a higher computational cost. However, these additional requirements are balanced by the improved description of hemodynamics and wall stresses and strains that FSI models produce. Vessel wall compliance is difficult to estimate, especially in a patient-specific manner; however, new noninvasive PC-MRI and ultrasound-based techniques have shown success in quantifying various measures of compliance in the research setting.

FSI techniques require coupling and simultaneous solution of equations governing blood flow (discussed above) and tissue biomechanics. Before this can be done, it is important to understand the physical laws underpinning common

models of arterial behavior. One of the most basic descriptions of blood vessel dynamics is provided by Laplace's law, which relates wall tension (T), internal pressure (P), and radius (r) as follows:

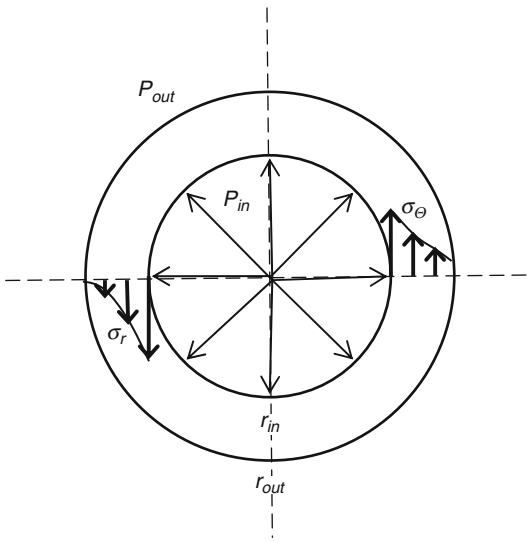
$$T = Pr$$

Essentially, the larger the vessel radius, the higher the wall tension required to withstand a given blood pressure. However, blood vessels cannot accurately be modeled as thin-walled tubes, and the variation in stress across the radial dimension of a blood vessel wall must be accounted for. Lamé's equations provide a convenient description of the radial (σ_r) and tangential (σ_θ) stresses on an arbitrary element in a thick-walled cylinder:

$$\sigma_r = \frac{P_{\text{in}} {r_{\text{in}}}^2 - P_{\text{out}} {r_{\text{out}}}^2}{{r_{\text{out}}}^2 - {r_{\text{in}}}^2} - \frac{{r_{\text{in}}}^2 {r_{\text{out}}}^2 (P_{\text{in}} - P_{\text{out}})}{r^2 ({r_{\text{out}}}^2 - {r_{\text{in}}}^2)}$$

$$\sigma_\theta = \frac{P_{\text{in}} {r_{\text{in}}}^2 - P_{\text{out}} {r_{\text{out}}}^2}{{r_{\text{out}}}^2 - {r_{\text{in}}}^2} + \frac{{r_{\text{in}}}^2 {r_{\text{out}}}^2 (P_{\text{in}} - P_{\text{out}})}{r^2 ({r_{\text{out}}}^2 - {r_{\text{in}}}^2)}$$

In the above equations, P_{in} and P_{out} refer to the internal and external pressures, respectively, and r_{in} and r_{out} refer to the inner and outer radii of the vessel. External pressures are often ignored, yielding the following distribution of radial and tangential stresses:



Another convenient expression of Lamé's thick-walled, plane-strain cylindrical model directly relates pressure and diameter and is given by the equation:

$$d_i = \left(\frac{1+v}{E} \frac{AB^2}{B^2 - A^2} + \frac{1+v}{E} \frac{A^3}{B^2 - A^2} \right) P_{\text{in}} + A$$

where d_i is internal diameter, v is Poisson's ratio, E is Young's modulus, A is internal diastolic diameter, and B is external diastolic diameter (A + wall thickness). More advanced models of tissue biomechanics take into account the complex constitutive properties of arterial tissue. Some studies have used a linear elastic model to describe arterial wall behavior, which assumes that the stress–strain relationship is linear, ignores yielding stress states, and only accounts for small deformations. This can be a reasonable first approximation to arterial wall behavior, as large arteries display nearly linear and isotropic material properties over the physiological pressure range [31]. However, linear elasticity is merely a simplification of the more general nonlinear theory of elasticity, and arteries are ultimately nonlinear and anisotropic in nature. Perhaps the most prolific viscoelastic tissue model is the quasilinear viscoelasticity (QLV) theory proposed by Fung [32] which can represent both linear viscoelastic and nonlinear elastic responses. Unlike entirely elastic materials, viscoelastic materials dissipate mechanical energy when subjected to cyclical mechanical loading. Several groups have developed and applied nonlinear hyperelastic models to a variety of biological tissues [4, 33, 34]. Hyperelastic materials are nonlinearly elastic, isotropic, and incompressible, have properties that are generally independent of strain rate, and are assumed to be capable of recovering large strains without damage. Rubber is a prototypical hyperelastic material. Most hyperelastic models have a microstructural basis and rely on a detailed understanding of arterial histology, connective tissue composition, and fiber orientation. Considerable work has focused on the orientation of collagen fibers in arterial walls. Some models have employed statistical distributions to account

for natural variation in the orientation of collagen fibers [35]. As with CFD, the actual formulations underlying arterial tissue biomechanics are complex, and readers are referred to more detailed reviews or texts addressing fundamental biomechanical principles. To avoid the complexities of image-based coupled FSI solvers, many groups have relied on reduced order models. In one-dimensional network models, researchers assign branching patterns, length, diameter, and material properties of vessel segments. In zero-dimensional lumped parameter models, circuit variables such as resistance, capacitance, and inductance are assigned to achieve the desired hemodynamic characteristics of upstream or downstream domains [36].

A final consideration when modeling arterial tissue is that of growth and remodeling. Accounting for long-term vascular adaptation can increase the complexity of the model, but is often important when attempting to assess the long-term effects of surgical intervention. There are two widely accepted approaches for modeling growth and remodeling in soft tissues. Rodriguez and colleagues proposed a mathematically convenient "kinematic growth" theory in 1994 which focused on the outcome of growth in lieu of the cell-mediated mechanisms by which it occurs [37]. Then, in 2003, Humphrey and Rajagopal generalized a "constrained mixture" approach which formulated the stress response by applying a rule of mixtures to tissue constituents whose mass fractions are continually evolving [38]. In arteries, it can accurately describe the response of vascular smooth muscle and collagen fibers to changes in mechanical stresses. Both approaches have led to a diverse array of applications, particularly in disease modeling, but the constrained mixture approach is generally considered to be more accurate when modeling unpredictable developmental or disease processes [39].

Iterative Refinement and Validation of Numerical Simulations

Once acceptable flow and pressure solutions are produced, they can be visualized at any location within the framework of the model or used to compute additional quantities of interest, including energy losses, wall shear stress, pressure gradients, and velocity fields. In some cases, the solver only converges on a final solution after multiple iterations of the simulation. These iterations can switch between mesh generation and solution of the governing equations or between these solutions and available clinical data. In the former case, the mesh is generated using sequentially greater numbers of elements, in a process called mesh convergence, until greater mesh detail no longer significantly alters the solution. When clinical data are available to corroborate the initial results of the simulation, the simulation parameters can be tuned to match them. When dealing with lumped parameter models, resistance, capacitance, and inductance parameters can be adjusted to match measured flow or pressure distributions from patient-specific models.

For many numerical modeling applications, validation is accomplished through comparison to an analytical solution. In this case, however, computational predictions must ultimately be compared with in vivo or in vitro experimental data. Comparison with in vivo measurements is quite challenging, but a few successful examples can be found in the literature. An early example is the work by Ku et al. who compared predicted flow rates with those obtained through MRI techniques in thoraco–thoraco aortic bypass procedures in pigs [40]. More recently, Zhang et al. validated their finite-element pulmonary artery model by obtaining patient-specific pressure-diameter curves for a single location, using both catheterization and ultrasound measurements [41]. When more complex anatomy is involved, making accurate and comprehensive biological measurements difficult, many researchers have turned to in vitro validation techniques. For instance, Hoi et al. successfully developed a validation study of CFD methods with particle image velocimetry data in an in vitro model of a cerebral aneurysm [42]. Figliola et al. reported on the construction of physical mock circuits useful in validating novel computational simulations of right heart circulation, Fontan circulation, and aortic coarctation [43]. Validation with

in vitro models has its place, but necessitates models with a high degree of physical and kinematic accuracy. Ultimately, the take-home message for investigators is that in vivo or in vitro validation serves a critical role in assessing the value of computational models. It is insufficient to simply verify that the simulation results are quantitatively realistic.

Applications in Congenital Heart Disease

This section provides examples of computational models used to optimize surgical/interventional procedures in pediatric cardiology or to evaluate the sequelae of cardiovascular device placement.

Tetralogy of Fallot

Tetralogy of Fallot (TOF), a congenital syndrome defined by pulmonary stenosis, right ventricular hypertrophy, VSDs, and an overriding aorta, accounts for the majority of patient cases with late-onset right ventricular failure. Repair of TOF typically involves closure of the septal defect and repair of the narrowed right ventricular outflow tract, with or without pulmonary valve replacement. Unfortunately, surgical management of TOF commonly results in anatomical and functional anomalies if not planned correctly. For instance, appropriate timing of pulmonary valve replacement is critical for avoiding permanent complications, related to severe pulmonary regurgitation and right ventricular dilation, following initial TOF repair [44].

Computational work in this area has largely been driven by del Nido and colleagues [6, 45], who have generated patient-specific bi-ventricle models to simulate pulmonary valve replacement surgery and optimize patch design. Cardiac magnetic resonance has become the reference modality in the assessment of TOF patients; the authors naturally used this modality to extract patient-specific anatomical information, as well as deformation and flow data. These models included fluid–structure interaction, anisotropic material properties, and active contraction. They were used to simulate blood flow, ventricular wall motion, and stress–strain distributions. Ultimately, the authors aimed to assess the effect of various remodeling procedures on right ventricular function and to identify the best patch design (conventional patch without scar tissue trimming versus small patch with aggressive scar tissue trimming and ventricular volume reduction). Because the authors used pre- and postoperative MRI data to adjust and validate the model, they were able to verify its accuracy and utility. They were also able to conclude that pulmonary valve replacement with a smaller patch and aggressive scar tissue removal yielded lower stresses in the patch area, which could aid recovery of right ventricular function. In the future, data from catheterization-MRI studies may provide even more detailed data on right ventricular mechanics, such as elastance or ventricular-arterial coupling [46], and further advance TOF simulations. Regardless of future developments, computational modeling will certainly have a role in comparing the suitability of various reconstructive options for the right ventricle in TOF patients.

Pediatric Ventricular Assist Devices

Ventricular assist devices (VADs) have found success in a variety of settings. The majority of these devices are placed in adult patients with end-stage heart failure in order to unload the failing left ventricle and restore appropriate systemic blood pressure. Such patients are candidates for heart transplant and VAD placement can serve as a bridge until a donor organ is available. As expected, there are several examples in the literature of CFD studies aimed at predicting the influence of implanted VADs on pressure and flow patterns in adults [47, 48]. Advances in pediatric mechanical circulatory support and modeling of VAD placement have lagged slightly. Extracorporeal membrane oxygenation (ECMO) is still the gold standard, likely due to its extensive use in the treatment of respiratory failure. In addition, new technologies for mechanical support of failing circulation have to contend

with pediatric-specific issues, including growth and development, atypical anatomy associated with congenital defects, and the increased risks related to anticoagulation and infection. Clinical pediatric experience in the United States is largely limited to a single centrifugal pump-based system, but several groups have evaluated the utility of VADs to support failing Fontan circulation in the research setting. For instance, Rodefeld and colleagues designed and tested a cavopulmonary assist system which used dual axial flow pumps placed in the inferior and superior venae cavae of an ovine total cavopulmonary connection (TCPC) model [49]. Similarly, Riemer et al. evaluated the influence of a single axial pump, positioned in the inferior vena cava of an ovine TCPC model, on cardiac output [50].

Computational single-ventricle models have also been developed to study the value of VADs in alleviating the high systemic venous pressure and poor pulmonary circulation that can accompany univentricular surgical corrections. In 2005, Pekkan and colleagues published their work developing a lumped parameter model of single-ventricle circulation coupled to a continuous or pulsatile VAD [51]. After assessing four unique pump designs and three patient-specific TCPC pathologies, they identified a few combinations that gradually produced adequate total cardiac output and physiologic mean pulmonary artery and systemic venous pressures. They also observed that post-Fontan elevated systemic venous pressures were reduced by the simultaneous action of the VAD and changes in the systemic venous compliance, highlighting the importance of vascular remodeling. More recently, Lacour-Gayet et al. developed a nonspecific computational model to evaluate a new axial flow pump designed to support failing Fontan circulation. They demonstrated a low suction inflow pressure and a moderate outflow pressure boost. Specifically, over a range of central venous pressures and a constant pulmonary resistance, they achieved an average increase in cardiac output of 2 L/min without significant risk of hemolysis. In this case, the computational study was validated by a physical in vitro model.

Interventional Procedures

Several transcatheter procedures, including balloon angioplasty/valvuloplasty and repair of atrial and ventricular septal defects, have become part of routine clinical care in pediatric cardiology. As new devices and procedures are approved and accumulate safety and efficacy data, one can expect to see broad acceptance of additional percutaneous procedures, such as implantation of flow restrictors or vascular plugs and stenting of patent ductus arteriosus. Like surgical operations, interventional procedures are prime candidates for predictive modeling and simulation.

Examples of such studies in the literature are limited, but can be found. For instance, Hunter et al. evaluated the effects of atrial and ventricular septal defect closure on the proximal pulmonary vasculature using a pediatric patient-specific computational model [52]. Limiting their model to the main pulmonary artery and right/left branches, they extracted pertinent vessel centerline and diameter information from x-ray angiogram images of two patients with pulmonary hypertension. After developing a structured surface mesh, they estimated wall thickness as a function of lumen diameter and applied patient-specific boundary conditions and coupled fluid–structure equations. Using this model, the authors were able to predict transient arterial wall motion and hemodynamic parameters, including blood velocity, pressure, and wall shear stress. They found that while defect closure resulted in only minor changes in transient arterial strain, there was a significant drop in wall shear stress in the post-intervention state. This was an interesting finding, since wall shear stress has a strong influence on downstream vascular tone and, ultimately, pulmonary hypertensive disease.

Conclusions and Future Directions

Cardiovascular modeling is no longer an immature field, but today's simulations still make many assumptions regarding anatomy and function as a result of limitations in imaging techniques, bounds on computational complexity,

or simplifications inherent to CFD and tissue biomechanics algorithms. For instance, many models assume that blood vessels have uniformly circular cross sections or derive wall thickness as a function of lumen diameter [2, 41], rather than extracting this information from imaging datasets. Moreover, few simulations take into account adaptive phenomena, such as long-term changes in cardiac and blood vessel behavior due to local remodeling and patient growth [53]. Another limitation of computational approaches to surgical planning is that there is no immediate and quantitative way of identifying the direct benefits of simulation. At the moment, it is difficult or impossible to measure the improvements in diagnosis, surgical decision-making, surgical procedures, or patient outcomes that result from the use of computational simulations [54]. It is not appropriate to speculate about the therapeutic options that would have been selected without access to computational tools, and it will be many years before randomized clinical trials are feasible in this field. For the moment, the accuracy of these methods can only be judged through comparison with patient-specific clinical data or in vitro models. Processing power also needs to develop further. Patient-specific Navier–Stokes simulations for detailed meshes ($\geq$1 million elements) and multiple cardiac cycles may take several days on typical machines, even when using modern parallel processing technology.

Even in light of these limitations, it is clear that patient-specific computational modeling has a bright future. The availability of robust open-source software packages for multidimensional image visualization, processing, segmentation, and registration (VTK, ITK, and applications built on these toolkits) now allows researchers to focus their efforts on specific applications, rather than tool development. The possibilities for this field are numerous and include the following:

1. Internet-based simulation and cloud computing to centralize data processing power and avoid software distribution hurdles [55]
2. Complete automation ("1-click" modeling and simulation)
3. Insight from fields like meteorology and geology in which computational models are more developed and highly integrated
4. Rapid 3D printing of simulated cardiovascular anatomies and incorporation into clinical decision-making [56]
5. Highly complex cardiovascular models, taking into account biomechanical feedback loops, molecular signaling pathways, and myocardial electrical activity

Regardless of what the future holds for computational modeling and simulation in pediatric cardiology, it is clear that progress will only be made through cooperation and understanding between clinicians and engineers. If the examples described in this chapter are prognostic of the rate of innovation yet to come, mainstream use of patient-specific simulations in clinical decision-making may be around the corner.

Clinical and Translational Research in Pediatric Cardiology and Cardiac Surgery

187

Michael G. Gaies, Sara K. Pasquali, Mark Russell, and Richard G. Ohye

Abstract

Performing clinical and translational research is a cornerstone for practicing evidence-based medicine. Yet, the majority of current practice in congenital heart disease is not based upon rigorous scientific data. The gold standard for evidence-based practice is the randomized clinical trial. Large, multi-institutional randomized clinical trials have been accomplished in congenital heart disease, including the NHLBI-funded Single Ventricle Reconstruction trial performed by the Pediatric Heart Network. However, many challenges exist to these types of trials, including cost, limited numbers of patients at any single center, and the effort necessary to complete such ambitious projects. Valuable information can also be gained from analyzing large databases and registries, such as the Society of Thoracic Surgeons Database. These databases and registries are facilitated by multi-institutional collaboration.

Introduction

Practicing evidence-based medicine is the optimal method for caring for the patients. In addition to being the gold standard for medical decision-making, outside groups, whether the government, third-party payers, parents, or US News and World Report, are rightfully holding everyone to this high standard. Yet, in pediatric cardiology and cardiac surgery, evidence to guide optimal care is limited. Many obstacles exist to performing clinical and translational research to develop these data, and the majority of current practice is based upon level C evidence (Table 187.1). The barriers to conducting clinical research in this population include the rarity and heterogeneity of disease, limited research infrastructure, cost of conducting large trials, and difficulty in identifying valid endpoints [1–3]. Instead of clinical trial data, most treatment decisions are based on small observational studies, extrapolation from adult data, or clinical experience. A recent survey conducted at Children's Hospital Boston evaluated over 1,000 clinical decisions made by 10 pediatric cardiologists during a 1-week period and found that <3 % of clinical decisions were based on a research study specific to the clinical question at hand [4].

There are several reasons why this approach to care may not be optimal [3]. First, off-label use of drugs and devices without adequate pediatric efficacy and safety data is common [5, 6]. It has been shown that >75 % of pediatric inpatients with cardiovascular disease receive one or more medications off-label and 31 % receive ≥ 3 off-label medications [6]. Inadequate information on drug efficacy and safety may deny children potential therapeutic benefits and can also place them at risk for adverse events. It is known that children are not simply "tiny adults," and adult dosing cannot necessarily be extrapolated to the pediatric population. For example, the optimal dose of clopidogrel in infants and children with a cardiac condition at risk for arterial thrombosis was found to be only one fifth of what would be given if extrapolating from adult data [7]. In addition, with limited evidence to guide the care of children with congenital heart disease, there are few best practice guidelines and significant variation in many aspects of care from center to center. Several recent analyses have demonstrated wide variation extending to numerous aspects of hospital and follow-up care [8–12]. In addition to variation in practice, multiple reports have demonstrated that outcomes also vary widely across centers [13–15]. For example, an evaluation of 2,342 infants from 69 centers undergoing the Norwood operation in the Society of Thoracic Surgeons (STS) Congenital Heart Surgery Database from 2005 to 2009 found that institutional adjusted in-hospital mortality rates varied from 7 % to 42 % [14].

For patients with congenital cardiac defects, clinical and translational research endeavors often require cooperation across multiple centers to enable the recruitment of sufficient numbers of patients with a specific cardiac condition to allow meaningful comparisons. Many different professional organizations and societies across pediatric cardiac surgery, cardiology, critical care, and anesthesia have developed platforms to encourage and support collaborative research. For example, in Europe, the European Association for Cardio-Thoracic Surgery (EACTS) society and the Association for European Paediatric and Congenital Cardiology (AEPC) encourage collaborative research, enhance professional development of member physicians, and promote best professional practices in pediatric cardiac care. In the United States, the American Heart

Table 187.1 Levels of evidence

Level of evidence	Data source

Association established the Council for Cardiovascular Disease in the Young with a similar focus. To more directly promote multicenter research efforts aimed at improving the care and outcomes for patients with congenital heart disease, the National Heart, Lung and Blood Institute of the National Institutes of Health established the Pediatric Heart Network in 2001 [2]. Since its creation, the PHN has developed observational studies and randomized clinical trials to address a broad range of issues related to congenital and acquired cardiac conditions in pediatric patients. The clinical trials have included an assessment of the addition of methylprednisolone to standard therapy on reducing coronary complications in patients with Kawasaki disease [16], an examination of ACE inhibitor treatment on growth and developmental outcomes in infants with a single-ventricle type of cardiac defect [17] and an evaluation of short- and long-term outcomes after two different approaches to Single Ventricle Reconstruction in patients with a functional single left ventricle [18].

Performing a Multicenter Randomized Controlled Trial: Lessons Learned

Background

Randomized trials are generally considered the gold standard for generating evidence and evaluating new therapies. The Single Ventricle Reconstruction (SVR) trial was a multi-institutional randomized trial comparing the modified Blalock-Taussig shunt to the right ventricle-to-pulmonary shunt for the Norwood procedure for single right ventricle anomalies. The NHLBI-funded SVR trial enrolled 555 patients from 15 North American centers through the Pediatric Heart Network (www.pediatricheartnetwork.com). The primary endpoint was a composite of death or cardiac transplantation at 12 months post-randomization. Further details on the Pediatric Heart Network and the SVR trial results have been previously published [2, 19, 20].

Preparation

Generally, medical school curriculum does not prepare physicians particularly well to perform clinical trials, and gaining background knowledge requires additional training. One needs to understand the various types of clinical trials; while considered the gold standard, a randomized clinical trial is not the only valuable research method, and other alternatives are reviewed later in this chapter. An understanding of basic biostatistics and general concepts of effectiveness versus efficacy, timing, and equipoise are important building blocks. There are various methods to developing these skills. Formal training, such as pursuing an MPH or the Robert Wood Johnson Clinical Scholars Program, requires a greater time commitment, but is more complete. For busy clinicians, many courses on clinical trials are offered locally, regionally, and nationally, such as the American College of Surgeons (ACS) Course in Clinical Trials Methods and the ACS/NIH Young Surgical Investigators Conference. There are also many good textbooks and articles on clinical trials and the importance of evidence-based medicine [20–22].

For beginning clinical researchers, in addition to getting a degree of basic understanding through course work and/or reading, a research mentor is crucial. The mentor provides guidance in all aspects of embarking on a career in clinical research, from education to protocol and grant preparation and through the conduct of the trial.

Mentors may be found within your division, or even outside of your department or institution.

Designing a Trial Protocol

The trial protocol is first and foremost designed to answer one study question. Identify this primary aim and remember that the protocol is formulated to answer that specific question. Secondary aims are secondary but are also answered by the study design. The primary question, as well as any secondary questions, must be carefully thought out and clearly defined. Subgroup analyses are prespecified and are based upon data from the primary aim. All questions and analyses are predetermined before the start of the trial. The data are not retrospectively mined for significant findings.

Limit the dataset to only the variables that are needed to answer the study questions. Avoid the temptation to collect variables that "might be interesting" or "we might want to look at later." Collecting unnecessary data only increases the risk of data entry and type I errors, is expensive, and is time consuming. Think ahead to how each variable will ultimately be used to produce some useful conclusion for publication. In addition, remember that all selected variables must be recorded in a consistent manner, or clearly defined or "operationalized," so all centers will be collecting exactly the same data. Each center will need to undergo periodic data quality assurance review of a cross section of all of the variables. Thus, for all of the above reasons, limit the dataset to those variables necessary to answer the primary and secondary aims.

Large clinical trials require the expertise of an established Data Coordinating Center. The Data Coordinating Center will be responsible for developing the data collection system, producing a manual of operations, training each site's research coordinator, collecting and managing the data, performing data quality assurance and site visits, circulating updates to the protocol, and ultimately analyzing the data.

Form a Data Safety Monitoring Board early and get them involved with protocol design. Do not underestimate the importance or complexity of adverse event recording, especially in a surgical trial. The key to adverse event recording, like any data collection, is consistency. Adverse event recording and analysis needs to be designed with the same rigor as a secondary aim.

If the protocol is to be submitted for federal funding, it is useful to visit the division of the NIH where the grant will be submitted for a pre-submission critique. The administrative arm of the branch of the NIH is separate from the study section and is very interested in helping to develop both the protocol and the grant.

Center Recruitment

Selecting the correct centers to participate in the trial is crucial, as the success or failure of the trial is dependent on patient recruitment. Center volume is important, as it costs just as much to prepare a large center as it does for a small center. However, researchers ought to keep in mind that a large center that recruits 30 % may enroll fewer patients than a small center that recruits 100 %, so volume is not the only important component to successful enrollment. As a general rule of thumb, minimize the number of centers.

Identify a site principle investigator (PI) and study coordinator at each center. They will be responsible to the conduct of the trial at their site, and hence it is important to select personnel who will be willing to put forth the effort to make the trial a success. They will also comprise the trial steering committee. Monthly or bimonthly steering committee conference calls are also important to cover significant issues and keep people engaged. Although the steering committee will be responsible for large-scale decisions, small groups or subcommittees are more efficient, easier to manage, and very useful when there are issue to work out quickly.

Investment

The single most important factor in the success of the trial is the degree to which the participants

are invested. Getting the centers invested in the trial is the key to recruitment, and recruitment is the key to the success of your trial. Involve them actively in the protocol development, so they see the protocol is their own creation. Recruiting patients to do research is very time consuming and requires an incredible amount of personal dedication. It cannot be handed off to the lowest person on the totem pole, who is usually the least well equipped to discuss the trial with the family. The more invested the site PI is in the trial, the more likely you will be successful.

Trial Maintenance

No protocol will be perfect, and there will likely be the need to make small changes during the conduct of the trial. However, remain focused, many proposed changes will not be necessary and even minor changes can be complicated and costly with respect to both time and money. Lastly, be proactive, especially with issues of maximizing enrollment, as it is enrollment that will make or break the success of the trial.

Summary

A well-designed randomized clinical trial provides the highest level of evidence for evaluating new therapies. However, clinical trials are not always feasible for every research question and can require significant funding and resources. In addition, there can be limited generalizability depending on inclusion and exclusion criteria. Several trials that have been performed in the congenital heart disease population have been limited by baseline knowledge gaps and have failed scientifically [23, 24]. These knowledge gaps include natural history of disease, baseline event rates, baseline treatment rates, and available sample size [3]. Thus, other methods for performing clinical research are often needed, including the use of large, multicenter databases and registries.

Multicenter Databases and Registries in Pediatric Cardiovascular Research

Background

Leveraging multicenter databases and registries in pediatric cardiovascular research can help to address many of the current knowledge gaps and aid in better planning future studies. These data sources can provide adequate power to answer important clinical questions and overcome the relative rarity and heterogeneity of many conditions [3]. Multicenter databases also allow evaluation of practice variation between institutions, and how this variation impacts outcome. This type of evaluation can help to identify areas of focus for future prospective study and may be a first step toward defining best practices. Many types of outcomes and comparative effectiveness studies can be conducted using databases and registries, and these analyses can also provide data on sample sizes, event rates, and natural history, which may aid in better planning future studies and trials [3].

There are currently multiple different databases and registries that collect information on pediatric cardiac patients and have become increasingly utilized in clinical research. Some of the largest databases include:

1. The STS Congenital Heart Surgery Database (pediatric cardiac surgery data)
2. The Congenital Cardiac Anesthesia Society (CCAS) Database (pediatric cardiac anesthesia data)
3. The Extracorporeal Life Support Organization (ELSO) Registry (extracorporeal membrane oxygenation data on cardiac and noncardiac patients)
4. The Virtual Pediatric Intensive Care Unit System (VPS) Database (intensive care unit data)
5. The American College of Cardiology Improving Pediatric and Adult Congenital Treatment (IMPACT) Database (cardiac catheterization data)
6. The Pediatric Heart Transplant Study Group Database (transplant data)

Table 187.2 Key elements of databases and registries [35]

Nomenclature: Use of common language and nomenclature
Structure: Established and defined core dataset
Complexity stratification: Mechanism for adjustment for differences in case mix and complexity across institutions
Data verification: Verification of the completeness and accuracy of the data collected
Subspecialty collaboration: Collaboration between medical and surgical subspecialities
Longitudinal follow-up: Incorporation of protocols for longitudinal follow-up after hospital discharge
Quality improvement: Strategies to facilitate quality improvement across institutions

This list is not comprehensive and there are several additional clinical registries, including databases related to cardiac catheterization, cardiomyopathy, and ventricular assist devices [3, 25–28]. The STS Congenital Heart Surgery Database is the largest existing registry in the field. It currently contains information on nearly 200,000 operations performed since 1998 at 96 centers across North America and represents approximately 80 % of all US centers performing pediatric heart surgery [29]. This registry provides biannual feedback reports to participating centers regarding outcomes benchmarked to national data for the purposes of quality improvement. The database has also been used extensively to conduct clinical research, including evaluation of outcomes following congenital heart surgery and associated factors, comparative effectiveness studies, and assessment of variation in outcome across institutions [14, 30–36].

Key Elements of Databases and Registries

In order to serve as a platform for meaningful outcomes analyses and quality improvement across institutions, several key elements of databases/registries have been proposed by Jacobs and colleagues as displayed in Table 187.2 [37]. The use of a common nomenclature and database structure with clearly defined data elements and variables is of primary importance [38]. Congenital heart defects are relatively rare and heterogeneous. The use of different nomenclature systems can make comparison of outcomes across centers and multicenter research studies virtually impossible. In order to address this, the International Pediatric and Congenital Cardiac Code was developed through an international collaborative effort of pediatric cardiologists and congenital heart surgeons and is used to code diagnoses and procedures in the STS Congenital Heart Surgery Database, the Database of the European Association for Cardio-Thoracic Surgery, the VPS Database, and the IMPACT Database [39]. A mechanism for accounting for differences in case mix/case complexity across institutions is also critical for reporting useful outcomes and benchmarking data. In the field of pediatric cardiac surgery, a risk stratification system based on empiric data from nearly 80,000 patients was recently developed [39]. This system classifies operations into five categories based on mortality risk [Society of *T*horacic Surgeons – European *A*ssociation for Cardio-*T*horacic Surgery (STAT) Mortality Categories (category 1 = lowest mortality risk, category 5 = highest mortality risk)] and is able to classify a greater number of operations compared with other risk stratification systems [39]. Finally, most databases currently focus on a particular episode of care such as an operation or catheterization procedure. Continued collaboration between medical and surgical subspecialties caring for patients with congenital heart disease, and further development of mechanisms to link databases (as discussed below), will facilitate longitudinal follow-up in the inpatient and outpatient setting of the child who may undergo multiple procedures and hospitalizations during their lifetime.

Administrative Claims Databases

In addition to clinical registries and databases, there are also several administrative databases (containing information derived from the hospital bill) that have been used in pediatric cardiovascular research. These include the Pediatric Health

Information Systems (PHIS) database, and several Agency for Healthcare Research and Quality Healthcare Cost and Utilization Project (HCUP) databases, including the Kids' Inpatient Database (KID) and others [3, 40, 41]. An important limitation of these data sources is that they rely on International Classification of Diseases, Ninth Revision (ICD-9) diagnosis and procedure codes to identify patients undergoing congenital heart surgery. These codes do not cover the breadth and depth of congenital heart disease and congenital heart surgery, and there can also be issues with miscoding [42, 43]. For example, there is no ICD-9 code for the Norwood operation, such that a combination of other codes must be used, the validity of which is not known. However, administrative datasets do contain valuable information concerning resource utilization and other patient and center information that may not be captured in disease-specific clinical registries [3]. Linking databases together (as discussed below) can capitalize on the strengths and mitigate the weaknesses of various types of data sources.

Linking Databases

Individual registries and databases can be useful in conducting a variety of different analyses. However, there are also certain limitations [3]. There are relatively few existing datasets, each containing limited data, which do not communicate with each other. In addition, there is no mechanism for efficient real-time data collection to answer important clinical questions that may arise.

It has been hypothesized that linkage of existing pediatric data sources can address many of the limitations associated with the use of individual datasets alone [40]. Linking databases expands the pool of available data for analysis and capitalizes on the strengths of different types of data sources. Linkage allows analyses otherwise not possible with single-center data or individual datasets alone.

There are several mechanisms for linking databases [3]. First, because direct, or unique, identifiers such as social security number have traditionally not been collected or readily available for analysis in many databases due to regulatory requirements, methodology has been developed to link patient information across databases through the use of "indirect" identifiers [40, 43, 45]. These include date of birth, date of admission, date of discharge, sex, and center where hospitalized. This method has been used to successfully link the STS Congenital Heart Surgery Database to the Pediatric Health Information Systems (PHIS) Database (a large pediatric administrative database) [40]. Linking these two types of data sources allows investigators to capitalize on the detailed diagnosis and operative information in the clinical database, and the resource utilization information (medication administration, hospital costs, etc.) in the administrative database to conduct studies not possible with either dataset alone (Fig. 187.1).

Some datasets do contain unique identifiers such as social security number, and this information can facilitate further linkages beyond those performed through linking on indirect identifiers. This methodology has been successfully used to link clinical data to the National Death Index and Social Security Death Master File to evaluate long-term mortality [46, 47]. Linking registry data to other center-level data through matching on center is also possible. For example, linking survey data regarding ICU care to the STS Congenital Heart Surgery Database enabled evaluation of the association of ICU care models with outcomes following surgery [48]. Linking data can also be accomplished through the development of a modular data collection system that enables collection of supplemental datapoints to the main registry. The modules, which are web-based, can be quickly created and deployed to allow "real-time" data collection to answer important clinical questions that may arise. They are more time and cost-efficient compared with traditional data collection methods that may duplicate data already being collected in the main registry. Modules are currently being designed for use with the STS Congenital Heart Surgery Database to collect data to pilot test several proposed quality measures [49]. Data can also be

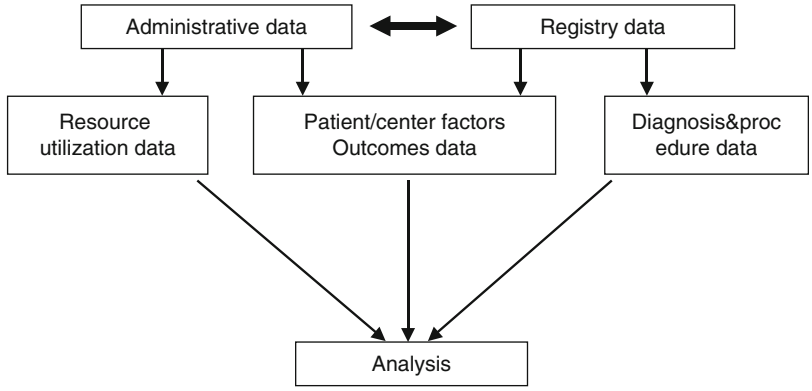

Fig. 187.1 Linking clinical registry data with administrative claims data capitalizes on the strengths of both types of datasets. Detailed diagnosis and procedure data from the registry are able to be linked with resource utilization data (such as medication administration and hospital charges) from the administrative dataset. Both types of data sources may contain useful information regarding other patient and center factors and outcomes. All of these data can be pooled together for analysis, which enables studies not possible using either dataset alone

shared or linked through collaboration/partnering between different subspecialty organizations and databases. For example, beginning in 2010, the Society of Thoracic Surgeons partnered with the Congenital Cardiac Anesthesia Society to add a new anesthesia section to the STS data collection forms [27]. Anesthesia data are now collected, harvested, reported, and analyzed along with surgical data for participating centers. This approach proved to be more time and cost-efficient than creating a separate anesthesia database in which many of the fields regarding patient characteristics and the operative procedure would have been duplicated between databases.

Summary

Leveraging multicenter databases in pediatric cardiovascular research can provide a variety of useful data. Linking databases can capitalize on the strengths and mitigate some of the weaknesses of different types of data sources and can allow analyses not otherwise possible with single-center data or individual datasets alone. Further development of this methodology and continued collaboration between subspecialties may facilitate analyses not only of outcomes associated with a particular operation, device, or medication but enable longitudinal evaluation of the child diagnosed with congenital heart disease throughout their lifetime.

Multi-institutional Collaborations

Background

Distinct from large clinical registry initiatives centered within professional societies, multi-institutional research consortia have become a mechanism for investigation in the fields of pediatric cardiac surgery, intensive care, and cardiology. Sprung from the recognition that small case numbers would forever limit the depth of analysis possible at even large institutions, and building on the blueprint for success laid out by international database projects, these collaboratives have developed with specific research agendas at their foundation. If traditional clinical research and quality improvement science are conceptualized as overlapping circles in a Venn diagram, then these consortia are positioned to occupy that zone of overlap. This section will focus on two recently established collaboratives, the National Pediatric Cardiology – Quality Improvement Collaborative and the Pediatric Cardiac Critical Care Consortium, and will

conclude with a list of principles necessary for creation and sustainability such efforts.

National Pediatric Cardiology: Quality Improvement Collaborative (NPC-QIC)

The NPC-QIC is a recent example of a grassroots effort to build a multi-institutional network of centers dedicated to raising the quality of care and improving outcomes for children with cardiovascular disease. NPC-QIC began as a leadership alliance with representatives from several leading professional organizations including the American Academy of Pediatrics Section on Cardiology and Cardiac Surgery, the American Heart Association Council on Cardiovascular Disease in the Young, the American College of Cardiology Adult Congenital and Pediatric Cardiology Committee, and the American Board of Pediatrics sub-board of Pediatric Cardiology [50]. Based out of Cincinnati, OH, the collaborative dedicated itself to quality improvement science centered on an initial clinical problem: improving outcomes between first- and second-stage palliative procedures for patients with single-ventricle heart disease.

The initial aims were to reduce mortality, hospital readmission, and growth failure during the interstage period. Leadership of the collaborative includes a multidisciplinary physician group as well as a dedicated improvement team of quality experts and implementation scientists. Using a structured process to postulate key drivers of these outcomes, several strategies for rapid quality improvement using the PDSA cycle concept [51] have been proposed and implemented [52]. Published work to date has included characterization of practice pattern variation at various stages: pre- and intraoperative care, [53] postoperative care, [54] and outpatient care [55].

The NPC-QIC is uniquely committed to the involvement of all pediatric cardiologists in a research and improvement network [52]. Unlike many other collaboratives, NPC-QIC has reached beyond the traditional boundaries of academic institutions where pediatric cardiovascular care is delivered and actively recruited private practice cardiologists who provide care to these patients. This is certain to provide a deeper level of understanding of practice and outcome variation and will add substantially to the generalizability of subsequent research findings.

Pediatric Cardiac Critical Care Consortium (PC^4)

Another example of recently developed multi-institutional collaborative is that of PC^4. In response to the growing recognition of significant barriers to clinical and quality improvement research within the field of pediatric cardiac intensive care, investigators from the University of Michigan C.S. Mott Children's Hospital, Children's Hospital Boston, University of California-San Francisco Children's Hospital, Lucille Packard Children's Hospital, Children's Hospital of Wisconsin, and Seattle Children's Hospital formed a consortium of pediatric cardiac intensive care units dedicated to standardized data collection and performance of multi-institutional research to track outcomes and quality metrics. Initially funded by the NIH and the Clinical and Translational Science Awards program, the consortium created a pediatric cardiac critical care registry module to complement data currently entered into the existing Virtual PICU System (VPS, LLC) critical care and STS congenital databases. This module focuses on data collection for patients admitted to intensive care units after surgery, with variables collected in the pre- and postoperative periods covering the domains of critical care practices, physiologic/laboratory data, and outcomes.

The Pediatric Cardiac Critical Care Consortium (PC^4) now includes ten participating institutions, with data collection beginning in the fourth quarter of 2011. PC^4 mission is to partner with professional organizations across geographic and subspecialty boundaries, integrate with existing databases, and harmonize the common efforts to define quality for patients with critical cardiovascular disease. The stated goals of the consortium are to (1) measure outcomes and describe the variability in outcomes between

institutions, (2) determine the specific structures and processes that differentiate high-performing centers, and (3) to disseminate those findings throughout the pediatric cardiac critical care community.

PC^4 demonstrates the power of multi-institutional collaboratives to straddle the domains of traditional observational clinical research and quality improvement and implementation sciences. Having built a standardized registry and by maintaining an active research agenda, PC^4 is positioned to measure and benchmark outcomes of cardiac critical care practices to develop a risk-adjustment method suitable for this highly-specialized clinical environment and to describe outcome variation and identify high-performing centers. Subsequently, investigators within the consortium will be able to perform in-depth analyses to determine the key structures and care processes associated with better hospital performance. This is due in no small part to the participating centers' commitment to transparency in data sharing and the willingness to be observed by peers. This iterative process can result in the formation of an evidence base for the organization of care and the specific processes of care delivered in pediatric cardiac intensive care units.

Keys to Success

The success of the two multi-institutional collaboratives presented here can be attributed to several important principles, which serve as a guide for development similar projects:

1. *Need for strong leadership* – For both NPC-QIC and PC^4, strong, centralized leadership was critical to maintaining early momentum for the project. It is important for all collaborators to participate in the formation of consortia to ensure their investment, but a focused core of leadership is crucial in the stages before organizational processes are well established.
2. *Inclusivity* – Recruitment of participating centers should never be limited to one particular segment of the clinical community of interest. The ability to detect variation in practice and outcome depends on inclusion of programs across the continuum of size, region, and setting. As previously mentioned in regard to the NPC-QIC, this also strengthens the generalizability of research findings.
3. *Forge a focused vision and mission statement* – Both consortia described here benefit from thoughtfully crafted missions that guide all aspects of their organization and function. In the case of PC^4, the mission statement directed the administrative structure, the research agenda, and the recruitment strategy.
4. *Partner with professional organizations and other collaboratives* – As the current landscape is replete with databases, registries, and quality initiatives, it is imperative for new projects to join existing efforts and form synergistic relationships. First, this allows for idea sharing and capitalization on previous successes. Use of a common nomenclature, for example, allows new database projects to integrate with other registries. Second, these relationships allow pooling of financial resources and limit duplication of work. This is critical to gaining member institutional buy-in and early sustainability. Finally, endorsement from professional societies can increase participation in very tangible ways; the NPC-QIC is an excellent example of this having enjoyed support from the American College of Cardiology and being recognized in the US News and World Report Rankings.
5. *Identify a return on investment for participants* – In the current health-care economy, participation on research and quality collaboratives is a marginal, nonessential cost to institutions and private practices. The reality is that every one of these projects has significant associated administrative costs, mostly due to the need to hire manual data collectors. Though this could be offset in the future by electronic data retrieval systems, this is not a panacea. While most every institution or practice would in theory want to participate in efforts to conduct high-quality research and improve outcomes, it is an active choice to

participate. In order to increase participation and sustainability, new collaboratives must identify and deliver a product to its members. This can be in the form of institutional prestige associated with participation as measured by national rankings, through maintenance of certification benefits to participating physicians and nurses, or by using unique analytic methods to demonstrate cost savings using the data collected.

Translational Research

Background

One of the greatest challenges for any medical discipline is translate advances in the understanding of disease processes into improvements in patient care. This "bench to bedside" approach holds great promise for improving patient outcomes and reducing morbidity and mortality through the implementation of disease management strategies guided by an understanding of the underlying pathophysiology. As refinements in surgical approaches and perioperative management strategies continue to improve outcomes for patients with congenital heart disease, it is becoming increasingly appreciated that further improvements in care will involve the introduction of basic research advances into the clinical practice.

Translational Research Efforts to Date in Congenital Heart Disease

While there can be broad and varied interpretation of what constitutes translational research, examples of the introduction of basic research advances into the clinical arena through the development of randomized clinical trials have involved patients with Marfan syndrome and hypertrophic cardiomyopathy (HCM).

Marfan syndrome, which is a multisystem connective tissue disorder with cardiac manifestations that include aortic root dilatation and aortic dissection, is due to mutations of the gene encoding the extracellular matrix protein fibrillin-1 [58]. A transgenic mouse model was used to characterize the pathologic changes that precede aneurysmal dilatation of the ascending aorta in response to fibrillin-1 mutation [59]. It was determined mutations associated with Marfan syndrome reduce fibrillin's ability to sequester TGFb, resulting in an inflammatory process in the aortic wall that degrades elastin and causes aneurysmal dilatation in response to wall stress [60]. Identification of the TGFb pathway in the pathogenesis of aortic root dilatation in the Marfan syndrome led to the identification of TGFb receptor mutations in patients with a closely related connective tissue disorder, Loeys-Dietz syndrome [61], and to clinical trials examining the effectiveness of TGFb receptor inhibition as an approach to slowing aortic root dilatation in Marfan syndrome patients [62]. While the results of a randomized clinical trial performed by the PHN are still being analyzed, preliminary reports suggest that the TGFb receptor inhibition using angiotensin II receptor blockers may promote aortic root remodeling and slow disease progression in patients with Marfan syndrome.

A similar approach has been used to develop and evaluate new therapeutic strategies in patients with hypertrophic cardiomyopathy. As with Marfan syndrome, investigative teams have developed animal and cell culture models to better understand disease manifestation and progression in patients with HCM [63, 64]. Identification and characterization of disease-causing mutations in patients with HCM suggested an important role of aberrant calcium handling in disease pathogenesis [65]. More than half of adult patients with HCM have mutations in one of the proteins that localize to the sarcomere, the basic contractile unit of striated muscle. Introduction of HCM-associated mutant sarcomeric proteins into cardiomyocytes in primary culture commonly resulted in increased calcium sensitivity of the sarcomere and hypercontractile responses to calcium release during excitation-contraction coupling. It is postulated that in vivo this hypercontractile state leads to cardiac hypertrophy and fibrosis, although the mechanistic

links have not been well defined. In order to determine if blunting the calcium release by the pharmacologic blockade of L-type calcium channels might alter disease onset or progression in response to HCM-causing mutations, the calcium channel blocker diltiazem was administered to mice with a b cardiac myosin heavy chain Arg403Gln missense mutation [64] and to transgenic mice overexpressing a cardiac troponin T I79N mutation [66]. In both animal models of HCM, diltiazem treatment led to improvements in cardiac function and to prevention of myocardial fibrosis. Translation of these findings to the clinical arena led to the development of a randomized clinical trial in which patients with an HCM-causing mutation who have not yet developed signs of hypertrophy receive "prophylactic" diltiazem (NCT00319982). The trial includes pediatric and young adult patients (ages 5–39 years) and will rely on serial evaluations to determine if L-type calcium channel blockade might be able to delay the onset and/or slow the progression of the myocardial hypertrophy and fibrosis in patients at risk for developing HCM.

The success of these efforts has demonstrated the feasibility of performing translational research in pediatric patients with congenital and acquired heart disease and established a working framework to facilitate the performance of new clinical trials.

Current and Future Directions for Translational Research in Congenital Heart Disease

In an effort to fuel advances in translational research in patients with congenital heart defects, the National Heart, Lung and Blood Institute recently developed the "Bench to Bassinette" program (http://www.benchtobassinet.org/). The program involves two consortia: the Cardiovascular Development Consortium (CvDC) which will focus on understanding the basic mechanisms of cardiac development using animal models and the Pediatric Cardiovascular Genetics Consortium (PCGC) which will characterize the contribution of genetic and genomic variation to the pathogenesis of congenital heart disease. The consortia will work together to identify potential disease mechanisms and evaluate their role in the causation of congenital cardiac defects. An important aspect of this effort will be the careful phenotypic evaluation of the patients, which will allow a full understanding of the spectrum of cardiac defects encountered in response to perturbation of a specific developmental pathway. The long-term goal will be to develop treatment strategies designed to limit the frequency or severity of congenital heart defects.

An important part of this effort will be to determine how the underlying pathophysiology contributes to patient outcomes. The specific pathophysiologic abnormality in each patient may affect not only the severity of the cardiac lesion but also the response of the patient to medical management and surgical intervention. For instance, in patients with pulmonary atresia, the presence of a genomic deletion of the DiGeorge syndrome critical region on chromosome 22 is associated with higher morbidity and mortality [67]. Understanding the spectrum of disease in patients with specific pathophysiologic defects and identifying associated complications may allow the development of translational research trials to assess the ability of targeted therapy to improve outcomes.

As survival rates for even the most complex cardiac surgeries have continued to improve, there is increasing emphasis on improving not only the "quantity of life" after heart surgery but the "quality of life." Functional outcomes such as growth, exercise tolerance, and neurodevelopmental performance are a major focus for future translational research and therapeutic intervention. Of these outcomes, the one most readily modeled "at the bench" is neurodevelopment. Deficits in neuropsychologic function occur in 50 % or more of patients with complex congenital heart defects that require neonatal repair [68]. While some of the observed deficits are due in part to genetic, in utero or socioeconomic factors that are not amenable to intervention, there are a number of perioperative factors that may affect neurologic injury [69]. These modifiable factors are potential targets for

translational research studies designed to assess strategies to improve neuroprotection in the perioperative period [70]. Yet, to date, technical modifications (including cooling and rewarming parameters, blood gas management strategies, and cardiopulmonary bypass support modifications) and pharmacologic interventions (including anesthetic management and administration of potentially neuroprotective agents) have not yielded consistent improvements in neurodevelopmental outcomes.

The more consistent performance of these strategies in animal models suggests that, in patients, individual factors may influence responses to treatment. In clinical trials, genomic and proteomic approaches are now being used to identify biomarkers associated with treatment success or failure. It is anticipated that identification of biomarkers associated with outcome variation will lead to an improved understanding of the injury response pathways most responsible for outcome variation and allow the development of treatment strategies designed to protect all patients from that mechanism of injury or allow the development of individualized treatment regimens designed to protect each patient from the injury processes to which they are most susceptible. In essence, this "bedside to bench" approach focuses basic research efforts on the most clinically relevant pathways and leads to the development of novel therapeutic strategies that can then be brought back to the bedside through translational research.

Summary

The future appears quite promising for translational research involving pediatric patients with congenital and acquired heart disease. The development of national and international collaborative efforts which has involved the creation of patient outcomes databases and the development of clinical research networks has enabled the translation of research advances into the clinical arena. Furthermore, increased dialogue between clinical and basic research investigators has encouraged a bedside to bench to bedside approach. Clinical observations and careful phenotypic characterization (gathered by quality improvement initiatives and observational studies and recorded in shared databases) guide basic research studies into disease pathophysiology. As basic research advances suggest novel therapies, clinical research networks can facilitate the performance of randomized clinical trials to translate these advances into improvements in patient care.

Training, Continuous Education and Simulation in Pediatric Cardiac Surgery

188

Patrick O. Myers

Abstract

Regardless of the paradigm, the primary goal of training in congenital cardiac surgery is to learn the complex management of patients with congenital heart disease, both in and outside of the operating room. A trainee can only become competent in a procedure if he/she has seen as well as been able to perform this procedure under supervision. Due to the high pressure and highly demanding nature of the specialty of pediatric cardiac surgery, it is rarely possible for trainees to obtain experience as a primary operating surgeon during their formal training but usually only after becoming independent attending surgeons who require mentorship during the more complex procedures.

Competency-based training ensures that training is tailored to the trainee's needs and abilities. Progress is made by achievement of predetermined competencies. Simulation provides the learner with an opportunity for repetitive and deliberate practice of procedural skills in a low-consequence environment and may counterbalance the reduced number of hours spent training (due to work-hour restrictions) by optimizing clinical exposure.

Training remains an art, which is highly dependent on individual mentor's educational philosophy and the trainee's involvement; despite close oversight by accrediting councils, not all training programs are equal, and work-hour restrictions are a reality, to which the subspecialty of pediatric cardiac surgery must adapt to or disappear.

Introduction

> "The most difficult thing about surgery – even open heart surgery – is getting a chance to do it. It certainly doesn't matter as much who does the operation, as how it is done." Norman E. Shumway, MD, PhD, 67th Annual meeting of the American Association of Thoracic Surgery Presidential Address

Pediatric cardiac surgery is a very particular specialty, and the famous quote from Norman Shumway [1], self-proclaimed "world's best first assistant," is no less true about his specialty, heart transplant and adult cardiac surgery, than it is about pediatric cardiac surgery. This specialty has a very low tolerance for errors and requires a high level of cognitive and technical performance and coordinated efforts of multiple individuals within a sophisticated organizational structure. It has also come under the pressure of both scrutiny, with outcomes reporting to organizational databases such as the Society of Thoracic Surgeons or the European Association for Cardio-Thoracic Surgery, and finances, as pay is sometimes tied to performance [2]. This further increases the pressure to obtain a good outcome and thus poses a direct conflict to intraoperative hands-on teaching. There is thus little incentive and time for education within a pediatric cardiac surgery program, and it is increasingly harder to "get the chance to do" pediatric cardiac surgery during training. As training progresses into the surgical super-subspecialties, as would befall congenital cardiac surgery, there is a loss of structure, uniformity, and regulation [3]. Training in many of these subspecialties is frequently viewed as an apprenticeship, with the fellowship year providing only an initial experience.

Despite these caveats, it remains a uniquely challenging, interesting, and rewarding specialty, and this chapter will focus on the training paradigms, continuous education, and the role of simulation in training in pediatric cardiac surgery.

Training, Continuous Education, and Simulation in Pediatric Cardiac Surgery

Goals of Training

For the trainee, the goal of training is to acquire the knowledge and abilities to handle any congenital cardiac surgery patient. This encompasses mastery of cardiac surgery and perfusion, notions of pediatric cardiology, intensive care, and anesthesia. It should also include fostering long-term relationships with mentors and peers, help acquire methods to continue learning after the conclusion of formal training, and acquire research methodology and, more importantly, curiosity.

Current Training Paradigms

Since its inception, surgical training was based on an apprentice model, with surgical trainees learning their skills from experienced barber surgeons by spending an unspecified number of years under supervision. Sir William Halsted changed the training of surgeons in 1889 at Johns Hopkins Hospital from a disorganized apprenticeship to the residency program model used today in the United States [4, 5] and variably applied around the world. This model has remained as the central paradigm of most residency programs today, although learning has remained an opportunistic process grafted onto clinical practice [6].

In the United States, medical graduates wishing to specialize in pediatric cardiac surgery have to complete a 5-year general surgery residency (not including 2 years of research between the junior and senior residency years) to be eligible for American Board of Surgery certification in general surgery, followed by a 2- to 2.5-year cardiothoracic surgery fellowship to be eligible for American Board of Thoracic Surgery (ABTS) certification in cardiothoracic surgery. These programs must be accredited by the Accreditation Council for Graduate

Medical Education (ACGME) for the training to be eligible for board certification, and the trainee must be in a position within the program that is designated as ACGME accredited. The ABTS recently introduced and ACGME-accredited 1-year fellowship in congenital cardiac surgery sanctioned by a subspecialty certificate.

US medical graduates wishing to enter the specialty are looking at 10 years of formal training before entering independent practice, with a median debt of $160,000 in 2010 [7]. Furthermore, the specialty of cardiothoracic surgery has seen a sharp decrease in applicants over the last 10 years, with fewer applicants than positions in 2004 and one third of positions going unfilled in 2007. Recognizing that the classic training model is obsolete, the ABTS recently dropped the requirement for general surgery board certification and introduced a parallel pathway in a 6-year integrated fellowship that leads to certification in cardiothoracic surgery directly after graduation from medical school, thus allowing for a more focused and longer training in cardiothoracic surgery. There are currently 15 ACGME-accredited integrated programs, and they have been completely filled since their inception. In a recent report from New York, a department that offers both traditional and integrated training had 27 applicants for their single traditional slot compared to 131 applications for their single integrated slot [8].

Prompted by the recognition that the discipline of congenital heart surgery requires unique skills and education that were not provided in a standard cardiothoracic surgery residency and that congenital cardiac surgery fellowships lacked uniformity and quality control [9], the ABTS established a fellowship in congenital cardiac surgery in 2007. The goal was to recognize and document a standard of education, operative experience, and cognitive knowledge for individuals practicing in this field, and to improve the overall quality of congenital cardiac surgical care in the United States. At present, there are 11 ACGME-accredited fellowship programs in the United States, which may graduate 1 congenital heart surgeon per year. Fellows are required to perform 75 index operations, including aortic arch repairs, atrioventricular canal repairs, arterial switch operation, tetralogy of Fallot, and Glenn/Fontan palliations.

The American system of training has the advantage of being highly structured, with clearly defined time and operative requirements, and is closely monitored by an accreditation council which requires that all duties of a trainee must be proven to have an educational value. Trainees spend time as the "chief resident" during the final year of each of their residencies in general surgery, cardiothoracic surgery, and congenital cardiac surgery, allowing them to manage an entire service and team, be offered the first choice on cases, tailor their operative experience to what their needs are depending on their stage of training, and have closer contact with faculty. On the other hand, the congenital certificate is still in infancy, with no formal oversight or evaluation of the programs to this date by the ACGME. Whether trainees actually get the operative experience that is required for certification remains to be demonstrated and is highly dependent on the training philosophy of the individual programs. From the programs' perspective, basing the management of an entire service on a single trainee works well as long as the process for selecting this trainee works; however, when this process fails, the entire program and its staff are at risk of being mismanaged by an incompetent leader, placing patients at risk, wasting resources, demotivating an entire team, and wasting the valuable training time of other trainees within the program, either earlier in their training or trainees in nonaccredited slots.

In Canada, an integrated 6-year program entered into from medical school was introduced in the 1990s, with "grandfather"-dedicated 3-year fellowships available for graduates of general surgery residency.

In Europe, the European Board of Thoracic and Cardiovascular Surgeons (EBTCS) sanctions a certificate in cardiac surgery, which complements (but does not replace) the board certification within participating European countries. The EBTCS requires 2 years of general surgery

experience and 4 years of cardiac surgery experience, as well as performance of 150 major cardiac operations as the primary operating surgeon. A specific certificate in congenital cardiac surgery does not exist, although the EACTS is working on developing the foundations for one. This European training paradigm has the advantage of being very flexible; the training is not restricted to specific accredited slots as in the US system and offers, in theory, a short and structured training. This paradigm does suffer from the total absence of oversight, which is left to the national boards in each participating country, and operative experience is often acquired during the initial years of mentored independent practice, rather than during formal training, even for the simplest cases. It is the trainees' responsibility to acquire the number of years and operative experience, with no predefined endpoint to training. There has been no formal evaluation of this training paradigm to this date.

The United Kingdom has one the most established training paradigms in Europe, comprising 2 years of general medical training as foundation doctors, 2 years of general surgery core training, followed by a 6-year program in cardiothoracic surgery. The cardiothoracic training is based on the Intercollegiate Surgical Curriculum Programme (ISCP), a detailed competency-based list of training targets.

The training paradigms vary tremendously across other parts of the world, and it is not the goal of this chapter to review each one, only to discuss the advantages and failures of the two most widely studied paradigms across the Atlantic Ocean.

Work-Hour Restrictions

Under social pressure to improve outcomes and avoid costly and avoidable medical errors, working-time restrictions have been instituted on both sides of the North Atlantic, although there is no empirical data to support that such restrictions improve outcomes. In the USA, the time spent in the hospital has been limited to 80 h per week since 2003, while the European Working Time Directive (EWTD) reduced the numbers of hours a trainee can work to 56 h per week initially and 48 h per week since 2009. These restrictions have been characterized as "a well-planned and organized assassination of surgery" [10] and have generated concerns over decreased exposure to the number of patients cared for, the number of operations performed, and particularly the number of follow-up operations participated in (e.g., a reoperation for hemostasis) [11]. There has also been concern, in the era of evidence-based medical practice, about the lack of empirical data to support work-hour restrictions [2].

The North American experience after introduction of work-hour restrictions is somewhat conflicted, with data that indicate a lengthening of the learning curve and a decrease in operative volume for trainees [12]. Some studies show that work-hour restrictions in surgery actually decreased the quality of patient care and increased errors [13], possibly the result of problems with handoffs, cross coverage, and communication. In a recent systematic review on the effects of the 80-h work week, Sadaba et al. [14] found eight studies that described a decrease in trainees' operative volume after introduction of the work-hour restrictions, five studies showed stable volumes and two showed increasing volumes. They concluded that, although the introduction of work-hour restrictions had produced overall a decrease in the number of cases performed by trainees, there was some evidence that the adoption of alternative working patterns could preserve or even increase the exposure of residents to surgical procedures. However, this review used procedural volume as a measure of proficiency, while many other aspects of surgical training were not taken into account.

A recent survey of residents by the EACTS surgical training and manpower committee [15] found that the EWTD was not applied across Europe, most trainees were dissatisfied with their training, and under the current training conditions, most trainees believe that the 48-h work week is insufficient to achieve an adequate level of surgical competence. It also found that most European surgeons do not go through a structured

and organized training program during their training, most European surgeons can achieve certification without being independently evaluated during their residency or without an exit exam, most surgeons get trained by unqualified trainers in centers not independently and regularly assessed for training capability, and there are significant disparities in the quality of cardiothoracic surgical training between European countries. This survey included all residents in cardiothoracic surgery, and no formal investigation has been made on the effects of the EWTD on training in congenital cardiac surgery.

Regardless of the effects of work-hour restrictions, these limits were imposed on the practice and training of medicine in general by the society and apply harshly in the surgical super-subspecialties such as congenital cardiac surgery. However, it would be futile to fight them; it would rather be useful to use them constructively to improve the delivery of care and training and as a call to "adapt or die" [16]. This pressure to improve the efficiency of training has lead to novel methods of teaching, such as simulation and multimedia teaching, and requiring *Training the Trainers* courses for trainers. This pressure has also help reorganize the work required of trainees, limiting strictly service requirements without an educational component to a minimum and having these noneducational tasks taken care of by mid-level practitioners (physician's assistants or nurse practitioners, where such certification exists).

Competency-Based Training

Training has historically been time and procedural based. However, with work-hour restrictions, a shift to competency-based training has occurred. The rate of progress during training varies among trainees. Establishing fixed training periods can therefore be considered unrealistic. Competency-based training ensures that training is tailored to the trainee's needs and abilities [17]. Progress is made by achievement of predetermined competencies. For instance, once a trainee is deemed competent in saphenous vein harvesting, he/she can move on to learn a new procedure. From then onwards, needlessly performing simple, repetitive tasks, such as vein harvesting, compromises the overall learning continuum and advancement of the trainee [16].

Fig. 188.1 *Miller's "pyramid of competence"* (Adapted from Miller [18])

Miller [18] defined a four-step pyramid to assess competence (see Fig. 188.1). In the first step, the trainee *knows*, which represents the factual knowledge base required to carry out a procedure and is tested in most board examinations. To progress beyond "idiot savants," they must also know how to use the knowledge acquired in a rational diagnostic or management plan and reach Miller's second step, *knows how*. In the next step, the trainee *shows how* he/she will perform with the acquired knowledge. Finally, the trainee actually applies or *does* what he/she has learned and applies it in practice in the final step of the competence pyramid.

The British ISCP was one of the first initiatives to integrate competence as the basis of training and graduation, rather than a preset number of years or operations. The ABTS has shifted its focus to competency-based training rather than practice-based training with the introduction of the congenital certificate [9]. Wang et al. proposed a competency framework in cardiothoracic surgery training and recertification based on an amalgamation of the various prior attempts [19]. The core

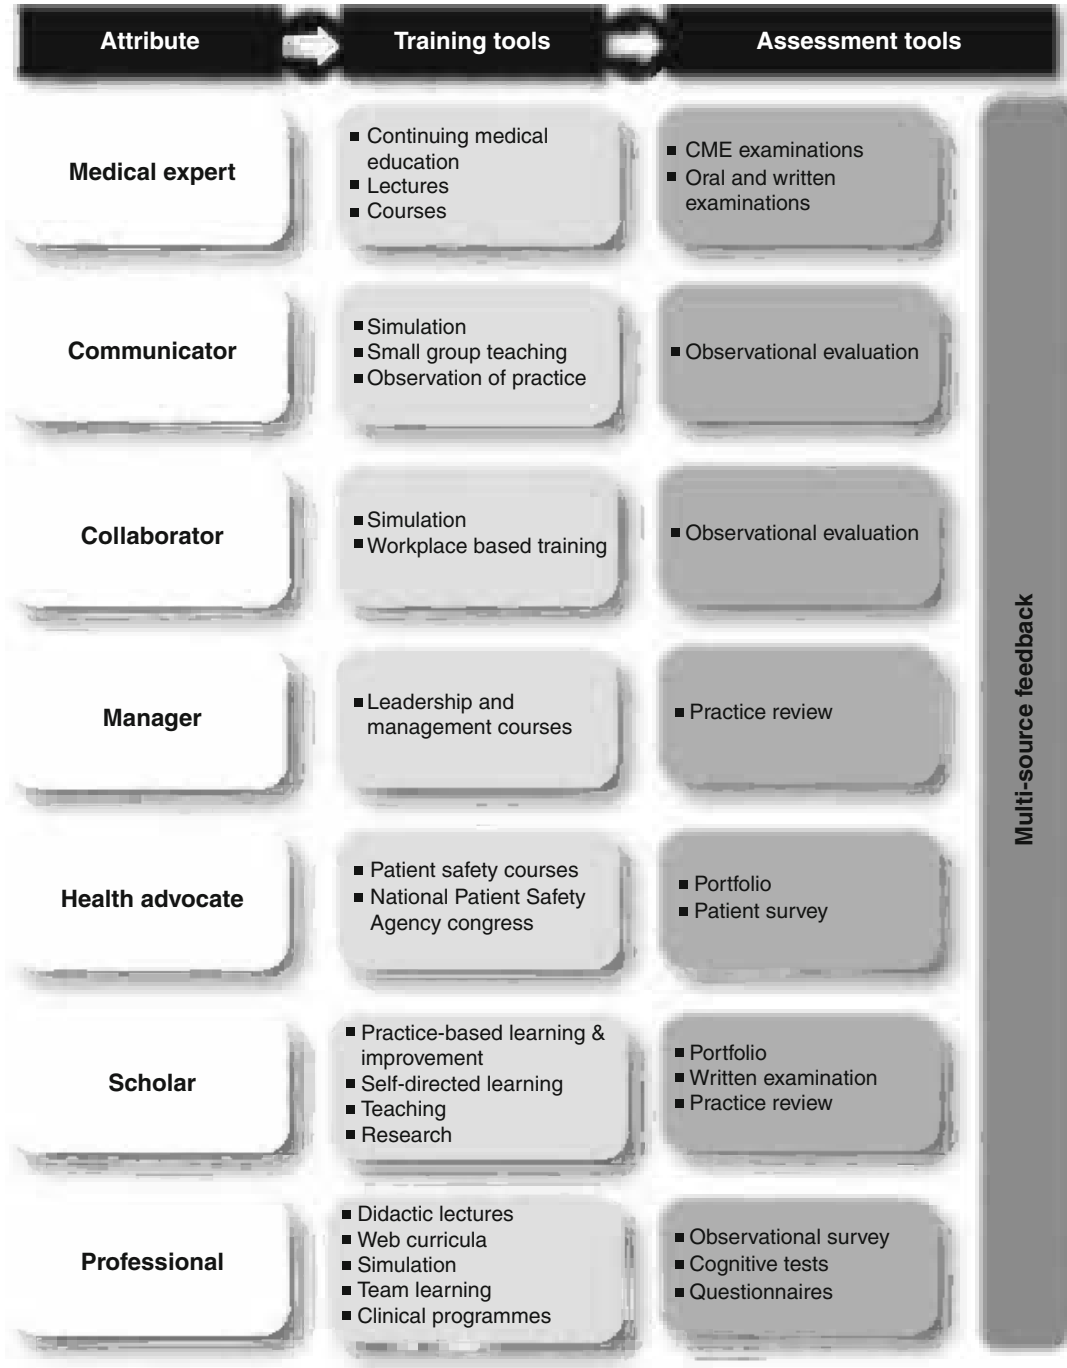

Fig. 188.2 *Proposed competency framework in cardiothoracic surgery* (Adapted from Wang et al. [19])

components of competency required of a cardiothoracic surgeon, actually applicable within any specialty, were that he/she be (1) a medical expert, (2) a communicator, (3) a collaborator, (4) a manager, (5) a health advocate, (6) a scholar, and (7) a professional (see Fig. 188.2). How successful these new training paradigms are remains to be studied.

One area of training research which has not seen much attention is particular subgroups of trainees. Cardiac surgery historically has attracted "the best and the brightest," although this may not be true in the current era, when lifestyle choices may be more important to most medical school graduates, and there has been little interest to making the specialty more amenable to underrepresented subgroups of trainees. The proportion of women within the specialty has remained small but has increased to just over 10 % in the USA [20], although they represent more than 50 % of medical graduates. Left-handed surgeons are also a minority, which has not been quantified among cardiac surgeons and pediatric cardiac surgeons. They are faced with a particularly difficult training, as all instruments are designed for right-handed manipulation, and the effects of this difficulty on the quality of their training has not been systematically investigated beyond a few surveys [21].

Continuous Medical Education (CME)

Recertification and maintenance or updating of knowledge and skills throughout the post-training career of physicians has been a reality for many years now. The development of innovative transcatheter techniques, new hybrid approaches to operations which were historically done solely by the surgeon, as well as minimally invasive surgery techniques and more innovations still to come require specific skillsets, which current practicing surgeons must learn. Much of what has been said about training is applicable to CME, although attending surgeons have been spared from the introduction of work-hour limitations for the most part, although this may not always be the case in the current era of focusing on medical errors and safety [22].

Simulation

The pressures from shortened training programs and reduced work hours for trainees demand that an increasing proportion of the surgical expertise of trainees has to be gained outside the operating room. Furthermore, the high-stress environment of the operating room may not be the ideal environment for new skill acquisition. These challenges have stimulated the pursuit of novel teaching techniques outside of the operating room, to improve the educational yield of time spent in the operating room.

The methods of formal didactic teaching have evolved from an opportunistic process grafted onto clinical practice to a science of learning and teaching, which are scientifically studied and taught. Multimedia-driven teaching has been shown to improve performance when compared with a traditional print medium handout [23]. Medical students, residents, and trainees are now used to online learning and can harness the advantages of Podcast or YouTube-channel video tutorials, discussion forums, and distance learning initiatives. The impact of ubiquitous tablets such as the iPad, with rich and multimedia textbooks and access in real time from anywhere to libraries and full-text journal article repositories larger than our predecessors could imagine, has not been formally studied. Interactive multimodal retraining has allowed improved attitude toward and application of off-pump CABG [24].

Taking the training and certification of pilots as a model, simulation has recently been identified as a way to improve surgical education [25]. Fitts and Posner's three-stage theory of motor skill acquisition [26] is widely accepted (see Table 188.1). In the cognitive stage, the learner intellectualizes the task, performance is erratic, and the procedure is carried out in distinct steps. With practice and feedback, the learner reaches the integrative stage, in which knowledge is translated into appropriate motor behavior. The learner is able to execute the task more fluidly, with fewer interruptions. In the autonomous stage, practice gradually results in smooth performance. The learner no longer needs to think about how to execute this particular task and can concentrate on other aspects of the procedure [27].

> Excellence is an art won by training and habituation. We do not act rightly because we have virtue or excellence, but we rather have those because we have acted rightly. We are what we repeatedly do. Excellence, then, is not an act but a habit. Aristotle

Table 188.1 The Fitts-Posner three-stage theory of motor skill acquisition

Stage	Goal	Activity	Performance
Cognition	Understand the task	Explanation, demonstration	Erratic, distinct steps
Integration	Comprehend and perform mechanics	Deliberate practice, feedback	More fluid, fewer interruptions
Automation	Perform the task with speed, efficiency, and precision	Automated performance requiring little cognitive input, focus on refining performance	Continuous, fluid, adaptive

Adapted from Fitts and Posner [26] and reproduced from Reznick [27]

Table 188.2 Types of simulation available

Simulation	Advantages	Disadvantages	Best use
Bench models	Cheap, portable, reusable, minimal risks	Acceptance by trainees; low fidelity; basic tasks, not operations	Basic skills for novice learners, discrete skills
Live animals	High fidelity, availability, can practice hemostasis and entire operations	Cost, special facilities, and personnel required, ethical concerns, single use, anatomical differences	Advanced procedural knowledge, procedures in which blood flow is important, dissection skills
Cadavers	High fidelity, only "true" anatomy simulator currently, can practice entire operation	Cost, availability, single use, compliance of tissue, infection risk	Advanced procedural knowledge, dissection, continuing medical education
Human performance simulators	Reusable, high fidelity, data capture, interactivity	Cost, maintenance, and downtime; limited "technical" applications	Team training, crisis management
Virtual reality surgical simulators	Reusable, data capture, minimal setup time	Cost, maintenance, and downtime; acceptance by trainees; three dimensions not well simulated	Basic laparoscopic skills, endoscopic and transcutaneous procedural skills

Reproduced with permission from Reznik [27]

Simulation provides the learner with an opportunity for repetitive and deliberate practice of procedural skills in a low-consequence environment. Deliberate practice of skills is the critical activity in developing expert abilities according to Ericsson's theory [28]. Simulation provides the trainee with an ideal opportunity to acquire this technical "habit." The addition of self-directed, after-hours practice on a low-fidelity simulator of microvascular anastomosis to expert-guided tutorial has been shown to improve technical performance, the speed of performance, and the end product in a realistic simulated operating room environment [29].

Recent advances in virtual reality technology have demonstrated the potential for improving surgical skills training, and many systems are now commercially available. Virtual reality provides the opportunity for very detailed feedback and may allow for more subtle measurement of trainee performance than is possible in the real world [30]. Measures of precision and accuracy as well as error rates can be calculated easily. However, high-fidelity virtual reality comes at a price. As a general rule, the higher the fidelity and the more realistic the model, the more expensive the training tool [27] (see Table 188.2). Fidelity may be less important at relatively junior levels of training.

A hybrid simulator using a specially prepared pig heart placed in a model of mediastinum to teach basic skills of cardiac cannulation, coronary bypass, and valve repair or replacement has been developed [31]. The Thoracic Surgery Directors Association (TSDA) has launched an annual "boot camp" course for trainees using this type of simulator [32–34]. The EACTS has just launched an EACTS Academy, which is planning similar courses for European trainees.

Finally, teamwork training with simulation has been instrumental in reducing errors in the

aviation industry [35]. The importance of teamwork in preventing medical error is well recognized, and simulator-based team training has been advocated as a possible preventive approach.

The cardiovascular program at Boston Children's Hospital has been a pioneer on integrating procedural and teamwork simulation as a teaching technique into the structured curriculum [2]. Cardiac surgery trainees are now an integral part of a monthly Crisis Resource Management (CRM)-simulation session that integrates all cardiac subdisciplines in various crisis scenarios [36]. In addition, a special trainer for teaching of ECMO cannulation skills was developed with the help of the Simulation Center at Boston Children's Hospital.

Beyond these applications of high-fidelity simulation to very specific situations, there have been few attempts at simulation and research in this field in congenital cardiac surgery. An intrinsic limitation of this specialty, the extreme variability of congenital heart disease, and the fact that practically no two cases are the same make it difficult to create simulators to reproducibly train for the wide skillset required for independent practice within this specialty. It would be impossible to create a simulator for every congenital anomaly. Simulators appear better suited to provide a set of skills which are not easily learned from the operating room, such as specific situations like emergent ECMO cannulation or teamwork in a crisis situation. Basic cardiac surgery skills, such as cannulation, approaches to valve surgery, and microanastomoses, exercised regularly can help the congenital surgeon in training acquire a basic skillset out of the operating room. Cardiopulmonary bypass simulators have been used to teach trainees how to manage specific issues with bypass, such as air embolism or oxygenator malfunction. These simulators, which are of very high fidelity, have the disadvantage of requiring a lot of personnel (surgeon trainer, perfusionist, possible anesthesia) and being very costly. Simulators that could replicate the delicate nature of neonatal tissues could be of particular help.

Conclusions

Regardless of the paradigm, the primary goal of training in congenital cardiac surgery is to learn the complex management of patients with congenital heart disease, both in and outside of the operating room. A trainee can only become competent in a procedure if he/she has seen as well as been able to perform this procedure under supervision. Due to the high pressure and highly demanding nature of this specialty, it is rarely possible for trainees to obtain experience as a primary operating surgeon during their formal training but usually only after becoming independent attending surgeons who require mentorship during the more complex procedures. Despite studies supporting the safety of trainees performing operations [37, 38], even in off-pump CABG [39] or complex mitral valve repairs [40], as the operating surgeon under direct supervision, trainees are still not learning these operations by doing them, although the ABTS requires it. Kogon et al. surveyed 28 (of 42) recent graduates of North American programs in 2006 [3] and found that only 1 (4 %) had performed any of the RACHS $\geq$4 procedures (arterial switch with ventricular septal defect, truncus arteriosus, interrupted aortic arch, Norwood stage 1 palliation) other than totally anomalous pulmonary venous drainage repair and only 10 (36 %), 12 (43 %), and 13 (46 %) had performed an arterial switch, common atrioventricular canal repair, and Fontan operation, respectively, during their training. These alarming numbers on the state of training prompted the ABTS to include the majority of these procedures as a requirement in their "index case requirement," which will hopefully improve the training of future graduates. After all, "you can't learn to fly a jet without flying a jet" and "you can't learn to operate without operating" [6].

Imposed requirements such as these are not enough, as they depend on self-reporting of operative procedures by the trainees. There are many incentives for residents not to report their numbers accurately, such as not meeting the criteria for graduation, the program losing its

accreditation, and the fear of not finding a job after training when few are available. An institutional willingness to teach and train and stand proud of its trainees, such as Dr. Shumway infused into his program and his graduates have disseminated to other programs, is much more important to providing an environment amenable to acquire under supervision the skills necessary to reach independent practice.

In conclusion, training remains an art, which is highly dependent on individual mentor's educational philosophy and the trainee's involvement; despite close oversight by accrediting councils, not all training programs are equal, and work-hour restrictions are a reality, to which the subspecialty of congenital cardiac surgery must adapt to or die.

The author would like to thank his teachers for having the patience to watch him get things wrong and correct him, although it would be so much more efficient to do it themselves, particularly when they are balancing managing a busy practice, service, or department, managing a research laboratory, having university lectures to prepare and give, and participating in professional societies, peer review, editorial boards, etc., with balancing a family life above all.

Soft Skills in Pediatric Cardiology, Cardiac Surgery and Cardiac Intensive Care

189

Brigitte Stiller

Abstract

Nowadays, in a time of excessive amounts of electronic information, modern and expensive technical tools together with curtailed financial resources of many pediatric cardiac intensive care units, the increasing flood of information requires additional training and development of the ICU staff's social and soft skills to cope with this situation.

Rules and standard operating procedures are necessary to control this situation to prevent a waste of resources, and medical errors. In a highly specialized intensive care team with a certain degree of burnout and dissatisfaction, each member has his or her role, responsibilities, and rights, and soft skills are more important than ever before. Soft skills include verbal and nonverbal communication, personal habits, friendliness, emotional maturity, a willingness to share knowledge, optimism, and other character traits that influence relationships with a professional and ethical attitude.

Soft skills are essential for leadership, teaching, and error prevention. They are needed for professional behavior in critical situations, the analysis of errors, the training of security-relevant behavior, and interpersonal and parental interaction and communication.

Granted, soft skill is a rather vaguely defined term. The focus on doctors with well-developed soft skills should not displace well-educated and trained, highly competent surgeons, cardiologists, and intensivists. These hard skills are imperative to achieve good results in this medical "high-tech" field. Additional positive soft skills can make the difference between good and excellent, and help to create a safer environment and a more supportive and congenial atmosphere for the pediatric patients and their families.

Introduction

Life and work in the era of the worldwide internet entails an endless amount of information available at all times from all over the world. At the same time, the financial resources of many clinics and pediatric cardiac intensive care units (PCICUs) have been curtailed or reduced. More and more technical tools are available along with an increasing flood of information. The social skills and soft skills of cardiologists, surgeons, and ICU staff are needed to cope with this changing situation. Rules and standard operating procedures are necessary to manage this state of affairs to prevent medical errors as well as a waste of resources. In a highly specialized PCICU team with a certain degree of burnout and dissatisfaction, each member has his or her role, responsibilities, and rights. Nowadays, with what is often an "accomplish more in less time" mentality, social skills and soft skills have become more important than ever before.

Children with congenital heart disease and the need for cardiac surgery and intensive care are characterized by being very sick, having a wide range of concomitant diseases, and individual natural conditions. These children often pass through several clinical situations such as the outpatient department, the normal ward, the operating theater, and intensive care and intermediate care. Since the complexity level is high and the patients often so young, high quality handover is vital for the children's safety and to minimize errors. There is a need for excellent teamwork among various specialists especially in intensive care. Supporting each other, clear thinking, and open and honest communication are crucial to optimize patient outcomes and minimize errors.

These human factors are called "soft skills," but actually they are "hard skills" – hard to learn, hard to quantify, and hard to teach [1].

Definition: What Are Soft Skills?

Although "soft skills" is a frequently used term, there is no unequivocal definition. It usually denotes a cluster of personal abilities and interpersonal behavior that determine an individual's capacity to fit into a team, often but not exclusively within the working environment. Soft skills include verbal and nonverbal communication, personal habits, friendliness, emotional maturity, a willingness to share knowledge, optimism, and other character traits that influence relationships with others. In the medical community, it also includes a professional relationship with patients and their parents, along with a professional and ethical attitude. Daniel Goleman defined soft skills as "emotional intelligence" and claimed that they contribute more to an individual's success or failure than technical skills or the intelligence quotient [2].

> Whether you think you can or think you can't both you are right. (Henry Ford)

Synonyms for soft skills are nontechnical or social skills as opposed to technical skills and occupational prerequisites. Soft skills complement but do not replace the latter, and for a

successful and productive working environment, there need to be a balance between "technical" and "soft" skills.

Categories of Soft Skills

As working places have become more complex and interdependent, soft skills have gained importance and are now a cornerstone of successful cooperation as well as hiring decisions. Executives are measured according to how well they can communicate a vision, define attainable goals, motivate a team of specialists, assess its performance, and make clear and well-considered decisions. The following Table 189.1 is far from complete, and may contain personal character traits which can be neither learned nor successfully simulated [2–5].

Even though these skills are grouped under five headings in the table, most of course are closely interrelated: Attitude awareness is difficult to carry off if someone's time management is faulty, as impatience can lead to rudeness. And too much attentive tolerance may interfere with successful progress monitoring, as showing too much patience may interfere with the timely achievement of goals. In medical emergency care, nontechnical skills have been classified and tools developed to measure individual or team performance [6].

Table 189.1 Some categories of soft skills important in clinical medicine

Self-management:	Interaction:
Compensation strategies	Attitude awareness
Decision making	Politeness and empathy
Willingness to learn	Showing respect
Self-assessment	Cooperation and sharing
Self-discipline	Conflict handling
Time management	Attentive tolerance
Stress resistance	Teamwork willingness
Communication:	Management:
Listening skills	Having and providing vision
Nonverbal contact	Initiative
Comprehensibility	Setting goals
Rhetoric abilities	Monitoring progress
Presentation skills	Sensing atmosphere
Delegating skills	Reconciling people
	Frustration tolerance
Organization:	
Defining smart goals	
Problem solving	
Thinking in perspectives	
Troubleshooting	

Soft Skills Are Essential for:

Leadership

The importance of soft skills for successful leadership is obvious, but a plethora of management courses suggests that this concept has been incompletely realized, not unlike the host of weight-reducing diets. Whereas "hard" or "technical" leadership focuses on progress and results alone, "soft" or "emotional" leadership also takes into consideration the performance of and relationships within the team [5]. Many executives, especially the successful ones, do not welcome their new role, particularly as it takes time and practice.

Teaching

In traditional teacher-centered learning, the teacher presented a topic (usually in front of the class on a blackboard), and the pupils – each one by and for himself – passively repeated this pattern in various forms. When the poor sustainability of this educational technique became evident, learner-centered teaching was developed, in which the pupils actively help decide on the topic, and in which discussion, group work, and the exchange of ideas are essential elements. The teacher's role changed from master to moderator. When lifelong learning became necessary, medical curricula likewise evolved from memorization to problem-oriented learning. With these modern styles of teaching, the soft skills of both teacher and learner are thought to be better developed and promoted.

Error Prevention

The study of error prevention originated in the aviation industry and has been introduced into medicine [7]. Reason et al. suggest that a cluster

of organizational pathologies known as the vulnerable system syndrome (VSS) renders some systems more liable to adverse events. The three important self-perpetuating elements in our (modern medical) systems are: blaming individuals, provoking weaknesses by denying the existence of systemic error, and the pursuit of *productive* and financial growth. The ability to recognize these symptoms is essential to improving patient safety [8].

Soft Skills in Pediatric Cardiac Intensive Care

> Success is not final, failure is not fatal; it is the courage to continue that counts. (Winston Churchill)

Soft skills complement hard skills (the part of a person's IQ), which are occupational requirements of every cardiac surgeon, cardiologist, or intensivist. The "hard" skills taught at universities and hospitals can be easily proven or tested. Most of our doctors and nursing staff are very well trained in occupational skills, but it is the soft skills that are becoming more important to the success of a team's accomplishments in congenital heart disease and pediatric cardiac surgery over the long term. Within pediatric cardiac intensive care, nontechnical skills are predominantly defined as teamwork skills, which include leadership, decision making, and situation awareness [6]. As certain life-threatening situations tend to occur with consistent frequency in this field of medicine, it benefits greatly from the awareness of soft skills.

Practical hints to improve quality:

1. Patient safety is paramount, and all decision making should be oriented toward this most important goal. Listen to your patients closely, show respect and smile, sit down while talking, think positive, and show a compassion and caring attitude.
2. The interruption of standard ICU procedures like writing prescriptions and notes, doing ward rounds, and the handover of care should be actively avoided. Interruptions occur due to telephone calls, visitors, specialists, etc., and they are often unnecessary, time-consuming, and unsafe for patients.
3. After making a diagnostic hypothesis, every detail and symptom that does not correspond to the diagnosis must be explained, not disregarded [9].
4. Standardized guidelines and algorithms should be readily available at all locations and distributed to all personnel (not only doctors).
5. Ensure that all the necessary equipments (checked repeatedly) are available at all locations at all times and are ready for use.
6. Establish routine training requirements well adapted to clinical demands.
7. Accept that anyone can make an error, and that prevention is as important as crisis management.
8. Avoid cynicism, search for meaning in your work, and celebrate team successes.

Acting in Critical Situations

Clear verbal communication is a major determinant of successful resuscitation, and programs have been developed to promote verbal communication, assertiveness, understanding, and task completion [10]. When you have made a mistake in patient care: admit it, inform the team, inform the patient's family, do your best to correct the situation, and institute a mechanism whereby such an error cannot be repeated. Since the diagnostic, surgical, and therapeutic specialization in congenital heart treatment continues to improve, and mortality in congenital heart surgery has fallen to under 4 %, it is specific, clear communication among members of the entire team that will make the difference between a good and an excellent team (Table 189.2).

> Success comes in cans, failure in cant's
> (Brahma Koumaris)

Analysis of Threads and Errors

Accept that technical and nontechnical threads and errors occur more often than acknowledged

Table 189.2 Key factors in crisis resource management (CRM) in the OR and pediatric cardiac intensive care units [11]

1. Know your environment	8. Use all available information
2. Anticipate and plan	9. Cross (double) check
3. Request help early	10. Use cognitive aids
4. Exercise leadership and cooperation	11. Reevaluate repeatedly
5. Distribute the workload	12. Practice good teamwork
6. Mobilize all available resources	13. Allocate attention wisely
7. Communicate effectively	14. Set priorities dynamically

Modified from Rall and Dieckmann [11] with permission

[12, 13]. The Clinical Incidence Reporting System (CIRS) is a widely used tool with which to detect near-mistakes and their causes [14]. The literature on the incident reporting system is extensive. Key elements for an effective CIRS are a positive and nonpunitive safety culture; the reporting system must be simple and independent from regulatory authorities, and both near-misses and actual accidents can be reported. These reports should be analyzed by experts, and oriented to systematic and human factors. The organization in question must react to the CIRS reports, warnings, and recommendations, and safety precautions and system changes should ensue [11].

CIRS approaches are part of the hospital's risk management, but have the disadvantage of acting in retrospect. For error prevention, other approaches are required. In pediatric cardiac operating rooms and intensive care units, safety must be considered predominant and be given the highest priority for everyone in the hospital at all times. A safety culture is one of its cornerstones. In a safety-culture environment, the first question after an accident is not "who is to blame?" but rather "how was this possible?" and "what can be done to prevent its happening again"?

Training Security-Relevant Behavior

The most productive and rewarding behavior in a critical situation can and must be trained, and the resource management system (RMS) derived from aviation has proved successful in medicine [13, 15]. It involves the periodical training of security awareness, communication, and decision models. A multicenter study demonstrated that even in the operating room, death and near-misses were highly dependent on human factors [16]. It also showed that the appropriate human defense mechanisms may compensate major and minor human failures [16].

Interaction and Communication with Parents

Like all pediatric subspecialties dealing with chronic disease, pediatric cardiology and pediatric cardiac surgery depends on successful communication with parents, who may be (at the worst) additional patients, or ideally, highly efficient fellow therapists. A generation ago, when more than a third of parents displayed poor comprehension of their child's congenital heart disease, "fundamental ignorance of the cardiovascular system" rather than deficient doctor-parent communication was blamed [17]. Fortunately, the situation has improved greatly, but there is still a need for further refinement and specific training. Of course, the doctor who must explain any significant heart problem to parents must also take their educational level into consideration, and assess their concerns as well as any knowledge deficits. As cardiac malformations and clinical problems differ greatly, such communication is inherently creative and cannot be dissected into individual skills [18]. An effective doctor-patient relationship helps reduce parental anxiety, enhances treatment compliance, lowers the need for rehospitalization, and raises the family's quality of life. Nearly all parents are convinced that clinical trials help to improve pediatric cardiac critical care, but to get parents to participate, the attending physician must communicate effectively and have or take enough time to educate parents about a specific clinical trial in cardiac critical care [19].

Teaching Soft Skills

Learning soft skills is the essential aspect of the successful human socialization that normally happens within the family, especially through the interaction between parents and siblings. As families, at least in the developed world, are becoming smaller and smaller, the opportunity to practice soft skills is being diminished. Moreover, interaction with electronic media, an activity taking up more and more time in many children's lives, does not encourage the development of these abilities to the same degree as did playing with brothers and sisters.

Though these skills are difficult if not impossible to teach theoretically – especially not within traditional teaching concepts – coaching programs can create specific tasks and, thus, provide skills-related learning experiences. The more they approach real situations in the working place, and the more they are coached by genuinely expert guides, the more they will succeed. There is a key difference between teaching and training, as the former is unlikely to modify an individual's performance in the intensive care unit. For resuscitation, puppets and interactive devices have been developed and are widely used. Video recordings have been successfully used for training purposes, quality assessment, and to improve cooperation within the team [20, 21]. However, this approach has its own ethical and legal problems.

Conclusions

"Soft skill" is a modern and rather vaguely defined term. The focus on doctors with well-developed soft skills should not displace well-educated and trained, highly competent surgeons, cardiologists, intensivists, and nurses. These hard skills are imperative to achieve good results in this medical "high-tech" field. It is the difference between good and excellent that can be attained by the additional implementation of well-honed soft skills. They help to create a safer environment and more supportive atmosphere for our pediatric patients and their families. Soft skills in conjunction with optimum support from other team members, with clear thinking and open and honest communication may not just minimize errors – they may also help prevent the waste of resources and staff burnout.

Psycho-emotional Stress in Pediatric Cardiac Units

190

Jeannie Zuk and Ayelet Talmi

Abstract

Healthcare professionals working with cardiac patients routinely confront emotionally challenging situations. Whether delivering bad news to families during the prenatal period, helping families make difficult decisions about treatment options, providing care to critically ill children, or experiencing patient losses, the cumulative experience of this work may have lasting impact on providers. A vast literature documents the psycho-emotional distress of critical-care providers, detailing experiences with constructs including burnout, compassion fatigue, secondary trauma, and moral distress. Characterizing such experiences and examining the contexts in which they emerge is essential for supporting the well-being and increasing the longevity of professionals working in critical-care environments.

Introduction

Psycho-emotional Stress

Unfortunately not all patient stories have a happy ending, and some may involve a long and stressful journey affecting not only families but healthcare providers as well. Psycho-emotional stress is a broad term that encompasses a variety of negative emotions including anger, guilt, helplessness, as well as several interrelated concepts such as moral distress, compassion fatigue, secondary trauma, and burnout. Described as the cost of working in a high stress, high-acuity environment across medical subspecialties and critical-care environments, this stress is most frequently manifested when provider team members are in conflict over patient-care goals or when personal values are different from patient and family values.

Consider the following hypothetical case: A 5-day-old term male infant presented to the emergency room at a rural hospital after 2 days at home with cyanosis, poor feeding, and floppiness. An emergency room echocardiogram revealed previously undiagnosed hypoplastic left heart syndrome (HLHS). The infant was transported to a tertiary care children's hospital and stabilized in their cardiac intensive care unit (CICU) with prostaglandins, intravenous fluids, and vasoactive drugs. A stage one Norwood procedure was performed and was relatively uneventful. The infant returned to the CICU intubated and on moderate dose epinephrine and milrinone for poor ventricular function. During the first night, his blood pressure and tissue perfusion abruptly decreased, and despite escalating epinephrine and intensive metabolic management, he required emergent ECMO support. His function improved over several days, he was weaned off ECMO, and his chest closed after 3 days.

For the next 18 days, this infant remained in the CICU for widely varying oxygen requirements and slow advancement of feeds. His 19-year-old mother stayed at her son's bedside as much as possible but had two other children at home, a 6-h drive from the hospital. She was aware of the serious nature of her son's condition, but emphasized she understood the surgical plan and complications for HLHS and wanted "everything done" for her baby.

Because of his deteriorating hemodynamics, the infant was taken to the cardiac catheterization laboratory where he was diagnosed with pulmonary hypertension and placed on an oscillator and inhaled nitric oxide. He began to have pulmonary hypertensive crises requiring aggressive respiratory support, medical paralysis, and sedation. His cardiac function continued to worsen and he was found to have a stenotic pulmonary vein, possibly eliminating his eligibility for the next stage of the 3-stage surgical repairs for HLHS. A heart transplant was discussed given his tenuous hemodynamics and worsening failure to grow. He was placed on the transplant list despite lack of consensus among nurses, physicians, and surgeons about the appropriateness of continued aggressive care. His mother was rarely at his bedside now, because of her other children but called the unit frequently to obtain updates. The baby was weaned to a conventional ventilator after several weeks but continued to require vigorous resuscitation. The team found these interventions distressing, expressing concerns about causing harm to this baby, as well as voicing concerns about the infant's apparent suffering and quality of life. At a care conference, disagreement among physicians, nurses, and other staff about the correct course of action led to heated discussions. Staff morale was said to be extremely poor, with several nurses stating, "I don't know how much longer I can do this."

This infant remained hospitalized in the CICU for 3 months at which time he was again placed on ECMO for another acute hemodynamic decompensation. His mother was kept informed about her son's deteriorating condition by phone. She said she understood how serious his condition was and urged the team to do "everything." Ten days later the infant was unable to be separated from ECMO and he died in the CICU. His mother was unable to make it to his bedside.

In spite of improved surgical techniques and medical management of infants and children with

congenital heart disease, stories like the one described above are an ongoing part of working in critical care. The medical and surgical management may lack consensus among the critical-care team, or else, even if consensual, it may be emotionally demanding, leading to psycho-emotional stress, poor morale, and possibly staff retention issues.

Several overlapping concepts are considered part of psycho-emotional stress and include burnout, compassion fatigue, secondary trauma, and moral distress. While there is considerable overlap among these concepts and they are often used interchangeably, each concept will be discussed separately in this chapter. Additionally, examples of provider stress when giving bad news and facing the death of a child will be discussed, using words from providers whenever possible.

Prenatal Diagnosis

Improvements in prenatal imaging, including ultrasonography, magnetic resonance imaging (MRI), and fetal echocardiography, over the last decade have made a four-chamber view of the fetal heart and verifying if the great vessels are well positioned a standard practice. Although some cardiac lesions may develop late in pregnancy, abnormal four-chamber views may detect approximately 50 % of congenital heart disease, including fetal arrhythmias and abnormal situs [1]. Care for the affected fetus requires a multidisciplinary approach, including obstetricians, perinatologists, neonatologists, cardiologists, cardiac surgeons, nurses, social workers, and others, all of whom bring a different set of experiences and perspectives to the pregnant woman and her family. In addition to providing valuable information about a fetal cardiac anomaly, when considered within an ethical framework, such information may require uncomfortable discussions and decisions about continuing the pregnancy, fetal interventions, postnatal management, and the possibility of an uncertain outcome. Results from an ultrasound or fetal echocardiogram may provide reassurance when a woman is referred for prenatal concerns. However, when the news is bad, the healthcare provider often faces parents' emotions including sadness, anger, or shock. Coping with such bad news impacts not only the parents but also those providers tasked with repeatedly giving the news and having to provide care for the mother and fetus. Providers may cope with delivering bad news by compartmentalizing, as one physician said during an interview (personal communication, July 2012):

> "I try very hard to keep how the family responds to the information separate from everything else about my job and my personal life. I try not to think about my own healthy family and how I would deal with this bad news. Yes, it's hard to see a woman crying because she's "lost" her perfect baby and it's even harder knowing my diagnosis may have led to termination of the pregnancy, but I can't dwell on that. I go home, have a glass of wine, and try not to think about all the families I saw that day. It works for now."

For other providers, the cumulative effect of giving bad news may lead to finding another position within the institution or leaving cardiology, neonatology, or critical care altogether. As one nurse stated:

> I'm not making a difference because the babies keep dying. All I can think about is the cost to the family and their child with single ventricle disease, the repeated hospitalizations, the strain to the marriage and the lack of available resources. I can't take it anymore and want to go where I can fix things.

The Case of the Hypoplastic Left Heart Syndrome

Dramatic changes in the diagnosis, management, and outcomes for hypoplastic left heart syndrome (HLHS) over the last two decades have changed the discourse. Prenatal diagnosis of HLHS has a prenatal detection rate as high as 85 % [2] in major medical centers, with up to 95 % of cases of HLHS confirmed on postnatal examination. Survival rates to adulthood with the three-stage approach are close to 70 % [3], although there is significant variation among centers. In spite of

improvements in surgical interventions and critical medical management, the optimal approach is still debated, with a lack of agreement on many of the management issues [3]. Of interest are the questions around comfort or palliative care, developmental outcomes, long-term survival, and quality of life.

HLHS accounts for up to 9 % of congenital heart disease [2]. With current estimates of 70 % infants diagnosed with HLHS surviving to adulthood with good management, comfort or palliative care may be controversial and not discussed in some centers [2]. Wernovsky [4] argued that palliative care is no longer a valid option for HLHS and not in the best interest of the child or the family, because palliative care is offered only out of frustration related to a specific challenging case where a child died with end-stage heart failure years after the third surgical intervention. Many, but not all, physicians are comfortable presenting families with management choices including the three-stage surgical procedures, a hybrid palliation, or cardiac transplantation. A survey of pediatric cardiologists and cardiac surgeons in North America showed that almost all (99.7 %) physicians discussed staged surgery, 67 % discussed cardiac transplantation, and 62.2 % discussed comfort care or palliative care; only 14.9 % included all three options in the discussion [5]. The authors stated that recommendations for nonintervention were associated with respondents' own hypothetical choice of comfort care for their own child or fetus.

Byrne [6] found that physicians have become more optimistic about surgical intervention outcomes with HLHS and may downplay the risks, calling the omission of offering palliative care ethically worrisome. At the same time, Johnson [7] reported that 64 % of physicians and 62 % of nurses reported discussing comfort care with parents. Kon [8] maintains that more educated parents with access to the Internet will find out about palliative care on their own, potentially disrupting parents' trust in their physician if not brought up as an available option.

A decade ago, palliative care, cardiac transplant, and the three-stage surgical reconstruction were all discussed equally with families; pregnancy termination of an affected fetus was also mentioned [9]. The discussion centered around survival with an emphasis on autonomy and supporting family decisions through provision of impartial information about survival statistics and comorbidities (e.g., neurodevelopmental delays). Zeigler [9] briefly refers to the importance of providers attending to their own values and contributions to the discussion with the family, without acknowledgement of the effect of such discussions on providers. A recent study from the UK with similar responses indicates that 50 % of parents with a prenatal diagnosis of HLHS before 20 weeks gestation would terminate [10] but highlights that counseling parents is difficult for the physician.

While some providers feel comfortable discussing how they would handle HLHS management for their own child [11], most prefer nondirective counseling that maintains boundaries between their personal and professional attitudes. In studies examining the choices nurses and physicians would make if their own or a family member's pregnancy involved HLHS, 48 % would terminate, 22 % would continue the pregnancy, and 30 % did not know what they would choose [12]. In a similar survey, 43 % of pediatric residents and 50 % of nurses reported they would terminate if faced with a prenatal HLHS diagnosis and 48 % of residents and 68 % of nurses chose or seriously considered comfort care with HLHS diagnosed postnatally, citing concerns about long-term quality of life and survival [13].

Such research suggests that while providers counsel families toward intervention, when personally facing an HLHS diagnosis, their choices become more ambiguous. Providers' differential responses and ambiguity around decisions reflect a tension between the professional and personal arenas that surfaces in critical-care environments. Although providers operate under institutional and professional practice parameters, they bring their own values, beliefs, and expectations to critical-care cases and, consequently, to their interactions with patients, families, and other professionals. When a discrepancy exists between the professional and the personal beliefs,

providers may experience discomfort, distress, and potentially more impairing emotions that directly impact the work they are tasked with doing. The conscious efforts to suppress their own feelings and maintain composure during interactions with families [14] may further exacerbate the situation.

Giving Bad News

It is commonly accepted that children and their parents are physically and emotionally stressed by being in the hospital and particularly with high risk cardiac surgery or an intensive care unit stay. Receiving bad news about a child's medical condition is also known to produce an acute stress response for family members. The consequences of delivering bad news on providers are less understood, with little information about the cumulative effect of stress on healthcare professionals. Ptacek and McIntosh [15] suggest that giving patients bad news about their medical condition is stressful for providers, especially medical students and residents early in their careers. Other authors [16] suggest that critically ill patients may elicit physicians' own emotions and can reflect a need to rescue feelings of failure and frustration, as well as powerlessness. The tendency to distance from intense emotions may affect the physicians' sense of well-being because unexamined emotions may lead to distress, disengagement, burnout, and poor judgment.

Physician stress appears to increase with the perception that the delivery of information did not go well, and many physicians report enduring stress beyond the patient encounter that may impact subsequent patient interactions. Cohen [17] postulated that physicians experience an acute stress response beginning with the anticipation of the actual delivery. The only study of pediatric cardiologists [18] suggests providers must be aware of parents' feelings as well as their own emotions and *know how to keep everything under control*. In this study, the authors also state that some cardiologists can create a closer relationship with parents by sharing stressful news, while others prefer more distance and argue they are careful about getting too close to families. Interestingly, cardiologists were asked what caused the most distress, and most felt making an incorrect diagnosis or a breakdown in communication with the family was more distressing than actually delivering the bad news.

Death of a Child

Nurse and physician experiences of the death of an infant or child they have cared for are possibly the most distressing aspect of working in the healthcare field. With death commonly described as a physician's personal failure or failure of the team [19–21], the impact of a patient's death can be long-lasting and associated with compassion fatigue, moral distress, or burnout. Jackson et al. [19] reference physicians' descriptions of a particular patient's death as a critical incident in their career, with lasting implications for how physicians care for other patients. In this study, physicians were most distressed when they had a recent personal experience with loss, identified with a patient or family, had a close relationship with the patient or family and the death was unexpected or traumatic, and finally if they had a sense of accountability for the death. As one physician stated when pronouncing death for a patient she does not know:

> . . .I did as all of us have done, have had to do: I stopped thinking about her life, her hopes, her dreams, even her family, and did my job. . .I went home [afterwards] and tried to never think about this patient again. And when my husband kissed me and asked how my day was, I just answered, 'Fine,' with a smile. [22]

This response is seen as the only possible response in a busy day – to shut off emotions quickly and keep all negative feelings in check so they never get in the way of *doing your job*. The tendency to suppress feelings because of the need to take care of the next patient may result in the accumulation of unresolved grief. In the USA, approximately 15 % of physicians are thought to experience clinical impairment at

some point in their careers with rates of anxiety, depression, and suicide higher than in the general population [14].

Physicians and nurses often suffer after the death of an infant or child yet frequently work in clinical settings where grief is inadequately acknowledged or even denied. Unit culture may have unwritten, unspoken rules about appropriate behavior when a child dies [20]:

> It was expected that grief responses would never be so intense as to impair clinical judgment or lead to emotional breakdown. . .suffering should never be apparent to other sick or dying children.

Suffering and grief may be seen as a sign of weakness, with the expectation that a good nurse or physician is invulnerable, strong, in control, and able to effectively cope with painful or distressing experiences [20].

Some physicians became emotionally shutdown and reported little emotional reaction at the time of the patient's death, only to have "unexplained" problems later. Unprocessed emotions and grief responses may manifest in ways that are not immediately evidenced or understood by the individual. As one physician stated (unpublished data), reflecting on the death of a patient many years previously, "I will never find a resting place for that one."

Findings from Papadatou's work suggest that physicians' and nurses' grief is a dynamic intrapersonal and interpersonal process for those working with critically ill infants and children where pain, suffering, and death are expected events and part of being a provider. Responses to grief may include recurrence of both positive and negative thoughts about the patient, sadness, depression, anger, and crying. Some providers seek peer support, while others prefer coping privately. Expressions of grief may come close to the patient's death or long after and may be different for physicians than for nurses [23–25].

The lingering sequelae of distress and unresolved grief can be manifested in compassion fatigue, burnout, and moral distress. Many providers are able to recall distressing events years and even decades later. Some are able to process the experience and learn from their experience, while others become distraught with the continuing suffering, repeated hospitalizations, and death of the child. It is important to understand the cost of working in pediatric critical care with infants and children diagnosed with congenital heart disease.

Burnout

Physician distress has received increased attention in the last decade with stress and burnout considered so pervasive to be called a public health issue [26] and linked to increased rates of self-medication, alcoholism, depression, and anxiety as well as poor patient care [27–29]. It has become part of the everyday vocabulary as when a healthcare provider says he or she needs a break or that he or she is "burned out." Burnout is not unique to a particular specialty area, affecting surgeons [30], oncologists [31], intensivists, obstetricians [32], and emergency or trauma physicians. Nurses are by no means immune to stress and burnout, which increases the risk of nurses leaving critical care or the nursing profession altogether. Additionally, burnout is not a US phenomenon with studies from Italy [33], Canada, the UK, and Germany [34] reproducing similar findings.

Burnout has been best described by Maslach and colleagues, developers of the Maslach Burnout Inventory (MBI) [35]. Burnout is defined as a "prolonged response to job stressors and measured by three dimensions: sense of overwhelming exhaustion, feelings of cynicism and detachment, and a sense of ineffectiveness at work or lack of accomplishment" [36]. Often used interchangeably with compassion fatigue, secondary trauma, or the more global distress term, subtle differences distinguish burnout from these other concepts. Maslach et al. describe *exhaustion* as the central quality of burnout and the most commonly reported but explain that exhaustion alone is not sufficient to portray the experience. Exhaustion frequently leads people to distance themselves, emotionally and

cognitively, from the source of the exhaustion, the healthcare providers, and the patient or family. Additionally, there seems to be a strong relationship between exhaustion and cynicism, or depersonalization. The association of the third dimension of burnout, inefficacy, or a sense of lack of accomplishment, to the other two is less clear. Burnout is important to identify and address in healthcare providers, especially those working in critical-care, oncology, and trauma units.

Many studies have focused on medical students and residents with concerns over serious potential consequences for student's health, professionalism, and patient care [28, 30, 37–39]. Additionally, burnout has been related to the quality of care physicians provide, affecting empathy and compassion, prescribing habits, depression, and the likelihood of making medical errors [40, 41].

Thought to be more common among nurses than physicians, many studies focus on the emotional exhaustion associated with burnout. In a large, six-country study of 54,000 nurses from the International Hospital Outcomes group, higher levels of burnout were associated with the provision of lower ratings of quality of care [34]. Pardoe [42] talks about the pediatric intensive care nurse emotionally devastated when her patient attempts suicide and her struggle to return to work. While some studies have focused on burnout rates among oncology, hospice, emergency department, and intensive care nurses and their association with increased use of alcohol and drugs, increased anxiety, and depression, others report that critical-care nurses are at no higher risk than other nurses [31, 43–45]. In a study comparing burnout across provider types (i.e., nurses, physicians, and residents), Hyman et al. [46] found global burnout scores higher in perioperative physicians than nurses and highest among residents suggesting that this phenomenon is by no means unique to nursing and perhaps may impact physicians more profoundly. Other studies have not found differences between physicians and nurses but found higher rates of burnout among providers with fewer years of experience [47].

Compassion Fatigue

Often used interchangeably with secondary trauma and described most frequently with emergency or trauma care providers, compassion fatigue is now thought to be a growing problem among all healthcare providers. It has been referred to as a "routine occupational hazard of exposure to working with the critically ill child" [48]. According to Meadors [49], there are nuanced differences between the symptoms of compassion fatigue, post-traumatic stress disorder (PTSD), secondary traumatic stress (STS), and burnout. Overlapping symptoms, interchangeable usage, and the lack of conceptual clarity make it difficult to distinguish among these constructs.

Figley [50, 51] attributes symptoms of compassion fatigue to the consequence of the empathic individual working with traumatized people, saying "those who work with the suffering suffer themselves because of the work." Hallmark signs of compassion fatigue have included sadness and grief, nightmares, avoidance, addiction, increased psychological arousal, detachment, and witness guilt [52]. Some attribute compassion fatigue as caring too much [53], as losing the capacity for compassion [54], or as a result of being good at empathizing [55]. In spite of the difficulties in identifying differences between compassion fatigue, secondary trauma, and burnout, there does seem to be a negative effect on providers, physicians, and nurses alike, resulting in decreased productivity, more sick days, and a higher rate of turnover [56]. Oncology nurses are thought to be at high risk of compassion fatigue because of the constant exposure to suffering [57] and the exposure to children's death [58]. Pediatric emergency department nurses [45] are also thought to suffer from compassion fatigue because of the societal value of protecting and caring for children [48, 49].

Several scales used to measure compassion fatigue and secondary trauma include the Secondary Traumatic Stress Scale, the Compassion Fatigue Self Test for Helpers, the Compassion Fatigue Scale-Revised [59], the

Compassion Satisfaction and Fatigue Test, and the Interpersonal Reactivity Index [48]. Compassion fatigue or secondary trauma may be difficult to measure because of the "culture of silence" often seen in critical care with admission of suffering seen as a professional weakness [48]. Study results of prevalence and specificity of compassion fatigue are mixed [60], and many using these scales are difficult to interpret because of limited sample sizes and inconsistent use of such scales. However, because of the negative impact on providers as well as patients, it is important to address provider suffering and to develop appropriate interventions.

Moral Distress

Moral distress, experienced by healthcare providers, has received increased attention in the past 5 years in both the popular and medical literature with the growing recognition of the physical and emotional toll on providers as well as on institutions with retention and medical errors. Originally defined by Andrew Jameton in 1984 to describe critical-care nurses' experience of knowing the right thing to do but prevented by institutional constraints [61], the concept has grown to include physicians, social workers, and other healthcare providers. The focus is on both physicians and nurses. While the patient-care experience may be different between these two groups of caregivers, the two disciplines have more in common than previously thought. Based on principles of moral theory, understanding moral distress in critical care is essential because it influences how patient-care decisions are made and how the unit functions as a team.

In the broadest sense, personal moral theory refers to how providers evaluate choices and decisions in the critical-care environment as "right" or "wrong." Timmons [62] posits that the purpose of moral theory is to examine the underlying features of actions that make them right or wrong, good or bad. Finally, role expectations refer to what one "should" do as a professional in a given situation [63]. For example, a nurse may say "my job is to support the family and to be a patient advocate," while a physician may define his or her role as making the best decisions about care for this family using his or her clinical expertise and judgment. Oberle and Hughes state that both physicians and nurses experience institutional constraints on moral agency while remaining ignorant of each others' limitations [63]. Other factors including age, gender, religious affiliations, or cultural background may contribute to how providers respond to critical-care situations.

Jameton expanded his definition to differentiate initial moral distress, where the nurse confronts a disturbing situation and experiences feelings of discomfort, frustration, anger, and anxiety, from reactive distress with reflection on the inability to act on the initial distress [61]. Reactive distress may have longer-lasting consequences, including physical symptoms such as heart palpitations, loss of self-worth, and depression, ultimately leading to job dissatisfaction and nurses leaving the profession entirely [64]. Fry et al. identified symptoms such as crying, loss of sleep, loss of appetite, nightmares, feelings of worthlessness, loss of confidence, heart palpitations, changes in body functions, and headaches when unresolved moral distress occurs over time [65].

Growing from approximately 35 articles identified in PubMed in the 1990s to over 200 between 2000 and 2010, nursing moral distress has been associated with powerlessness in hospital settings [66–69], failure to uphold patient autonomy [70], witnessing patient harm or suffering [67, 71], poor ethical climate [72], and end-of-life issues with overly aggressive care or the perception of futile care [73]. Increasingly, nurses attribute symptoms of physical, emotional, and social problems to moral distress [65, 68, 74], including feelings of sadness, anger, and frustration; physical symptoms such as headache, neck pain, and muscle pain; and reluctance to come to work, emotional or physical withdrawal from others, or reluctance to take on patients with complex ethical issues. Paradoxically, moral distress among nurses has also been reported to enhance relationships with other nurses and an increased desire to advocate for patients [74].

Experiences of moral distress involve complex patient-care issues, are not easily measured, and are rarely resolved. Moral distress has been identified as a grave area of concern particularly among critical-care nurses because of high patient acuity and high levels of stress, often leading to high turnover rates. The American Association of Critical-Care Nurses' position statement on moral distress challenged nurses and their employers to address the consequences of moral distress [75]. Intensive and critical-care nurses experience high levels of moral distress; new and inexperienced nurses may experience tremendous stress because of patient situations or communication and collaboration failures among nurses and physicians [70]. These new nurses may experience secondary trauma witnessing or participating in distressing situations such as aggressive futile care of patients, with feelings of guilt or incompetence. Acknowledging the negative effects of unresolved moral distress, some institutions have developed educational programs and debriefing sessions to try and mitigate nurses' experiences of moral distress [76, 77].

Corley conducted rigorous and systematic work on moral distress and developed the Moral Distress Scale (MDS) [78, 79] that measured levels of distress as well as intensity. Corley found that inadequate staffing causing the most distress with 15–26 % of nurses reporting they had resigned a position because of intolerable levels of moral distress. The MDS has been used extensively in studies examining nursing moral distress. Moral distress increases with years of nursing experience, futile care situations, and inadequate pain management situations, as well as experience caring for oncology and transplant patients [80], inappropriate aggressive care associated with the highest intensity of moral distress, high rates of job dissatisfaction, and interestingly, nurses' reluctance to participate in blood and organ donation [81].

While the MDS is the most frequently used scale in studies of moral distress, the scale was normed with both adult and pediatric nurses and physicians were not included in the development. Long thought to be a nursing issue because of the power differential between nurses and physicians, physician experiences have not been discussed until relatively recently. Davis, a physician, recognizes that doctors feel as powerless and frustrated as do nurses when they do not have the ability to make clinical decisions they feel are most appropriate [82] or with institutional constraints on physician authority [83]. Davis states that the physician most typically expresses moral distress with anger, with caustic attitudes or verbal abuse of residents and nurses. Interest in moral distress has reached the popular press as well with a column in *The New York Times* [84] by Pauline Chen, a surgeon, where she notices moral distress in conversations with nurse and physician colleagues who are caught between competing obligations to patients, insurance companies, and families.

Medical students and residents are often "caught between" competing interests and medical hierarchy [85] but also experience moral distress when witnessing poor patient care, when placed in situations without adequate supervision or training, or when seeing disrespect for colleagues [86–88]. Hamric and Davis [82] discuss that while nurses are particularly vulnerable because of the hierarchy of hospital structure, both nurses and physicians feel powerless in many situations and say that speaking out arouses their fears of criticism. In one of the few studies to include physicians, a survey of perspectives on caring for dying patients in an adult ICU setting showed that physicians did experience moral distress but had higher satisfaction with quality of care perception and of institutional ethical environment and higher perceptions of collaboration [89].

The discussion on moral distress has shifted in recent years from studies describing the nursing experience to examining the range of experiences and the development of moral distress as an umbrella concept [90], while others question whether moral distress can accurately identify a wrong being done to patients [91]. Epstein and Hamric [92] see the definition of moral distress becoming blurred, minimizing the experience to emotional distress over a tragic patient-care situation rather than identifying the issue as an

ethically challenging situation. Moral distress is increasingly described in professions other than nurses or physicians and includes rehabilitation professionals [93], podiatrists [94], genetics professionals [95], respiratory therapists [96], childbirth educators [97], and psychiatric professionals [98]. Recently, specific aspects of moral distress have been examined such as "inappropriate care." As defined by Piers et al. [99] inappropriateness of care involves specific patient-care situations where the provider acts in a manner that is contrary to personal or professional beliefs, with the most common reasons given by providers as excessive or aggressive care, feeling care was disproportionally provided, and end-of-life decisions being made too late.

Moral distress is variably experienced by healthcare providers. Gaps still remain in the understanding of moral distress in experienced physicians rather than in medical students or residents where moral distress is attributed to their lack of power and position in the hospital hierarchy. There is also a need to better identify differences and similarities in the nurse and physician experience of moral distress in order to develop strategies to support providers in caring for critically ill children.

Conclusion

Providing medical care to critically ill children in pediatric cardiac units can be rewarding and challenging, with opportunities for healthcare providers to make a difference in the lives of these children and their families. For some healthcare providers, the challenges may become stressful, and for a few, it may become overwhelming, leading to psycho-emotional stress. This stress may be manifested at work or involve changes in providers' personal lives. Constructs including burnout, compassion fatigue, secondary trauma, and moral distress have gained recognition as important issues that need to be openly addressed to improve healthcare providers' job satisfaction as well as the safe, compassionate, and effective provision of patient care. While it is probably not possible to prevent all psycho-emotional stress, some institutions have implemented programs to address aspects of this stress, including multidisciplinary debriefing sessions, workshops, and conferences. Psycho-emotional stress has also increased visibility in medical school and residency training programs as our understanding of the long-term consequences of stresses such as burnout has grown. Acknowledging psycho-emotional stress among healthcare providers is as important as providing excellent patient care in pediatric cardiac units.

Surgical Site Infection in Pediatric Cardiac Surgery: Classification, Risk Factors, Prevention and Management

191

Faith A. Fisher and James Jaggers

Abstract

Postoperative surgical site infections are a major cause of postoperative morbidity and mortality in cardiac surgery. While surgical site infection in adult cardiac surgery has been well characterized and studied, in pediatric cardiac surgery, the classification, prevention, and management is less well studied and significant practice variation exists. Many centers have entered a phase of process improvement in pediatric cardiac surgery, with significant effort devoted to decreasing morbidity associated with cardiac surgery, of which surgical site infection is one of the most persistent. Risk factors for surgical site infection documented in the literature are quite variable, but consistent factors include young age, long operations, and longer preoperative stay. Gram-positive cocci are the most common pathogen, but gram-negative and fungal organisms are not infrequently found. Preventive strategies have mirrored those that have been successful in the adult cardiac surgical population. These include optimizing antibiotic prophylaxis, decreasing bacterial contamination of the surgical site skin, limiting blood product utilization, and limiting duration of surgery. In children, optimization of nutrition is also of significant importance. Many centers have adopted quality improvement protocols in an effort to decrease the risk of surgical site infection and decrease the variability in management strategy. With these efforts, morbidity associated with infection following cardiac surgery in children can be reduced significantly.

Introduction

Surgical site infections (SSI) are known to increase cost of care, length of hospitalization, and readmission rate following pediatric cardiac surgery. In adult patients, the economic impact is well documented, increasing cost by up to $299,237 for deep infection or mediastinitis after open cardiac surgery [1]. One pediatric center reported a $27,288 average increase in cost per surgery in patients that developed SSIs [2]. Consequently, medical care providers and quality improvement agencies have spent significant effort to characterize surgical site infection risk prevention and treatment. While there have been several single-center retrospective studies and administrative database investigation regarding surgical site infection, there is very little prospective evaluation in the pediatric cardiac surgical patient population [3, 4]. Variability in classification plagues the literature with some studies reporting mediastinitis while others report superficial, deep, and mediastinal infections and applying different definitions to each. Practice variation exists regarding the choice and duration of antibiotic prophylaxis, skin preparation before and during surgery, and management of surgical incisions and infections. Clinical guidelines established in adult patients may not necessarily apply to infants and children and require further study. The purpose of this entry is to present current classification systems for SSI and examine risk factors, prophylactic measures, and common treatment options for SSI.

Pathogenesis

A recent survey among congenital heart programs (43 % responder rate) reported a mean incidence rate for surgical site infections (including superficial, deep, and organ space) of 1.53 % with a mean yearly volume of 237 operations (large range of surgeries among responders) [5]. The incidence of mediastinitis has been reported to occur in 0.2–1.4 %. The median time to diagnosis is 11–14 days after surgery, usually longer than for superficial infections [6, 7].

A surgical site infection occurs when the contaminating pathogens overcome the host defense system allowing a local infection to occur. These pathogens are typical normal skin flora that enters the operating site either by direct contamination from the patient's skin or internal organs, through the hands and instruments of the surgical staff, or by bacteria-carrying particles that are airborne in any operating theater. Small numbers of low-virulence bacteria are eliminated by the innate immune system in the tissue. The ability to withstand contaminating bacteria depends on both the local and the systemic host defense. While most SSI result from inoculation during the surgical procedure, contamination can occur after the surgical procedure either before the incision has epithelialized or if there is disruption of the neoepithelium by trauma or abrasion. The source of infection may be from oral, endotracheal or nasal secretions, native skin flora, air contaminants, or health care providers. Methicillin-sensitive *Staph aureus* is the most common organism, but others like gram-negative rods *Pseudomonas*, *Enterococcus*, *Escherichia coli*, and *Serratia* have all been reported. Fungal infections occur often in the setting of prolonged open-chest or immune-compromised patient with poor nutrition and/or poor tissue viability.

Classification

In efforts to properly characterize and classify postoperative complications and morbidity, the Multi-Societal Database Committee for Pediatric and Congenital Heart Disease (MSDCPCHS)

Table 191.1 Multi-Societal Database Committee for Pediatric and Congenital Heart Disease criteria for surgical site complications

Sterile sternal instability	Superficial, deep layers and skin intact and sternal edges separated. May also coexist with separation of superficial and deep tissue but is no longer sterile sternal instability and categorized as dehiscence. May be caused by infection, use of corticosteroids, trauma, vitamin C deficiency, rupture of sternal closing material
Sterile wound dehiscence	Separation of tissue layers of surgical site (may include the skin, superficial and/or deep tissue, sternum) and can occur in the absence of infection
Foreign body complication	Pain caused by sternal wires necessitating removal, sutures or sterna wires resulting in sinus tracts requiring excision, pacemaker generators necessitating removal
Hematoma	Sterile extravasated blood within the space adjacent to surgical wound
Superficial wound infection	Infection involving only the skin and subcutaneous tissue and must have at least one of the following: (1) purulent drainage; (2) isolated organisms from aseptic culture of fluid or tissue; (3) pain, swelling, redness, or heat or incised by physician with positive culture; 4) diagnosis as superficial infection by attending physician
Deep wound infection	Involvement of facial or muscle layers of the incision and not the organ space with no evidence or sternal osteomyelitis and must have one at least one of the following: (1) purulent drainage; (2) fever, localized pain, or tenderness; (3) abscess or other histopathologic or radiologic evidence of infection; (4) diagnosis by attending physician
Mediastinitis	Organisms cultured from mediastinal tissue or fluid that is obtained in a sterile manner, or the patient has visual evidence of mediastinitis on exploration. The patient may also have either fever, chest pain, or sternal instability in addition to purulent drainage, positive culture, or widening of the mediastinum. This definition is modified in infants that have the above findings and evidence of sepsis
Seroma	A localized collection of serum confined within a space or potential space within or adjacent to a surgical incision that does not have organisms or obviously purulent

was convened to address the issues. In the document that followed, a classification system was proposed that has since been adopted by the major professional societies involved in the care of pediatric cardiac patients [8]. Consistent classification of complications like surgical site infection will enable providers to track incidence and consequently develop and employ evidence-based prevention and management strategies. The MSDCPCHS has created a list of surgical site complications including cardiac surgical site infection criteria, which, in large part, were adapted from the CDC's National Healthcare Safety Network Criteria [9] (Table 191.1). The criteria for mediastinitis and other structural postoperative complications were adopted from The Society of Thoracic Surgeons. The Center for Disease Control (CDC) recently updated criteria for procedures on the heart, valves, or septum tracking infection that occurs within 30 days of surgery. Infection at the surgical site following heart transplantation or insertion, manipulation, or replacement of pacemaker must be tracked up to 90 days postoperatively. The MSDCPCHS has not updated their criteria to reflect this change. For the most part, quality initiatives across the USA are utilizing the CDC's NHSN criteria for the purpose of consistency. The CDC SSI criterion for adult and pediatric patients is available at www.cdc.gov/nhsn/pdfs/pscmanual/9pscssicurrent.pdf.

SSI is typically superficial or deep. Those involving the organ space are synonymous with mediastinitis. In general, separation of the skin edges without cellulitis and sterile disruptions of the wound at the site of suture knots are not considered SSI. The presence of cellulitis and/or positive tissue culture that is collected in a sterile fashion is criteria for SSI. Positive culture from the organ space with or without sternal instability is criteria for mediastinitis.

Risk Factors for Surgical Site Infection

It has long been recognized that SSI is associated with many presurgical factors, some of which can be modified. Those that can't be modified include the presence of prematurity, genetic syndrome,

cyanotic heart disease, concomitant illness or morbidity, and necessity of preoperative hospitalization. Modifiable risk facts include nutritional status; duration of surgery; duration of cardiopulmonary bypass, blood transfusion, and antibiotic prophylaxis; and the necessity of open chest after surgery [10–12]. In an important study by Costello, the independent risk factors for any type of SSI were age younger than 1 year and duration of cardiopulmonary bypass greater than 105 min. Risk factors for mediastinitis included aortic cross-clamp time greater than 85 min and postoperative exposure to at least three separate red blood cell transfusions [13, 14]. When only those potential risk factors known preoperatively were considered, age younger than 1 year independently predicted the subsequent development of any type of SSI, and preoperative hospitalization independently predicted the subsequent development of organ space SSI. In this study the presence of an open chest following surgery was not independently associated with SSI.

Prevention

Preoperative

The risk of developing SSI is directly related to the presence of normal skin flora or contamination of the skin of the surgical site. Every effort must be made to reduce the bacterial burden on the wound. Recent or current treatment with antibiotics may alter the normal skin flora or predispose to colonization with pathogenic or resistant organisms like fungus or methicillin-resistant Staph aureus. Similarly, a long preoperative hospital stay should be avoided whenever possible. Patients may become colonized with the more resistant hospital flora even during a short hospitalization. Currently, most centers perform routine MRSA screening on any hospitalized patient. Same-day surgical admission is preferable for most elective cardiac surgical procedures. Preoperative showering using chlorhexidine-containing soaps or shower gels will reduce the bacterial counts on the skin. However, there is little evidence in children that SSI is reduced with this preoperative cleansing. But it is a simple and inexpensive procedure with few or no side effects. Often overlooked, nutritional status may be very important in the prevention of SSI. Nutritional supplementation is often instituted prior to a surgical procedure especially in the neonate and infant. The benefit of this must be weighed against the potential increased risk associated with parental intravenous nutrition.

Operative

It is well documented in adult patients that shaving of the skin over the operating site will increase the bacterial colonization and the risk of SSI especially if done the day before surgery. This is due to the microscopic injury to the outer skin layer that the shaving blade induces and the subsequent rapid bacterial growth on the abraded skin. This is usually not an issue in children, but if hair removal is necessary, clipping with scissors or electric clipper on the day of surgery is preferred. Operating room personnel should perform a thorough hand and forearm scrubbing with antimicrobial soap or alcohol-based surgical hand scrub that will reduce the number of bacteria on the hands of personnel in contact with the wound and instruments. During operations, minimal punctures of gloves are very common and may go unnoticed. With punctured gloves comes an increased risk of bacterial contamination of the wound with bacteria from the hands. This may be alleviated with the use of double gloves. However, whether double gloving actually reduces the rate of postoperative infections has not yet been shown.

All personnel and the patient in the operating theater will shed microscopic particles, some of them carrying bacteria that will float in the air and may land in the wound. Ventilation of the operating room is essential for reducing the number of particles in the air. Laminar airflow systems have been widely adopted in most modern operating room facilities. The use of ultraviolet lights to decrease viability of airborne bacteria has been demonstrated to be helpful in the orthopedic setting but is less commonly used in cardiac settings.

Another finding has been the relationship of operating room traffic with SSI. Limitation of traffic door openings can decrease the risk of airborne contamination. Personnel with active skin infections or severe active psoriasis have increased risk of shedding bacteria and particles and should not participate in surgery until healed or medically controlled. This may also apply to personnel with acute airway infections.

The surgical wound will be epithelialized within 24 h and the risk of infection as a consequence of postoperative direct contamination rapidly decreases thereafter. The sterile dressing applied in the OR must be left untouched during this vulnerable time period. The patient's temperature has often been associated with risk of SSI [15]. In cardiac surgery and systemic cooling, temperature variation is unavoidable, but effort should be made to restore the patient to near normothermia and limit hypothermia in the postoperative period in order to decrease potential risk.

Antibiotic prophylaxis

Proper antibiotic prophylaxis will reduce the rate of postoperative infections, although it will not eliminate them entirely. The choice of antibiotic, the dose, the timing, and the duration of prophylaxis are important, but it is even more important that the intended prophylaxis regime is actually accomplished. In general a first- or second-generation cephalosporin is adequate coverage for routine cardiac surgery. However if the patient has been documented to be colonized with MRSA or is allergic to penicillin, vancomycin is usually administered. If the patient has been hospitalized for an extended period of time before surgery, or has a document ventilator-associated or urinary tract infection, targeted antibiotics should be delivered within 1 h of surgical incision.

The most important aspect of antibiotic prophylaxis is strict adherence to the process. The most common violation of protocol is poor timing of the preoperative dose and prolonged duration of the prophylaxis. A single dose of antibiotics just prior to incision is probably sufficient for most surgeries. More than 24 h prophylaxis is not justified for any surgery. There is absolutely no support for continuing prophylaxis until drains or chest tubes are removed [16]. An antibiotic effective against the most important pathogen, which in the case of cardiac surgery is *S. aureus*, in a sufficient dose to achieve a tissue concentration above MIC during the entire operation, is recommended. Because cardiopulmonary bypass will result in dilution of antibiotic dosing, a second dose within one hour after conclusion of bypass is recommended [17].

Operative

The most important first-line defense against bacterial invasion is intact skin and mucous membranes. In the surgical setting, this defense is by definition compromised. The surgical technique is an important but difficult to evaluate factor in the pathogenesis of SSI. However, it is logical that devitalization of tissue, extensive tissue trauma, excessive electrocautery, dead space creation, and introduction of foreign material may all increase the risk of SSI. As much as possible, these sins should be avoided. In congenital heart surgery, especially in neonates, it may be necessary to leave the incision open and covered with the plan for delayed sternal closure. While some single-center reports have suggested that patients with delayed sternal closure are not at increased risk of SSI or other hospital-acquired infections, Johnson et al. have reported in a large multicenter database study that centers that used delayed sternal closure in >25 % of their cases of stage 1 palliation for hypoplastic left heart had a significantly higher rate of SSI [18]. In the current era, with improvement in surgical technique and management of cardiopulmonary bypass, the need for routine-delayed sternal closure has become less common. While it is imperative that an accurate and precise surgical repair be performed, it is reasonably clear that prolonged cardiopulmonary bypass time and open chest time may be a risk factor for SSI [19]. Excessive transfusion has been associated with both catheter-related blood stream infections and surgical site infections in pediatric cardiac patients [20].

Postoperative

In the postoperative period, it is important to maintain careful coverage of the incision until it has epithelialized which is usually within 24–48 h. It is important to note that the epithelial layer covering surgical incision is fragile within the first several days and it may be advisable to prevent abrasion or disruption of the incision for some period of time after surgery. This is particularly important in children that are likely to scratch or pick at the incision. Also, coverage of the incision beyond the first couple of days is advisable in infants that have significant oral secretions. Maintenance of optimal tissue oxygen delivery and early institution of nutrition may also play a role in proper wound healing and prevention of SSI. If transthoracic echocardiography is necessary soon after surgery, it is important to cover the incision and use a sterile condom or glove to prevent contamination by the echocardiography probe. Table 191.2 describes these authors' protocol for prevention of infection at Children's Hospital Colorado. After institution of this protocol, the SSI rates over the last 3 years have decreased by 100 %.

Surgical Site Infection Management

Mediastinitis

The diagnosis of mediastinitis can be challenging with optimistic suspicion being key. Most mediastinitis will manifest in the first 2–3 weeks after surgery but may present several weeks after surgery especially in the case of a more indolent pathogen like *Staph epidermidis*. Most patients will present with cellulitis, drainage of purulent material, and/or wound separation. Some but not all will also have sternal instability or sternal dehiscence incision. Associated bacteremia is not uncommon, present in at least 40 % of patients in one series [21]. The optimal treatment of mediastinitis in children remains somewhat controversial. In patients in whom the sternum is unstable and infection is clear, principles of early therapy include extensive debridement of devitalized tissue and bone, wide drainage antibiotic therapy, and control of systemic sepsis. In some centers, aggressive coverage of the open wound with various vascularized muscle flaps of muscle or omentum is employed [22]. This is a good strategy for refractory cases, but is rarely necessary in most children, and in fact may complicate future surgery and prolong hospitalization [23]. In the case of obvious mediastinitis, therapeutic-targeted antibiotic therapy is indicated preferably with antibiotics that have good bone penetration and are bactericidal.

Superficial and Deep Surgical Site Infection

Many patients present with less obvious mediastinitis or the infection is clearly limited to the subcutaneous or fascial tissues. In this situation, the sternum is stable and there may not be communication with the mediastinal organ space. In these patients, local wound care principles may be employed. It is still necessary to debride devitalized tissue to decrease the bacterial contamination, but reopening the sternum may not be necessary. Local wound therapies such as wet-to-dry saline dressings or iodine-impregnated sponges have fallen out of favor. While these techniques are often successful, dressing changes often have to be performed with sedation for pain control and the duration of therapy can be quite prolonged requiring caregivers to perform the dressing changes at home after discharge. Techniques and technology employing negative pressure therapy have been increasingly used in sternal SSI in pediatric patients [24]. Proposed advantages of negative pressure therapy include arteriolar dilatation and increased microcirculation, thereby improving local tissue oxygen delivery, evacuation of excess fluid and decreasing of edema, fluid excess and tissue edema, and maintenance of a more sterile environment. These positive effects on the wound promote granulation tissue proliferation and accelerated wound healing often within 2–3 weeks for even the most serious wounds (Fig. 191.1).

Table 191.2 Children's Hospital Colorado practice guidelines for the prevention of SSI

General	Strict hospital-wide hand washing campaign
Preoperative	Chlorhexidine scrub the night before and morning of surgery
Preoperative	ECG leads as far away and lateral from incision site as possible
Preoperative/ Intraoperative	MRSA screen of bilateral nares at preop visit the day before surgery with antibiotic dosing according to MRSA status
	MRSA (−) Cefazolin 40 mg/kg prior to skin incision and every 6 h intraoperatively with redosing within 1 h of patient coming off CPB
	MRSA (+) Vancomycin 15 mg/kg over 45–60 min and completed within 1 hour prior to incision and subsequently dosed every 8 h and given within 1 h of patient coming off cardiopulmonary bypass. Renal function should be taken into account
	Perioperative antibiotics are continued for 24 h postoperatively
	Patients with delayed sternal closures should remain on prophylactic antibiotics 24 h post chest closure
Intraoperative	Use of clippers rather than razors for necessary hair removal
Intraoperative	Strict adherence to the 1999 CDC guidelines for prevention and 2011 updated recommendations published in the Annals of Surgery regarding asepsis in the operating room environment
Intraoperative	All surgical staff wear hospital-issued scrubs and change between cases
Intraoperative	Cloth hats are to be covered with hospital-issued disposable scrub cap
Intraoperative	Skin preparation with chlorhexidine 2 % alcohol 70 % and allow to completely dry before draping
Intraoperative	Antibiotic irrigation applied to each layer during closure
Intraoperative	Non-exothermic-drying skin glue applied in thin layer along incision site
Postoperative	Consideration of alternative closure to intradermal sutures if chest closure is delayed longer than 24 h (i.e., running proline suture or staples)
	Chest closure is to be as sterile as possible with minimal traffic and sterile attire donned by all persons in surgical area
Postoperative	Sterile Telfa and occlusive dressing applied to incision site and maintained for 48 h. A member of the cardiac surgery team removes the dressing and incisions are checked on all postop patients on Monday, Wednesday, Friday by a surgical nurse or NP unless a problem is reported
Postoperative	For children under 1 year old and patients with Trisomy 21, apply Mepilex to incision site for protection and change every day for 7 days postoperatively
Postoperative	2 × 2 gauze applied to chest tube sites and covered with occlusive until removal of chest tubes. Once chest tubes are removed, sites are covered with folded 2 × 2 gauze and occlusive dressing for 48 h post removal unless soiled or loose
Postoperative	Personal stethoscopes for each patient and cleaned with disinfectant wipes prior to patient first use on that patient or when soiled. Never place stethoscope on sternal incision site
Postoperative	After removal of sterile surgical dressing, daily cleansing of surgical site with warm soap and water unless otherwise instructed by cardiothoracic surgery team
Postoperative	External pacing wires, chest tubes, and intracardiac lines should be removed as quickly as the patient's hemodynamic status will allow
Postoperative	If a method other than intradermal sutures and Indermil glue has been employed for closure (i.e., staples or external suture), the removal will be performed by cardiothoracic surgery team
Postoperative	Hydro scan barrier used by echocardiography sonographers in the immediate postoperative period (first 2 weeks) to protect incision from pressure applied by probe, contamination by gel, or probe

With proper surveillance, many wound complications can be dealt with before severe infection sets in. A protocolized approach to incision management and surveillance is the optimal strategy. Early wound separation or local care of stitch abscess will often avert progressive infection. Treatment of wound separation of early infection with osmotic agents like Medihoney® and collagen agents that promote the migration of fibroblast into the wound will likely be all that is

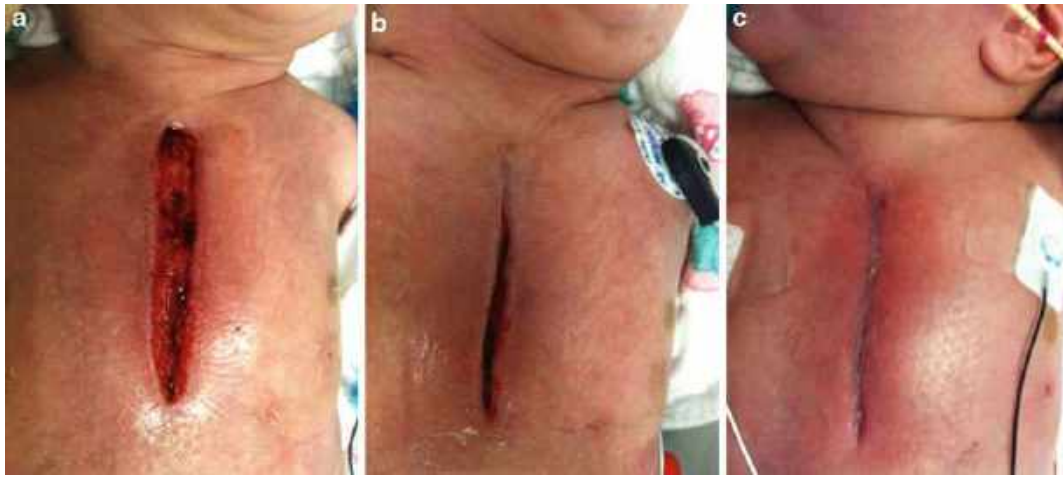

Fig. 191.1 Open sternal wound in a 2-week-old HLHS patient after a Norwood palliation that developed deep wound infection in the sternotomy. The sternum was intact, but there was communication to the mediastinal space without gross contamination or positive cultures. The wound was debrided under sedation and a negative pressure device was placed. (**a**) is the initial open wound after debridement, (**b**) is 1 week after vacuum therapy, and (**c**) is 2 weeks after therapy. Following this, the vacuum was removed and collagen therapy was commenced. The wound was completely healed in 3 weeks

necessary. In the case of superficial or deep wound infections, systemic antibiotic therapy is often used initially, but the rationale for long-term use is skeptical.

Conclusion

Surgical site infection in pediatric cardiovascular surgery is relatively uncommon, but the consequences can be quite sever and definitely prolong hospitalization and cost of care. The classification of SSI in children is becoming more standardized, but discrepancy between adult and pediatric definition exists. Independent risk factors for SSI in pediatric patients include prolonged operation, genetic syndromes, young age, need for open chest after surgery, and need for excessive blood transfusion. The use of and adherence to an infection prophylaxis and incision care protocols has been shown to significantly decrease the risks of SSI in pediatric cardiac surgical patients. The management of SSI in children has also evolved and the necessity of aggressive surgical measure are now, thankfully, relatively rare and survival is very good.
