Considerable anatomic and morphologic variability exists at the level of the aortic valve in the borderline left heart [4]. The aortic valve may be morphologically normal but hypoplastic, anatomically small and dysplastic, or of adequate size for the patient's body surface area but morphologically dysplastic and stenotic. The leaflets are often thickened, restricting mobility, and commissures can have a variable degree of fusion. The entire ventriculo-aortic junction and root are most often hypoplastic.

The left ventricle has a variable degree of hypoplasia. The papillary muscle anomalies have been described along with the mitral valve previously. Endocardial fibroelastosis is a frequent feature in the borderline left heart. Secondary EFE is commonly associated with left heart obstructive lesions, although it may also occur in structurally normal hearts (primary EFE) [14, 15]. Mechanisms underlying the development of secondary EFE are unknown, although endocardial ischemia and decreased ventricular blood flow in utero have been proposed. EFE is thought to cause relative diastolic noncompliance

in the fetus and neonate with left heart disease and may impair left heart growth after in utero aortic valvuloplasty [16].

Shone's Complex

Shone's complex, described by Shone, Edwards et al. in 1963 based on eight pathological specimens, is characterized by the tetrad of a parachute mitral valve, supravalvar stenosing mitral ring, subaortic stenosis, and coarctation of the aorta [5]. The "parachute mitral valve" refers to a mitral valve dysplasia in which two mitral leaflets are attached by chords to a single LV papillary muscle. The mitral orifice is composed solely of the interchordal spaces, which effectively creates mitral stenosis. In current practice, the term Shone's syndrome or complex is often applied to patients with a combination of left heart obstructive defects, which includes a congenital abnormality of the mitral valve with or without obstruction.

Unbalanced Atrioventricular Canal

Unbalanced complete AVC has been defined as where the AV junction is committed primarily to one ventricle which results in hypoplasia of the contralateral ventricular cavity and outflow structures [17, 18]. Unbalanced complete AVC can be left or right dominant, and this chapter will concentrate on the right-dominant unbalanced AVC characterized by hypoplasia of one or more components of the LV, including the inflow, trabecular, or LV outflow segments. Determination of "dominance" is predominantly made by echocardiographic determination of relative orifice area of the common atrioventricular valve which resides over each ventricular chamber, as initially described by Cohen et al. [19] and corroborated in other studies [20, 21]. Ventricular volumes and dimensions as measured by echocardiography or more recently by cardiac magnetic resonance imaging (CMR) are important in decision-making [22] (see below). Although there are no standardized criteria that favor one- versus two-ventricle repair, there are certain characteristics that are important to consider. In addition to ventricular size, these include anatomy of the outflow tracts and atrioventricular valve architecture and function that include the predicted postoperative mitral valve annular size, papillary muscle(s), and chordal attachments.

Perinatal (Neonatal) Considerations

Borderline left heart in the neonatal period is a unique congenital heart problem because clinicians often feel compelled to make immediate binary decisions about the fate of the left heart. More recently, several centers, including our own, have been pursuing a strategy of left heart rehabilitation, in order to enable subsequent biventricular repair. In this approach, the patient may undergo initial palliative surgery, which also includes modifications to promote left heart growth such as EFE resection and mitral valvuloplasty. In some instances, the palliative circulation can be taken down and the heart converted to a biventricular circulation in the infant or childhood periods (see below) [23].

When faced with a newborn with a borderline left heart, there are two important questions: (1) should this child be initially managed as a univentricular or biventricular circulation and (2) if a univentricular palliative strategy is chosen initially, is there potential to later convert the child to biventricular circulation? Although much has been written about decision-making at birth in different types of left heart hypoplasia, most importantly with regard to neonatal critical aortic stenosis, Shone's complex, coarctation, and multiple left heart obstruction, this continues to be an evolving subject. In light of improved surgical techniques and critical care management, as well as a growing understanding of the recovery, growth, and developmental potential of the myocardium, the field of cardiology has started to reexamine this entire issue with different considerations for multiple left heart obstructions with an apex-forming left ventricle, Shone's complex versus neonatal aortic stenosis with a globular ventricle and EFE.

Preoperative Imaging Evaluation

Echocardiography

Echocardiography is important in determining key aspects of left ventricular hypoplasia pre- and postnatally, including qualitative and quantitative assessment of anatomic structures: (1) anatomy, (2) ventricular size and volume, and (3) systolic and diastolic function. Two- and three-dimensional echocardiography, color flow Doppler, and Doppler tissue imaging (DTI) are readily applied in the day-to-day noninvasive evaluation of these patients. Echocardiography is noninvasive, can be used in multiple clinical settings, and can be easily applied serially to evaluate these patients. Two- and three-dimensional echocardiography allows depiction of ventricular size and shape from the fetus through infancy and childhood.

Fetal Echocardiography

In utero, perhaps the single most important two-dimensional determinant of left ventricular competency for systemic ventricular work is the ratio of the LV length in comparison to the entire ventricular length. In addition to measurement of ventricular length, in the pre- and postnatal period, two-dimensional imaging allows determination of mitral and aortic annular size, as well as size of the ascending aorta and transverse aortic arch. These measurements are indexed as z-score values. The most important determinant of the potential adequacy of the left ventricle is the trajectory of changes that occur throughout gestation.

Echocardiographic Evaluation of the Endocardium and Myocardium

Two-dimensional echocardiography is important in visualization of the left ventricular endocardial and myocardial regions. The extent and position of bright glistening appearance of EFE can be seen, to provide an estimation of EFE [16]. Two-dimensional echocardiography can readily be applied for measurement of myocardial wall thickness.

Echocardiographic Evaluation of Ventricular Volumes

In our laboratory, we apply the bullet method (i.e., 5/6 area × length) for determination of left ventricular volumes, mass, and ejection fraction. In specific cases, we can apply the use of three-dimensional echocardiography to measure left and right ventricular volumes, mass, and ejection fraction. Three-dimensional analysis using the summation method of short-axis cuts can be more accurate than two-dimensional imaging when it comes to assessment of chamber size, as it does not make assumptions about ventricular shape and thus relies on potentially non-applicable mathematical formulas. This is apparent in the population of LV hypoplasia in which the LV is no longer elliptical but rather spherical in shape or when the interventricular septum is midline or deviated into the LV. We have performed comparative studies between MRI and three-dimensional echocardiography for both the right and left ventricle in LV hypoplasia. Using summation of disc methodology, good correlations were found between these two imaging modalities. The acquisition for three-dimensional images occurs over four to six heartbeats, and the off-line analysis, applying summation of disc technology from the data sets, requires approximately 15 min. Hence, we currently apply three-dimensional volumes, mass, and ejection fraction only to select patients (Fig. 101.3).

Echocardiographic Evaluation of Ventricular Function

Even when the LV has shown extensive growth with apparent good systolic function, the diastolic function is often the rate-limiting step to the LV sustaining systemic work with acceptable hemodynamics. Left atrial size often provides an indirect determinant of left ventricular compliance, but left atrial size is also affected by left ventricular systolic and mitral valve function. Presently, we measure the left atrial circumference in two orthogonal planes but do not have normative data in younger patients. Doppler tissue imaging (DTI) also provides some important information concerning systolic and diastolic properties of the LV [24]. Currently, we measure

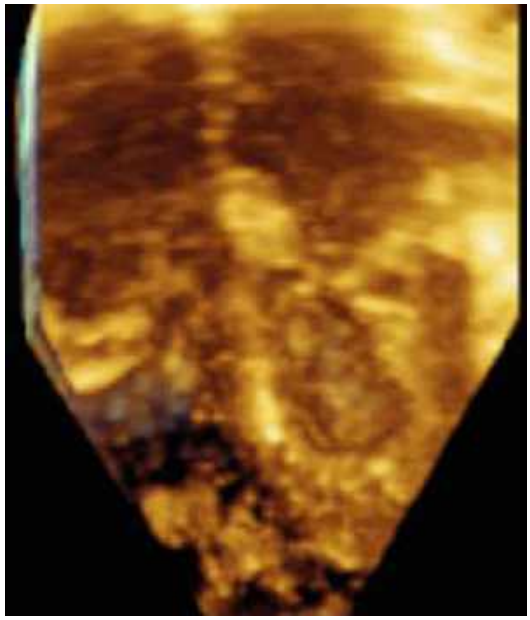

Fig. 101.3 Three-dimensional echocardiogram of patient hypoplastic left heart syndrome

the Doppler tissue velocities in the mitral valve region along the LV lateral wall, septum, and in the lateral wall of the RV at the region of the tricuspid valve. We have shown that the patients with LV hypoplasia have a marked decrease in the peak amplitude of systolic and diastolic DTI patterns, which implies decreased systolic and diastolic properties of the LV. However, these velocities are related to longitudinal motion. We are currently investigating the application of speckle tracking to measure myocardial strain and strain rate imaging. This will allow simultaneous depiction of myocardial motion and deformation in multiple regions of the heart, in order to estimate myocardial systolic and diastolic function in the radial, circumferential, and longitudinal planes.

Echocardiographic Analysis of the Aortic and Mitral Valves

A major component of successful LV rehabilitation is dependent on the size and hemodynamic function of the mitral and aortic valves. Two- and three-dimensional imaging are often applied for determination of the size and shape of the annulus and the delineation of the leaflets, chordae, and papillary muscles. This analysis is particularly important in patients with LV hypoplasia, as the mitral valve is often the single most important determinant for the left ventricle to sustain an acceptable cardiac output with low left atrial filling pressures. Echocardiography has important advantages over both CT and MRI in analyzing the aortic and mitral valves, due to higher frame rate acquisitions. Three-dimensional echocardiography provides additional information, as it gives a three-dimensional perspective of the dynamic function of the entire valvular apparatus. This is especially applicable in the analysis of the malformed mitral valve, where the pathologic changes often occur simultaneously at multiple levels and regions.

While two-dimensional imaging allows a quick assessment of the orthogonal diameters of the mitral valve annulus, three-dimensional imaging further allows direct enface views of the annulus allowing for digital tracing of the annular circumference, regardless of the shape. As is common in patients with unbalanced CAVC, patients with LV hypoplasia similarly often have either a forme fruste parachute mitral valve with two closely spaced papillary muscles or a more pure form of a parachute mitral valve with a truly single LV papillary muscle. Often, there is a very basally displaced anterolateral papillary muscle with extensive amorphous tissue that narrows the mitral annular region. Additionally the patients have extensive tissue on the atrial surface of the leaflets that can extend down the leaflets, creating significant narrowing. At our center, we have termed this "stenosing mitral membrane." This tissue often is amorphous and similar to EFE. As mentioned, the interchordal space is often narrowed, with thickening and immobility of the chordae as they coalesce to a single or closely space papillary muscles, further narrowing the mitral valve effective orifice area. Three-dimensional imaging is particularly adept at showing the markedly reduced interchordal space in these patients, with the stenosis often related to obstruction at the interposition of the chordae and papillary muscles.

As mentioned above, stenosing mitral membranes are an important aspect of mitral valve

stenosis in patients with varying degrees of LV hypoplasia. They often exist circumferentially or as an amorphous mass of tissue most similar to EFE and can occur at any region along the mitral valve including the intervalvular leaflet region. These stenosing membranes can be seen by two-dimensional imaging but are often difficult to differentiate from the thickened dysplastic mitral valve tissue. Three-dimensional echocardiographic imaging allows placement of serial cut planes through the long axis of the mitral valve and simultaneous orthogonal views that significantly aid in the detection and determination of this abnormal tissue and resulting mitral stenosis.

Similar to the mitral valve, the aortic valve is carefully evaluated by two- and three-dimensional echocardiography. Many of these patients have undergone cardiac catheterization procedures with resultant tears or avulsion of the aortic leaflet [25–27]. Due to the younger age and size, these patients have also frequently had aortic valve repairs rather than replacement. Echocardiographic imaging is employed to determine the aortic valve annulus size, commissural fusion, aortic valve cusp size, and functional relationship of aortic valve cusps and commissures.

In our laboratory, we apply the diameter of the regurgitant jet vena contracta as an estimate of valvar regurgitation. Doppler methods are utilized to measure valve gradients. However, this is difficult, as many of these patients have left ventricular dysfunction which affects systolic aortic valve gradients or elevated left ventricular diastolic pressures which affects mitral valve gradients. Future research is necessary to optimize techniques such as effective orifice area of the aortic and mitral valve in these complex situations as they are often inaccurate in children. Doppler can also be applied to determine the pressure drop across a restrictive atrial septal communication, as an indirect estimate of left atrial pressure. Oftentimes, a reversal of flow velocity in the pulmonary veins is indicative of a simultaneous restrictive atrial septal communication and mitral valve in LV hypoplasia.

Magnetic Resonance Imaging

When the LV is hypoplastic and abnormally shaped, as is often the case in patients with borderline left heart, two-dimensional echocardiographic assumptions relating to ventricular geometry can yield inexact volumetric and functional data, while the accuracy and reproducibility of three-dimensional echocardiographic data can be limited by acoustic windows [28, 29]. Cardiac magnetic resonance imaging (CMR) provides a tomographic assessment of ventricular volumes, mass, and function independent of acoustic windows [30–34] and can be an important adjunctive tool in perioperative decision-making and longitudinal assessment of patients with borderline left hearts (Fig. 101.4) [35, 36].

In addition to quantification of left ventricular size, function, and mass, CMR provides valuable information regarding the relative contribution of the left ventricle to total cardiac output by comparison of left and right ventricular stroke volumes. Valve morphology and function can be assessed, including quantification of relative flow through the left- versus the right-sided valves and identification of regurgitant lesions that may need to be addressed at the time of surgery [36–38]. Shunts such as atrial septal defects and aortopulmonary collaterals can be quantified [38–41], associated anomalies such as coarctation of the aorta identified, and the presence and extent of EFE visualized using myocardial delayed enhancement imaging (Fig. 101.5) [42].

Management of the Marginal Left Ventricle

Prenatal (Fetal) Considerations

Counseling families with a prenatal diagnosis of borderline left heart can often be challenging, and it is particularly important to initiate managing the parents' expectations. Prenatal counseling in this situation is especially difficult given that parents' decisions about pregnancy termination may be dependent on fetal assessment for the potential for a biventricular circulation.

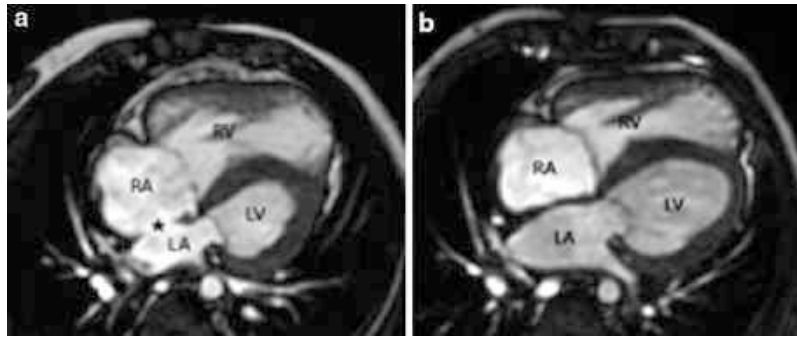

Fig. 101.4 Longitudinal CMR evaluation in a patient with borderline left heart. (**a**) Cine steady-state free precession (SSFP) imaging in a ventricular 4-chamber view in a patient after initial stage 1 palliation followed by a bidirectional Glenn procedure with the right ventricle to pulmonary artery conduit left in situ. The left ventricle is non-apex forming and hypoplastic (indexed end-diastolic volume 23 ml/m^2) with depressed function (ejection fraction 27 %) and minimal flow through the left heart (mitral/tricuspid inflow ratio 0.1:1 and left/right ventricular stroke volume 0.14:1). (**b**) The same patient after fenestrated atrial septal defect closure and upsizing of the right ventricle to pulmonary artery conduit. The left ventricular size has increased (indexed end-diastolic volume 62 ml/m^2) with improved function (ejection fraction 52 %) and increased flow through the left heart (mitral/tricuspid inflow ratio 0.87:1 and left/right ventricular stroke volume 0.61:1) (Abbreviations: *LA* left atrium, *LV* left ventricle, *RA* right atrium, *RV* right ventricle, * atrial septal defect)

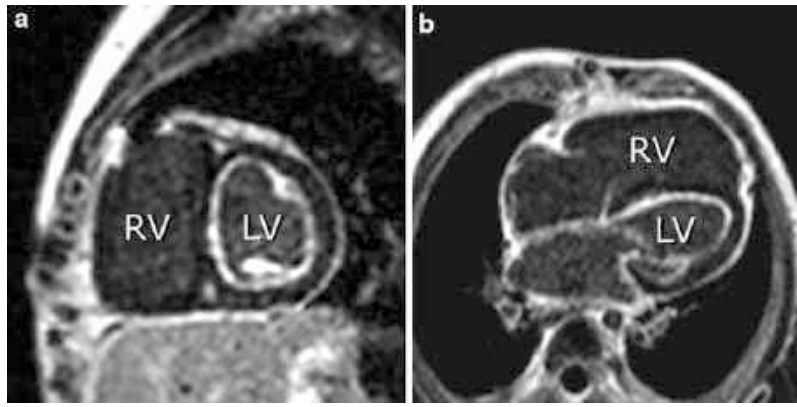

Fig. 101.5 CMR image of endocardial fibroelastosis. Late gadolinium enhancement imaging in a ventricular short-axis (**a**) and left ventricular two-chamber (**b**) planes showing hyperenhancement along the entire endocardial surface of the left ventricle consistent with endocardial fibroelastosis (Abbreviations: *LV* left ventricle, *RV* right ventricle)

Unfortunately, information on which to base these predictions for successful biventricular repair is limited. The extremes of the spectrum – predicting a normal-sized or severely hypoplastic left ventricle – are relatively easy. However, the middle ground is fraught with ambiguity and creates challenging counseling situations. Additionally, during prenatal counseling, one must consider where the neonate will be delivered and managed. Surgery for HLHS is at least somewhat predictable, with its increased early mortality and uncertain longer-term outcomes. In contrast, the path towards biventricular circulation is one of uncertainty and can have equally disappointing results; however, if the heart remodels satisfactorily, the longer-term outcomes can be encouraging.

Neonatal Critical Aortic Stenosis

Critical aortic stenosis (AS) is associated with variable hypoplasia of other left heart structures. In some of these patients, the left heart borders on being insufficiently developed to support the systemic circulation in a biventricular repair. It can be challenging to predict whether patients with a borderline left heart are suitable candidates for biventricular repair.

Predictors of Successful Biventricular Repair in Neonatal Critical AS

Several studies have focused on establishing morphologic predictors associated with successful biventricular repair in patients with critical aortic stenosis and/or other left heart obstructive lesions. Parsons et al. reported that among infants younger than 3 months who underwent aortic valvotomy, survivors had a larger aortic annulus and larger LV end-diastolic dimensions and indexed LV end-diastolic volume than did non-survivors [43]. Rhodes et al. reviewed 45 neonates with critical AS to identify anatomic features that limited the capacity of the left heart complex to support a systemic cardiac output in a biventricular circulation. The Rhodes score (14 [BSA] + 0.943 [indexed aortic root diameter] + 4.78 [LV long-axis to heart long-axis ratio] + 0.157 [indexed mitral valve area] – 12.03) allowed discrimination between patients who survived with a biventricular circulation and those who died or required conversion to a univentricular circulation in 90 % of patients [8]. Colan et al. assessed the validity of the Rhodes score in 89 neonates who underwent biventricular repair for critical AS since the original study and revised the score to [10.98 (body surface area) + 0.56 (aortic annulus z-score) + 5.89 (left ventricular to heart long-axis ratio) – 0.79 (grade 2 or 3 endocardial fibroelastosis) – 6.78] with the same level of discrimination (90 %) [44].

The Congenital Heart Surgeon's Society (CHSS) performed a prospective multi-institutional study, including 320 neonates with critical aortic stenosis, to determine predictors of the best chance of survival with a biventricular or a univentricular type of repair [4]. Independent predictors of operative mortality were younger age, presence and degree of EFE, LV length and lower aortic valve Z-score for biventricular repair, presence of $\geq$ moderate tricuspid regurgitation, and smaller ascending aortic diameter for univentricular repair. A Critical Aortic Stenosis Calculator, consisting in a multiple variable equation, was created to predict the pathway of better survival for individual patients.

Survival Advantage of Univentricular Repair in Critical AS

The CHSS updated this study, looking at the survival advantage of univentricular management compared to biventricular repair [3]. Risk factors after biventricular repair were minimum left ventricular outflow tract diameter, EFE, LV dysfunction, and smaller mid-aortic arch. These variables formed the univentricular survival advantage tool. Discordant management (i.e., patients managed with the pathway which was predicted to have worse survival based on the tool) was more common with biventricular than with univentricular repair, and discordant pursuit of biventricular repair was associated with significantly more observed versus expected deaths.

Clinical Decision-Making for Critical AS

In addition to the morphometric data just mentioned, clinical decision-making is also based on physiologic parameters. In the presence of antegrade flow in the ascending aorta and arch and left-to-right ductal flow or a closed ductus arteriosus with the oxygen saturation in the upper and lower extremities matched, biventricular repair generally can be accomplished safely. In contrast, when there is retrograde flow in the ascending aorta and lower post-ductal saturation, the left ventricle is most likely incapable of delivering efficient antegrade cardiac output and univentricular palliation is indicated [45].

Fetal Aortic Valvuloplasty for Critical AS

With the advent of fetal aortic valvuloplasty (see ▶ Chap. 15, "Fetal Cardiac Intervention") at select centers, left heart rehabilitation is now

being considered in fetuses with critical AS that would otherwise be born with HLHS. At Boston Children's Hospital, between March 2000 and October 2008, 70 fetuses underwent attempted aortic valvuloplasty for critical AS with evolving HLHS. Relative to 21 untreated comparison fetuses, subsequent prenatal growth of the aortic and mitral valves, but not the left ventricle, was improved after intervention. Seventeen patients, 15 from birth, had a biventricular circulation postnatally. Larger left heart structures and higher left ventricular pressure at the time of intervention were associated with biventricular outcome. A multivariable threshold scoring system was able to discriminate fetuses with a biventricular outcome with 100 % sensitivity and modest positive predictive value [46, 47]. To date, there have been variable outcomes; some fetuses are born having an adequate LV for biventricular circulation, while others are born with a borderline left heart hypoplasia. In these neonates with critical AS and a borderline left heart, we are again left with the complex decision of uni- versus biventricular repair and are still in the early phase of these procedures, and the ultimate outcomes are yet to be determined.

Neonatal Management of Critical AS

In terms of management in neonatal aortic stenosis, it should be remembered that considerable anatomic and morphologic variability exists within this patient group: the aortic valve may be normal morphologically but be anatomically small or hypoplastic; or be of adequate size for the patient's body surface area but morphologically dysplastic and stenotic. Transcatheter aortic valvuloplasty has been shown to be effective in relieving the aortic valve gradient [48], allowing for aortic annulus and left ventricular growth; however, it is complicated by significant aortic regurgitation in 15–23 % of patients [6, 49] and aortic wall injury in 15 % of patients [50]. Surgical management can vary from aortic valvotomy, with thinning of aortic valve leaflets and tricuspidization, to valve replacement with a Ross-Konno operation. Associated lesions, such as mitral stenosis or EFE, should also be managed at the operation, as will be discussed later in the section on HLHS.

Unbalanced AV Canal

Unbalanced AVC occurs in about 10–25 % of patients with AVC defects [19, 51]. In a retrospective series of 259 complete AV canal (CAVC) patients, Delmo-Walter reported 7 % to be right dominant [52]. In our series of 94 patients with unbalanced AVC at Boston Children's Hospital, 62 % were right dominant.

Feasibility of Biventricular Repair in Patients with Unbalanced AVC

Surgical management of unbalanced AVC with hypoplastic left-sided structures depends on the degree of ventricular hypoplasia. Determination of ventricular hypoplasia can be made using multiple modalities including two- and three-dimensional echocardiography, cardiac catheterization, and CMR.

In those patients with significant LV hypoplasia, management continues along the single-ventricle pathway. However, in those patients with borderline left ventricles, management can be either primary or staged biventricular repair using an initial palliative approach followed by biventricular conversion. Decision-making on adequacy of the left ventricle for a successful biventricular repair is often based on 2D-echocardiographic evaluations that assess (1) left ventricular volumes, (2) common atrioventricular valve distribution, and (3) left ventricular inflow. In patients in whom biventricular conversion from single ventricular palliation is being considered, three-dimensional echocardiographic estimates of volume and CMR estimates of ventricular volume and geometry play a particularly important role in decision-making.

LV volume in unbalanced AVC remains one of the important determinants of biventricular repair. Van Son and colleagues reported on successful primary biventricular repair when preoperative indexed potential LV volumes were >15 ml/m^2 [53]. They used a theoretic model that normalized septal bowing to calculate potential LV volume. A similar approach can be used by CMR to assess the potential LV size after repair [35]. Adequacy of atrioventricular (AV) valve distribution is determined using

a modified atrioventricular valve (AVVI) index, where the left AV valve area (LAAVarea) is divided by the common AV valve area (CAVarea). (AVVI = LAVVarea / CAVarea) [19–21]. In order to assess LV inflow, Szwast indexed secondary color flow diameter on echo to the left atrioventricular valve annulus [21]. LV long-axis rotation based on cardiac catheterization has also been used to determine feasibility of biventricular repair [52].

Surgical Technique for Primary Biventricular Repair for Unbalanced AVC

Primary biventricular repair can often be achieved in patients presenting with a well-balanced circulation in the neonatal period. During primary biventricular repair, septation of the common AV valve is carried out such that an equal or slightly larger component of the valve is positioned over the LV to allow for adequate inflow to sustain the systemic circulation and continued LV growth. The ventricular septal defect (VSD) patch is carefully shaped such that it allows the ventricular septum to be lifted up towards the AV valves and away from the LVOT. During reconstruction, any accessory AV valve tissue in the LVOT should be resected. Right ventricular outflow tract (RVOT) reconstruction should be with native tissue when feasible and occasionally requires a valved conduit, if the pulmonary arteries are diseased or if there is associated pulmonary hypertension.

Left AV valve abnormalities are commonly seen in these patients, as in patients with congenital mitral stenosis. In patients with single or closely spaced papillary muscles, the left lateral leaflet is often deficient and the left AV valve orifice is predominantly composed of the cleft between the superior and inferior bridging leaflet. Cleft closure in these patients is individualized, and the cleft is usually left partially open, in order to leave a valve orifice large enough to pass a Hegar dilator equivalent to a mitral annulus anteroposterior diameter with a Z-score of at least −2, keeping in mind that the annular orifice may not be the only limiting factor, particularly with a single LV papillary muscle. Splitting of the papillary muscle head may slightly improve mobilization and the left ventricular inflow orifice at the subvalvar level. Additional release of the papillary muscle attachments from the septum and LV free wall is often required to elongate and improve mobility. Accessory chordae frequently need to be resected, particularly those traversing the LV outflow tract and attaching to the septum. Thickened chordae need to be thinned. Prolapsing leaflet components may need to be supported by suturing adjacent commissures or leaflet tissue, and occasionally the placement of artificial chordae may be considered.

There has not been a consensus with regard to the management or calibration of an atrial level fenestration. We have often fenestrated the atrial patch to serve as an LV pop off during the initial period when the hypoplastic LV is noncompliant. A fenestration allows for a lower left atrial pressure in the initial postoperative period, preserving cardiac output. Once the LV adapts to receiving a full cardiac output and the atrial level shunt decreases, the fenestration will often close spontaneously with time, or if not, it can be closed either surgically or with a device in the catheterization laboratory. Leaving too large a fenestration can potentially also unload the left atrium sufficiently so as not to allow enough of the pulmonary blood flow through a noncompliant left heart, thus possibly restricting growth of the left AV valve and LV; the decision of fenestration and sizing are thus critical.

Surgical Technique for Biventricular Conversion for Unbalanced AVC

A staged approach may be required if there are associated left-sided lesions or if there are concerns about adequacy of the LV. This approach may be particularly important in symptomatic neonates and young infants. For example, many neonates with unbalanced AV canal are initially palliated with coarctation repair and/or pulmonary artery (PA) band, with a definitive biventricular repair at 3–6 months of age. With this approach, however, great care must be taken to ensure that the ventricular septal defect is unrestrictive and that the LV outflow is unobstructed. In such cases, a Stansel connection

with a systemic to pulmonary shunt or conduit may be a better palliative option.

Biventricular conversion requires not only repair of the unbalanced AVC using the principles described above, but it also requires takedown of the palliated circulation. These additional procedures often include takedown of previously placed PA bands, Stansel connections, and cavopulmonary shunts including bidirectional Glenn (BDG) and Fontan anastomosis (see below). When removing the PA bands, one has to determine whether the pulmonary arteries need additional arterioplasty. Frequently, in younger infants, removal of the bands is all that is required. With takedown of the BDG and reconstitution of the systemic venous pathway between the superior vena cava (SVC) and right atrium, one has to be particularly cognizant of the sinoatrial node as well as the potential for SVC-RA anastomotic and PA stenosis. During reconstruction of the systemic venous pathway, it is important to maintain as much native tissue as possible to allow for somatic growth; however, patch augmentation of the anterior aspect of the SVC-RA junction is often required [54] (see below).

Outcomes After Biventricular Repair in Patients with Unbalanced AVC

Outcomes in unbalanced AVC have historically been poor and particularly those having undergone single-ventricle palliation. Patients with trisomy 21 are particularly at risk because of their propensity to develop early pulmonary vascular obstructive disease.

In an ongoing review at Children's Hospital Boston, we have identified 62 patients with a right-dominant unbalanced AVC of which approximately half underwent initial single-ventricle palliation, one-third underwent primary biventricular repair, and one-tenth underwent biventricular conversion. As has been previously reported, early results suggest a higher mortality in the single-ventricle group compared to the biventricular or biventricular conversion groups [22, 51, 55–57]. Primary biventricular repair or conversion can be safely undertaken in patients with unbalanced AVC and a borderline LV although there will be a higher re-intervention rate than in balanced AV canal patients. Survival rates, however, appear to remain acceptable and are improved compared to single-ventricle management strategies.

Shone's Complex and Hypoplastic Left Heart Syndrome

Infants with HLHS and borderline hypoplastic left heart structures present a unique yet challenging opportunity. Traditionally, these patients have undergone single-ventricle management culminating in the Fontan circulation. Given the poor long-term outcomes with single-ventricle management [58], there has been recent interest in LV recruitment in a selected group of patients with borderline left hearts.

Physiologic Consideration

In patients with an apex-forming LV, the physiology of the neonatal circulation may be more important than the anatomic appearance or the measurement of left heart structures. The ultimate test in the neonatal period is whether the left heart structures can support the systemic circulation with the ductus arteriosus closed. Although these patients can appear clinically stable, this stability can be at the expense of significantly elevated left atrial (LA), pulmonary artery (PA), and right ventricular (RV) pressures. It is likely that this persistently elevated PVR is related to decreased ventricular compliance and under filling of the left heart throughout gestation. Despite a biventricular circulation, residual lesions such as LVOT obstruction and/or mitral stenosis can result in an elevation of LA pressures that can exacerbate the elevation of PA and RV pressures. Meticulous medical management including invasive monitoring and titration of vasoactive medications is then critical to continue with a biventricular circulation.

Feasibility of Biventricular Repair in Neonates with Left Heart Hypoplasia

Following birth, a neonate with the diagnosis of borderline left heart hypoplasia is managed in the cardiac intensive care unit. The initial postnatal

echocardiogram is used to guide initial management. If the borderline left heart demonstrates favorable anatomic characteristics as discussed above, the patient is monitored closely in the intensive care unit without prostaglandins. Specifically, systemic perfusion, pulmonary edema due to left atrial hypertension, and pulmonary artery hypertension demand immediate attention and reinstitution of prostaglandins. Interventions commonly performed to promote initial biventricular circulation may consist of relief of inflow and outflow tract obstructions, either by catheter-based balloon dilation of the aortic valve or surgical repair of coarctation of the aorta [51, 59]. However, the presence of EFE, which impedes both systolic and diastolic myocardial function, may lead to persistent left atrial hypertension, pulmonary edema, and pulmonary hypertension despite relief of anatomic obstructions.

Primary Left Heart Rehabilitation

The surgical management of multiple small left heart structures is complex and often involves addressing problems in the aortic arch, mitral valve, LVOT, and LV. Generally, the arch reconstruction is relatively straightforward, however; operating on the mitral valve and LVOT can be extremely challenging in small neonates and is sometimes impossible if obstruction is severe enough. If the initial attempts at biventricular circulation succeed in the neonatal period, the infant is closely monitored following discharge from the hospital. Specifically, signs and symptoms of heart failure herald the need for diagnostic imaging with echocardiography, CMR, and/or catheterization. Failure of biventricular circulation may be due to interval recurrence or development of left-sided obstructive lesions (aortic or mitral stenosis) or progression of ventricular systolic or diastolic dysfunction from EFE.

A surgical strategy consisting of relief of LV inflow and outflow tract obstructions by aortic and mitral valvuloplasty, relief of coarctation, and resection of EFE has been applied to a subgroup of patients with borderline hypoplastic left heart structures and EFE. The goal of this strategy, which we have termed "primary left heart rehabilitation," is to improve the likelihood of a two-ventricle circulation and avoid the need for long-term single-ventricle palliation in this group of patients in an attempt to improve the outcomes with biventricular circulation. The LV rehabilitation strategy employs a combination of techniques to relieve mitral inflow and LVOT obstructions and resection of EFE.

The procedure is performed through a median sternotomy with cardiopulmonary bypass and moderate hypothermia. The mitral valve is approached transeptally and inspected to determine the mechanisms of mitral stenosis or regurgitation. Commonly employed techniques to reduce inflow obstruction include division of secondary or accessory chordae, separation or splitting of fused papillary muscles, chordal elongation, commissurotomy, augmentation of deficient or underdeveloped leaflets, and debridement of thickened leaflet tissue (Fig. 101.6). EFE resection involves removal of this noncompliant endocardial material by sharp dissection, either with a surgical scalpel or tenotomy scissors. Resection is approached through the mitral valve orifice and/or the LVOT (Fig. 101.7).

Neonates who fail aggressive attempts at initial biventricular repair may require pursuit of single-ventricle palliation with subsequent attempts to rehabilitate the left heart (also see staged LV recruitment below). In this setting, initial palliative surgery can still be performed but is augmented with the creation of a restrictive atrial septum to force blood through the left heart in an attempt to encourage the left heart structures to grow. Determining how much to restrict the atrial septum is often difficult and occasionally requires an adjustable external atrial septal suture. It is then critical to monitor left and right atrial pressures and/or PA pressures postoperatively in the intensive care unit (ICU).

Outcomes with Primary Left Heart Rehabilitation

At Boston Children's Hospital between January 1999 and December 2008, there were nine patients who underwent primary left heart rehabilitation as a means of maintaining

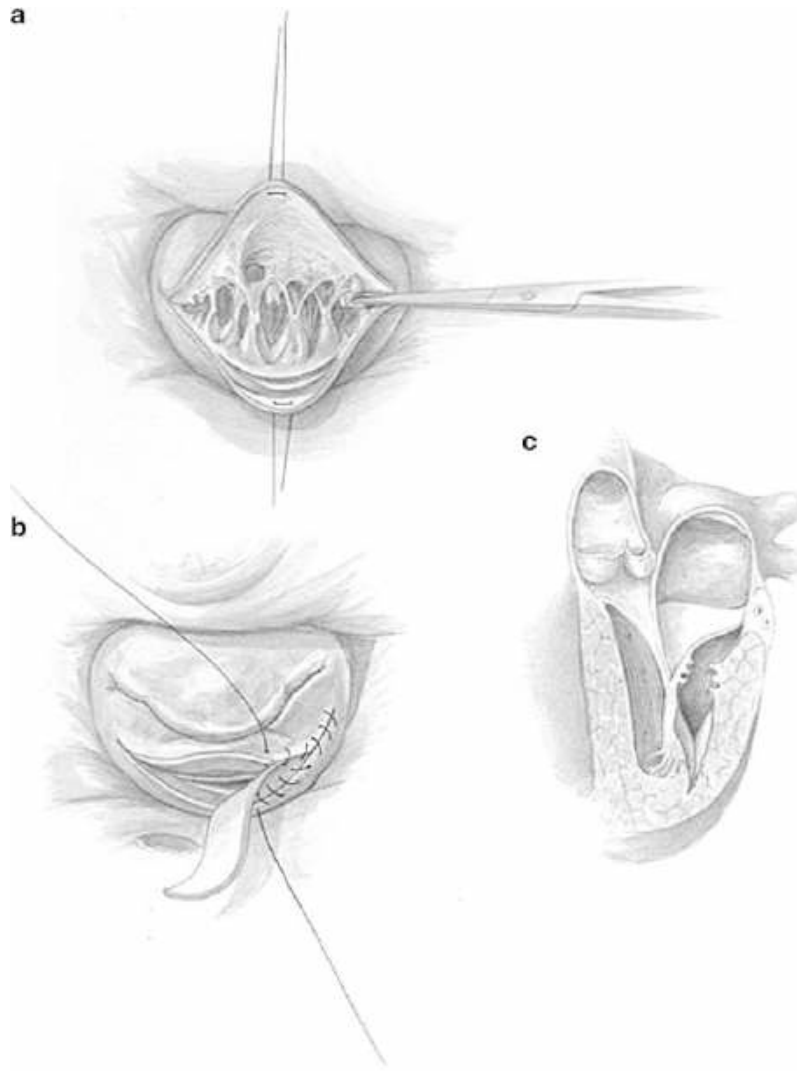

Fig. 101.6 Surgical approach for patients with congenital mitral valve disease. (**a**) Transeptal exposure of the mitral valve with exposure of the subvalvar apparatus after radially incising the posterior leaflet along the annulus. (**b**) There are often many secondary tethering, fused, or shortened chords that can be separated, mobilized, or resected. (**c**) Re-approximation of the posterior leaflet is often done using a treated piece of autologous pericardium

biventricular circulation in patients with borderline left heart disease [23]. The median age at operation was 5.6 months (19 days to 3 years). Although the initial postoperative management can be challenging for patients undergoing this procedure, in the CHB series, ICU and hospital length of stays were 17 days (1–45 days) and 27 days (5–64 days), respectively, and there was improvement in left atrial and right ventricular pressures, LV ejection fraction, and maintenance of biventricular circulation at midterm follow-up. There was no operative mortality, and at a median follow-up of 25 months (6 months to 10 years), there was 1 death from a noncardiac cause and two required reoperation. Further follow-up is needed to establish whether the hemodynamic improvements will translate into long-term survival and improvement in quality of life.

Staged Left Ventricular Recruitment

Neonates who fail initial attempts at biventricular circulation and the inability to wean off prostaglandin E1 typically undergo stage 1 palliation, either with the traditional Norwood or newer hybrid approaches, with

Fig. 101.7 Surgical specimen of resected endocardial fibroelastosis

subsequent attempts to rehabilitate the left heart at various stages of single-ventricle palliation. This approach has been termed "staged left ventricular recruitment" [60]. The growth potential of the left ventricle has been demonstrated in patients with borderline left heart structures who undergo initial biventricular repair by balloon dilation of the aortic valve, with adjunctive surgical repair of coarctation, aortic stenosis, and mitral stenosis when necessary. The staged LV recruitment strategy is designed to facilitate flow through and loading of the left heart in an effort to stimulate flow- and load-mediated growth, while supporting the circulation by single-ventricle palliation.

In addition to resection of EFE and valvuloplasty of the aortic and mitral valves, staged LV recruitment entails restriction of the atrial septal defect to promote flow through the LV. At the time of superior cavopulmonary anastomosis or bidirectional Glenn (BDG), additional pulmonary blood flow with aortopulmonary shunt or right ventricular-pulmonary shunt may provide additional loading of the left ventricle. Many of the rehabilitation procedures are performed at the time of the second stage palliation (i.e., BDG) since many of the techniques are difficult to apply in the small neonatal heart.

Outcomes with Primary Left Heart Rehabilitation and Biventricular Conversion

Restriction of the atrial septal defect has been found to be an important predictor of the increase in size of left heart structures. Near normalization of left heart structures has been demonstrated in a series of patients at Boston Children's Hospital between 1995 and 2010, with nearly one-third of the cohort subsequently undergoing a biventricular conversion procedure. Biventricular conversion following staged left ventricular recruitment involves takedown of the Damus-Kaye-Stansel and cavopulmonary anastomoses, reestablishment of LV to aorta and RV to pulmonary artery continuity, and management of residual valvular stenoses. Left heart dimensions increased significantly over time following LV recruitment. After early analysis, overall mortality was improved compared to the controls, and clinical outcomes following biventricular conversion have been favorable, but the long-term results of this strategy are yet to be determined.

Postoperative Management

The initial postoperative management in these patients can be extremely challenging and begins with a detailed review of the operative findings upon arrival to the cardiac ICU. It is critically important to begin with the post-cardiopulmonary bypass echocardiogram and the intraoperatively measured hemodynamic parameters including systemic, pulmonary, and intracardiac pressures. This information focuses on the quality of the repair or palliation as well as an assessment of systemic and pulmonary cardiac output. This prepares the clinicians as these patients respond suddenly to physiologically stressful circumstances with dramatic changes in cardiac output, which can be expressed as rapid changes in pH, lactic acid, glucose, and temperature.

In order to monitor for acute changes in pulmonary blood flow, end-tidal carbon dioxide monitoring is done. Arterial oxygen saturation is

monitored in several ways with different limitations and advantages. Peripheral oxygen saturation (SpO_2) is the least invasive but is less accurate with significant hypoxemia. In these patients, it is critical to directly measure the oxygen saturation of arterial blood (SaO_2) by co-oximetry due to the significant potential for intracardiac mixing and hypoxemia. By continuously measuring oxygen saturation (SaO_2), significant reductions in arterial saturation can be immediately detected. Intracardiac or transthoracic PA and right and left atrial catheters are particularly important as pressure waveform and oxygen saturation data can provide a profile of cardiac function. PA catheters are useful in patients with left-to-right shunts and providing real mixed venous oxygen saturation levels. These patients have many potential etiologies for an elevated left atrial pressure including the following: increased ventricular end-diastolic pressure, decreased ventricular systolic or diastolic function, ischemic myocardium, mitral valve disease, aortic valve disease, left ventricular hypoplasia, volume overload, and cardiac tamponade. Measurement of left atrial oxygen saturation provides useful information about right to left atrial level shunting and abnormal gas exchange resulting in pulmonary venous desaturation.

Even after optimizing the volume status, calcium levels, and cardiac rhythm, these patients often have decreased myocardial contractility. Inotropic drugs including combinations of low-dose epinephrine or dopamine in combination with an afterload reducing agent such as nitroprusside or milrinone are used. Epinephrine is generally preferred to norepinephrine because of less vasoconstriction.

Controversies in the Management of the Marginal LV

Univentricular Versus Biventricular Repair

While borderline left heart disease treatment has traditionally been seen as dichotomous single-ventricle palliation or biventricular repair, more recently "hybrid" type approaches have allowed us to make more informed decisions about the most appropriate treatment pathway. Interventions commonly performed to promote initial biventricular circulation consist of relief of mitral inflow and LVOT obstructions by catheter or surgical maneuvers [59, 61]. However, the presence of EFE, which impedes both systolic and diastolic myocardial function, is a risk factor for biventricular repair and may necessitate eventual pursuit of single-ventricle palliation [4].

Secondary LV recruitment after initial single-ventricle palliation in patients at high risk of initial biventricular repair in the neonatal period has blurred the line between these dichotomous distinctions. The choice of univentricular versus biventricular repair does not appear as a fork in the road but merely different reversible options within the physiological range. Such creativity in managing a complex and diverse patient population has even spurred some to use a "reverse double-switch" in older patients after a failed biventricular repair, to remain in a biventricular physiology using the better ventricle (in this case, right, trained by pulmonary hypertension) as the systemic pumping chamber [62]. However, it should be cautioned that the initial decision to pursue either single-ventricle palliation or biventricular repair is crucial [63]: a biventricular repair that fails can often only be converted to a single-ventricle palliation with considerably increased risk [4]. Conversely, the pursuit of single-ventricle palliation in a potentially adequate left ventricle can unnecessarily subject a patient to the morbidity of single-ventricle physiology.

Timing of Biventricular Repair

There are certain situations in which the timing of biventricular repair is particularly important. In patients with complex associated malformations, such as heterotaxy syndrome with severely unbalanced AVC, strong consideration should be given to an initial palliative approach.

In many of these patients, there are associated lesions such as systemic and pulmonary venous anomalies, common atrium, interrupted IVC, bilateral SVC, and unroofed coronary sinus, all of which considerably increase the surgical complexity.

Similarly, patients with DORV often have VSDs that are multiple and remote from the semilunar valves. They may require an extensive baffle that is difficult in small infants, which could lead to left ventricular outflow tract obstruction from the baffle. Furthermore, these VSDs often require enlargement that could lead to heart block.

Takedown of Cavopulmonary Connections

Biventricular conversion often requires takedown of the cavopulmonary anastomosis, reestablishing continuity between the right atrium (RA) and superior vena cava (SVC) with reconstruction of the pulmonary artery (PA). Historically, there have been a number of concerns about takedown of a cavopulmonary anastomosis due to the location and reconstruction required. These concerns have included damage to the sinoatrial (SA) node, atrial arrhythmias, resultant SVC-RA stenosis, and PA stenosis from the anterior PA dislocation. Takedown of a BDG with SVC-RA and PA reconstruction has been reported [64] and described [54] with acceptable results; however, the number of reported patients is small with limited follow-up. Currently, we are analyzing the techniques and outcomes of 41 patients undergoing takedown of their BDG with biventricular repair from Boston Children's Hospital from 2000 to 2012. There was 93 % survival at latest follow-up with only one patient having undergone heart transplant.

Conclusions

While currently there are no algorithms for managing these complex neonates, management has to be based on clinical judgment and a case-by-case basis, as well as the capabilities of the individual institution. Either pathway has its own advantages and pitfalls. The path of HLHS with high-risk surgery and long-term complications of the univentricular heart has to be weighed against a systemic left ventricle that has suboptimal function that often leaves the patient with other confounding issues. There is much work that has to be done in this field, both in patient selection for a particular therapy and in understanding the recovery of the LV myocardium. We do not have a well-established formula as yet to determine which patients in the "gray zone" of hypoplasia can undergo a biventricular repair, and it is still unclear at this point which circulation will yield the best long-term outcomes. Managing parents' expectations is also extremely difficult and has to be factored into any decision-making in this gray zone.

Surgical Approaches to the Hypoplastic Left Heart Syndrome

102

Peter J. Gruber and Thomas L. Spray

Abstract

Hypoplastic left heart syndrome is a uniformly fatal disease if untreated. It represents 5 % of all congenital heart diseases and is responsible for nearly 25 % of cardiac deaths in the first week of life. Hypoplastic left heart syndrome comprises a wide spectrum of anatomic abnormalities with the common feature of left ventricular hypoplasia and hypoplasia of the ascending aorta. Of 10,000 live births, approximately 1.8 will be born with hypoplastic left heart syndrome, with a slight male predominance. Hypoplastic left heart syndrome is the single congenital heart disease phenotype that has undergone the most dramatic change in the last two decades. Surgery for hypoplastic left heart syndrome has been one of the great successes in the management of congenital heart disease, as before the 1980s, hypoplastic left heart syndrome was a uniformly lethal condition. With contemporary 3-stage palliative repair, 70 % of newborns born today with hypoplastic left heart syndrome may reach adulthood. This chapter will provide a review of this entity and its management.

Introduction

Hypoplastic left heart syndrome (HLHS) is a uniformly fatal disease if untreated. It represents 5 % of all congenital heart disease and is responsible for nearly 25 % of cardiac deaths in the first week of life. HLHS comprises a wide spectrum of anatomic abnormalities with the common feature of left ventricular hypoplasia and hypoplasia of the ascending aorta. At one end of the spectrum, there may be some mild left ventricle hypoplasia, mild aortic stenosis, and aortic coarctation. At the other end of the spectrum, however, there is complete absence of the left ventricle, aortic atresia, and aortic arch hypoplasia or even interrupted aortic arch. Of 10,000 live births, approximately 1.8 will be born with HLHS, with a slight male predominance. Of these, 25 % will also have a noncardiac anomaly and 5 % a chromosomal abnormality (trisomies 13, 18, and 21). Syndromic lesions are rare, with Turner syndrome (monosomy X) the most commonly found. The family recurrence risk is 2.2 % for one affected sibling and 6 % for two affected siblings, suggesting some genetic predisposition but arguing against a simple, single gene effect. Primary defects of myocardial growth are unlikely to be a mechanism for this disease because the myocardium appears normal. In addition, approximately 5 % of patients with aortic atresia demonstrate an unrestrictive ventricular septal defect, and in such cases, there is nearly always normal development of the left ventricle and mitral valve.

HLHS is the single congenital heart disease phenotype that underwent the most dramatic change in the last three decades. Surgery and the understanding of pathophysiology and medical management for HLHS has been one of the great successes in the management of congenital heart disease. Before the 1980s, HLHS was a uniformly lethal condition. However, over the last 25 years, the repair of HLHS has become a standard operation in nearly all institutions. With contemporary 3-stage palliative repair, close to 70 % of newborns born today with HLHS may reach adulthood. However, significant variation still exists between centers with an increasing but incomplete set of evidence to drive management.

Historical Development of Surgical Palliation

Maldevelopment of the left-sided cardiac structures in combination with a small ascending aorta and transverse arch was first described by Lev in 1952. By 1958, Noonan and Nadas made further contributions by defining the syndrome to describe a variety of cardiac malformations of left heart structures. In 1961, Redo first reported an attempt to palliate a patient with mitral atresia with an atrial septectomy using inflow occlusion through a right thoracotomy; the patient died soon after the operation. Sinha made a seminal contribution in 1968 by outlining management principles still in use today. These include [1] creation of an unobstructed atrial communication, [2] unrestricted ductal flow, and [3] control of pulmonary blood flow. Thereafter followed a series of surgical experiments that culminated with successful palliation. Cayler described an anastomosis between the right pulmonary artery

(PA) and ascending aorta with banding of both right and left pulmonary arteries. It is of interest that 35 years later, PA banding is being used as part of hybrid palliation strategy; this first-stage hybrid procedure involves stenting the ductus arteriosus and atrial septal defect and using bilateral PA bands. As will be discussed later, it is unclear when this palliative strategy is best implemented – rarely, selectively, or routinely. Litwin, Mohri, and others performed operations that were variations of the principles of palliation that were unsuccessful but contributed to the development of the knowledge of the disease and its repair. In 1977, Doty described a complete primary reconstructive strategy that included atrial septation and a right atrium (RA)-to-PA Fontan circuit. Although no patients survived, this experience established an important principle that one-stage reconstruction with a Fontan repair would not be successful due to high neonatal pulmonary vascular resistance. Levitsky, Behrendt, and others described multiple variations of surgical procedures that, although they demonstrated no long-term success, established the principle of staged reconstruction with initial palliation followed by later separation of the systemic and pulmonary circulations. However, it was Norwood who in 1980 first achieved successful palliation in infants. In 1983, he described the first successful staged approach culminating in a Fontan repair. The Norwood procedure remains the primary reconstructive approach.

Anatomy

HLHS can be anatomically categorized on the basis of atrioventricular (AV) and semilunar valvular morphology into three primary subsets: [1] *aortic atresia with mitral atresia* (40 %), [2] *aortic stenosis with mitral stenosis* (30 %), and *aortic atresia with mitral stenosis* (30 %) (Fig. 102.1). Aortic stenosis with mitral atresia is rare. There are a considerable number of anatomical variants that encompass single-ventricle physiology, including malaligned AV canal, double-outlet right ventricle with mitral atresia, tricuspid atresia with transposed great arteries, and univentricular heart with aortic stenosis. Frequently, leftward and posterior deviation of the sepal attachment of the septum primum is

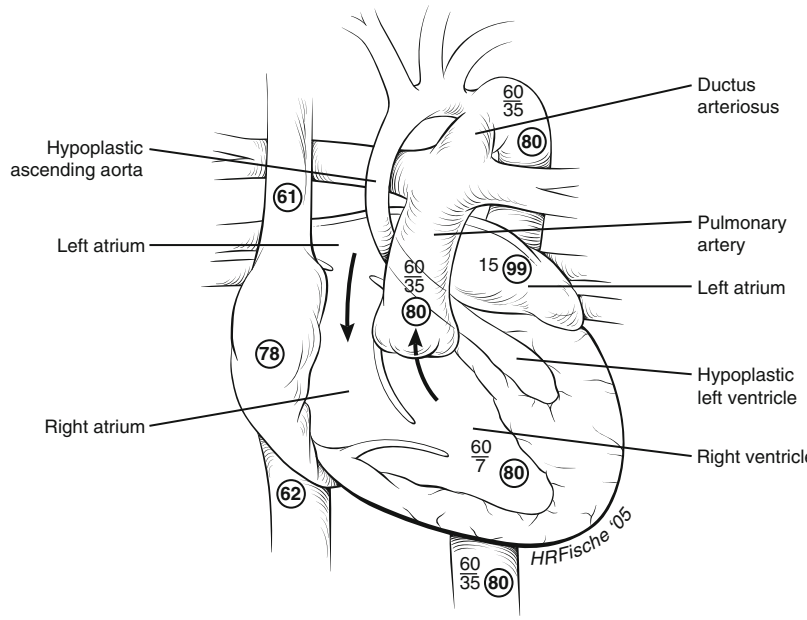

Fig. 102.1 Anatomic features and representative hemodynamic parameters for unrepaired hypoplastic left heart syndrome. Oxygen saturations are enclosed in circles, and blood pressures are indicated by standard nomenclature

observed, but this feature is unlikely to be a causal developmental mechanism as it is commonly seen in other congenital heart disease phenotypes. The superior vena cava (SVC) and inferior vena cava (IVC) are normally connected to the right atrium, although in about 15 % of patients, a left SVC-to-coronary sinus is present. Other structural abnormalities of the heart are rare, with less than 5 % of patients demonstrating AV valvular dysplasia. Also rare in nonsyndromic forms (<5 %) are abnormalities of pulmonary venous return or an interrupted aortic arch. Abnormalities in brain development are increasingly associated with children with severe congenital heart disease, and these may be a high-risk group for operative repair. The pulmonary vascular tree is also abnormal, with an increase in number of vessels as well as muscularity.

Presentation and Initial Management

Clinical Diagnosis

The fetus supports single-ventricle physiology before birth via parallel circulations with three communications (the ductus venosus, foramen ovale, and ductus arteriosus). These communications shunt oxygenated placental blood largely past the hepatic and pulmonary beds to supply the splanchnic circulation. In this prenatal physiology, HLHS is not a lethal anatomical arrangement. For those children who harbor HLHS that die prenatally, it is more likely a secondary result of early obstructive lesions of either mitral or aortic valvular development or comorbidities. The primary cause of HLHS is unknown. Despite the existence of genetic associations in some families, the vast majority of HLHS is without a direct attributable cause. There are no published genetic animal models that fully recapitulate HLHS despite the existence of a large number of mutations that affect valvular development. This argues for a complex, multifactorial early event or an early insult influence by subsequent modifiers. However, testing for extracardiac anomalies remains important for prognosis. HLHS has been rarely associated with Turner syndrome, trisomy 13, trisomy 18, Holt-Oram, Smith-Lemli-Opitz, partial trisomy 9, Jacobsen syndrome, and others. Extracardiac anomalies associated with HLHS include agenesis of the corpus callosum, diaphragmatic hernia, and omphalocele, among others. It is well recognized that genetic disorders and extracardiac anomalies in association with a diagnosis of HLHS carry a worse prognosis.

The presentation of infants with congenital heart disease has changed dramatically over the last 15 years. In most large centers, the majority of patients are identified through prenatal echocardiography, although there is conflicting data regarding the impact on surgical outcome. The preponderance of data suggests that prenatal diagnosis does not reduce mortality, though infants with a prenatal diagnosis of HLHS have overall better preoperative condition, including lower lactate levels, better renal function, and fewer neurological events (e.g., seizures). Importantly for many families and practitioners, prenatal evaluation allows families to prepare for a child with a life-altering disease.

Clinically, although some tachypnea and mild cyanosis may be present, it is not until the ductus arteriosus begins to close that the children exhibit impaired systemic perfusion with pallor, lethargy, and diminished femoral pulses. A dominant right ventricular impulse, a single-second heart sound, and often a nonspecific soft systolic murmur may appear on cardiac examination.

Physical examination of children with HLHS with an open ductus arteriosus often appears normal. However, the underlying anatomy as well as the duration of the disease will influence the findings on exam. Poor perfusion, weak distal pulses (present or not, depending on the size of the ductus arteriosus), acidosis, and a sepsis-like picture may all confound the diagnosis. In the absence of risk factors or laboratory findings consistent with an infectious etiology, caregivers should rule out a left-sided obstructive cardiac lesion. In contrast to a septic picture, there are no specific laboratory indicators of HLHS, with most patients exhibiting normal values. With

ductal closure and resultant malperfusion, end-organ compromise may be reflected by altered tests of end-organ perfusion, especially of hepatic and renal function.

Perhaps surprisingly, many mothers of fetuses with HLHS will have had a fetal echocardiogram at 20 weeks with reasonable visualization of cardiac structures. It is neither feasible nor cost-effective to screen all pregnancies; therefore, a selective approach is taken in which only those mothers at high risk are screened. Frequently, a ventricular size discrepancy is the first hint of impending problems. The presence of intact or restrictive atrial septum with HLHS is often a salvageable situation and should prompt the term high-risk delivery in an institution in which an urgent postdelivery palliation can be performed safely and rapidly. Emergent operative atrial septectomy is poorly tolerated and is probably best not attempted. Catheter-based intervention is also high risk but better tolerated. It is critical to distinguish HLHS from other diseases that may mimic certain features, and in nearly all cases, two-dimensional and Doppler echocardiography appropriately defines the anatomy for medical and surgical decision-making.

Complementary Investigations and Preoperative Management

Electrocardiogram examination reveals right atrial enlargement and right ventricular hypertrophy.

Chest radiography often demonstrates mild cardiomegaly and excessive pulmonary blood flow.

In order to minimize the risks of systemic heparinization required for cardiopulmonary bypass, a *head ultrasound* should be obtained in all patients to rule out intracranial hemorrhage.

Patients with medical necrotizing enterocolitis should complete the course of intravenous antibiotics while on prostaglandins for maintenance of ductal patency before repair, if hemodynamically stable.

In all situations, preoperative stabilization is critical to the ultimate outcome of patients with HLHS regardless of anatomic subtype. For the latter purpose, caregivers must concentrate on preserving adequate systemic tissue perfusion, while avoiding metabolic (lactic) acidosis and progression toward multiorgan dysfunction. Failure of medical management should prompt surgical intervention.

Regardless, stage I palliation should not be substantially delayed. Pulmonary vascular resistance (PVR) falls following birth in a time-dependent fashion. Thus, a delay in palliative operation is at the expense of reduced systemic perfusion, and the balance of systemic and pulmonary circulations is crucial. Nearly all patients with suspected HLHS are transported on prostaglandin E_1 at a dose of 0.01–0.025 mcg/kg/min. Two clinically important dose-dependent side effects of prostaglandin E_1 infusion are hypotension and apnea, although these are infrequent. Central access is not required, although umbilical arterial and umbilical venous lines are used for most patients. Most patients will not require assisted ventilation and in fact, hemodynamics are improved without mechanical ventilation. Supplemental oxygen should generally be avoided as it acts as a pulmonary vasodilator, decreasing pulmonary vascular resistance, increasing the ratio of pulmonary-to-systemic blood flow, and thus decreasing systemic perfusion. Inotropic support is rarely necessary, although it may be required for support in patients who have suffered a perinatal insult. The goal of these maneuvers is to get the patient to the operating room in as stable condition as is possible.

Principals of Surgical Palliation

The primary therapy for HLHS is staged reconstructive surgery leading to a Fontan procedure. Over the last 25 years, the Norwood procedure has evolved and is now a standard operation for hypoplastic left heart syndrome in nearly all institutions. There are three primary goals of stage I Norwood palliation: (1) establishment of unrestricted interatrial communication to provide complete mixing and avoid pulmonary venous hypertension; (2) establishment of a reliable

source of pulmonary blood flow, allowing pulmonary vasculature development and minimizing the volume load on the single ventricle; and (3) providing unobstructed outflow from the ventricle to the systemic circulation. An additional two strategies for the neonatal management of HLHS have evolved over the last few decades: (1) hybrid palliation with surgical bilateral pulmonary artery banding and transcatheter ductal stenting and (2) orthotopic heart transplantation. In most centers with a large operative experience, stage I surgical palliation is offered to nearly all patients with HLHS, including very low birth weight infants and those with nonlethal genetic syndromes. In certain complicating situations, hybrid approaches or primary transplantation may be considered. Two prominent such cases include severe aortic or atrioventricular regurgitation or dilated cardiomyopathy.

Stage II cavopulmonary (bidirectional Glenn or hemi-Fontan) palliation eliminates the high-pressure, systemic arterial (Blalock-Taussig shunt) or ventricular (Sano modification) source of pulmonary blood flow and connects the superior vena cava (SVC) with the pulmonary artery. Cavopulmonary conversion results in reduced pulmonary arterial pressure and volume, improved circulatory efficiency, and higher arterial saturation.

Stage III palliation incorporates the remaining desaturated blood returning from the lower body to the pulmonary circulation.

Surgical Approaches: Stage I Palliation, Classic Norwood

Surgical Technique

One well-defined technique that has been successfully performed on over a thousand patients with HLHS is described. A child with HLHS (or physiologic single-ventricle equivalent) is brought to the operating room ventilated on room air, with care taken to avoid hyperventilation. Induction of anesthesia ought to be performed by highly trained cardiovascular anesthetists to avoid critical decompensation. A full midline sternotomy is performed and a sternal retractor placed. The thymus is removed in its entirety, with care being taken to avoid the phrenic nerves. The pericardium is opened, and an obligatory mediastinal inspection is performed to confirm the echocardiography, especially to identify abnormalities of the aortic arch and coronary arteries as coronary orientation may alter the surgical approach. The ascending and descending aorta, brachiocephalic vessels, ductus arteriosus, and pulmonary arteries are extensively mobilized, with care taken to avoid damage to the recurrent laryngeal nerve. No attempt is made to dissect the systemic veins. Purse-string sutures are placed in the proximal main pulmonary artery and generously around the right atrial appendage, through which heparin is administered. A previously thawed pulmonary homograft hemipatch is then trimmed in an extended arrowhead shape and set aside (Fig. 102.2a). Two perfusion techniques are commonly used for operative repair: *deep hypothermic circulatory arrest (DHCA)* and *selective antegrade continuous cerebral perfusion*. Despite intensive investigation, there is no consensus regarding a superior approach. On one hand, avoidance of DHCA appears logical and provides a level of security if the operation cannot be completed with accuracy and efficiency in under 45–60 min. In contrast, use of DHCA provides an operative field devoid of distractions and enhances the specificity of repair. To date, it is clear that a single technique cannot be ideally matched to all surgeons or patients.

After the activated clotting time reaches 300 s, the patient is cannulated with the arterial cannula at the base of the main pulmonary artery and a single venous cannula in the right atrium. Cardiopulmonary bypass is initiated and tapes brought down around the branch pulmonary arteries. The patient is cooled to 18 °C at least 15 minutes; during which time any remaining dissection is performed. During this period of cooling, a side-biting clamp is placed on the innominate artery, and a polytetrafluoroethylene (PTFE) graft (usually 4.0 mm for patients >3.2 kg and 3.5 mm in smaller infants) is anastomosed in an end-to-side fashion. The clamp is

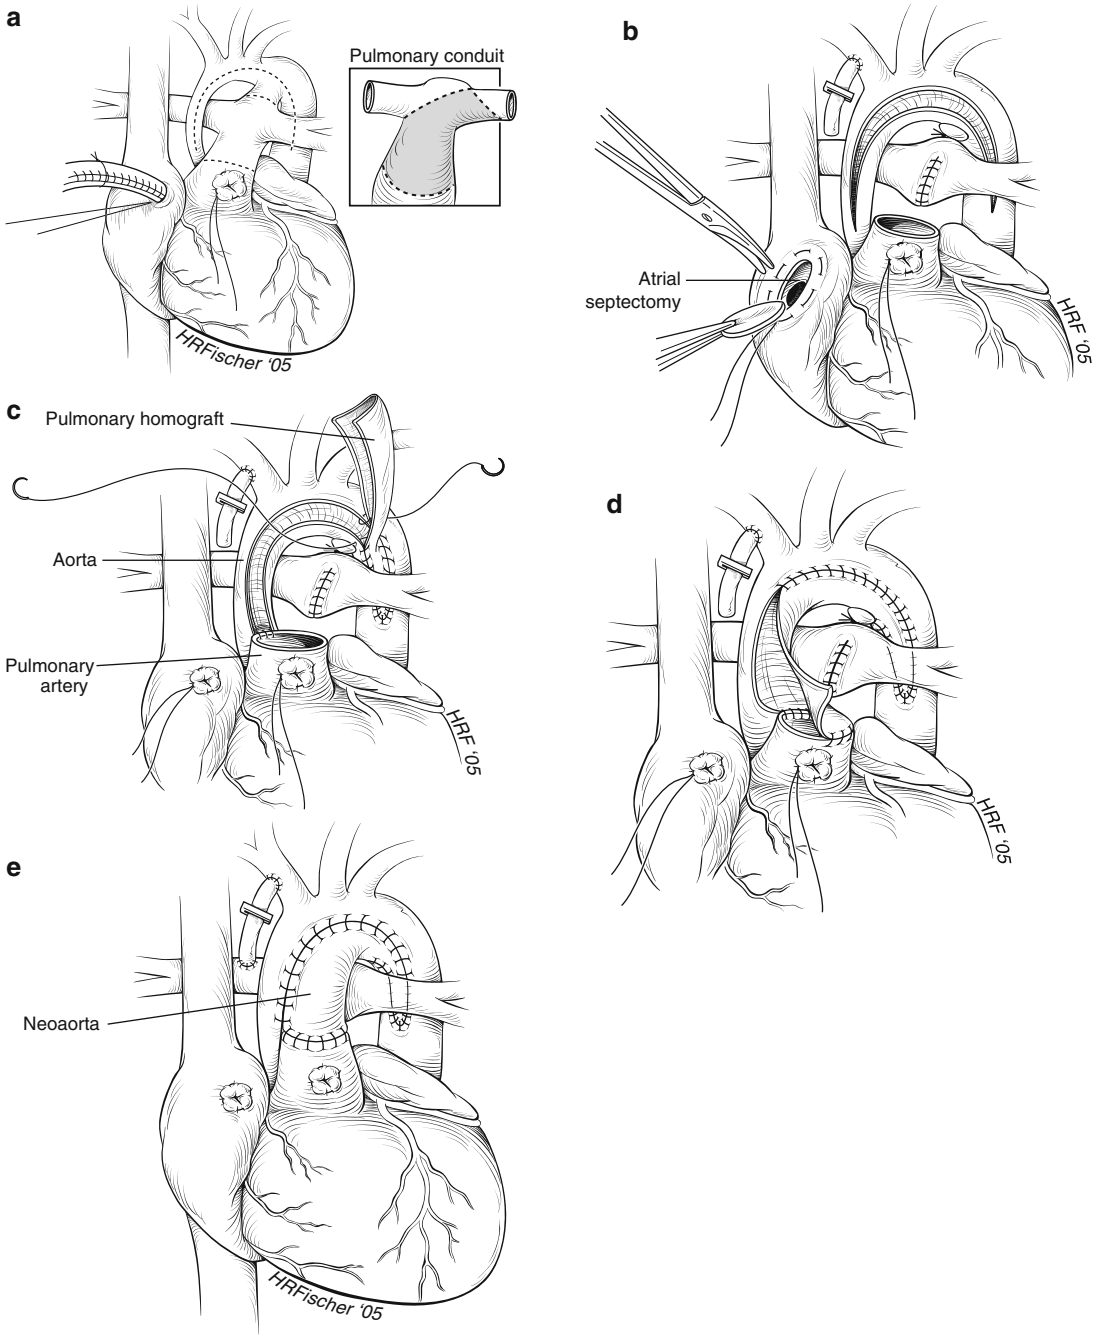

Fig. 102.2 Standard repair of hypoplastic left heart syndrome by the Norwood procedure. (**a**) Incision sites are shown for the main pulmonary artery, which is transected just proximal to the origins of the branch pulmonary arteries, and the diminutive aorta, which is incised along the inferior aspect past the insertion of the ductus arteriosus. (**b**) The proximal portion of the right modified Blalock-Taussig shunt (RMBTS), usually 3.5–4.0 mm, is completed during cooling. After deep hypothermic circulatory arrest is initiated, the main pulmonary artery segment is closed, and the atrial septum is excised through the atrial purse string. (**c**) The posterior aspect of the Damus-Kaye-Stansel (DKS) anastomosis is completed with interrupted sutures, and the aortic arch is augmented with a homograft patch. (**d**) The remainder of the DKS is completed with the homograft patch. (**e**) The distal end of the RMBTS is completed to the right pulmonary artery

removed and flow assessed. If blood does not briskly flow from the open shunt, the anastomosis should be revised. A hemoclip is placed to temporarily occlude the shunt. On initiation of circulatory arrest, tapes are brought down around the brachiocephalic vessels, and a vascular clamp is placed on the descending aorta distal to the ductal insertion site. Cardioplegia is administered retrograde through a side port on the arterial cannula. After draining the patient of blood, all cannulas and PA tapes are removed. The ductus arteriosus is ligated on the PA side and divided on the aortic side. The atrial septum is completely excised working through the atrial purse string (Fig. 102.2b). Visualization can be improved through a right atriotomy, although this is seldom necessary. Next, the main pulmonary artery (MPA) is divided close to the branch pulmonary arteries, and the defect in the distal MPA segment is closed either with an oval homograft patch or primarily in a vertical fashion.

At a point beginning immediately adjacent to the divided main pulmonary artery (MPA), the diminutive aorta is incised medially and the incision carried superiorly along the underside of the transverse arch through the ductal insertion site to a point approximately 1 cm distant. It is important that all redundant ductal tissue is excised from the previous insertion site and the coarctation shelf be either debrided or the segment excised and the remaining vessel reanastomosed. The proximal aortic-to-proximal PA connection is now performed using interrupted, fine polypropylene sutures (Fig. 102.2c). Next, the arch is reconstructed using the homograft patch, carrying this suture line down to complete the Damus-Kaye-Stansel proximally (Fig. 102.2d). The distal Blalock-Taussig shunt-PA anastomosis is now performed to the origin of the right pulmonary artery (RPA), although some surgeons prefer to do this with the cross-clamp off during warming (Fig. 102.2e). The arch is infused with cold saline to assess the geometry or residual obstruction, the atrium is infused with cold saline to de-air, and the cannulas are replaced. Cardiopulmonary bypass is begun and the patient warmed to 37 °C. It is important at this point to assess prompt and equivalent filling of coronary distributions. Any perfusion defect should be addressed immediately with revision of the aortic-to-PA anastomosis. During warming, obvious bleeding should be controlled. After the patient has been warmed to 37 °C, the clip is removed from the shunt, and atrial lines are brought through the chest wall and positioned in the right atrium. The patient is begun on low-dose dopamine and milrinone support and weaned off cardiopulmonary bypass; modified ultrafiltration is routinely performed. Oxygen saturations should be in the low-to-mid-80 % range, indicative of adequate but not excessive pulmonary blood flow. Any base deficit is corrected completely with sodium bicarbonate, and continued persistent acidosis is a relative indication of poor cardiac function requiring examination of the repair. After protamine is administered to reverse the heparin, hemostasis is meticulously obtained. If there are no issues with bleeding, the chest is routinely closed. In approximately 20 % of cases, either hemodynamic or respiratory instability or continued potential bleeding results in the potential for cardiac compromise with chest closure. In these cases, a PTFE patch is cut to an appropriate size and approximated to the skin edges, leaving the sternum open for 12–24 h.

Postoperative Course

Postoperative management of these patients includes low-dose dopamine and milrinone, although some centers use phenoxybenzamine as an afterload-reducing agent. The use of afterload reduction results in vasodilation with right ventricular support and generally removes the need for any greater inotropic therapy. In some cases, low-dose epinephrine is used if there is significant hypotension. Great attention needs to be paid to the maintenance of an adequate balance between systemic and pulmonary flow (Q_p:Q_s), prioritizing on the follow-up of tissue perfusion markers. A fine balance can be achieved by titration of cardiovascular drugs, ventilation, and avoiding triggers for increased systemic (which would deteriorate systemic tissue perfusion and induce pulmonary edema) or

pulmonary resistances (that would induce cyanosis). Patients are lightly sedated and administered either low-dose fentanyl as a continuous drip or intermittent morphine. Patients are not routinely paralyzed with pancuronium unless the sternum is left open. An attempt is made to allow the patient to awaken and to wean the ventilator support such that extubation can be performed on the first to second postoperative day. If the chest is left open, the chest is generally closed the day after surgery and the patient allowed to awake, weaning from the ventilator over the next 24–48 h. Rapid de-intensification with removal of nasogastric feedings and removal central lines is preferred. Aspirin is usually administered after the first night when heparin is used at a low dose to decrease the risk of shunt thrombosis. When oral intake is established, low-dose aspirin is administered enterally. Patients are usually extubated between postoperative days 1 and 3. Average duration of hospitalization is between 2–4 weeks, the limiting factor often being establishment of adequate oral caloric intake. In all cases, the principle is continued advancement, and any migration from that pathway should prompt investigation into the cause of deviation.

Surgical Approaches: Stage I Palliation, RV-PA Conduit/Sano Modification

Surgical Technique

In the standard Norwood stage I palliation, there is a relative decrease in pulmonary-to-systemic vascular resistance, resulting in continuous forward flow into the BT shunt in both systole and diastole. This may result in "coronary steal" with decreased myocardial perfusion. Indeed, coronary arterial flow and oxygen delivery are decreased in patients following the Norwood procedure. It is hypothesized that this relative coronary arterial insufficiency secondary to the coronary steal may play an important role in the significant mortality of the palliated patient. Early reports including a multi-institutional collaborative effort organized through the Pediatric Heart Network suggest that a right ventricular-to-pulmonary artery (RV-PA) shunt as popularized by Sano may improve outcome after the stage 1 reconstruction (Fig. 102.3). However, a number of contradictory studies further comment that before broad adaptation of the RV-PA conduit, other considerations apply. For example, there may be anatomic substrates better suited to one shunt type compared to another. With respect to the RV-PA conduit, there is an increased incidence of shunt re-intervention, an earlier return for stage II reconstruction, and no difference in overall mortality. Certainly, consensus exists that staged palliation consists of multiple surgeries that result in the Fontan circulation. Increasingly, there is an understanding that uniform adaptation of any approach prior to stage III data may be premature, as these studies have yet to be performed.

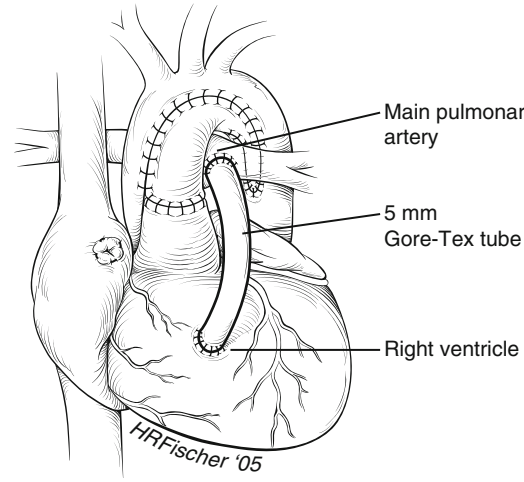

Fig. 102.3 Alternative approach to stage I palliation using the Sano modification. Instead of a right modified Blalock-Taussig shunt, pulmonary blood flow is supplied by a 5.0-mm polytetrafluoroethylene (Gore-Tex) shunt from a right ventriculotomy to the main pulmonary artery

Surgical Approaches: Stage I Palliation, Hybrid Procedure

In a resurgence of a physiologic approach described three decades earlier, Gibbs in 1992 and subsequently Ruiz and others proposed

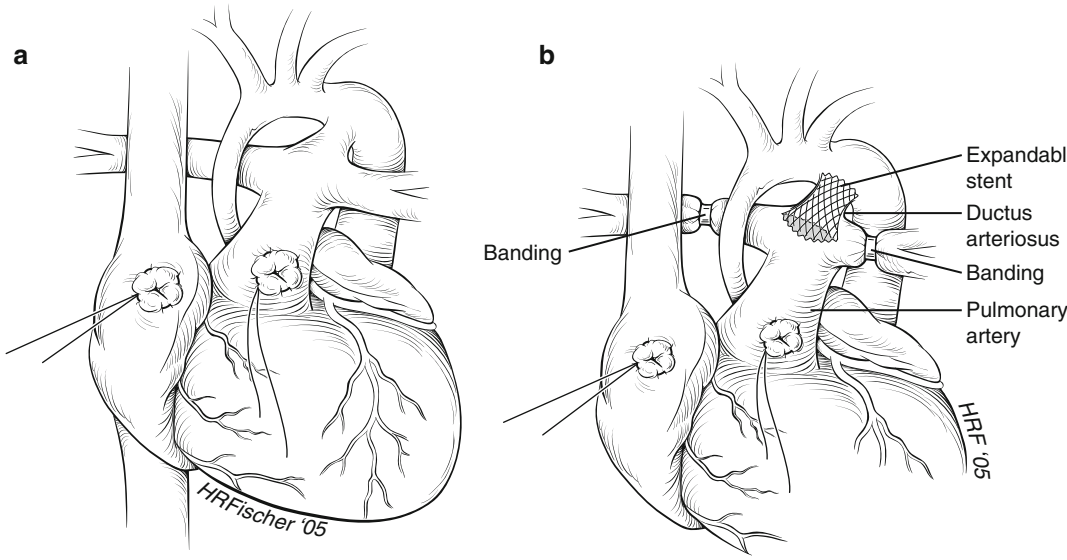

Fig. 102.4 Alternative approach to stage I palliation using ductal stenting and pulmonary artery bands. (**a**) Unrestricted, stable systemic and pulmonary blood flow is created by insertion of an expandable stent in the ductus arteriosus. (**b**) Next, pulmonary blood flow is restricted by placement of bilateral pulmonary artery 3.0-mm bands

hybrid palliation of HLHS using percutaneous patent ductus arteriosus (PDA) stent implantation and surgical bilateral pulmonary artery banding without cardiopulmonary bypass. Despite poor initial outcomes, the approach has seen renewed interest and improved results. For high-risk infants, some have advocated catheter-based hybrid approach: Stage 1 palliation includes ductal stenting and PA banding; stage II includes septectomy, arch augmentation, and cavopulmonary anastomosis; and stage III includes catheter-based Fontan completion. Although there have been promising results, these techniques may be limited in certain anatomic subsets such as aortic atresia in which preductal, retrograde coarctation is a significant problem (Fig. 102.4). Palliative catheter-based hybrid approaches may be the most useful in identifiable subsets of patients with HLHS who have very low birth weight or associated cardiac anomalies. These patients are still a high-risk group for stage I reconstruction in most series. Otherwise, catheter-based approaches have no demonstrable advantage over surgical staged palliation.

Galantowicz and Cheatham with one of the largest US experiences to date have settled on the following approach: (1) placement of surgical bilateral pulmonary artery bands via a small median sternotomy off cardiopulmonary bypass and PDA stent delivery through a surgically placed sheath in the main pulmonary artery above the pulmonary valve and (2) subsequent balloon atrial septostomy in a separate procedure 1–2 weeks later. The delay allows patient stabilization and left atrial enlargement permitting the use of a larger balloon, thus decreasing the need for repeat septostomy. Importantly, retrograde aortic arch obstruction with the PDA fully open is considered a contraindication to the hybrid stage I palliation. Some have advocated the use of the "reverse BT shunt" at the time of hybrid palliation to protect coronary blood flow, but this has not been universally accepted. The definitive role of the hybrid approach in stage I palliative approaches has yet to be determined. Two specific chapters dedicated to this alternative can be found in this textbook, one focused on the catheter-based technique and the other one on the comprehensive discussion of this approach.

Surgical Approaches: Stage II Palliation, Classic Bidirectional Glenn

Surgical Technique

Two important observations by Norwood and colleagues early in the reconstructive experience prompted the institution of an intermediate stage. The first was recognition of a time-related interstage mortality. Current data report death following stage I palliation and prior to stage II is low, but with a consistent mortality of 2–16 %. The second was that the chronic volume load of a systemic-to-pulmonary shunt could on accession result in diastolic ventricular dysfunction. Thus, an intermediate stage was initiated as either a bidirectional cavopulmonary (Glenn) shunt or a hemi-Fontan procedure. A bidirectional cavopulmonary anastomosis sets the stage for an extracardiac conduit, whereas a hemi-Fontan sets the stage for a lateral tunnel completion Fontan. There is no long-term data that prove the efficacy of one approach over another. In general, at approximately 4–6 months of age, stage I survivors undergo either cardiac MRI or catheterization for evaluation of both pressures throughout the heart and the anatomy of pulmonary arteries. Use of a cavopulmonary anastomosis before approximately 3 months of age is sometimes associated with increased hypoxia and upper-body venous congestion, although bidirectional Glenn shunts have been done in children at even 6–8 weeks of age with good results when there is clearly demonstrable low pulmonary vascular resistance.

There are various techniques for a bidirectional cavopulmonary anastomosis that may include the avoidance of cardiopulmonary bypass. These authors' techniques utilize bypass in an attempt to maximize the precision of the anastomosis (Fig. 102.5). In short, after surgical exposure and systemic heparinization, the patient is cannulated in a standard fashion and an arterial cannula placed high in the aortic reconstruction. Importantly, every attempt is made to prevent narrowing of the superior vena cava that will become the sole source of pulmonary blood flow. The azygous vein is ligated and divided. Cardiopulmonary bypass is begun and a tourniquet is applied around the SVC cannula. A vascular clamp is placed at the SVC-RA junction and the SVC divided. Often, a vent is placed in the divided SVC rather than through a purse-string suture. The atrial portion is closed in two layers with fine monofilament suture. The SVC-RPA anastomosis is completed with monofilament suture and occasionally augmented at the prior shunt insertion site. The patient is removed from cardiopulmonary bypass, and a period of modified ultrafiltration is begun. All suture lines are checked for hemostasis. At the completion of modified ultrafiltration, the SVC pressure is measured directly with a transthoracic line and subsequently removed. An additional monitoring line is placed in the right atrium. All cannulas are removed, and protamine is administered. The chest is then closed in a standard fashion and the patient returned to the ICU. In general, these patients are extubated either in the operating room or soon after return to the ICU.

Management of additional sources of pulmonary blood flow at the time of superior cavopulmonary anastomosis remains controversial. Leaving an additional source of pulmonary blood flow (BT shunt or RV-PA conduit) has the potential advantage that the increased flow may enhance pulmonary artery growth; however, the increased flow is not tolerated in all patients and occasionally leads to unacceptable elevation of SVC pressure. Additionally, there is no definite evidence that leaving additional sources of pulmonary blood flow improves outcomes.

Postoperative Course

Postoperative progression after a bidirectional Glenn is usually uneventful. Inotropic support is seldom intense and encompasses the use of low-dose milrinone and dopamine. Patients are rapidly extubated in order to optimize cardiopulmonary interactions. It is of vital importance to avoid and aggressively manage triggers for

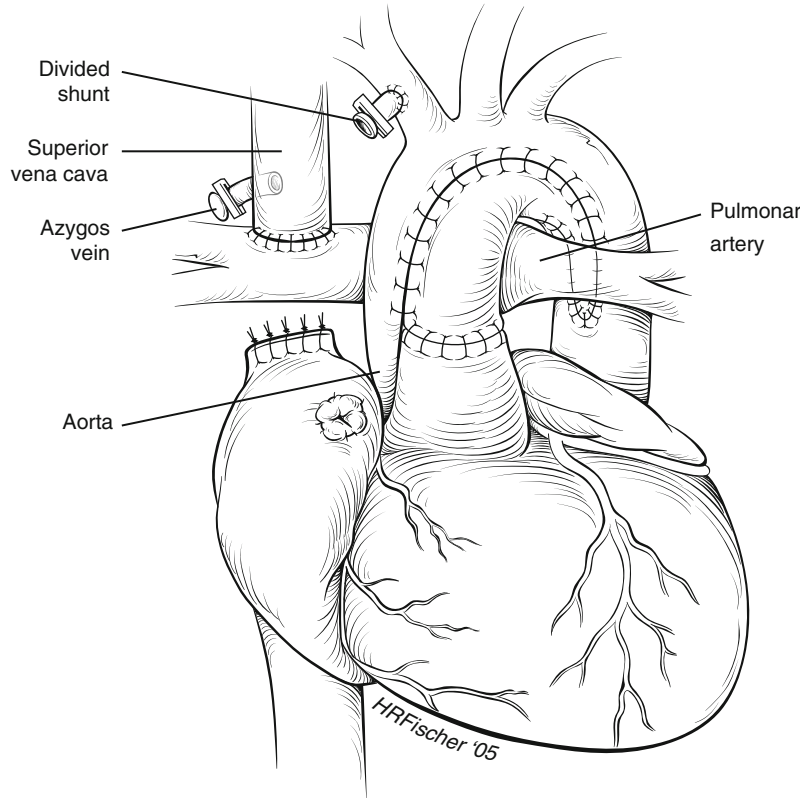

Fig. 102.5 The bidirectional Glenn procedure. The Blalock-Taussig shunt is ligated proximally and removed distally from the right pulmonary artery. The azygous vein is ligated and the superior vena cava (SVC) is detached from the right atrium, oversewing the atrial portion. Finally, the SVC is anastomosed to the right pulmonary artery

increased pulmonary resistances and arrhythmias. Pain control and sedation are also capital. In patients with increased pulmonary resistances and significant desaturation, it may be useful to combine permissive hypercapnia to promote cerebral vasodilation and therefore increased venous return to the lungs, with alkalinization to induce a normal to slightly high pH for better control of pulmonary vascular resistances.

Surgical Approaches: Stage II Palliation, Classic Hemi-Fontan

Surgical Technique

An alternative operative approach is the hemi-Fontan procedure, which can be performed under either deep hypothermic circulatory arrest or conventional bypass. The approach is through a reoperative median sternotomy, during which time care is taken around the dissection of the neo-aorta. The patient is cannulated in a standard fashion with an arterial cannula in the neo-aorta and a single straight venous cannula in the body of the right atrium. Cardiopulmonary bypass is begun, and the patient is cooled to 18 °C. The previous shunt is divided and ligated and the azygous vein ligated. After cardioplegic arrest, the PAs are opened on the anterior aspect and the pulmonary insertion of the shunt excised. If preoperative catheterization revealed pulmonary arterial stenosis, the incisions are carried beyond this point well onto the left PA and onto the right lower lobar branch. Next, the right atrium is incised superiorly and medially from 12 to 6 o'clock beginning just superior to the cannulation site and ending at the level of the right upper pulmonary artery (Fig. 102.6). The SVC and right aspect of the pulmonary arteriotomy are anastomosed with fine monofilament suture. Next, an extended triangular pulmonary homograft patch is used to

augment the pulmonary arteries and create a roof over the anastomosis of the SVC to the RPA as well as simultaneously create a dam to prevent blood flow between the SVC and right atrium. The patch-augmented PAs are infused with saline to examine anatomy and de-air. The venous cannula is replaced, cardiopulmonary bypass is reinitiated, aortic cross-clamp is removed, and warming to 37 °C is completed. One or two right atrial lines are inserted into the body of the right atrium or into the PA through the suture line. The patient is weaned from cardiopulmonary bypass, and modified ultrafiltration is performed; during which time all suture lines are checked for hemostasis. All cannulas are removed, and protamine is administered. The chest is then closed in a standard fashion and the patient returned to the ICU.

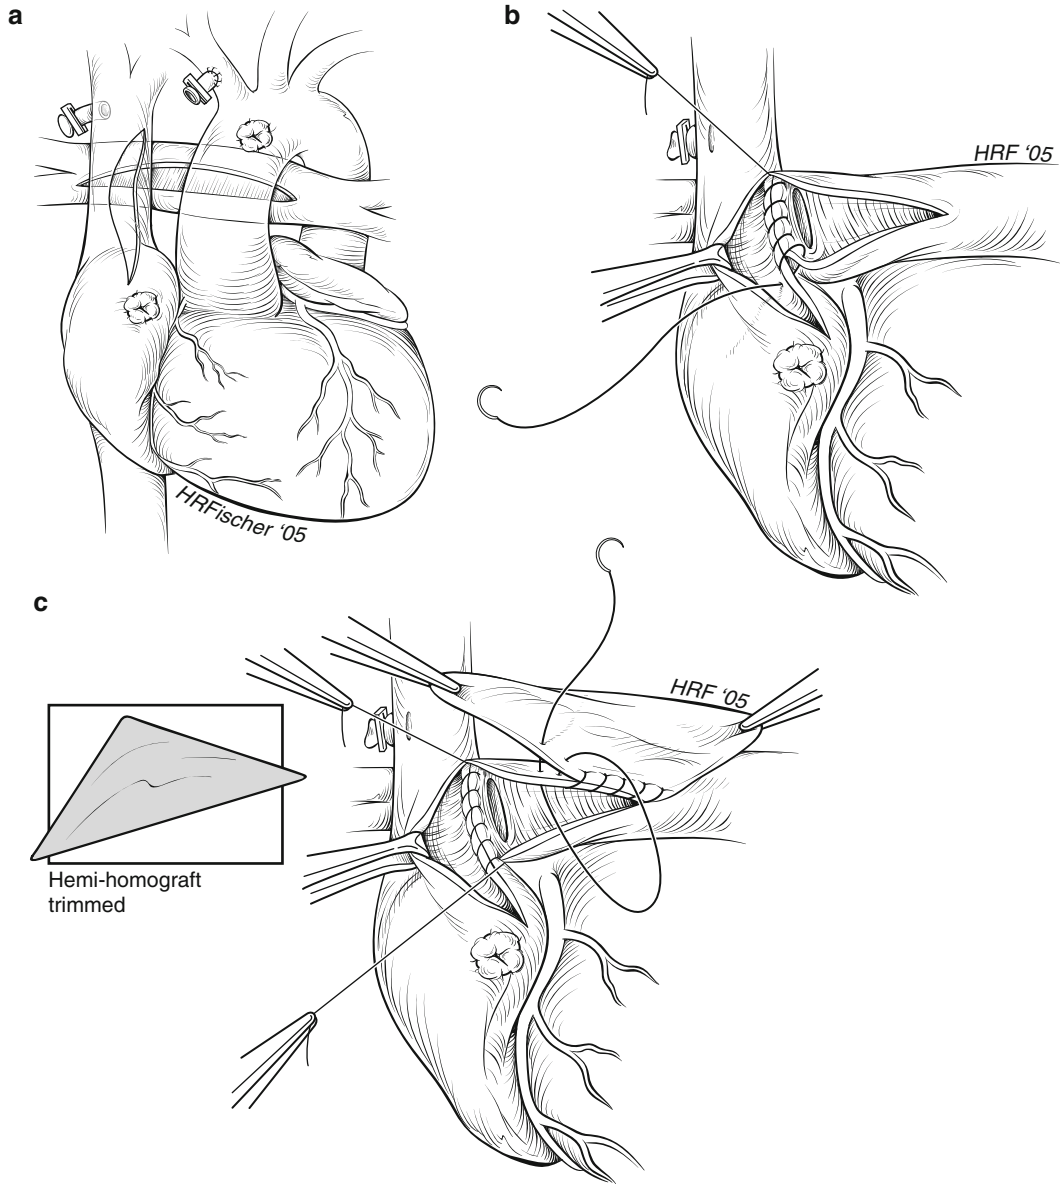

Fig. 102.6 (continued)

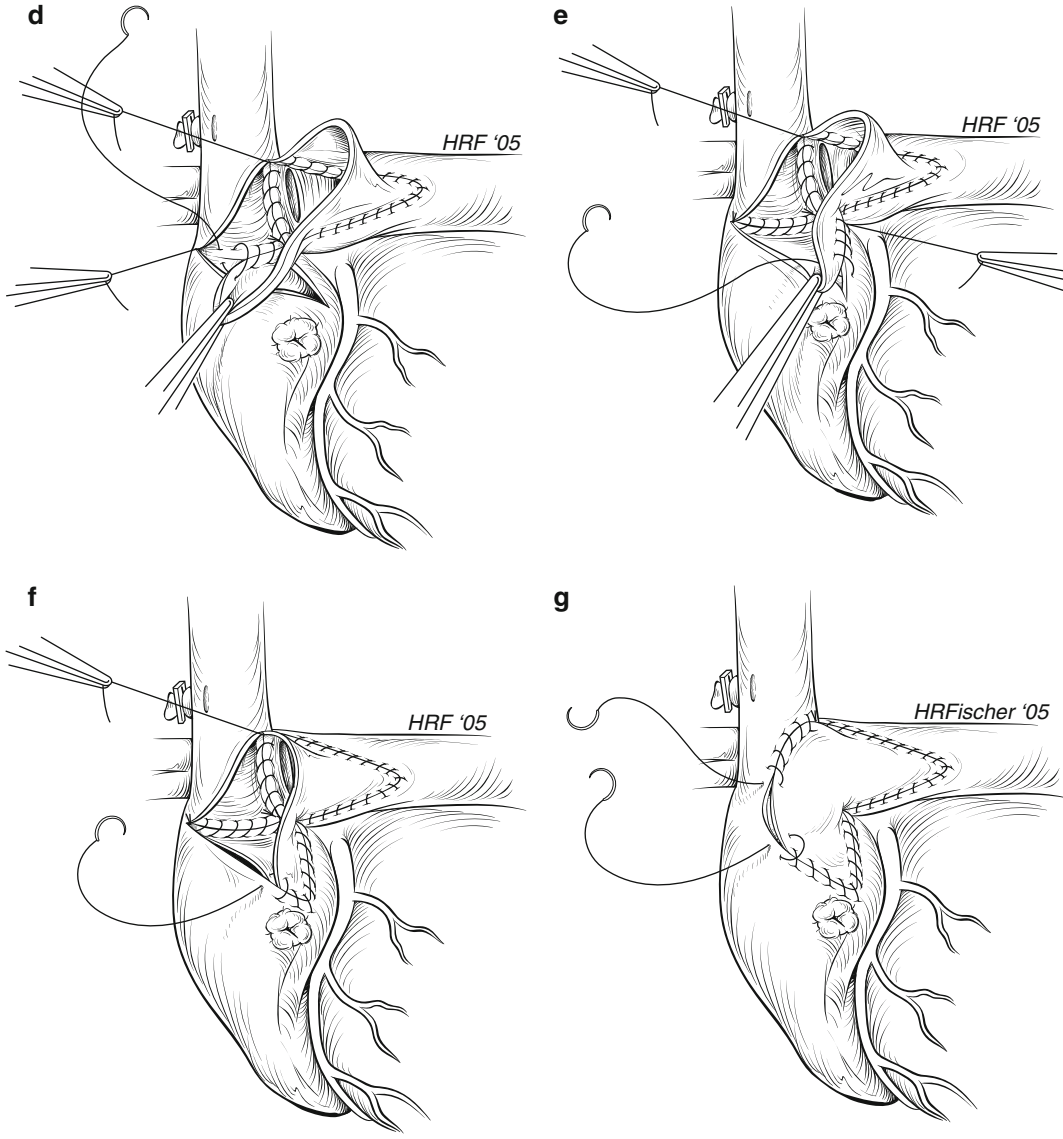

Fig. 102.6 The hemi-Fontan procedure. (**a**) The pulmonary artery is incised widely from the left lower pulmonary artery to the left pulmonary artery. The right atrium is incised vertically in a spiral clockwise fashion from the superior portion of the right atrial (RA) appendage into the superior vena cava (SVC) to the superior aspect of the right pulmonary artery. The azygous vein is ligated. (**b**) The posterior aspect of the incision in the SVC is anastomosed to the rightward aspect of the pulmonary arteriotomy. (**c**) An extended triangular homograft patch is trimmed and sewn to augment the pulmonary arteries. (**d**) The homograft patch suture line continues along the SVC-RA junction to create the bottom of the dam. (**e**) The patch is folded on itself to create a triangular-shaped dam. (**f**) The suture line is continued to complete the dam. (**g**) The same homograft patch is used to simultaneously complete the pulmonary artery augmentation and SVC-PA anastomosis

Postoperative Course

In general, as with the bidirectional Glenn, hemi-Fontan patients can be extubated either in the operating room or soon after returning to the ICU. With reduction of the volume load provided by this procedure, inotropic support is usually brief. Blood-oxygen saturations are generally

from 80 % to 90 %, and patients are generally discharged within 5–7 days after surgery.

Surgical Approaches: Stage III Palliation, Extracardiac Fontan

In 1971, Fontan became the first to place the pulmonary and systemic circulations in the setting of tricuspid atresia. Soon after in 1973, Kreutzer added to this experience. As an alternative to the atriopulmonary Fontan, a decade later, de Leval introduced the concept of the total cavopulmonary connection. The Fontan circulation has become the accepted final arrangement for the single-ventricle pathway. In order to minimize cyanosis, most Fontan completions occur when children are 2–3 years of age, whereas other groups delay Fontan until 3–5 years to decrease the longer recovery period and risk of failure. Fontan failure is a multifactorial event that is a result of the new circulation that includes right atrial dilation, inefficient flow dynamics, baffle thrombus, repeated subclinical pulmonary emboli, and atrial arrhythmias. In the most common univentricular situation, there is a systemic tricuspid valve, also at risk for failure over time. Although an aggressive approach toward tricuspid valve repair at the time of completion Fontan is common, the durability of repair is unpredictable and subject to ongoing investigation.

If there are no anatomic issues to be addressed via catheterization (e.g., distal arch coarctation), the patient is referred for Fontan reconstruction via either an *extracardiac conduit* or *lateral tunnel* completion Fontan. Again, there are many operative approaches to Fontan completion. Two, well-characterized techniques follow. The approach is again through a reoperative median sternotomy.

For patients who underwent a stage II palliation with a bidirectional Glenn, an extracardiac Fontan procedure is the most common approach. The patient is bicavally cannulated in a standard fashion and an arterial cannula placed high in the aortic reconstruction. Cardiopulmonary bypass is begun, and tourniquets are applied around the caval cannulas. A vascular clamp is placed at the IVC-RA junction, and the IVC is divided (Fig. 102.7). The atrial portion is partially closed in two layers with fine monofilament suture. The conduit

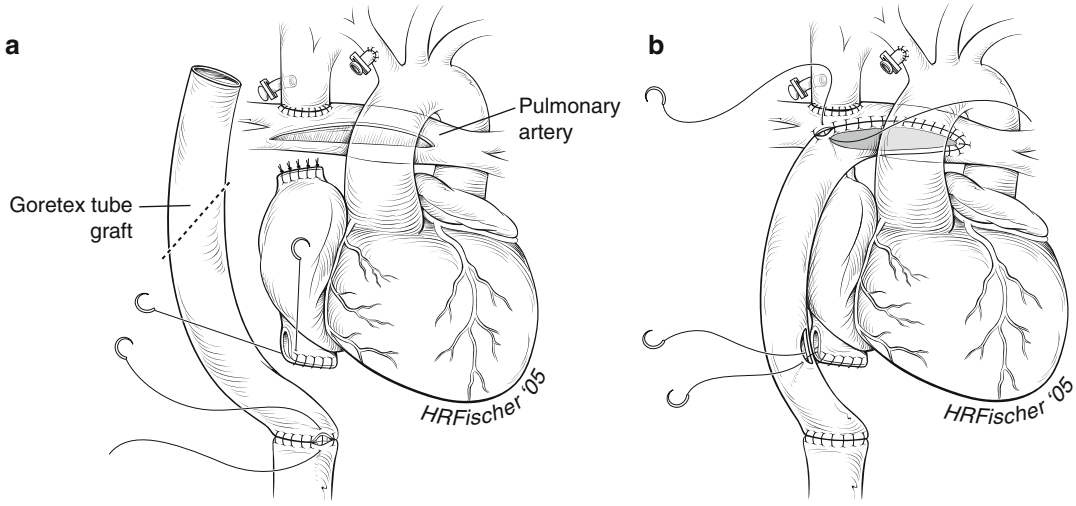

Fig. 102.7 The extracardiac Fontan procedure. (**a**) The inferior vena cava is detached from the right atrium, and the right atrial portion is partially closed. An 18–22-mm polytetrafluoroethylene (PTFE; Gore-Tex) conduit is anastomosed to the inferior vena cava (IVC), and a 4.0-mm fenestration is created next to the partially closed IVC. (**b**) A side-to-side anastomosis is fashioned between the fenestration and IVC opening in the right atrium. The distal end of the PTFE conduit is beveled to create a large opening that augments the pulmonary arteries, and the conduit-PA anastomosis is completed

(18–22-mm PTFE) is trimmed to the appropriate length to avoid compression of the right pulmonary vein (shorter than the operator might expect), and a 4-mm fenestration is punched in the medial aspect near the IVC portion. Increasingly, the use of a fenestration (shown to improve postoperative cardiac output and exercise performance, effusions, ascites, and reduced protein-losing enteropathy) is being used selectively. The IVC-conduit anastomosis is completed with monofilament suture followed by a side-to-side anastomosis of the remaining cardiac portion of the IVC opening with the exterior conduit, leaving a rim of conduit around the fenestration. Next, the PAs are opened along the inferior margin and inspected directly. If preoperative studies revealed any pulmonary arterial stenosis and the beveled end of the PTFE conduit will not span the area of stenosis, this is addressed with pulmonary homograft patch augmentation. The conduit is then anastomosed to the inferior aspect of the pulmonary arteries angled slightly medial to the SVC. Practically, the angled nature of the superior portion of the conduit augments the PAs from left pulmonary artery (LPA) to the RPA. The conduit is infused with saline to de-air, and the patient is weaned from of cardiopulmonary bypass. The SVC cannula is removed, and a period of modified ultrafiltration is begun. All suture lines are checked for hemostasis. At the completion of modified ultrafiltration, the SVC pressure is measured directly with a transthoracic line and subsequently removed. An additional monitoring line is placed in the right atrium. All cannulas are removed, and protamine is administered. The chest is then closed in a standard fashion and the patient returned to the ICU. In general, these patients are extubated soon after return to the ICU.

Surgical Approaches: Stage III Palliation, Lateral Tunnel Fontan

An alternative approach is the lateral tunnel Fontan using a piece of fenestrated PTFE patch to baffle blood from the IVC to the PAs (Fig. 102.8). The patient is cannulated in a standard fashion with an arterial cannula in the neo-aorta and a single straight cannula in the body of the right atrium. Cardiopulmonary bypass is begun, and the patient is cooled to 18 °C. An aortic cross-clamp is applied and cardioplegic arrest achieved. The patient is drained of blood and the venous cannula removed. A vertically based incision is made in the body of the right atrium parallel to Waterson's groove. The previously constructed PA-RA homograft dam is excised, and the Eustachian valve is removed. A 10-mm PTFE tube graft is split longitudinally and trimmed to length, and a 4-mm fenestration is created. Inferiorly, the graft is sewn around the IVC orifice and the suture line carried superiorly along the line of the interatrial communication. Superiorly, the baffle is sewn around the edge of the newly created opening between the atrium and PAs. Care must be exercised here to assure that the trabecular portion of the atrium contains no leaks. The free, superior edge of the PTFE baffle is then closed in a single sandwich between the two free edges of the right atrium. Thus, the medial aspect of the lateral tunnel is PTFE, whereas the lateral aspect is native right atrial tissue. The heart is infused with saline to de-air and the venous cannula replaced. Cardiopulmonary bypass is reinitiated, and the patient is warmed to 37 °C over 22 min. Atrial lines are brought into the atrium on either side of the baffle through the suture line. The patient is weaned from bypass and undergoes modified ultrafiltration. Inotropic support is rarely necessary.

Each approach, extracardiac and lateral tunnel, has advocates. The extracardiac Fontan described above has the theoretical advantages of anatomic flexibility, avoidance of sinus node manipulation, decreased pressure in the right atrium, and avoidance of cardioplegic arrest. Advantages for the lateral tunnel Fontan may include growth potential, avoidance of a prosthetic conduit with the reduced risk of thromboembolism. Despite each technique's theoretical advantages, there are many series reporting excellent outcomes in for each. Short-term survival after Fontan completion for HLHS is over 95 %, whereas longer-term survival rates are 72–91 % at 10 years.

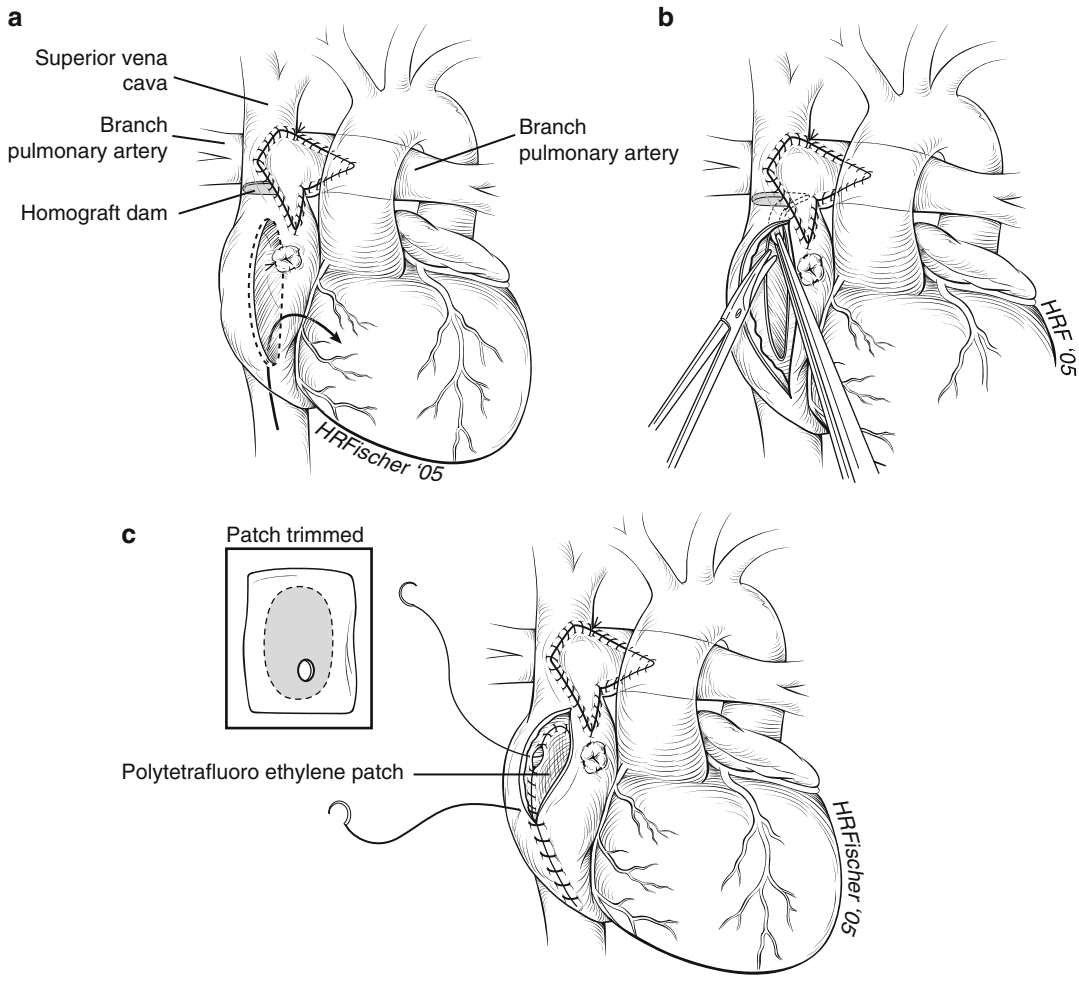

Fig. 102.8 The lateral tunnel Fontan procedure. (**a**) The right atrium is opened in a vertical fashion medial to Waterson's groove. (**b**) The homograft dam is excised, creating an unobstructed opening from right atrium to pulmonary artery. (**c**) A polytetrafluoroethylene (PTFE) baffle is sewn along the posterior rim of the remnant atrial septum, on the medial aspect of the inferior vena cava (IVC), and to the medial aspect of the superior vena cava-pulmonary artery (PA) junction. The free edge of the PTFE dam is sewn in a sandwich to close the right atrium, baffling blood from the IVC to the PA

Surgical Results

Overall, 50–70 % of newborns with HLHS will survive the three surgeries and live to the age of 5. Regardless of intensive individual efforts, national consortiums, and international collaborative efforts and developments, patients with HLHS continue to present formidable challenges. Since its institution in 1984, results from staged reconstruction have improved significantly. This has been the case across multiple institutions, and many centers report excellent outcomes, often exceeding 90 % of hospital survival. Despite some differences of opinion, it appears that the HLHS is not a predictor of mortality compared to stage I palliation for other HLHS variants. However, nonanatomic determinants such as low birth weight, associated cardiac anomalies, longer total support time, and extracorporeal membrane oxygenation (ECMO) or ventricular assist device (VAD) support are predictors of operative

mortality. Additional perioperative or operative treatment strategies may improve morbidity and mortality based upon combinatorial stratification strategies. Home surveillance programs for interstage infants are now common practice in most institutions with significant benefits toward the reduction of interstage mortality.

There has been an intensive study comparing the outcomes of neonates undergoing stage I reconstruction with use of the RV-PA conduit and modified Blalock-Taussig shunt. The use of the RV-PA conduit over the BT shunt was embraced in some centers and rejected in others. However, the PHN-based multi-institutional study of single-ventricle reconstruction supports the notion that local, team-based factors may outweigh shunt type. Regardless, this large PHN cohort has not yet been followed to Fontan completion. As a result, it is premature to conclude a superior approach.

Although promising for certain high-risk populations, catheter-based hybrid approaches are still in an experimental phase. These techniques may be inadvisable in certain anatomic subsets such as aortic atresia in which preductal retrograde coarctation is a significant problem. However, as there is now considerable experience with this technique in many centers, prospectively studying this approach compared to Norwood reconstruction will be important. Data to date suggest possible equivalency.

Postoperative Management

The newborn with HLHS has a higher risk of systemic malperfusion than children with two ventricles. Insufficient cardiac output is common in the first 12 h following neonatal cardiac surgery. The newborn with HLHS has the additional vulnerabilities of reduced total ventricular mass with double the normal cardiac output, along with parallel pulmonary and systemic circuits with resultant desaturation – optimizing oxygen delivery is crucial. Two newer techniques, the use of continuous venous oximetry and near-infrared spectroscopy (NIRS), are becoming more commonly used. Conflicting reports of improved outcomes prevent their uniform application, but there is increased interest in rigorous testing.

In contrast, there is near uniform agreement on the importance of afterload reduction. One technique uses alpha-adrenergic blockade. Drugs such as phenoxybenzamine and phentolamine directly block the systemic vasoconstriction that results from increased endogenous or exogenous catecholamines. Reduction of systemic vascular resistance has been associated with reduced incidence of early circulatory collapse. Another technique uses the phosphodiesterase-3 inhibitor milrinone and its multiple positive effects, including positive inotropy and lusitropy, vasodilatation, with little chronotropic effect. Sedative-analgesic medications can be used in the early postoperative period to reduce metabolic demands. However, most patients who return from the operating room in a stable condition can be extubated by postoperative day 2. Delayed sternal closure is employed selectively, but is not a routine technique. In rare circumstances, ECMO support may be required as rescue therapy for acute cardiovascular collapse or acute shunt obstruction. In a multicenter randomized control trial of infants who had stage I palliation, approximately 75 % had delayed sternal closure, 10 % were placed on ECMO during the postoperative period, and 15 % required cardiopulmonary resuscitation.

Conclusion

Developments in preoperative evaluation, operative techniques, and postoperative management based on rigorous controlled trials and rational application or these results will provide continued progress with this challenging disease. Increasingly, there is recognition that the major determinants of outcome following surgical intervention for HLHS have less to do with intraoperative support strategies than with patient-related factors such as gestational age and associated genetic syndromes. Without the knowledge of discrete etiologies for HLHS, it will be difficult to further stratify patients based upon anatomic factors. An intensive effort is

underway to unravel these causes using large data sets enabled by whole genome sequencing technologies.

Peri-operative and Interstage Considerations for the Hybrid Approach for Hypoplastic Left Heart Syndrome

103

Mark Galantowicz, Andrew Yates, Clifford Cua, Aymen Naguib, Janet Simsic, and John P. Cheatham

Introduction

The quest for improved outcomes, both quantity and quality of life, for our patients with complex congenital heart disease has led to increased use of hybrid procedures. These hybrid procedures are the manifestation of seamless collaboration between disciplines such as congenital heart surgery and pediatric interventional cardiology. However, the true success of these procedures, as well as any procedure for these complex patients, requires the collaboration of multiple disciplines focused on the inpatient and outpatient care of these children overtime through the typical series of cardiac interventions they require. This necessary collaboration is nicely exemplified in the Hybrid Approach for hypoplastic left heart syndrome (HLHS). Here-in our Heart Center group with representation from surgery, interventional cardiology, anesthesiology, intensive care, and cardiology share our current management strategy from birth through both the first and second stage procedures. This strategy has been an evolution with remarkable dedication from the aforementioned disciplines as well as perfusion and nursing. The actual procedural details of the Hybrid Stage 1 and Comprehensive Stage 2 operations are covered elsewhere. This chapter focuses on the perioperative and interstage management which are equally critical to the overall success of this hybrid approach.

Preoperative Management and Timing of the Hybrid Stage 1

Most newborns with ductal-dependent systemic or pulmonary blood flow undergo palliation within the first week of life. Prior to surgical palliation, it is not uncommon for them to suffer from pulmonary over circulation which puts them at risk for impaired systemic perfusion and resultant end-organ dysfunction.

Preoperative management strategies of patients with ductal-dependent systemic or

E.M. da Cruz et al. (eds.), *Pediatric and Congenital Cardiology, Cardiac Surgery and Intensive Care*,
DOI 10.1007/978-1-4471-4619-3_39, © Springer-Verlag London 2014

pulmonary blood flow include (1) maintaining patency of the ductus arteriosus with prostaglandin E1 (PGE_1), (2) minimizing the side effects of PGE_1, and (3) supportive therapy for pulmonary overcirculation and the subsequent reduction in systemic blood flow. Preoperative strategies aimed at balancing pulmonary and systemic circulation have been anecdotal with significant practice variation and lack of abundant evidence to support the various treatment modalities [1, 4]. Stieh et al. retrospectively reviewed the preoperative management strategies of 72 neonates with hypoplastic left heart syndrome and identified use of inotropic medications and mechanical ventilation, and lack of afterload reduction as risk factors for end-organ dysfunction and mortality [2].

Our management strategy begins at the birth hospital and is aimed at minimizing interventions. At the birth hospital after delivery, we do not encourage elective intubation for transport on PGE_1. We prefer intubation only for significant respiratory distress or respiratory failure. If a PGE_1-dependent newborn is admitted to the cardiothoracic intensive care unit (CTICU) intubated, we make every effort to extubate in a timely fashion. Elective preoperative intubation secondary to PGE_1 and transport from birth hospital to tertiary care facility is diminishing in frequency. In fact, preoperative mechanical ventilation has been associated with worsening outcomes in this patient population [2, 3].

Our choice for access obtained at the birth hospital is a double lumen umbilical venous catheter or two peripheral IVs. An umbilical arterial catheter is not necessarily placed unless easily obtained at the birth hospital or clinically indicated. If the newborn is admitted to the CTICU without arterial monitoring and we are able to obtain blood from the venous catheter, we do not electively place an arterial catheter preoperatively. If the newborn is admitted to the CTICU without central venous access, we have a double lumen peripherally inserted central catheter (PICC) placed in interventional radiology.

We recommend a PGE_1 starting dose of 0.025 mcg/kg/min to be started at the birth hospital after access is obtained. Negative effects of PGE_1 may be minimized by using a lower dose. We have not had any significant complications secondary to apnea during transport of the newborn from the birth hospital to the CTICU (usual transport distance is less than 25 miles). For longer transports or if there are concerns for PGE_1-related apnea, we recommend preemptively starting caffeine.

All ductal-dependent patients greater than 35 weeks gestation with congenital heart disease as their primary issue are admitted to the CTICU directly from the birth hospital. A neonatology consult is obtained on all newborns admitted to the CTICU. Our routine admission laboratories and tests include i-stat blood gas, i-stat lactate, electrolytes, complete blood count, liver function tests, neonatal type and cross, chromosome analysis, chest and abdominal radiograph, echocardiogram, electrocardiogram, cranial ultrasound, renal or abdominal ultrasound (for spleen in patients with heterotaxy) as appropriate. A Casmed regional oximeter is placed on the head of all newborns as a noninvasive measure of mixed venous oxygenation. We routinely follow i-stat blood gas and lactate every 4–8 h – frequency determined based on hemodynamics, metabolic acidosis, lactates, cerebral oximetry, and daily electrolytes, liver function, bilirubin, magnesium, and complete blood count. We do not routinely start inotropic support or afterload reduction therapy unless clinically indicated. Furosemide 1 mg/kg IV every 12 h is started after pulmonary vascular resistance falls if the newborn shows signs of pulmonary overcirculation and inadequate urine output.

Preoperative management strategy of balancing pulmonary and systemic blood flow by controlled hypoventilation has been replaced by acceptance of peaceful tachypnea associated with pulmonary overcirculation in the absence of end-organ dysfunction [1, 4]. We do not treat high systemic saturations (>90 %), tachypnea, or elevated pO2 alone as the hemodynamic burden of pulmonary overcirculation is well tolerated in most newborns. Pulmonary overcirculation is treated only if the newborn shows signs of metabolic acidosis (base deficit of −4 mmol/L or less), elevated lactate

(> 2 mmol/L), decreased urine output (< 1 cc/kg/h averaged for 12 h period), or cerebral saturations consistently less than 40 %. Our treatment plan includes afterload reduction with milrinone 0.25–0.5 mcg/kg/min and/or subambient oxygen therapy delivered via noninvasive oxyhood depending on the needs of the newborn. Therapeutic concept of afterload reduction is that lowering the systemic vascular resistance allows for increase in systemic blood flow, thus avoiding active increase in pulmonary blood flow often seen with mechanical ventilation [2]. Systemic afterload reduction has been shown to avoid preoperative mechanical ventilation which has been identified as a risk factor for preoperative end-organ dysfunction and in-hospital mortality [2]. If a newborn requires milrinone or subambient oxygen therapy for systemic low cardiac output secondary to pulmonary overcirculation, we refer for surgery earlier than necessarily planned.

There is much debate regarding the treatment of metabolic acidosis (base deficit >−4 mmol/L) with bicarbonate. Our general belief, not necessarily supported in the literature, is to treat metabolic acidosis with bicarbonate to prevent end-organ compromise while also evaluating and treating the cause of the metabolic acidosis.

All newborns are initially fastening (NPO) on intravenous fluids (D10W) for first 24 h following admission. Initiation of enteral feeds preoperatively varies in the literature; however, there is a paucity of data evaluating the efficacy [1, 4]. Thoughts behind the institution of preoperative enteral nutrition include stimulation of the bowel and potentially an earlier time to reaching full volume enteral feeds by mouth postoperatively. Our strategy is to initiate enteral feeds on hospital day 2, according to our enteral feeding guidelines, if the newborn meets our baseline feeding criteria (lactate <2 mmol/L, base deficit <−4 mmol/L or anion gap <12, arterial pH > 7.35, venous pH > 7.30, not on epinephrine, not on dopamine >5 mcg/kg/min). Our enteral feeding guidelines begin with allowing the newborn to bottle-feed either breast milk or formula of parent's choice for the first 24 h. If the newborn is not able to bottle-feed on the subsequent day, supplemental nasogastric tube feeds are initiated (3 ml/kg every 3 h advancing by 3 ml/kg every 12 h until goal is reached). If baseline feeding criteria for our enteral feeding guidelines are not met, total parental nutrition is started. Baseline feeding criteria must be maintained with enteral feedings or enteral feedings are discontinued.

Our strategy regarding hematocrit is to tolerate lower hematocrits as long as the newborn has adequate systemic and cerebral saturations, and is without metabolic acidosis or elevated lactates. Blackwood et al. prospectively studied the association of hemoglobin and blood transfusions with outcomes in neonates undergoing the Norwood operation and demonstrated that transfusion was not associated with improved outcomes [5]. If the preoperative newborn shows signs of low cardiac output with low hematocrit, we consider transfusion of packed red cells to increase oxygen-carrying capacity with the hopes of minimizing potential end-organ dysfunction. Our management strategy is support by a retrospective study by Kuo et al. [6].

Prophylactic antibiotics are only started if there are maternal indications or concerns for sepsis pending culture results. Maternal indications include inadequately treated maternal Group B *Streptococcus*, maternal fever, rupture of membranes >18 h prior to delivery, amniotic fluid discoloration, and maternal urinary tract infection.

To maintain patient comfort our first choices of therapy are as needed comfort measures, swaddling, and Tylenol. Intermittent benzodiazepines and narcotics are used as second-line therapy, if needed.

In terms of timing of the Hybrid Stage 1, our typical goal is for the baby to have a few days to recover from delivery, have an overview of all other organ systems, initiate enteral feeding, and allow some time for bonding between baby and parents. Our median time from birth to Hybrid Stage 1 is 7 days with a range from day of life 1 to 4 weeks later. If the baby is manifesting significant pulmonary overcirculation with systemic hypo-perfusion despite the interventions discussed, we will proceed to an earlier Hybrid Stage 1 to stabilize the hemodynamics.

Anesthetic Strategies for the Hybrid Stage 1

A complete understanding of the anatomy and the associated physiological consequences are of utmost importance, while caring for a patient with HLHS. It is important to point out that the hemodynamic changes that are associated with the Hybrid Stage 1 procedure as described by our group at Nationwide Children's Hospital (NCH) [7, 8] are different than the hemodynamic changes associated with the traditionally described Norwood procedure. Accordingly, the monitoring, intravenous lines placement, and approach to postoperative extubation should be handled differently from the Norwood procedure.

Typically, patients with the different variants of the HLHS will arrive to the hybrid cardiac catheterization suite or the hybrid operating room on an infusion of prostaglandin E1 (PGE_1). Standard American Society of Anesthesiologist (ASA) monitors are applied including electrocardiogram (ECG), pulse oximetry, and an esophageal temperature probe [8]. The temperature probe is utilized to provide both temperature monitoring and is an important radiographic marker for the ductal (PDA) stent positioning during the procedure. It is preferable to place either invasive (right radial) or noninvasive blood pressure monitoring in the right upper extremity. The right upper extremity's blood pressure would reflect the retrograde aortic pressure, especially in the setting of aortic atresia subtype where there is no antegrade flow through the ascending aorta that supplies the coronary and the carotid arteries. Typically, we do not place a central venous access, except in select group of patients due to clinical needs or difficulty in obtaining a peripheral intravenous access. Placement of a cerebral saturation monitor is advised and has proven to be a good tool in monitoring cerebral perfusion during pediatric cardiac surgery [9, 10].

It is useful to divide the anesthetic approach to the hybrid case into four phases [11]. The first phase involves the anesthetic induction and intubation where a narcotic technique is advised using fentanyl, typically in a dose of 3–5 mcg/kg divided between induction and prior to skin incision and pancuronium in a dose of 0.1–0.2 mg/kg. Anesthesia is maintained with inhalational agents, typically isoflurane. A supplemental analgesic dose of acetaminophen, either as a suppository in a dose of 30–40 mg/kg or as an intravenous dose at 15 mg/kg can be given. Balancing the pulmonary (QP) and systemic (QS) circulations using different ventilation techniques and room air is a basic tenet for caring for unrepaired HLHS patients. The second phase of the procedure includes the time between sternotomy and placement of the branch pulmonary artery bands. From the anesthesia perspective, this is the most hemodynamically unstable period of the entire case. The surgeon typically places a band around the right branch of the pulmonary artery (PA) and then addresses the more anatomically challenging left PA. Placement of the right PA band first allows the surgeon to rapidly tighten the band and mechanically alter the QP/QS ratio in the event that hemodynamic instability is encountered. Typically arrhythmias in the form of supraventricular tachycardia (SVT), due to the proximity of the left PA band placement site to the left atrial appendage, or bradycardia and hypotension as a result of compression to the flow through the PDA while placing the left PA band, may be encountered. These hemodynamic changes typically are brief and self-limited, but might require pharmacological interventions in the form of adenosine for the SVT or epinephrine for the bradycardia/hypotension. Tightening of the PA bands typically results in a rise in the systolic blood pressure (SBP) of about 10 mmHg and a drop in the arterial oxygen saturation of about 10 % [11]. The third phase of the procedure involves the deployment of the ductal stent. A precipitous drop in the right upper extremity's pressure, the cerebral saturation, or the development of ST segment depression on the ECG could be an indication of a possible development of retrograde aortic arch obstruction and is typically addressed by the interventional cardiologist. This is a rare event which occurred in one of 77 patients included in a recent

retrospective review at NCH [11]. Blood transfusion requirement is uncommon since blood loss is typically minimal during the Hybrid Stage 1 procedure.

Finally, the fourth phase of the procedure includes removal of the PA cannula, ensuring hemostasis, chest closure, and preparation for possible extubation and transition of care to the cardiac intensive care unit. We typically prepare for extubation of these patients at the end of the procedure, unless the patient arrived to the hybrid suite already intubated or if significant hemodynamic instability occurred during the case. In a retrospective review of 77 patients who underwent the Hybrid Stage 1 procedure at NCH [11], 17 patients arrived intubated and were left intubated at the end of the procedure. Of the remaining 60 patients, 36 patients (60 %) were extubated at the end of the procedure. No patients required reintubation following extubation; three patients were placed on nasal continuous positive airway pressure for transitional respiratory support.

Postoperative pain management after the Hybrid Stage 1 procedure is typically achieved with fentanyl nurse controlled analgesia (NCA) at a dose of 0.5 mck/kg with a lockout of 10–20 min. We typically do not utilize a basal rate for the NCA. There might be a role of dexmedetomidine in the postoperative sedation/analgesia for these patients. In a recent retrospective review of postoperative pain management of patients who underwent the Hybrid Stage 1 procedure for HLHS at NCH, the fentanyl requirement during the first 48 h was significantly less in the group of patients who received dexmedetomidine when compared to patients who received fentanyl only [12].

Postoperative CTICU Management After a Hybrid Stage 1

Our principles for the postoperative management of a baby undergoing a Hybrid Stage 1 are the same as the preoperative strategies in that the physiology is very similar. In fact the PGE_1 has been substituted by the PDA stent without inherent change in physiology while the branch PA bands improve the balance of systemic to pulmonary perfusion. While this is in the context of a stress response to surgery, this impact is minimal given the typical lack of significant hemodynamic instability during the procedure, minimal if any blood loss, no use of cardiopulmonary bypass, and overall minimal tissue handling. The majority of our patients, following hybrid palliation, return to the CTICU breathing spontaneously with peaceful tachypnea. In some instances, the systemic saturations are still elevated (high 1980s−low 1990s); however, we do not treat high systemic saturations, tachypnea, or elevated pO_2 associated with pulmonary overcirculation in the absence of end-organ dysfunction, since the hemodynamic burden of pulmonary overcirculation is well tolerated in most newborns. We monitor for signs of metabolic acidosis (base deficit of −4 mmol/L or less), elevated lactate (>2 mmol/L), decreased urine output (<1 cc/kg/h averaged for 12 h period), or cerebral saturations consistently less than 40 %. Our treatment plan if metabolic acidosis is present includes afterload reduction with milrinone 0.25–0.5 mcg/kg/min. Therapeutic concept of afterload reduction is that lowering the systemic vascular resistance allows for increase in systemic blood flow, thus avoiding active increase in pulmonary blood flow often seen with mechanical ventilation. Respiratory acidosis and in some cases continued metabolic acidosis in spite of milrinone therapy is treated with noninvasive respiratory support including high flow nasal cannula, nasal CPAP, or BiPAP, as needed.

All patients post hybrid palliation are initially NPO on intravenous fluids or total parenteral nutrition (TPN) until postoperative day 1. Our strategy is to initiate enteral feeds on postoperative day 1, according to our enteral feeding guidelines, if the newborn meets our baseline feeding criteria (lactate <2 mmol/L, base deficit <−4 mmol/L or anion gap <12, arterial pH > 7.35, venous pH > 7.30, not on epinephrine, not on dopamine >5 mcg/kg/min). Our enteral feeding guidelines begin with allowing the newborn to bottle-feed either breast milk or formula of parent's choice for the first 24 h. If the newborn

is not able to bottle-feed on the subsequent day, supplemental nasogastric tube feeds are initiated (3 ml/kg every 3 h advancing by 3 ml/kg every 12 h until goal is reached). If baseline feeding criteria for our enteral feeding guidelines are not met, total parental nutrition is started. Baseline feeding criteria must be maintained with enteral feedings or enteral feedings are discontinued.

As for the preoperative phase, our strategy regarding hematocrit is to tolerate lower hematocrits as long as the newborn has adequate systemic and cerebral saturations, and is without metabolic acidosis or elevated lactates.

Interstage Management Between Hybrid 1 and Comprehensive Stage 2

Close follow-up of patients who have undergone the hybrid procedure during the interstage period is crucial for optimal outcomes. Morbidity and mortality during this time period, encompassing the interval from hospital discharge after the hybrid procedure to just prior to the Comprehensive Stage 2 procedure, may occur. The incidence of unexpected hospitalizations, catheterizations, and deaths during this time period appear to be similar to patients undergoing more traditional forms of palliation for hypoplastic left heart syndrome (HLHS) [13–18]. Clinical exam and history, ECG results, echocardiographic findings, and the judicial use of cardiac catheterization are the main tools used to monitor these patients to maximize outcomes.

Outpatient Visits

The routine practice at our institution has been to evaluate these patients every 2 weeks in clinic if there are no specific concerns that have arisen. If there are concerns present, which will be discussed later, then clinic visits are more frequent and at the discretion of the primary cardiologist. Decisions to intervene, either via catheterization or surgically, are made on a case-by-case basis after discussion has occurred between the primary cardiologist, the interventionalist, and the surgeon.

At each clinic visit, vitals measured include heart rate, oxygen saturation, weight, and a right upper and lower extremity blood pressure. Interval history and physical exam are also obtained. Heart rate should be within the normal range for age. Heart rates that are bradycardic or tachycardic should be worked up to find an underlying etiology so that it may be corrected. Causes for an abnormal heart rate may be due to common general pediatric issues such as an intercurrent illness, but cardiac issues such as a retro-aortic arch obstruction (RAAO), causing ischemia, must be ruled out.

Oxygen saturations are usually high during the first few clinic visits as the pulmonary artery bands are relatively “loose” and it is not that uncommon to document saturations in the low 90 % range. As the infant grows, the oxygen saturations should gradually decrease as the bands become more restrictive in nature. One cardiac etiology for saturations remaining high may be a band that has become loose due to dehiscence. Conversely, a pulmonary artery band that has migrated and obstructed a branch pulmonary artery could be a cause for unexpected desaturations. These are relatively rare occurrences in our experience, but should be evaluated either echocardiographically or via catheterization if concerns arise [7]. Another reason for excessive desaturations could be increasing restriction at the atrial septum. The occurrence of restriction at the atrial level during the interstage period has significantly decreased since delaying the timing of the balloon atrial septostomy during the initial hospitalization [7, 8, 19]. Progressive pulmonary vein stenosis is another cause of desaturations in this patient population and, though rare, carries a poor overall prognosis. There are no pathognomonic oxygen saturations for increasing stenosis in the PDA stent or retro-aortic arch, but this area must be carefully evaluated if all other reasons for abnormal saturations are ruled out.

Weight gain is carefully monitored during this time period and calories are maximized as

tolerated. The preference is for oral feeding, but if this is not possible, then placing a gastrostomy tube to supplement caloric intake is performed. Similar to other patients with HLHS undergoing more traditional palliative surgeries, patients undergoing the hybrid procedure are at risk for necrotizing enterocolitis (NEC) [20–22]. However, the incidence of NEC appears to occur during the initial hospitalization and not during the interstage period.

Discrepancies in right upper and lower blood pressure measurements are concerning for a RAAO. In general, a 10–15 mmHg gradient, with the lower extremity blood pressure being higher is not unusual, but gradients $\geq$20 mmHg should prompt close inspection of the retro-aortic arch. This "reverse coarctation" due to a RAAO needs to be ruled out, especially in patients whose only systemic cardiac output is supplied via the ductus arteriosus, since the retro-aortic arch is the only source of coronary blood flow. In patients where there is antegrade flow in the ascending aorta, this "reverse coarctation" phenomenon may not be as appreciable and may not be as concerning [16].

Interval history focuses on overall well-being of the patient. Similar to other children with congenital heart disease, increase work of breathing, decrease enteral intake, intolerance of enteral intake, and poor weight gain are all worrisome indicators. Findings on physical exam that are also concerning include increasing congestion on the lung exam, tachypnea/retractions, decreased palpable right upper extremity pulses compared to lower extremity pulses, and hepatomegaly. All these findings should elicit a complete workup for possible cardiac etiologies.

Similar to other hospitals, a home monitoring program has been established at our institution for patients with single ventricle physiology during this time period [23, 24]. A small number of specially trained cardiac nurses are at the core of our home monitoring program. They make contact with the patient's family at least weekly. Daily weights, oxygen saturation, and enteral intake are documented by the caregivers. Specific criteria are relayed to the caregivers and they are told to contact the cardiac nurses if the patient breaches these criteria (Table 103.1). If the caregiver has any other concerns, they are also encouraged to notify cardiology. A follow-up appointment is subsequently made and a workup is performed to determine the cause of the breach. In addition, this program has added a dietician to aid in maximizing weight gain during this time period. Initial review of our data has shown that this program has significantly improved weight gain during this time period, but has not necessarily decreased interstage mortality. More data will be needed to determine the overall impact of home monitoring on patients undergoing the hybrid procedure during the interstage period.

Table 103.1 Home monitoring breach criteria

Weight gain less than 0.01–0.02 kg over 3 days
Goal of 0.01 kg weight gain per day
Formula intake less than 100 ml/kg/day
Loss of 0.03 kg or more over a 3 day span
Oxygen saturation less than 75 %

ECG

ECGs are performed at each clinic visit and anytime the patient has been admitted to the hospital. Sinus rhythm, atrial enlargement, and ventricular hypertrophy are the usual findings on the ECG. ST segments are the most important aspect to evaluate on the ECG for these patients. Any change in ST segments, either depression or elevation indicative of ischemia (Figs. 103.1, 103.2, and 103.3), should warrant a thorough evaluation to rule out RAAO. These changes may be one of the earliest findings to indicate an underlying cardiac issue. The evaluation can be done echocardiographically, but there should be an extremely low threshold to proceed to cardiac catheterization if clinical suspicion is high even if the echocardiogram is read as "normal" since this area may be difficult to visualize echocardiographically. ST segments should return to baseline once the RAAO, if present, is relieved.

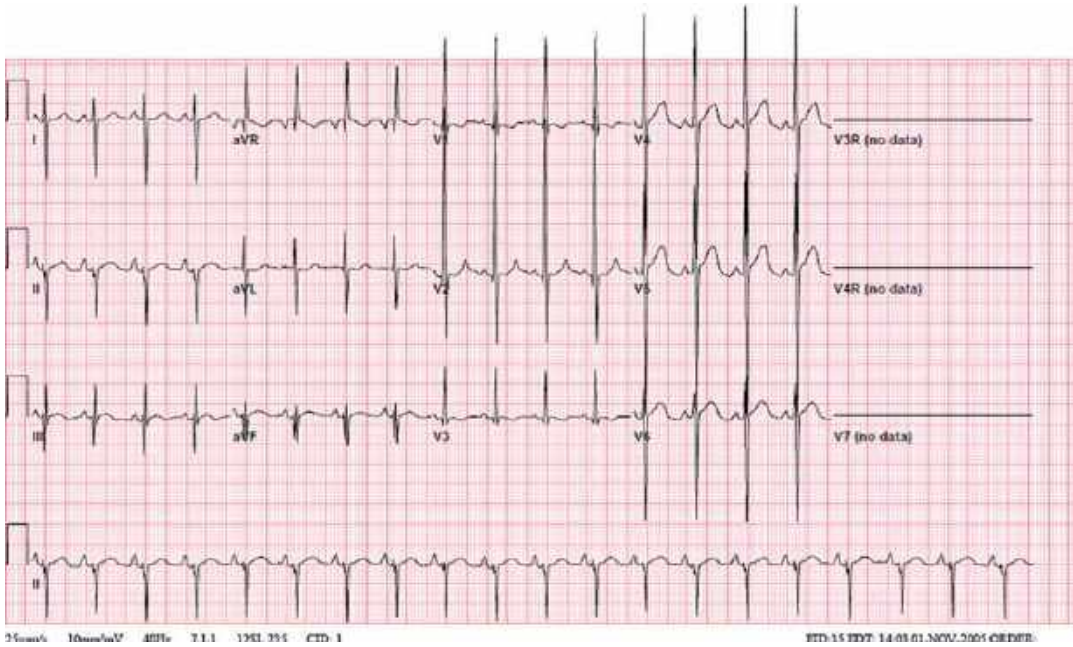

Fig. 103.3 ECG performed after stent placed in the retro-aortic arch due to stenosis. ST segment and T waves back to baseline

Echocardiogram

A complete echocardiogram is performed at each clinic visit and anytime the patient has been admitted to the hospital. Specifically, the atrial septal, pulmonary artery band, PDA stent, and retro-aortic arch gradients are always measured. Overall function and atrioventricular valve regurgitation are also noted. The echocardiogram is the main imaging modality used for these patients as a screening tool to determine if further procedures are needed.

The atrial septal mean gradient is usually best obtained in the subcostal view (Fig. 103.4). A mean gradient $\geq$ 8 mmHg has been used as an indication for a repeat balloon atrial septostomy at our institution. As stated above, the need for repeat septostomies during the interstage period has decreased since changing the timing of the initial septostomy [7, 8, 19]. A mean atrial gradient $\geq$4.9 mmHg on the post-hybrid hospital discharge echocardiogram was associated with an interstage intervention [25].

The pulmonary artery band gradients are best measured in a high parasternal short axis

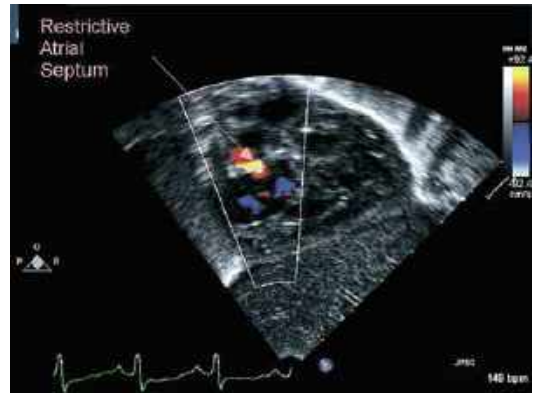

Fig. 103.4 Subcostal view of the atrial septum with color flow analysis

view (Fig. 103.5). These gradients gradually increase over time in a predictable manner and have a distinct waveform with continuous forward flow [25]. If these gradients do not increase, then dehiscence of the pulmonary artery band or distal obstruction/increased pulmonary vascular resistance should be ruled out. If there is a decrease of diastolic forward flow, either bilaterally or unilaterally, then

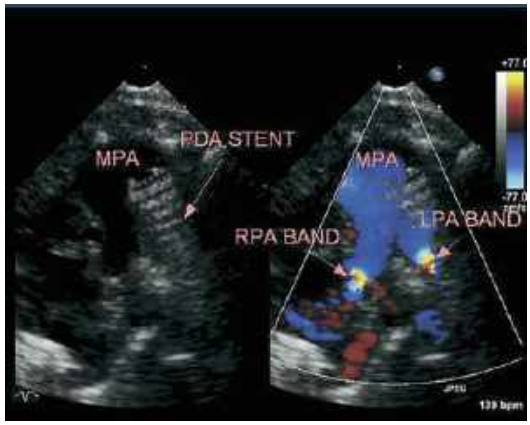

Fig. 103.5 High parasternal short axis view with color flow analysis evaluating ductal stent and branch pulmonary arteries. *LPA* = left pulmonary artery, *MPA* = main pulmonary artery, *RPA* = right pulmonary artery

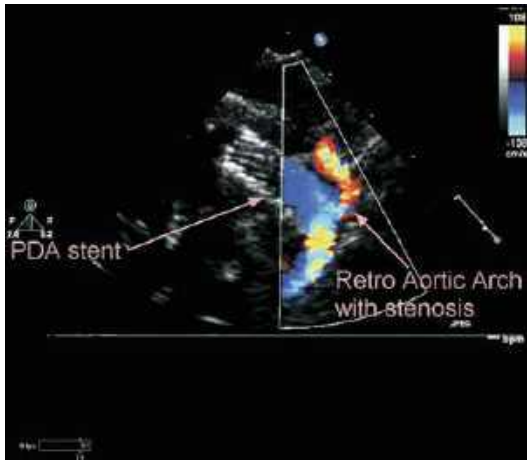

Fig. 103.6 High parasternal ductal view evaluating ductal stent and retro-aortic arch anatomy

downstream obstruction must also be ruled out and corrected as needed. This obstruction is usually at the atrial level, but could also occur at the pulmonary venous or arterial level.

The PDA stent gradient is best seen in the high parasternal short axis or ductal view (Figs. 103.5 and 103.6). These gradients also tend to increase over time as fibrin deposition, inflammation, chronic inflammation, and vascular smooth muscle cell proliferation occur in and around the stent [25, 26]. A peak PDA velocity of 1.7 m/s on the post-hybrid hospital discharge echocardiogram was also associated with an interstage intervention [25]. In general, velocities in the 2.5 m/s range are not uncommon, but velocities $\geq$3 m/s with other concerning signs or symptoms in the patient warrant further workup such as a cardiac catheterization for diagnostic and possibly interventional purposes.

The retro-aortic arch is also best seen in the high parasternal ductal view (Fig. 103.6). This area is of critical importance to image since most if not all the systemic cardiac output and coronary perfusion is supplied via this pathway. These velocities gradually increase over time, similar to the PDA velocities [25]. Velocities in the 2.5 m/s range are within reason. Echocardiographic findings of a smaller aortic root size and higher retro-aortic arch velocity pre-hybrid procedure and increased rate of change in retro-aortic velocities over time all predicted RAAO [15]. In addition, a diagnosis of aortic atresia was associated with increased risk for RAAO [16]. Though imaging of this area is feasible and for the most part readily obtainable, a "normal" velocity in the setting of other concerning findings should still trigger further workup since the echocardiogram is not a 100 % sensitive in ruling out a RAAO.

Currently, right ventricular function and tricuspid regurgitation is qualitatively graded during this time period. Patients that had an interstage intervention had significantly worse right ventricular function and tricuspid regurgitation versus those that did not need an interstage intervention; however, echocardiographic findings were not useful in predicting major morbidity or mortality in relation to the Comprehensive Stage 2 procedure [25, 27]. Newer echocardiographic techniques such as tissue Doppler imaging and strain analysis to monitor interstage ventricular function changes have not been used in this patient population. Limited reports have shown quantitative changes using these techniques in patients undergoing more traditional HLHS palliative surgeries during this time period, but only

future research will determine if these techniques will be useful in guiding care for patients undergoing the hybrid procedure [28, 29].

Catheterization

The use of cardiac catheterization during the interstage period for these patients has evolved at our institution. During our early experience, catheterizations were normally performed on all patients just prior to their Comprehensive Stage 2 procedure; however, we no longer routinely perform catheterizations unless there are specific concerns as discussed above [7, 8]. There were a few reasons for this change. The catheterization data did not appear to add additional information that was pertinent for the Comprehensive Stage 2 procedure that could not be obtained via other noninvasive imaging modalities. Since the catheterization data did not appear to be essential, limiting radiation and contrast exposure to the patients was advantageous. In addition, since these patients would likely have their vessels instrumented multiple times in the future, it was felt that minimizing procedures would thus be beneficial.

The incidence of interstage interventions for this population appears to be in the 25–30 % range [7, 15, 16]. Various interventions are performed, but the majority of interventions pertain to the ductal stent or retro-aortic arch. Even though catheterizations are no longer routinely performed, there should be an extremely low threshold for this procedure for diagnostic and possible interventional procedures if there are any concerning clinical, ECG, or echocardiographic findings. Stenosis is usually relieved via balloon angioplasty or stent placement as discussed elsewhere. A reverse modified Blalock-Taussig shunt is not performed at our institution because results have been better with catheter interventions [7, 30].

In summary, the interstage period is a critical time for patients who underwent the hybrid procedure. Any patient that is not progressing as expected should have a thorough workup to rule out a cardiac etiology and there should be a low threshold for a cardiac catheterization. Abnormalities in the ductal stent and retro-aortic arch are the major issues that need to be evaluated if concerns arise. Future studies are needed to determine if stenosis in these two areas can be minimized. The effect of a regimented home monitoring program on these patients will need to be determined, but as more experience accrues, morbidity and mortality should improve for this complicated patient population during this time period.

Timing and Preoperative Considerations for the Comprehensive Stage 2

The timing of the Comprehensive Stage 2 procedure is similar to the general strategy for a bidirectional Glenn procedure in that the pulmonary vasculature is typically of low enough resistance to accept passive venous flow at around 6 months of age. Early in our experience, we routinely performed a preoperative catheterization; however, with experience, we have found that the Hybrid Stage 1 procedure yields a reliable, reproducible anatomy and physiology favorable for a Comprehensive Stage 2. Therefore, we no longer routinely obtain a preoperative catheterization. This is reserved for rare patients with concerns based on history, exam, or echocardiography. Moreover, preoperative advanced imaging with MRI or CT scans has not been routinely used.

Anesthetic Strategies for the Comprehensive Stage 2

Preoperative Evaluation

Although the physiology of patients presenting for Comprehensive Stage 2 procedure is different from those presenting for the classic Glenn procedure following the traditional Norwood

procedure, the goals of restricting the pulmonary blood flow and maintaining the systemic blood flow are the same.

When addressing these patients preoperatively, it is essential to have a complete understanding of the underlying lesion, if it is an aortic atresia subtype, where there is no antegrade flow through the ascending aorta and the coronary and cerebral blood flow is dependant solely on the retrograde aortic arch flow through the ductal stents [7, 8]. The presence of any ductal stent stenosis or retrograde arch obstruction will present in these patients with a possible single ventricle systolic and/or diastolic dysfunction, in addition to atrioventricular valve regurgitation [25, 27]. A special attention should be observed while inducing these patients, as the myocardial dysfunction could be exacerbated with the use of inhalational induction by itself or due to the possible drop in the systemic vascular resistance with a further drop in the already decreased coronary blood flow through the retrograde arch with the possible myocardial depression or cardiac arrest.

Another preoperative issue that has to be evaluated is the possible variability in the pulmonary blood flow, depending on the tightness of the branch pulmonary artery bands [31, 32]. Loose bands, as evidenced by preoperative echocardiography or the rare pre-Comprehensive Stage 2 catheterization data, should be considered during the induction and prebypass period. Exposing these patients to higher oxygen concentration would lead to higher QP: QS ratio with the resulting volume overloading of the single ventricle and possible decrease in systemic blood flow. On the contrary, a tight band could indicate the need for increasing the inspired oxygen requirements.

Intraoperative Anesthetic management

The main goals of monitoring, induction, and maintenance of anesthesia should be directed toward three specific goals. First, induction and monitoring should be tailored to the specific underlying lesion and patient's clinical status. Patients with good ventricular function and no atrioventricular valve regurgitation should tolerate inhalational induction with sevoflurane. We try to avoid placing central lines in these patients if we have two good peripheral intravenous lines. Our goal is to save the jugular and femoral veins for the many possible interventions later on. In addition, we place an arterial line, cerebral saturation monitor, and the standard American society of anesthesia monitors such as electrocardiogram (ECG), pulse oximetry (SPO_2), nasal and core temperature probes. Tracheal intubation is facilitated by using muscle relaxants such as pancuronium at 0.2–0.3 mg/kg.

Second, our anesthetic technique is tailored toward the goal of tracheal extubation at the end of the surgery, and it consists of a combination of narcotics (usually fentanyl at a dose between 12 and 15 mcg/kg) and inhalational agents (isoflurane). We also use dexmedetomidine as an adjunct at a loading dose of 1 mcg/kg over 10 min and then a continuous infusion at 0.5 mcg/kg/hr. In a recent review at our institution, out of 36 patients who underwent Comprehensive Stage 2, twelve patients received dexmedetomidine in addition to an average dose of 11.24 mcg/kg of fentanyl. A recent prospective, randomized, and blinded study that was done at our institution showed that the combination of dexmedetomidine and fentanyl at a dose of 10 mcg/kg was sufficient to significantly blunt some of the stress response markers, including glucose, lactate, norepinephrine, when compared to fentanyl only. The continued use of dexmedetomidine in the postoperative period in patients after Comprehensive Stage 2 was associated with a significant reduction in the total narcotic requirements.

Our third goal in managing these patients is minimizing blood transfusion and assuring hemostasis due to the extensive suture lines in the aorta. Our protocol is to start with platelets and cryoprecipitate. Cryoprecipitate is preferable to fresh frozen plasma due to the ability to restore the fibrinogen levels with less volume. If bleeding continues after two rounds of platelets and cryoprecipitate, we start fresh frozen plasma. In the Jehovah's Witness population, we try to perform acute normovolemic hemodilution (ANH),

with a goal of removing 15–20 ml/kg of whole blood as tolerated prior to incision. After separation from CPB and reversal of heparin, in this group of patients, we give back this autologous whole blood with 90 mcg/kg of recombinant factor VIIa. In a recent review of this practice, the early administration of factor VIIa in these patients was associated with marked reduction in the blood and blood products requirements during the perioperative period. This was not associated with increased incidence of thrombosis or strokes in these patients.

Postoperative Pain Management

This unique subgroup of patients presents a particular challenge to optimal pain control due to the extensive nature of the surgery, the young age of the patients, and the goal of early tracheal extubation. In a recent retrospective review at our institution of 36 patients who underwent Comprehensive Stage 2 procedure, extubation in the OR occurred in 10 patients, and a total of 17 patients were extubated within the first 24 h postoperatively. Fentanyl was the primary agent that was used in this cohort of patients, where 34 of 36 patients were started on fentanyl NCA (Nurse Controlled Anesthesia). A change to either morphine or hydromorphone was deemed necessary due to inadequate sedation or pain management in 6 of the 36 patients (17 %) following Comprehensive Stage 2. There are potential applications of adjuvant medications such as dexmedetomidine, acetaminophen, or nonsteroidal anti-inflammatory agents in improving analgesia and decreasing opioid requirements.

Postoperative CTICU Management After a Comprehensive Stage 2

Many of the postoperative management principles for cavopulmonary anastomosis apply to patients after Comprehensive Stage 2. Patient goals of early extubation to minimize intrathoracic pressure, elevation, and midline head positioning to promote pulmonary blood flow still apply. However, a longer cardiopulmonary bypass time (mean 291 min with a mean cross clamp time of 85 min) yields additional considerations for care [7].

Bleeding and Hemostasis

Bleeding and hemostasis are one of the initial goals of the perioperative period. We have performed a Comprehensive Stage 2 procedure on several occasions without the use of blood products. However, replacement of coagulation factors, fibrinogen, and platelet supplementation are frequently employed. In addition, if a sufficient blood product volume has been administered without achieving hemostasis, we will use activated factor VII [33].

Diastolic Dysfunction

All cavopulmonary shunts result in volume unloading of the single ventricle with preserved ventricular mass. This alone essentially results in reduced preload on a stiff ventricle resulting in diastolic dysfunction. Additionally, a long bypass and a period of cross-clamping can further impair diastolic performance. Our current practice is to use milrinone in all Comprehensive Stage 2 patients in an effort to improve diastolic function, systolic function, and minimize changes in pulmonary vascular resistance associated with cardiopulmonary bypass. Fluid resuscitation during the immediate postoperative period is done in a judicious manner to minimize edema formation from third spacing while promoting sufficient preload and cardiac output.

Fluid Balance Management

Initial fluid management begins with limiting input and maintenance fluids to approximately ½ maintenance. During the initial postoperative period, efforts are made to minimize additional fluid resuscitation and diuresis is augmented at approximately 6 h post-op with scheduled diuretics. Electrolytes are supplemented as

needed to prevent hypokalemia and hypocalcemia. Negative fluid balance is the goal by 24–36 h postoperatively at the latest.

Pleural effusions are aggressively managed with drainage in intubated patients with a goal of maximizing cavopulmonary flow and pulmonary mechanics in an effort to promote extubation. In those patients with effusions who are extubated, we attempt to diurese more aggressively prior to placement of additional infectious sources.

Ventilator Management

Early extubation once hemostasis is obtained with stable hemodynamics is highly encouraged. Nearly 50 % of our Comprehensive Stage 2 patients are extubated in the operating room with 86 % extubated by 24 h postoperatively [7]. Our large experience with this population has demonstrated that an inability to extubate patients within 72 h is suggestive of a residual anatomic lesion or major underlying pulmonary pathology that needs to be thoroughly evaluated and aggressively managed. Our initial evaluation is with bedside echocardiography to look at systolic function, tricuspid regurgitation, arch repair, atrial level shunt, pulmonary venous flow, and cavopulmonary shunt flow. Given limitations in imaging SVC and PA flow in a low pressure system, we have a low threshold for advanced radiographic imaging with CT or MRI, as well as for invasive imaging studies in the interventional catheterization laboratory.

In those patients that are intubated, we attempt to minimize mean airway pressures with volume ventilation and physiologic PEEP and allow for permissive hypercapnia to promote additional cavopulmonary flow and improve hemodynamics [34]. Respirator settings are titrated to promote ventilation at functional residual capacity (FRC) allowing for the lowest pulmonary vascular resistance. We are aggressive about extubation to allow for negative intrathoracic pressures to further promote cavopulmonary flow and, on rare occasions, have utilized negative pressure ventilation in an effort to extubate from positive pressure respiratory support [35].

Hypoxia

There is frequently a greater degree of pulmonary venous desaturation in comprehensive stage patients, compared to patients with a superior cavopulmonary shunt procedure alone, secondary to pulmonary inflammation and interstitial edema. Thus, we will tolerate saturations as low as the mid 1960s until adequate diuresis and extubation has been accomplished. Our current practice employs completion angiography, and thus, residual anatomic or surgical impediments to pulmonary blood flow have already been addressed prior to leaving the operating room [36]. Once negative intrathoracic pressures have been achieved and edema has improved, saturations rise to those typical of other patients with a superior cavopulmonary shunt.

Patients with undue hypoxia in the initial postoperative period are frequently trialed on inhaled nitric oxide for presumed elevated pulmonary vascular resistances, and if deemed, a responder is maintained for ~24 h prior to starting adjunctive pulmonary vasodilators, such as sildenafil. iNO nonresponders are quickly weaned off iNO and additional reasons for hypoxia are further explored.

For patients with persistent hypoxia which is unexplained by parenchymal lung disease, effusions, or other rational explanation, we pursue catheterization to look for veno-venous decompressing veins, competitive collateral flow, obstruction to cavopulmonary flow, in addition to direct measures of pulmonary vascular resistances. Anatomic lesions are addressed in the catheterization laboratory if possible and the hemodynamic measurements are used to maximize medical therapies targeted at the source of the complication.

Anticoagulation

The Comprehensive Stage 2 procedure results in endothelial disruption, establishment of a low flow cavopulmonary shunt, and alteration of coagulation homeostasis from cardiopulmonary

bypass surgery, which together may be a setup for thrombotic complications. Our center has experienced several postoperative complications due to thrombosis in the newly established cavopulmonary connection. Thus, there may be a benefit from anticoagulation after hemostasis has been adequately obtained. Currently, our patients are started on a heparin infusion at 24 h postoperatively, or 12 h after hemostasis has been obtained, whichever occurs latest. We maintain activated partial thromboplastin times (APTTs) in the 60–80 range and transition to enoxaparin sodium once invasive lines have been removed. In those patients requiring aggressive diuresis during heparin anticoagulation, close monitoring of APTT levels is warranted to prevent fluctuations in anticoagulation. We continue enoxaparin injections for 6 weeks when endothelial recovery from surgery has occurred and the theoretical risk of thrombosis is decreased, at which point patients are transitioned to aspirin therapy.

As discussed, many of the postoperative management strategies and principles are similar to patients who undergo a superior cavopulmonary anastomosis with a few additional considerations. Defining specific risk factors for Comprehensive Stage 2 patients is still being explored within our center and we have not established preoperative echocardiographic markers that are helpful in predicting morbidity or mortality in this patient population [27]. Further refinement of postoperative care offers possibilities of further improving outcomes in this patient population.

Conclusion

The keys to success to the perioperative management with the Hybrid approach for hypoplastic left heart syndrome start with close collaboration and communication among a multidisciplinary team, focused on the unique anatomy and physiology manifest with these palliations. After the Hybrid Stage 1, home monitoring and frequent echocardiographic imaging have been critical to the early identification of patients that need further assessment and treatment in the catheterization laboratory, to maintain optimal hemodynamics. After the Comprehensive Stage 2, a completion angiogram with a low threshold to intervene on any suboptimal pulmonary blood flow coupled with full postoperative anticoagulation for 6 weeks, have eliminated the main source of morbidity and mortality in these patients. With these lessons learned, most patients can be successfully brought forward for a low risk Fontan completion.

104 Orthotopic Heart Transplantation as an Alternative Treatment Strategy for Hypoplastic Left Heart Syndrome

Scott R. Auerbach, David N. Campbell, and Shelley D. Miyamoto

Abstract

Heart transplantation as a primary therapy for infants with hypoplastic left heart syndrome (HLHS) has decreased in frequency over the last two decades as outcomes of surgical palliation have improved. However, waitlist mortality has decreased, and transplantation remains a viable option for some infants with HLHS, especially those at highest risk of poor outcomes following surgical palliation. Pre-transplant management is complicated by the need to maintain ductal patency while balancing systemic and pulmonary blood flow, which leads to prolonged exposure of the pulmonary vasculature to high pulmonary artery pressure and resistance. Primary graft failure and pulmonary hypertension, with or without isolated right ventricular failure, are most likely to complicate the postoperative period. Given small patient size and a higher risk of complications with frequent biopsies, rejection surveillance in this population is usually noninvasive. Immunosuppression can be minimized due to a more plastic

immune system, with many infant heart transplant recipients on a single-drug maintenance immunosuppression regimen for the long term. During the most recent era, overall survival from the time of listing is 60 % at 5 years. Infants that make it to transplant have the best graft survival of all age groups, with a median graft survival of 18 years.

Introduction

The first successful heart transplant in a 4-year-old boy at Columbia University in 1984 offered infants and children with end-stage heart failure or congenital heart disease a therapeutic option beyond comfort care. Pioneering work at Loma Linda University showed that infant transplantation was a therapeutic option that provided excellent outcomes in this population. However, the limited supply of infant donors led to significant waitlist mortality. Concomitantly, surgical outcomes for HLHS improved, causing the number of institutions offering primary transplantation as treatment for HLHS to decrease. Studies directly comparing outcomes of listing for transplantation and surgical palliation in HLHS are lacking, limiting the ability to properly compare the strategies. While there is likely a population of patients with HLHS that would benefit more from transplantation than surgical palliation, identifying those patients prior to surgical palliation has proven daunting.

Brief Historical Background

Prior to the late 1970s, the only treatment option for newborns with hypoplastic left heart syndrome (HLHS) was comfort care. Primary cardiac transplantation and staged palliation in infancy as primary treatment options for HLHS increased in use during the 1980s [1–5]. While posttransplant survival was acceptable, overall waitlist mortality has been shown to be as high as 25 % [6]. As the results of staged surgical palliation improved and donor availability remained a challenge, the majority of infants with HLHS now undergo surgical palliation rather than transplantation; primary transplantation as a treatment strategy is now rare [4, 7–11]. Early data comparing the two strategies showed that 5-year survival was better with primary transplantation, with most of the mortality in both groups having occurred within the first year of life [12]. Mortality associated with transplantation was largely while awaiting transplant, while deaths after stage I palliation were largely related to the perioperative period. Decision-making analysis suggested that the decision to proceed with either strategy should depend on the local organ availability, surgical mortality rates of the center, and patient risk factors [13]. Currently, most centers consider only patients at highest risk for death at the time of the Norwood procedure to be listed for primary transplantation. Multiple single center reports of short-term and interstage outcomes of surgical palliation are available. However, there is a dearth of long-term studies that evaluate survival from birth through all stages of palliation, and, therefore, overall survival through all

stages of palliation can only be estimated [9, 10, 14–17]. By contrast, outcomes of infants with HLHS following listing and through transplantation have been studied in great detail by the Pediatric Heart Transplant Study Group, and recent 5-year survival following listing for transplantation in infants with HLHS was found to be nearly 60 % [6, 18]. Considering the overall 1-year survival of 68 % for all infants undergoing the Norwood procedure in the Pediatric Heart Network's Single Ventricle Reconstruction Trial, it is very likely that 5-year survival of staged palliation will be, at best, no different than the 5-year survival of children with HLHS listed for primary transplantation [19].

Decision Making

The decision to list a patient for transplantation, perform surgical palliation, or provide comfort care is typically made by the patient's pediatric cardiologist, the pediatric cardiac surgeon, and the patient's family. The role of comfort care in the current management landscape is controversial, and opinions vary by physician and institution [9, 20]. However, most believe that comfort care should remain in the discussion, as most families are unable to comprehend the potential emotional and financial toll the long-term care of an infant with HLHS may take on their families. Ideally, counseling should allow an equal amount of time for discussion of palliation, transplantation, and comfort care while avoiding over emphasis of any particular option. However, the strengths and weaknesses of an individual center should be taken into account. Care should be taken to describe the potential time commitment and financial and emotional impact each decision may have on the family. Prior to counseling, risk factor assessment should take place to determine if one particular option may be better for a specific patient. Ventricular dysfunction prior to palliation has been shown to be associated with poor outcomes 18 months following stage I palliation [14]. Historically, risk factors for poor outcomes following stage I palliation included obstructed pulmonary venous return (including both an intact and a highly restrictive atrial septum), aortic atresia, right atrioventricular valve regurgitation, prematurity, extracardiac anomalies, and genetic syndromes (especially Turner's syndrome) [12, 17, 21–26]. Intermediate-term follow-up of the Single Ventricle Reconstruction Trial (mean follow-up time 2.7 $\pm$ 0.9 years) confirmed that many of these characteristics are risk factors for death or transplantation following stage I palliation, including obstructed pulmonary venous return, a lower right ventricular fractional area of change, a genetic syndrome, lower socioeconomic status, non-HLHS diagnosis, lower gestational age, and pre-Norwood surgery [17]. Consideration should be given to these data when determining a treatment strategy for an individual patient. Long-term follow-up of these data is still needed and will hopefully help determine which infants have characteristics prior to stage I palliation that result in a high likelihood of death or transplantation following staged palliation. In addition to Norwood outcomes, waitlist times and posttransplant outcomes specific to each center should be taken into consideration as well [13, 26].

Fetal echocardiography has made it possible to diagnose HLHS in utero, allowing families and physicians to decide to choose transplantation as the primary treatment strategy for HLHS prior to birth. Identification of risk factors for poor outcome following palliative surgery, such as ventricular dysfunction or atrioventricular valve regurgitation, may aid in the decision-making process.

The pre-transplant evaluation is discussed in detail elsewhere in this text. However, when transplantation is considered in a neonate, special attention must be paid to the evaluation for other congenital anomalies, especially those related to central nervous system, lungs, and kidneys. Evaluation by a geneticist should be considered for any clinical suspicion for a genetic syndrome or metabolic abnormality, while hypotonia necessitates further evaluation by a neuromuscular specialist. Contraindications to transplantation are addressed in the section dedicated to heart transplant. In general, the presence of a noncardiac

condition that limits the lifespan of the recipient compared to that of the transplanted heart is a contraindication to transplantation. The contraindication most likely to be encountered in this population is end-organ dysfunction related to difficulty in balancing systemic and pulmonary blood flow.

Waitlist Mortality

Waitlist mortality has decreased by two-thirds over the last 20 years for all pediatric heart transplant candidates; however, it is still a significant problem due to the scarce donor supply [27]. During the era of 1993–1999, waitlist mortality for infants in the PHTS database with HLHS was 27 %. However, during the era of 2000–2006, there was a reduction in waitlist mortality to 16 % at 6-month post-listing, while 82 % had been transplanted, and only 2 % were still awaiting transplant [18]. Despite improvements in waitlist mortality, methods to decrease waiting time and increase organ availability are needed. Recently, ABO incompatible transplantation, fetal listing, and utilization of organs from donors after cardiac death have shown promise as methods of decreasing time on the waiting list.

ABO incompatible heart transplantation is generally contraindicated in children and adults due to the risk of hyperacute rejection caused by preformed anti-A or anti-B blood group antigen antibodies. However, infants have a delayed antibody response to T cell-independent polysaccharide antigens and delayed maturation of the complement system, making transplantation across ABO blood groups possible in the first 12–14 months of life. West and colleagues demonstrated the ability to perform ABO incompatible heart transplantation in their landmark article that showed no hyperacute rejection, slightly lower rate of rejection, and survival of 80 % at 1 year in 10 infants that underwent ABO incompatible transplantation [28]. Waitlist mortality in this ABO incompatible transplant group was only 7 % compared to 58 % in their group of infants undergoing standard ABO compatible listing. Competing outcomes analysis by Almond et al. showed that a strategy utilizing ABO incompatible transplantation resulted in 31 % of patients transplanted at 30-day post-listing, compared to 16 % transplanted at 30-day post-listing in the ABO compatible group. The authors estimated that ABO incompatible listing decreased waitlist time by 20–25 % [29]. Since that publication, multiple studies have shown that ABO incompatible transplantation has resulted in excellent outcomes when used in infants [30–32]. Production of anti-blood group antibodies posttransplant is rare, and there is suggestion that anti-HLA antibody production is lower in ABO incompatible transplant recipients, suggesting that some degree of B cell tolerance may occur in these patients [28, 33–35].

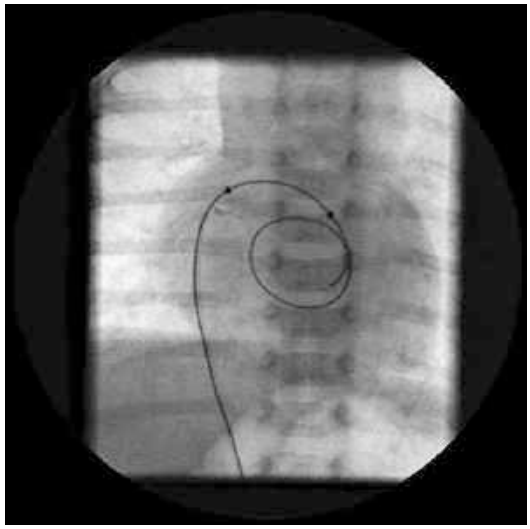
Data from the PHTS shows that prenatal listing for transplantation leads to a shorter time from listing to transplantation compared to postnatal listing. In competing outcomes analysis, 50 % of patients with fetal listings had undergone transplantation by 1 month after listing, which was significantly shorter than the 3 months needed for 50 % of the postnatal-listed infants to be transplanted [36]. The reason for this difference is unclear and still a focus of investigation, as fetal listing does not allow for accrual of time on the waiting list until a patient is born. Since it is possible for a fetus to be offered a donor heart prior to delivery and cesarean section must be timed with arrival of the donor organ, prenatal listing should not be performed if there is any doubt about the fetal cardiac diagnosis or about the viability of other vital organs.

The feasibility of donation after cardiac death (DCD) has been demonstrated without adverse effects on posttransplant survival [37]. Boucek et al. reported three recipients of DCD donors all survived transplantation with excellent graft function. One of those recipients was a critically ill neonate on ECMO that was transplanted using a DCD donor prior to the availability of a brain-dead donor. Mathur et al. showed that 4.3 % of infants undergoing withdrawal from life support at their institution over a 5-year period would have been suitable donors for heart transplantation, showing the great potential of a DCD strategy to expand the donor pool [38].

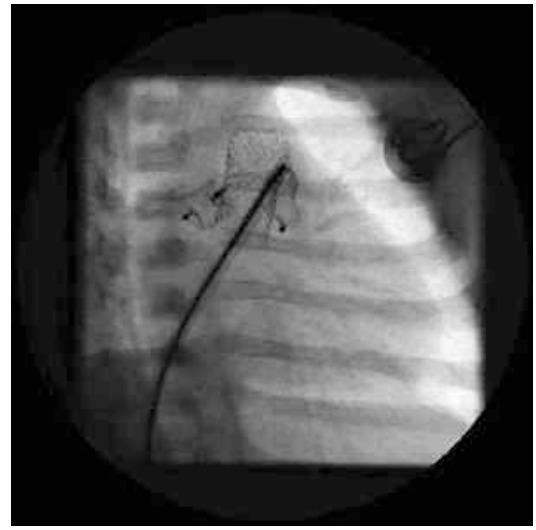
Medical Management While Awaiting Transplantation

Successful transplantation of infants with HLHS relies heavily on the clinical status of the patient at the time of transplantation. A simplified, non-intensive approach to management leads to the best outcomes, and up to a third of patients may be able to await transplant at home after stabilization [39].

Immediately after birth, prostaglandin E_1 (PGE_1) is used to maintain ductal patency. The lowest dose of PGE_1 is used to maintain ductal patency, with a goal dose range of 0.00625–0.0125 mcg/kg/min, in order to minimize the side effects of fever, apnea, and relaxation of smooth muscle in the pulmonary vasculature. Long-term IV access is best achieved with a peripherally inserted central venous catheter (PICC), but umbilical venous and arterial catheters are often needed in neonates until stabilization has occurred. The greatest challenge of managing patients with HLHS while awaiting transplantation is balancing systemic and pulmonary blood flow over a period of time that can last even beyond 6 months. While positive pressure ventilation can alter pulmonary vascular resistance, the risks of mechanical ventilation outweigh the benefits over the long term, as it has been shown to be a significant risk factor for poor outcomes following transplantation [40, 41]. Mechanical ventilation should be weaned as soon as tolerated, but preferably avoided altogether after birth if possible in favor of noninvasive respiratory support. Inhaled nitrogen has been useful in minimizing pulmonary overcirculation. It is usually initiated early after birth and weaned off after 5–6 weeks, usually at the time the atrial septum becomes more restrictive [39]. However, the use of hypoxic ventilation as a method of increasing pulmonary vascular resistance is controversial and center dependent [39, 42, 43]. The F_iO_2 should be no higher than 21 % unless there is concern for restriction of pulmonary blood flow and a pulmonary-to-systemic flow ratio (Qp:Qs) of <1. Initially, blood gas determination can guide management with a goal to keep the PCO_2 in the 40–45 and the PaO_2 35–45 mmHg. Hematocrit should be maintained at levels $\geq$40 % in order to maintain blood viscosity and pulmonary vascular resistance as well as improve systemic oxygen delivery. Maintenance of the hematocrit is best done by minimizing blood draws and providing iron supplementation. However, it may be necessary to give transfusions of packed red blood cells to maintain a hematocrit of $\geq$40 %. Theoretically, there may be benefit to giving a dose of cyclosporine before and after a blood transfusion to minimize the immune system's response to foreign antigens. However, this practice is center dependent, and renal function should be taken into consideration prior to administering cyclosporine to those awaiting transplantation [44]. While inotropic support is not always necessary for initial stabilization, many centers empirically start milrinone and/or dopamine. Theoretical benefits of milrinone include lusitropy and decreased systemic vascular resistance, but these benefits may be negated by a concomitant decrease in pulmonary vascular resistance. At low dose ($\leq$5 mcg/kg/min) dopamine may increase contractility, may decrease systemic vascular resistance, and may increase renal blood flow, but at higher doses an increase in systemic vascular resistance may be seen and can adversely affect Qp:Qs. A mild-to-moderate amount of restriction of the atrial septum is favorable in balancing the systemic and pulmonary circulation. Moderate or greater restriction of the atrial septum, the definition of which varies across institutions, should lead to consideration of enlarging the atrial communication with septostomy or septoplasty. Stenting of the atrial communication is sometimes necessary. Persistent oxygen saturations below 60 % with evidence of restriction at the atrial septum are also an indication for atrial septostomy. After 3 months of restriction at the atrial septum, the likelihood of an elevated pulmonary vascular resistance increases substantially, and atrial septoplasty with or without atrial stent placement in the cardiac catheterization laboratory should be considered. Video 104.1 shows balloon atrial septoplasty being performed in a cardiac catheterization lab in a patient with HLHS who over time developed a restrictive atrial septum. Enlargement of the atrial communication should

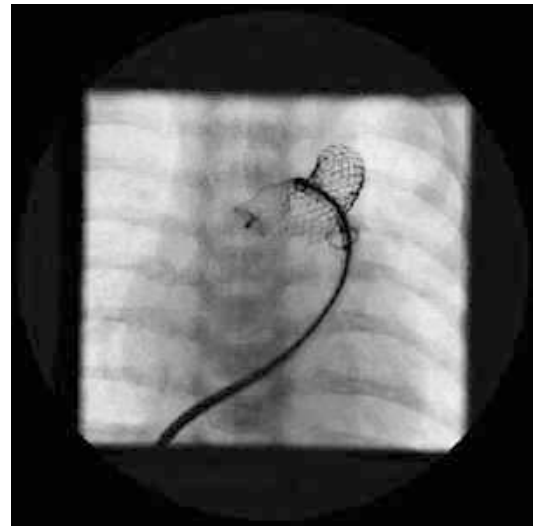


Video 104.1 This video shows balloon atrial septoplasty being performed in the cardiac catheterization lab in a patient with HLHS listed for transplantation. This patient developed a restrictive atrial septum while awaiting transplantation



Video 104.2 An internal pulmonary artery flow restrictor is inserted percutaneously into the proximal left pulmonary artery. A ductal stent and right-sided internal pulmonary artery flow restrictor are also seen. Using this percutaneous strategy, systemic output is maintained with a prostaglandin infusion, and pulmonary blood blow is controlled to prevent the onset of pulmonary hypertension

be performed using echocardiographic guidance, and adequacy of the size of the communication is determined based on the patients physiological response to the size of the communication in the catheterization laboratory (i.e., increase is oxygen saturations). Factors such as atelectasis and pulmonary edema resulting in pulmonary venous desaturation must be taken into account, as an oxygen saturation of 70 % immediately post-procedure in the catheterization laboratory could become a saturation of 90 % once pulmonary status improves. Control of pulmonary overcirculation after enlargement of the atrial communication by banding of the branch pulmonary arteries should be considered and ideally performed in conjunction with or shortly after the atrial septostomy. Banding of the pulmonary arteries can be performed either surgically through a median sternotomy or, as was done historically, percutaneously in the cardiac catheterization laboratory using flow restrictors as internal pulmonary artery bands [45, 46]. Video 104.2 shows deployment of a left pulmonary artery internal pulmonary artery band while Video 104.3 shows confirmation of placement of



Video 104.3 A right pulmonary artery angiogram is performed in this patient with HLHS awaiting heart transplantation just prior to deployment of an internal pulmonary artery flow restrictor to confirm its placement in the proximal right pulmonary artery. A ductal stent and left-sided internal pulmonary artery flow restrictor are also seen

a right pulmonary artery internal pulmonary artery band, both of which were placed in patients with HLHS awaiting transplant. Percutaneous internal pulmonary arterial banding did not result in long-term pulmonary artery stenosis, distortion, or in the need for pulmonary artery reconstruction [45, 46]. Video 104.4 shows an angiogram of the pulmonary arteries done 1-year posttransplant in a patient who had internal pulmonary artery banding while awaiting transplant. Banding of the pulmonary arteries should be performed no later than 3 months of age in order to decrease the risk of posttransplant right ventricular failure caused by elevated pulmonary vascular resistance and need for ECMO posttransplantation (unpublished data). To further limit risks of infection and complications while awaiting transplant, ductal stenting has also been commonly performed in these infants. Procedural complications associated with ductal stenting were dependent on the position and length of the ductus arteriosus. A more rightward position with a shorter length of the ductus arteriosus was seen in 11 of 40 patients with ductal stenting. While complications of ductal stenting were seen in less than 25 % of patients with a leftward positioned ductus, 75 % of patients with a rightward positioned ductus had a complication (Fig. 104.1) [47, 48].

Video 104.4 This patient was transplanted as an infant for HLHS and was bridge to transplantation with a ductal stent and bilateral internal pulmonary artery flow restrictors. The main pulmonary artery angiogram shown in this video was performed 1 year after heart transplantation and shows normal pulmonary arteries without pulmonary artery distortion, stenosis, or dilation

Unfortunately, internal pulmonary artery bands are not currently being manufactured.

Once the patient has been stabilized, the patient's care should be de-intensified, and efforts should be made to prevent iatrogenic complications. Invasive lines should be minimized and ideally should consist of only a PICC for PGE_1 infusion. Medications other than PGE_1 should be given orally if possible. Qp:Qs can be estimated by monitoring oxygen saturations from pulse oximetry and intermittently measuring

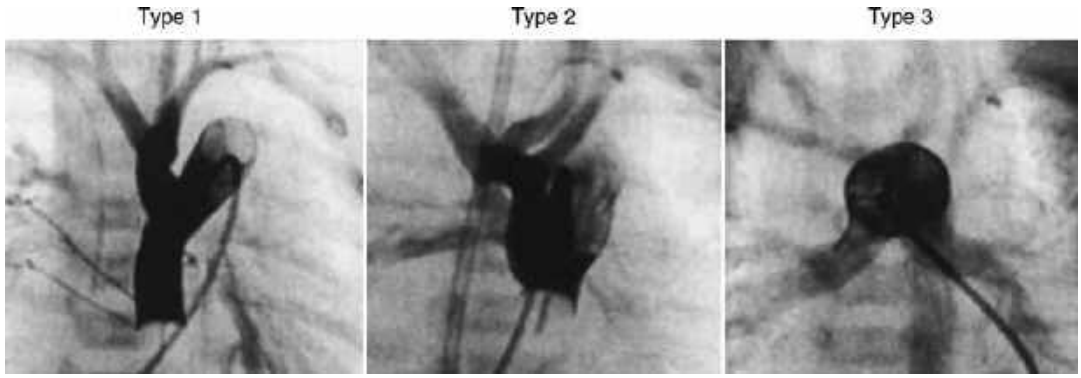


Fig. 104.1 Angiograms of the ductus arteriosus showing the three types of ductal anatomy based on orientation and deviation from the vertical plane. A leftward rotation is toward the patient's left. A rightward rotation is toward the patient's right. Type 1 PDA is a rotation >10°, type 2 is between 0 and 10° from the vertical plane, and type 3 is a rightward deviation from the vertical plane. The angiograms are typical for the three ductal types

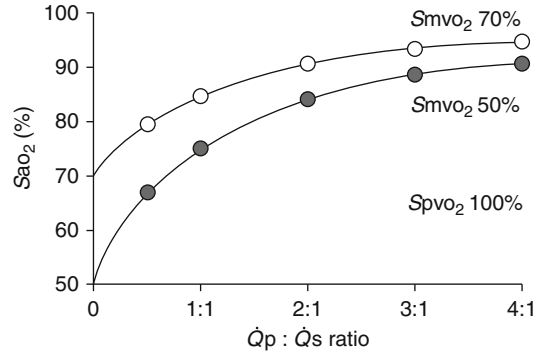
If pulmonary venous oxygen saturation is 100% and mixed venous oxygen saturation is 50%

$\dot{Q}$p/$\dot{Q}$s ratio	Final saturation
0.5:1	66.6%
1:1	75%
2:1	83.3%
3:1	87.5%
4:1	90%

If pulmonary venous oxygen saturation is 100% and mixed venous oxygen saturation is 70%

$\dot{Q}$p/$\dot{Q}$s ratio	Final saturation
0.5:1	80%
1:1	85%
2:1	90%
3:1	92.5%
4:1	94%



Effect of the pulmonary-systemic ratio (Qp:Qs) on systemic arterial oxygen saturation (Sao$_2$) when there is complete admicture of both systemic and pulmonary venous returns. It is assumed that pulmonary venous oxygen saturation (Spvo$_2$) is 100%; two curves are drawn, assuming mixed venous oxygen saturation (Smov$_2$) at 50% and 70% respectively.

Fig. 104.2 The systemic oxygen saturation prior to transplantation will depend on the mixed venous oxygen saturation and the ratio of systemic to pulmonary blood flow (Qp:Qs) (Table and Figure from Rudolph, Congenital Diseases of the Heart, 3rd Edition)

a mixed venous saturation oxygen saturation from the PICC (Fig. 104.2). While this method of combining pulse oximetry and mixed venous saturations can help estimate the Qp:Qs, one must keep in mind that pulse oximetry becomes less reliable as saturations fall and may vary by 5 % or more once the saturation is less than 70 % [49]. Clues to pulmonary overcirculation can be readily obtained by physical examination and include tachypnea and a gallop rhythm.

The use of erythropoietin and iron supplementation should be considered, and blood draws should be judiciously planned to be as infrequent as possible to minimize the need for transfusion and risk of infection of the PICC. Antiplatelet therapy with aspirin should be considered if the patient has significant ventricular dysfunction and in any patient with a ductal stent.

Optimizing nutritional status plays a critical role during the time awaiting transplant with respect to both maximizing the chance of survival to transplantation and survival to the perioperative period. While necrotizing enterocolitis (NEC) has been associated with HLHS, data do not support enteral feeding to be a significant risk factor for development of NEC [50]. A protocolized approach to feeding newborns and infants with HLHS may decrease the incidence of NEC. However, more data on when and how to initiate feedings are needed [51, 52]. Oral feeding should be initiated as soon as is considered safe by the care team in order to develop oral motor skills and to prevent bacterial translocation from the gastrointestinal tract. Nasogastric feedings should be used only when oral feeding is not feasible or to provide unmet caloric needs based on inadequate oral intake. If enteral feedings are deemed unsafe, then total parenteral nutrition should be started.

Surgical Technique

The surgical technique for heart transplantation is covered in detail elsewhere in this text, but surgical techniques pertinent to infants transplanted for HLHS will be discussed briefly. Biatrial anastomosis is used in infant transplantation due to the risk of systemic venous stenosis with a bicaval approach in children of this size. Harvesting of a large portion of donor aorta is critical for reconstruction of the aortic arch.

Arch reconstruction is typically performed by anastomosis of the underside of the donor aortic arch to the usually diminutive recipient aortic arch, allowing for incorporation of the subclavian and carotid arteries into the newly constructed arch. Enough donor arch should be incorporated to alleviate narrowing at the isthmus and minimize the chance of re-coarctation in the future. Re-coarctation was shown to occur in 21 % of patients that underwent extensive arch reconstruction at the time of transplant, which was treated successfully with either balloon angioplasty or surgical repair [53]. A standard anastomosis of the donor to the recipient pulmonary artery can usually be performed. If there are significant proximal pulmonary artery abnormalities in the recipient, then plans to harvest the donor pulmonary arteries should be made prior to transplantation. If the lungs are being harvested from the donor and pulmonary artery reconstruction is needed in the recipient, a large segment of descending aorta should be harvested from the donor to be used instead.

Cardiac and vascular anomalies associated with HLHS can complicate the surgical approach to transplantation for HLHS. Associated abnormalities possibly encountered in infants with HLHS include dextrocardia, abnormalities of systemic venous return, anomalous pulmonary venous return, and heterotaxy syndromes. Most of these anomalies can be managed by experienced transplant surgeons with modification of standard techniques [54].

Postoperative Management

Many of the principles related to postoperative management following cardiac surgery apply to the postoperative management of heart transplantation in infants. Management of patients in the operating room at the time of removal from cardiopulmonary bypass is best facilitated by a team approach consisting of the transplant surgeon, the transplant cardiologist, the anesthesiologist, and the cardiac intensivist. The postoperative management of the transplant patient is described in detail in elsewhere in this text. However, the concerns most specific to the infant transplanted for HLHS are an increased pulmonary vascular resistance with resulting right ventricular (RV) failure and primary graft failure.

Due to a prolonged period of time with the pulmonary arteries exposed to systemic pressure, infants with HLHS often develop increased pulmonary vascular resistance. A history of an intact or highly restrictive atrial septum places a patient at even greater risk of increased pulmonary vascular resistance causing significant RV dysfunction and/or failure postoperatively. If transplantation occurs within 3 months of life, the risk of RV failure is low. The newly transplanted heart, which in most cases was accustomed to pumping against a low-resistance pulmonary vascular bed, is unable to accommodate rapidly to an elevated pulmonary vascular resistance. Empiric treatment with pulmonary vasodilators, such as inhaled nitric oxide, is prudent, and evidence supports its prophylactic use to minimize RV dysfunction and failure, especially in infants transplanted for ductal-dependent lesions such as HLHS [55]. Pulmonary arterial monitoring lines are extremely helpful and can help guide management with pulmonary vasodilators. The velocity of the tricuspid regurgitation jet can underestimate the true pulmonary artery pressure due to poor RV function and/or elevated right atrial pressures and should, therefore, not be used alone to guide postoperative management. Inhaled nitric oxide should be available in the operating room, and treatment should be initiated if the pulmonary artery pressure is greater than 40 % of systemic pressure. In addition to inhaled nitric oxide, prostaglandin E_1 is an effective pulmonary vasodilator and can be used as an additional pulmonary vasodilator if inhaled nitric oxide is ineffective [56]. If a pulmonary arterial monitoring line is unavailable, an elevated or rising central venous pressure (CVP) can be used as an indicator of RV dysfunction due to pulmonary hypertension. Inotropic support with milrinone and low-dose epinephrine is preferential for inotropy (milrinone and epinephrine) and decreasing pulmonary vascular resistance (milrinone). As the denervated heart will depend on circulating catecholamines, postoperative

pacing is often necessary. Isoproterenol or epinephrine and atrial pacing are beneficial in the setting of bradycardia early posttransplant for augmenting cardiac output by increasing chrontropy in addition to inotropy. Chronotropic support with catecholamine infusions or temporary pacing should be continued until heart rate is adequate to maintain cardiac output, and some centers empirically continue low-dose catecholamine infusions for 3–5-day posttransplant. If treatment of postoperative pulmonary hypertension is unsuccessful and there is evidence of RV failure with inadequate cardiac output, ECMO or right ventricular assist device support may be necessary as a bridge to recovery while the newly transplanted heart accommodates to the increased afterload of the recipient's pulmonary vasculature [57, 58].

ECMO support may also be necessary in the setting of primary graft failure. Primary graft failure was shown to account for 54 % of posttransplant deaths in the HLHS population, which is much higher than the 11 % in all pediatric heart transplant recipients in the ISHLT registry [6, 59]. While 1-year posttransplant survival has clearly improved across eras, studies demonstrating that improved early posttransplant survival is specifically due to fewer patients with primary graft failure in the recent era are lacking. A detailed discussion of risk factors, causes, and treatment of primary graft failure is presented elsewhere in this text.

Immunosuppression Strategies

Immunosuppression strategies vary from institution to institution and are discussed in detail elsewhere in this text. Due to a more plastic immune system, infants transplant recipients are felt to have a higher likelihood for the development of variable degrees of tolerance or chimerism and typically require lower amounts of overall immunosuppression. The use of induction immunosuppression is center-dependent, but its use has increased over the last decade [59]. Maintenance immunosuppression for infant transplant recipients consists of a calcineurin inhibitor and an antiproliferative agent in the first-year posttransplant. The use of maintenance steroids in infant transplant recipients varies from center to center. If there has been no significant rejection episode in the first posttransplant year, consideration can be given to transition to single-drug maintenance immunosuppression (cyclosporine or tacrolimus) [60]. Long-term outcomes in infants with single ventricle physiology without prior surgery using a protocolized approach to single-drug immune suppression are excellent, with 5-, 10-, and 15-year graft survival of 76 %, 67 %, and 61 %, respectively (Fig. 104.3).

Rejection Surveillance

Rejection surveillance protocols vary by institution, but the small size of infant transplant recipients presents unique challenges in diagnosing acute rejection. Routine rejection surveillance is discussed in detail elsewhere in this text. Clinical signs of acute rejection in infants are nonspecific and may include fever, tachypnea, sinus tachycardia, arrhythmias, poor feeding, irritability, diaphoresis, emesis, or lethargy. However, rejection may occur in the absence of these symptoms. Due to the small size of infants and the likelihood of long-term issues with vascular access, many programs perform far fewer catheterizations and endomyocardial biopsies in the infant transplant population than in children transplanted at older ages. While most centers use endomyocardial biopsies for rejection surveillance, routine surveillance for rejection in infant transplant recipients can also be based on echocardiographic changes [61]. An example of an echocardiographic-based rejection surveillance protocol includes echocardiographic and clinical evaluation twice weekly for the first 3-month posttransplant, then weekly for 6 weeks, then every other week for 6 weeks, then monthly for 6 months, and then every 4 months. If there are changes on echo that are concerning for acute rejection, then catheterization for hemodynamic assessment and endomyocardial biopsy may be considered or the patient may be treated without performing a biopsy. Patients with an atypical presentation are more likely to undergo

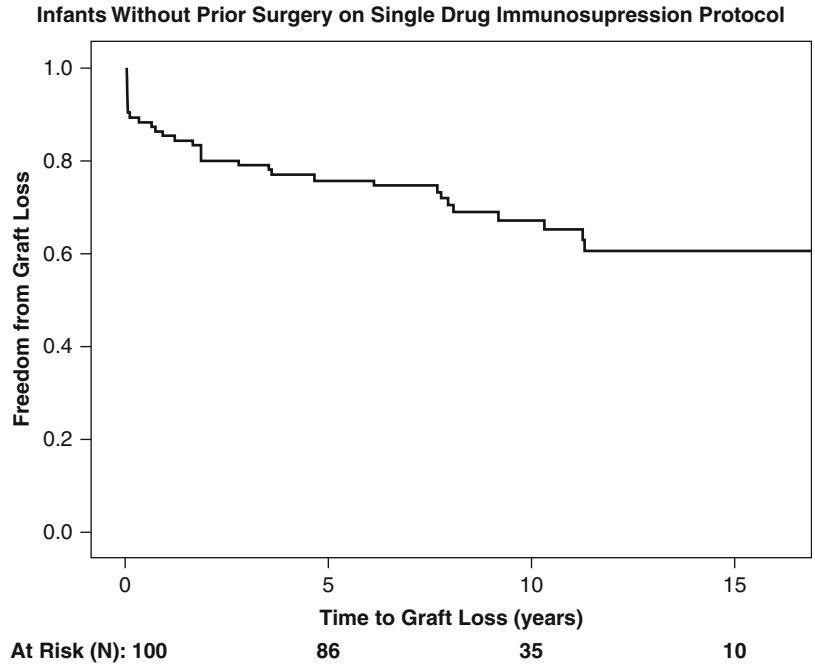


Fig. 104.3 Kaplan-Meier analysis of graft survival in 102 infants transplanted for single ventricle physiology without prior surgery at the University of Colorado

catheterization and biopsy than those with a clear clinical picture for acute rejection. Echocardiographic surveillance using digitized M-mode tracings and a computer-assisted scoring system has been shown to correlate with biopsy-proven rejection in infants and children, with sensitivity, specificity, and negative predictive value of 92 %, 98 %, and 98 %, respectively (Fig. 104.4) [61, 62]. Patients with a higher rejection score have a higher left ventricular (LV) mass and a lower LV volume, as well as abnormal indices of systolic and diastolic function. Specifically, infants and children with moderate to severe acute cellular rejection had significantly lower left ventricular posterior wall thickening fraction, left ventricular posterior wall thinning velocity, and left ventricular shortening fraction, as well as an increased LV mass. Figure 104.5 shows serial M-mode tracings in an infant transplant recipient and compares an M-mode tracing in the absence of rejection with an M-mode tracing during moderate acute cellular rejection [63]. The scoring algorithm with its threshold values is shown in Table 104.1, and the grading scale is shown in Table 104.2 [61]. The average echocardiographic scores in patients with no more than mild vs. $\geq$ moderate acute cellular rejection were 2.2 ± 0.3 vs. 5.4 ± 0.7 ($p < 0.001$) [62]. While this type of echocardiographic surveillance for rejection has been shown to be useful, it is dependent on the availability of the digitizing technology, on technician skill, and on the experience of the transplant physician in its use and interpretation, all of which significantly limits its widespread use.

The timing of the first routine posttransplant surveillance cardiac catheterization with endomyocardial biopsy varies across centers and may occur anywhere from 1-month to 1-year posttransplant in infant heart transplant recipients. Coronary angiography is typically performed approximately 1 year following transplantation. Although intravascular ultrasound evaluation is a useful adjunct for the diagnosis of coronary vasculopathy, its use is limited by patient size, as it is difficult to perform safely in children with weights under 15 kg.

Long-Term Outcomes

Long-term outcomes of infant transplants included in the International Society of Heart

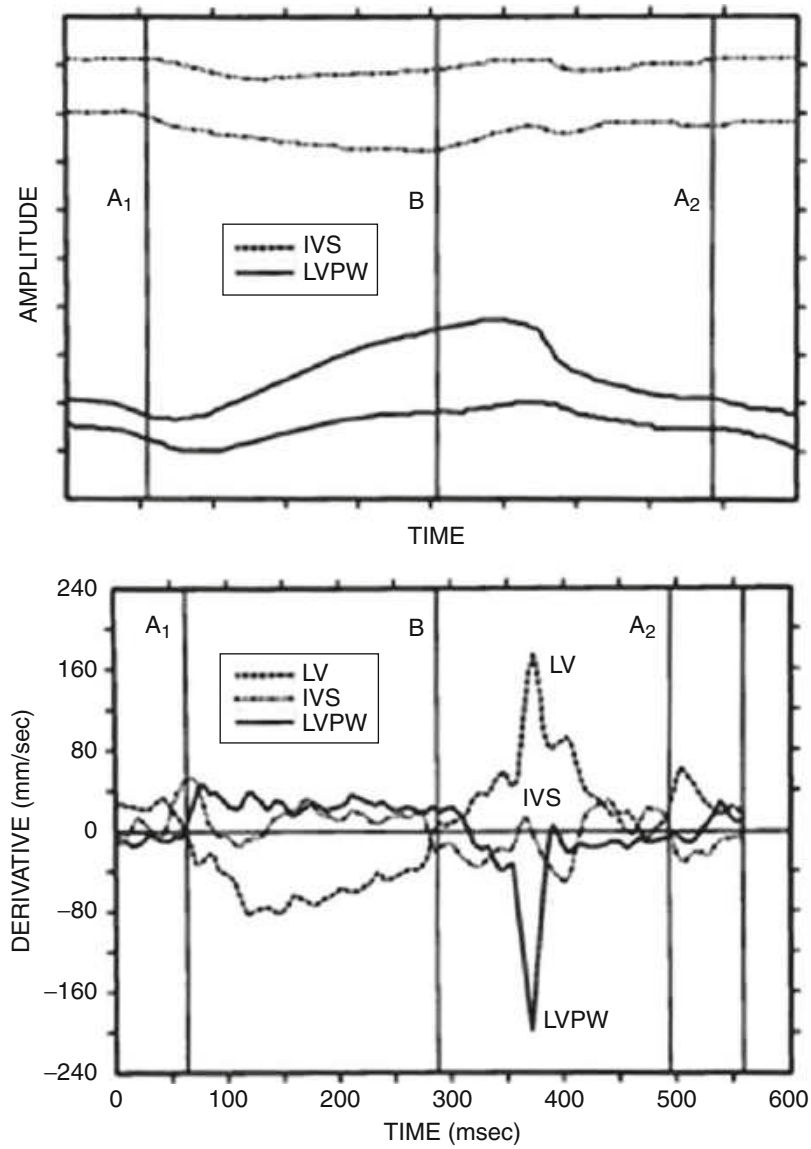

Fig. 104.4 Computer reconstructed M-mode echocardiographic tracing of the left ventricular posterior wall (LVPW) and interventricular septal (IVS) endocardial surfaces during a single cardiac cycle (*top panel*). The mean of three cycles was used for subsequent calculations. A_1 indicates the computer-designated left ventricular end-diastolic dimension; B_1 designates left ventricular end-systolic dimension, and A_2 designates left ventricular end-diastolic dimension at end of cycle (*bottom panel*). The trace of the instantaneous and first derivative of change is shown with respect to time for the left ventricular (LV) dimension, LVPW, and IVS thickness

and Lung Transplantation (ISHLT) registry during the period 1982–2009 were excellent, with a median graft survival in infant transplants of 18.4 years, compared to 16.4 years in children and 12 years in adolescents. Infants who survived the first posttransplant year had a median graft survival of over 20 years. Posttransplant survival of all infants in the ISHLT registry at 30 days, 1 year, 5 years, and 10 years was 80–85 %, 75 %, 65 %, and 60 %, respectively [59]. The PHTS has specifically evaluated outcomes in infants with HLHS, and perioperative survival has improved across eras, with 1-year survival of 77 % between 1993 and 1999 improving to 82 % between 2000 and 2006. Survival at 5 years was 72 % and was essentially unchanged across eras [18]. Single center data from the Loma Linda program showed overall posttransplant survival in the infant HLHS population at 1 year, 5 years, and 10 years to be 84 %, 76 %, and 68 %, respectively [64, 65]. Of infants transplanted for HLHS surviving more than 30 days, the most common

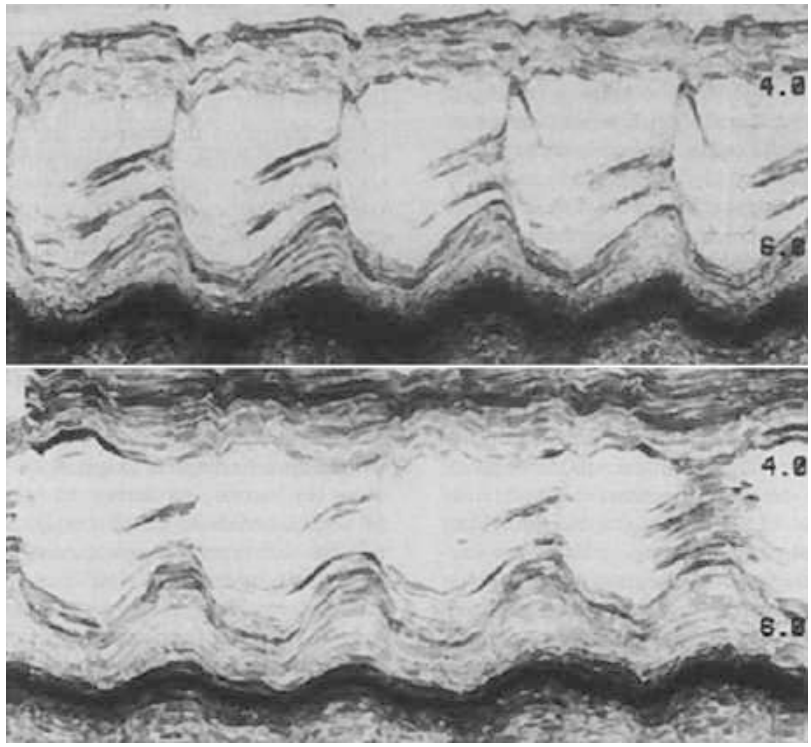

Fig. 104.5 Differential M-mode echocardiogram of a 15-month-old patient who underwent transplantation at 13 weeks of age, taken before (*top*) and at the day of biopsy (*bottom*) with evidence of moderate acute rejection (Billingham classification grade IIIB). *Top panel*: M-mode (taken at 12.2 months) supports normal indices of LV chamber size and systolic and diastolic function with an echocardiographic score of 0. *Bottom panel*: M-mode (taken at 15.6 months) demonstrates evidence of diminished LVEDV, LV filling, and LVPW thinning velocities with a total echocardiographic rejection score of 4. IVS wall thickness (at end-diastole) increased from 6.38 to 8.45 mm; LVPW thickness was unchanged

causes of death included rejection (27 %) and infection (27 %) [6]. Transplant coronary artery disease was not listed as one of the causes of death in this population, and the risk of developing transplant coronary artery disease has been shown to be lower than in older recipients. Infant transplant recipients have lower maximal intimal thickness by intravascular ultrasound despite an equal or longer time posttransplant than those transplanted after one year of age [66, 67]. The reason for this difference may be that infant transplant recipients have fewer rejection episodes and are less likely to be CMV positive than older recipients, as transplant coronary artery disease has been associated with both of these risk factors [66, 68, 69].

Few studies have evaluated neurodevelopmental outcome following heart transplantation for HLHS. At the University of Colorado, these authors evaluated 26 children over 2 years of age. Bayley Scales of Infant Development results revealed a median Mental Developmental Index of 88 (range <50 to 102) and a Psychomotor Developmental Index of 86.5 (<50 to 113). There was a significant inverse correlation between outcome and length of waiting period before transplantation [70]. These results are similar to a recent study of 323 transplant-free survivors from the Single Ventricle Reconstruction trial of the Norwood procedure with modified Blalock-Taussig shunt versus right-ventricle-to-pulmonary-artery

Table 104.1 Threshold values for echocardiographic rejection parameters in children

Parameter	Threshold	Score
IVS thickening (%)	<25 %	1
LVPW thickening (%)	<70 %	2
LVEDV (% normal)	<65 %	2
LVM (% normal)	>130 %	1
LVEDV/LVM (%)	<45 %	1
$Velocity_{avg}$ of LV enlargement	<60 mm/s	1
$Velocity_{max}$ of LVPW thinning/ LVEDD	<11/s	1
$Velocity_{avg}$ of LVPW thinning	<25 mm/s	1
Mitral insufficiency	>mild	1

LVEDV left ventricular end-diastolic volume, *LVM* left ventricular mass, *LVPW* left ventricular posterior wall, *IVS* intraventricular septum

Table 104.2 Echocardiographic rejection grade in children

Grade		Cumulative score
1	(Normal)	0
2	(Probably normal)	1–3
3	(Probably rejection) or new pericardial effusion (>4 mm) or new mitral regurgitation >2+	4–6
4	(Rejection) or LVSF <28 % (normal septal motion)	7–11

LVEDV left ventricular end-diastolic volume, *LVM* left ventricular mass, *LVPW* left ventricular posterior wall, *IVS* intraventricular septum

shunt with mean Psychomotor Development Index (74 ± 19) and Mental Development Index (89 ± 18) scores [71].

Although primary transplantation for infants with HLHS is uncommon in the current era, outcomes are acceptable and waitlist mortality is now lower due to fewer infants on the waiting list [18]. Furthermore, outcomes of infant transplantation are comparable to surgical palliation as improvements in perioperative mortality have been made in the recent era, and long-term survival in infant transplant recipients is the best of all age groups [19, 59]. Longer-term outcome studies of infants undergoing surgical palliation for HLHS will be useful in helping determine what subgroups are at highest risk of failure of surgical palliation. Identification of such subgroups could potentially improve outcomes in the population of HLHS as a whole by allowing for primary transplantation in patients who are likely to fail surgical palliation.

Cardiac Malpositions and Anomalies of Situs

105

Shinya Ugaki, Prashant Bobhate, Charissa Pockett, and Ian Adatia

Abstract

The congenital cardiac anomalies associated with abnormalities of cardiac position and thoracic and abdominal situs are often the most complex and fascinating in the field of congenital heart disease. Sadly, these patients continue to have a poor early and late survival. The nomenclature and terminology used to describe the cardiac lesions associated with abnormal situs have generated considerable, heated, and polarized debate over the last three decades. Modern practitioners owe a huge debt to Stella and Richard van Praagh, Robert Freedom, Fergus McCartney, and Robert H. Anderson for this debate conducted through elegant and erudite writing.

In this chapter, the authors acknowledge that both classifications of heterotaxy and isomerism are useful and helpful in a practical approach to the diagnosis, management, and outcome prediction for a neonate with complex congenital cardiac disease. Congenital cardiac malformations

associated with atrial isomerism and visceral heterotaxy are among the most challenging to manage. Comprehensive, systematic cardiac and extracardiac evaluation is important. Although in recent cohorts there is improved survival, the long-term outcome for patients with a single ventricle, especially if requiring neonatal surgery for pulmonary vein anomalies, remains poor. However, optimistically, in a selected population of patients with atrial isomerism who survived to Fontan completion, exercise tolerance and quality of life indicators were similar between those with and without heterotaxy.

Introduction

The congenital cardiac anomalies associated with abnormalities of cardiac position and thoracic and abdominal situs are often the most complex and most fascinating in the field of congenital heart disease. Sadly, these patients continue to have a poor early and late survival. The nomenclature and terminology used to describe the cardiac lesions associated with abnormal situs have generated considerable, heated, and polarized debate over the last three decades. Modern practitioners owe a huge debt to Stella and Richard van Praagh, Robert Freedom, Fergus McCartney, and Robert H. Anderson for this debate conducted through elegant and erudite writing.

In this chapter the authors acknowledge that both classifications of heterotaxy and isomerism are useful and helpful in a practical approach to the diagnosis, management, and outcome prediction for a neonate with complex congenital cardiac disease.

Cardiac Malpositions

Cardiac malpositions may be primary or secondary [1]. Primary cardiac malpositions are due to a disturbance of cardiac looping or somatic lateralization. The position of the heart in the thorax and the direction of the cardiac apex may be described as *levocardia* (in the left chest with apex to the left), *mesocardia* (midline with cardiac apex to midline), or *dextrocardia* (heart in the right chest with cardiac apex to the right). Secondary cardiac malpositions are due to non-cardiac malformations such congenital diaphragmatic hernia, which result in displacement of the heart. Cardiac displacement to the right is called *dextroposition*. Other secondary cardiac malpositions are associated with Cantrell syndrome, thoracic ectopia cordis, or conjoined twins. Cardiac malpositions describe only the position of the heart and do not indicate the presence or absence of cardiac abnormalities. However, an unusual cardiac position usually detected on a chest X-ray may prompt referral of the patient to the pediatric cardiologist for further assessment.

Malposition of the atrial appendages, great arteries, or ventricles (usually called ventricular inversion) may also be a feature of congenital cardiac malformation complexes. *Juxtaposition of the atrial appendages* is detected in 280 per 100,000 echocardiograms and 760 per 100,000 in autopsies [2, 3]. Before 23 days gestation, the left juxtaposition of the atrial appendage is the usual arrangement. Between 23 and 27 days, the conotruncus moves to the left of the right atrial

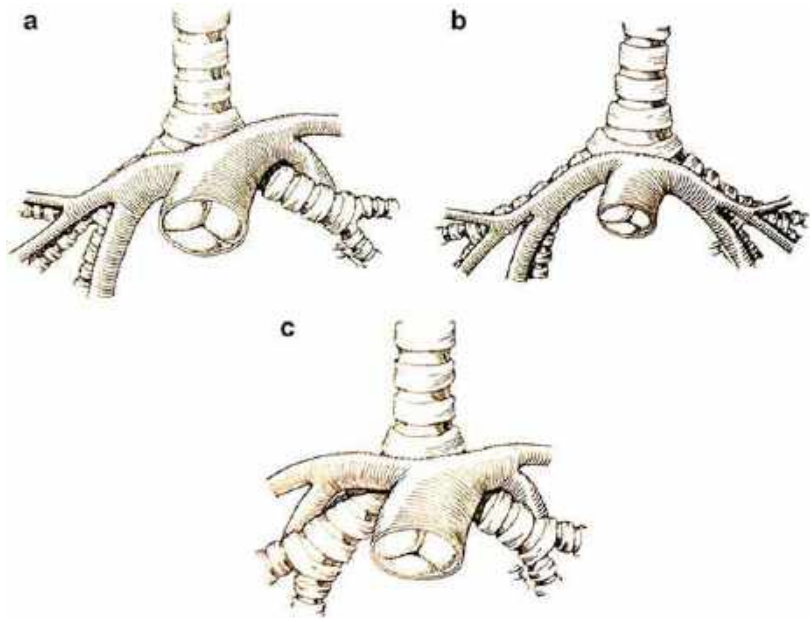

Fig. 105.1 (**a**) Normal bronchial anatomy demonstrates right-left asymmetry with eparterial bronchus on the right and hyparterial on the left. (**b**) Bilateral eparterial typical of right atrial isomerism and asplenia. (**c**) Bilateral hyparterial bronchi typical of left atrial isomerism and polysplenia (Reproduced with permission pending from reference [23])

appendage as the ventricular loop swings right to the left. If this does not occur, then left juxtaposition of the atrial appendage and dextrocardia may occur together [4]. Juxtaposition of left atrial appendage often occurs with mitral stenosis or atresia, left-sided tricuspid valve, aortic atresia, common atrioventricular valve, and heterotaxy syndromes [5]. Juxtaposition of the right atrial appendage is associated with tricuspid atresia or stenosis, right ventricular hypoplasia, subaortic or bilateral conus, subpulmonary stenosis, and ventricular septal defect [6]. Juxtaposition of the right atrial appendage may occur with transposition of the great arteries and complicate balloon atrial septostomy [2, 7, 8]. Juxtaposition of the atrial appendages may also complicate atrial baffle procedures including the Mustard, Senning, or Fontan operations [9, 10].

Isolated *ventricular inversion* occurs with atrioventricular discordance and ventriculo-arterial concordance {S,L,S} or rarely {I,D,I} and has been described with ventricular septal defect (VSD), hypoplasia of the tricuspid valve, and right ventricle and coarctation of the aorta.

Anatomically corrected malposition is described by ventriculo-arterial concordance but parallel arrangement of the great vessels. If the ventricular loop is *D*, the aorta will be leftward and anterior to the pulmonary artery, and if *L*-looped, the aorta is rightward and anterior. This arrangement may support normal physiology, but related cardiac abnormalities are common and include VSD, juxtaposition of the right atrial appendage, right ventricular (RV) hypoplasia, subpulmonary stenosis, and a high frequency of coronary artery anomalies with a single coronary artery originating from the right sinus of Valsalva [11, 12].

Situs solitus is a term used to describe the normal situation of the right and left asymmetry in the thorax and abdomen. The right lung typically has three lobes, a horizontal right main stem bronchus which branches earlier than the left and is, therefore, shorter. The right upper lobe bronchus is, therefore, above the right pulmonary artery and described as eparterial (Fig. 105.1a). The left lung has two lobes, the left mainstem bronchus is longer and branches after crossing the pulmonary artery; the bronchial branches are, therefore, hyparterial or below the artery. There is a close correlation between bronchial branching and isomerism. Thus, left atrial isomerism (polysplenia) is associated with bilateral hyparterial bronchi and right atrial isomerism (asplenia) with eparterial bronchi [13] (Fig. 105.1b, c). The usual or abdominal situs

solitus consists of a right-sided liver and gallbladder with left-sided spleen. The inferior vena cava is on the right of the spine and the aorta on the left.

Situs inversus describes the mirror image of the usual thoracoabdominal visceral arrangement with reversal of the usual body asymmetry, and if dextrocardia is also present, it is called *situs inversus totalis*. The latter, of course, may occur without congenital heart disease. Situs inversus totalis {I,LI} may also be associated with tetralogy of Fallot, VSD and, rarely, with hypoplastic left heart syndrome. The aortic arch is usually right-sided.

Kartagener syndrome includes situs inversus totalis with sinusitis and bronchiectasis due to cilial immotility and has stimulated research into the role of cilial dysmotility and maldevelopment of the thoracoabdominal visceral asymmetry [14].

The incidence of *dextrocardia* in the fetus is 220–830 per 10,000 fetuses [15].

Postnatally, dextrocardia is found in 2.8 % of cyanotic and 0.4 % of acyanotic cardiac diseases [16]. Dextrocardia with situs inversus totalis is estimated at 1 in 10,000, and situs inversus with levocardia is estimated at 1 in 22,000 [17, 18].

Situs solitus or ambiguous with dextrocardia carries a very high likelihood of cardiovascular malformation, but 89 % of cases with situs inversus totalis have normal heart anatomy [19].

Isomerism of the Left and Right Atrial Appendages, Polysplenia, Asplenia, and Visceral Heterotaxy

Patients with visceral heterotaxy syndrome comprise about 0.8–1 % of children with congenital heart disease. According to Stella van Praagh, a case of asplenia with a malformed heart was described in 1826. Subsequently, Polhemus recognized that asplenia and polysplenia were associated with complex congenital heart disease [20]. Ivemark suggested that certain cardiac malformations were more frequent with asplenia, particularly atrioventricular canal defects and conotruncal anomalies which – he suggested – might be related to the fact that these areas in the heart and the splenic primordial appear at 30–32 weeks' gestation [21]. Van Mierop described the concept of the left and right atrial isomerism, and this was refined to the right and left atrial appendage isomerism by McCartney and Anderson [22]. Thus, agreement was reached that there was an association of asplenia, bilateral eparterial bronchi, and trilobed lungs with bilateral right atrial appendages. Likewise, bilateral left atrial appendage morphology was associated with polysplenia and bilateral hyparterial bronchi.

Thus, two nomenclatures have developed, each of which has helped us to understand the clinical syndromes and associated cardiac defects.

Cardiac defects occurring with *visceral heterotaxy* (heterotaxy is derived from a Greek word meaning "other than the usual arrangement") may be broadly grouped into cardiac defects more frequently seen with asplenia and those with polysplenia [23]. The terms *left atrial isomerism* (*polysplenia*) and *right atrial isomerism* (*asplenia* or a single right-sided spleen) are favored by others. Many arguments against one or the other term seem to stem from unusual cases which break the rule, and so although the appearance of the atrial appendage seems to be a common feature at autopsy, in day-to-day clinical practice, it is hard to visualize the atrial appendage morphology, although this may change with the routine use of cardiac (cMRI). It is thought that the bronchial-to-pulmonary artery arrangement is most consistent with cardiac lesions and visceral heterotaxy (Fig. 105.1). Thus, the presence of atrial isomerism is usually surmised based on the abdominal situs or heterotaxy. Furthermore, in clinical practice, atrial situs is often indeterminate as often there is a common atrium with only remnants of atrial septum present. In these cases the term situs ambiguous is often used. In addition, the clinical relevance of precise diagnosis of the atrial morphology is questioned as the outcome of children – for the most part – depends on the management of the constellation of cardiac lesions, and these vary sufficiently that each child requires careful and individual cardiac analysis.

Although there are broad diagnostic categories, there remains considerable variation between abdominal situs, the cardiac lesion, and the presence of polysplenia and asplenia.

Right Atrial Isomerism, Asplenia Syndromes, and Systemic and Pulmonary Venous Drainage

The inferior vena cava (IVC) is usually intact in patients with asplenia or right-sided single spleen. Hepatic veins join the IVC in the majority of patients (72 %), the hepatic veins draining the lobes of the liver opposite to the IVC and connecting directly with the atrium in 28 % [23, 24]. The coronary sinus is unroofed in 95 % of patients with asplenia. Bilateral superior vena cava occurs in most patients with asplenia or right atrial isomerism (Figs. 105.2–105.4) .

Pulmonary venous connections to a systemic vein or via a confluence to the atrium are much more common (60–70 %) in asplenia than in left atrial isomerism (polysplenia). The connection between the confluence and the atrium may become obstructed (Fig. 105.5).

Left Atrial Isomerism or Polysplenia Syndromes and Systemic and Pulmonary Venous Drainage

Interruption of the Inferior Vena Cava

The suprarenal and infrahepatic portion of the IVC is usually (80 %) interrupted or absent, and venous drainage occurs via an azygous on the right or hemiazygos on the left, related to right or left superior vena cava, respectively (Figs. 105.6 and 105.7) [23, 24].

If the IVC is intact, then the hepatic veins usually join the IVC directly or rarely connect with the coronary sinus. If the infrahepatic IVC is interrupted, the hepatic veins join the atrium usually on the right side as a common trunk or as separate veins on the right and left side. Accurate demonstration of the hepatic venous drainage is extremely important before the total cavopulmonary surgery. If the hepatic veins remain connected inadvertently to the atrium after the Fontan, there will be a right-to-left shunt with cyanosis, and by direct exclusion of the hepatic veins from the pulmonary circulation, there is a predisposition to develop pulmonary arteriovenous malformations [6, 8, 9].

The coronary sinus is unroofed in 26 % of patients with polysplenia, and other abnormalities of the coronary sinus may exist and be clinically relevant if the superior cavopulmonary surgery is performed as a palliative procedure [25].

Bilateral superior vena cava (SVC) occurs in about 50 % of cases of polysplenia or left atrial isomerism (Fig. 105.2).

Anomalous pulmonary venous connections to a systemic vein are an uncommon finding in left atrial isomerism and estimated to occur in 2 % of cases. However, the right and left pulmonary veins often appear by echocardiography to attach to the right and left side of a common atrium, respectively. This is called ipsilateral drainage and is considered by van Praagh to represent malposition of the septum primum. This situation has surgical implications, and resection of the malpositioned septal remnant may allow the pulmonary venous drainage to be incorporated into the left atrium by positioning a new atrial septum and facilitating a biventricular repair (Fig. 105.10a–d).

Common Atrioventricular Valve and Atrioventricular Septal Canal Defect

A common atrioventricular (AV) valve occurs in 70 % of patients with asplenia. The presence of two AV valves, often with atresia of one component, is seen in only 2 % of patients with asplenia and right atrial isomerism (Fig. 105.11a, b).

In polysplenia or left atrial isomerism, about 33 % of patients have a common AV valve. Two separate and patent AV valves occur in 33 % of patients. In addition, an intact ventricular septum with a primum atrial septal defect and cleft left AV valve may be associated with polysplenia.

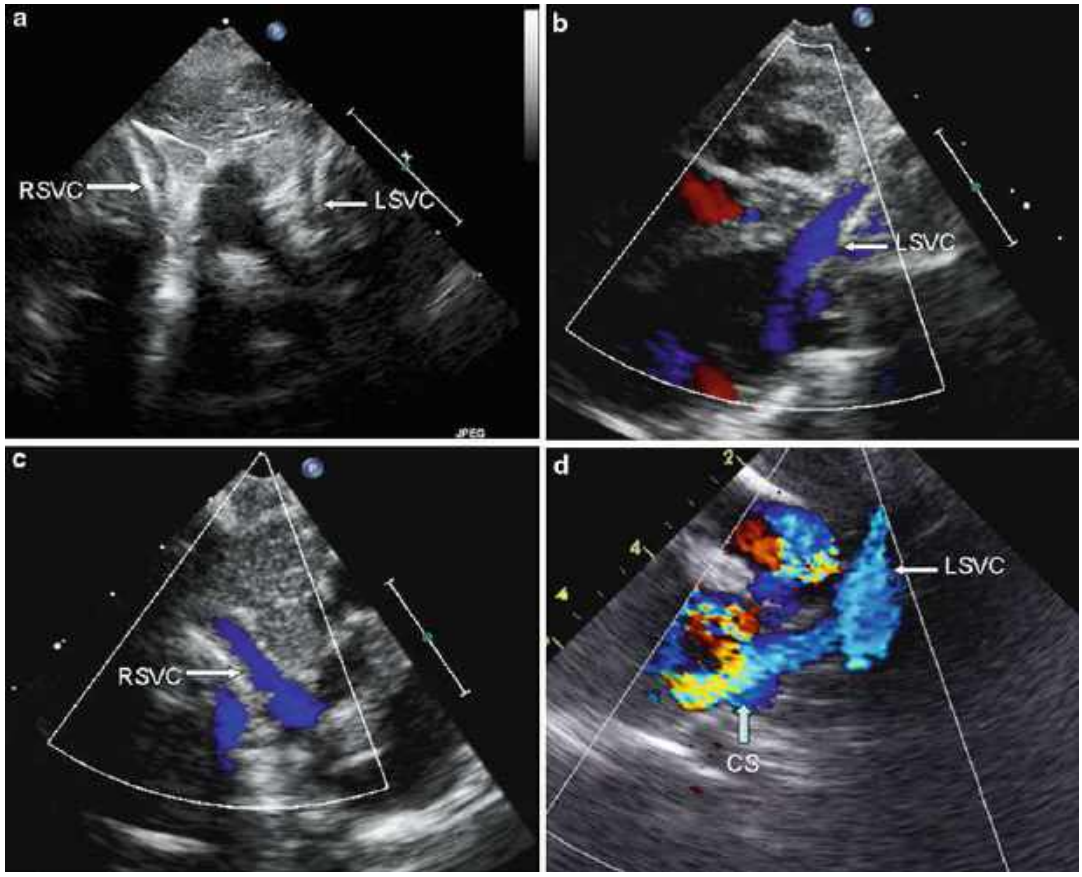

Fig. 105.2 Variation in systemic venous drainage is very common in patients with atrial isomerism. Bilateral superior vena cava (*SVC*) with or without connecting vein is commonly seen in both patients with right and left atrial isomerism. The left-sided SVC may connect directly into the respective atrium or to the right-sided atrium via the coronary sinus (*CS*). It is important to demonstrate SVC anatomy accurately before superior cavopulmonary surgery. (**a**) Echocardiogram suprasternal short axis view showing bilateral SVC. (**b**) Echocardiogram with color flow Doppler shows that the left-sided SVC (*LSVC*) connects to the left-sided atrium. (**c**) Echocardiogram with color flow Doppler demonstrates the connection of a right SVC (*RSVC*) to the right-sided atrium. (**d**) LSVC is seen draining into the coronary sinus

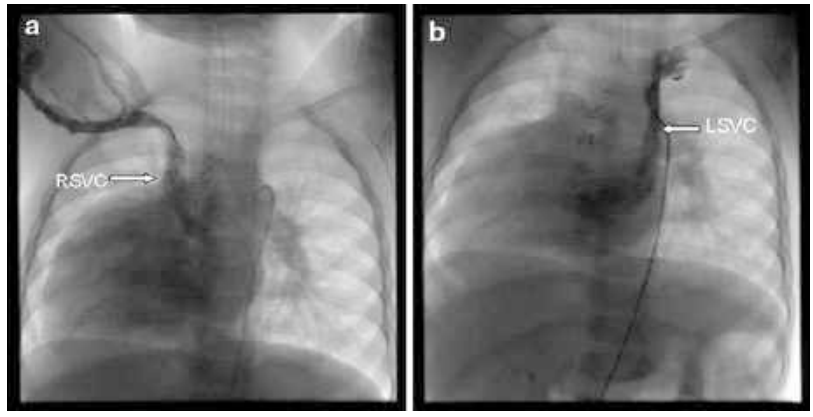

Fig. 105.3 Venogram demonstrates bilateral SVC without a connecting vein

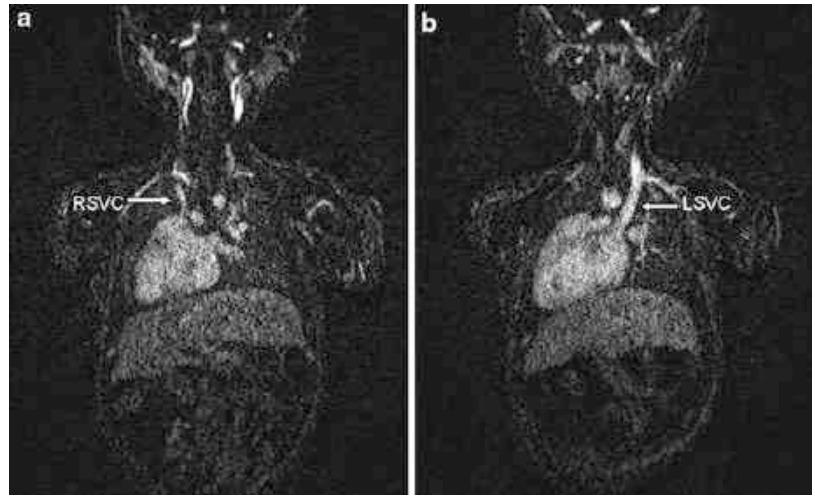

Fig. 105.4 cMRI demonstrates RSVC and LSVC connecting to the respective atrium

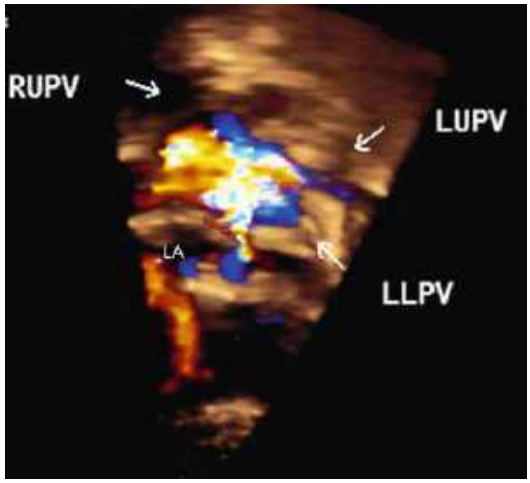

Fig. 105.5 Echocardiography can be used effectively in demonstrating the drainage of pulmonary veins. In patients with right atrial isomerism, the pulmonary veins may form a confluence and drain into one of the atrium. This communication between the pulmonary venous confluence may become narrow which adversely affects outcome. A color 3D echo showing an apical four-chamber view, which demonstrates the pulmonary venous confluence draining into the left-sided atrium. The narrow communication is marked by a *red arrow*

Ventricular Abnormalities

Ventricular *D*-looping occurs as frequently in right as in left atrial isomerism (60–70 %). Ventricular *L*-looping tends to correlate with dextrocardia. Right ventricular dominance is common to both left and right atrial isomerism.

Pulmonary outflow tract obstruction is very common in asplenia (subvalvar and valvar) occurring in over 90 % of cases. Rarely, aortic atresia may occur.

In polysplenia, the outflow tract morphology is variable with pulmonary stenosis in 43 %, subaortic stenosis in 22 %, and unobstructed in 35 % of cases [23, 24].

Ventricular Arterial Connections or Alignment

In asplenia or right atrial isomerism, double outlet right ventricle (DORV) is found in 82 % of cases and transposition of the great arteries (TGA) in 9 % of cases. Normally related great arteries are rarely found (9 %). In contrast, in polysplenia, the great arteries are normally related in 61 %, and DORV is documented in 37 % of cases. TGA occurred in only 2 % of Stella van Praagh's autopsy series with bilateral absent conus leading to direct fibrous continuity between both semilunar valves and the anterior common AV valve [23]. Malposition of the great arteries may also be a feature of both right and left atrial isomerism (Fig. 105.11b).

Common constellations of cardiac findings in asplenia or right atrial isomerism include intact IVC, bilateral SVC, unroofed coronary sinus, total

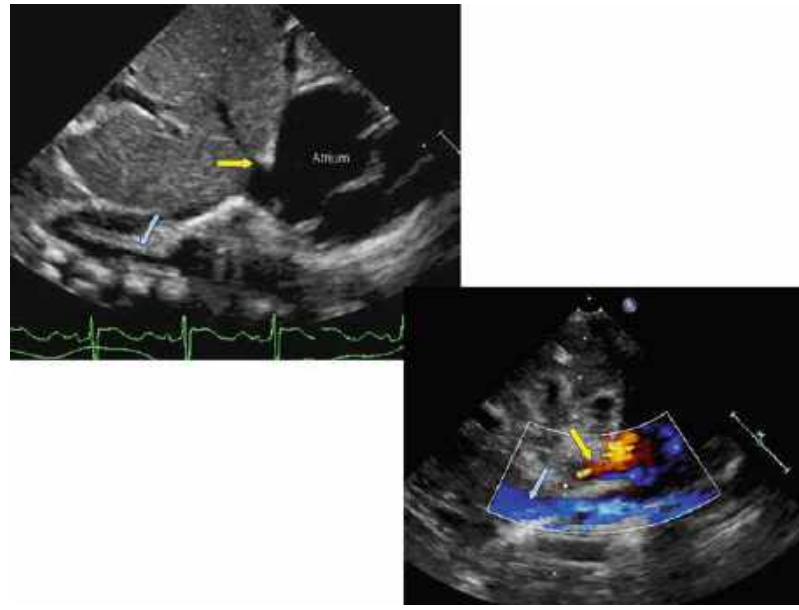

Fig. 105.6 Echocardiogram with color flow Doppler demonstrates from a subcostal sagittal view the azygous vein (*blue arrow*) ascending above the diaphragm. The hepatic veins (*yellow arrow*) connect separately to the atrium

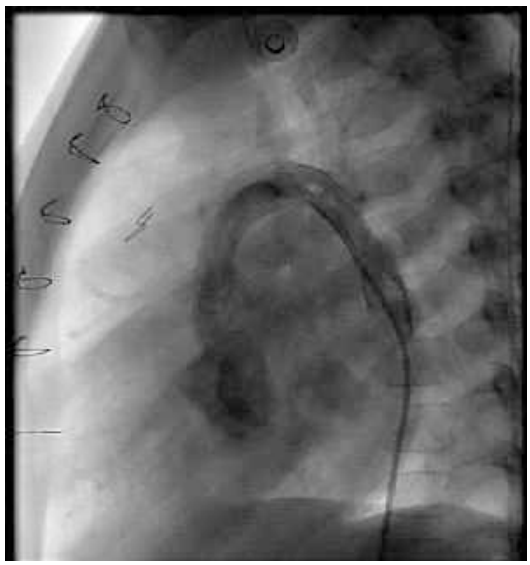

Fig. 105.7 Venogram in a lateral projection in the same patient, showing the typical appearance of the interrupted IVC draining into the superior vena cava via an azygous continuation between the suprarenal and infrahepatic IVC

anomalous pulmonary venous connections to the systemic vein, common atrioventricular canal, DORV or TGA with bilateral conus or subaortic conus, and pulmonary atresia or stenosis [23, 24].

Common constellations of cardiac findings in polysplenia or left atrial isomerism include interrupted infrahepatic IVC, bilateral SVC, ipsilateral pulmonary venous drainage or total anomalous drainage to the right side of the common atrium, complete or partial atrioventricular canal, normally related great arteries, or DORV without subaortic conus even in the presence of AV discordance [23, 24].

Investigation of Heterotaxy Syndrome

Clinical Recognition

Patients with right atrial isomerism are more often male and present with cyanosis as newborns, with ductal-dependent pulmonary blood flow, or with cyanosis due to pulmonary vein obstruction.

In contrast, patients with polysplenia are usually female with a more variable presentation in keeping with a wider spectrum of cardiac abnormalities.

Rarely, visceral heterotaxy occurs in siblings or within families [26].

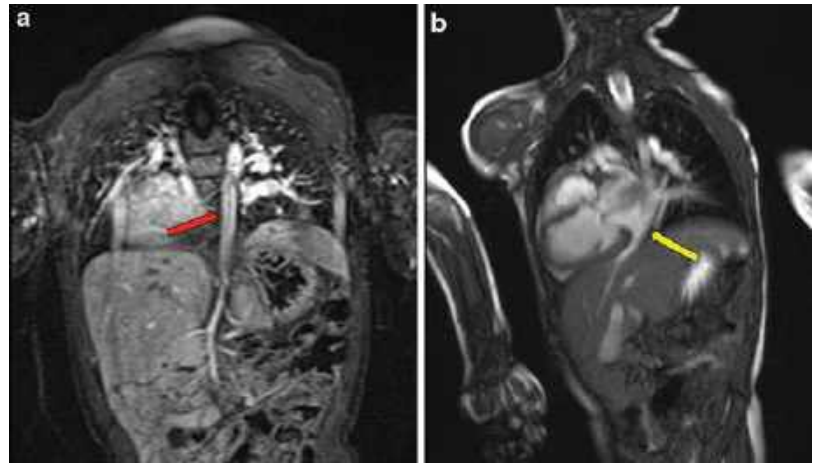

Fig. 105.8 cMRI images of interrupted IVC and hepatic venous drainage. (**a**) *Red arrow* demonstrates the azygous continuation of the infrahepatic IVC joining the LSVC. (**b**) The *yellow arrow* shows the connection of the right hepatic veins directly with the atrium

Electrocardiogram

Atrial situs inversus can be suspected from the electrocardiogram (ECG) that displays a frontal p wave axis with inverted p waves in leads 1 and V6. Patients with left atrial isomerism show a coronary sinus rhythm with inverted p waves in leads 2, 3, and aVF. These patients have slow atrial rates and are at risk for progressive bradycardia and complete heart block. The sinus node cannot be identified with certainty in many specimens. In right atrial isomerism there are more often bilateral sinoatrial and atrioventricular nodes which form a substrate for reentry tachycardia [27–30].

Echocardiography

Echocardiography is the mainstay of diagnosis especially in the neonate. It is essential to image each part of the heart and the venous and arterial connections sequentially and logically. This may take some time or require multiple evaluations by sequentially more experienced echocardiographers, before an anatomic conclusion can be drawn.

The positions of the abdominal IVC and the aorta are readily imaged by subxiphoid views, provide valuable clues, and may help to differentiate left and right atrial isomerism. In situs solitus, the inferior vena cava is situated to the right and slightly anterior to the descending aorta. In situs inversus, the mirror image of this relationship is observed. In right atrial isomerism, the IVC lies directly in front of the descending aorta, and both vessels are situated either to the left or to the right of the spine. There may be partial anomalous drainage of the hepatic veins directly to the atrium. In left atrial isomerism, there is very often interruption of the infrahepatic IVC, and the azygous vein may be imaged posterior to the descending aorta. The hepatic veins will drain anomalously to the atrium directly rather than to the hepatic IVC [30] Figs. 105.6–105.9.

Cardiac MRI and Cardiac Catheterization

Cardiac magnetic resonance (cMRI) imaging and cardiac catheterization are invaluable adjuncts to image the anatomy in right or left atrial isomerism, are rarely required in the neonatal period, but are essential to assess the anatomy after surgical intervention and particularly before and after superior cavopulmonary and total cavopulmonary anastomosis [31, 32].

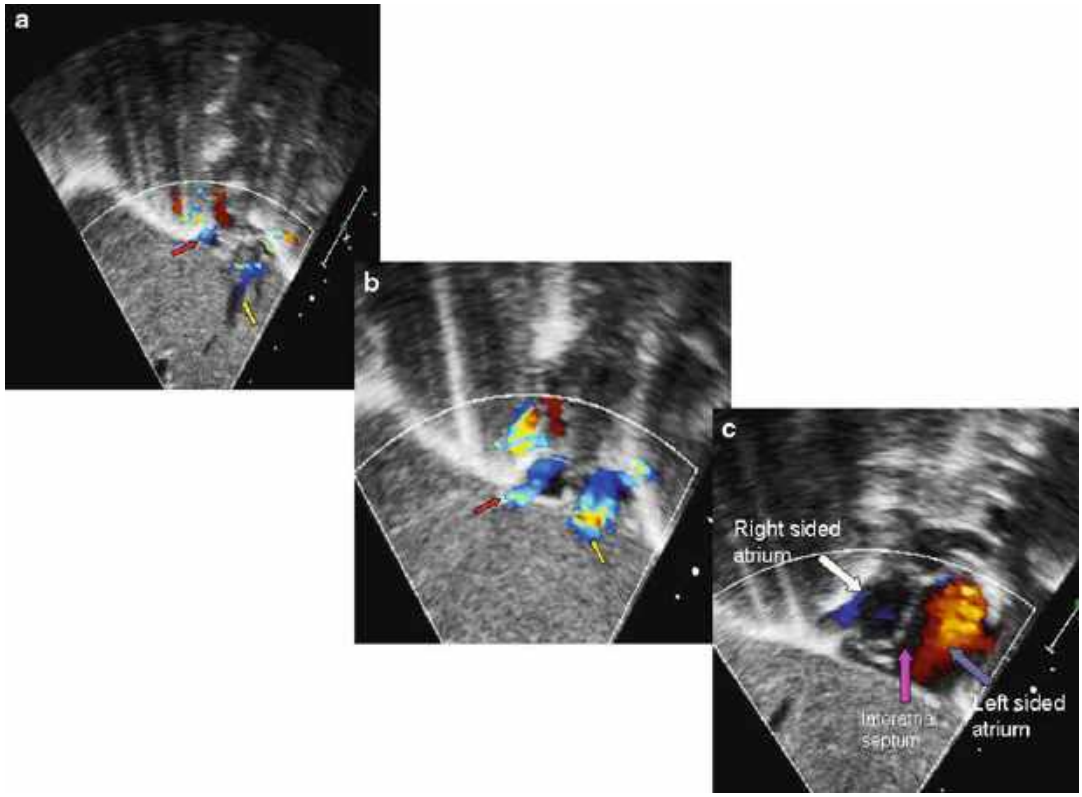

Fig. 105.9 (**a**–**c**) Echocardiogram with color flow Doppler from subcostal coronal sweeps demonstrating the right-sided hepatic veins (*red arrow*) draining into the right-sided atrium and left-sided hepatic veins (*yellow arrow*) draining into the left-sided atrium

Assessment of the Spleen and Extracardiac Morbidities

Patients with asplenia are at risk of overwhelming sepsis, particularly from pneumococcal and Haemophilus infection. In the first 6 months of life, these patients are also at risk from infection with gram-negative organisms. Patients with polysplenia may have poorly functioning splenic tissue and are also at risk for infection with encapsulated organisms. These patients require pneumococcal, Haemophilus, and meningococcal vaccination and daily antimicrobial prophylaxis with penicillin, amoxicillin, or trimethoprim sulfamethoxazole.

The splenic status may be imaged by ultrasound, CT scan, MRI, or radionuclide spleen scan. The presence of Howell-Jolly bodies or pitted red blood cells on a peripheral smear suggests impaired splenic function.

Extracardiac congenital defects, apart from splenic abnormalities, are found often, and autopsy studies suggest that 75 % of patients with heterotaxy have an extracardiac anomaly [33]. Organ systems involved can include pulmonary, gastrointestinal, hematological, genitourinary, neurological, endocrine, and musculoskeletal systems [24].

Congenital abnormalities of the gastrointestinal system include, but are not limited to, intestinal rotation abnormalities, hiatal hernia, and biliary atresia. It is important to note however that tracheoesophageal fistulas or atresia and omphaloceles also occur in patients with any

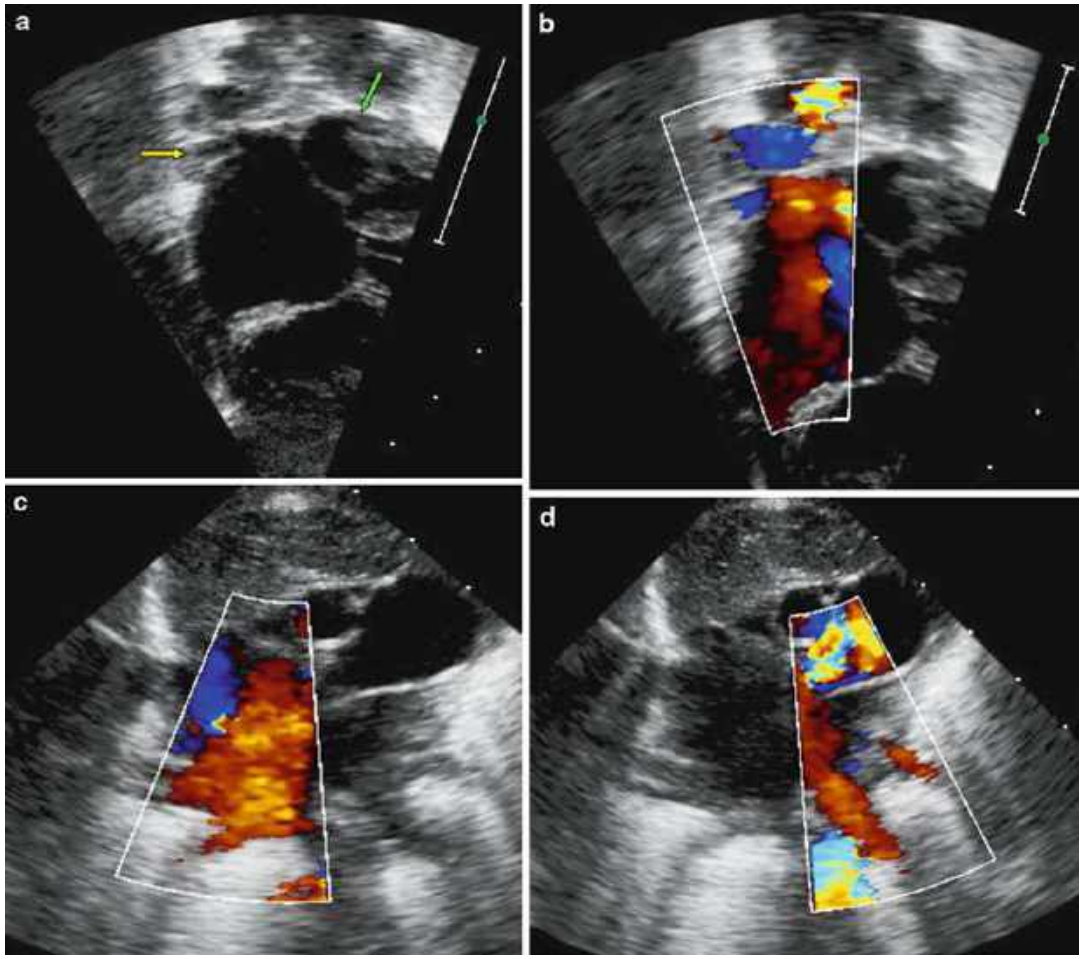

Fig. 105.10 Pulmonary venous connection in left atrial isomerism. Lateralized or ipsilateral pulmonary venous connection to the right- and left-sided atrium is seen commonly in patients with left atrial isomerism. (**a**, **b**) Echocardiogram with color flow Doppler demonstrates from an apical four-chamber view the right-sided pulmonary veins (*yellow arrow*) entering the right-sided atrium and left-sided pulmonary veins (*green arrow*) draining into the left-sided atrium. (**c**, **d**) Echocardiogram with color flow Doppler demonstrates from a suprasternal view the ipsilateral pulmonary venous connection of the right-sided pulmonary veins to the right atrium and left-sided pulmonary veins to the left atrium

form of heterotaxy syndrome. Midline defects such at anal stenosis or atresia occur exclusively in patients with right atrial isomerism. Pyloric stenosis can occur in patients with left atrial isomerism.

Intestinal rotation abnormalities are defined as any aberration of arrangement in left-right axis of abdominal organs that deviate from complete situs solitus or situs inversus. The most common intestinal rotation abnormality is malrotation which can affect the foregut or more commonly the midgut. Estimates in the literature indicate that approximately 33–90 % of children with heterotaxy syndrome have some form of intestinal malrotation, and the incidence is equal in all forms of heterotaxy (both right and left isomerism) [33–36]. The broad range in incidence estimates can be explained by inconsistent definitions of malrotation, lack of diagnostic investigations that are easily interpretable with high sensitivity

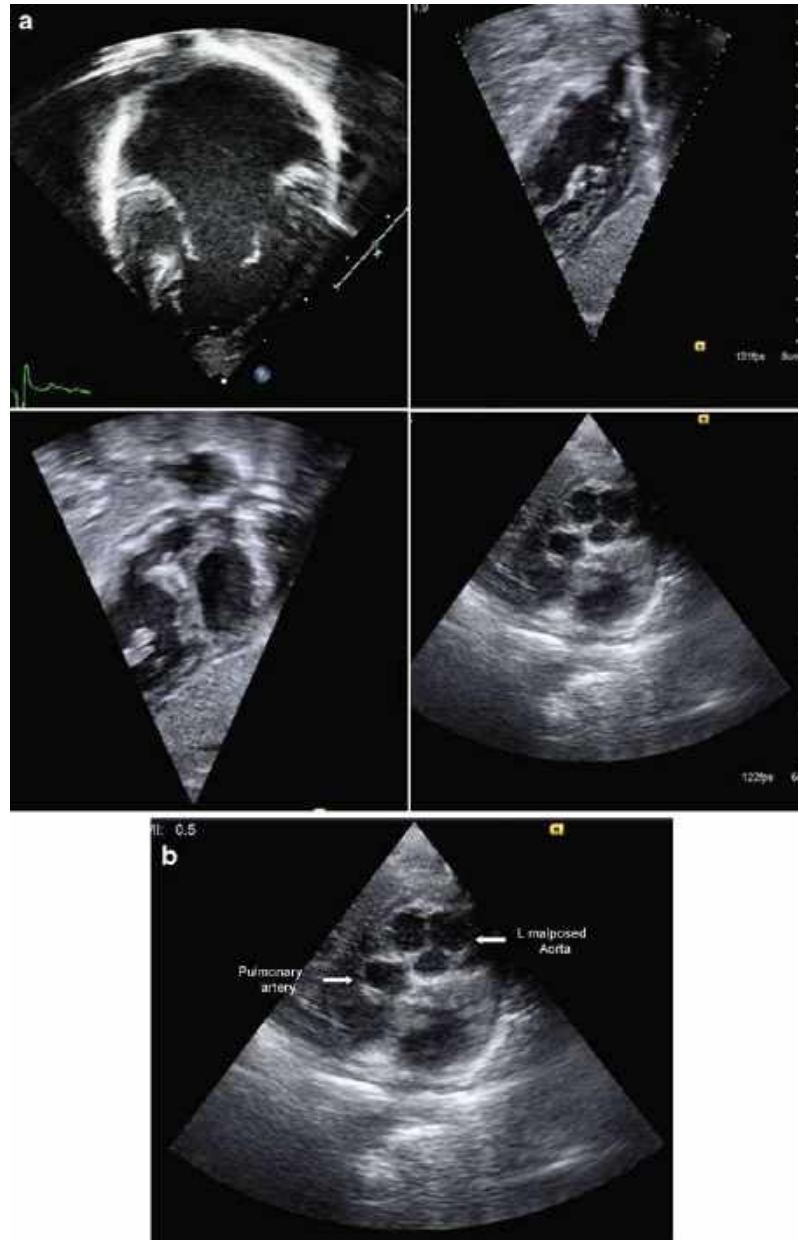

Fig. 105.11 (**a**, **b**) Unbalanced atrioventricular septal defect with hypoplastic right-sided ventricle, with *L*-malposed aorta, and subpulmonic stenosis is demonstrated in an echocardiogram of a patient with right atrial isomerism. There is a common atrium

and specificity, and the lack of universal screening for malrotation in all patients with heterotaxy syndrome.

Malrotation carries an uncertain risk of developing life-threatening midgut volvulus. However, most patients will not develop volvulus and there is no place for prophylactic Ladd's procedure, but rather careful follow-up and a high index of suspicion to intervene if symptoms develop [36].

Biliary atresia is an important manifestation of left atrial isomerism and may be associated with absence of the gallbladder and pancreatic abnormalities. Ten to 35 % of children with biliary

atresia also have left atrial isomerism, and conversely approximately 20 % of patients with left atrial isomerism will have biliary atresia. Biliary atresia in left atrial isomerism has been treated with the Kasai operation and liver transplantation [37].

Fourteen percent of patients with right atrial isomerism have hiatal hernias. If severe, defects can be diagnosed prenatally on routine ultrasound. However, these anomalies rarely cause lung hypoplasia. Small- or moderate-sized defects may present at any time during childhood with symptoms of gastroesophageal reflux or vomiting (47 %), recurrent bronchiolitis or pneumonia (41.2 %), and upper gastrointestinal bleeding (11.8 %) [38]. Albeit there is no significant impact on mortality of patients with hiatal hernias, this diagnosis carries significant morbidity. Fundoplication and correction of the defect can be performed if the patient is symptomatic.

Ticho et al. report a 14 % incidence of genitourinary anomalies in patients with heterotaxy syndrome [33]. Observed defects include hypoplastic or absent kidneys, horseshoe kidney, hypospadias, urethral duplication, uterus anomalies (bicornuate, duplicated, unicornuate), and vaginal duplication or atresia.

Craniofacial defects occur in approximately 9 % of heterotaxy patients [33]. These anomalies include cleft lip and palate, agnathia, micrognathia, choanal atresia, high-arched palate, laryngeal cleft, and cyclopia.

The central nervous system midline defects can occur at a reported incidence of 7 %. These defects include, but are not limited to, meningomyeloceles, cerebellar agenesis, encephalocele, Dandy-Walker cysts, porencephalic cysts, holoprosencephaly, diplomyelia, and hydromyelia.

Midline fusion of the adrenal glands occurs in 10 % of patients with right atrial isomerism. Unilateral adrenal atresia has also been reported [24]. These patients do not appear, however, to have any clinical consequences as a result of these anomalies, and they are often only recognized postmortem.

Finally, the musculoskeletal system may be involved with midline anomalies. Most commonly, this is manifested as kyphosis or scoliosis, occurring with an incidence of 5.5 %. Scoliosis presents in the neonatal period in up to half of the cases and can be severe and debilitating. Other anomalies include pectus deformities, vertebral anomalies (hemivertebra, fused vertebra), or sacral anomalies (bifid or sacral agenesis) [24, 33].

Extracardiac manifestations of left and right atrial isomerism are common and contribute to mortality and morbidity. Thus, these patients may benefit from preemptive diagnosis and multidisciplinary follow-up and management [39, 40].

Management and Outcomes

The management of patients with heterotaxy syndrome depends on the specific cardiac defects and the associated extracardiac anomalies [39, 40]. Almost all children with right atrial isomerism will have complex congenital heart lesions and will require palliation in the newborn period. If pulmonary blood flow is duct dependent, the usual palliation consists of an aortopulmonary or ventricular-to-pulmonary artery shunt, with a subsequent progression along a staged pathway through the Glenn- and the Fontan-type operations. The presence of systemic venous anomalies and pulmonary venous anomalies complicates each step and requires thorough anatomical evaluation and, often, innovative surgical approaches. A particular constellation with an especially poor outcome is pulmonary atresia or stenosis with anomalous and obstructed pulmonary veins. The relative dominance of each lesion may be difficult to appreciate in the neonatal period while pulmonary vascular resistances are changing. For instance, the presence and degree of pulmonary vein obstruction may be challenging to ascertain in the presence of reduced pulmonary blood and may be unmasked by a change in pulmonary vascular resistance or following a surgical shunt as pulmonary blood flow increases. Patients may be exceedingly labile postoperatively with episodic pulmonary vasoconstriction and overcirculation with decreased systemic blood flow. Neonates with pulmonary atresia and pulmonary vein obstruction or hypoplasia

have a high mortality. The presence of atrioventricular valve regurgitation can be particularly difficult to manage. Atrial arrhythmias are common with even minor interventions. Postoperative low cardiac output syndrome, with atrioventricular valve regurgitation associated with atrial arrhythmias, poses particular challenging postoperative management with often incompatible medical therapies. This scenario has prompted many to consider immediate or early use of mechanical life support for the first 72 h postoperatively [41].

Outcome

The long-term outcome of patients with right atrial isomerism is poor and for patients with a single ventricle worse than with left atrial isomerism [39, 40]. The 25 year survival is approximately 30 % overall. However, the mortality for patients requiring a neonatal cardiac surgery was 75 % versus 51 % for those patients receiving first operations later in life. Attrition is particularly high in neonates requiring repair of the pulmonary veins with or without a surgical systemic to pulmonary shunt, with a mortality of 95 %. The mortality rate in subsequent series has decreased with the use of extracorporeal life support, but it remains nevertheless around 50 %. Independent risk factors for death in neonates with right atrial isomerism include absence of pulmonary outflow tract obstruction, presence absence of severe atrioventricular valve regurgitation, and obstructed pulmonary veins. Progressive pulmonary vein stenosis may occur and severely limits any effective treatment strategy. For neonatal survivors with atrial isomerism and heterotaxy, the rate of Fontan completion has increased from 22 % with 21 % surgical mortality to 86 % early survival and 83 % survival at 5 years after the total cavopulmonary anastomosis is achieved [42].

Cardiac transplantation has been performed in patients with atrial isomerism, and for those transplanted at 3 years following previous cardiac surgery, the 10-year graft survival is 50 %.

The outcome of patients with left atrial isomerism is influenced by the severity of the cardiac malformations and the presence of extracardiac malformations [40]. Gilljam et al. reported a 28-year experience from 1970 to 1998. Of the 22 patients with a normal heart, 18 % died from extracardiac anomalies. Overall survival rate of 163 patients was 80 %, 68 %, 59 %, and 51 % at 1 month, 1 year, 5 year, and 15 years, respectively. In patients with nearly structurally normal hearts, survival was 82 %. In patients with balanced ventricles who could undergo biventricular repair, survival was 66 % and for those who required single ventricle surgical staging, survival was 37 % at 20 years. Described cardiac factors independently associated with increased mortality are complete atrioventricular block, single ventricle, and coarctation of the aorta. Survival may also be influenced by three extracardiac diagnoses, namely, biliary atresia (with a survival of only

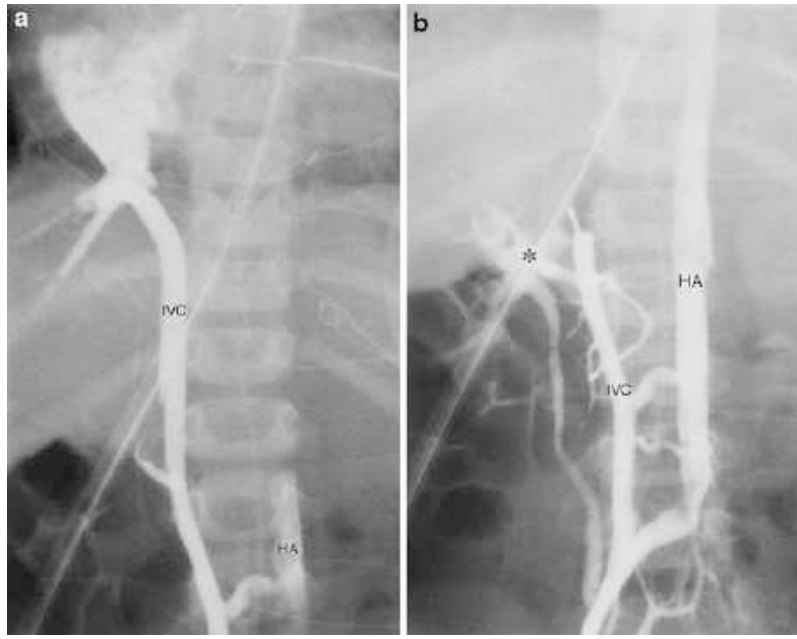

Fig. 105.13 (**a**) Inferior vena cavogram after a Kawashima operation shows hemiazygos (*HA*) continuation of IVC with persistence of patent but underdeveloped IVC, which causes cyanosis by decompressing pulmonary artery blood to the common atrium. (**b**) Balloon occlusion inferior vena cavogram in the underdeveloped IVC is required to show persistence of the renal-portal-hepatic venous plexus (*) providing another pathway to decompress the pulmonary artery and cause a right-to-left shunt. *HA* hemiazygos (Reproduced with permission pending from reference 45)

31 %), low birth weight, and other important gastrointestinal malformations.

Patients with left atrial isomerism may have normal cardiac anatomy or minor lesions and are diagnosed by the finding of an azygous continuation of the suprarenal IVC. However, patients with ductal-dependent systemic circulations require modifications of the Norwood operation and have a higher mortality.

Cavopulmonary surgery is complicated by azygous continuation of the IVC. The Kawashima modification of the cavopulmonary anastomosis directs all systemic venous return to the lungs with the exception of the hepatic venous blood. These children are prone to develop pulmonary arteriovenous malformations, and redirection of hepatic blood flow may be required to reverse the resulting severe cyanosis [43]. In addition, unusual venovenous collaterals that steal blood from the pulmonary arterial circulation and cause right-to-left shunting by a connection with the atrium or pulmonary veins seem to be more frequent in patients with heterotaxy, especially left atrial isomerism. Often, this involves persistence of the hepatic venous plexus. Balloon occlusion angiography low in the azygous or IVC may be required to delineate these connections (Figs. 105.12 and 105.13) [44, 45].

The outcome of patients with atrial isomerism is best assessed from population data at birth or in utero because surgical series distort the true outcomes by analysis of highly selected groups. When population data from diagnosis at birth is considered, then patients with right atrial - isomerism have a very poor prognosis [46].

Conclusions

Congenital cardiac malformations associated with atrial isomerism and visceral heterotaxy are among the most challenging to manage. Comprehensive, systematic cardiac and

extracardiac evaluation is important. Although in recent cohorts there is improved survival, the long-term outcome for patients with a single ventricle, especially if requiring neonatal surgery for pulmonary vein anomalies, remains poor. However, optimistically, in a selected population of patients with atrial isomerism who survived to Fontan completion, exercise tolerance and quality of life indicators were similar between those with and without heterotaxy [47].

Single Ventricle (Non HLHS) 106

Puja Banka, Diego Porras, John E. Mayer, and Sitaram M. Emani

Abstract

Patients with certain forms of congenital heart disease other than hypoplastic left heart syndrome require surgical management with single ventricle palliation. Anatomic considerations distinguish this group of patients from those with hypoplastic left heart syndrome. The initial evaluation, considerations for staged palliation, and postoperative management are discussed.

Keywords

Aortopulmonary amalgamation • Bidirectional Glenn procedure • Bulboventricular foramen • Damus-Kaye Stansel anastomosis • Fontan procedure • Hemi-Fontan procedure • Heterotaxy syndrome • Norwood procedure • Single ventricle palliation

Introduction

Patients with certain complex cardiac malformations, alike those with hypoplastic left heart syndrome (HLHS) anatomy, may require management with single ventricle palliation due to hypoplasia of one ventricle, atresia or severe hypoplasia of one atrioventricular (AV) valve, or anatomy that is deemed unsuitable for biventricular repair due to complexity of reconstruction. Patients with ventricular hypoplasia can be characterized according to the dominant ventricle (right or left). The diagnoses listed below are among most commonly encountered forms of heart disease that require single ventricle palliation, but many others may present with lower frequency:

1. Tricuspid atresia (dominant left ventricle (LV) or right ventricle (RV))
2. Pulmonary atresia with intact ventricular septum, RV-dependent coronary circulation, and hypoplastic right ventricle (dominant LV)
3. Double inlet ventricle (dominant LV or RV)
4. Severely unbalanced atrioventricular (AV) canal defect (dominant LV or RV)

5. Straddling AV valve
6. L-loop transposition of the great arteries with pulmonary atresia and univentricular hypoplasia
7. Double outlet right ventricle with mitral atresia

This chapter describes the classification, imaging, surgical treatment, and postoperative care for this group of patients.

Classification/Anatomy

Since the spectrum of anomalies that encompass single ventricle anatomy are myriad and complex, careful determination of the anatomic details is critical to allow for appropriate medical and surgical therapy. A segmental approach is the preferred means of describing the various anatomic structures and their relationships.

A detailed review of the segmental approach is beyond the scope of this chapter. In brief, each segment of the heart is described by its typical morphological characteristics to allow determination of atrial situs, ventricular morphology and looping, semilunar valve configuration, and the relationship between these segments. For example, atrial morphology can be determined by examining the position and drainage of the major horns of the sinus venosus, the configuration of septum primum and secundum, morphology of the appendages, and the extent of the pectinate muscles. Situs solitus of the atria exists when the right atrium is right-sided and inversus when it is left-sided. Ventricular morphology can similarly be established using the typical characteristics of each ventricle (e.g., smooth superior septal surface of the left ventricle, and the presence of a moderator band and coarse trabeculations in the right ventricle) and looping (determined by the principal of chirality). Semilunar valve relationships and conal anatomy can be codified and atrioventricular and ventriculo-arterial alignments and connections described. Finally, associated anomalies such as abnormalities of venous drainage, septal defects, valve pathology, and abnormal arterial connections can be assessed to provide a complete description of the intracardiac and extracardiac vascular anatomy. The anatomy and classification of the most common congenital cardiac conditions are described below.

Tricuspid Atresia

This lesion is defined by atresia of the tricuspid valve but varies in the ventriculo-arterial alignments, presence and size of the ventricular septal defect, and degree of ventricular outflow tract obstruction. The defect is classified according to the ventricular-great vessels relationship:
Type 1 – normally related great vessels
Type 2 – D-transposed of the great arteries
Type 3 – L-transposed of the great arteries

Further classification depends on the presence or absence of ventricular septal defects and ventricular outflow tract obstruction.

Pulmonary Atresia with Intact Ventricular Septum

The spectrum of disease with this abnormality includes variable degrees of hypoplasia of the right ventricle and tricuspid valve stenosis or atresia. Mild forms of the disease with isolated membranous atresia of the pulmonary valve are amenable to biventricular repair. Patients with tricuspid inflow and a significantly hypoplastic RV cavity will often have significant sinusoids or fistulae that allow communication between the RV and the coronary artery system. When severe, the coronary flow becomes dependent on these sinusoids, and patients with this anatomy have a poor outcome with RV decompression and are not candidates for biventricular repair.

Double Inlet Ventricle

The anatomy of double inlet ventricle is characterized by both atria connecting to the single ventricular chamber either via a single or two separate AV valves. Most often, the ventricular morphology is that of a dominant left ventricle

which communicates with an outflow chamber via a bulboventricular foramen. The great vessels can be transposed with ventriculo-arterial discordance (more common) or normally related with ventriculo-arterial concordance (less common, termed "Holmes heart"). A more unusual configuration of double inlet ventricle is that of a single right ventricle with both atrioventricular valves committed to the single RV and both outflow tracts also arising from this ventricle.

Unbalanced AV Canal Defect

There are no strict criteria for defining unbalanced AV canal defect, although ventricular size and distribution of common AV valve over each ventricle (AVVI) can be used to determine relative imbalance [1]. It can be associated with normal segmental anatomy or variations including situs inversus, L-looping, and heterotaxy syndrome. Trisomy 21 is a common association in patients with normal segmental anatomy and AV canal defect.

Presentation/Diagnosis

In the current era, diagnosis is often made in utero by fetal ultrasonography and confirmed by fetal echocardiography. For patients without a prenatal diagnosis, presentation is usually within the first few weeks of life as ductal closure results either in pulmonary or systemic hypoperfusion. Severe systemic hypoperfusion manifests with poor feeding, tachypnea, hypertension, and acidosis. Intestinal malperfusion may result in necrotizing enterocolitis with abdominal distension and bloody stools. On physical examination, weak or absent distal pulses, poor capillary refill, and cool skin tone are common. The chest X-ray may demonstrate pulmonary edema due to congestive heart failure. A less debilitating form of postnatal presentation is development of pulmonary over-circulation due to unrestrictive pulmonary blood flow with or without obstruction to systemic outflow. These neonates and infants present with tachypnea, failure to thrive, and are found to have oxygen saturations greater than 90 % suggesting elevated pulmonary to systemic blood flow (Qp/Qs) ratio. Pulmonary hypoperfusion in patients with ductal dependent pulmonary circulation presents with cyanosis, and chest X-ray will demonstrate origami lung fields.

Echocardiography

Initial Assessment

A thorough and accurate initial echocardiogram, defining the segmental anatomy and performing a detailed assessment of the various cardiac segments, connections, valves, and septa with particular focus on discrete components of interest, is critical to the subsequent care of patients with single ventricle physiology.

Systemic and pulmonary venous anatomy must be defined in detail. The drainage of individual pulmonary veins must be assessed to exclude both partially and totally anomalous connections. This is particularly important in the case of totally anomalous connections as this can alter initial management. If present, therefore, the pathway of drainage must be delineated and areas and degree of obstruction noted. Systemic venous anomalies must also be examined as these have implications both for catheterizations as well as the second and third palliative surgeries. Of note, both systemic and pulmonary venous anomalies are more common in patients with heterotaxy syndrome.

Assessment of the atrial septum for presence and size of defects is particularly important in patients with atresia of one of the atrioventricular valves (such as in double outlet ventricle with mitral atresia) where the atrial septal defect may provide the only egress for blood flow from one of the atria. Atrioventricular valve size (normalized to body surface area), morphology, and function should also be carefully assessed and, if present, degree of mechanism of regurgitation delineated. 3D imaging can be helpful for the latter in select cases. Size and location of ventricular septal defects or the bulboventricular

foramen is also important, especially in patients in whom either systemic or pulmonary blood flow is dependent on the size of these defects.

Since dominant ventricular morphology (right vs. left) and function can have implications for long-term outcome and mortality, assignment of ventricular dominance can be important. Furthermore, assessing ventricular looping is also a key part of the initial echocardiogram as patients with L-looped ventricles are at long-term risk of spontaneous heart block which is exacerbated by procedures such as catheterizations and must be considered in the risk-benefit analysis of performing interventions.

In order to assess the need for and details of any neonatal palliations, determining the adequacy of systemic and pulmonary blood flow is essential. This includes assessment of the subvalvar region such as the conus and conal septum, semilunar valve size (normalized to body surface area) and morphology, and valvar function. Patients with significant subvalvar and valvar obstruction to systemic outflow, for example, may be candidates for an aortopulmonary anastomosis, whereas those with isolated aortic arch obstruction may be able to forego the aortopulmonary anastomosis in place of arch augmentation alone. Size and configuration of the aortic arch, as well as risk for evolution of arch obstruction should be assessed, particularly in patients with systemic outflow obstruction. Size and continuity of the branch pulmonary arteries is particularly important to evaluate in patients with single ventricle in anticipation of future Fontan completion. Although rare, discontinuous pulmonary arteries must be specifically excluded. Additional sources of pulmonary blood flow such as patent ductus arteriosus (PDA) or aortopulmonary collateral vessels should also be delineated. Finally, coronary artery origins should be interrogated to exclude the rare coronary anomaly such as a coronary artery from the pulmonary artery.

Follow-up Echocardiograms

Follow-up studies are generally targeted at assessing for changes in ventricle and valvar function, evaluating postoperative anatomy such as the site of prior cavopulmonary anastomosis, or identifying hemodynamic lesions that need attention. These are particularly important in the face of symptoms such as feeding intolerance, poor weight gain, or respiratory distress or in anticipation of catheter or surgical procedures. The specific imaging protocol will depend on the anatomic details and prior interventions. For instance, in patients with an unbalanced AV canal defect prior to superior cavopulmonary anastomosis, changes in common AV valve function and determination of regurgitation mechanism may be paramount prior to surgical palliation, in order to determine the need for and plan any surgical AV plasty. By contrast, in patients with a double inlet left ventricle with transposed great vessels who have undergone a prior stage 1 palliation including arch reconstruction, exclusion of residual arch obstruction may be an important part of the imaging protocol, especially when faced with a child who is failing to thrive or has new ventricular dysfunction. After Fontan completion, periodic echocardiograms are important for longitudinal follow-up and early identification of abnormalities requiring intervention.

Advanced Cardiac Imaging

Echocardiography remains the primary imaging modality for patients with single ventricle pathology due to its excellent spatial and temporal resolution, easy accessibility, and its ability to assess the hemodynamic burden of associated anomalies such as arch obstruction via the use of Doppler. However, in selected cases, cardiac computed tomography (CT) and magnetic resonance imaging (CMR) may provide adjunctive data, with CMR preferred when possible for most patients in order to avoid exposure to ionizing radiation. For instance, for patients with pulmonary venous anomalies where echocardiography is unable to clearly delineate the drainage of all pulmonary veins, CT or CMR angiography can provide detailed assessment of the veins and their course. In patients with restricted acoustic windows reducing the sensitivity of echocardiography, CT and CMR can allow visualization of the intra and extracardiac

anatomy and quantification of ventricular function. The ability of CMR to quantify flow can provide information on degree of valvar regurgitation as well as aortopulmonary collateral flow, which may help guide pre- and perioperative interventions. In a subset of patients undergoing preoperative evaluation prior to stage 2 or 3 palliation, CMR (in conjunction with echocardiography) may supplant cardiac catheterization, provided interventions such as pulmonary artery or aortic arch balloon dilation or collateral embolization are not required. Finally, CMR may also have a role in longitudinal follow-up of single ventricle patients by allowing not only visualization of Fontan pathways and vasculature, as well as quantification of ventricular and valvar function, but also providing a means for assessing myocardial viability and detecting thrombus, all of which may have implications for long-term outcomes. In patients in whom the presence of metallic artifacts (such as by stainless steel coils) or pacemaker dependency precludes CMR, CT may be used for assessment of ventricular function and visualization of Fontan pathways and thoracic vasculature.

Cardiac Catheterization

Diagnostic catheterization is occasionally necessary in the evaluation of the child with a new diagnosis of single ventricle lesion. Patients with pulmonary atresia and intact ventricular septum deserve catheterization to evaluate the presence of coronary sinusoids and proximal coronary artery atresia or stenosis. Delineation of PA anatomy may be necessary if echocardiography raises suspicion for discontinuous pulmonary arteries. Diagnostic catheterization solely for the purposes of measuring pulmonary vascular resistance or Qp:Qs is rarely necessary in the neonate, although patients who present beyond infancy with unguarded pulmonary blood flow would benefit from evaluation of pulmonary artery pressures and resistance, particularly if the first procedure contemplated is a cavopulmonary shunt.

Management Strategies

Single Ventricle Management

The ultimate goal of this strategy is to utilize the single ventricle for systemic perfusion while depending upon passive drainage of venous return from the upper and lower extremities for pulmonary blood flow. Attainment of this circulation may require staged surgical procedures. The need for neonatal palliation depends upon the state of the systemic and pulmonary perfusion. Typically, palliation in a child 4–6 months of age involves creation of a superior cavopulmonary anastomosis and is termed "second" stage procedure. Finally, between 2 and 4 years of age, creation of an inferior cavopulmonary anastomosis completes the Fontan circulation.

Biventricular Repair

In certain anatomic configurations, the decision to pursue single ventricle versus two ventricle repair can be challenging. This is particularly true in patients with mildly unbalanced AV canal defect or two near normal-sized ventricles but straddling valvular apparatus or criss-cross AV valve anatomy necessitating complex intracardiac baffling. Single ventricle management carries a low but predictable mortality, whereas biventricular repair may carry significant operative risk [2]. On the other hand, single ventricle physiology may be poorly tolerated long term in patients with borderline anatomy and noncardiac comorbidity such as trisomy 21 and heterotaxy syndrome [3–5]. In these patients, a biventricular repair may be preferred over single ventricle management due to concerns over long-term survival [4, 6]. Although there are several tools to help inform the decision by predicting the risk of biventricular repair based upon anatomic criteria, none of these have been widely validated in a prospective clinical trial [7, 8]. Initial single ventricle palliation does not

preclude eventual biventricular conversion, so it is possible to pursue single ventricle management in a neonate with borderline anatomy with the intention of eventual biventricular conversion when the child is larger and the anatomy is more amenable to biventricular repair [9, 10].

Cardiac Transplantation

Although most centers do not advocate primary cardiac transplantation over staged single ventricle management in patients with uncomplicated single ventricle anatomy, there are certain situations in which transplantation should be considered. Patients with pulmonary atresia and intact ventricular septum with coronary ostial atresia have over 50 % mortality with a Blalock-Taussig shunt procedure and are managed at the institution by maintenance of prostaglandins and primary cardiac transplantation [11]. Similarly, single ventricle neonates with significant AV valve regurgitation have increased mortality, and valvular repair has low durability [12]. Unfortunately, wait list mortality is significantly elevated, and there are very few options to provide bridge to cardiac transplantation [13]. The experience with ventricular assist devices in neonatal patients as a bridge to transplant is limited and also carries a high mortality.

Transplantation may be an option for a patient with failing single ventricle physiology who has undergone neonatal, stage II, or Fontan palliation. Some centers have advocated transplantation as an alternative to the Fontan procedure following stage II palliation in high-risk Fontan candidates [14]. Patients with protein-losing enteropathy following the Fontan procedure may experience resolution with cardiac transplantation [15].

Single Ventricle Management Versus "One and a Half Ventricle" Management

In certain patients, the intracardiac anatomy is well suited for maintenance of pulmonary blood flow from an anatomic pulmonary ventricle (often RV) in addition to cavopulmonary anastomosis. The strategy, termed "one and a half ventricle" management, is most commonly employed for patients with pulmonary atresia and intact ventricular septum with patency but hypoplasia of the pathway between the right atrium and the main pulmonary artery. Right heart structures are unable to support a full cardiac output, but may be able to handle inferior vena caval blood flow. A bidirectional Glenn anastomosis provides pulmonary blood flow while reducing the volume load on the right heart. The advantage of this circulation over pure single ventricle circulation lies in the ability for the RV to contribute to pulmonary flow and energetics, which reduces dependency upon passive flow through a Fontan circulation [16].

Initial Palliation (Neonates and Infants <4 Months)

The need for a procedure in the neonate and young infant is determined by balance of pulmonary and systemic blood flow. This balance is typically determined by clinical measures and direct physiologic measurement, with a reasonable range for Qp:Qs between 1:1 and 2:1. The patient who presents postnatally with profound systemic or pulmonary hypoperfusion is stabilized by initiation of prostaglandin infusion, intubation, and inotropic support. Once stabilized, further definitive management can be pursued. Inadequate pulmonary blood flow is palliated with a systemic to pulmonary shunt, whereas inadequate systemic blood flow is managed either with pulmonary artery banding or aortopulmonary amalgamation. In patients with a large PDA and VSD, the adequacy of the LVOT may be difficult to assess by echocardiography (see above), and adequacy may be assessed following discontinuation of prostaglandins. Careful monitoring warranted following discontinuation of prostaglandins, as decreased systemic perfusion may result from development of coarctation or LVOT obstruction. Total

anomalous pulmonary venous drainage must be delineated as it may affect neonatal surgical palliation. Theoretically, unobstructed total anomalous pulmonary venous connection does not require neonatal surgical correction; however, these patients are at high risk for rapid progression of obstruction in the interstage, and therefore, repair with anastomosis to the common atrium at the time of neonatal palliation is preferred.

Nonsurgical Interventions

Ductal Stenting

Neonates with ductal dependent pulmonary blood flow require a stable source of pulmonary blood flow. Although this has traditionally been achieved through surgical shunt placement, increasing expertise with catheter-based interventions has led many centers to pursue ductal stenting as the preferred method of stabilization of pulmonary blood flow. Factors that limit feasibility of this approach include tortuosity of the ductus, presence of branch pulmonary stenosis, and size of the introducer system relative to the patient [17]. Pulmonary atresia with intact ventricular septum tends to be associated with an extremely tortuous ductus, and this is less amenable to effective stent placement.

Stent Placement Within the Ventricular Septal Defect or Bulboventricular Foramen

There has been recent experience with placement of a stent within the systemic ventricular outflow tract, particularly in non-neonatal patients with tricuspid atresia [18]. Stent fracture continues to be a problem with this approach but may help avoid surgical intervention in selected patients.

Balloon Atrial Septostomy

Patients with restrictive atrial septal defect may develop either systemic or pulmonary venous hypertension, which necessitates intervention. Balloon septostomy, blade septectomy, and stent placement are the most commonly utilized techniques [19]. These techniques are most effective in neonates and infants with thin interatrial septa.

Surgical Intervention

Neonatal Surgical Procedures

Systemic to PA Shunt

Augmentation of pulmonary blood flow may be required in neonates with decreased pulmonary blood flow. This can be achieved either via a placement of an aortopulmonary shunt or interventional methodology (see above). Historically, the classic Blalock-Taussig (BT) and Waterston shunts resulted in progressive increase in the amount of pulmonary blood flow over time, which is not desirable in the current era of staged palliations. Surgical options for pulmonary blood flow include modified Blalock-Taussig (BT) shunt (tube graft from innominate artery to PA) or central aortopulmonary shunt. Although several centers have described favorable experience with central aortopulmonary shunts, distortion of the pulmonary arteries and the graft have limited its use [20].

In a patient with a left aortic arch, a right BT shunt is preferred since the pathway between the innominate artery and the right PA (to the right of the ascending aorta) is unobstructed, whereas in a patient with a right aortic arch, a left modified BT shunt lays more favorably. Although BT shunts have been placed through right or left thoracotomy approaches, most centers perform a median sternotomy to reduce the risk of PA distortion associated with thoracotomy approach. [21]. Typically this can be performed without the use of cardiopulmonary bypass, although neonates with severe cyanosis may not tolerate temporary occlusion of the right PA. A 3.5 mm Gore-Tex tube graft is typically utilized for a neonate between 3 kg and 4 kg and is sewn into the distal portion of the innominate artery [22]. In a patient with left aortic arch and aberrant right subclavian artery, placement of a right modified BT shunt from the right carotid artery is not

desirable since it may compromise cerebral blood flow and reduce the amount of pulmonary blood flow. In this situation, a central shunt or a left modified BT shunt is preferred. Management of the PDA at the time of shunt placement is controversial, with many centers advocating ligation to prevent competitive flow and potential increased risk of shunt thrombosis. Others have shown that it reduces postoperative resuscitation in the situation of acute shunt thrombosis [23]. The mortality rate after the neonatal modified Blalock-Taussig shunt is between 7 % and 10 %, and risk factors for mortality include weight less than 3 kg and diagnosis of PA/IVS [11, 24].

PA Banding

Patients with unobstructed systemic and pulmonary outflow tracts (Holmes heart, unbalanced AV canal defect with large ventricular septal defect) may eventually develop elevated pulmonary blood flow and over-circulation and require restriction of pulmonary blood flow if they demonstrate symptoms of failure to thrive attributable to congestive heart failure. Prior to PA banding, one must ensure that the systemic outflow tracts are truly unobstructed. Congestive heart failure symptoms may be precipitated by systemic outflow tract obstruction in a patient with patent pulmonary outflow tract. A gradient may not be detected either by echocardiography or by blood pressure measurement in a patient with significant left ventricular outflow tract or aortic arch obstruction due to low systemic blood flow in the presence of unobstructed pulmonary outflow. However, placement of a PA band may unmask the presence of systemic outflow tract obstruction, and the patient may struggle due to increased afterload on the single ventricle. Careful evaluation of the absolute size of left heart structures with normalized Z scores is preferable to reliance upon gradients in making the decision to place a PA band. Special consideration must also be given to patients with pulmonary or systemic outflow tract dependent upon flow through a ventricular septal defect or bulboventricular foramen (see below).

At surgery, a thoracotomy or sternotomy approach is utilized. Several formulae have been described to determine the circumference of the PA band based upon diagnosis, but most surgeons preferred to adjust the band according to physiology in the operating room [25]. The band is loosely placed and tightened until the desired effect is achieved, a QP:QS ratio of between 1:1 and 2:1. This may require several manipulations and intraoperative measurement of systemic and mixed venous oxygen saturations (see below). Of note, the calculation of Qp:Qs using Fick method is valid only in patients who demonstrate adequate mixing at the atrial level. In patients with transposition physiology and straddling tricuspid valve managed with single ventricle strategy, disadvantageous streaming results in significantly more hypoxemia than would be expected for a given value of Qp:Qs. These patients may require maneuvers to optimize atrial level mixing (see below) and a slightly looser PA band. The PA band must be placed in such a way so as to avoid impingement upon the pulmonary valve or branch pulmonary arteries. Typically, the band material is a reinforced Silastic strip that is encircled around the PA several millimeters proximal to the bifurcation of the main PA. Once the final band diameter is achieved, several retention sutures are placed between the adventitia of the main PA and the band material, to prevent distal migration of the band.

Surgical Stage 1 Procedure

Patients with inadequate systemic blood flow associated with restrictive bulboventricular foramen or hypoplasia of the LVOT, aortic valve, or ascending aorta require aortopulmonary amalgamation and arch reconstruction (stage 1 procedure, Fig. 106.1) in order to provide a reliable outflow from the functional single ventricle into the systemic circulation. An aortopulmonary amalgamation (Damus-Kaye-Stansel or DKS) anastomosis should also be considered as anticipatory management in patients with systemic outflow dependent upon a bulboventricular foramen that is unrestrictive (see Special Considerations below).

The stage I procedure is performed through a median sternotomy with cardiopulmonary bypass. A Gore-Tex tube graft may be sewn end

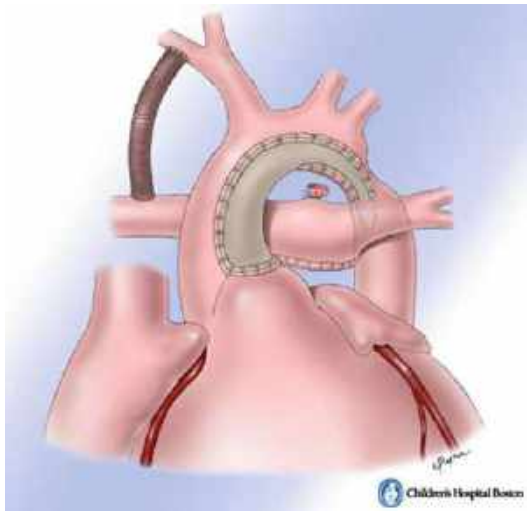

Fig. 106.1 Stage 1 procedure (Norwood operation) for single ventricle palliation. Aortopulmonary amalgamation, aortic arch reconstruction, atrial septectomy, and right modified BT shunt are key components of the repair

to side onto the innominate artery for systemic arterial perfusion, regional cerebral perfusion, and delivery of cardioplegia. For patients undergoing BT shunt, this graft will subsequently serve as the source of pulmonary blood flow. Although a brief period of circulatory arrest is necessary, attempts should be made to perform much of the arch reconstruction with antegrade regional cerebral perfusion. The arch reconstruction may be performed with homograft material, autologous pericardium, or native tissue. Resection of the coarctation segment reduces the risk of recurrent coarctation [26].

Options for Pulmonary Blood flow: The options for pulmonary blood flow at the time of surgical stage 1 procedure include a BT shunt (Fig. 106.1) or ventricle to PA (PA) conduit (Fig. 106.2). In the recent randomized SVR trial comparing BT shunt to ventricle-PA conduit, transplantation-free survival 12 months after randomization was higher with the ventricle-PA conduit than with the BT shunt (74 % vs. 64 %), although this difference did not persist beyond 12 months, and ventricle-PA group had more unintended PA interventions [27]. In a single left ventricle, placement of a ventricle-PA shunt raises several concerns. Most surgeons are reluctant to perform a left ventriculotomy in patients with a single left ventricle due to concerns of deterioration in ventricular function, although there is no data to support this practice [28, 29]. In a patient with dominant left ventricle, anteriorly located infundibular chamber, and a restrictive ventricular septal defect, placement of a ventricle to PA conduit arising from the infundibular chamber may lead to reduction in pulmonary blood flow as the VSD becomes restrictive. Careful identification of the left ventricular body either by inspection through the pulmonary valve or the atrium ensures appropriate placement of the conduit into the ventricle that is less likely to become obstructed over time. Nevertheless, the preference in patients with a single left ventricle is placement of a BT shunt (see above).

Placement of ventricle-PA conduit coursing to left of the neoaorta avoids its position behind the sternum, which reduces the risk of sternal reentry. In contrast, conduit placed to the right of the aorta traverses just behind the sternum but is much easier to dissect at the second stage procedure, as the window between the aorta and the superior vena cava is more centrally located. Over the past few years, a technique for transmural conduit implantation utilizing a externally reinforced Gore-Tex tube has been utilized that limits the size of the ventriculotomy as well as prevents obstruction due to muscular ingrowth on the endocardial surface of the ventricle (Fig. 106.2) [30]. Hospital mortality following stage 1 procedure ranges from 10 % to 20 %, with socioeconomic status, noncardiac abnormalities, aortic atresia, unbalanced AV canal defects, and AV valve regurgitation being significant risk factors for increased mortality [31–33]. There is data to suggest that non-HLHS single ventricle malformations carry worse prognosis than HLHS [34].

Hybrid Stage 1 Procedure

Patients with ductal dependent systemic blood flow who would typically undergo traditional stage 1 palliation may be candidates for hybrid stage 1 palliation. This strategy consists of placement of bilateral branch PA bands and a stent within the PDA. This approach may be the

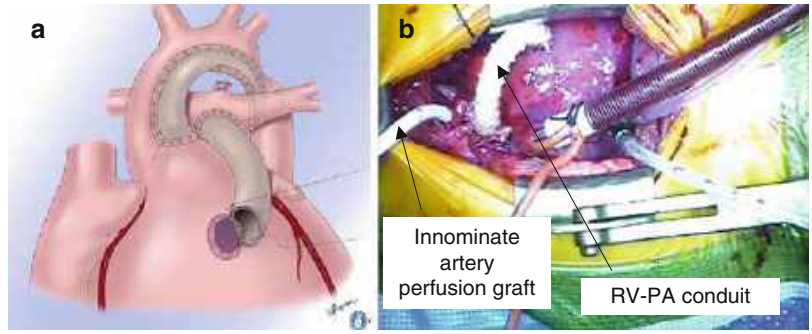

Fig. 106.2 Ventricle to pulmonary artery conduit (Sano) modification of the stage 1 procedure (**a**). Externally reinforced graft can be inserted transmurally into the right ventricle to prevent muscle bundle obstruction (**b**)

lower risk option for patients who are unsuitable for cardiopulmonary bypass, including those with intracranial bleed or significant noncardiac comorbidities. Several centers prefer this approach for any neonate who requires a stage I palliation, and outcomes are similar to traditional surgical management at midterm follow-up [35, 36]. Retrograde aortic arch obstruction is more common in patients with aortic atresia and may be treated with catheter-based approaches or surgical reverse central shunt between the main PA and innominate artery [37]. At the comprehensive stage II palliation, aortopulmonary amalgamation, arch reconstruction, superior cavopulmonary anastomosis, and atrial septectomy are performed.

Postoperative ICU Management Following Neonatal Palliation

The physiology following neonatal palliation procedures is best characterized as systemic and pulmonary circulations in parallel. Most of the postoperative monitoring and management focuses on maintaining a balance of systemic and pulmonary blood flow. The physical examination, laboratory tests, and imaging studies allow assessment of this balance and its consequences upon overall oxygen delivery.

On physical examination, peripheral vasomotor and pulse characteristics give an indication of the cardiac output. Warm and pink extremities, palpable peripheral pulses, and brisk capillary refill are suggestive of adequate cardiac output, whereas skin that is cool to touch, weak pulses, and prolonged capillary refill suggest low cardiac output. Mottled skin appearance is typically considered to be associated with poor perfusion. Cyanosis may be diffuse or primarily perioral and suggests decreased pulmonary blood flow. Acute change in clinical status should prompt evaluation of airway and air movement by chest auscultation, followed by cardiac auscultation to determine loss of shunt murmur. It is therefore imperative to have a baseline cardiac examination upon arrival to the intensive care unit for subsequent comparison. Daily chest X-rays allow for evaluation of distribution of pulmonary blood flow. Asymmetric distribution should suggest preferential flow to one lung and prompt further workup. Excessive pulmonary blood flow may manifest as hilar fullness, whereas diffuse oligemia suggests hypoperfusion and reduced pulmonary blood flow.

Laboratory evaluation of the fresh postoperative patient should include complete blood count, coagulation profile, and electrolytes. Generally, hematocrit level close to 40 is maintained to optimize oxygen delivery. Lactic acid levels and mixed venous oxygen saturation from the superior vena cava are surrogate markers of cardiac output and oxygen delivery. Increasing use of mixed venous oxygen saturation has led to improvement in outcome [38]. A gradient between the systemic arterial and the mixed venous oxygen saturation is indicative of oxygen extraction, with elevated extraction suggesting low cardiac output. The balance of pulmonary blood flow is estimated utilizing the Fick equation.

$QP/QS = (SaO2 - SVO2)/(PVO2 - SaO2)$, where SaO2 is systemic arterial oxygen saturation, SVO2 is the mixed venous oxygen saturation, and PVO2 is the pulmonary venous oxygen saturation (estimated at 97 % since it is not directly measured).

Noninvasive monitoring with near-infrared spectroscopy (NIRS) can allow surrogate assessment of mixed venous oxygen concentration and cardiac output. The advantage of this modality is the ability to measure the value continuously over time. The probe strips are placed on the forehead but also may be placed on the right flank to measure abdominal perfusion. The latter is less valuable than the former. Attention must be paid to proper placement of the NIRS probe, since midline placement on the forehead may yield artificially low values due to measurement of sagittal sinus blood. The absolute value of the NIRS may not be as important as the trend over time, and a decrease in NIRS should prompt further workup (see below). Initial calibration of NIRS can be performed by concomitant measurement of a mixed venous oxygen saturation. Intensive monitoring of venous oximetry and NIRS have been shown to improve outcomes in patients undergoing stage I palliation [39].

Decreased pulmonary function resulting in pulmonary venous desaturation may be due to atelectasis, lung collapse, or pulmonary edema. Presence of pulmonary venous desaturation will complicate estimation of the balance of pulmonary blood flow and potentially mislead overall management, since the initial reaction may be to assume that there is decreased pulmonary blood flow, when in fact there may actually be excess pulmonary blood flow leading to pulmonary edema and consequently pulmonary venous desaturation. Therefore, interventions to increased pulmonary blood flow in the setting of pulmonary venous desaturation may prove to be detrimental. Adequate tidal volumes must be ensured by assessment of ventilatory mechanics and chest radiography. Atelectasis may result from inappropriate endotracheal tube position, presence of mucus secretions within the airway, pleural effusions, or pneumothorax. Acute or significant desaturation should initially be approached by evaluation and treatment of airway and pulmonary abnormalities.

The balance of pulmonary blood flow to systemic blood flow is estimated as mentioned above, and treatment can be tailored if there is significant imbalance. Decreased pulmonary blood flow may also manifest with a significant end-tidal CO_2 to arterial CO_2 gradient, and chest X-ray may show hypoperfused lung fields. Treatment entails increasing systemic afterload with vasopressor agents (vasopressin or norepinephrine) to drive more pulmonary blood flow, or relieving obstruction to pulmonary blood flow. The obstruction to pulmonary blood flow can be further subdivided into shunt or branch PA obstruction or increased intraparenchymal vascular resistance. Any of these can present with sudden desaturation and loss of end-tidal CO_2. Shunt obstruction is almost unheard of with ventricle to PA conduit, but is more common with the BT shunt, and shunt thrombosis requires reexploration with "milking" of the shunt to evacuate clot into the distal pulmonary vascular bed. Proximal obstruction of ventricle to PA conduit may present with more gradual decrease in oxygen saturations. Distal migration of a PA band might present with unilateral hypoperfusion, although bilateral branch PA obstruction can also occur. This can be further evaluated with echocardiography or cardiac catheterization. The latter may be therapeutic as well since balloon dilation may effectively correct the abnormality. Heparinization is indicated if shunt thrombosis is suspected. Stent placement in the proximal RV to PA and shunt or in the branch pulmonary arteries may be necessary to relieve mechanical obstruction. Distal migration of the PA band is best treated with operative repositioning, although transcatheter treatment can offer temporary palliation. Reactive pulmonary vascular bed is an unlikely cause of pulmonary hypoperfusion, but may manifest postoperatively in patients who had intact atrial septum preoperatively. Treatment with nitric oxide is indicated if this etiology is suspected.

Decreasing cardiac output may similarly be subdivided into obstruction to systemic blood flow or over-circulation due to unrestrictive pulmonary blood flow. Systemic blood flow obstruction may be due to residual coarctation or neoaortic constriction at the aortopulmonary amalgamation, or subvalvar LVOT obstruction. Unrestrictive pulmonary blood flow may be managed medically with afterload reduction

(milrinone or ACE inhibitor) or maneuvers to further restrict pulmonary blood flow. The FIO_2 delivered by the ventilator should be minimized to 21 % to avoid pulmonary vasodilation. Ventilatory management to allow mild acidemia and hypercarbia may lead to mild increase in pulmonary vascular resistance which may be sufficient to augment systemic blood flow. Care must be taken when using this strategy to modulate systemic blood flow, as this could lead to decreased systemic oxygen saturations due to pulmonary venous desaturation and a false sense of adequate balance of QP/QS. Mechanical manipulation of shunt with clip placement is an alternative in a patient who continues to demonstrate pulmonary over-circulation despite maximal medical management. Oxygen delivery is maximized by maintaining a hematocrit close to 40 %. Coronary insufficiency due to restriction of the aortopulmonary connection may result in ventricular dysfunction that leads to low cardiac output. This complication is more likely to occur in patients with aortic atresia and small diameter ascending aorta. Prompt identification by cardiac catheterization and subsequent surgical relief is indicated.

The interval between neonatal palliation and second stage procedure may be characterized by instability related to shunted circulation and may manifest with failure to thrive and feeding difficulties. Placement of a gastric tube for enteral feeding may reduce the risk of aspiration and improve overall nutrition, which favorably affects growth [40, 41]. Interstage mortality has been reported as high as 10 %, with arrhythmias and ventricular dysfunction being risk factors [42–44]. Home monitoring of oxygen saturations and growth parameters has been shown to improve interstage mortality and helps determine optimal timing of the second stage procedure [45]. Development of cyanosis or failure to thrive should prompt aggressive reevaluation with echocardiography and possibly catheterization. Development of arch obstruction in the interstage may result in secondary ventricular dysfunction and should be promptly managed by transcatheter or surgical approaches to reduce mortality [46]. Afterload reduction with ACE inhibitors has not been shown to improve interstage mortality, but may be indicated in patients with AV valve regurgitation [47, 48].

Stage II Palliation

The goals of stage II palliation are to eliminate dependency of pulmonary blood flow upon systemic circulation and create upper body venous drainage into the pulmonary circulation as a prelude to total cavopulmonary shunting. The resistance of the pulmonary circulation decreases over the first several months of life, thus permitting adequate pulmonary blood flow with venous pressure alone as the driving force. The two commonly performed surgical procedures to establish the superior cavopulmonary anastomosis are the bidirectional Glenn and the hemi-Fontan procedures. The bidirectional Glenn procedure involves separation of the superior vena cava from the right atrium, and anastomosis to the right PA. The hemi-Fontan procedure not only requires superior cavopulmonary anastomosis but also prepares the anatomy for subsequent Fontan procedure by creation of atrial pulmonary connection and intra-atrial patch exclusion of the remaining atrium from the superior cavopulmonary anastomosis. The advantage of the bidirectional Glenn procedure is the ability to perform the operation without the use of cross-clamp. On the other hand, the hemi-Fontan procedure simplifies the subsequent Fontan operation.

The second stage procedure is performed between 4 and 6 months of age unless clinical scenario (desaturation) dictates earlier operation. Centers have demonstrated safety in patients as young as 2 months of age, although hospital lengths of stay are prolonged in the patients under 4 months of age [49]. The preoperative evaluation should exclude the presence of PA and aortic arch obstruction, elevated pulmonary vascular resistance, and restrictive interatrial communication. It is common for patients to develop aortopulmonary collaterals in the interstage period, although management of collaterals with coil occlusion prior to second stage differs among institutions [50–52].

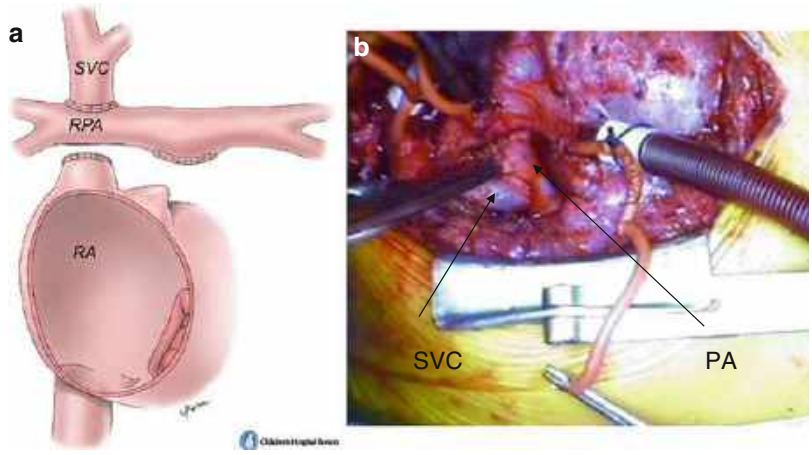

Fig. 106.3 Bidirectional Glenn procedure. The superior vena cava is disconnected from the right atrium and is anastomosed to the right pulmonary artery

The preoperative evaluation typically involves cardiac catheterization or MRI in addition to echocardiography; catheterization is preferred if coil embolization of collaterals is deemed necessary.

Residual lesions must be addressed at the time of the stage II procedure in order to optimize postoperative recovery and reduced interstage mortality prior to the Fontan procedure. Specifically, residual aortic arch obstruction must be treated with balloon dilation or surgical repair. Greater than moderate AV valve regurgitation may not improve significantly with ventricular unloading associated with shunt removal and must be addressed surgically with a valvuloplasty. Atrial septectomy is performed for restrictive atrial septal defect.

The operation is performed through a redo median sternotomy and cardiopulmonary bypass with dual venous cannulation (Fig. 106.3). For most bidirectional Glenn procedures, aortic cross-clamp is unnecessary, although concomitant intracardiac procedures for tricuspid valve repair or atrial septectomy would necessitate complete cardiac or fibrillatory arrest. The patient who has undergone hybrid stage I palliation as a neonate requires much more extensive reconstruction with aortopulmonary amalgamation, arch reconstruction, branch PA reconstruction, and atrial septectomy concomitant with superior cavopulmonary anastomosis. This procedure requires hypothermic circulatory arrest and regional cerebral perfusion. Similarly, the patient with aorta arising from an infundibular chamber may benefit from aortopulmonary amalgamation if neonatal palliation was not performed. If bilateral cavopulmonary anastomoses are performed, the central PA section between the anastomoses must maintain an adequate caliber in preparation for the Fontan procedure. Ligation of the azygos vein and other decompressing veins avoids development of hypoxemia postoperatively.

Management of pulmonary valve in patients with antegrade flow across the pulmonary valve is controversial. Advantages of maintaining antegrade flow at stage II palliation include prevention of development of arteriovenous malformations, which are particularly prevalent in patients with heterotaxy syndrome [53]. An additional advantage of maintaining antegrade pulmonary blood flow may be augmented pulmonary blood flow and ability to delay the Fontan procedure until the child is older. In some patients with favorable anatomy, maintenance of "one and a half" ventricle repair may provide adequate definitive palliation without the need for Fontan procedure. Although there is some data to suggest that maintenance of supplementary pulmonary blood flow increases mortality and morbidity following the stage II palliation, recent studies have not shown a difference in outcomes [54–56]. If the main PA is divided at the time of the stage II procedure, the pulmonary valve leaflets must be resected in order to prevent development of thrombus distal to the valve leaflets, which is at risk for systemic embolization.

Postoperative Management Following Stage II Palliation

Maintenance of a central venous line as well as a common atrial line allows measurement of transpulmonary gradient and ventricular compliance. In the absence of supplemental pulmonary blood flow, oxygen saturations range from 75 % to 85 % following superior cavopulmonary anastomosis. Pressure within the superior vena cava is expected to be in the mid-teens. The physiology is characterized by reduced ventricular volume loading due to removal of systemic to PA shunt. Pulmonary blood flow is dependent upon venous return from the upper body and relative resistance of the pulmonary vascular bed. Ventilator management to maintain a pCO_2 of 40 and a pH of 7.40 promotes low pulmonary vascular resistance. However, mild hypercarbia increases cerebral blood flow and thereby may augment systemic venous return through the superior vena cava, leading to augmentation of pulmonary blood flow following stage II palliation [57, 58]. Systemic hypertension is common following stage II procedure and may be managed with afterload reduction in the immediate postoperative period [59]. Positive pressure ventilation may impede pulmonary blood flow, and strategies to minimize mean airway pressure (low peak and expiratory pressure, shortened inspiratory time) should be pursued. Early extubation is recommended to reduce mean airway further and improve pulmonary circulation.

Hypoxemia following the stage II procedure may result from branch PA stenosis, anastomotic stricture, pulmonary arteriovenous malformations, or development of decompressing venous collaterals from upper body veins to the lower body veins. Catheterization for coil embolization of venovenous collaterals is effective, but transcatheter intervention is ineffective for arteriovenous malformations. The mortality following stage II procedure in the absence of significant ventricular dysfunction or AV valve regurgitation is low [60]. If circulatory support with ECMO is necessary, drainage of upper and lower venous systems should be considered, and mortality is high in this population [61].

Fontan Procedure

The total cavopulmonary connection completes staged reconstruction for single ventricle physiology. The procedure involves creation of continuity between the inferior vena cava and the pulmonary arteries. Timing of the operation ranges from 18 months to 4 years of age. The major impetus for early Fontan procedure is the development of pulmonary arteriovenous malformations, which are thought to occur due to absence of unidentified hepatic factor within the pulmonary circulation.

The preoperative workup for the Fontan procedure includes echocardiography to rule out AV valve regurgitation and restrictive atrial septal defect and evaluate ventricular function. ECG evaluation is required to confirm sinus rhythm and normal AV conduction. Cardiac catheterization or MRI may be used to evaluate the branch pulmonary arteries, arch obstruction, and degree of aortopulmonary collateral development. Venovenous collaterals from upper to lower body are less consequential at this stage as the blood will eventually perfuse the lungs through the total cavopulmonary connection. Management of aortopulmonary collaterals is controversial as there is discrepant data regarding the benefit on postoperative outcomes [62]. Aggressive recruitment of stenotic pulmonary arteries and veins by transcatheter intervention is recommended, since outcomes of single lung Fontan physiology are poor.

The Fontan procedure is performed with cardiopulmonary bypass and dual venous cannulation. Two major techniques are utilized for the total cavopulmonary connection: lateral tunnel (Fig. 106.4) and extracardiac tube graft (Fig. 106.5). In a patient with interrupted inferior vena cava who has undergone superior cavopulmonary anastomosis (Kawashima procedure), an alternative to the Fontan is direct hepatic vein-azygos vein connection, which may provide the most reliable mixing and bilateral distribution of hepatic venous blood [63]. The lateral tunnel Fontan utilizes native atrial tissue as one wall of the intracardiac baffle, with

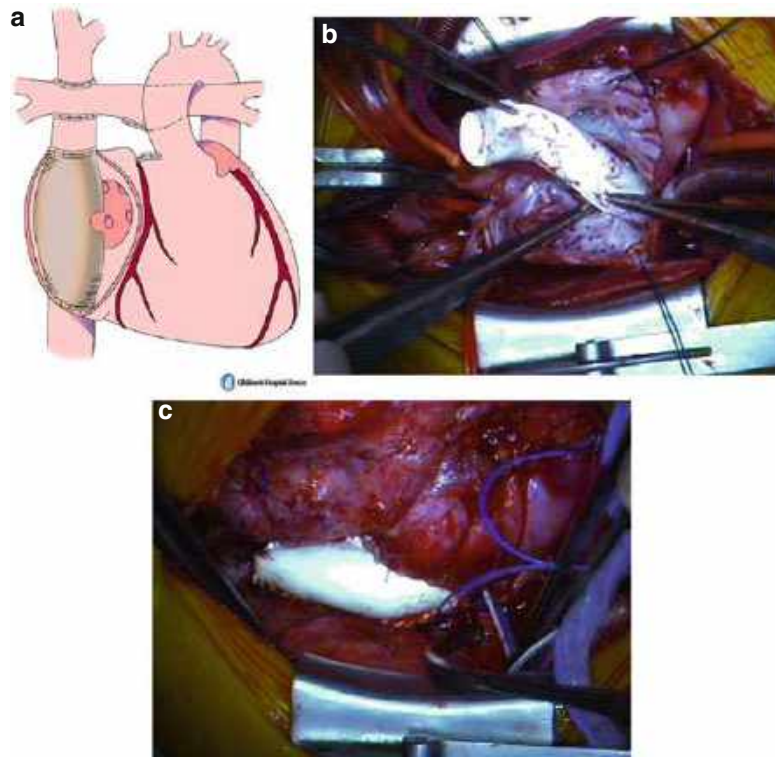

Fig. 106.4 Lateral tunnel Fontan procedure. Continuity is created between the inferior vena cava and the pulmonary artery (**a**). An intra/extracardiac baffle is constructed with Gore-Tex material, with the atrium comprising one wall of the baffle (**b**, **c**)

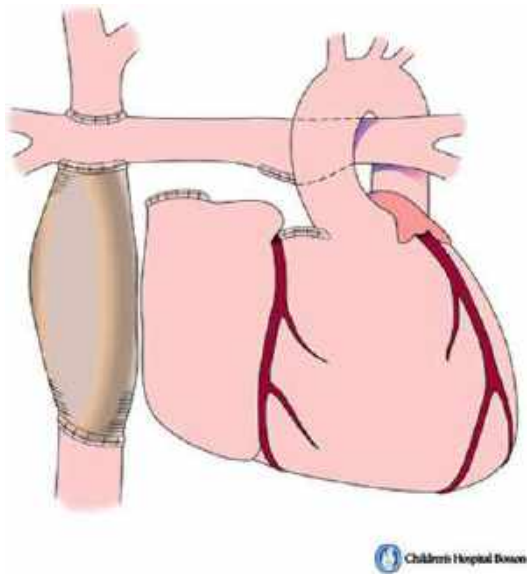

Fig. 106.5 Extracardiac Fontan utilizes a circumferential Gore-Tex tube graft to establish continuity between inferior vena cava and pulmonary artery

the remaining tunnel being created with Gore-Tex graft material. The theoretical advantage of the lateral tunnel Fontan is the potential for growth and decreased risk of thrombosis in contrast to the circumferential tube graft. The lateral tunnel may be particular advantageous in smaller children in whom an adult-sized graft may not be implantable. The extracardiac Fontan can be performed without the use of cardiac arrest, and some centers have performed it without the use of cardiopulmonary bypass, whereas the lateral tunnel technique requires fibrillation or cardioplegic arrest [64]. Several studies have shown decreased incidence of sinus node dysfunction with extracardiac Fontan, although this result has not been consistently reproduced [65–67]. Clinical studies have not consistently demonstrated a difference in outcomes between techniques with regard to mortality and functional status [66, 68, 69]. Computational flow dynamics suggests that both techniques may be associated with

preferential streaming of blood flow to the right lung and may lead to left lung pulmonary arteriovenous malformations [70].

Placement of a fenestration between the atrium and the Fontan pathway allows maintenance of cardiac output immediately postoperatively and has been shown to reduce the severity of postoperative effusions and shorter postoperative hospital length of stay [71–73]. However, recent data suggests that clinical outcomes are equivalent between fenestrated and non-fenestrated Fontan procedure, particularly in older children undergoing palliation [74].

Postoperative Management Following Fontan Procedure

Central venous pressures following the Fontan procedure are dependent upon low pulmonary vascular resistance, which must be maintained by adequate ventilation. Within the first 24 h following the procedure, volume administration may be necessary to maintain cardiac output. Mild hepatic insufficiency is not uncommon following the Fontan procedure, but progressive transaminitis and DIC-type picture should suggest the presence of Fontan baffle obstruction and prompt immediate imaging and therapy by cardiac catheterization and surgery. In the early postoperative period, the patency of the fenestration allows maintenance of cardiac output, and acute thrombosis of the fenestration may manifest with elevated systemic arterial saturations, elevated central venous pressures, hepatomegaly and ascites, prolonged chest tube drainage, and persistent volume requirement. Positive pressure ventilation will impede Fontan circulation, and early extubation is recommended to improve hemodynamics. Atrial arrhythmias should be aggressively treated antiarrhythmic agents, atrial pacing, or radiofrequency catheter ablation of the reentrant circuit [75, 76]. Persistent hypoxemia following the Fontan procedure can be due to arteriovenous malformations, obstruction of the inferior cavopulmonary anastomosis, excessive flow through the fenestration, or presence of a baffle leak in a lateral tunnel Fontan.

Important long-term complications following the Fontan procedure include arrhythmias, protein-losing enteropathy, plastic bronchitis, thromboembolism, poor neurodevelopmental outcomes, valvular regurgitation, and cardiac failure [77, 78]. Spontaneous closure of the fenestration occurs in approximately 40 % of patients, and transcatheter device closure can be performed to normalize systemic oxygen saturations [73, 79]. However, fenestration closure has not been clearly associated with improved exercise capacity or functional status [73, 80].

The Fontan procedure is associated with low operative mortality, and survival following the procedure is approximately 90 % at 10 years [81–83]. Risk factors for mortality include presence of right ventricular morphology, heterotaxy, tricuspid regurgitation, and presence of arrhythmias [84, 85]. Protein-losing enteropathy, the sequela of elevated Fontan pressures, and cardiac failure are considered indications for cardiac transplantation [86]. Although early post-transplantation survival is slightly lower in Fontan patients compared to other patients with congenital heart disease, long-term results are encouraging, and protein-losing enteropathy can be expected to resolve [87]. Actuarial survival following cardiac transplantation for the patient with a failing Fontan is approximately 60 % at 10 years [88, 89].

Special Considerations

AV Canal Defects

Patients with unbalanced AV canal defect frequently have downstream abnormalities that may require further consideration. Patients with right dominant atrioventricular canal defect frequently have concomitant hypoplasia of the aorta, coarctation, and left ventricular outflow tract obstruction. Initial palliation in these patients must include relief of outflow obstruction by performing a Damus-Kaye-Stansel anastomosis and arch reconstruction. Patients with AV canal defects may be more prone to

developing AV valve regurgitation, which may worsen prognosis and require surgical intervention.

Ventricular Septal Defect/ Bulboventricular Foramen

Systemic or pulmonary outflow tract may depend upon adequacy of interventricular communication in certain forms of non-HLHS single ventricle anatomy, and restriction to flow across the VSD may alter the delicate balance of Qp:Qs. Patients with tricuspid atresia and ventricular septal defect may have unrestricted flow across the VSD following birth but overtime may develop VSD restriction. In patients with normally related great vessels (type I), this may result in decreasing pulmonary blood flow and oxygen saturations over time. A patient with adequate or excessive pulmonary blood flow initially may develop appropriate balance or even reduced pulmonary blood flow within a short period of time. Therefore a PA band, which may seem to be appropriate in the neonatal period, would prove to be detrimental within a short period of time. Similarly, patients with transposition and tricuspid atresia (type II) or double inlet left ventricle and a bulboventricular foramen (BVF) who are dependent upon the latter for systemic blood flow may develop subaortic obstruction with time as the ventricular septal defect becomes more restricted [25]. The size of the ventricular septal defect may predict future development of restriction, with bulboventricular foramen area less than 2 cm^2/m^2 (indexed to body surface area) being associated with increased risk of eventual restriction [90]. Anticipatory management with performance of aortopulmonary amalgamation in the postnatal period prevents insidious development of subaortic obstruction in these patients. Alternatively, some groups have advocated for PA banding in the neonatal period, with subsequent aortopulmonary amalgamation or enlargement of the VSD at the time of the second stage operation [91–93]. Thus the management in the immediate postnatal period must take into consideration the natural history of potential restriction of this ventricular septal defect.

Nonconfluent Pulmonary Arteries

Discontinuous PAs can be successfully connected in most patients with a cavopulmonary circulation, although nonconfluent PAs appear to increase the risk of poor outcome after Fontan. Recurrent PA occlusion is usually diagnosed in the early postoperative period. In patients with sole supply to one lung through collaterals, unifocalization and shunt placement prior to stage II palliation may optimize outcome [94]. A low threshold for investigation of the reconnected PA is warranted in the interstage prior to stage II palliation [95, 96].

Total Anomalous Pulmonary Venous Connection

Obstructed total anomalous pulmonary venous connection may occur as a part of the single ventricle complex and is more common in patients with heterotaxy syndrome. The specific pulmonary venous anatomy may range significantly, with well-defined pulmonary venous confluence on one end of the spectrum and mixed drainage with hypoplastic pulmonary veins at the other end. Correction of the confluence to the back of the left atrium with surgical anastomosis may suffice for uncomplicated forms, whereas primary sutureless repair may be necessary for more complex variations [97]. Presence of obstructed total anomalous pulmonary venous connection is a risk factor for single ventricle management, and subsequent development of pulmonary vein stenosis following the repair further increases the risk of single ventricle management and may require catheter or surgical intervention [98]. Heterotaxy patients undergoing total anomalous pulmonary venous return repair have a higher pulmonary vein reoperative rate compared to non-heterotaxy patients [99].

ASD/Necessity of Mixing

The success of a single ventricle strategy depends upon adequate mixing of blood flow and

unobstructed systemic and pulmonary venous inflow. Patients with complex transposition who are managed with single ventricle palliation may develop disadvantageous streaming of blood flow due to in adequate mixing at the atrial level. Patients with tricuspid atresia and mitral atresia are dependent upon transseptal blood flow to maintain cardiac output. Patients with double inlet ventricle and unobstructed AV valves, however, may tolerate a restrictive interatrial septum. Although it is unusual for a patient with tricuspid atresia to develop restrictive interatrial septum in the neonatal period, further stricture has been described at later stages [100, 101]. Treatment with transcatheter approach may be less effective in older children or those with thick interatrial septa [19]. Surgical septectomy with extension into the coronary sinus ensures unobstructed interatrial septum in such patients.

Management of AV Valve Regurgitation

Single ventricle patients with AV valve regurgitation have a higher mortality compared to those without regurgitation. Unfortunately, maneuvers to correct regurgitation in the neonatal period are rarely effective or durable. Evaluation of the mechanism of regurgitation is limited by current imaging modalities, and there is often significant discrepancy between the echocardiographic assessment and visual findings at the time of operation. Regurgitation through a cleft in a patient with unbalanced AV canal defect is managed with cleft closure, whereas annular dilation is managed with suture annuloplasty.

Heterotaxy

Patients with heterotaxy and single ventricle physiology may have distinct anatomic considerations and different prognosis compared to the general population of single ventricle patients. They typically demonstrate unbalanced AV canal defect, frequently with pulmonary stenosis or atresia. Patients with heterotaxy can be subdivided by the presence of multiple spleens (polysplenia) or absent spleen (asplenia). Many patients with asplenia have dominant RV and double outlet RV, bilateral superior vena cava, and total anomalous pulmonary venous connection. Abnormalities of systemic venous drainage include presence of bilateral superior vena cava, separate entry of hepatic veins directly into the ipsilateral atria. Other significant abnormalities include the presence of bilateral sinoatrial nodes and bilateral trilobed lung morphology with bilateral eparterial bronchi. Patients with polysplenia are more likely to have interruption of the inferior vena cava with azygos continuation. The sinoatrial node may be absent. Pulmonary anatomy consists of bilateral bilobed lung morphology and bilateral hyparterial bronchi.

Total anomalous pulmonary venous connection, pulmonary vein stenosis, abnormalities of systemic venous drainage, and common AV valve regurgitation may require attention at the time of staged palliation. Arrhythmias and conduction abnormalities may be present or emerge following operative procedures. Specifically, ectopic atrial tachycardia due to dual sinus node, or reentrant tachycardia due to dual AV node require medical or interventional management. Patients with heterotaxy may also be prone to premature development of pulmonary arteriovenous malformations following the superior cavopulmonary shunt and thus may benefit from early conversion to total cavopulmonary shunting.

Aortopulmonary Collaterals and Their Management

Aortopulmonary collaterals may frequently develop in cyanotic single ventricle patients at various stages of palliation. Collaterals can provide excessive pulmonary blood flow and lead to symptoms of congestive heart failure due to volume loading of the single ventricle. Over time, collaterals also contribute to development of hemoptysis. Management of aortopulmonary collaterals varies significantly across institutions, with routine coil occlusion of collaterals performed prior to staged palliation at some and selective occlusion only in symptomatic patients

at other centers. Coil occlusion is therapeutic in a majority of patients who present hemoptysis, although surgical management with tracheal devascularization may be necessary in refractory cases.

Conclusion

In conclusion, patients with non-HLHS single ventricle physiology undergo the sequence of palliative procedures similar to patients with HLHS. However, each anatomic variant carries a unique set of preoperative, intraoperative, and postoperative considerations that distinguishes this group from those with HLHS. Management in the neonatal period can be particularly complex since many have adequate pulmonary blood flow to obviate immediate intervention. Timing of palliative procedures may differ based upon the presence of heterotaxy syndrome due to the risk of developing arteriovenous malformations. Long-term prognosis depends upon the dominant ventricular morphology as well as comorbidities and genetic syndromes.

Partial and Total Anomalous Pulmonary Venous Connections and Associated Defects

107

Parth M. Patel, Alexandre T. Rotta, and John W. Brown

Abstract

Anomalous pulmonary venous return is a relatively rare congenital cardiac malformation in which the pulmonary veins do not return to the left atrium. If all four pulmonary veins drain anomalously, the designation of total anomalous pulmonary venous return (TAPVR) is applied; if only one to three pulmonary veins drain anomalously, the designation of partial anomalous pulmonary venous return (PAPVR) is applied. TAPVR is classified into supracardiac, infracardiac, cardiac, and mixed types according to the location of the anomalous drainage. The prognosis of patients with TAPVR depends on the degree of pulmonary venous obstruction and associated defects. TAPVR generally requires neonatal surgical correction. Early and late mortality for simple TAPVR is 10 % and 4 %, respectively. Patients with TAPVR and pulmonary venous obstruction have a higher early and late mortality (17 % and 11 %, respectively) than unobstructed patients (4 % and 6 %, respectively). TAPVR associated with other cardiac anomalies (other than an ASD or PDA) have worse early and late mortality (14 % and 18 %, respectively). There are two types of PAPVR that are identified by name, sinus venosus PAPVR and scimitar syndrome. The prognosis for surgically corrected non-scimitar PAPVR is excellent. Scimitar syndrome PAPVR has

a less favorable prognosis due to other associated cardiac and pulmonary lesions. PAPVR requires surgical correction whenever diagnosis is made or whenever the patient becomes symptomatic, not necessarily during the neonatal period. Patients with non-scimitar PAPVR do well with a 0 % early mortality and less than 1 % late mortality. Patients with scimitar syndrome have a higher risk of mortality (6 %) compared to other forms of PAPVR. Patients with scimitar syndrome who require a pneumonectomy or lobectomy have a higher mortality (25 %) than patients who have their anomalous drainage repaired without the need for lung resection (4 %). The prognosis for all anomalous venous return patients has improved since the first surgical corrections were described. The management of pulmonary vein obstruction continues to be the largest obstacle to successful management of anomalous pulmonary venous return.

Partial anomalous pulmonary venous return • Pulmonary vein stenosis • Scimitar syndrome • Sinus venosus PAPVR • Total anomalous pulmonary venous return • Warden procedure

Introduction

Anomalous pulmonary venous returns including total anomalous pulmonary venous return (TAPVR), partially anomalous pulmonary venous return (PAPVR), and scimitar syndrome are relatively rare congenital cardiac malformations. Anomalous pulmonary venous return is present when one or more pulmonary veins do not return to the left atrium. The anomalous vein or veins usually drains to a systemic vein or directly to the right atrium. These three anatomic subtypes comprise the entire spectrum and may or may not be associated with pulmonary vein stenosis. TAPVR accounts for 1–1.5 % of all congenital heart defects [1]. PAPVR is found at a rate of 0.6 %, determined from autopsy findings [2]. Scimitar syndrome is a rare subtype of PAPVR and has a constellation of associated anomalies.

Embryology

During fetal development, the lung buds drain into a common area of the splanchnic plexus. This splanchnic plexus is also initially the drainage area for the central cardinal and the umbilico-vitelline venous systems. As the lung buds grow, the drainage into the splanchnic plexus from the cardinal and umbilico-vitelline veins decreases, and the drainage of the lung buds to the splanchnic plexus increases [3]. As the lungs develop, a part the splanchnic plexus differentiates into the premature pulmonary vascular bed, and the rest of the splanchnic plexus becomes part of the hepatic portal system. The common pulmonary vein forms next, and the location of its origin is the most heavily debated part of pulmonary vein embryology. The most recent literature suggests that the pulmonary portion of the splanchnic plexus forms into a solitary pulmonary vein, which later connects to the left atrium [4]. As development continues, four veins are derived from the pulmonary portion of the splanchnic venous plexus. Later in development, the common pulmonary vein is incorporated into the left atrium, and the four pulmonary veins connect directly to the left atrium. Anomalous pulmonary venous return is the result of a misstep during pulmonary development and can result in pulmonary vein drainage to anywhere from the innominate vein to the hepatic portal system. However, all of this development initially occurs over a distance of 250 μm, so the

large range of anomalous connections should not be surprising [3]. Recent experiments confirm that the origin of the pulmonary veins is distinct from systemic venous return [3, 5].

Anatomy

TAPVR

There are four types of TAPVR classified by Darling and colleagues based on where the pulmonary veins return; these four types in rate of occurrence are supracardiac (45 %), cardiac or coronary sinus (25 %), infracardiac (25 %), and mixed (5 %) [6] (Fig. 107.1). In most patients with supracardiac TAPVR, the pulmonary veins join at a venous confluence behind the left atrium, a remnant of the common pulmonary vein, and drain into the left innominate vein via a vertical vein. Less commonly, the vertical vein connects to the right superior vena cava (SVC). In most patients with cardiac-type TAPVR, all four pulmonary veins drain into a common vein that connects to the coronary sinus. The connection to the coronary sinus is at the atrioventricular groove, and because of the extra flow in the coronary sinus, the orifice into the right atrium is usually enlarged. In the rare event that the common pulmonary vein connects directly to the right atrium, right atrial isomerism is usually also present. In infracardiac TAPVR, the four pulmonary veins again drain into a common pulmonary vein that then goes through the diaphragm and connects to one of the intra-abdominal veins, in most cases the portal vein. Less commonly, the descending common pulmonary vein drains into the ductus venosus, the hepatic veins, the gastric vein, or even the IVC. Mixed TAPVR is a combination of supracardiac, cardiac, and infracardiac TAPVR where all four pulmonary veins do not drain to the same place. It can be further classified based on the pattern in which the four veins drain; the two most common subtypes of mixed TAPVR are 3 + 1 and 2 + 2 mixed TAPVR. In 3 + 1 mixed TAPVR, the lower left pulmonary vein and the two right pulmonary veins drain into a common confluence which joins the right atrium adjacent to the SVC connection, while the upper left pulmonary vein drains into the left innominate vein via a vertical vein. In 2 + 2 mixed TAPVR, the two right pulmonary veins drain into the right atrium via a common confluence and the two left pulmonary veins drain into a common confluence which drains into the innominate vein via a vertical vein. While other types of mixed TAPVR are seen, they are less common [8]. Additionally, the type of repair needed can be classified based on other cardiac lesions seen with the TAPVR. Simple TAPVR repair refers to the patients whose only congenital anomaly is TAPVR with an associated atrial septal defect (ASD) and/or patent ductus arteriosus (PDA). Complex TAPVR refers to patients who have other associated cardiac lesions and TAPVR.

PAPVR and Scimitar Syndrome

Most PAPVR types do not have a specific name and are simply defined by how the pulmonary veins drain. There are two types of PAPVR that are identified by name. The first is sinus venosus PAPVR; this is when the right upper and/or right middle pulmonary veins drain to the SVC, and a sinus venosus ASD is present. Sinus venosus PAPVR is the most common type of PAPVR comprising 65 % of all PAPVR cases [9] (Fig. 107.2). The right pulmonary veins are most often the anomalous veins in PAPVR (90 %) [9]. The other type of PAPVR with a specific designation is scimitar syndrome, since it is also associated with a variety of other congenital anomalies. Other anomalies often found in patients with scimitar syndrome are dextrocardia, hypoplastic right lung and right pulmonary artery, and a systemic arterial connection between the thoracic or abdominal aorta and the right lower lobe. The anomalous systemic arterial connection is often the main source of blood supply to the right lower lobe. Additionally, 70 % of patients with scimitar syndrome have an ASD or a patent foramen ovale (PFO) [10]. The right pulmonary veins drain into the upper part of the inferior vena cava, either above or below the diaphragm, and usually drain the lower and sometimes the middle lobe of the right lung, or, less commonly, the entire right

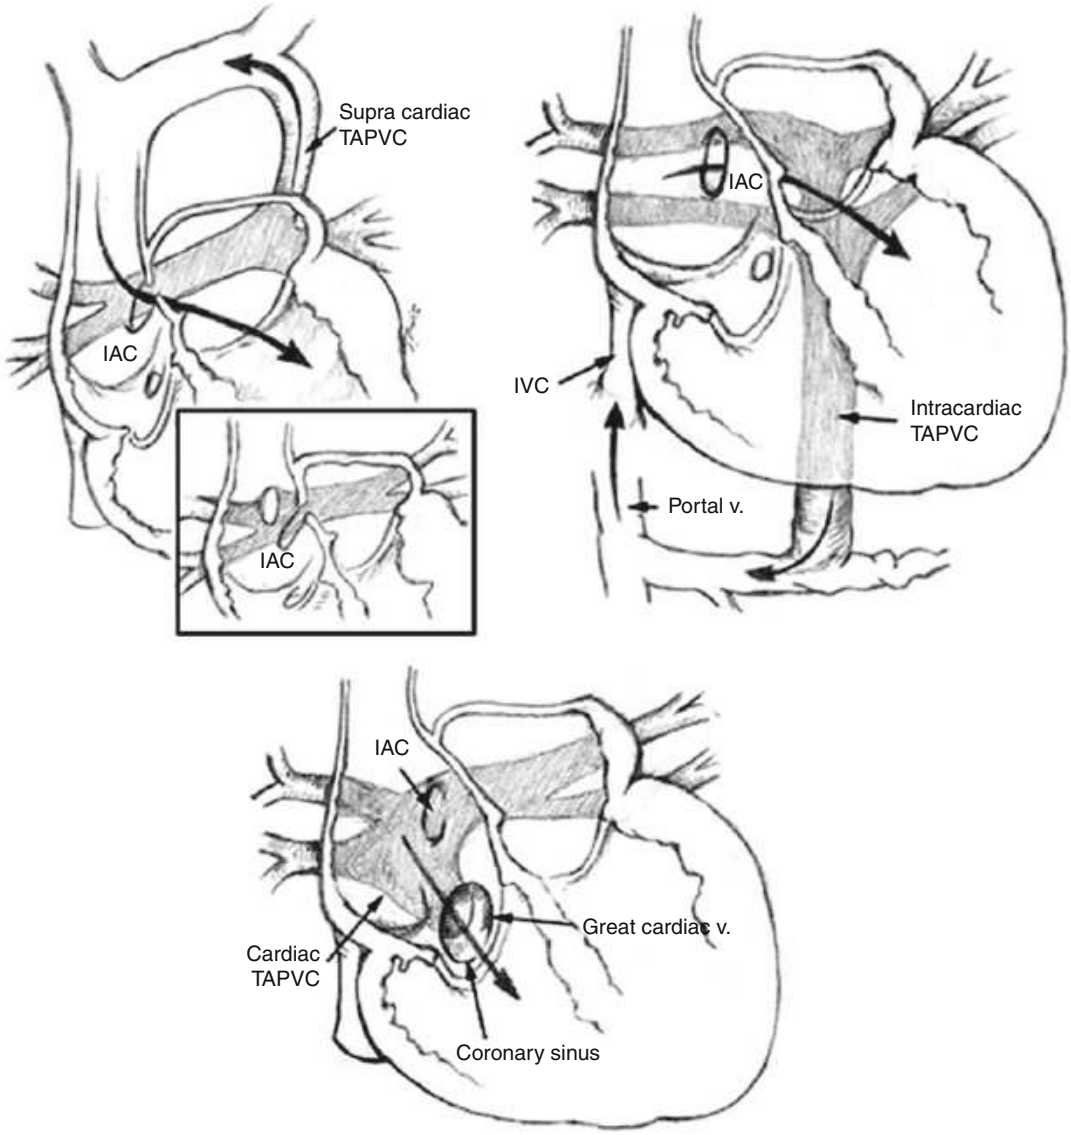

Fig. 107.1 A picture of the different types of TAPVR, from *top* to *bottom*: Supracardiac, Infracardiac, and Cardiac type TAPVR. *IAC* Intra-Atrial Connection (From Wilson [7])

lung [11] (Fig. 107.3). The anomalous pulmonary vein gets broader as it descends in the right chest and gives the appearance of a scimitar sword on the chest X-ray, thus the name scimitar syndrome. Because of the anomalous arterial blood supply and venous drainage, the right lung is frequently hypoplastic. The rarest form of PAPVR is isolated PAPVR in which the left pulmonary veins connect to the left innominate vein via a left vertical vein.

Pathophysiology

TAPVR

In TAPVR, all the systemic and pulmonary venous blood returns to the right atrium, resulting in a large left-to-right shunt. To maintain the necessary cardiac output and patient survival,

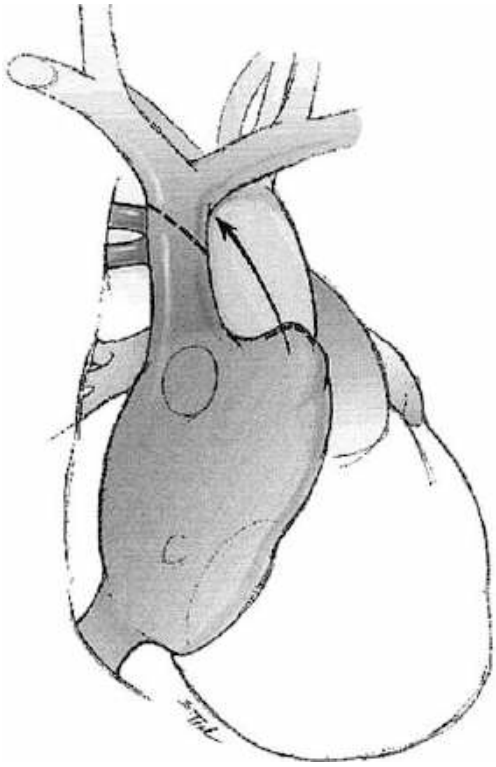

Fig. 107.2 A picture of Sinus Venosus PAPVR with connection of the right pulmonary veins to the SVC (From Shahriari [44])

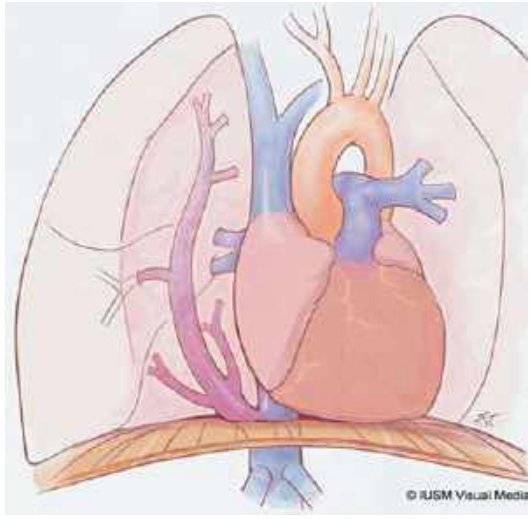

Fig. 107.3 A picture showing the anomalous right pulmonary vein in scimitar syndrome (From Gudjonsson and Brown [12])

a right-to-left intracardiac shunt must also be present, usually a secundum ASD [13, 14].

The clinical spectrum of TAPVR is determined by the presence and/or severity of pulmonary vein obstruction. Pulmonary vein obstruction occurs to some degree in approximately 50 % of all TAPVR cases. The type of TAPVR and the rate of occurrence of obstruction are as follows: supracardiac 40 %, cardiac 22 %, infracardiac 80–100 %, and mixed 40 % [1, 15, 16]. For all types of TAPVR, obstruction occurs either at a junction from the pulmonary vein to its respective systemic vein, producing increased pressure in the pulmonary veins, or it can occur on the path that connects the pulmonary veins to their respective systemic vein. In supracardiac TAPVR, the obstruction occurs at the vertical vein-innominate vein junction or a narrowing of the vertical vein as it passes between the left pulmonary artery and the left main bronchus on its path to the innominate vein. In infracardiac TAPVR, the obstruction occurs at the descending pulmonary vein-abdominal vein junction or a narrowing of the descending pulmonary vein as it passes through the diaphragm on its way to an abdominal vein. Obstruction of cardiac TAPVR is normally at the pulmonary vein connection to the coronary sinus or to the right atrium.

Postnatally, as pulmonary vascular resistance decreases, there is an increase in pulmonary blood flow. Increased pulmonary blood flow combined with the pulmonary venous obstruction results in increased pulmonary artery pressure and eventually volume and pressure overload of the pulmonary venous system, resulting in pulmonary edema. The resulting pulmonary hypertension leads to increased muscularity in pulmonary arterioles, which makes them more reactive to any sort of stress adding a reactive component of pulmonary artery hypertension [17]. If the pressure in the pulmonary artery becomes greater than the systemic arterial pressure, then right ventricular pressure/volume overload, right ventricular dilation, and eventually right heart failure can result. Because of right heart volume overload and an indirect pulmonary venous return, the left atrium and ventricle may

become hypoplastic and less compliant. Left ventricular (LV) volume is usually decreased as well. The decreased LV volume is either due to the leftward deviation of the ventricular septum, secondary to right ventricular hypertension, or it is due to the absence of pulmonary venous return directly to the left atrium during the fetal development [18–20]. The severity of these effects will of course depend on the severity of the pulmonary vein obstruction.

Though some of the most severe cases of TAPVR result from pulmonary vein obstruction, unobstructed TAPVR patients also have potential for significant morbidity. Due to the drop in pulmonary vascular resistance upon birth and the left-to-right shunting due to the TAPVR, there is increased pulmonary blood flow, and this leads to increased pulmonary artery pressure. This increased pulmonary artery pressure is less than the one observed in patients with obstructed pulmonary venous drainage but is still sufficient to result in right ventricular dilatation, if left uncorrected. Changes in the pulmonary arterioles can be seen in these patients, as is seen in patients with obstructed TAPVR; these changes eventually lead to increased right ventricular pressure [17]. Ultimately, regardless of the degree of obstruction, most patients with TAPVR do not survive to the age of 1 year without repair.

PAPVR and Scimitar Syndrome

As shown above, the clinical spectrum of TAPVR is related to pulmonary artery flow and pulmonary vein obstruction. The clinical spectrum of PAPVR is related to the amount of left-to-right shunting caused by the number and size of the anomalous vein(s), the degree of pulmonary venous obstruction, and the degree of lung hypoplasia. Pulmonary hypertension can develop in patients with PAPVR similarly to those with TAPVR. The right atrial and ventricular dilation seen in patients with TAPVR can also be found in PAPVR patients with significant left-to-right shunting. The physiological changes seen in scimitar syndrome, however, are usually more dependent on the associated systemic and bronchial anomalies than they are on the left-to-right shunt since the right lung is often small.

Presentation

TAPVR

Patients with unobstructed TAPVR often present with subtle signs and symptoms, at least initially, including mild cyanosis and mild arterial desaturation due to the obligatory right-to-left shunting at the atrial level. However, as the infant grows over the first few months, symptoms become more obvious with diaphoresis on feeding, failure to thrive, dyspnea, and persistent cyanosis [16]. More significant dyspnea is seen in obstructed TAPVR patients [15]. The clinical presentation of patients with obstructed TAPVR depends on the severity of obstruction. Patients with obstructed TAPVR present with hypoxemia and cyanosis and, if the obstruction is severe enough, acute respiratory failure [15]. The severity of obstruction is inversely proportional to how long it takes for symptoms to present [4]. Patients with obstructed TAPVR also often present with tachycardia as a compensatory mechanism for the decreased stroke volume from the poorly compliant left ventricle [21]. Both obstructed and unobstructed TAPVR patients often present with an enlarged liver due to right heart failure. However, one of the main differences in physical examination between unobstructed TAPVR and obstructed TAPVR is the presence of a murmur. Patients with unobstructed TAPVR often have a systolic ejection murmur in the left upper sternal border, due to increased flow across the pulmonary valve [22]. Patients with obstructed TAPVR normally do not have a murmur. Further, patients with unobstructed TAPVR are more likely to have tachypnea and heart failure. Echocardiography is currently the most commonly used tool in the diagnosis of TAPVR, being capable of determining the type of abnormal venous connection and the severity of the obstruction, if present [23]. A chest radiograph is helpful in determining the extent of pulmonary

over-circulation and obstruction. Angiography and computed tomography with contrast can be used to obtain more precise anatomic detail in cases where echocardiography alone is insufficient. However, both of these imaging techniques involve intravascular administration of contrast and fluids that can lead to further deterioration of an already fragile patient with congested pulmonary circulation [16].

PAPVR and Scimitar Syndrome

Much like unobstructed TAPVR, patients with PAPVR in which one or two pulmonary veins are anomalous often present with mild symptoms. In fact patients with isolated PAPVR often go undiagnosed for years and may need surgical intervention only if the pulmonary to systemic blood flow ratio is greater than 1.5: 1 [21]. As the amount of left-to-right shunting increases, so does cyanosis and other respiratory symptoms. The most symptomatic patients with PAPVR are infants with scimitar syndrome. Within the first few months of life, these patients often present with failure to thrive, cyanosis, respiratory distress, and heart failure [10]. Another subset of patients with scimitar syndrome can exhibit much milder symptoms and often present later in life with mild exertional dyspnea and recurrent respiratory infections [24]. Older patients with PAPVR may also present with atrial arrhythmias from an enlarged right atrium due to increased left-to-right shunting [25]. Echocardiography is the main tool in the diagnosis of PAPVR. Cardiac catheterization may be performed to precisely delineate the anatomy, although magnetic resonance imaging (MRI) has been shown to be just as effective [26]. Cardiac MRI may aid in the determination of the amount of left-to-right shunting in isolated PAPVR of a single pulmonary vein to the innominate vein. Although unremarkable in most cases of PAPVR, a plain chest radiograph can provide important diagnostic clues in patients with scimitar syndrome. The anomalous pulmonary venous connection between the right lung and the inferior vena cava creates a radiographic shadow resembling the shape of a scimitar sword [27] (Fig. 107.4). In addition, some of these patients will also exhibit reduced right lung volume, atelectasis, and rightward displacement of the cardiac silhouette [27]. Cardiac catheterization is often part of the preoperative investigation of patients with scimitar syndrome to help determine the exact pulmonary venous anatomy and the trajectory of the systemic collateral to the right lower lobe.

Fig. 107.4 A picture of a Scimitar Sword (From Gudjonsson and Brown [12])

Preoperative Treatment

TAPVR

TAPVR, especially obstructed TAPVR, is one of the congenital heart defects that often requires surgery within the first few hours or days of life. While medical management, including mechanical ventilation, can be used to ameliorate some of

the symptoms and stabilize vital signs, it will not relieve the obstructed pulmonary venous return, pulmonary parenchymal congestion, or maintain cardiac output. The degree of intervention preoperatively will depend on the degree of pulmonary vein obstruction. Patients with TAPVR usually present with metabolic acidosis, systemic hypotension, pulmonary hypertension, and, depending on the obstruction, severe respiratory distress [28]. These problems are initially managed with mechanical hyperventilation with a fraction of inspired oxygen of 1 and inotropic drugs [16]. Administration of inhaled nitric oxide preoperatively may also decrease the potential risk of pulmonary hypertension postoperatively [29]. Preoperative ECMO is required in the most severe cases. Prostaglandins can also be administered to patients with obstructed TAPVR to maintain patency of the ductus arteriosus. For these patients, the patent ductus can serve as a channel for right-to-left shunting to relieve pulmonary hypertension [16]. Prostaglandins should not be administered to patients with unobstructed TAPVR since this may increase left-to-right shunting and worsen hypoxemia and pulmonary hypertension. Balloon atrial septostomy can also be done via cardiac catheterization if the atrial communication is restrictive. Additionally, balloon dilation of stenotic pulmonary vein segments, with and without stent placement, has been shown successful in relieving pulmonary congestion temporarily [29–32]. Stenting of the vertical vein as a palliative procedure has been described. Failure to stabilize the patient after aggressive clinical management dictates the need for emergency corrective surgery or extracorporeal membrane oxygenation (ECMO).

ECMO serves as a means to oxygenate the patient, decompress the pulmonary circulation, and increase systemic perfusion before or after the surgical correction in these more extreme cases [27]. The need for ECMO in these patients has been positively associated with mortality [32]. Additionally, survival rates are worse for patients with TAPVR requiring ECMO preoperatively compared to those only requiring ECMO following surgical correction [33]. Need for preoperative ECMO is a surrogate marker for severity of the pulmonary venous obstruction. The need for emergency surgery in the neonate with obstructed TAPVR has its own inherent risks, as one considers the technical challenges of performing surgery in a critically unstable patient with small veins.

PAPVR and Scimitar Syndrome

The need for preoperative intervention in PAPVR is uncommon. In young infants with scimitar syndrome, coil occlusion of the anomalous systemic artery or arteries coming through the diaphragm can significantly reduce the left-to-right shunt and palliate these infants to a significant degree [27, 34]. Right lower lobe sequestration is not uncommon with scimitar syndrome and can be confirmed by CT or MRI. One study suggests that aorta, pulmonary artery, and pulmonary vein angiography is essential along with CT, bronchoscopy, bronchography, spirometry, lung scintigraphy, and spirometry [35]. An abdominal aortogram, pulmonary arteriography with pulmonary venous follow-through, and echocardiography are the studies recommended prior to surgery for scimitar syndrome.

Surgical Treatment

TAPVR

Correction for all four types of TAPVR, supracardiac, infracardiac, cardiac, and mixed, is similar in concept, in that the pulmonary vein confluence must be separated from the systemic vein and connected to the left atrium. Additionally, any intracardiac or extracardiac shunts must be closed. The surgery is done via median sternotomy under hypothermic cardiopulmonary bypass around 20–25 °C and cold potassium cardioplegic arrest. Deep hypothermia with circulatory arrest is sometimes required in small newborns.

There are four approaches to repair supracardiac and infracardiac TAPVR. In all four methods, the heart is accessed through

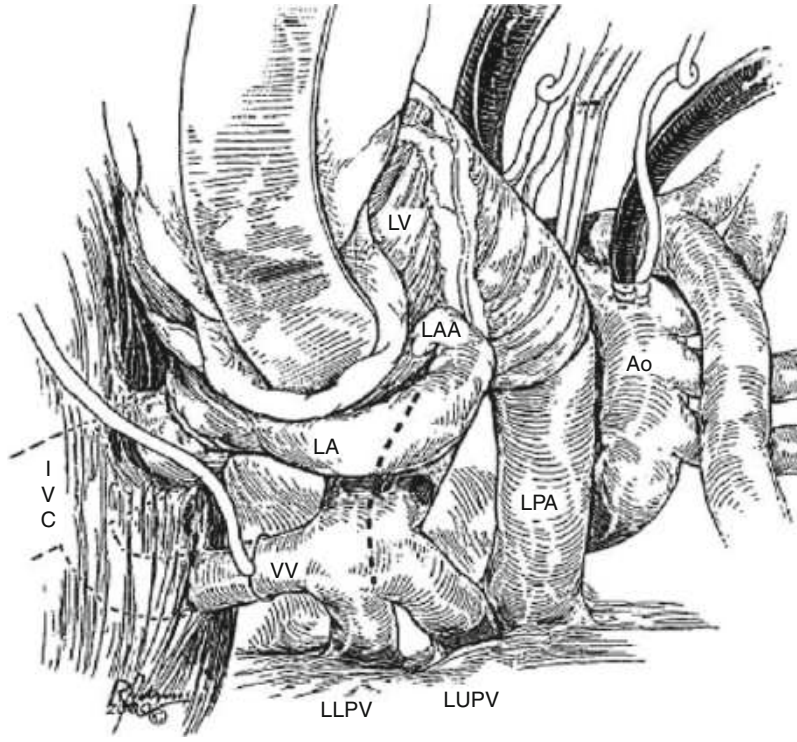

Fig. 107.5 A picture which shows the retrocardiac method to correct Supracardiac and infracardiac TAPVR. The *dotted line* corresponds to the incision that would be made along the left atrium and common pulmonary confluence (From Mavroudis and Backer [38])

a median sternotomy; thymectomy may be needed to reach the pericardium. If a PDA is present, this is ligated. Opening the right pleural space and displacing the heart to the right and to access the pulmonary vein confluence through the posterior pericardium underneath the left atrium are recommended; this is often called the retrocardiac method. Once the common confluence and the four pulmonary veins are identified, the confluence can be opened widely and anastomosed with the least tension to a correspondingly large incision in the left atrium. If the patient has supracardiac TAPVR, then a vertical or oblique incision is made into the confluence from the inferior aspect of the confluence to the proximal end of the vertical vein [36, 37]. A corresponding incision is made into the left atrium and the PV confluence is sewn to the left atrium. If the patient has infracardiac TAPVR, then a vertical incision is made in the center of the confluence down to the proximal end of the descending vertical vein above the diaphragm. A corresponding incision is made into the left atrium and the confluence is sewn to the left atrium [36, 37] (Fig. 107.5). The ascending and descending vertical vein confluence is freed from the overlying pericardium in supracardiac and infracardiac TAPVR, respectively. It is not necessary to free the confluence circumferentially since excessive dissection could lead to pulmonary vein stenosis. Primary or patch closure of the ASD is also done via a right atriotomy. Another method for TAPVR repair is the right atrial approach; this method has the advantage of keeping the heart in its natural position while making the anastomosis from confluence to left atrium [27]. The right atrial approach is thought to limit the size of the confluence – left atrium anastomosis particularly in the small neonate. In this method the left atrium is accessed through an anterior lateral right atriotomy and atrial septostomy which extends through the crista terminalis to the back of the left atrium. The common confluence is then opened longitudinally and is anastomosed to the posterior wall of the left atrium. The ASD is then closed with a patch, which is placed to the right of

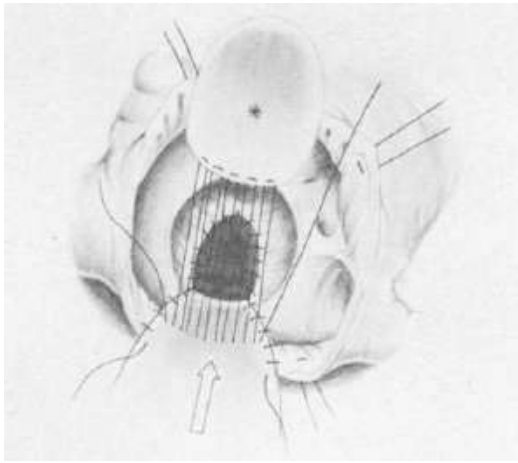

Fig. 107.6 A picture looking into the left atrium at the left atrium-pulmonary vein confluence through the ASD via a right atriotomy for the two patch technique for TAPVR correction (Corno et al. [39])

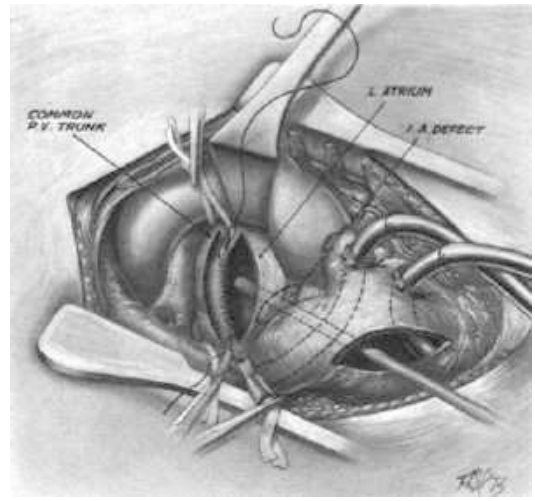

Fig. 107.7 A sketch midway through the superior access technique for TAPVR correction. One side of the pulmonary confluence and the left atrium have been anastomosed (From Tucker et al. [40])

the original septum so as to slightly increase the volume of the left atrium. The ascending and descending portions of the vertical vein are circumferentially dissected in supracardiac and infracardiac TAPVR so that ligation of the vertical veins can be accomplished, after the anastomosis is complete. The right atrial approach can also be done with a second patch which is used to augment the right atrial wall so that right atrial volume is not lost in patching the ASD; this is known as the two-patch technique [39] (Fig. 107.6). Access to the left atrium heart can also be gained superiorly for supracardiac TAPVR. In this technique the common pulmonary venous trunk is mobilized on bypass. The left atrial roof is then opened by carefully moving the aorta and the common pulmonary arterial trunk. An incision is made on the common pulmonary vein, and a corresponding incision is made on the left atrium; the two structures are sewn together so that the anastomosis is as large as possible (Fig. 107.7). After the anastomosis, the vertical vein is ligated and patch or primary closure of the ASD is completed [40].

There are two techniques to correct cardiac or coronary sinus TAPVR. The heart is accessed through a median sternotomy in both techniques. If patent, the PDA is ligated. The preferred method depends on the where exactly the pulmonary veins drain. If the pulmonary veins drain into the coronary sinus via a common pulmonary vein, then the coronary sinus is unroofed into the left atrium [21]. The ASD and coronary sinus are closed with a single patch. If the common pulmonary vein drains directly into the right atrium, then an intra-atrial baffle is created which diverts the pulmonary venous flow through the ASD to the left atrium [41]. In this case, the baffle also serves as the ASD patch.

Intraoperative echocardiography is done after weaning from bypass to confirm the adequacy of the repair. Should significant pulmonary hypertension that is unresponsive to mild hyperventilation and inhaled nitric oxide develop, the patient can be placed on ECMO for temporary support. One study reported a 57 % mortality rate for infants requiring ECMO for pulmonary hypertension following repair of congenital cardiac lesions [42]. Use of temporary RA, PA, and LA pressure lines for postoperative management in complex patients is recommended. If the patient is edematous and the heart is dilated or if left ventricular function is decreased, it is prudent to delay sternal closure and only close the skin incision, if possible [23].

PAPVR

Unlike in TAPVR, immediate surgery is not usually necessary in the first few months of life for patients with PAPVR. The age of the repair will depend on the degree of left-to-right shunting and the age at diagnosis [43, 44]. If symptoms develop, then repair can be done before the patient's first birthday. There are three primary methods to correct PAPVR excluding scimitar syndrome. All three PAPVR techniques require median sternotomy and bicaval cannulation. One common way to correct PAPVR is creating an intra-atrial baffle from the pulmonary vein connection on the SVC to the sinus venosus ASD [21] (Fig. 107.8). The baffle can be made from Gore-Tex or glutaraldehyde-treated pericardium. Untreated pericardium is unpredictable and may shrink, narrowing the pulmonary venous pathway. The second PAPVR technique is a modification on the first. It was developed as a way to avoid potential SVC stenosis. This second method also creates an intra-atrial baffle, but it uses a second patch to augment the SVC near its junction to the right atrium [9]. The third PAPVR technique is the Warden procedure and is used if the pulmonary vein connection to the SVC is too far cephalad from the right atrium to make an intra-caval baffle practical. In the Warden technique, the SVC is transacted above the highest pulmonary vein entrance. The divided distal end of the distal SVC is over sewn. The proximal SVC is then connected to the right atrial appendage. The right atrium is opened, and a simple patch is then placed over the sinus venosus ASD and SVC orifice inside the RA to divert the anomalous pulmonary vein blood through the ASD into the left atrium [9, 45] (Fig. 107.9). All three methods are done via a right atriotomy. The Warden procedure avoids excessive sewing around the SA node and thus decreasing the chance for transient and/or permanent atrial arrhythmias.

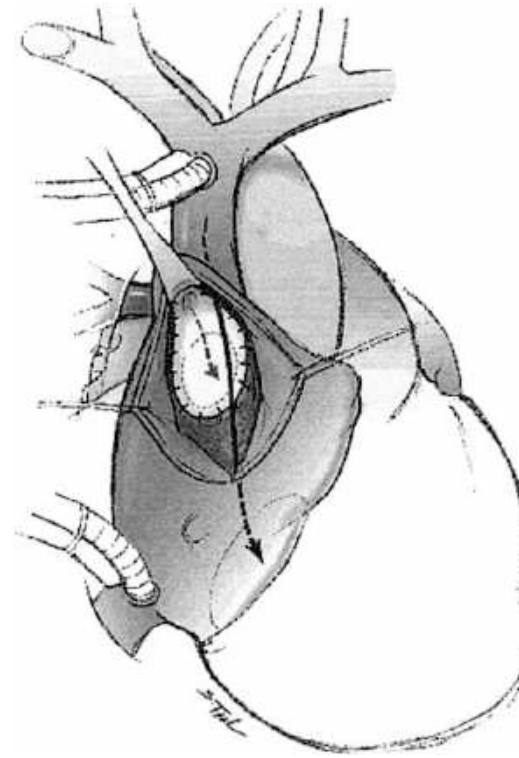

Fig. 107.8 Figure showing the intra atrial baffle from the anomalous vein connection in the SVC to the ASD for PAPVR repair (From Shahriari [44])

Scimitar Syndrome

Since scimitar syndrome is associated with many different congenital defects, each operation should be individualized to the patient. The arterial anomalous connections between the abdominal aorta and the right lung should be coil occluded preoperatively in infants. Furthermore, because of the bronchial abnormalities, recurrent infections, and right lower lung sequestration, a portion of the right lower lung can be resected if necessary [21]. One study suggested a right pneumonectomy for patients who have their scimitar vein draining the entire right lung [11]. Pulmonary resection, except in right lower lung sequestration, is not recommended. In that case the sequestration and/ or lobectomy can also be done. Several methods have been proposed to correct scimitar syndrome. One technique is not to divide the scimitar vein connection to the IVC (Fig. 107.10). This technique requires use of cardiopulmonary bypass and the construction of a long intra-atrial baffle. This long intra-atrial baffle increases the risk of tunnel thrombosis, and the excessive baffling will put the conduction

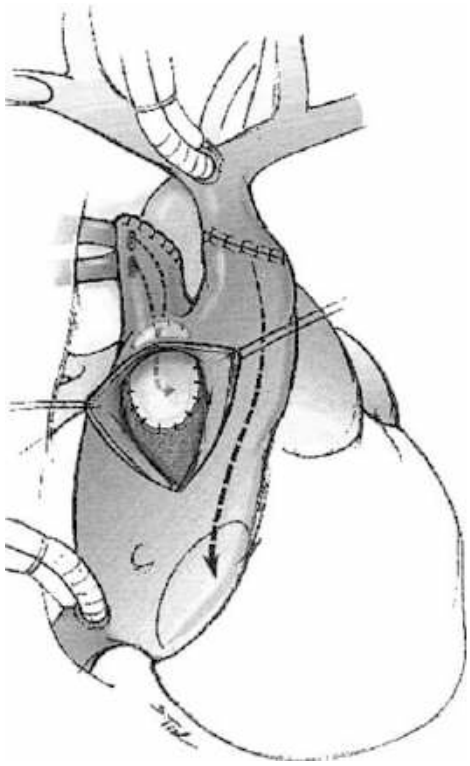

Fig. 107.9 A picture looking at the SVC to ASD Patch via right atriotomy when performing the Warden technique to correct Sinus Venosus PAPVR (From Shahriari [44])

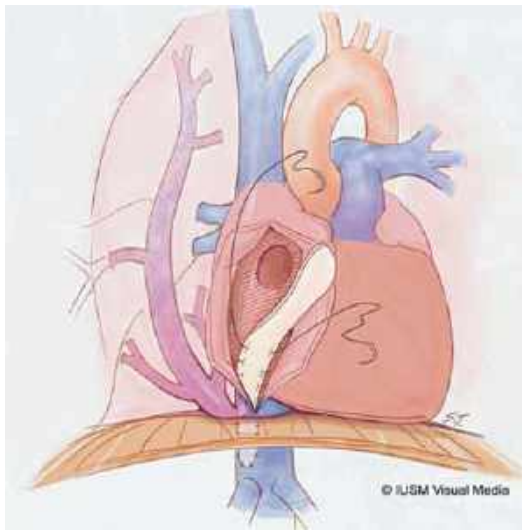

Fig. 107.10 A picture showing the intra-right-atrial baffle created during the baffle technique to correct scimitar syndrome (From Gudjonsson and Brown [12])

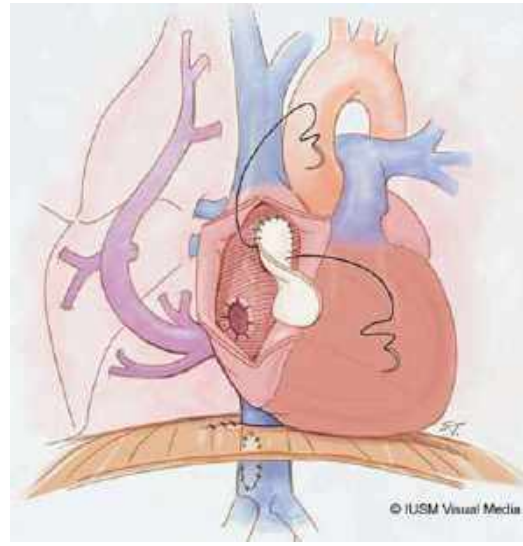

Fig. 107.11 A picture showing the shorter intra-right-atrial baffle created when the right pulmonary vein is reimplanted closer to the ASD to correct scimitar syndrome (From Gudjonsson and Brown [12])

tissue in danger [46]. Another technique involves excising the right scimitar vein from the right IVC and reconnecting it to a location in the right atrium closer to the ASD. A shorter baffle is used to direct the scimitar venous flow to the ASD (Fig. 107.11). Since pulmonary vein stenosis is a risk for scimitar patients, the right pulmonary vein is patch augmented [47]. The recommended method of scimitar repair is to detach the scimitar vein from the IVC and directly reimplant it to the left atrium [11]. The ASD if present can be closed through the thoracotomy. A multitude of other techniques and modifications have been performed; however, the one used will depend on the patient and the nature of their scimitar syndrome [12].

Postoperative Treatment

TAPVR

Postoperative care for TAPVR is based mostly on preventing or treating pulmonary hypertension and maintaining systemic cardiac output. Ideally, the pulmonary artery pressure will decrease to

less than half of the systemic pressure soon after separating from cardiopulmonary bypass [15]. Pulmonary artery pressure monitoring may be very helpful in the first few hours or days after repair [23]. Those patients with severe pulmonary hypertension due to pulmonary venous obstruction will be especially susceptible to reactive pulmonary hypertension because of the increased muscularity of their pulmonary arterioles. To counteract pulmonary hypertension, patients are normally placed on nitric oxide and/or a low dose of milrinone [48]. The PCO_2 should also be kept near 30–35 mmHg by adjusting ventilator settings, and the blood pH should be kept mildly alkalotic [21]. To decrease the effects of a stress-induced pulmonary hypertensive episode, analgesia with fentanyl can be very helpful [16].

PAPVR and Scimitar Syndrome

The postoperative care for PAPVR resembles that of TAPVR depending on the amount of preoperative left-to-right shunting, but the degree of postoperative pulmonary hypertension is generally less. Care must be taken to observe for postoperative atrial arrhythmias which can be seen in all types of PAPVR [9, 11, 25, 44, 49]. If a pneumonectomy was not done to correct scimitar syndrome, then the postoperative treatment will be similar to that of PAPVR patients. The bronchial abnormalities of patients with scimitar syndrome make them more prone to right lower lung atelectasis and pneumonia [35]. The reduced blood flow in the right pulmonary veins makes scimitar patients prone to thrombosis, particularly if an intra-atrial tunnel or baffle is used for repair. In that case, aspirin is recommended postoperatively. A pneumonectomy (rarely done) simplifies postoperative care from a cardiac and respiratory infection standpoint but is generally a poor choice for repair since it immediately reduces the lung function and can result in chronic respiratory insufficency [50]. The postoperative care for scimitar syndrome will also depend on associated cardiac anomalies.

Outcomes

TAPVR

Preoperative and/or postoperative pulmonary vein obstruction and associated cardiac lesions are the two main determinants of early and late mortality [51–53]. Complex TAPVR requires repair of other major cardiac lesions. Since 1990, 43 % of TAPVR patients have had other cardiac abnormalities. Single ventricle with TAPVR and/or heterotaxy is not an uncommon combination of cardiac lesions and deserves to be reported independently [51, 54].

Early mortality for simple TAPVR patients has significantly decreased since the initial repair described by Muller in 1951. As late as the 1970s, the operative mortality for simple TAPVR was reported to be as high as 50 %, but it has recently been reported to be as low as 5 %. There has been a 2 % operative mortality for 63 cases since 1990 and no mortality since 1995 [53] (Table 107.1). Additionally, late mortality for simple TAPVR repair has decreased to between 2 % and 5 % in the recent literature [23, 55, 56]. Early and late mortality for higher-risk patients following complex TAPVR repair remains elevated, approaching 14 % (Table 107.2).

Current literature shows that preoperative pulmonary vein obstruction has a significant impact on mortality, especially early mortality (Table 107.3). Postoperative pulmonary vein obstruction also has a significantly negative impact on mortality, which approaches 40 % in the first 3 postoperative years for patients with postoperative pulmonary vein obstruction [52]. Postoperative pulmonary vein obstruction also remains one of the major reasons for reoperation among post-TAPVR patients. The rate of reintervention due to postoperative pulmonary vein obstruction has decreased to around 10 % for simple TAPVR in recent literature and has been reported as low as 8 % (Table 107.1). The rate of postoperative reintervention for pulmonary vein obstruction following combined simple and complex TAPVR repair has been reported as low as 13 % in the literature (Table 107.2) [51].

If postoperative pulmonary vein obstruction persists, the suture-less surgical technique is the suggested procedure to correct it [58]. Those patients who survive the surgery have a low pulmonary vein obstruction recurrence rate, and 90–98 % are reported to be in NYHA class 1 [41, 55, 56].

PAPVR

Unlike in TAPVR, PAPVR is often diagnosed late, and patients are scheduled electively for surgery, generally between 1 and 5 years of age. For those who present with significant symptoms, surgery can be performed at any age. The evidence of postoperative pulmonary vein obstruction is low except in scimitar syndrome, where it is higher depending on the technique of repair [9]. The recent literature of non-scimitar PAPVR focuses on sinus venosus PAPVR since it is the most common type. Right atrial baffling near the SA node may produce postoperative arrhythmias [9, 11, 25, 44, 49]. The incidence of atrial dysrhythmias in single patch versus 2 patch technique is roughly the same [43, 49]. The Warden technique has been shown to have the least incidence of prolonged postoperative arrhythmias since no suturing is required near the SA node area [44]. Superior vena cava narrowing is another known risk of PAPVR repair and is more common after the one- or two-patch techniques than after the Warden technique. Both early and late mortality after sinus venosus PAPVR repair approach 0 % (Table 107.4).

Scimitar Syndrome

Much like PAPVR, patients who present with scimitar syndrome and mild symptoms are not offered surgery immediately. One institution has shown that 43 % of its patients diagnosed with scimitar syndrome do not require urgent surgical treatment and do well with either medical treatment or no treatment at all [35]. Pulmonary hypertension is an important prognostic indicator following surgical repairs. One study reported a 50 % mortality within 90 days in patients with significant postoperative pulmonary hypertension [59]. Older patients with scimitar syndrome generally do better than young infants [11]. The incidence of scimitar vein stenosis is higher in patients who underwent the long intra-atrial

baffle technique [11]. The left atrial reimplantation technique has been used at our institution with excellent results, with no stenosis or mortality at latest follow-up, and is our procedure of choice for scimitar syndrome [12] (Table 107.5).

Summary

TAPVR remains one of the few congenital cardiac lesions that may require emergency early neonatal surgical correction. Surgery for

PAPVR and/or scimitar syndrome can usually be delayed. Multiple surgical techniques have been proposed for TAPVR, PAPVR, and scimitar syndrome, and each has its own proponents with certain benefits. No one technique is perfect for all PAPVR correction. The Warden technique is recommended for PAPVR correction when the anomalous pulmonary veins drain high on the SVC. Additionally, reimplanting the scimitar vein to the left atrium for scimitar syndrome via a right thoracotomy and without bypass unless a significant ASD is present is recommended. Unroofing the coronary sinus and covering the coronary sinus and ASD with a single patch for cardiac TAPVR patients is also recommended. The retrocardiac technique is preferred for supracardiac and infracardiac TAPVR. While the early and late postoperative results of simple TAPVR have been quite favorable, there is room for improvement with complex TAPVR.

Finally, treatment of preoperative and postoperative pulmonary vein obstruction remains a vexing problem with all types of anomalous pulmonary venous returns and is the cause of the early and late mortality. Improving the management of pulmonary vein stenosis is the challenge for the future in improving the results of correction of anomalous pulmonary venous return.

Pulmonary Vein Stenosis

108

François Lacour-Gayet, Leo Lopez, Jesse Davidson, and Eduardo M. da Cruz

Abstract

Pulmonary vein stenosis is a relatively rare, complex, challenging, and often lethal condition among pediatric heart diseases, with a guarded prognosis. The pathophysiology is poorly understood, and the search for an effective treatment remains a source of frustration. There are two different forms of pulmonary vein stenosis. The *primary* "*congenital*" form, which is isolated or associated with other congenital heart diseases, has a severe prognosis. *Acquired* or *secondary* pulmonary vein stenosis, which occurs most commonly after repair of total anomalous pulmonary venous return (TAPVR), fosters a better prognosis. This chapter will discuss embryological, anatomical, physiological, clinical, and diagnostic details; medical and surgical management; and outcomes of the disease.

Introduction

Pulmonary vein stenosis (PVS) is a relatively rare, challenging, and often lethal condition among pediatric heart diseases, with a guarded prognosis. The pathophysiology is poorly understood, and the search for an effective treatment remains a source of frustration. There are two different forms of PVS. *Primary* "*congenital*" PVS, which is isolated or associated with other congenital heart diseases, has a severe prognosis. *Acquired* or *secondary* PVS, which occurs most commonly after repair of total anomalous pulmonary venous return (TAPVR), fosters a better prognosis. PVS following radiofrequency ablation of atrial fibrillation is seen in the adult population.

Surgical management has evolved over the past two decades, with traditional patch enlargement techniques eventually replaced by the "sutureless" repair technique in many centers. Interventional cardiology procedures are used in recurrent PVS. New pharmacologic agents that may prevent the progression of the disease are currently under investigation.

Anatomy and Embryology

The left atrium and the cardinal system develop separately at 24–28 days of gestation and initially consist of the paired anterior and posterior cardinal veins. At 27–29 days, an endothelial outgrowth from the posterior superior wall of the primordial left atrium develops to the left of the developing septum primum, and these primordial pulmonary veins connect to the left and right horns of the sinus venosus. The anterior cardinal vein and the two posterior systems form parts of inferior vena cava and its main branches, as well as the azygous and the hemiazygous systems. The paired vitelline veins, which originally drain the yolk sack, are also a major contributor to the venous system. As the embryo matures, the vitelline veins give rise to the hepatic sinusoids, the portal system, parts of the inferior vena cava, and the ductus venosus. Ultimately, in the course of normal development, the left-sided cardinal and vitelline veins regress, while the right-sided ones give rise to the great veins, which, in turn, connect to the right atrium.

The development of the pulmonary veins trails that of the systemic veins by about a week. Initially, the lung buds are drained by the splanchnic plexus, which interconnects extensively with the cardinal and the vitelline systems, but does not reach the heart. By the end of the first gestational month, the common pulmonary vein buds off the posterior wall of the left atrium and soon connects the pulmonary venous plexus to the sinoatrial portion of the heart. By 38–40 days of gestation, the pulmonary-splanchnic connections disappear, leaving four major pulmonary veins that empty into the common pulmonary vein, which in turn drains into the left atrium. As cardiac development continues, the common pulmonary vein is also incorporated into the left atrium, while the four pulmonary veins connect separately and directly to the left atrium [1–3].

Pathophysiology and Clinical Presentation

In pediatrics, PVS may be primary or secondary (acquired) to surgery or other interventions. The primary form of PVS may be related to inadequate embryological connections between the intrapulmonary venous system, the common pulmonary vein, and the left atrium. This stenosis in usually not static and postnatal worsening may be caused by abnormal neoproliferation of unusual myofibroblastic cells. It is unclear

whether the same type of abnormal cells is involved in secondary PVS.

Primary "Congenital" PVS

Congenital PVS is a progressive disease [4]. The congenital nature of the disease is controversial, and the term "primary" may be more appropriate as pulmonary vein stenosis may not be evident at birth in many cases. Primary pulmonary vein stenosis without prior surgery seems to result from abnormal incorporation of the common pulmonary vein into the left atrium during the later stages of cardiac development [5].

Risk factors are unclear but some data has become apparent. Prematurity appears to be a risk factor for primary PVS [6, 7]. Balasubramanian et al. [8] published a cohort of 82 cases followed longitudinally and reported that bilateral disease at diagnosis, age <5 months at diagnosis, and involvement of more than two pulmonary veins at diagnosis were associated with shorter time to death in univariate analysis. In multivariate analysis, both bilateral disease and age <5 months at diagnosis were independently associated with time to death. The progressively worsening obstruction occurs in the absence of inflammation and resembles a neoproliferative process [4]. Pathological studies conducted by the group in Boston Children's Hospital have found proliferation of myofibroblastic cells that can differentiate into either a myocyte or a fibroblast [9]. In addition, molecular biological studies [10] have revealed evidence for expression of receptor tyrosine kinases by the lesional cells. Based on these findings, antiproliferation chemotherapy is under investigation [11].

In approximately half of cases, congenital PVS is associated with another congenital heart disease, ranging from simple malformations like atrial or ventricular septal defects to major anomalies like single ventricle with heterotaxy syndrome [4, 12].

The natural history of congenital PV stenosis reveals poor prognosis, with most cases evolving into worsening pulmonary venous hypoplasia and even atresia.

Secondary Acquired Pulmonary Venous Obstruction

PVS occurs in approximately 10 % of patients after repair of total anomalous pulmonary venous returns (TAPVR) [12–18]. The obstruction may occur at the anastomosis of the pulmonary venous confluence to the left atrium. However, the obstruction is more frequently seen along individual pulmonary veins, with stenosis, hypoplasia, or atresia occurring anywhere up to the lung hilum. The stenosis can involve a single pulmonary vein or all four pulmonary veins. Cases involving at least one right and one left pulmonary vein are the most severe. When the obstruction occurs immediately after surgery, it is usually related to a restrictive anastomosis. More commonly, however, PVS can occur one to several months after surgical repair, many times after an uneventful intraoperative and postoperative course.

Complex forms of TAPVR are associated with a significantly higher risk of PVS. Postoperative PVS can occur after repair of TAPVR associated with a single ventricle and right atrial isomerism in 20–50 % of all cases [14, 15, 19]. Mixed drainage, anomalous pulmonary venous drainage associated with scimitar syndrome, the presence of a genetic syndrome, and a weight less than 2.5 kg are all associated with increased occurrence of PVS. Pulmonary venous obstruction may appear to occur more frequently in the setting of infracardiac TAPVR, but this may be due to the fact that the most common type of TAPVR is infracardiac [17]. Hypoplasia of the common pulmonary venous trunk is the most common finding in cases of complex TAPVR. PVS with native intra-hilar pulmonary venous hypoplasia occurs rarely after TAPVR repair, but it has been reported in the setting of single ventricle [13, 15, 20].

The pathology of PVS following TAPVR surgery usually involves fibrous intimal hyperplasia with some medial hypertrophy [12, 13]. The spectrum of lesions can be large, depending on the degree of obstruction and whether this obstruction is unilateral or occurs on both sides. Recent efforts are under way to prevent PVS after TAPVR repair by limiting the degree of

pulmonary venous manipulation ("no-touch technique") at the time of repair [17]. In addition, the group in Toronto [21, 22] is now using the "sutureless" technique as the primary procedure in TAPVR with hypoplasia of the common pulmonary vein, in order to limit the risk of late PVS.

PVS following radiofrequency ablation procedures for treatment of atrial fibrillation is seen in adults [23]. However, it occurs more rarely with improvement in technique, and it is treated exclusively using angioplasty procedures. Recurrences are frequent. PVS after non-TAPVR cardiac surgery has been described [24] highlighting the unclear boundary between acquired and primary PVS.

Diagnosis

Clinical

Patients with pulmonary venous stenosis may not present from birth with significant clinical findings. Timing and severity of symptoms depend largely on the number of pulmonary veins involved, the severity of obstruction, and the presence of associated cardiac defects or genetic syndromes [4]. Patients become symptomatic between the first few months and first few years of life. The severity of the symptoms depends on the duration of the disease and on the number of pulmonary veins involved [4, 8]. Patients may succumb at any time to sudden death because of supra-systemic pulmonary hypertension crises.

As PVS evolves, patients present with symptoms and signs of cardiorespiratory failure with progressive pulmonary arterial hypertension (PAH). Cyanosis may be identified in the presence of intra- or extracardiac right-to-left shunts that become more evident as the PAH progresses. The latter may eventually cause major life-threatening syncopal events that not uncommonly reveal the disease for the first time. Patients are usually tachypneic and may have a history of multiple admissions with recurrent pneumonia. Failure to thrive is a frequent clinical pattern in patients who develop chronic respiratory and cardiac failure. Patients with PVS tolerate respiratory viral illnesses very poorly and the latter may be the major contributing factor for decompensation. In older patients, hemoptysis is not uncommon and may also be recurrent. Noninvasive evaluations may indicate the need for complementary invasive strategies; extensive differential diagnosis is sometimes necessary and complex, all the more that PVS may coexist with other complex and confounding entities (i.e., pulmonary veno-occlusive disease or PVOD, pulmonary capillary hemangiomatosis, or other causes of PAH). As a matter of fact, evaluation for stenotic pulmonary veins is indicated in any infant with severe pulmonary hypertension [4].

Echocardiography

Noninvasive evaluation suffices to provide a reliable diagnosis in most young patients, owing to their adequate acoustic window. Echocardiographic assessment of PVS requires a good understanding of the echocardiographic characteristics of normal unobstructed pulmonary venous return. Color flow mapping of the left atrium and surrounding structures in a high left parasternal short-axis or transverse view, often referred to as the "crab view," usually provides excellent qualitative delineation of three or four of the pulmonary veins (Fig. 108.1). The right upper pulmonary vein is often difficult to evaluate in this view, especially since it can easily be confused with the right middle pulmonary vein. Subcostal short-axis and right sternal border views usually provide better characterization of the right upper pulmonary vein (Fig. 108.2).

Normal pulmonary venous flow is pulsatile, and the usual determinants of pulmonary venous flow patterns include left atrial contraction and relaxation, mitral annular motion, and left ventricular systolic function and compliance. Spectral Doppler interrogation of individual pulmonary veins requires setting the filter to the lowest level, decreasing the Nyquist limit to account for low-velocity flow, orienting the echocardiographic beam so that it is parallel to the pulmonary venous flow, and assuring that the sampling occurs in the pulmonary vein and not

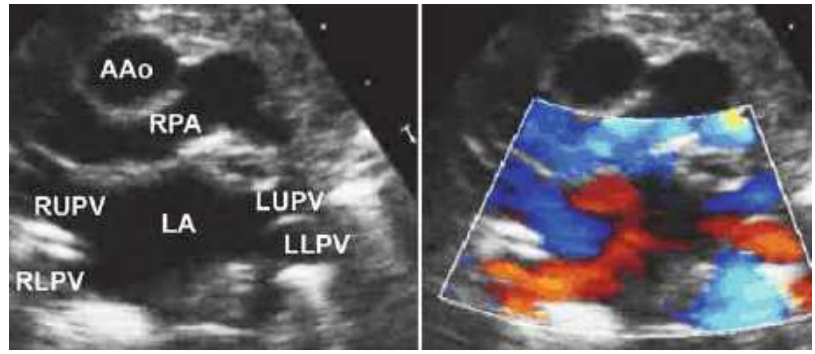

Fig. 108.1 Echocardiographic "crab view" incidence showing four normal pulmonary veins draining onto the left atrium

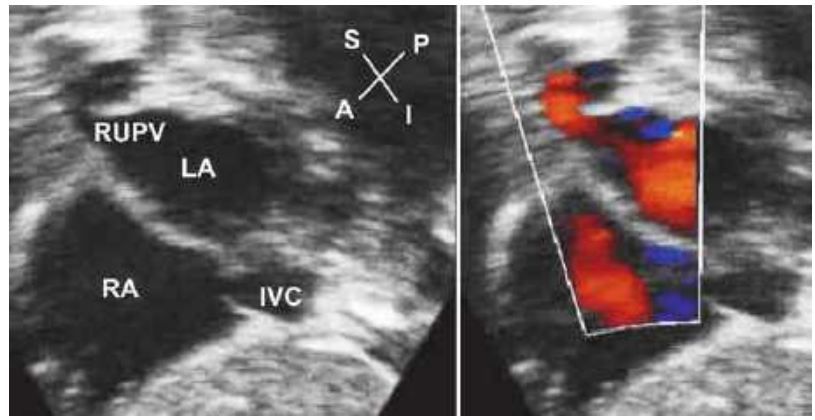

Fig. 108.2 Echocardiographic view showing the normal drainage of the right upper pulmonary vein

in the left atrium. This evaluation may be technically challenging.

The Doppler pattern for normal pulmonary venous flow is usually biphasic or triphasic with forward flow during systole and diastole and reverse flow during atrial contraction. The factors that determine the amount of systolic forward flow (S wave) include active atrial relaxation, mitral annular displacement, and pulmonary blood flow. Diastolic forward flow (D wave) occurs during rapid ventricular filling and is affected primarily by ventricular compliance. The amount of late diastolic reversal (A wave) is usually determined by pressure during atrial contraction and pulmonary vein compliance, especially in the neonatal patient (Fig. 108.3). Other physiologic and determinant factors that affect the pulmonary venous flow pattern include respiration, heart rate, and age. The effects of a fast heart rate are especially important in neonates where there is frequent fusion of the S and D waves in the setting of normal pulmonary venous flow.

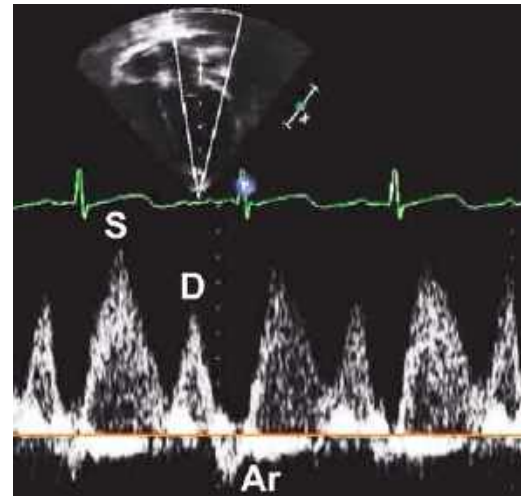

Fig. 108.3 Normal pulmonary vein Doppler pattern

Echocardiographic diagnosis of PVS can be quite difficult, and many case reports have been published highlighting the limitation of echocardiography for this disease [25, 26]. Diagnosis is

also complicated by the fact that PVS is a progressive disease and can develop after a normal initial echocardiogram [27]. The echocardiographic hallmark of PVS is the presence of turbulence at the junction between one or more pulmonary veins and the left atrium. Turbulence may also be seen in the setting of pulmonary overcirculation secondary to associated large left-to-right shunts [28]. The Doppler pattern will appear monophasic with continuous forward flow which has usually (though not always) high velocity and no reversal (Fig. 108.4). Operators must remember that this pattern can be seen normally up to 8 h after birth in the absence of any pulmonary venous abnormalities [29]. It is important to recognize the limitations of measuring mean gradient by echocardiography for PVS, particularly because of inadequate Doppler angles in most views and because gradients are attenuated by the decreased pulmonary blood flow which generally accompanies PVS.

Because primary PVS can occur in the setting of congenital heart diseases such as complete atrioventricular canal defects, atrial and ventricular septal defects, and functional single ventricles, careful interrogation of the pulmonary veins should always be part of any preoperative or postoperative echocardiogram for these patients. Primary PVS should also be considered when there is unexplained pulmonary hypertension with elevated tricuspid regurgitation jet velocities and no right ventricular outflow tract obstruction. Acquired PVS should always be considered in the follow-up echocardiograms after TAPVR repair, atrial switch operation for transposition of the great arteries, and palliative procedures for functional single ventricle.

Transesophageal echocardiography (TEE) can be helpful in characterizing each individual pulmonary vein and in delineating the mechanism of the PVS, particularly in the setting of poor echocardiographic windows secondary to body habitus or previous surgeries. However, operators must recognize the fact that the TEE probe can physically obstruct one or more of the pulmonary veins with consequent turbulence in flow by color mapping without true PVS.

Cardiac Magnetic Resonance and Cardiac Computed Tomography

In patients with poor acoustic windows, especially after surgical intervention, echocardiography may not provide adequate information regarding the degree and type of PVS. Cardiac magnetic resonance imaging (cMRI) and computed tomographic angiography (CTA) (Fig. 108.5) have provided additional information in these instances with tomographic and three-dimensional views. The decision to use one modality over the other depends on several factors: availability of the modality, local expertise to perform and interpret the examination, the ability of the patient to tolerate prolonged image acquisition times and the need for deep sedation and even anesthesia with cMRI, and the radiation exposure associated with CTA. An interesting study looking at the utility of cMRI in PVS has shown that unilateral pulmonary vein stenosis is associated with diastolic reverse flow in the ipsilateral branch pulmonary arteries and diastolic forward flow in the contralateral branch pulmonary arteries, whereas bilateral pulmonary vein stenosis is associated with diastolic forward flow in most or all of the branch pulmonary arteries [30]. cMRI or CTA are also useful in cases with pulmonary veins atresia (Fig. 108.6).

Diagnostic Catheterization and Angiography

Catheterization and angiography are important components of PVS evaluation when echocardiography is limited by patient's characteristics, there is a need for further delimitation of the anatomy, or whenever anticipating interventional procedures as a complement to surgery. It allows for accurate measurements of pulmonary arterial pressure. Selective injections into the branch pulmonary arteries can confirm and characterize PVS: discrete stenosis, hypoplasia, or atresia of one or more of the pulmonary veins. Although selective retrograde venograms also provide useful information, operators should always remember that

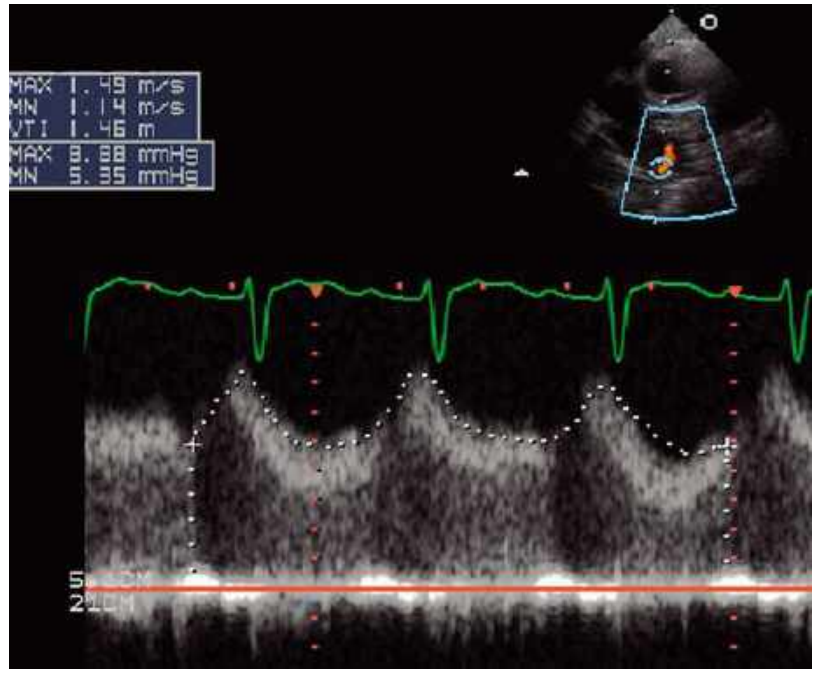

Fig. 108.4 Pulmonary vein stenosis Doppler pattern

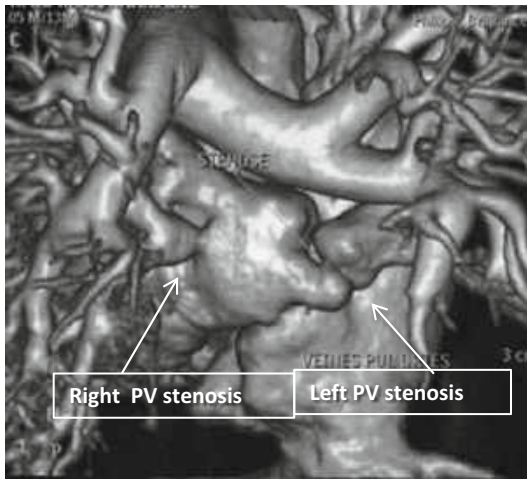

Fig. 108.5 CT Scan: bilateral primary pulmonary vein stenoses Posterior view

Fig. 108.6 CT Scan: Right pulmonary vein atresia

the presence of a catheter in a stenosed pulmonary venous ostium can increase the gradient between the pulmonary vein and the left atrium. Primary balloon angioplasty or stenting is almost never performed because of markedly poor success rate (see below) [12, 18, 31].

Preoperative Medical Management

Many patients with pulmonary vein stenosis have chronic mild to moderate symptoms and do not require significant preoperative management. Efforts in these patients should focus on the rigorous search for concomitant pulmonary infection, limitation of pulmonary edema by avoiding fluid overload and through judicious diuretic use, and assessment for pulmonary hypertension, all of which may increase postoperative risk of right heart failure and the need for prolonged

ventilation. Decision to treat non-emergent preoperative pulmonary hypertension in these patients can be particularly difficult. Pulmonary hypertension due to fixed obstruction of multiple postcapillary vessels may respond poorly to pulmonary vasodilators, resulting in severe pulmonary edema and respiratory failure. Reactive pulmonary hypertension in patients with more limited pulmonary vein obstruction is due to chronic volume overload of the unaffected pulmonary segments and may be responsive to perioperative pulmonary vasodilators (oxygen, nitric oxide, sildenafil). In cases of moderate pulmonary hypertension where cardiac catheterization is performed for anatomic assessment of pulmonary vein obstruction, intra-procedure pulmonary vascular reactivity testing with oxygen or nitric oxide may be beneficial to identify candidates for perioperative treatment of pulmonary hypertension.

In more severe cases, preoperative condition may be deleteriously affected by a combination of pulmonary hypertension and right heart failure. Septated biventricular patients with severe pulmonary hypertension will primarily demonstrate decreased systemic perfusion. Hypoxemia may be variably present based on the amount of associated pulmonary edema. Patients with residual septal defects will usually have preserved systemic output at the expenses of increased right-to-left shunt and worsening cyanosis. Single-ventricle patients with partial or total cavo-pulmonary connections are very sensitive to pulmonary venous obstruction. Elevated postcapillary pressures will result in decreased systemic output (unless a fenestration is present) and elevated intrapulmonary pressures. Pleural effusions are likely, and preoperative evaluation should include the search for other chronic manifestations of elevated cavo-pulmonary pressures such as liver disease, plastic bronchitis, chylous leaks, and protein-losing enteropathy.

Treatment of severe preoperative pulmonary hypertension should focus on right heart function and preservation of systemic cardiac output. Inotropic support with dopamine or epinephrine is usually required. Milrinone may also be beneficial, although pulmonary and systemic vasodilation may be poorly tolerated in cases with severe multivessel obstruction. Primary pulmonary vasodilators may be used with caution to address reactive disease, acknowledging that they may also increase pulmonary edema. Preoperative mechanical ventilation should be reserved for the most serious cases due to the risk of precipitating pulmonary hypertensive crisis and cardiac arrest during intubation. Initiation of inotropic support is warranted prior to attempted intubation. Once successfully intubated, ventilation strategy should target normal carbon dioxide levels and maintenance of functional residual capacity without overdistension in order to minimize obstruction to right ventricular output. Adequate sedation should be established to minimize oxygen demand and pulmonary vasoconstriction. In patients with refractory low cardiac output or cyanosis, mechanical circulatory support with venoarterial extracorporeal membrane oxygenation may be considered as a bridge to surgery if a surgically correctable lesion such as focal obstruction of previous TAPVR repair is present.

Pulmonary hemorrhage is a particularly devastating complication of severe pulmonary vein obstruction. Intubation and application of high positive end-expiratory pressure often provides adequate tamponade to control bleeding. Transfusion of packed red blood cells is the treatment of choice for resulting severe anemia or hypovolemic shock. Use of fresh frozen plasma, platelets, cryoprecipitate, or activated factor VII may be necessary to achieve hemostasis, particularly in the setting of a preexisting coagulopathy or massive transfusion. Selective pulmonary artery embolization or pulmonary lobectomy may be indicated in the case of single-vessel obstruction with severe pulmonary hemorrhage.

Surgical Treatment

Since the first repair reported by Kawashima et al. in 1971 [32], several surgical and percutaneous techniques have been proposed with minimal success due to restenosis and persistence of pulmonary hypertension.

Timing of Surgery

The surgery is indicated when the pulmonary artery (PA) pressure is over 50 mmHg [4, 12, 17, 18]. The indication may become urgent to prevent the evolution toward an atresia of an individual pulmonary vein. It is always indicated in presence of an anastomotic stenosis following a TAPVR repair.

One isolated PV stenosis is usually well tolerated and may not be an indication for repair.

Anastomosis Stenosis Repair

A narrowing of the anastomosis between the common PV trunk and the left atrium is rare and is usually associated with individual PV stenosis. When isolated, the technique is quite simple. The stenotic area is resected, and the anastomosis of the common PV tissue with the left atrium is redone with or without a patch enlargement.

Traditional Venoplasty

Intraoperative instrumental dilation of PV ostium is constantly associated with restenosis [17, 18]. The same applies to the endothelium resection of the stenotic ostium. Patch enlargement of the PV is nearly always a failure on the right side. On the left side, some centers [33] are reporting satisfactory results when using the left appendage to patch the upper left PV.

Sutureless Pulmonary Vein Repair

The authors first published this technique in 1996 [34] in a patient presenting with PVS after a TAPVR repair and published a series of seven patients in 1999 [17]. The principles of the sutureless technique [12] are *to avoid any direct suture on the pulmonary veins and to totally resect* the abnormal PV stenotic scar tissue due to the natural tendency of the PV tissue to restenose. This resection creates a large opening on the lateral wall of the left atrium that is managed differently on the right and the left side. The technique is easier in patients presenting after TAPVR repair, due to the presence of pericardial adhesions. In primary PVS, the technique requires particular attention to avoid bleeding into the lung hilum or in the posterior pericardium. If circulatory arrest is simpler, a bicaval cannulation with full flow may be the preferred technique. After cardioplegic arrest, the left atrium is approached through a transseptal incision. The PV stenotic ostia are identified. These ostia can be reduced to pinholes and difficult to identify. The segment of stenotic pulmonary vein scar tissue is dissected all the way until normal PV tissue is found. The individual PV is then cut one centimeter from the pericardial reflection, in avoiding further dissection toward the lung hilum. A 4 mm atrial fenestration is left in place to allow access to the left atrium for potential further angioplasty procedures. The remainder of the technique is different on the right and left side.

On the right side (Fig. 108.7a, b, c)

The right pericardium is used to create a pouch that will drain passively one or two open PV stumps into the left atrium. The posterior wall of the left atrium needs to be securely closed and, if needed, sutured to the posterior pericardium, particularly in primary PVS without pericardial adhesions. Then, the pericardial wall is anastomosed to the right atrial wall, above the Sondergaard sulcus, creating a neo-left atrial pouch made by the pericardial sac (Fig. 108.7a, b, c). The right phrenic nerve is located below the anastomosis and should be permanently watched. In some instances, the phrenic nerve needs to be carefully dissected free from the pericardium.

On the left side (Figs. 108.8 and 108.9)

From the inside (Fig. 108.8). Following TAPVR repair, with robust posterior pericardial adhesions, the left pulmonary veins are resected and the defect in the left atrial wall is left open. The left pulmonary veins are allowed to drain passively into the left atrium through the posterior pericardial cavity maintained closed by the pericardial adhesions.

From the outside (Fig. 108.9). In primary PVS or in absence of robust pericardial adhesions, it is necessary to lift up the left ventricle to access the left PV stumps. The approach could be made

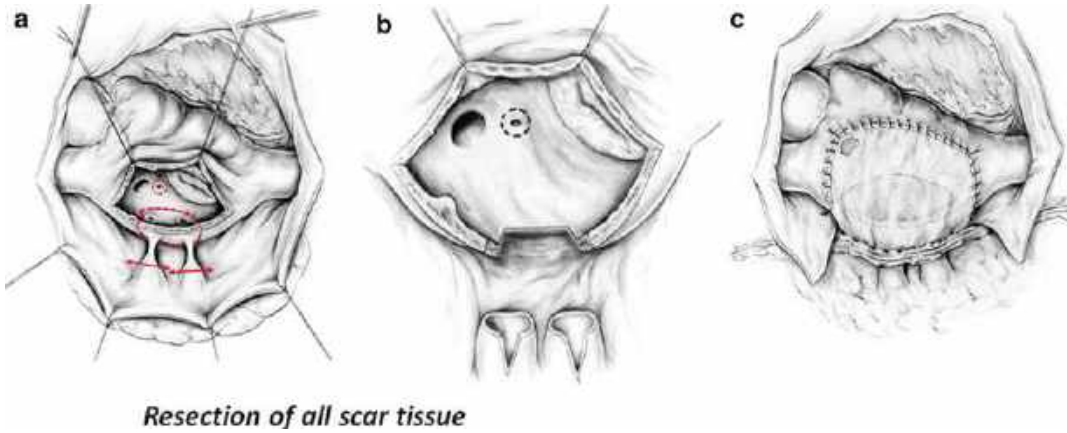

Fig. 108.7 Sutureless pulmonary vein repair Right side

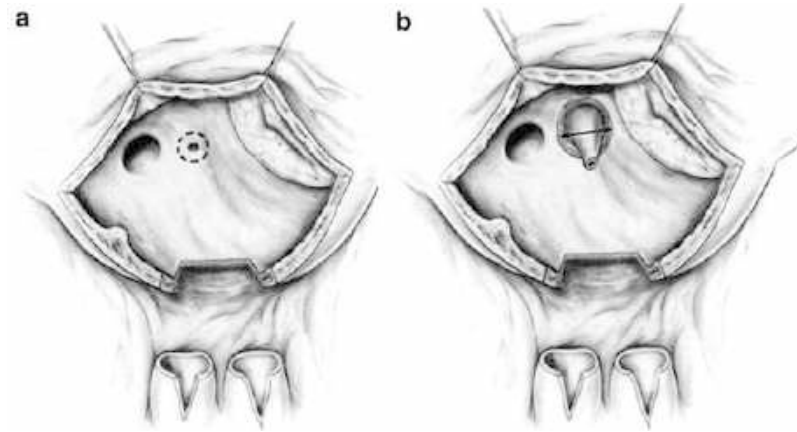

Fig. 108.8 Sutureless pulmonary vein repair Left side from inside the left atrium, with pericardial adhesions

easier in dividing the inferior vena cava [35]. Then, the lateral wall of the left atrium is anastomosed onto the pericardium, at least at one centimeter away from the PV open stumps. It is important to ensure that the suture line does not involved the pulmonary vein and that it is an atrio-pericardial anastomosis (Fig. 108.9b). The left phrenic nerve is located above the anastomosis and should be permanently watched. Hemorrhage into the pulmonary hilum or inside the pleural cavity has not occurred in the author's experience with redo TAPVR. It has occurred once in a patient with native congenital PV stenosis repair with intact pericardium. The bleeding was controlled by suturing the pleural tissue to the pericardium.

Van Arsdell's group at the Hospital for Sick Children in Toronto is routinely using this technique of sutureless repair as the initial procedure technique for TAPVR repair, in patients with hypoplasia of the common pulmonary vein trunk [35]. The critical element of the technique is to perform the atrial anastomosis directly to the pericardium around the incised common pulmonary vein.

PV atresia either primary or secondary is seen in numerous cases during the evolution of the PV occlusive disease. PV atresia repair was attempted, using sutureless repair associated with percutaneous procedures, with quite poor early results [7]. Unilateral pneumonectomy has been rarely attempted to control severe pulmonary hypertension [45].

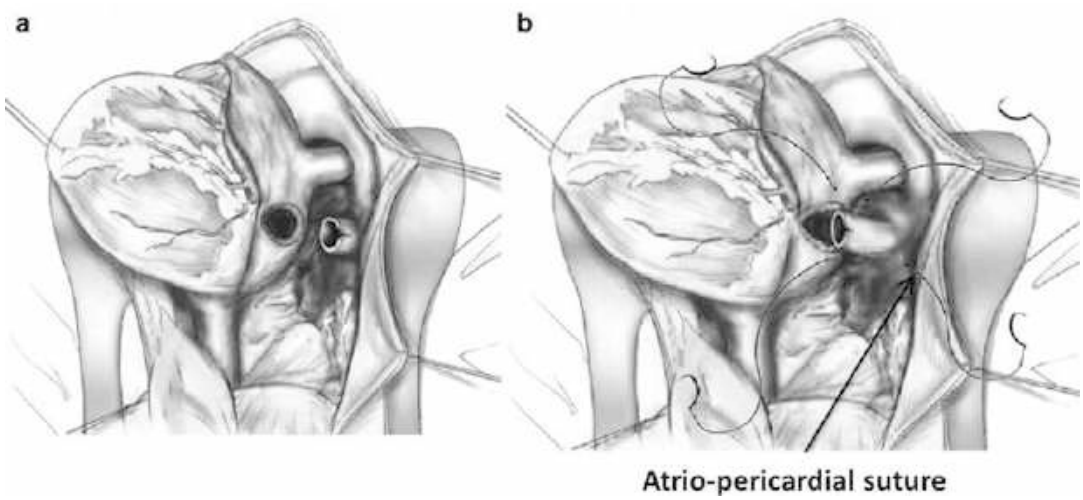

Fig. 108.9 Sutureless pulmonary vein repair Left side from outside

Lung transplantation, either unilateral or bilateral, may be the ultimate salvage resource but long-term outcomes remain disappointing [36].

Interventional Catheterization

Interventional catheterization of patients with PVS has had limited accomplishments in the long term, although immediate good results are often seen [37, 38]. Repeated procedures are often needed. Low-pressure balloons tend to be inefficient, while high-pressure balloons show better immediate angiographic results. Cutting balloons may be cautiously used in resistant stenotic segments [31, 39]. The use of stents for PVS, both percutaneously and intraoperatively, has not been consistently capable of palliating these patients, as almost always restenosis rapidly develops [40, 41]. The latter is further limited by the technical challenges related to their insertion [4] and the restrictions when needing to further expand the stent diameter to adapt to patient's growth [40]. Drug-eluting stents may offer better alternatives in the future [42]. Newer technologies (i.e., sono- or cryo-dilation), albeit promising, still require accumulative data to prove their effectiveness. Bingler et al. reported that cryoballoon angioplasty of PVS is safe and results in acute relief of stenosis. However, it appears minimally effective as the sole therapy in maintaining long-term relief of PVS [43].

Postoperative Care

Few data exist regarding the exact frequency or severity of early postoperative complications following repair of pulmonary venous obstruction. Typically excellent early results are achieved with significant reduction or elimination of gradient with improved flow through the repaired vessel. Most patients are able to progress rapidly to weaning of inotropic and ventilator support. Less commonly, postoperative complications, including pulmonary hypertension, reperfusion injury, and atrial arrhythmias, may occur, especially in patients with more severe disease, associated cardiac malformations, or preoperative complications. Assuming adequate relief of the anatomic obstruction, postoperative pulmonary hypertension is typically reactive in nature and responsive to usual pulmonary hypertension treatment (pulmonary vasodilators, right heart support, sedation). Intraoperative placement of a pulmonary artery catheter may be useful in patients with preoperative pulmonary hypertension to aid in the diagnosis and goal-oriented management of postoperative pulmonary hypertension. Reperfusion injury manifests as increased opacity

on chest radiograph in the distribution drained by the repaired vein. This injury may be accompanied by a change in pulmonary mechanics and inadequate ventilation or oxygenation. Treatment is supportive and should include lung-protective ventilation strategies to limit ventilator-induced lung injury. High-frequency ventilation may be useful in these circumstances. Atrial arrhythmias may occur in the setting of left atrial surgical manipulation and chronic right atrial injury from exposure to elevated pulmonary and right ventricular pressures. Treatment with rhythm or rate control is similar to other causes of atrial arrhythmias. Placement of temporary atrial pacing wires may be useful in high-risk patients to aid in the diagnosis of abnormal supraventricular rhythms and the treatment of atrial reentry arrhythmias (atrial flutter) through the use of overdrive pacing.

Future Directions: Chemotherapy

The rationale to attempt chemotherapy in patients with PVS targets the modulation of intraluminal myofibroblastic cell neoproliferation. At Boston's Children's Hospital, chemotherapy has been prospectively trialed in infants and children with PVS targeting the presence of myofibroelastic cells within the lesions, based in the experience with myofibroblastic proliferation associated with desmoid tumors [44]. Twenty-eight patients were treated with weekly vinblastine and methotrexate for a period of a year. Outcomes were stratified for patients with isolated PVS and PVS with congenital heart disease and evaluated by echocardiographic criteria of response. Of the total cohort, 23 patients were evaluable for response (2 isolated and 21 with CHD). Both patients in the isolated group had progressive disease and died, whereas 33 % of the patients with CHD had stable disease. Both cardiac-related (19 %) and chemotherapy-related (53 %) toxicities were common. The study limitations and low empowerment hindered the ability to determine the true efficacy of this approach to treat PVS.

Outcomes

PVS is a complex and progressive disease with guarded prognosis.

T. Yun et al. [21] reported a series from Toronto of 60 patients with PVS, including 36 primary PVS, 17 acquired PVS, and 7 primary sutureless repair on TAPVR with small PV. Sutureless repair was used in 40 patients. A PVS score was proposed based on the number and severity of the PV stenosis. A higher score predicts the risk of death or restenosis. Sutureless repair was associated with better late outcome. Several percutaneous procedures were applied to treat restenosis. The outcomes of primary sutureless repair in complex TAPVR were encouraging.

E. Devaney et al. [12] published a series of 36 patients with PVS from Ann Harbor, including 14 congenital PVS and 22 acquired PVS following TAPVR repair. There were 11 sutureless repairs. The overall survival was 58 % at 10 years. The risk factors were congenital PVS, single ventricle, bilateral lesions, and nonuse of sutureless technique. Restenosis occurred in 60 % and was the cause of late deaths. Initial stent placement was abandoned and stent placed on restenosis had better results.

N. Viola et al. [22] reported a series from Toronto focusing on primary PV stenosis. Twenty-three patients, all with associated CHD presenting with primary PV stenosis, underwent sutureless repair. The overall survival was 64 % at 1 year, 47 % at 5 years, and 31 % at 10 years. It is concluded that the mortality and rate of restenosis in primary PVS were high despite the adoption of the sutureless repair technique.

M. Song et al. [33] reported from Seoul a multicentric study of 34 primary PVS. The mortality rate was 47 % regardless of the surgical technique used, with a higher risk for patients with at least three PV involved.

Mendeloff et al. [36] reported a series of six lung transplantation in primary PVS with a 50 % mortality at 2 years.

Conclusions

Pulmonary venous obstruction remains a condition with guarded prognosis. After surgery or interventional catheterization techniques, recurrence of stenosis in both primary and secondary PVS occurs in the majority of patients. Lung transplantation is reserved as a salvage therapy for patients in whom all other strategies have failed. Future developments might bring new interventional approaches and modulation of intraluminal cell proliferation.

Simple Transposition of the Great Arteries

109

Shriprasad Deshpande, Michael J. Wolf, Dennis W. Kim, and Paul M. Kirshbom

Abstract

Transposition of the great arteries (TGA) is one of the more common cyanotic congenital heart defects with an incidence of about 300 per million live births. In TGA, the ventriculo-arterial connection is reversed such that the majority of the aorta arises from the right ventricle while the majority of the pulmonary artery arises from the left ventricle. This defect is incompatible with long-term survival without surgical correction. Since the arterial switch procedure was introduced in the 1970s, early anatomic and physiologic repair has become the standard of care for these children with an expectation of excellent long-term outcomes for the majority.

Historical Background

Dr. Wollaston of St. Edmundsbury gave a unique heart specimen from a 2-month-old child, who died unexpectedly, to Mathew Baillie who described it in his book on morbid anatomy in 1797 [1]. The description included the aorta arising from the right ventricle and the pulmonary artery from the left. He also described the unique circulatory physiology in the condition and recognized the importance of the atrial level mixing that kept the child alive for 2 months. This, as we know, is the first description of the anatomy and pathophysiology of transposition of great arteries (TGA). The word "transposition," however, is attributed to John Richard Farré [2].

Later, Thomas B. Peacock described a case of TGA in the Pathological Transactions (Path. Trans.,vol.vi.1854-55, p. 117) and included the case in his book titled "On Malformations of the Human Heart" published in 1858 [3]. He described a child who died suddenly at 8 months of age. The description of this child's heart was consistent with TGA, probably in the setting of double inlet left ventricle. Over the following decades, there was an increasing awareness of the pathology as evidenced by documentation of lectures given by Dr. Arthur Keith at the Hunterian Lectures wherein he talked about examination of 25 cases

of transposition [4]. Even though this condition was identified two centuries ago, the first real treatment options did not become available until the 1960s when balloon atrial septostomy and surgical palliation became available.

Introduction

Alternative names: complete transposition, simple TGA

Although a rare anomaly, TGA is one of the most common cyanotic heart defects. Hoffman and Kaplan in their landmark analysis (2002) found that the worldwide incidence of TGA was 315 per million live births (or about one per 3,200 live births) [5]. There is a strong male predilection with a male-to-female ratio of 1.6 to 3.2:1 [5]. Maternal diabetes, exposure to pesticides, antiepileptic medications, ibuprofen, and maternal influenza have been postulated as potential risk factors [6–9]. Mutations and dysregulations in various genes (CFC1, GDF1, PROSIT240, Hif1) have been implicated, but they explain only a minority of the cases [10–15]. The natural history of TGA demonstrates high fatality within the first year of life with 29 % mortality by 1 week and 89 % by 1 year [15].

The currently accepted description involves atrioventricular concordance with ventriculo-arterial discordance. This form of transposition was described as "complete transposition" in the past. Similarly, the use of prefixes "d" or "l" or "a" to qualify the spatial relationship of the great arteries are not necessary to define the basic anatomy and the diagnosis. The "d" in the d-TGA also refers to the normal dextroposition of the bulboventricular loop leading to the placement of the right ventricle to the right of left ventricle. This is in contrast with l-TGA which is a result of atrioventricular and ventriculo-arterial discordance.

Anatomy

The anatomy of TGA has been a topic of debate for decades. The current debate surrounds the nomenclature used to describe the morphology. The congenital heart surgery nomenclature report on TGA is an excellent review of the currently accepted terminology [16].

The essence of TGA is that the pulmonary artery originates from the morphologic left ventricle while the aorta originates from the morphologic right ventricle. The pulmonary venous blood returns to the left atrium and is then pumped out to the pulmonary artery by the left ventricle. Similarly, the systemic venous return to the right atrium is pumped out to the aorta by the right ventricle. This creates a system of "parallel circulation," rather than the normal "in-series" circulation. When the circulations are in parallel, tissue oxygen delivery will not be sustained unless there is some level of mixing between the two circuits. This mixing can occur at the atrial, ventricular, or arterial level.

The cardiac anatomy can be described using the segmental approach as described by Van Praagh [17]. The majority of patients with TGA demonstrate visceroatrial situs solitus {S,-,-}. In these patients, the right atrium is to the right of the left atrium and receives systemic venous blood normally. The left atrium receives the pulmonary venous return. An atrial level communication may be present. The presence of a large atrial communication aids in mixing of the systemic and pulmonary venous blood streams. A minority of patients do not demonstrate visceroatrial situs and may represent a form of heterotaxy syndrome {I,-,-} or {A,-,-}. Up to 9 % of patients with heterotaxy syndrome have TGA [18].

The ventricles constitute the second stage in segmental analysis. There is atrioventricular concordance by definition in TGA. This constitutes the more common D looping of the ventricles {S,D,-}. The same concordance can be found with mirror-image arrangement with situs inversus and L looping of the ventricles {I,L,-}. The interposed atrioventricular valves are morphologic mitral and tricuspid valves, respectively, in majority of cases. However, findings of common atrioventricular valve, mitral atresia, and tricuspid atresia have all been described.

The interventricular septum is intact in about 60 % of cases (also referred to as "simple TGA"),

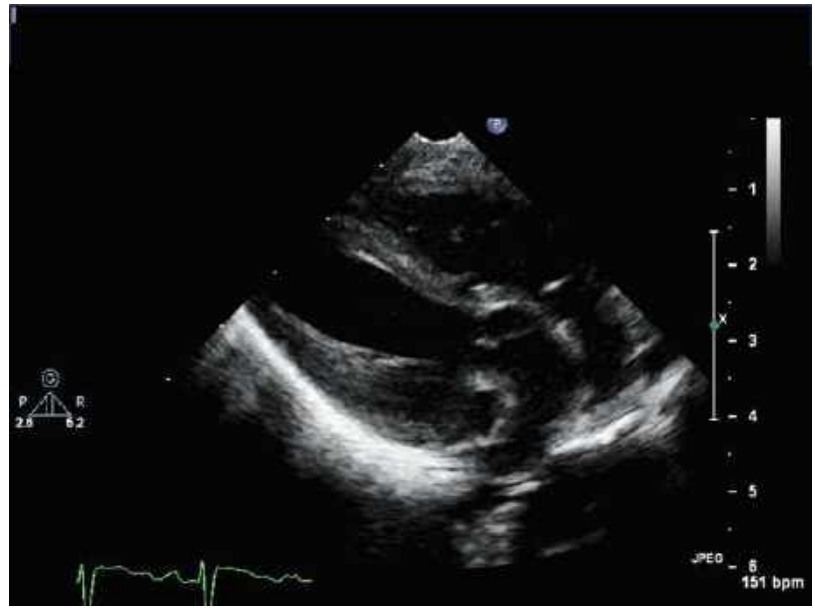

Fig. 109.1 Postnatal parasternal long-axis image from an echocardiogram demonstrating left ventricle to pulmonary artery continuity

while the rest have a ventricular septal defect (TGA with VSD). The type of VSD is variable with 25 % in the perimembranous region. In one-third of patients, the VSD is hemodynamically insignificant. These septal defects are often associated with mal-alignment of the septum and can contribute to outflow tract obstruction. Left ventricular outflow tract obstruction is more common than right ventricular outflow tract obstruction resulting in varying degrees of pulmonary stenosis. In the presence of a VSD, thorough investigation of both the outflow tracts is obligatory, as this has a significant impact on the operative techniques. These complex forms of TGA with outflow tract obstruction are reviewed in other chapters.

The *sine qua non* of TGA is the presence of ventriculo-arterial discordance (Fig. 109.1). Morphologically this is demonstrated by the persistence of subaortic conus leading to fibrous discontinuity between the aortic valve and the atrioventricular valve (tricuspid valve). This orients the aorta anteriorly and over the right ventricle. Simultaneously, resorption of the subpulmonary conus pushes the pulmonary valve posteriorly to align with the left ventricle and develop pulmonary-mitral continuity. The relationship of the great arteries is variable, but the aorta is most commonly anterior and rightward relative to the pulmonary artery, giving rise to a {S,D,D} configuration. Other variations of the aortopulmonary relationship include an aorta that is anterior and to the left {S,D,L}, side by side {S,D,X} or even posterior in relation to the pulmonary valve. Irrespective of the great artery orientation, the basic hemodynamics of TGA are unaltered.

The coronary arteries demonstrate "typical" origin and branching (left main coronary arising from the "right-hand facing" sinus and the right coronary from the "left-hand facing" sinus, per the Leiden classification in which the perspective is that of a person standing in the aorta "facing" the pulmonary artery) in 67–72 % of patients with TGA. Origin of the left circumflex artery from the right coronary artery is seen in 18 % of patients with TGA [19]. The remainder demonstrates variation in the origin and branching patterns. Evidence shows that patients with coronary patterns other than "usual" have significantly higher postoperative mortality [20].

Multiple attempts have been made to formalize the classification of coronary artery patterns in these patients. This has only added more confusion. The author's practice is to describe the coronary anatomy in terms of origin, course, and branching as seen by echocardiography. In most cases, the coronary arteries originate from

adjacent sinuses. The description and nomenclature of these adjacent sinus and coronary origin put forth by Quaegebeur and Gittenberger-de-Groot, known as the Leiden convention, is broadly accepted [21]. The origin of the coronary arteries themselves could be "high" above the sinotubular junction in (10 %) of patients [19, 20]. Oblique and eccentric origins (in relation to the sinus) have also been described. Similarly, part of the coronary course may be intramural, adding to the complexity of the surgery. The surgical transfer of the coronaries during an arterial switch may also be complicated by the commissural alignment of the aortic and the pulmonary valves. Although these commissures tend to be in alignment in most cases, malalignment may lead to an increase in the distance of transfer of the coronary arteries.

The conduction system in TGA is similar to a concordant heart with important variations in the presence of a ventricular septal defect (VSD). As in concordant hearts, the posterior-inferior rim of a perimembranous defect is the most vulnerable part due to close proximity to the atrioventricular bundle. In muscular defects, however, the relative position of the VSD within the muscular septum dictates the position of the conduction system. In addition, the coronary artery supplying the AV node is vulnerable to damage during coronary relocation.

Pathophysiology

As mentioned, the unique feature of TGA is that systemic and pulmonary blood flows are "in parallel" rather than "in series." Postnatally, this leads to cyanosis and metabolic acidosis as systemic venous return recirculates through the systemic arterial system. Unless intervened upon, this leads to rapid and early neonatal demise. The important factor that influences this natural history is the presence of mixing lesions in the form of an atrial septal defect (ASD), VSD, or a patent ductus arteriosus (PDA). Presence of a large intracardiac shunt will ensure adequate mixing and continued oxygen delivery to the tissues. In TGA with intact ventricular septum, atrial level mixing can be supplemented by maintaining an adequate PDA. This may warrant use of prostaglandin to maintain ductal patency. A restrictive ASD may require immediate intervention in the form of balloon septostomy or open septectomy. In TGA with VSD, the intracardiac mixing is often adequate and thereby maintenance of ductal patency is not required.

A newborn with TGA can escape detection in the newborn nursery in the presence of adequate mixing. Following ductal constriction, however, infants may develop acute hypoxia and circulatory collapse. Patients with TGA with VSD may continue to be asymptomatic beyond that point until pulmonary vascular resistance drops (over the first 4–6 weeks of life) and they develop pulmonary over-circulation. In these patients, the left ventricle will undergo remodeling and deconditioning due to rapid reduction in its afterload as the pulmonary vascular resistance drops. A particular worrisome consequence of pulmonary over-circulation in these patients is the development of pulmonary vascular disease (PVOD), as early as 2 months of life [22]. This may be partly related to pulmonary over-circulation. However, development of PVOD has been reported even in patients with restrictive VSDs or intact septum as well as patients after reparative surgeries in the first few days of life [23, 24]. The etiology of this is poorly understood, but abnormal fetal circulation, ductal constriction, restrictive foramen ovale, or postnatal pulmonary microemboli may all contribute.

Diagnosis

Prenatal diagnosis of TGA is often missed as the current guidelines for obstetric ultrasound do not mandate an outflow tract evaluation. On the other hand, when prenatal evaluations are done by fetal echocardiographers, the likelihood of missed diagnosis is extremely low [25, 26]. Patients with TGA who are diagnosed prenatally by fetal echocardiography have better neurocognitive outcomes compared to those diagnosed postnatally [27]. There is a strong case, therefore, for early and accurate diagnosis of TGA.

Fig. 109.2 Fetal echocardiogram demonstrating the great vessels in parallel, suggestive of transposition of the great arteries

Routine screening of newborns for critical congenital heart defects with pulse oximetry is recommended by the American Academy of Pediatrics. Large studies using pulse oximetry screening have shown excellent sensitivity for detection of TGA. In the Swedish study, pulse oximetry detected 100 % of TGA cases [28]. Thus, as more hospitals adopt the screening strategy, fewer patients with TGA will be discharged from the nursery and present later with cardiovascular collapse.

As alluded to earlier, the clinical presentation after birth can vary significantly depending on the degree and level of mixing. TGA with intact ventricular septum and a small atrial communication will be cyanotic rapidly after birth. These newborns rapidly develop severe metabolic acidosis along with progression toward cardiovascular collapse. A high degree of suspicion, prompt evaluation, and often emergent intervention in the form of balloon septostomy are necessary for these patients.

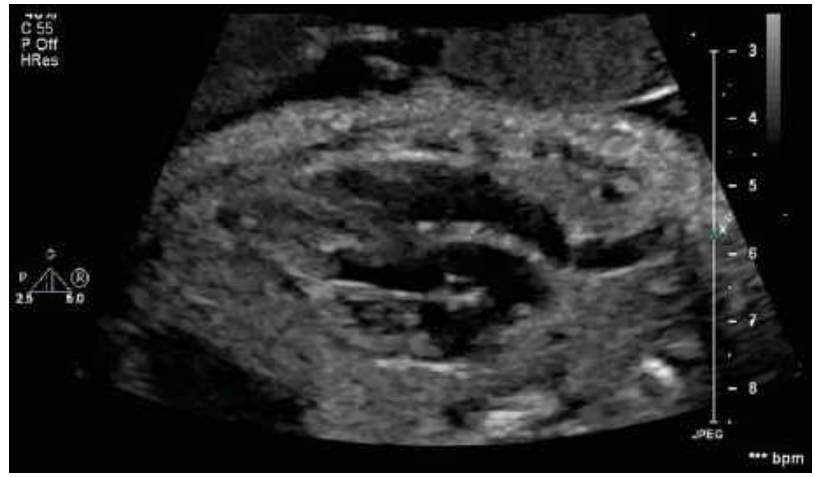
Newborns with large atrial communication may escape detection early on. Cyanosis may be the only clinical finding. Examination may yield a single S2 as the pulmonary component is often posterior and masked by the anterior and prominent aortic component. Heart murmurs related to a constricting duct or outflow tract stenosis may be audible.

Undiagnosed patients with TGA and unrestrictive VSD will present later in the neonatal period with heart failure symptoms. Poor weight gain, diaphoresis, feeding difficulty, increased work of breathing, and occasional cyanosis are the common presenting features. Clinical exam may be noteworthy for tachypnea, tachycardia, and hepatomegaly. Cardiac examination may reveal a prominent cardiac impulse, holosystolic murmur related to pulmonary blood flow, and a gallop rhythm.

Chest X ray can show a "narrow mediastinum" especially when the great arteries are oriented in the anterior-posterior relationship. This has been described as the "egg on a string" appearance. Evidence of pulmonary interstitial edema in the setting of over-circulation may be evident.

Electrocardiogram is often unrevealing in the newborn period. Patients presenting later in life may show evidence of right axis deviation, right ventricle hypertrophy, or biventricular hypertrophy depending on the anatomy.

Modern echocardiography, with extremely high temporal and spatial resolution, has become the mainstay of diagnosis. Fetal diagnosis of TGA can be done with high degree of sensitivity by a trained fetal echocardiographer. The presence of great arteries in "parallel" rather than the normal spiraling or crisscrossing is an important tipoff (Fig. 109.2, Videos 109.1 and 109.2). The fetal evaluation should focus on the presence of mixing lesions (ASD, VSD), ductal flow patterns, pulmonary vascular resistance, as well as



Video 109.1 Fetal echocardiograms in long-axis and apical angulation demonstrating the great arteries in parallel rather than spiraling

Video 109.2 Fetal echocardiograms in long-axis and apical angulation demonstrating the great arteries in parallel rather than spiraling

cerebral perfusion [25]. Presence of restrictive patent foramen ovale or restrictive ductus is associated with poor outcomes postnatally [29]. Utilizing segmental analysis, the postnatal echocardiography should be able to define all aspects of the anatomy of TGA. From the subcostal views, the great vessels will appear to be side by side without crisscrossing. The parasternal long-axis view demonstrates a "posteriorly diving" great artery (pulmonary artery) originating from the left ventricle and bifurcating (Video 109.3). Insuring that the pulmonary valve is competent and adequate is of critical importance as it will be the designated systemic or neo-aortic valve after arterial switch operation. The aorta along with the coronary origins can be seen as the anterior vessel in this view (Fig. 109.1). Parasternal short-axis view is utilized to assess the orientation of the semilunar valves (anterior-posterior or side by side) (Fig. 109.3, Videos 109.4 and 109.5). Assessment of commissural alignment can be accomplished in this view (Video 109.6). Associated lesions such as ASD, PDA, VSD, and outflow tract obstructions should also be defined.

Catheterization plays a limited diagnostic role except in cases where the anatomy cannot be adequately defined by echocardiography. Patients with TGA with intact ventricular septum or a very restrictive VSD who present late may require a hemodynamic catheterization to assess pulmonary vascular resistance and left ventricular pressures.

Video 109.3 Postnatal parasternal long-axis view of the left ventricular outflow vessel (main pulmonary artery) bifurcating and coursing posteriorly

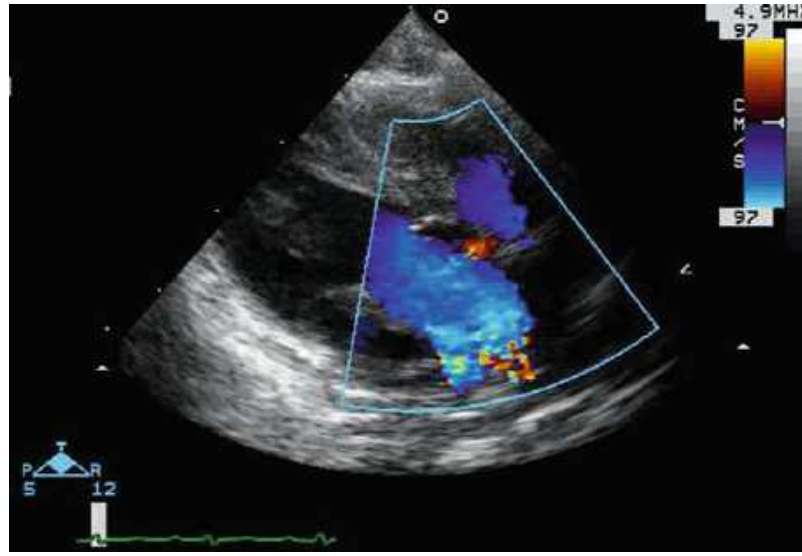


Fig. 109.3 Parasternal short-axis view of the semilunar valves and commissure orientation

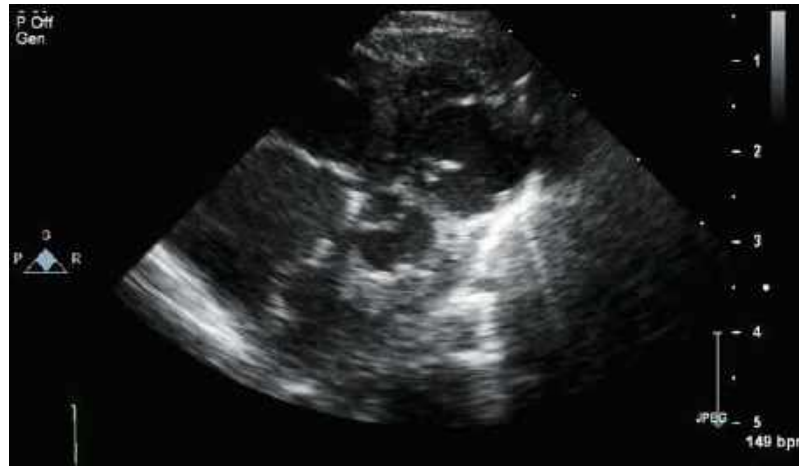
Medical Management

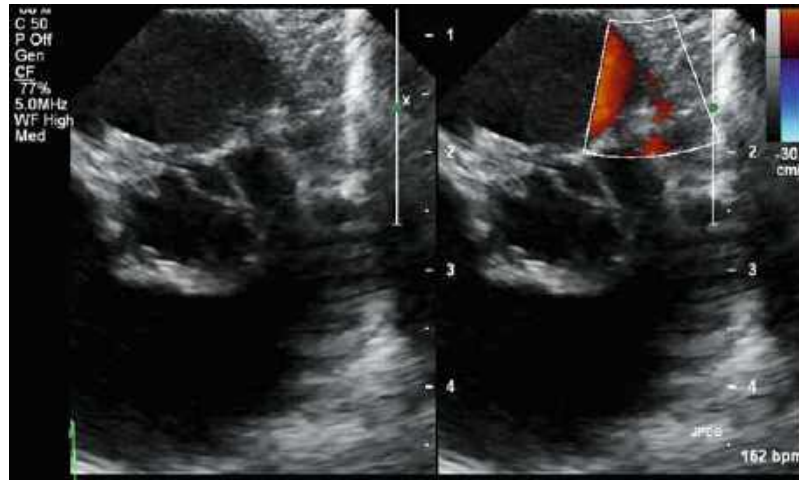
In a newborn with TGA, the initial management should focus on stabilization, correction of acidosis, and hypoxia as warranted. In patients with cyanosis, it is appropriate to start prostaglandin E_1 (PGE_1) to maintain ductal patency. Adequate ductal shunt (left to right) will result in an increase in the net pulmonary blood flow, increasing pulmonary venous return, and the left atrial pressure, thus leading to improved atrial level mixing.

Ductal shunting alone is often inadequate in the presence of a restrictive ASD. These patients warrant an emergent atrial septostomy (described below). Once adequate mixing has been achieved at the atrial level, discontinuation of the PGE_1 is often possible.

Other resuscitation measures include colloids for volume expansion, oxygen, and correction of metabolic acidosis with sodium bicarbonate.



Video 109.4 Parasternal short-axis demonstration of the aortic valve anterior and to the left (video 4) and right (video 5) relative to the posterior pulmonary valve



Video 109.5 Parasternal short-axis demonstration of the aortic valve anterior and to the left (video 4) and right (video 5) relative to the posterior pulmonary valve

Hypoxia and acidosis may also necessitate intubation and sedation to minimize metabolic demands. Patients with persistent cyanosis in the presence of unrestrictive atrial (or ventricular) communication may have pulmonary hypertension and should be treated as such. Roofthooft found that 12.5 % of newborns with TGA had persistent pulmonary hypertension [30]. For these, it may be preferable to use inhaled nitric oxide to assess vascular responsiveness. If oxygenation improves, it may be useful to allow 48–72 h for stabilization and then proceed with surgery.

For patients presenting late, heart failure management is important, often entailing milrinone and diuretics.

Cardiac Catheterization

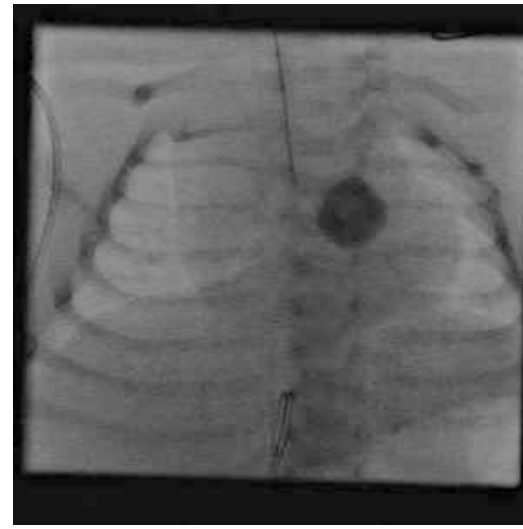
The primary indication for cardiac catheterization in a newborn infant with d-TGA is for atrial septostomy in order to promote improved intracardiac mixing and systemic oxygenation. After surgical repair, the primary indications for cardiac catheterization are to treat branch pulmonary artery stenoses, recurrent coarctation of the aorta, and angiographic assessment of coronary artery anatomy.

Atrial Septostomy

Atrial septostomy is indicated if there is inadequate systemic oxygenation due to insufficient intracardiac mixing. Occasionally, inadequate

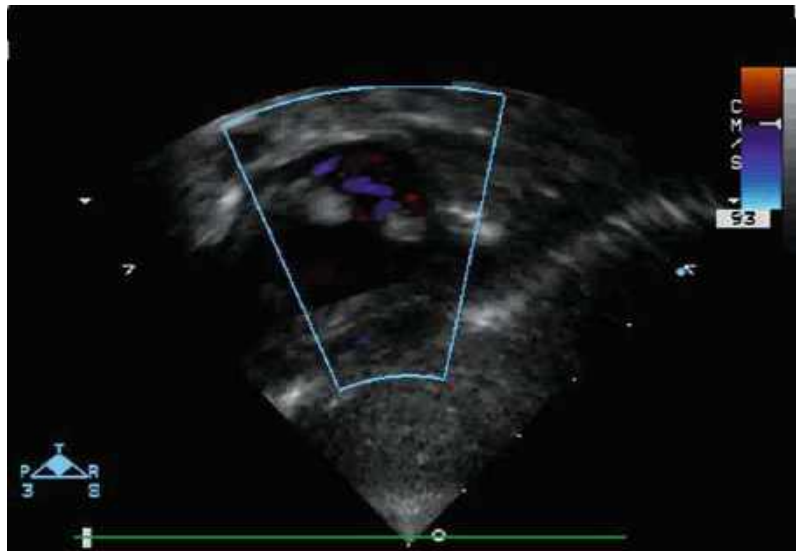
Video 109.6 Parasternal short-axis view of the aortic and pulmonary valves with mal-aligned commissures

systemic oxygen saturation is also encountered with d-TGA and VSD due to selective streaming of venous blood to the rightward aorta and pulmonary venous blood to the pulmonary artery. Balloon atrial septostomy (BAS) was initially described in 1966 by W. Rashkind and is considered to be the first interventional cardiac procedure developed for treating infants with cyanotic congenital heart disease [31]. While BAS initially was intended as a palliative procedure to allow for several months of acceptable systemic saturation prior to an atrial switch procedure, currently it is considered to be a short-term intervention prior to the more definitive surgical arterial switch repair. The basic premise of balloon atrial septostomy is to create a larger interatrial communication by manual disruption of the atrial septum via rapid passage of an inflated relatively noncompliant balloon-tipped catheter from the left to the right atrium through the foramen ovale (Videos 109.7 and 109.8). Most typically, this is performed via the femoral vein, though it is also easily performed via the umbilical vein. Due to the orientation of the atrial septum, balloon septostomy is much more difficult from a cephalad approach.



Video 109.7 Anterior-posterior projection of a balloon atrial septostomy as the inflated balloon is forcibly withdrawn through the atrial septal defect

The ideal physical location in which to perform BAS varies from institution to institution. BAS with echocardiographic guidance is performed routinely in some intensive care units, while in others the preference is to perform this procedure in the cardiac catheterization laboratory. The benefits of performing the procedure in the ICU include not requiring additional transport to and from the catheterization laboratory in patients who may be critically ill and unstable, easy accessibility and capability for delivery of medications, and continuity of provider care. However, institutional preference may be for



Video 109.8 Echocardiogram post-balloon atrial septostomy demonstrating the enlarged atrial communication

BAS to be performed in the cardiac catheterization laboratory. Advantages for performing this procedure in the catheterization laboratory include the ability to map the location of the ductus venosus if a trans-umbilical venous approach is to be used and could not previously be crossed with an umbilical venous catheter, guidewire visualization across a particularly small atrial level opening, and the ability to perform coronary angiography at the same session.

While BAS is very effective in newborn infants, thickening of the atrial septum in infants more than 1 month of age may make balloon septostomy more difficult. If excessive thickness is encountered, alternative methods for improving atrial patency include blade atrial septostomy, cutting balloon dilation with subsequent static balloon dilation, and interatrial stenting.

Improvement in systemic saturation should occur immediately after successful atrial septostomy and is pleasantly indicated by the increasing pitch of the pulse oximeter. However, if systemic saturation does not immediately increase, this does not necessarily imply that the septostomy was inadequate or unsuccessful. In the presence of high pulmonary vascular resistance, improvement in systemic saturation may be delayed until the resistance decreases.

Controversies

Brain Injury and Balloon Atrial Septostomy

With growing concern for the potential deleterious impact on neurodevelopmental outcomes for infants undergoing invasive cardiovascular procedures, there has been increasing attention focused on the effects of BAS. Systemic anticoagulation is often not performed during the procedure due to the concern for the development of intracerebral hemorrhage in hemodynamically unstable patients. In this context, concern has been raised that BAS may be associated with additional risk for preoperative brain injury such as infarct or intraventricular hemorrhage, as well as white matter injury/periventricular leukomalacia (PVL) [32]. However, a subsequent report did not support this initial premise and suggested that preoperative brain injury in d-TGA is related to the degree of preoperative hypoxemia and length of time to initial surgery [33]. This study also described a relatively high incidence of PVL detected by MRI, but did not find an association with embolic stroke. Both of these reports may be confounded by low patient numbers (less than 30); however, a larger query of the University Health System

Consortium Clinical Database/Resource Manager (UHC CDB/RM) did not find an increased incidence of clinical stroke in infants with d-TGA who had undergone preoperative BAS [34]. This analysis investigated the incidence of clinical stroke, whereas the previous studies described MRI findings which may not have had direct clinical sequelae. Further complicating this picture is a recent report that BAS is associated with an increased incidence of clinically recognized stroke based on analyses of alternate inpatient databases [35].

Routine Balloon Atrial Septostomy

In the setting of progressive hypoxemia, metabolic acidosis, and hemodynamic instability, BAS can provide almost immediate improvement in patient status. It is less clear whether routine BAS in all patients presenting with d-TGA is indicated. While surgical palliation for d-TGA is considered as early as feasible, there may be situations where delay of surgery for a period of time may be preferable. These circumstances may include antibiotic treatment due to concern for perinatal infection, recovery from end organ insult, or the wish to have pulmonary vascular resistance fall further prior to surgery. Simplification of thought may provide the best insight in making the decision to proceed with BAS. The goal of BAS should be for augmentation of systemic saturation in the setting of excessive hypoxemia, particularly with developing metabolic acidosis. This assessment should be made based on measured arterial paO_2 rather than by pulse oximetry, although pulse oximetry is useful for monitoring saturation trends.

Surgical Management

Surgical management of TGA underwent a major change in the mid-1980s from the atrial baffle procedures [36, 37] to the arterial switch operation (ASO) as initially described by Jatene and colleagues in 1976 [38] and subsequently modified by Lecompte and colleagues in 1981 [39]. The atrial baffle procedures were associated with low mortality and excellent early outcomes, but the long-term results were suboptimal due to atrial arrhythmias, baffle stenoses, and late dysfunction of the systemic morphologic right ventricle [40–43]. Subsequent studies have shown that long-term outcomes are significantly better following the ASO [42, 44–46]. There are many technical variations to the ASO including the method of coronary artery reimplantation, the material and shape of the patch utilized for the neo-pulmonary artery reconstruction, cannulation and cardiopulmonary bypass techniques, and many others. In this section, the authors will describe the methods used most often in Atlanta and Connecticut.

The importance of an experienced anesthesia and perfusion team for the performance of neonatal procedures such as the arterial switch cannot be overstated. Perioperative monitoring includes arterial and central venous lines, ECG, pulse oximetry, nasopharyngeal and core temperatures, capnography, and cerebral near-infrared spectroscopy (NIRS). A median sternotomy is performed and a portion of the anterior pericardium can be harvested and treated in glutaraldehyde if that is the chosen material for patch reconstruction of the neo-pulmonary artery (or for ventricular and/or atrial septal defect closure if necessary). The aorta, main and branch pulmonary arteries, and ductus arteriosus are then carefully mobilized and the coronary anatomy is inspected. Many surgeons prefer to mark the planned coronary button reimplantation sites with a fine suture at this point, while the great vessels are distended and properly oriented. These techniques are illustrated in the linked **Surgery Clips 109.1–109.5**.

The patient is then heparinized with 300 units/kg of heparin for a goal activated clotting time of >400. Either bicaval or single atrial venous cannulation can be used depending upon personal preference. In either case, we cool to 30–32 °C and divide the ductus arteriosus upon institution of cardiopulmonary bypass (CPB). The aortic cannulation site should be placed on the proximal aortic arch so that the aortic cross-clamp can be placed as distally as possible on the ascending aorta. At this point, further mobilization of the branch pulmonary arteries beyond the take-off of the lobar branches should be performed to ensure adequate mobility for the Lecompte maneuver later on. A left ventricular vent can be placed

either through the right aspect of the left atrium or through the left atrial appendage, depending upon surgeon preference. Again, there is variability in practice as some surgeons who use single venous cannulation rely upon the atrial septal defect to decompress the left side. A cardioplegia cannula should be placed high on the ascending aorta so as to allow for subsequent venting of the aorta through this site. The aorta is then clamped and cardioplegia is given (4:1 crystalloid:blood in the authors' practice).

The majority of ventricular septal defects can be closed through the tricuspid valve in the usual fashion prior to initiating the arterial switch procedure. While there are occasional cases in which

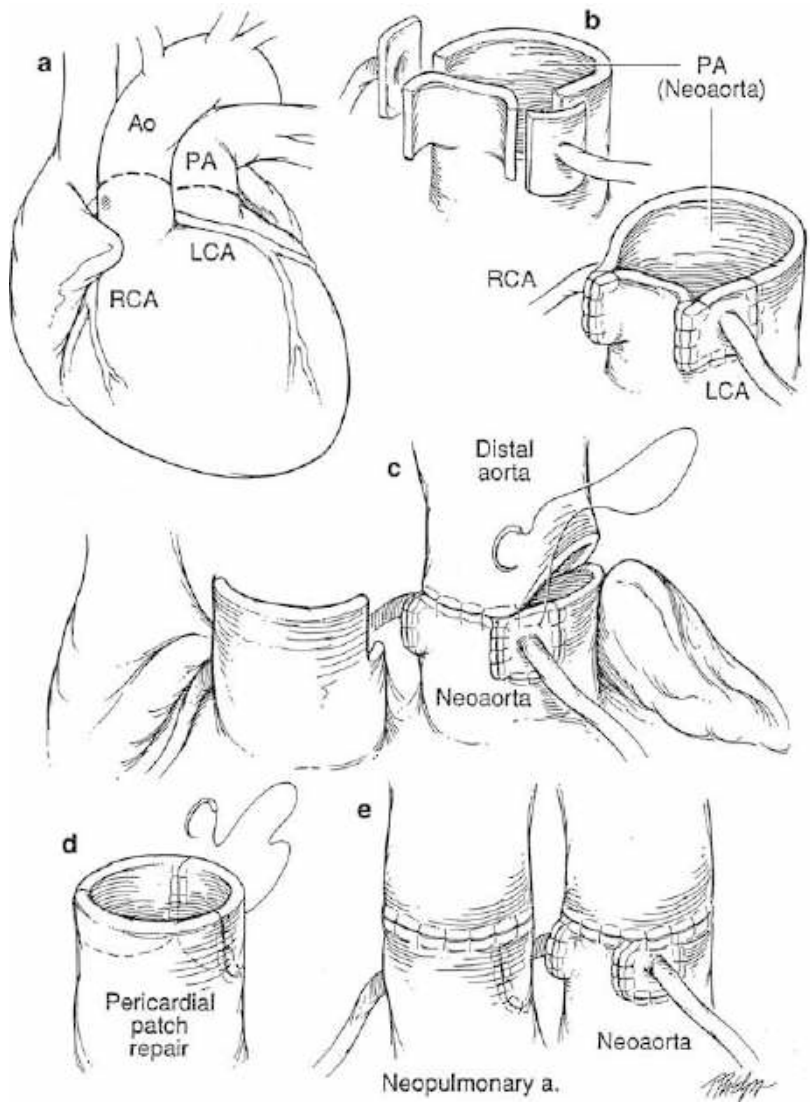

Fig. 109.4 Techniques involved in the arterial switch procedure. (**a**) External anatomy of typical transposition. The transection sites for the aorta and pulmonary artery are marked. (**b**) Demonstration of the medially based flaps utilized in the "trap-door" coronary artery reimplantation technique. (**c**) Aortic anastomosis after the Lecompte maneuver (not shown). (**d**) Neo-pulmonary artery reconstruction, with two pericardial patches in this case. (**e**) Completed repair. *LCA*: Left coronary artery, *RCA*: Right coronary artery (Reprinted from Critical Heart Disease in Infants and Children, Karl TR and Kirshbom PM, *Transposition of the Great Arteries and the Arterial Switch Operation*, pg. 721, 2006, with permission from Elsevier)

the defect can be better visualized through the neo-pulmonary artery after transection of the great vessels, such outlet or sub-arterial ventricular defects are the exception to the rule in TGA with VSD. Following closure of the septal defects, the ascending aorta is transected several millimeters above the sinotubular junction. The coronary arteries are then disconnected from the aorta with a generous button of surrounding aortic sinus (Fig. 109.4b). Care must be taken to avoid damaging the neo-pulmonary valve while harvesting the buttons. The proximal coronaries are mobilized for several millimeters to allow for tension-free rotation of the buttons to the neo-aorta. Initial mobilization of the coronaries is safest directly adjacent to the valve annulus and then into the plane between the coronary and the underlying myocardium. Small coronary branches must be divided to improve mobilization on rare occasions, but in most cases, simply incising the epicardium adjacent to the branches is sufficient.

The main pulmonary artery is then transected several millimeters proximal to the level of the aortic transection. Care must be taken to avoid injury to the neo-aortic valve. This slight

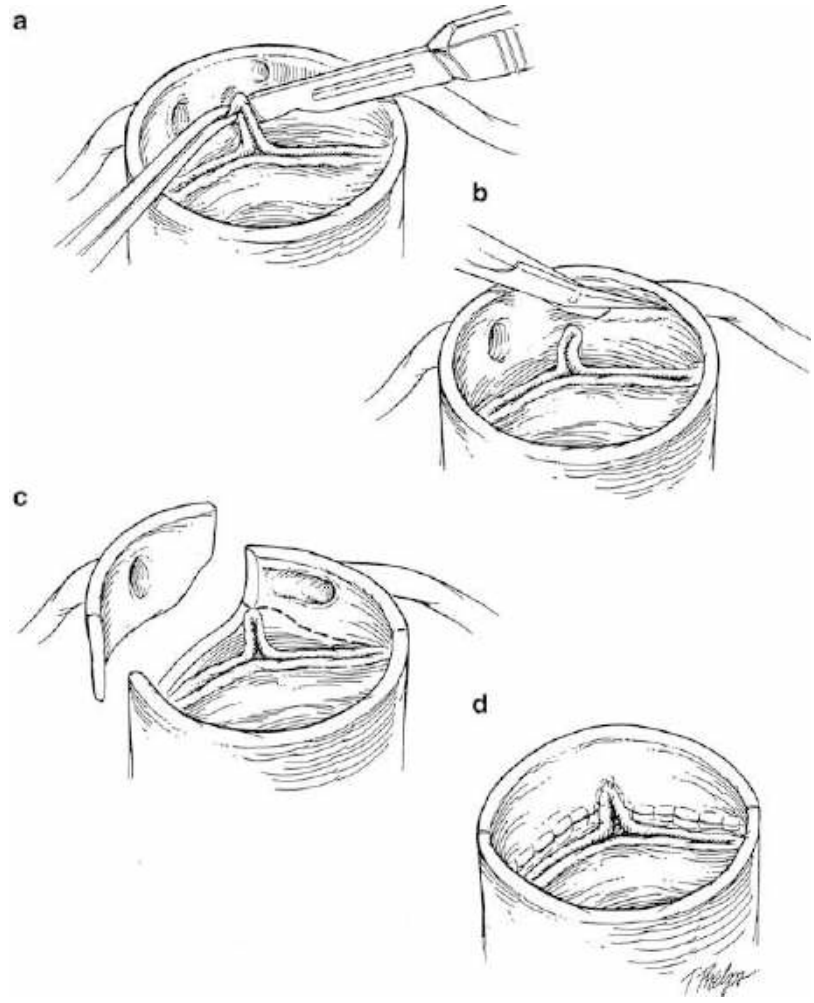

Fig. 109.5 Technique for management of an intramural coronary artery. (**a**) The commissure of the aortic valve is detached from the aortic wall. (**b**) The intramural portion of the coronary is "unroofed." (**c**) The coronaries are harvested from the aorta with surrounding aortic wall tissue. (**d**) The neo-pulmonary artery is reconstructed with a patch and the commissure is resuspended (Reprinted from Critical Heart Disease in Infants and Children, Karl TR and Kirshbom PM, *Transposition of the Great Arteries and the Arterial Switch Operation*, pg. 723, 2006, with permission from Elsevier)

difference in the level of transection of the great vessels results in a relative shortening of the aorta, which generally must move posterior to the translocated pulmonary bifurcation. It also makes the neo-pulmonary artery relatively longer, allowing the pulmonary bifurcation to lie distal to the reimplanted coronaries, rather than draping the branches directly over the proximal neo-aorta.

There are many methods utilized for the coronary button reimplantation. Depending upon the anatomy, one can use a medially based "trap-door" flap designed to minimize rotation of the proximal coronary ostium (Fig. 109.4b), a triangular resection of the neo-aortic implantation site designed to decrease size mismatch between the proximal neo-aorta and the distal aorta, a simple incision in the proximal neo-aorta, or an aortic punch to create a proximal orifice rather than a "distal to proximal" incision, to name just a few of the options. Coronary implantation is typically performed with 7-0 monofilament suture. In cases involving an intramural coronary artery, the coronary may course either directly adjacent to or behind one of the neo-pulmonary valve commissures, which must be taken down to allow for unroofing of the intramural portion of the coronary and harvesting of the button (Fig. 109.5). During the neo-pulmonary artery reconstruction, the mobilized commissure must be resuspended on the reconstructed pulmonary artery wall.

Once the coronaries are reimplanted and inspected, the distal pulmonary bifurcation is translocated anterior to the distal aorta, and the aorta is anastomosed to the proximal neo-aorta. At this point, the heart is de-aired through the cardioplegia site and the cross-clamp is removed. The proximal aortic and coronary suture lines are inspected as is the distribution of myocardial perfusion. The epicardial coronaries should be visibly perfused, the myocardium should pink up quickly, and the heart should return to a normal sinus rhythm promptly after removal of the cross-clamp. If this does not occur, suspicion of a coronary issue should be high and revision of the coronaries should be considered.

The proximal neo-pulmonary artery is then reconstructed, again with a variety of options available depending on surgeon preference. Either two patches or a single "pantaloon" patch can be used and the material is generally either autologous pericardium or a pulmonary homograft patch (Fig. 109.4d). Ruhdra and colleagues have reported on inferior outcomes using Goretex as the pulmonary artery patch [47]. Following reconstruction of the proximal neo-pulmonary artery, it is anastomosed to the distal pulmonary bifurcation. In some cases where the great vessels arise in a side-by-side relationship, the pulmonary anastomosis can be shifted onto the proximal right branch pulmonary artery with primary closure of the leftward portion of the distal pulmonary artery orifice.

Once the pulmonary artery reconstruction is complete, pacing wires and atrial monitoring lines are placed and the patient is weaned off of bypass. A postoperative transesophageal echocardiogram is performed to confirm closure of all septal defects and to assess valvar and ventricular function. If all is well, then it follows a modified venovenous ultrafiltration, decannulation, and reversal of heparin. Great care must be taken at this stage of the procedure to avoid volume overload, as the left ventricle tends to be noncompliant and small volume boluses can result in a dramatic increase in the left atrial pressure. Subsequent ventricular distension can lead to torsion or stretch of the coronary arteries, which can result in a vicious cycle of progressive myocardial ischemia, further distension, and further ischemia. This cycle can be very difficult to break once it is initiated, but removal of intravascular volume combined with inotropic support and afterload reduction can reverse the process. Not infrequently, however, a return to bypass to allow for myocardial recovery may be necessary, in which case serious consideration should be given to revision of any suspect coronary anastomoses. In the vast majority of cases, however, the hemodynamic status remains stable, hemorrhage comes under control, and the sternum can be closed in standard fashion.

Initial Postoperative Management

Initial postoperative management following the ASO has some unique aspects that separate it from other lesions. Early goals of management include control of coagulopathy, avoidance or treatment of low cardiac output syndrome, and management of capillary leak and total body volume overload following cardiopulmonary bypass. In patients with d-TGA with intact ventricular septum (TGA/IVS), the added factor of rapid LV training must also be considered. Older infants with d-TGA with ventricular septal defect (TGA/VSD) generally will have an easier transition to systemic LV support as the VSD has prepared the LV to pump against systemic pressures. When the ASO is done within the first week of life the LV adjustment to systemic pressure load is usually rapid, but full adaptation can take days to weeks [48].

Hemodynamics

Patients typically receive milrinone (0.5–1 mcg/kg/min) and low-dose dopamine (3–5 mcg/kg/min) to augment ventricular function if needed. Patients needing further afterload reduction are maintained on sodium nitroprusside (1–4 mcg/kg/min).

Central venous pressure (CVP) is monitored via a central venous catheter in the internal jugular vein or a right atrial (RA) catheter. Left atrial (LA) pressure monitoring is helpful in assessing LV function in the immediate postoperative

period. Mean arterial pressures of 35–45 mmHg are acceptable for newborns following ASO. Older children with TGA and VSD will tolerate higher systemic arterial pressures. LA pressures should be maintained in the 8–10 mmHg range as volume boluses to increase this pressure are not well tolerated by the noncompliant LV. The presence of RV hypertension is unusual following ASO and its presence should be promptly investigated by echocardiogram. Residual intracardiac shunt and branch pulmonary artery stenosis, following the Lecompte maneuver, have both been implicated in elevated RV pressures following ASO [49].

The acid–base status, mixed venous saturations, and serum lactate levels are excellent markers of oxygen delivery [50]. All infants are also monitored with cerebral near-infrared spectroscopy (NIRS). Cerebral NIRS is a good surrogate marker of mixed venous oxygen saturation and hence a good continuous monitor of cardiac output and oxygen delivery [51, 52].

Ventilator Management and Sedation

Patients who have achieved hemostasis and are maintaining adequate hemodynamics should be weaned from mechanical ventilation over 12–24 h. Sedation and analgesia may be achieved with intermittent morphine (0.05–0.1 mg/kg/dose) and midazolam (0.05–0.1 mg/kg/dose). Infants with ongoing bleeding, unstable hemodynamics, rhythm abnormalities, and those with delayed closure of the sternum should remain mechanically ventilated until stability is achieved. Such patients receive continuous fentanyl (1–4 mcg/kg/h) or morphine (0.05–0.2 mg/kg/h) infusions and intermittent midazolam. A continuous midazolam (0.05–0.1 mg/kg/h) infusion can be used in patients who are difficult to sedate. Intermittent neuromuscular blockade with vecuronium (0.1 mg/kg/dose) is used as needed in unstable patients, but a continuous infusion is avoided if possible, even in patients with delayed closure of the sternum.

Low Cardiac Output

Persistent systemic hypotension in the setting of poor peripheral perfusion, elevated LA pressure, elevated serum lactate or decreased cerebral NIRS, and other signs of LV dysfunction should be promptly investigated. The presence of ST-T segment changes on ECG or segmental wall motion abnormalities on echocardiogram are signs of potential coronary insufficiency. Any suspicion of coronary insufficiency should be addressed immediately with re-exploration and revision. In the absence of coronary insufficiency, low cardiac output can be caused by LV dysfunction due to an inadequately prepared LV. Pharmacologic support with milrinone, dopamine, and low-dose epinephrine can be helpful. In extreme cases, mechanical circulatory support with extracorporeal membrane oxygenation or a ventricular assist device may be indicated.

Fluid Management

Fluid overload can have a profound influence on the initial postoperative course. Modified ultrafiltration (MUF) performed in the operating room can improve the initial fluid balance in the intensive care unit [53]. Intravenous (IV) fluids are given at 50 % maintenance for the first 24 h and liberalized gradually after that time. Hypotension because of hypovolemia is treated with bolus infusions of 5 % albumin (5–10 mL/kg). If there is ongoing bleeding, fresh frozen plasma, platelets, and packed red blood cells are used.

Urine output is a poor indicator of cardiac output and oxygen delivery following CPB in infants. Transient renal insufficiency is fairly common and is usually responsive to diuretic administration. A continuous furosemide infusion (0.3 mg/kg/h) is typically started 8–12 h following surgery. If adequate urine output ($\geq$1 mL/kg/h) is not sustained with a furosemide infusion alone, then additional doses of intravenous chlorothiazide (10 mg/kg/dose) are given. Close monitoring of electrolytes, specifically potassium and calcium, is essential with diuretic administration. Ionized calcium levels should be maintained at $\geq$4.5 mg/dL, potassium levels at $\geq$4 mmol/L, and magnesium levels at $\geq$2 mg/dL. If urine output is excessive on a continuous furosemide infusion, then bolus intravenous dosing (1mg/kg/dose) can be used.

Hyperglycemia may be a postoperative risk factor for morbidity and mortality [54]. Close monitoring of glucose levels is imperative and sustained hyperglycemia (serum glucose ≥200 mg/dL) should be treated with an insulin infusion (0.01–0.1 units/kg/h). Hypoglycemia (serum glucose <50 mg/dL) should be treated with a glucose infusion (1–2 mL/kg of 25 % dextrose in water).

Inpatient Management

As patients stabilize, vasoactive infusions and mechanical ventilation are weaned. High-flow nasal cannula can aid the transition to spontaneous ventilation. Afterload reduction can be achieved with intermittent oral angiotensin converting enzyme inhibitors such as captopril, with eventual transition to enalapril or lisinopril for ease of outpatient administration (once-twice daily dosing). Oxygen is weaned as tolerated and diuretics are transitioned to oral dosing in preparation for discharge.

Feeding

Enteral feeding is started when the hemodynamics are stable. If enteral feeds cannot be started by postoperative day 2, then total parenteral nutrition should be initiated. Mechanically ventilated patients can be fed via nasogastric tube (NGT) or post-pyloric feeding tube (naso-jejunal tube) if there is concern for gastroesophageal reflux. Spontaneously breathing patients with stable respiratory mechanics can be trialed with oral feeds, though many infants require NGT supplementation. Ongoing need for NGT feeds is not a barrier to discharge, as transition to oral feeding can occur as an outpatient.

Aggressive anti-reflux treatment should be undertaken in all infants with ranitidine as the initial medication. Transition to a proton pump inhibitor (i.e., lansoprazole) should be considered in infants who remain symptomatic on ranitidine.

Imaging

An echocardiogram with Doppler interrogation should be completed prior to discharge. Particular attention should be given to LV systolic function, neo-aortic valve competence, coronary artery origins, proximal branch pulmonary artery stenosis, and the presence of residual atrial or ventricular shunting. The aortic arch should be inspected in patients who required arch augmentation. Any concern for technical coronary issues should be investigated, typically by cardiac catheterization, prior to discharge if adequate imaging is not obtainable via echocardiogram. Following discharge, close follow-up is needed to continuously evaluate the above echocardiographic parameters (Video 109.9).

Outcomes

Reported surgical mortality has declined from the initial reports of the ASO in the mid-1980s. Recent reports include mortality rates between 2 % and 11 % [47, 55–59]. At Children's Healthcare of Atlanta, there were 230 ASO performed between January 2002 and March 2012 (139 TGA/IVS; 91 TGA/VSD). Overall surgical mortality was 2.6 % (95 % CI: 1.0–5.7 %): 2.2 % (95 % CI: 0.4–6.7 %) for TGA/IVS and 3.3 % (95 % CI: 0.7–9.7 %) for TGA/VSD. Reported risk factors for increased morbidity and mortality following ASO include low birth weight, prematurity, complex coronary artery anatomy, aortic arch obstruction, and presentation beyond 4 weeks of age [47, 55–59]. Programmatic surgical volume (specifically number of ASO per year) has also been shown to influence outcome [56].

Long-Term Survival

Long-term survival and function remain excellent. Survival past 15 years following surgery is >90 %, with reoperation free survival exceeding 80–85 % [60–64]. Freedom from arrhythmia or ventricular dysfunction is greater than 95 %, a significant improvement compared to the atrial baffle procedures for TGA. More than 90 % of long-term survivors are in the pediatric equivalent of New York Heart Association functional class I [60–64]. Ongoing long-term concerns for survivors of the ASO include the fate of the reimplanted coronary arteries, function of the

Video 109.9 Short-axis view of the branch pulmonary arteries draped over the posterior ascending aorta after the Lecompte maneuver

neo-aortic valve and root, right ventricular outflow tract (RVOT) obstruction, branch pulmonary artery stenosis, and exercise tolerance.

Coronary Arteries

The optimal modality for evaluating the patency of the reimplanted coronary arteries has not been clearly delineated, though angiography, cardiac magnetic resonance imaging (cMRI), and metabolic exercise testing have all been utilized. Angiography can identify anatomic abnormalities and obstructions. In a series of 58 patients undergoing coronary angiography, a mean of 7.6 years following the ASO, 6.6 % had late coronary artery complications [65]. Myocardial perfusion MRI was performed in a series of 28 asymptomatic ASO survivors at 13–16 years of age. There were no myocardial perfusion abnormalities identified in this cohort [66].

The incidence of late coronary artery reintervention is low, but a 7 % incidence of silent coronary lesions has been reported [67]. Asymptomatic patients with coronary obstructive lesions may benefit from stent placement in the catheterization laboratory [68]. Mavroudis et al. [69] reported the need for surgical coronary reintervention in 7 patients from a cohort of 258 ASO survivors (2.7 %). Mean age at reoperation was 9.8 years and two of the surgeries were in addition to aortic valve and root replacement. The most common coronary intervention is coronary artery bypass grafting to treat proximal stenosis, likely secondary to ostial fibrosis, fibrocellular intimal thickening, mechanical kinking or stretching with growth, or reactive injury from surgical manipulation.

It remains unknown whether ASO patients will experience a higher incidence of late ischemic events including sudden death. Patients in whom the original coronary anatomy included an intramural course or a single ostium have increased risk for morbidity and mortality [67].

Recurrent Coarctation of the Aorta

Recurrent coarctation of the aorta in the setting of d-TGA is approached in a similar fashion to isolated coarctation of the aorta. First-line therapy is typically balloon angioplasty. The method of surgical coarctation repair may influence the success of transcatheter balloon angioplasty. Improved results are seen in the setting of recurrent coarctation after extended end-to-end repair as opposed to repairs involving prosthetic patches. Balloon angioplasty in the setting of an

undersized interposition graft is unlikely to achieve satisfactory results.

In older children, recurrent coarctation can be treated with aortic stenting. Currently the arsenal of intravascular stents that will ultimately achieve adult diameter (>20 mm) is limited. As of this writing, there are no FDA approved stents available in the United States specifically designed and marketed for use in the aorta. Instead, biliary stents are commonly used.

Neo-aortic Valve and Aortic Root

Aortic valve competency in the years following the ASO is another area of concern. Lange et al. [70] reported on the competency of the neo-aortic valve in a series of 479 ASO survivors. More than 50 % of this cohort had no aortic insufficiency (AI). Eleven patients (2.3 %) required aortic valve replacement (AVR) at a mean of 11.2 years following ASO, and freedom from the need for aortic valve replacement was 85 ± 6 % at >10 years following surgery. Risk factors predicting the need for AVR included Taussig-Bing anomaly, VSD, prior pulmonary banding, age >12 months at the time of ASO, and postoperative incidence of trivial or greater AI. The fate of the neo-aortic valve following ASO mirrors that of the valve following the Ross procedure, Damus-Kaye-Stansel, and Norwood procedures, in which the native pulmonary valve is placed in the aortic position [71].

Aortic root dilation is a common finding after ASO, but there is not a consistent correlation with the presence of AI. The etiology of aortic root dilation is likely multifactorial and is influenced by pre-ASO anatomy and interventions. Patients with complex coronary anatomy, LVOT obstruction, and previous pulmonary artery banding have a higher incidence of aortic root dilation [71]. Indications for surgical intervention to address aortic root dilation include aneurysm and dissection. Aortic root replacement when the internal diameter of the aortic root is ≥5 cm has been suggested due to the potential risk of dissection [72], but this issue is controversial and many clinicians feel that the risk of aortic dilation in this group is not the same as in native aortic root aneurysms.

When appropriate, a valve sparing aortic root replacement should be undertaken. Aortic valve insufficiency may be secondary to severe root dilation and subsequent improvement in valve competency is expected following valve sparing procedures [70, 73]. If valve replacement is indicated, then a combined aortic valve and root replacement should be considered.

Right Ventricular Outflow Tract and Branch Pulmonary Arteries

RVOT and main pulmonary artery (MPA) obstruction is an uncommon long-term complication following ASO. Etiologies of RVOT and MPA obstruction include supra-valvar pulmonary stenosis, Taussig-Bing anomaly, abnormal coronary artery anatomy requiring unusual reconstruction techniques, and rapid somatic growth [62]. The need for RVOT intervention has been reported as low as 2.3 %. Techniques for the MPA reconstruction during the initial ASO vary with some advocating the use of a patch and others advocating direct anastomosis [69, 74]. Late MPA stenosis has been demonstrated in both groups.

Interventions to treat RVOT, MPA, and branch pulmonary artery obstruction include interventional catheterization and surgical intervention. Transcatheter balloon dilatation has been effective to treat RVOT and MPA obstruction [75]. Balloon dilatation combined with intravascular stent placement is effective in treating branch pulmonary artery stenosis [74]. Surgical intervention to treat pulmonary stenosis is typically accomplished with a patch repair. While neo-pulmonary insufficiency is fairly common following the ASO, the need to intervene is negligible, as opposed to the presence of neo-AI.

Exercise Tolerance

When compared with long-term survivors of atrial baffle procedures, survivors of the ASO have shown marked improvement in exercise testing as measured by peak heart rate and oxygen consumption [76]. Despite this dramatic improvement, there remains ongoing concern that the exercise capacity of these patients is diminished when compared with healthy age-matched controls [77, 78]. Up to 82 % of

65 survivors demonstrated decreased exercise tolerance at 20 years following ASO. The etiology of the intolerance remains unclear but is postulated to be a combination of subacute coronary insufficiency, neo-aortic valve insufficiency, and aortic root dilation.

Neurodevelopmental Outcomes

As with all congenital heart lesions requiring operative intervention, long-term neurological, behavioral, and functional outcome of these patients is an area of interest. The Boston Circulatory Arrest Study analyzed long-term neurologic outcomes in a cohort of patients with the diagnosis of d-TGA [79–82]. At 16-year follow-up, Belinger et al. [83] reported on the cognitive and neurodevelopmental function of 139 patients with d-TGA who underwent ASO. While most patients fell within the normal range for their age on neuropsychological testing, there were significant differences in some domains when compared to age-matched controls. The d-TGA cohort required more therapy and behavioral interventions, was four times more likely to require psychiatric medication, and had a higher incidence of executive dysfunction.

It is clear that patients with congenital heart disease requiring surgery in the newborn period, including those with d-TGA, are at higher risk for developing neurological and cognitive deficits as they approach adolescence and beyond. Ongoing surveillance of these children and early intervention with therapy can be helpful [84]. Therapeutic interventions in the neonatal period including method of bypass and the avoidance of deep hypothermic circulatory arrest have not yet provided a clear etiology for the developmental difficulties that many of these children face. Patients with d-TGA, who can expect excellent surgical and medical outcomes, demonstrate the ongoing challenge of insuring appropriate neurocognitive development.

Congenitally Corrected Transposition of the Great Arteries

110

Alain Serraf and James Jaggers

Abstract

Congenitally corrected transposition of the great arteries is a complex and rare cardiac malformation; the management of this defect should be based on the knowledge of anatomy, physiology, and natural history. It may present as an isolated defect but is frequently associated to other cardiac defects, such as ventricular septal defect, pulmonary stenosis, and Ebstein's anomaly of the tricuspid valve. The morphologic left atrium is connected to the morphologically right ventricle across the tricuspid valve, and the latter is connected to the aorta; the morphologically right atrium connects to a left ventricle that is related to the pulmonary artery. Because of this double discordance, the systemic venous return is pumped to the lungs, while the pulmonary venous return is directed to the systemic circulation. Symptoms are produced not by the segmental arrangement of the cardiac components but by the presence of associated anomalies, and symptoms or complications of the defect may present early in infancy or later in adulthood.

Surgical management of such an anomaly requires a highly dedicated team. It may include palliative and/or non-anatomic repair or anatomic repair. Anatomic repair is the preferred approach and usually consists of an atrial switch either by Senning or Mustard operations associated with an arterial switch operation, when there is no pulmonary stenosis, or

with a Rastelli procedure in presence of right outflow tract obstruction. Physiologic repair by ventricular septal defect closure alone or in association with left ventricle-to-pulmonary artery conduit might be achieved in selected cases. In some cases, single-ventricle palliation with total cavo-pulmonary connections may be appropriate. Heart transplantation may be indicated in the presence of systemic ventricular failure.

Surgical mortality after the anatomic repair should be expected to be below 10 %, with a 75 % freedom of reoperation rate at 10 years. Comparison between physiologic versus anatomic repair remains difficult because there is no long-term follow-up for the latter technique and because the surgical eras are drastically different.

Congenitally corrected transposition, when associated with other cardiac defects, can be managed with anatomic repair with good results. Nevertheless, long-term outcome data demonstrating superiority of anatomic repair is lacking.

Introduction

First described by the Baron Rokitansky, in 1875 [1] (Fig. 110.1), congenitally corrected transposition of the great arteries (CCTGA) consists of the combination of discordant atrioventricular and ventriculo-arterial connections. Around 94 % of CCTGA cases are associated with other cardiovascular lesions [2], with the most common abnormalities involving the tricuspid valve (in up to 91 % of patients) [3].

In CCTGA, the morphologically right atrium is connected to a morphologically left ventricle across the mitral valve, with the left ventricle then connected to the pulmonary trunk. The morphologically left atrium is connected to the morphologically right ventricle across the tricuspid valve, with the morphologically right ventricle connected to the aorta. When the atrial chambers are arranged in their usual fashion, the morphologically left ventricle is usually positioned to the right, and the aorta, arising from the right ventricle, is left-sided. Congenitally corrected transposition is also described as "double discordance" and therefore the discordant connections at both the atrioventricular and ventriculo-arterial junctions resulting in normal physiology. Because of the double discordance, the systemic venous return is directed to the lungs, while the pulmonary venous return is directed to the systemic circulation. Symptoms are produced not by the segmental arrangement of the cardiac components but by the presence of associated anomalies or by systemic right ventricular dysfunction. A triad of malformations, made up of an interventricular communication, obstruction of the outlet from the morphologically left ventricle, and anomalies of the morphologically tricuspid valve, are sufficiently constant to be considered as frequent variations of the malformation. Abnormalities of atrioventricular conduction are also frequent [4].

Other synonyms for this defect include L-TGA and corrected transposition. L-TGA is an incomplete term and is misleading, because many complex conditions, including univentricular hearts, have an "L"-positioned aorta. Simply corrected transposition also is incomplete because complete transposition of the great arteries (TGA)

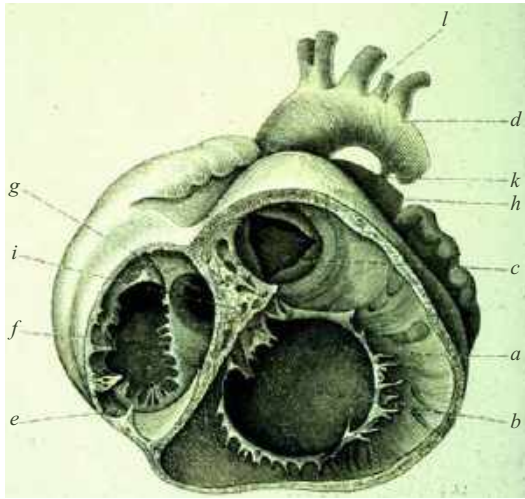

Fig. 110.1 Original illustration of a specimen with CCTGA from the atlas of the Baron von Rokitansky short axis of the ventricular mass viewed from the ventricular aspect

with an atrial, arterial, or intraventricular switch operation is also "corrected," but not on a congenital basis.

For the purposes of this chapter, univentricular hearts, hearts with crisscross atrioventricular connections, and hearts with aortic atresia will not be discussed. A small proportion of patients (1 –9 %) with CCTGA have no associated lesions [5–7]. This percentage probably underestimates the real incidence, because patients without symptoms may remain undiagnosed for many years or even decades.

Embryology

Corrected transposition in visceroatrial situs solitus develops when the primitive heart tube loops to the left instead of the right, resulting in the lack of spiral rotation of the conotruncal septum. Therefore, the aorta is connected to the morphologic right ventricle, and the pulmonary artery is connected to the morphologic left ventricle. The ventricles are attached to the normally positioned atria, making this abnormality physiologically corrected. Based on fetal diagnosis and follow-up, survival from the in utero diagnosis to birth is 75–80 % [8, 9].

Epidemiology

This is a rare cardiac condition with an incidence of 1/33,000 live births, thus accounting for 0.05–1.4 % of all congenital heart defects, and with a male-to-female ratio of 1.3:1 [5–7, 10].

Morphology

In the patient with normal or solitus atrial arrangement, the systemic venous return connects with the morphologically right atrium. This atrium is connected by a mitral valve without septal attachments, usually supported by paired papillary muscles located in inferomedial and superolateral positions, with the morphologically left ventricle which in turn supports a discordantly connected, transposed pulmonary artery. When the ventricular septum is intact, the attachments of the leaflets of the atrioventricular valves to the septum are reversed, with the mitral valve on the right side attached higher than the tricuspid valve on the left side at the crux of the heart. Nearly always there is fibrous continuity between the leaflets of the pulmonary and mitral valves in the roof of the right-sided morphologically left ventricle (Fig. 110.2). The pulmonary valve is wedged between the atrial septum and the mitral valve, resulting in deviation of the atrial septum away from the ventricular septum and producing an abnormal arrangement of the atrioventricular conduction axis. The pulmonary veins connect to the normally positioned left atrium. Blood from the left atrium then passes through a tricuspid valve into a left-sided right ventricle. The morphologically right ventricle, in turn, connects to the aorta. The aortic valve is anterior and to the left of the pulmonary valve. A subaortic infundibulum is well developed, promoting discontinuity between the tricuspid and the aortic valves [4, 11–14] (Fig. 110.3). In a small proportion of patients with situs solitus and CCTGA, the aorta can be positioned to the right or directly anterior to the pulmonary trunk. Anterior and right-sided positioning of the aorta is the rule when congenitally corrected transposition

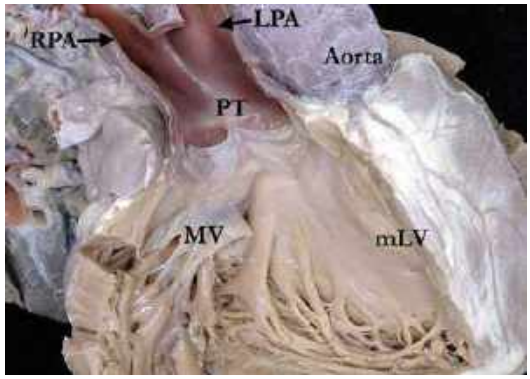

Fig. 110.2 A ventricular septal defect (VSD) is present below the pulmonary valve. The majority of VSD are perimembranous and subpulmonary and associated with the septal leaflet of the left-sided tricuspid valve. This type of defect extends posteriorly and inferiorly toward the crux of the heart, opening into the inlet of the morphologically left ventricle

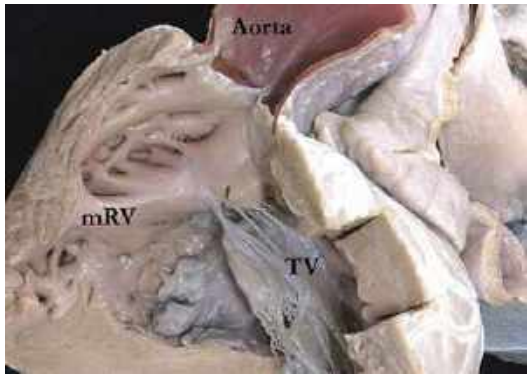

Fig. 110.3 Specimen displays fibrous continuity between the leaflets of the pulmonary and mitral valves in the roof of the right-sided morphologically left ventricle. The pulmonary valve is wedged between the atrial septum and the mitral valve

associated with situs inversus. The ventricles are usually positioned relatively side by side rather than anterior posterior; however, it is also possible to have rotational abnormalities. It is a marked abnormal rotation that produces the additional malformations known as crisscross relationships, while excessive tilting produces supero-inferior ventricles. Dextrocardial or mesocardial position of the cardiac mass is not unusual.

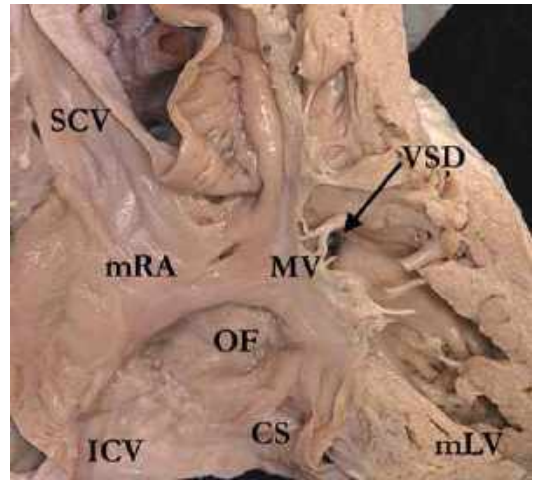

Fig. 110.4 Specimen demonstrates the coarsely trabeculated right ventricle in continuity with the aorta which is supported by a complete muscular infundibulum interposed between the hinges of the aortic and tricuspid (TV) valves

Associated Malformations

The majority of cases of congenitally corrected transposition have one or more coexisting malformations. The most common are an interventricular communication (VSD), seen in approximately 60–80 % of patients; obstruction of the pulmonary outflow tract, found in 30–50 % of patients; and anatomic abnormalities of the morphologically tricuspid valve, seen in nearly 90 % of patients, but functional disturbance is considerably less common [15].

The Ventricular Septal Defect

Ventricular septal defect is very commonly associated with CCTGA. It may be of variable size and not uncommonly closes spontaneously over time. The majority of VSD are perimembranous and subpulmonary and associated with the septal leaflet of the left-sided tricuspid valve (Fig. 110.4). This type of defect extends posteriorly and inferiorly toward the crux of the heart, opening into the inlet of the morphologically left ventricle. The VSD is usually large, reflecting the

malalignment between the atrial septum and ventricular septum characteristic of hearts exhibiting atrioventricular and ventriculo-arterial discordance, and the resulting left-to-right shunt is important. An extensive area of fibrous continuity between the leaflets of the pulmonary, mitral, and tricuspid valves forms the posterosuperior margin of the ventricular septal defect. The ventricular septal defect may be subarterial and roofed by the semilunar valves. This is uncommon in the Occidental, but not uncommon at all in the Oriental patients [16]. The VSD can occupy any position. In the presence of a straddling and overriding tricuspid valve, the VSD involves the inlet portion of the ventricular septum which is malaligned to the left side from the atrial septum and crux cordis, while in the rare situation where the mitral valve straddles, the VSD involves the anterior portion of the ventricular septum.

Pulmonary Outflow Tract Obstruction

Obstruction to the outflow tract of the morphologically left ventricle is identified in 30–50 % of patients with corrected transposition of the great arteries and atrial situs solitus [4]. Pulmonary outflow tract obstruction is typically associated with a VSD but may occur in isolation or only at the infundibular level. The left ventricular outflow tract obstruction may be muscular, reflecting wedging of the subpulmonary outflow tract between the infundibular septum and the ventricular free wall, with contributions from the right-sided ventriculoinfundibular fold as well. Fibrous tissue derived from the membranous septum may contribute to left ventricular outflow tract obstruction, and this may be resectable at the time of anatomic repair, allowing a double-switch procedure instead of a Rastelli repair. Tissue tags derived from the tricuspid or mitral valve or from the pulmonary valve itself may obstruct flow into the pulmonary trunk [17]. Valvar stenosis is usually accompanied by subpulmonary obstruction as well. The latter may take the form of muscular hypertrophy of the septum and the ventricular free wall, a fibrous diaphragm, or else an aneurysmal dilation of fibrous tissue derived from the interventricular component of the membranous septum. More rarely, fibrous tags may originate from either of the atrioventricular valves or even from the leaflets of the pulmonary valve. Subvalvar pulmonary obstructions, when present, are intimately related to the non-branching atrioventricular bundle.

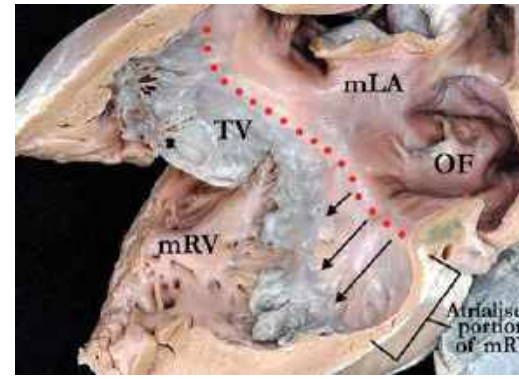

Fig. 110.5 Pathologic specimen of the apically displaced tricuspid valve (Ebstein's malformation)

Tricuspid Valve

Abnormalities of the morphologically tricuspid valve are intrinsic to hearts exhibiting congenitally corrected transposition of the great arteries [4, 15]. While at autopsy, approximately 90 % of hearts exhibit some abnormality of the morphologically tricuspid valve, considerably fewer demonstrate a functional disturbance during life. The most common and important underlying pathology is dysplasia of the valve, with or without displacement of the septal or posterior leaflets of the tricuspid valve. Some hearts with congenitally corrected transposition of the great arteries will exhibit an unguarded tricuspid orifice, while in others the tricuspid valve may straddle and override a muscular inlet ventricular septal defect [18–21]. The most common underlying pathology is valvar dysplasia, with or without apical displacement of the septal and mural leaflets, the latter, of course, being the essence of Ebstein's malformation (Fig. 110.5). Unlike the situation in hearts with concordant atrioventricular connections, atrialization and thinning of the inlet portion of the morphologically right ventricle, as

commonly seen in Ebstein's malformation of the tricuspid valve with concordant atrioventricular connections, are not always found in the setting of congenitally corrected transposition. A stenotic, Ebstein-like tricuspid valve dividing the morphologically right ventricle has also been described. Inflow tract obstruction from a supravalvular stenosing tricuspid ring has also been observed.

Less Common Associated Anomalies

Atrioventricular discordance can occur with double outlet of both great arteries from the morphologically right ventricle, double-outlet left ventricle, single-outlet aorta with pulmonary atresia, or with normal ventriculo-arterial connections. This latter condition has also been designated as isolated ventricular inversion or isolated atrioventricular discordance [15].

The Specialized Conduction Tissue

Hearts exhibiting atrioventricular discordance have a particularly unique and fragile specialized conduction system [22, 23]. It is the unusual disposition of the conduction tissue that predisposes patients with atrioventricular discordance to progressive and spontaneous third-degree heart block. The sinus node is normally positioned in these hearts, but the atrioventricular conduction tissue is grossly abnormal and has been extensively described [4] (Fig. 110.6). In brief, the basic anatomy dictates that the regular atrioventricular node, located at the apex of the triangle of Koch, cannot give origin to a penetrating atrioventricular conduction bundle. Instead, the atrioventricular node is located beneath the opening of the right atrial appendage, positioned at the lateral margin of the area of pulmonary-to-mitral valvar fibrous continuity. This places the conduction axis in direct relationship to the leaflets of the pulmonary valve. The long non-branching bundle runs down the anterior surface of the subpulmonary outflow tract and bifurcates into a right bundle branch, which extends leftward to reach the morphologically right ventricle. The left bundle branch runs down the smooth surface of the morphologically left ventricle. This abnormal course of the conduction system is of upmost significance to the surgeon in the presence of a ventricular septal defect or subpulmonary obstruction, since the electrical system of the heart is vulnerable during any attempted surgical repair of the ventricular septal defect, with the potential for producing

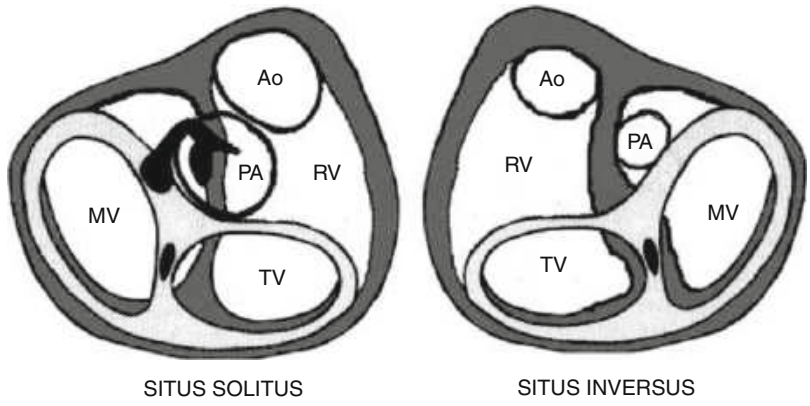

Fig. 110.6 In situs solitus CCTGA, the AV node does not penetrate to ventricular tissue. Thus, a secondary node, located in area of pulmonary valve (*PA*)-to-mitral valve fibrous continuity, has a penetrating bundle that courses along the anterior and left ventricular aspect of the interventricular septum and VSD. In situs inversus, alignment of atrial and ventricular septa is good, and His bundle has its origin in normal AV node. *Ao* aortic valve, *MV* mitral valve, *TV* tricuspid valve, *RV* right ventricle

surgical heart block. Rarely, as in the case reported by Kurosawa, in a patient with congenitally corrected transposition of the great arteries, large perimembranous ventricular septal defect, and straddling mitral valve, there is a regularly positioned posterior node and bundle as in situs inversus [24].

The Coronary Arteries in Congenitally Corrected Transposition

The coronary arteries arise from the two aortic sinuses that are adjacent to the pulmonary trunk, their precise position varying in relation to the location of the aortic root. It is not uncommon to find all three coronary arteries arising from one aortic sinus. The epicardial distribution of the coronaries is constant, following their respective ventricles. Thus, in the setting of usual atrial arrangement, the right-sided coronary artery will exhibit the pattern of a morphologically left coronary artery, with its short main stem dividing into anterior interventricular and circumflex branches. The circumflex artery will encircle the mitral valvar orifice in the AV groove. The left-sided coronary artery will be arranged as a morphologically right coronary artery, giving origin to the infundibular and marginal branches as it encircles the tricuspid valve. The anterior interventricular artery is an excellent guide to the location of the muscular ventricular septum. Variations in origin and courses of coronary patterns have been described but seem to be less frequent than in D-TGA [17, 25, 26].

Clinical Features

The timing of clinical presentation of a patient with CCTGA depends on the type and severity of additional associated lesions. In the few CCTGA patients without associated defects, there is usually no indication of abnormality early in life, and diagnosis would be suspected only serendipitously. In these patients, diagnosis is often made only with the onset of complete heart block, cardiac arrhythmias, atypical chest pain, or the onset of tricuspid insufficiency or systemic (right) ventricular dysfunction [27]. Those patients with a large ventricular septal defect in the absence of obstruction to the morphologically left ventricular outflow tract will present with signs of congestive heart failure (CHF). CHF may also be the presenting sign in those subjects with morphologically tricuspid valve incompetence. Patients with associated aortic coarctation or aortic arch defects may present in the neonatal phase or early infancy with congestive heart failure or cardiogenic shock. Patients with left ventricular outflow tract obstruction and VSD may have a relatively balanced systemic and pulmonary blood flow at least initially and may be asymptomatic without signs of significant CHF or cyanosis. When there is severe pulmonary stenosis or atresia of the morphologically left ventricular outflow tract, the infant will be cyanotic, often having a ductal-dependent pulmonary circulation. This patient may have variable degrees of left ventricular hypoplasia. Occasionally, complete heart block may be the presenting sign. Complete heart block has not uncommonly been reported in the neonatal and antenatal period though it is usually a later finding.

Diagnosis

Physical Findings

Physical findings often depend upon the presence or absence of associated defects. The cardiac impulse may be maximal on the right side of the chest in the presence of dextrocardia. A systolic impulse can be felt in the second or third left intercostal space. Auscultation of the heart may reveal a single loud second heart sound, which is often palpable to the left sternal border because of the anteriorly positioned aortic valve. A murmur will be present if there is an associated ventricular septal defect, pulmonary stenosis, or tricuspid regurgitation. A left parasternal lift and a systolic murmur alike the murmur found on mitral regurgitation patients can be heard at the left sternal border in the presence of tricuspid regurgitation. A murmur of pulmonic stenosis may be heard at

the mid-left sternal border. In patients with conduction abnormalities, bradycardia is the most common finding related to high-degree atrioventricular block.

Chest X-Ray

The posteroanterior chest X-ray often shows features characteristic of CCTGA. There may be dextrocardia, mesocardia, or levocardia. The aorta and pulmonary artery do not twist around each other as in the normal heart; rather they arise parallel to one another in a side-by-side or slightly oblique plane. Because of the leftward placement of the aorta, the upper left heart border is formed by the aorta and appears straight or gently sloping. The pulmonary artery knob is absent due to the rightward, posterior displacement of this great vessel. There may also be cardiomegaly if associated conditions such as ventricular septal defect, tricuspid regurgitation, or right ventricular failure are present. The pulmonary vascularity may be increased if a shunt is present without protective pulmonary stenosis, or the vascularity may be significantly decreased with associated severe pulmonary stenosis or atresia (Fig. 110.10).

Electrocardiogram

Electrocardiographically (ECG), the presence of Q waves in the right, instead of the left, precordial leads suggests the diagnosis. Because of the ventricular inversion, the right and left bundles are inverted, resulting in septal activation from right to left. The ECG documents varying degrees of AV block and any concomitant arrhythmia.

Echocardiography

Patients with CCTGA are most commonly diagnosed by echocardiography, which remains the mainstay of diagnostic tools. Increasing experience and expertise with fetal echocardiography have enabled several groups to make the diagnosis of CCTGA in the fetus. In some situations and cultures, prenatal diagnosis allows the potential for elective termination of the pregnancy. However, in the absence of complicating anomalies, most children will have relatively uneventful perinatal period and childhood. Hornberger et al. studied 27 fetuses with right-sided tricuspid valve regurgitation and concluded that significant tricuspid valve disease in utero portends an extremely poor prognosis [28]. This may also be the case with in utero left-sided tricuspid regurgitation in corrected transposition.

Multiple standard planes currently described for the transthoracic echocardiographic examination of the heart are very useful in making the noninvasive diagnosis of CCTGA. Since dextrocardia or mesocardia occur in approximately 25 %, the position of the heart within the thorax should initially be determined from the subcostal planes. Subsequently, the atrial and ventricular morphology should be described and the atrioventricular and ventriculo-arterial connections defined. Atrial morphology is defined by the systemic and pulmonary venous return and the position of the atrial appendages from subcostal, parasternal short-axis, and suprasternal notch coronal views. Ventricular morphology is best defined from the subcostal and apical four-chamber views and the parasternal short-axis views. The morphologic right ventricle is heavily trabeculated, with an identifiable moderator band and muscular as well as tricuspid valve attachments to the interventricular septum. The mural leaflet of the tricuspid valve is often significantly displaced toward the right ventricular apex, giving the appearance of Ebstein's malformation (Fig. 110.7a, b). The parasternal long axis view demonstrates tricuspid–aortic discontinuity due to the subarterial infundibulum. Since the morphologic left ventricle lacks an infundibulum, there will be mitral–pulmonary continuity. The ventriculo-arterial connections and the spatial relationships of the great arteries can be defined most easily using multiple planes of the subcostal, apical, and parasternal views. The aorta will be situated anteriorly and

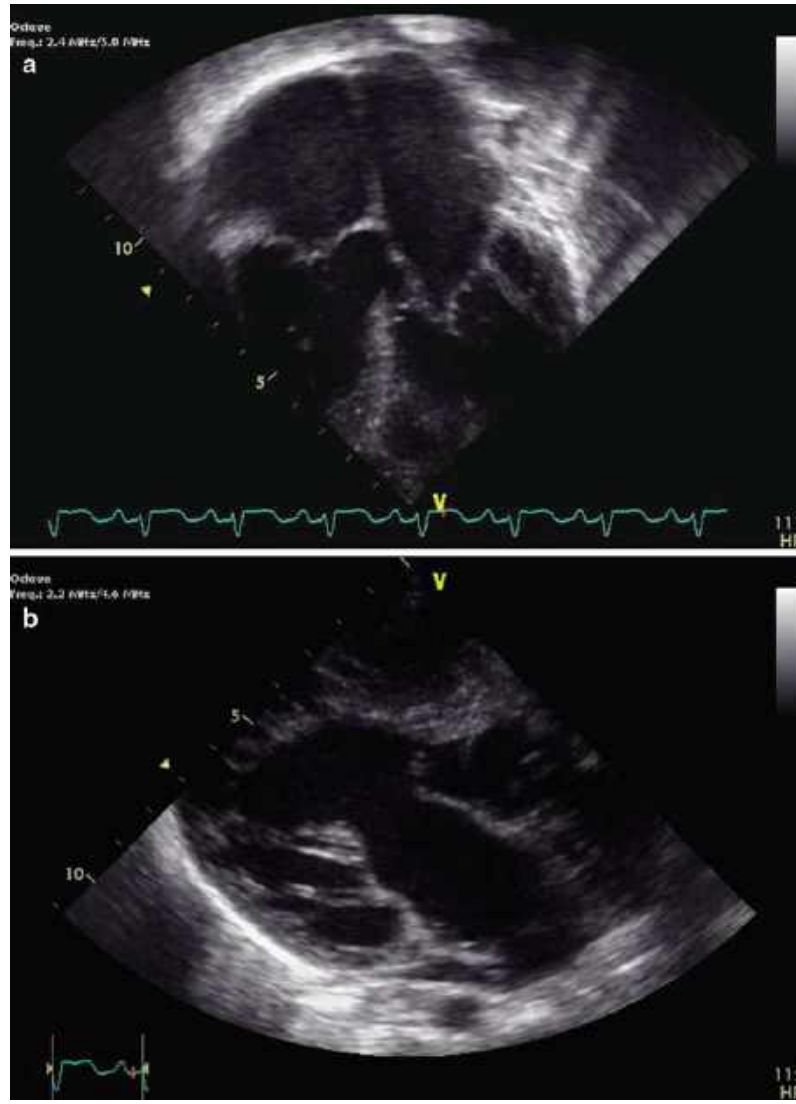

Fig. 110.7 (**a**, **b**) The mural leaflet of the tricuspid valve is often significantly displaced toward the right ventricular apex, giving the appearance of Ebstein's malformation

leftward, the pulmonary artery rightward and posterior in the usual case of CCTGA. The branching of the posterior great vessel, which thus defines it as the pulmonary artery, should be demonstrated. The coronary artery anatomy, which is usually mirror image in CCTGA compared to normal, can also be determined from these views.

Morphologic left ventricle wall thickness, mass, and volume can be measured, as a prerequisite to anatomic repair, following retraining of this ventricle. However, hemodynamic parameters and cardiac magnetic resonance imaging (cMRI)-derived LV mass measurements may prove more useful.

Cardiac Catheterization and Angiography

These modes of investigation have become almost obsolete for either infants or older patients. Because of the delicate nature of the conduction system, there is a significant risk of

Fig. 110.8 (**a**) Sagittal section of patient with CCTGA demonstrating the large posterior right ventricle and the smaller crescent-shaped anterior-positioned left ventricle, (**b**) CMRI demonstrating the right atrium with discordant connection to the anteriorly placed left ventricle and the posterior coarsely trabeculated right ventricle in connection with the left atrium. Note the reverse offset of the anterior mitral valve and the posterior tricuspid valve

inducing transient or permanent complete heart block during cardiac catheterization of patients with CCTGA. Transvenous pacing capability should therefore always be available. Indications for catheterization include hemodynamic and angiographic assessment of pulmonary stenosis and shunt size as well as determination of pulmonary vascular resistance and its reactivity in preparation for therapeutic intervention. Angiography may be necessary in situations where there are multiple ventricular septal defects, which cannot clearly be seen using echocardiography.

Rarely, in those patients with pulmonary atresia, major aortopulmonary collateral arteries supply most of the blood to the lungs. The origin and course of these arteries can more clearly be shown with angiography. When anatomic repair is planned, such as the double-switch procedure, coronary angiography may be helpful in delineating the anatomy of the coronary arteries. When there has been prior construction of a systemic-to-pulmonary arterial shunt, or the pulmonary trunk has been banded to reduce the flow of blood to the lungs or to train the morphologically left ventricle, hemodynamic and angiographic data is required to demonstrate the anatomy of the pulmonary arteries and to show whether the morphologically left ventricle has been adequately trained so that it can support the systemic circulation. Patients deemed candidates for a pulmonary artery banding as a measure to improve tricuspid regurgitation may benefit from a preoperative catheterization with the aim of assessing tricuspid functional performance upon controlled occlusion of the subpulmonary outflow tract.

Computerized Axial Tomography and Magnetic Resonance Imaging

Computerized axial tomography and cMRI are currently available for noninvasive imaging to evaluate the morphology and hemodynamics of patients with congenitally corrected transposition.

Magnetic resonance imaging is also of value in the postoperative situation to check the patency of the venous and arterial pathways subsequent to reconstructive surgery (Figs. 110.8a, b and 110.9).

Natural History of Congenitally Corrected Transposition of the Great Arteries

The natural history of CCTGA is defined by the associated malformations and by the timing and approach to surgical palliative and definitive repair. Approximately one-tenth of infants born with congenitally corrected transposition have complete heart block [4]. In patients born with normal cardiac conduction, the risk of developing

Fig. 110.9 Coronal section from CMRI demonstrating left ventricular outflow tract obstruction secondary to prolapsing tricuspid valve tissue through VSD

heart block over time increases by 2 % per year until it reaches a prevalence of 10–15 % by adolescence and 30 % in adulthood [29]. The etiology of the disordered conduction is related to the abnormal position of the atrioventricular node and the conduction axis. As time passes, the PR interval prolongs, until complete heart block becomes manifest. By the age of 45 years, half of the patients with associated lesions, and one-third of those without significant associated lesions, present with dysfunction of the systemic morphologically right ventricle. In the setting of CCTGA without any other associated anomalies, the ventricular function is adequate to maintain a "normal" activity level into adult life, although the function of the systemic right ventricle tends to deteriorate gradually after the second decade of life [30–32].

The systemic morphologically right ventricle has an impaired response to exercise when compared to a normal systemic left ventricle [33]. The presence of associated malformations further affects the development of myocardial dysfunction and heart block. Patients with large, hemodynamically significant ventricular septal defects will develop atrioventricular valvar regurgitation and early heart failure [34]. The natural history of the left-sided morphologically tricuspid valve is variable. The valve tends to remain competent during the first decade of life but slowly becomes progressively incompetent during the second to fifth decades of life. This process may be accelerated in patients with large VSD, possibly related to the volume load on the systemic right ventricle and tricuspid valve. If there is an Ebstenoid malformation of the tricuspid valve, the regurgitation can be seen at very early stages.

Preoperative Management

Patients with CCTGA progressing toward right ventricular (systemic) dysfunction and/or tricuspid regurgitation may need ambulatory management with diuretics and angiotensin-converting enzyme inhibitors.

Decompensated congestive heart failure in patients of any age is managed with diuretics; drugs with inotropic (to improve contractility), lusitropic (to enhance diastolic performance), and vasodilator properties (to reduce afterload); and sodium restriction.

Cyanotic neonates with severe obstruction of the right ventricular outflow tract in the form of subpulmonary or pulmonary obstruction, or pulmonary atresia, require PGE_1 infusion and careful balance of the Qp/Qs ratio, in preparation to elective palliation. Balance of the Qp/Qs may be tenuous when the systemic ventricle is failing, as increased diastolic overload of that ventricle is poorly tolerated. Cyanotic infants and children with CCTGA beyond the neonatal period tend to be more stable, and their surgical outcomes are less compromised by poor preoperative status [35].

Complete heart block, if abrupt, may need the emergent placement of a transvenous pacemaker, but caution will need to be taken as it can precipitate deterioration in right ventricular function and worsening of the tricuspid regurgitation. Isoproterenol may be useful in increasing the

ventricular rate and therefore the stroke volume, even it not restoring the normal atrioventricular conduction. Regardless of the ventricular rate in the presence of complete AV block, the indication of definite pacemaker insertion is mandatory.

Patients with CCTGA should always receive prophylaxis for bacterial endocarditis.

Surgical Management

Controversy between conventional versus anatomic repair tends to be less ardent, and it seems that anatomic repair is favored when applicable.

Indications for surgery have been well outlined by Brawn [36]. While still controversial, CCTGA without associated anomaly, no tricuspid regurgitation, and no systemic ventricle failure may be managed conservatively without elective anatomic repair, although some authors would recommend elective anatomic repair even in early infancy or childhood. In younger patients less than 15 years of age, with significant tricuspid regurgitation or systemic ventricular dysfunction, a pulmonary artery band may be placed in an effort to prepare the left ventricle for possible anatomic repair. Placement of the pulmonary band may improve the tricuspid insufficiency by altering the geometry of the right ventricle and shifting the papillary muscle attachments of the TV such that better coaptation may occur [37, 38].

In older patients in whom the risks of anatomic repair are greater, tricuspid valve replacement may be indicated if the systemic right ventricle functions reasonably well; heart transplantation may be indicated in those patients with severe systemic ventricular failure. Patients with a large VSD and unobstructed pulmonary arteries often present early in life with signs of CHF. Although double-switch procedure can be performed very early in life, a pulmonary artery band may be performed in order to delay the double switch and VSD repair. This is useful to prevent early pulmonary vascular occlusive disease, but not for the purposes of retraining. Some teams would simply perform the double switch without banding if there is evidence of systemic left ventricular pressure. In presence of CCTGA, VSD, and PS, intervention can be deferred as long as the hemodynamic situation is well balanced. In patients with cyanosis secondary to inadequate pulmonary blood flow, a modified Blalock–Taussig shunt is indicated, until a more definitive repair can be performed. This definitive repair may be anatomic, with a Senning procedure and Rastelli operation or a physiologic repair with VSD closure and LV-to-PA conduit placement. Even in the case of significant left ventricular outflow tract obstruction, it is important to accurately determine the ability of the left ventricle to assume systemic ventricular function.

In those patients with significant hypoplasia of one of the ventricles or severe irreparable straddling AV valve chordae, a single-ventricle palliation may be indicated [39, 40].

Palliation

Procedures to increase the blood flow to the lungs are usually accomplished with a modified Blalock–Taussig shunt. In the presence of excessive pulmonary blood flow through a large VSD and CHF, a pulmonary artery band can be placed. In patients with CCTGA, no pulmonary stenosis, and intact ventricular septum, a pulmonary artery band may be used to train or prepare the left ventricle to assume systemic ventricular function. In some patients with severe tricuspid insufficiency and intact ventricular septum, banding may cause septal shift and may reduce the tricuspid regurgitation and symptoms in many of the patients. This may be a definitive therapy or for preparation for a more definitive double-switch procedure [37, 38].

Physiologic Repair

Associated cardiac anomalies can be mended with a physiologic repair leaving a morphologically right ventricle as the systemic ventricle. The ventricular septal defect, if present, can be closed; obstruction within the left ventricular outflow tract can be relieved by either resection

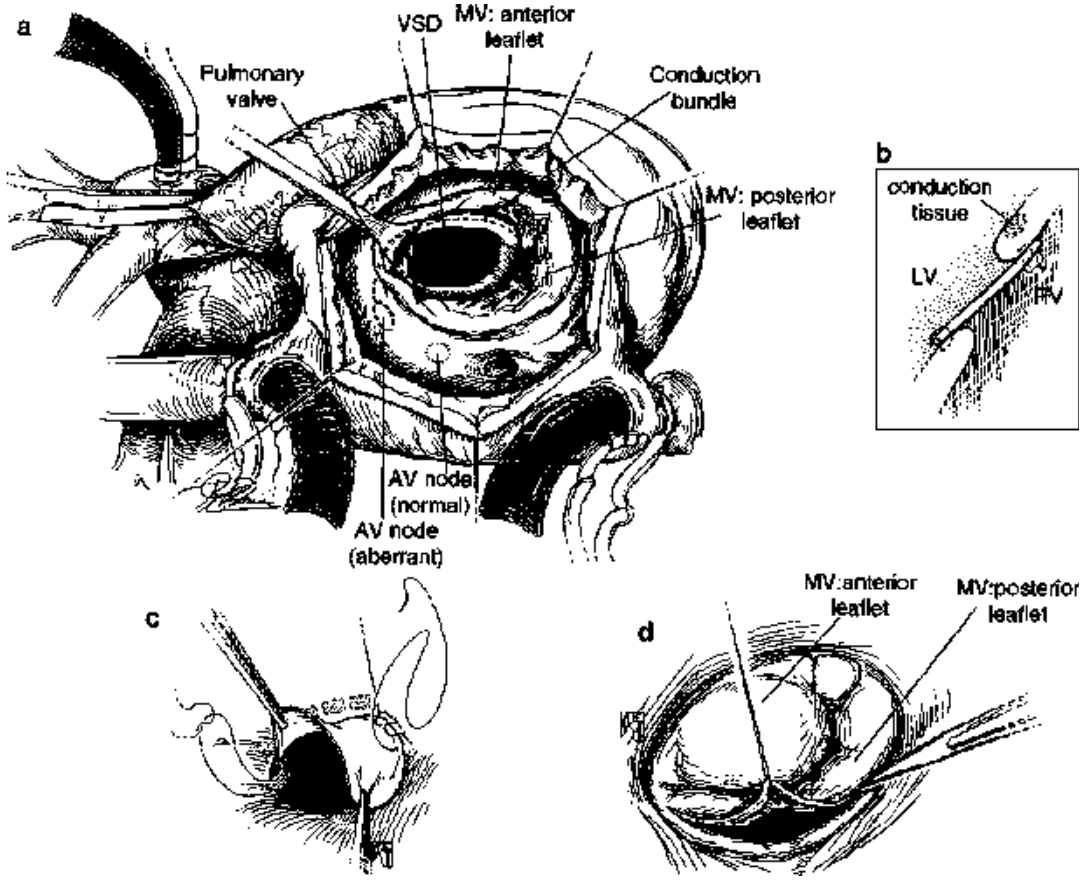

Fig. 110.10 VSD (ventricular septal defect), closure as visualized across the mitral valve (*MV*). This technique is applicable to both physiologic (classic) and anatomic repairs. The VSD may be closed with either a running or interrupted pledgeted horizontal mattress technique. In selected cases, partial detachment of the septal mitral leaflet may be helpful (*AV*), atrioventricular

or placement of a valved conduit; and the tricuspid valve, if leaking, can be repaired or replaced. Usually, the ventricular septal defect is perimembranous. It is typically approached through an incision in the right atrium and then closed through the morphologically mitral valve. The conduction system passes in antero-cephalad border of the VSD and on the left ventricular side around the pulmonary outflow tract. To avoid damaging the conduction system, either continuous or interrupted sutures are placed on the morphologically right ventricular margin of the defect superiorly and from the morphologically left ventricular side of the margin inferiorly [41] (Fig. 110.10).

In addition to the transmitral approach, the VSD may also be closed from the aortic valve. This approach is more suitable for patients with situs inversus and in older patients with a larger aorta [42]. The transaortic approach allows direct exposure of the right ventricular side of the defect, reducing the risk of conduction injury. This technique is rarely suitable, however, for most young infants because of the small size of the aortic annulus and its leftward position. When a left ventriculotomy is required for conduit placement, the VSD may be closed through this incision taking similar precautions to avoid the conduction tissue at the superior anterior rim of the defect. Finally, when CCTGA coexists with

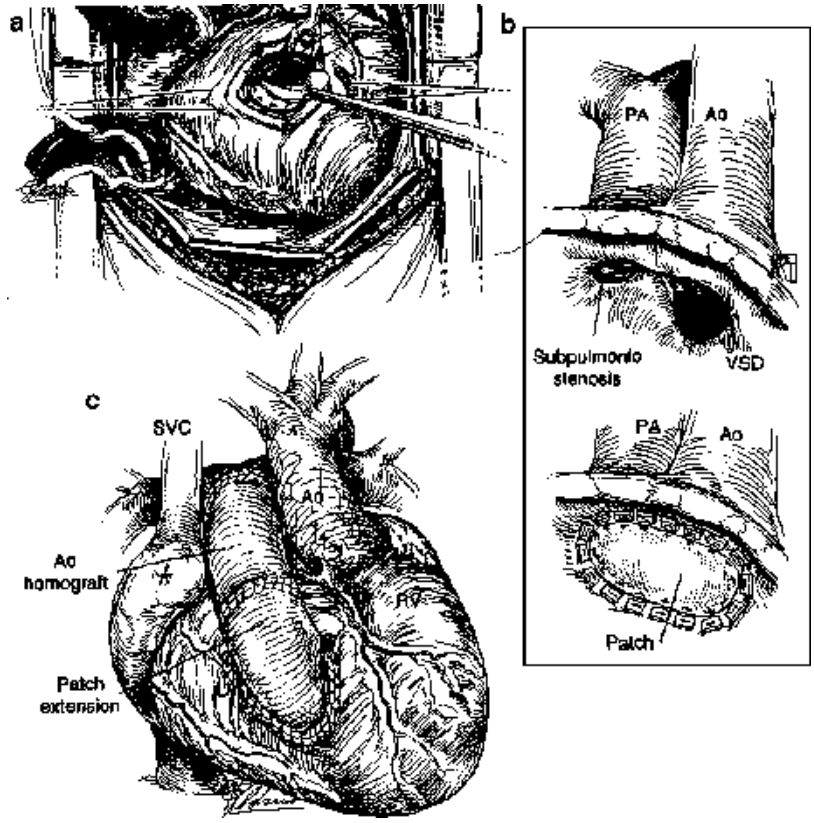

Fig. 110.11 Physiologic (classic) repair of congenitally corrected transposition of the great arteries with left ventricular outflow tract obstruction and ventricular septal defect (*VSD*). (**a**, **b**) VSD closed from a left ventriculotomy approach or a transmitral approach leaving both orifices of the semilunar valves on the right ventricular (*RV*) side of the baffle. (**c**) A valved conduit is used to provide (*LV*) left ventricle to (*PA*) pulmonary artery the LV-to-pulmonary artery (*PA*) continuity. *Ao* aorta, *SVC* superior vena cava

situs solitus with dextrocardia or situs inversus with levocardia, an incision in the left atrium can be done which will allow exposure of the VSD through the tricuspid valve from the right ventricular side. This exposure decreases the risk of injury to the conduction tissue.

In some situations, relief of left ventricular outflow tract obstruction may be accomplished via pulmonary valvotomy and resection of accessory valve tissue or redundant mitral valve chordal tissue. However, with severe obstruction, placement of a valved conduit will be necessary. In order to avoid the conduction system, and the papillary muscle of the mitral valve, the ventriculotomy, through which a VSD can be closed and a conduit placed, is placed toward the apex of the left ventricle (Fig. 110.11).

Repair or replacement of the morphological tricuspid valve may sometimes be necessary when there is severe tricuspid regurgitation. Tricuspid insufficiency is associated with cardiac failure, since often the morphologically right ventricle is failing by the time such surgery is entertained. In addition, particularly in younger patients where there is marked dysplasia of the valvar leaflets, repair can be extremely difficult, if not impossible. Under these circumstances, replacement may be necessary. It might be useful in such cases not to resect the posterior leaflet from subvalvar apparatus to preserve ventricular function.

Anatomic Correction

With anatomic repairs, the morphologically left ventricle is restored as the systemic ventricle either by combining atrial and arterial switch procedures (double-switch procedure) (Fig. 110.12) or by performing the atrial switch along with ventricular re-routing or Rastelli procedure (Senning and Rastelli procedure) (Fig. 110.13).

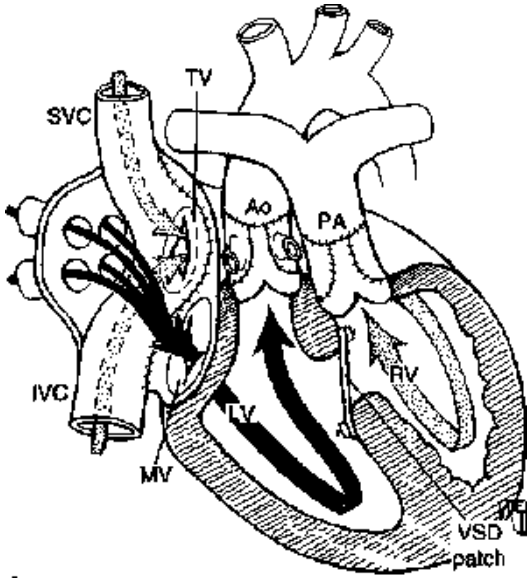

Fig. 110.12 The double-switch procedure: atrial level switch may be with either a Senning or a Mustard procedure, and the arterial switch is performed in an inverted manner typical arterial switch procedure. *Ao* aorta, *PA* pulmonary artery, *MV* mitral valve, *IVC* inferior vena cava, *SVC* superior vena cava, *VSD* ventricular septal defect. *RV* right ventricle, *LV* left ventricle

The VSD can usually be closed in combination with the double-switch procedure in most situations. Double-switch procedure can usually be performed when the following conditions are met:

1. No ventricular outflow tract obstruction from either ventricle.
2. The ventricular septum can be septated successfully (no important AV valve straddling).
3. Balanced ventricular sizes.
4. Left ventricular pressure is at least 75 % of systemic blood pressure.
5. The coronary arteries can be successfully translocated.

In patients in whom there is a small VSD, it may be repaired along with the double-switch procedure. If the patient is a candidate for the latter procedure and the interventricular septum is intact or the VSD highly restrictive, the left ventricle will be pumping against the significantly lower afterload of the pulmonary circuit and consequently will likely be deconditioned and unable to accommodate systemic afterload after the double switch. In this situation, the left ventricle will require "training" by placement of a pulmonary artery band to increase the afterload on the ventricle. The timing of the band and the duration of retraining the left ventricle is not clearly established and has been reported for as little as 2–3 weeks and as long as greater than 2 years. The time necessary is likely less in neonates and infants (approximately 3 months). After the neonatal period, increase in mass of the left ventricle is likely a process of hypertrophy of existing myocytes rather than hyperplasia of myocytes [43]. When placing the band, the operator must be careful so as to not make it too tight initially, as this may result in significantly impaired LV function and possibly permanent left ventricular damage from acutely elevated LVEDP and consequent subendocardial ischemia. The band is progressively tightened to achieve successively higher pressures, while the LV is monitored for diminished systolic function and for shift of the interventricular septum and decreased tricuspid regurgitation. Important indicators of band effectiveness include a shift of the interventricular septum toward midline by echocardiogram imaging and increase in LV pressure to two-thirds to three-quarters of systemic pressure [38].

Indicators of effectiveness of training of the LV include LV mass, usually as measured by cMRI and compared to normal values; LV wall thickness; LV pressure as measured at cardiac catheterization; and preserved LV systolic function. In the authors' experience, the presence of preserved LV systolic function, LVEDP $<$12–14 mmHg, and a 75–90 % LV/RV ratio are usually adequate indications to proceed to double-switch procedure, regardless of whether the LV mass, as measured by cMRI, is greater than 80 % of normal.

Double-Switch Procedure

The atrial switch may be performed by either the Mustard or Senning technique. Most surgeons favor the Senning because the risk of important sinus arrhythmia and superior vena caval baffle

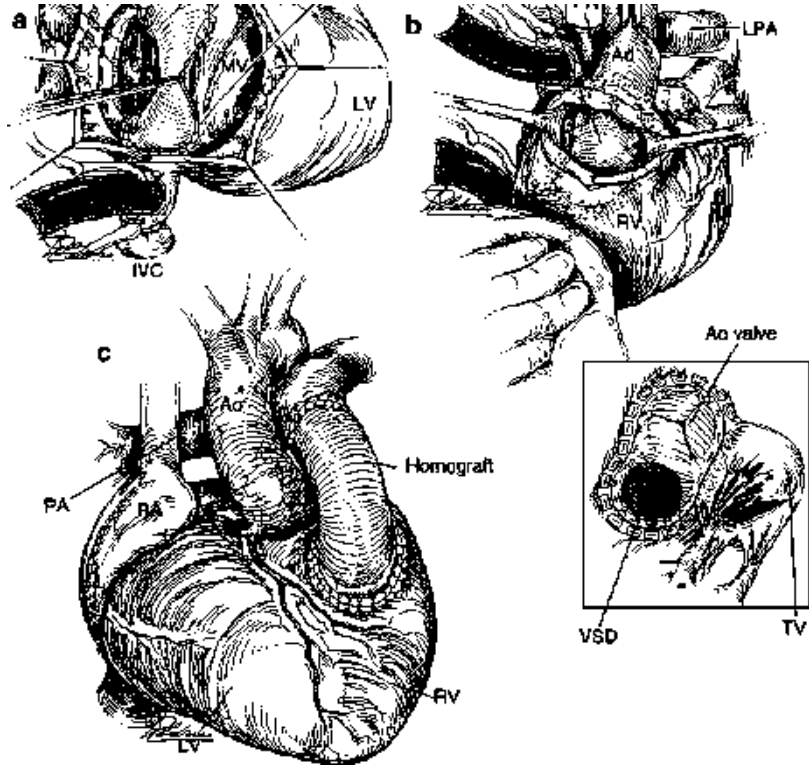

Fig. 110.13 Mustard plus Rastelli repair for CCTGA and VSD. The atrial switch may be performed with either Mustard or Senning procedure. Right ventricle to pulmonary artery conduit placed preferably to left of aorta. *Ao* aorta, *IVC*, *SVC* inferior, superior vena cava, *LPA* left pulmonary artery, *MV* mitral valve, *PV* pulmonary veins, *TV* tricuspid valve

obstruction is less, although some groups obtain excellent results with the Mustard procedure [44]. The presence of situs solitus with dextrocardia makes exposure within the right atrium more difficult and complex. The issues and potential long-term complications of the atrial switch procedure are present with CCTGA repair, just as they are with D-TGA. These include obstruction to right atrial inflow at the level of the vena cava or pulmonary venous pathways and the development of atrial dysrhythmias that are potentially serious late concerns. The Senning procedure appears to have less risk of these important complications.

The double-switch operation is performed with cardiopulmonary bypass, mild to moderate hypothermia, and cardioplegic arrest. In some situations, the use of deep hypothermic circulatory arrest (DHCA) may be required, but it is usually not necessary. It is important to ensure reliable myocardial protection because these can be prolonged operations.

Cannulation requires high superior vena cava (SVC) and low inferior vena cava (IVC) purse strings. The SVC should be cannulated above the level of the azygous vein to avoid the cannula interfering with the creation of the superior venous pathway; the azygous must not be ligated because it can provide an important runoff for the SVC flow should there be any degree of obstruction to the superior limb in the completed Senning. The IVC cannulation should be as close as possible to the diaphragmatic reflection of the IVC, so that the cannula sits below the level of the Eustachian valve; this will allow the surgeon to utilize the Eustachian valve tissue to help create the inferior limb pathway (the prominence of the valve is variable and it can only be used if well developed).

Atrial incisions and different layer constructions are performed as described by Barron et al. [44]. Prior to third layer construction, the VSD, if present, is closed in the same fashion as earlier described. The third layer of the atrial switch

involves creation of a pulmonary venous pathway. This may be modified by the use of a pericardial flap as described by Shumaker [37].

The arterial switch is then performed as described for D-TGA. The coronary artery pattern is most often simply inverted from the usual and the coronary arteries follow the ventricles. However, single coronary arteries or coronary arteries all arising from the same sinus are relatively common. Coronary transfer may be complicated especially in the case of side-by-side great vessels. This may necessitate significant mobilization of the proximal coronary arteries to facilitate transfer. Most surgeons prefer the use of the Lecompte maneuver, but some prefer to leave the pulmonary arteries in a posterior plane especially in the case of side-by-side great vessels. There is some evidence that there may be greater risk of re-intervention with the use of the Lecompte maneuver in the double-switch procedure [45].

Mulhatra and the group at Stanford University have recommended a novel approach for the patient with CCTGA who is a candidate for anatomic repair [46]. Their approach is to combine the arterial switch procedure with a "hemi-Mustard" atrial switch in combination with a bidirectional Glenn shunt. In the authors' experience, the purported advantages of this approach include decreased risk of SVC baffle obstruction and sinus arrhythmias, because the superior limb of the atrial switch procedure is eliminated. The authors also imply that in patients who undergo the Rastelli operation and atrial switch, conduit survival is prolonged because of decreased flow secondary to the bidirectional Glenn shunt.

Senning and Rastelli Procedure

When there is a pulmonary stenosis or atresia in association with a large ventricular septal defect, the atrial switch is combined with baffle closure of the VSD to the aorta and placement of a valved conduit from the morphologically right ventricle to the pulmonary arteries [47, 48]. In this operation, after completion of Senning or Mustard atrial switch, the main pulmonary artery is divided proximally and sutured closed, incorporating the leaflets of the stenotic pulmonary valve. A ventriculotomy in the morphologic right ventricle is positioned to avoid injury to coronary artery branches and as cephalad and leftward as possible to avoid compression of the conduit by the sternum. The direction of the ventricular incision is toward the central point of pulmonary artery confluence. Through this incision, the VSD is identified. Under ideal circumstances, it is of sufficient size and does not require enlargement. If it needs to be enlarged, the latter should be performed toward the apex to avoid the conduction pathway. An intraventricular tunnel through the right ventricle is then created to connect the morphologic left ventricle to the aorta. Sutures are placed on the morphologic RV side of the septum, and an abundant-sized patch is required to avoid subaortic obstruction. Connection between morphologic right ventricle and pulmonary arteries requires a valved conduit of adequate size, appropriate for the age and size of the patient. The confluence of the left and right pulmonary arteries is widely opened. The distal anastomosis of the conduit to the pulmonary artery confluence is oblique and completed with running suture. Extensive mobilization of the pulmonary arteries generally allows moving their confluence on the left side of the aorta. In most infants, conduit most often used is a pulmonary allograft, although bovine jugular venous valves and Dacron valved conduits have been used with good results. The proximal anastomosis of the conduit to the morphologic right ventricle is completed with running suture. In most cases, it is more convenient to position the conduit to the left of the aorta where it is less likely to be compressed by the sternum.

Weaning from bypass with adequate volume loading, inotropic support, and appropriate control of afterload is followed by intraoperative transesophageal echocardiographic assessment of the repair and heart function. Specific attention should be directed to assess the outflow gradients, AV valve function, residual intracardiac shunts, and obstruction in venous atrial pathways. A full complement of pacing wires are placed; a left atrial pressure line is placed prior to weaning from bypass.

Postoperative Management

Postoperative management of patients with CCTGA depends on the type of intervention, the associated lesions, and the presence of significant systemic ventricular dysfunction and/or tricuspid regurgitation and arrhythmias or conduction disorders.

Patients undergoing the double-switch procedure often experience low cardiac output postoperatively. Most patients will return from the operating room mechanically ventilated and heavily sedated. In some cases, with prolonged operation, mediastinal swelling, or bleeding, chest closure may be voluntarily delayed.

Potential complications and derived challenges of the double-switch operation may be atrial arrhythmias, sinus node dysfunction, conduction and dissynchrony disorders, baffle leaks (cyanosis, ventricular volume overload), and baffle obstruction (systemic venous baffle: superior vena cava syndrome, anasarca, capillary leak, low cardiac output syndrome; pulmonary venous baffle: pulmonary edema, deterioration of the pulmonary compliance, pulmonary hypertension, low cardiac output syndrome).

Cardiovascular Support

Inotropic support is always necessary and a balance between its benefits and impact on arrhythmias and myocardial oxygen consumption is mandatory. Usual combination of drugs includes low-dose dopamine or low-dose epinephrine with inodilators like milrinone. Milrinone offers the advantage of the inotropic and systemic vasodilator support combined with lusitropism, especially useful in the face of the previously banded patient who will undoubtedly have some degree of a poorly compliant left ventricle. Nonetheless, it is not unusual to observe disproportionate systemic vasodilation requiring a very fine titration of the drug or the adjunction of low-dose vasoconstrictors. Many surgeons, cardiovascular anesthetists, and intensivists advocate for the use of nitroglycerine to promote dilation of the transferred coronary arteries. Adjunction of further systemic vasodilation (i.e., sodium nitroprusside or calcium inhibitors) may be useful when requiring further reduction of the systemic ventricular afterload. The use of conventional monitoring modalities allied with follow-up of markers of tissue perfusion (blood lactates, near-infrared spectroscopy, continuous or intermittent monitoring of mixed venous saturations) is vital to manage the titration of cardiovascular drugs. Pharmacological cardiovascular support and ventilatory management are maintained until the cardiac output and tissue perfusion are stable, and the ventricular function is monitored by sequential echocardiographic evaluation.

Extracorporeal life support should be proactively considered in patients with refractory low cardiac output syndrome and progressive acidosis, deteriorating markers of tissue perfusion or multiorgan dysfunction, malignant arrhythmias, or respiratory distress syndrome. If such is a need, the presence of residual lesions needs to be exhaustively ruled out.

Cardiac Rhythm and Conduction

It is very important to ensure sinus rhythm and an adequate atrioventricular and interventricular synchrony. The incidence of complete AV block after a physiology repair is relatively high, and the risk of important sinus node dysfunction after an atrial switch procedure is also significant and may result in sudden death events. Temporary pacing wires are mandatory after these repairs.

Prevention of arrhythmias is capital, thus it is very important to anticipate and treat potential triggers (i.e., electrolytic disturbances). Arrhythmias ought to be exhaustively defined in order to utilize goal-oriented therapy as much as possible. For this purpose, atrial ECG performed on the atrial pacing wires may be very useful

indeed. Antiarrhythmic drugs will be chosen upon the type of arrhythmias, and pacemaker strategies prove beneficial to promote appropriate synchrony.

Respiratory Management

As described above, mechanical ventilator should be maintained until the patient is deemed stable, free of bleeding, and without any significant multiorgan dysfunction. From that point onward, proactiveness to extubate the patient before ventilator-associated complications arise is vital. In patients with an open chest, the intensivist needs to facilitate optimal conditions for chest closure by ensuring good hemodynamic stability and a negative fluid balance.

Specific Issues

Many of these operations will be re-interventions and bleeding is always a risk, no different from other re-sternotomy surgeries. Meticulous control of the hemostasis and bleeding disorders is required.

There is potential for compression of the ventricles and the RV-to-PA conduit, if present, behind the sternum, particularly in patients with meso- or dextrocardia where the venous structures lie posterior to the ventricular structures on which may be placed a valved conduit behind the sternum.

Caregivers need to closely follow parameters of multiorgan function, with the objective of anticipating, preventing, or else aggressively managing any documented disturbance.

Management of specific complications, including systemic or pulmonary baffle obstruction or leaks, requires an intense multidisciplinary effort; a low threshold needs to be kept with regard to re-intervention or cardiac catheterization that will allow diagnosis and palliation of these complications (i.e., baffle dilation and/or stenting, device or coil occlusion of baffle leaks).

Outcomes

Physiologic Repair

The outcome for physiologic repair of CCTGA has very good early survival, usually with less than 10 % of mortality. Most of the reports are relatively historical so may not reflect the current state of the art for complex congenital surgery. Karl and colleagues reported a 4 % hospital mortality rate and an 85 % survival rate at 10 years. Twenty of the 24 long-term survivors were in NYHA class I. However, two-thirds of these patients had important tricuspid insufficiency, and half had decreased systemic right ventricular function [49]. Deterioration in tricuspid valve and right ventricular function has been reported by other authors. Complete heart block either results from physiologic repair with VSD closure or develops in a significant number of these patients. In total, most patients that undergo a physiologic repair will require re-intervention within 10 years after initial repair [50].

Double Switch

Early to midterm outcomes are excellent for the Senning/arterial switch operation; Bove and colleagues reported 91 % 10-year survival [51]. Significant tricuspid regurgitation and impaired right ventricular function before repair have been widely documented to be risk factors for mortality after physiologic and anatomic repair for CCTGA [52, 53].

There is a significant risk of late left ventricular dysfunction after anatomic correction. This is predominantly seen in those patents that have had an atrial and arterial switch procedure.

Senning and Rastelli

In a report by Gaies and the group at the University of Michigan, survival rate for the Senning/Rastelli operation was significantly less than with

the double switch, with 1-, 5-, and 10-year survival of 91 % versus 71 %, 55 %, and 55 %. This difference may be due to the more complex anatomy and the increased number of palliative procedures in the Senning/Rastelli groups. This study also revealed a greater incidence of neurologic injury in the Senning/Rastelli groups. When a VSD enlargement was necessary, the risk of complete heart block was increased (5/8) [51].

Many authors have reported good left ventricular function after anatomic repair; however, others have found contradictory results [54, 55].

Exercise capacity has been shown to be no different [56] or reduced [57] at intermediate follow-up in patients who have undergone anatomic repair compared with patients repaired conventionally. Furthermore, newer data suggest that left ventricular dysfunction and neo-aortic valve regurgitation develop frequently [58, 59].

Although the popularity of the double switch has grown over the last 20 years, only relatively early results for this type of repair have been published in the literature, particularly from North America, Japan, and Europe [47, 54, 60–64]. Early mortality varies from 0 % to 9 %. Freedom from reoperation of all patients is around 75 % at 10 years. Reoperations mainly take place for conduit replacement in the Rastelli group, and this will be a continuing necessity. New aortic valve regurgitation and dilation of the neo-aortic root in the atrial arterial switch group has been described. This type of complication seems limited to the double-switch group, in which the old pulmonary valve becomes a new aortic valve.

Although anatomic correction started 20 years ago, there is scarce information regarding the functional status of these patients. Several studies demonstrated excellent functional status at mid-term follow-up, but longer follow-up studies are necessary to confirm the initial impression [42, 48, 51, 54, 65]. On the other hand, several studies have demonstrated a significant attrition rate on those patients who underwent physiologic repair with an increase of conduction disturbances, tricuspid insufficiency, and systemic ventricular failure [66]. A recent study based on literature analysis compared anatomic versus physiologic repair in patients with CCTGA and pulmonary stenosis [67]. This chapter revealed that the anatomic (Rastelli) repair of CCTGA was associated with a significant improvement in the incidence of the in-hospital mortality. It is not mentioned however if long-term follow-up gives any advantage to each of the approaches.

Historical experience with the Mustard and Senning atrial switch procedures has identified a significant incidence of systemic venous and, to a lesser extent, pulmonary venous obstruction over the long term [68, 69]. Moreover, late development of sinus node dysfunction after the atrial switch procedure can be as high as 40 % and is a risk factor for sudden death [70, 71]. A word of caution was applied in patients with CCTGA, no VSD, and tricuspid regurgitation who underwent retraining of the left ventricle via pulmonary artery banding. The pulmonary artery banding technique can adequately prepare the LV for the double-switch procedure with early satisfactory results comparable to those patients not requiring training. However, early deterioration in LV function in the trained group of patients has been reported, and there is concern that this will be a long-term problem [72].

Long-term outcomes and complications have been reported in a series of 113 anatomic repairs for CCTGA [45] including:

1. *Persistent tricuspid valve insufficiency*: postoperative incidence of mild to moderate tricuspid regurgitation was 27.6 % in the double-switch group and 40 % in the Rastelli/Senning group.
2. *Systemic or pulmonary baffle re-interventions*: Senning pathway re-intervention rate was 11 %, the majority of which were managed with interventional catheterization.
3. *Neo-aortic incompetence* after double switch: 70 % of those undergoing double switch had at least mild aortic insufficiency. This may be associated with aortic root dilation and may be improved with annular plication; six aortic valve replacements were required in the double-switch group for severe aortic insufficiency.
4. *Impaired left ventricular function*: 25 % of double-switch patients had severely impaired left ventricular function not related to the age

at placement of a PA band or the duration of the band. No patients (or a total of 45) with the Senning/Rastelli operation had poor left ventricular function.

5. *Re-interventions*: greatest for pulmonary artery stenosis and conduit issues. Significant number in the double-switch group and this seemed to be related to the Lecompte maneuver. Freedom from re-intervention overall was 50 % at 10 years.

This study showed no difference in mortality between these patients. However, there was a significantly worse outcome for the double-switch patients when looking at a combined outcome of death, transplant, or poor left ventricular function. This study highlights the fact that these are very complex patients and that long-term outcome is not free of risk. Perhaps the double-switch operation should be used selectively. Certainly these outcomes make us question whether a "prophylactic" double switch should ever be performed.

Conclusion

CCTGA has now entered a new era of anatomic repair. Surgery in this subset is very demanding and requires well-trained team in order to achieve optimal results. Although anatomic repair seems to offer excellent early and midterm functional results, there are emerging trends to suggest that long-term outcomes may not be as good as it had been hoped. Heart transplantation or Fontan procedure might be used in complex anatomic substrate or in patients with a failing systemic ventricle unable to retrain. Retraining of the left ventricle remains a good option for those patients without VSD; however, ventricular function should be regularly evaluated. The ultimate question is whether anatomic repairs convey long-term benefits in terms of survival, functional status, and quality of life, which outweigh the early morbidity and mortality associated with these repairs. This question will be very difficult to answer since the prevalence of physiologic repairs has decreased substantially as the early success of the anatomic repair has improved. Nevertheless, ongoing surveillance of these patients should provide some long-term outcome to guide future strategies.

Complex Transposition of the Great Arteries

111

Victor Morell, Alejandro J. López-Magallón, Nils Welchering, Juliana Torres Pacheco, and Ricardo Muñoz

Abstract

Complex transposition of the great arteries includes cases of D-transposition of the great arteries that also have important coexisting malformations, such as ventricular septal defects, left or right ventricular outflow tract obstruction, and aortic arch anomalies. These patients represent approximately 25 % of all patients with D-transposition of the great arteries. The diagnosis and management of these patients can be considerably more complex than for simple transposition of the great arteries. With the improvement in diagnosis and perioperative management, new more advanced surgical procedures have been developed and the outcomes for these patients have improved. The current state of art for the care of these patients will be presented in this chapter.

Introduction and Classification

Complex transposition of the great arteries (TGA) includes all cases of D-TGA that also have important coexisting malformations, such as ventricular septal defects, left or right ventricular outflow tract obstruction, and aortic arch anomalies. This group of cardiac malformations (double-outlet right ventricle patients not included) comprised 23.8 % from 829 patients with D-TGA presenting for an arterial switch operation in a 24-center trial report [1]. Because of the complexity of the cardiac defects, no single approach is uniformly accepted or appropriate. For example, in patients with D-TGA, ventricular septal defect (VSD), and pulmonary stenosis (PS), traditionally, a staged approach including a palliative shunt procedure and subsequent Rastelli procedure was commonly performed. The approach requires the use of a right ventricular-to-pulmonary artery (RV-PA) conduit and commits the child to potentially multiple reoperations. More recently, there has been increased enthusiasm for definitive procedures that do not require conduits and often can be performed as a single-stage procedure. This would include an arterial switch operation and repair of left ventricular outflow tract obstruction (LVOTO) or an arterial translocation procedure (Nikaidoh procedure). These are formidable operations with low but not insignificant risk. However, regardless of the strategy, the outcome for these children has improved significantly in the last several years. This chapter will address the diagnosis and management of the more complex TGA patients.

Anatomy, Physiology, and Clinical/Diagnosis

D-TGA with a Ventricular Septal Defect

Ventricular septal defect is a common coexisting anomaly in patients with D-TGA (about 40–45 % of all TGA). Nevertheless, the size of the ventricular septal defect is not significant from the clinical point of view in one-third of these patients, and presentation is undistinguishable from neonates with TGA and intact ventricular septum. The ventricular septal defect can be categorized because of its location. Roughly close to a third of the total VSD in reported series can be ascribed to perimembranous, malalignment, and muscular types with a small residual percentage for inlet and conal septal defects [2]. Left ventricular outflow tract obstruction is present in one-eighth to one-third of cases, being far more common in the presence of a ventricular septal defect. This impediment to the blood flow can be caused by a wide spectrum of lesions, either at valvar or subvalvar level, and deviation of the muscular outlet septum is but one of them. Bulging of the septum, a fibrous shelf or fibromuscular tunnel, tissue tags, and anomalous attachment of the atrioventricular valvar tension apparatus can also be substrates for stenosis.

Clinical Evaluation of TGA with VSD

Patients with a large ventricular septal defect and TGA, in the absence of important LVOTO, may develop signs of congestive heart failure within 2–6 weeks of age, in parallel with the normal fall in pulmonary vascular resistance and an increasing pulmonary blood flow.

The physical examination of patients with D-TGA and ventricular septal defect often reveals an increased right ventricular impulse. During auscultation, a 2–3/6 systolic ejection murmur over the left lower sternal border, as well as a normal first sound and a loud second sound with a narrowly split or single S2, may be heard in patients with restrictive septal defects. Hepatomegaly may be present. Arterial oxygen saturation is usually between 75 % and 90 % and arterial oxygen level is around 40, whereas pH and pCO2 are within normal limits.

The chest X-ray often shows mild to moderate cardiomegaly and increased pulmonary vascular markings, depending on pulmonary blood flow. There may be a narrow upper mediastinum due to anterior and posterior relationship of the great vessels, rectification of the pulmonary artery, and thymus hypoplasia. The ECG may be normal or reveal right ventricular hypertrophy. Echocardiogram is helpful for anatomic and physiological diagnosis, including spatial relationship of semilunar valves and size, coronary pattern, and ventricular septal defect size and location [3]. Some patients with relatively restrictive VSD may have a suboptimal intracardiac mixing; in the latter scenario, echocardiography is capital in understanding the need for an atrioseptostomy. Cardiac catheterization is indicated only if the need for an atrioseptostomy is documented clinically and by echocardiography or in cases in which coronary artery anatomy is in question. In the latter situation, coronary angiography with caudal angulation and the catheter positioned in the ascending aorta with distal balloon occlusion during contrast injection can be useful for coronary anatomy delineation [4].

D-TGA with a Ventricular Septal Defect and Left Ventricular Outflow Tract Obstruction

D-transposition of the great arteries (D-TGA) with a ventricular septal defect and left ventricular outflow tract obstruction (LVOTO) is a rare association and represents 0.67 % of all congenital heart defects [5] and between 3.6 % and 10.3 % of all infants with D-TGA presenting for surgery [1, 6]. In comparison with those patients with D-TGA and an intact ventricular septum, left ventricular tract obstruction (LVOTO) in patients with ventricular septal defect tends to be more severe and mostly subvalvular. It can result from muscular obstruction due to posterior malalignment of the outlet septum, a fibrous ring, or a fibromuscular tunnel. Other mechanism for LVOTO may be redundant tissue of the tricuspid valve bulging into the ventricular septal defect as well as abnormal attachment of the anterior mitral valve leaflet to the muscular outlet septum [7, 8].

Clinical Evaluation of TGA with VSD and LVOTO

Clinical presentation is variable, depending on the severity of obstruction and interventricular mixing. Infants with critical LVOTO have the same symptoms as neonates with critical pulmonary stenosis or pulmonary atresia, including severe hypoxemia and cyanosis, tachypnea, and respiratory distress with ductal-dependent pulmonary circulation. Patients with moderate to severe LVOTO will exhibit reduced pulmonary blood flow. Accordingly, the clinical presentation may be similar to neonates with tetralogy of Fallot, with cyanosis and a systolic ejection murmur. On the other hand, patients with mild to moderate LVOTO have variable symptoms of congestive heart failure including tachypnea, tachycardia, sweating, and poor feeding. Cyanosis is usually mild or absent in this last group of patients.

Physical examination of patients with D-TGA, ventricular septal defect, and LVOTO reveals mostly a long ejection systolic murmur at the left upper sternal border and/or a holosystolic murmur at the left lower sternal border. The murmur may be absent in patients with critical obstruction to the pulmonary blood flow.

The chest X-ray findings are variable as well and correlate with pulmonary blood flow, going from no significant cardiomegaly and normal or

decreased pulmonary blood flow to cardiomegaly and increased pulmonary vascular markings.

ECG can show right ventricular or biventricular hypertrophy.

Echocardiography is the most useful diagnostic tool. Besides the usual anatomic and physiologic features, it is essential to ascertain the spatial relationship and size of the semilunar valves, the size and location of the ventricular septal defect, the characteristics of the atrial shunt, the coronary artery anatomy, and the mechanism and severity of LVOTO and pulmonary valvar stenosis. These diagnostic goals can be achieved with echocardiography alone most of the time. A cardiac catheterization will provide additional information if needed, most usually coronary artery anatomy. CT scan could also be an alternative technique [9].

D-TGA with Aortic Coarctation

D-TGA is rarely associated with aortic coarctation. In a large multicenter study, 4 % of patients with D-TGA had a concomitant aortic coarctation [1]. Complex TGA with coarctation is often combined with a ventricular septal defect. In a study reporting 25 years of experience with the arterial switch operation from Utrecht, Netherlands, 10 of 12 complex TGA with coarctation were associated with a ventricular septal defect [10]. This group may also have variable degrees of aortic arch hypoplasia, right ventricular hypoplasia, and right ventricular outflow tract obstruction.

Clinical Evaluation of TGA and Aortic Coarctation

Patients with TGA and aortic arch obstruction usually have ductal-dependent systemic circulation and, if not diagnosed very soon after birth, may present with low cardiac output and shock. Because of increased pulmonary blood flow, patients may present with tachypnea and respiratory failure. Further, patients may experience reverse-diferential cyanosis. With a restrictive ductus, femoral pulses may be absent or decreased with signs of poor systemic perfusion or even catastrophic cardiovascular collapse if the ductus is completely closed.

Chest X-ray findings include cardiomegaly with an increased pulmonary vascular marking. The ECG findings are variable, from normal ECG to biventricular hypertrophy. Echocardiography is the primary tool for diagnosis and ascertaining of important anatomic features additional to the standard D-TGA findings, i.e., the presence of a concomitant ventricular septal defect, aortic arch anatomy, and patency of the ductus arteriosus. A cardiac catheterization or CAT scan will be useful in cases with difficult anatomy [4, 9].

Double-Outlet Right Ventricle with Subpulmonic VSD

In this anomaly, the so-called Taussig-Bing arrangement, aortic and pulmonary annuli lay side by side; there is a subpulmonic conus and VSD, with unrestricted pulmonary blood flow; and the aortic valve is distant from the VSD [11]. A more in-depth discussion about this anomaly may be found in another chapter in this textbook.

Clinical Evaluation of DORV with TGA and Subpulmonic VSD

Clinical presentation is similar to D-TGA with a ventricular septal defect, including variable signs of congestive heart failure and cyanosis in early infancy. More severe failure to thrive and frequent respiratory tract infections can be present. Precordial bulge and right ventricular impulse are noted at the left sternal border. There can be no murmur or a systolic flow murmur at the left midsternal border in patients with unobstructed outlet to both great vessels or a rough systolic murmur with variable pitch at the left midsternal border in patients with subaortic obstruction. With increased pulmonary blood flow, an apical diastolic rumble may be present. Patients with obstruction at the aortic arch will show diminished pulses in lower extremities together with a noninvasive blood pressure gradient between the right arm and the remaining limbs.

The chest X-ray findings include pronounced increase in pulmonary vascularity along with cardiomegaly, and the ECG may reveal right ventricular hypertrophy.

Echocardiography remains the definitive modality for diagnosing this entity as it demonstrates the anatomic features of VSD and muscular outlet septum and the spatial relationship of the great vessels to the VSD. The semilunar valve function, the presence of associated obstructive lesions, and the identification and delineation of the origin and course of the coronary arteries are essential also. Certain variations of coronary arterial anatomy, as intramural course, are known to complicate the arterial switch and must be identified if present [12, 13].

Angiographic observations reveal the side-by-side relationship of the great arteries and a high VSD related directly to the pulmonary valve and no flow obstruction from VSD to pulmonary valve [14]. Investigation of pulmonary vascular reactivity is of paramount importance, especially in older children without significant manifestations of heart failure. The assessment of pulmonary vascular resistance by cardiac catheterization does not always represent the true status of the patient. An analysis using post-oxygen echocardiography suggested an ability to predict operability accurately in 83 % patients with TGA-VSD physiology in whom operability assessment was not straightforward [15].

Double-Outlet Right Ventricle with D-Transposition and Pulmonary Stenosis

Subaortic right ventricular outflow tract obstruction and arch obstruction are frequent in children with Taussig-Bing, but subpulmonary stenosis is a rare finding [16, 17].

Clinical Evaluation of DORV with TGA and Pulmonic Stenosis

Physical findings are similar to D-TGA with ventricular septal defect and LVOTO and also depend on the severity of obstruction. Cyanosis and polycythemia may be severe with an early presentation, along with less evidence of heart failure. A loud holosystolic murmur as well as an ejection-type systolic murmur can be heard. The second heart sound is loud and single and is most notably related to the proximity of the aorta.

In the chest X-ray, the pulmonary vasculature is reduced or normal, and the heart size is normal or increased. ECG can show right ventricular or biventricular hypertrophy and echocardiography is again the most useful diagnostic tool [18].

Double-Outlet Right Ventricle with D-Transposition and Aortic Coarctation or Subaortic Obstruction

Aortic arch obstruction is a commonly associated feature of Taussig-Bing anomaly due to preferential flow pattern from the left ventricle to the pulmonary artery caused by the septal malalignment. The flow into the ascending aorta would therefore be limited and flow across the isthmus reduced, with resultant aortic arch obstruction. Subaortic right ventricular outflow tract obstruction is found in 50–60 %, and arch obstruction is common and present in 39–52 % [11]. Aortic arch obstruction, by way of comparison, is present in only 6 % of cases of D-TGA with VSD [15]. Patients with Taussig-Bing and aortic arch obstruction present for operation earlier in life than infants without obstruction [15].

Clinical Evaluation of DORV with TGA and Aortic Coarctation or Subaortic Obstruction

Clinical features are similar to patients with D-TGA and aortic coarctation with tachypnea and respiratory failure besides diminished pulses in lower extremities. Diagnostic exams are also similar, with chest X-ray findings showing cardiomegaly and increased pulmonary vascular marking. Echocardiography is also the primary tool for diagnosis and cardiac catheterization or CAT scan may be needed to confirm anatomy [4, 9].

Preoperative Management

Depending on clinical presentation, therapeutic approach should be directed at optimization of intracardiac mixing and effective pulmonary

blood flow as well as balancing pulmonary and systemic output. In case of critical LVOTO, ductus arteriosus opening with PGE_1 is essential to preserve effective pulmonary blood flow. Pulmonary overcirculation physiology should be treated aggressively with a strategic goal to balance Qp/Qs, optimization of systemic afterload reduction with or without the use of normoxic or hypoxic gas mixtures to manipulate pulmonary vascular resistance (PVR) [19]. Those patients presenting with a naturally *balanced circulation* with absent or only mild signs of congestive heart failure and adequate effective pulmonary blood flow can potentially be managed conservatively before an elective surgery.

On the other hand, infants with D-TGA and aortic arch obstruction can present with profound cardiogenic shock or cardiovascular collapse during spontaneous ductus arteriosus closure. Initial approach includes a vigorous resuscitation with appropriate airway and ventilation support, preload optimization, PGE_1 infusion for ductus arteriosus opening, and inotropic support with epinephrine drip titrated to effect. Milrinone can be started once there is improvement in systemic arterial pressure. Metabolic acidosis can be severe and should be corrected. Once the ductus arteriosus opening is achieved and myocardial dysfunction is improved, the next priority will be to avoid pulmonary overcirculation and obtain multiorgan dysfunction recovery before surgical repair [20]. Notwithstanding this being a common practice, there are conflicting reports on outcomes related to the use of steroids before heart surgery in children [21–23].

Surgical Management of Complex Transposition of the Great Arteries

The operative management of these complex lesions requires surgical exposure via a median sternotomy incision. For cardiopulmonary bypass, these authors' preference is to use bi-caval cannulation, but many centers utilize a single venous cannula in the right atrium. Moderate to deep hypothermia, with or without a period of circulatory arrest, is usually required.

TGA with VSD

The authors' preferred operative approach has been to proceed with VSD closure, followed by the arterial switch procedure. The VSD is usually closed through the tricuspid valve using a prosthetic patch. The conduction tissue runs along the inferior margin of the defect and should be avoided. With this lesion, there tends to be a significant size discrepancy between the (larger) main pulmonary artery and the (smaller) aorta, which results in a technically challenging aortic anastomosis. The STS congenital database reports 5.1 % mortality associated with the repair of this lesion [65].

TGA with VSD and LVOTO

For complex transposition of the great arteries with left ventricular outflow tract obstruction and a ventricular septal defect, there are four surgical options: the *Rastelli repair, réparation à l'etage ventriculaire* (REV procedure), the *Nikaidoh procedure*, and the *pulmonary root translocation*. Frequently, cyanotic neonates and infants require initial management with a systemic to pulmonary artery shunt before proceeding with a complete repair.

Rastelli Repair

Introduced in 1969 by Jan Carlo Rastelli, this technique requires the construction of an intraventricular tunnel, baffling the left ventricular blood into the anterior aorta (Fig. 111.1) [24, 25]. In many cases, the VSD should be enlarged anteriorly in order to decrease the incidence of postoperative subaortic stenosis [26]. After ligation and division of the proximal main pulmonary artery, the right ventricular-to-pulmonary artery continuity is reestablished using a conduit. The non-anatomical mediastinal course of the conduit, because of its proximal origin from the distal RVOT incision, frequently results in anterior compression by the sternum.

There are several anatomic variables that complicate the performance of a Rastelli repair.

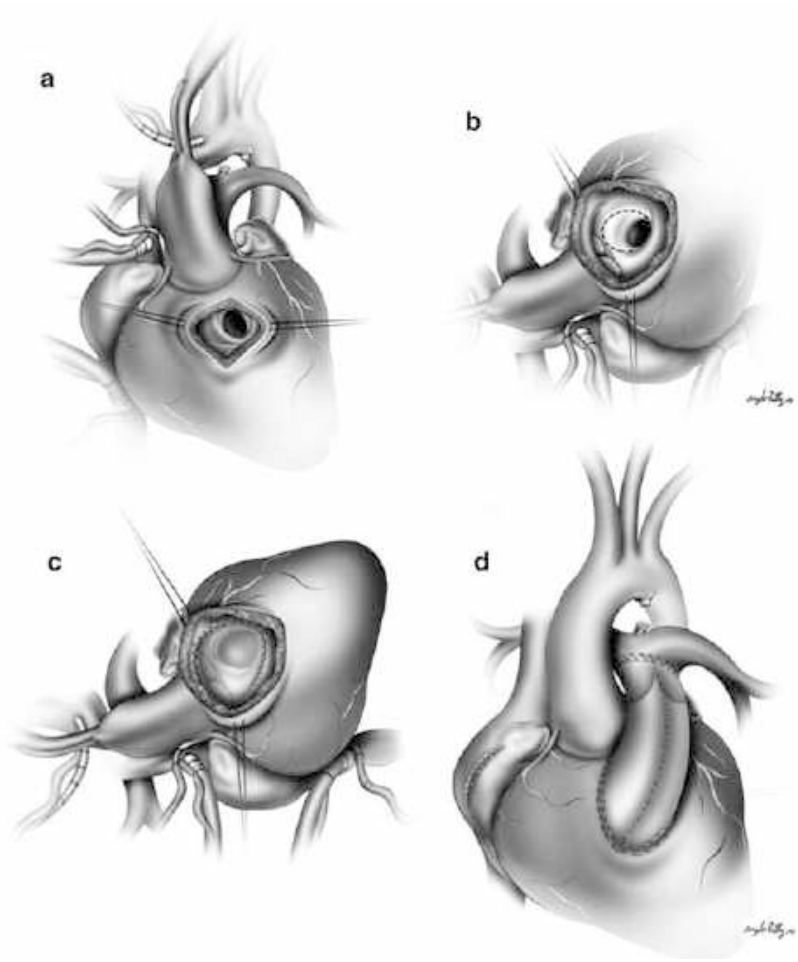

Fig. 111.1 *Rastelli repair*. Via a median sternotomy and under cardioplegic arrest, a (**a**) distal RVOT incision is made. (**b**) The VSD is enlarged along the anterosuperior margin, and then (**c**) the intraventricular tunnel is created, funneling the LV blood into the aorta. (**d**) Finally, the main pulmonary artery is ligated and divided and the conduit is sutured in place

The abnormal course of a major coronary artery crossing the right ventricular outflow tract could prevent the performance of a distal right ventriculotomy. The presence of an inlet or restrictive VSD or a straddling mitral or tricuspid valve may prove to be major anatomic obstacles in creating the intraventricular tunnel. Interestingly, the presence of a straddling tricuspid valve has been associated with increased early and late mortality after a Rastelli repair [27]. Also, the right ventricular volume is partially compromised by the interventricular tunnel; thus, the presence of right ventricular hypoplasia can be considered a contraindication to a Rastelli repair.

Kreutzer and associates [4] reported their experience with the Rastelli repair in 101 patients with atrioventricular concordance and a VSD (LVOTO was present in 91 patients) during a 25-year period. The overall mortality was 7 %. Freedom from reintervention for right-sided obstruction was 21 % at 15 years, and there was a 10 % incidence of LVOTO. The overall freedom from death or transplantation at 20 years was 52 %. Surprisingly, the Mayo Clinic (Rochester, USA) published similar results with a 59 % survival at 20 years [28]. These published reports raise questions about the long-term physiologic implications of the Rastelli repair. Graham and associates [29] have reported abnormal contractile function and increased mean end-systolic stress and left ventricular mass in a group of patients after a Rastelli repair.

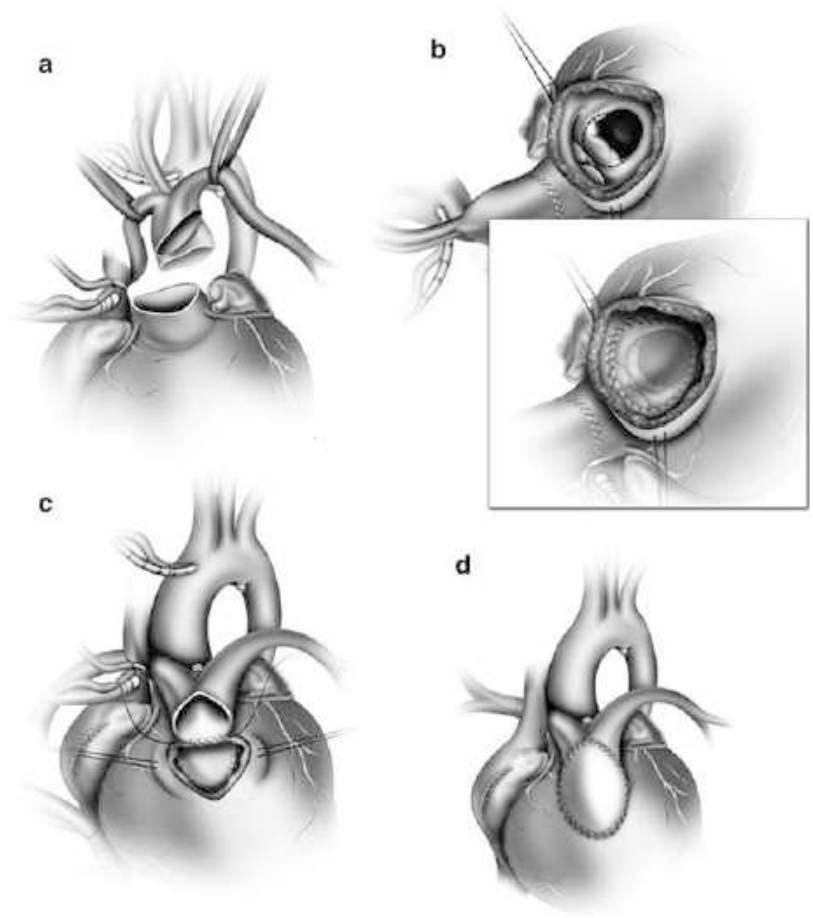

Fig. 111.2 *REV procedure*. Via a median sternotomy and under cardioplegic arrest, (**a**) the pulmonary arteries are translocated anterior to the aorta. (**b**) After the reconstruction of the aorta, a distal right ventriculotomy is performed, the outlet septum excised, and the VSD patch is placed, funneling the LV blood to the aorta. (**c**) The posterior wall of the pulmonary artery is sutured to the distal aspect of the right ventriculotomy, and (**d**) the pulmonary anastomosis is completed with a pericardial patch

The STS congenital database reports 4.8 % mortality associated with this repair [65].

Réparation à l'Etage Ventriculaire (REV)

In 1982, Lecompte and associates [30] described an alternative surgical procedure. The intracardiac aspect of the repair differs from the Rastelli in that the muscular outlet septum is completely excised, providing a more direct alignment of the aorta to the left ventricle. It also allowed for reconstruction of the right ventricular outflow tract without the use of a prosthetic conduit. With this technique (Fig. 111.2), called by the group from Paris "**r**éparation **à** l'**é**tage ventriculaire," the pulmonary arteries are translocated anterior to the aorta, the so-called Lecompte maneuver, and the posterior wall of the pulmonary arteries is sutured to the distal aspect of the right ventriculotomy. The anastomosis is completed with an anterior patch, with or without a monocusp valve.

This repair offers the advantage of avoiding the use of a conduit between the right ventricle and the pulmonary arteries. The anterior location of the pulmonary arteries subsequent to the procedure, however, may create the potential for obstruction within the right ventricular outflow tract, and this complication was observed in one-quarter of patients in one series [31]. To prevent this problem, Metras et al. [32] described a modification of the technique that utilizes a segment of aortic autograft to reconstruct the right ventricular outflow tract, keeping the pulmonary arteries in their anatomic position posterior to the aorta. With this modification, they

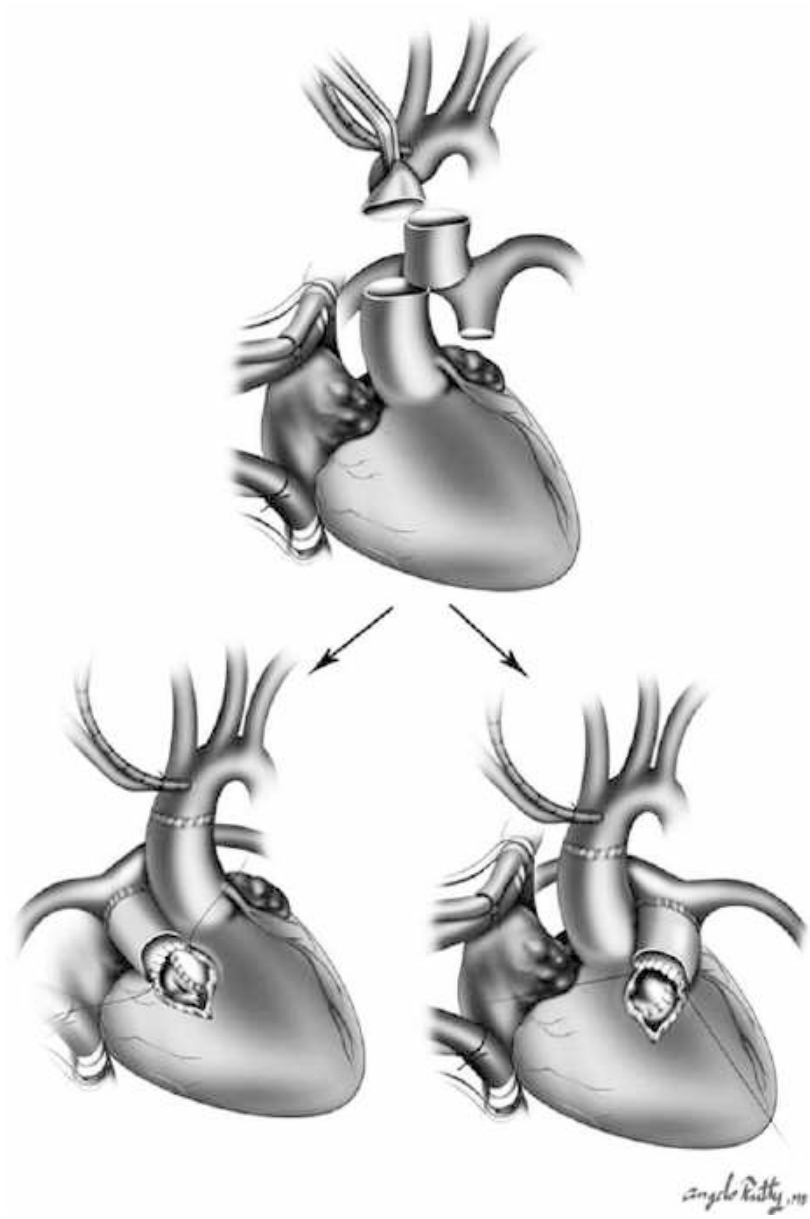

Fig. 111.3 *Metras modification*. A segment of the ascending aorta is harvested and used as an interposition graft between the right ventricle and the pulmonary arteries. Note that the branch pulmonary arteries are kept in a normal anatomic position, posterior to the aorta

found no instances of obstruction within the right ventricular outflow tract and described normal growth of the autograft. This modification, therefore, makes the REV repair an attractive alternative for the management of patients with transposition of the great arteries with a ventricular septal defect and obstruction to the left ventricular outflow (Fig. 111.3). The STS congenital database reports a 23.1 % mortality associated with the REV repair [65].

Pulmonary Root Translocation

The concept of reconstructing the RVOT with the native pulmonary valve by translocating the

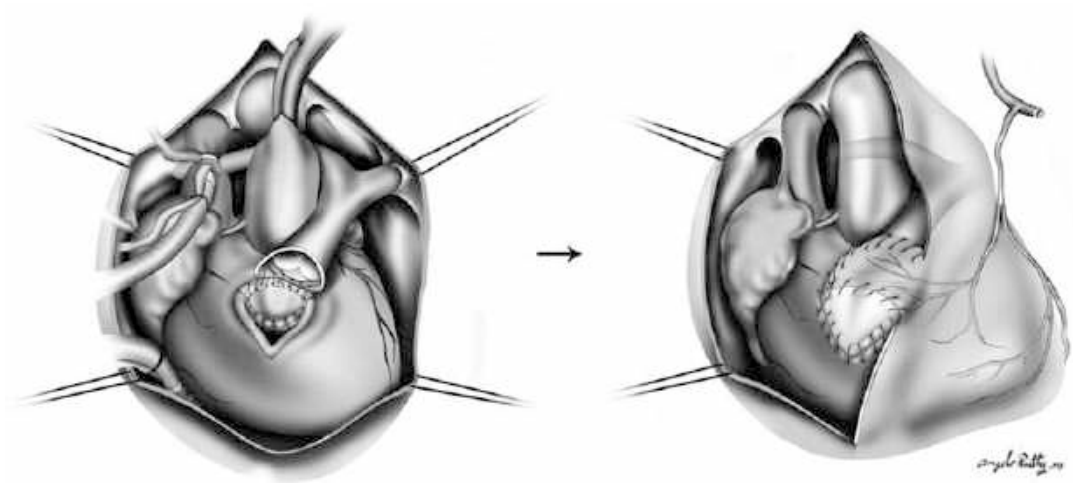

Fig. 111.4 *Pulmonary root translocation*. The pulmonary root is moved anteriorly to the right ventricle, and the VSD is closed. The RVOT is completed with a vascularized patch of pericardium

pulmonary root in patients with TGA with VSD and PS was introduced by da Silva and associates in 2000 [33]. The surgical technique consists of pulmonary root translocation from the left ventricle to the right ventricle after construction of an intraventricular tunnel, diverting blood flow from the left ventricle to the aorta (Fig. 111.4). In their latest publication, the authors reported excellent results in 44 consecutive patients that were managed with this surgical technique [34]. The early mortality was 6.8 % and on follow-up only four patients required reinterventions owing to right ventricular outflow tract problems. The authors utilize a vascularized pedicle of pericardium in the RVOT to promote growth.

Aortic Translocation (Nikaidoh Procedure)

In 1984, Nikaidoh [35] introduced a surgical approach for the management of TGA, VSD, and pulmonary stenosis (PS), which he called "aortic translocation and biventricular outflow tract reconstruction." The repair consisted of harvesting the aortic root from the right ventricle, with or without the coronary arteries attached, and relieving the LVOTO by dividing the outlet septum and pulmonary valve annulus. The left ventricular outflow tract is then restored by posteriorly translocating the aortic root and closing the VSD. Finally, the right ventricular outflow tract is reconstructed with a pericardial patch. Although technically challenging, this approach results in a more "normal" anatomic repair.

Several modifications to the original technique have been described [36–38], but the main technical point remains the repositioning of the native aortic root over to the left ventricular cavity, avoiding the creation of a long tortuous intraventricular tunnel (Fig. 111.5). This technique appears to prevent the development of LVOTO, which is a frequent complication of the Rastelli repair. The addition of the Lecompte maneuver may prevent branch pulmonary artery stenosis that may occur secondary to compression of the PA by the posteriorly displaced, translocated aortic root. Also, it allows for a direct RV to PA anastomosis, avoiding the use of a conduit, which should decrease the incidence of RVOT reinterventions.

Anatomic studies and clinical experience have helped identify a subset of patients with TGA/VSD/PS that appear to be better managed with a Nikaidoh procedure [5, 39, 40]. These include patients with the following findings: inlet-type or more apically located VSD, hypoplastic RV, and straddling AV valve. The published data in a relatively small number of patients is certainly

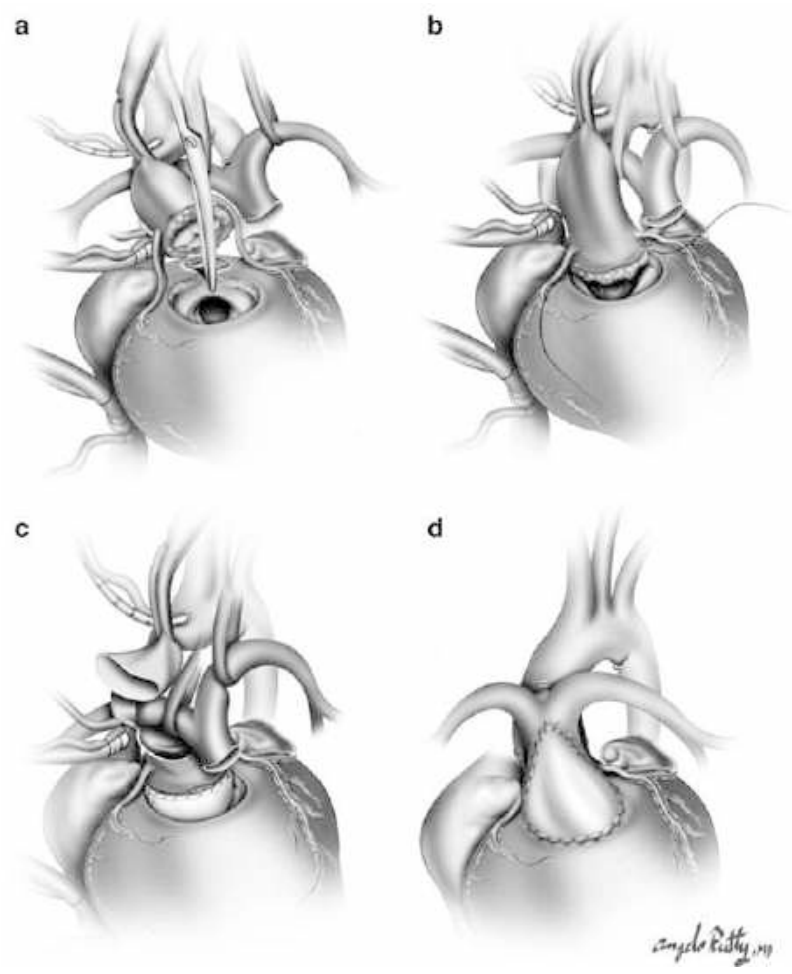

Fig. 111.5 *Aortic translocation procedure*. (**a**) After the aortic root is harvested from the right ventricle and the proximal main pulmonary artery transected, the outlet septum is divided. (**b**) The aortic root is then translocated so that it is closer to the left ventricle. (**c**) After closure of the VSD, the Lecompte maneuver is performed and a (**d**) direct RV to PA connection is created with an anterior patch of autologous pericardium

encouraging, reporting an acceptable operative mortality with good long-term survival. The late development of aortic insufficiency has been noted in some series and requires further follow-up. The STS congenital database reports 5.4 % mortality associated with this repair [65].

TGA with Aortic Arch Obstruction

The combination of transposition of the great arteries and aortic arch obstruction (AAO) is a rare condition, much less frequently observed than the Taussig-Bing anomaly. In this complex cardiac defect, arch obstruction can present as hypoplasia, coarctation, or interruption and is usually associated with the presence of a VSD. These patients can also present with hypoplasia of right ventricular structures, including the tricuspid valve, the right ventricular outflow tract, and the neopulmonary valve annulus [41]. A very detailed echocardiogram should delineate the RV structures, which when significantly underdeveloped (z-scores <2.5) may preclude a biventricular repair.

Surgical repair is undertaken via a median sternotomy. Complete repair consists of an arterial switch operation with arch repair and VSD closure. A period of deep hypothermic circulatory arrest is utilized while intervening on the

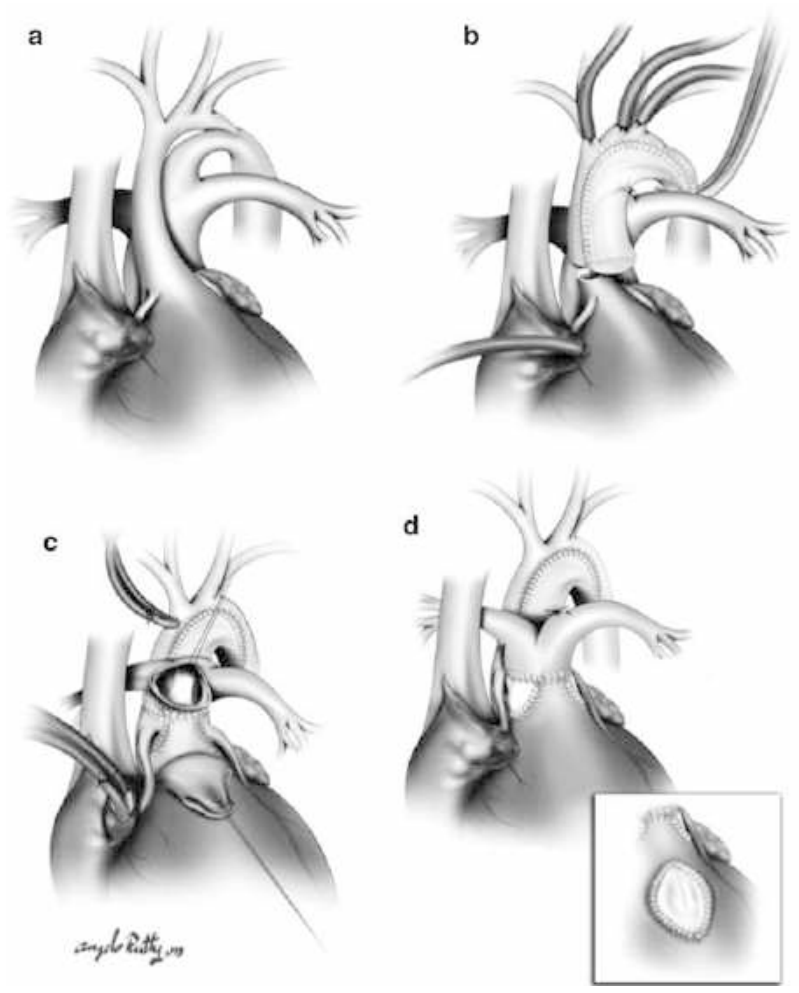

Fig. 111.6 *Repair of TGA with aortic arch obstruction*. (**a**) D-TGA with aortic arch hypoplasia and coarctation. (**b**) Patch aortoplasty is performed; note that it extends from the proximal ascending aorta to the mid-descending aorta. (**c**) The coronary arteries are reimplanted and the aortic anastomosis completed. (**d**) Finally, the pulmonary anastomosis is performed after the reconstruction of the neopulmonary trunk with pericardium. A right ventricular outflow patch is occasionally needed in the presence of right ventricular hypoplasia

arch. The aortic arch can be addressed by either direct anastomosis or patch aortoplasty, which allows for enlargement of the distal ascending aorta in order to better match the size of the proximal neoaorta, facilitating the aortic anastomosis (Fig. 111.6). A RVOT pericardial patch might be required in patients with RV hypoplasia. The STS congenital database reports a 11.9–12.9 % mortality associated with the surgical management of these patients [65].

Postoperative Management

We discuss here general considerations on postoperative management for all these complex heart malformations, with particular aspects for each one at the end.

General Context

Cardiopulmonary bypass (CPB) and aortic cross-clamp times can be prolonged in these patients, especially those undergoing the Nikaidoh operation [5]. Consequently, a marked systemic inflammatory response and variable degrees of myocardial and multiorgan dysfunction can be expected during the first 24–72 postoperative hours [42, 43].

Monitoring

The patient will be admitted to the CICU from the OR with mediastinal drainage tubes and very likely with a peritoneal dialysis catheter. A urinary catheter is mandatory to assess renal

perfusion and function. Various central indwelling catheters will be in place, including right and left atrial lines for monitoring and fluid or medication administration. Atrial and ventricular pacemaker wires will be placed also. Serial lactate and mixed venous saturation trends are followed to assess oxygen delivery status. Brain and splanchnic near-infrared spectroscopy (NIRS) monitoring trend is a useful adjunct to assess regional perfusion status [44]. Postoperative troponin I levels during the first 24 postoperative hours are predictive of severe complications and prolonged intensive care stay [45]. Continuous electrocardiographic monitoring is essential for early detection of atrioventricular conduction abnormalities, arrhythmias, and coronary insufficiency. Transoperative transesophageal echocardiography (TEE) results should be readily available to the intensive care team, as well as serial echocardiographic follow-up.

Cardiovascular Management

The patient may arrive with an open chest. Prophylactic use of milrinone is the standard of care for these patients, with dose adjustments to optimize afterload reduction and its inotropic and lusitropic properties [46]. Low-dose epinephrine is used and adjusted to increase systemic arterial pressure. Sodium nitroprusside is used most of times during the first postoperative days. Significant capillary leak is common with a depleted intravascular volume physiology. Continuous vasopressin infusion at very low rates is used occasionally to support vascular tone and decrease sympathomimetic drug infusion requirements [47, 48]. Consequently, preload conditions should be optimized according to filling pressures, usually requiring an increased intravenous fluid intake with a combination of blood products and crystalloid or colloid solutions according to the clinical situation. As cardiopulmonary bypass induces marked and persistent depression of circulating thyroid hormone levels, T3 supplementation has been showed to provide clinical advantages in patients younger than 5 months of age [49]. Stress-dose hydrocortisone supplementation can be considered after cardiac surgery in neonates to blunt other organ dysfunction, since an inappropriate adrenal response to stress may occur after cardiopulmonary bypass in this cohort [50]. Chest closure can be considered once myocardial function has recovered and total body edema has decreased. ECMO should be considered if warning trends are detected on the various indicators of systemic cardiac output. Early ECMO initiation strategy is preferred against one with ECMO start after cardiopulmonary collapse. When patients trend poorly, these authors adhere firmly to a troubleshooting philosophy with an early and thorough diagnostic investigation to rule out significant correctable residual lesions, with a low threshold for cardiac catheterization.

Respiratory Management

Patients undergoing this surgery will need mechanical ventilation during the first postoperative days. Tidal volumes (usually 8–10 ml/kg) and PEEP (4–6 cm H_2O) should be adjusted for optimal alveolar recruitment. Extubation can be planned once the chest is closed and total body edema has subsided. This is usually reflected by improved lung compliance and an accompanying decrease in mean airway pressure needs. Hypoxemia should be studied to rule out residual intracardiac shunting.

Fluid, Electrolyte, and Nutritional Management

Total maintenance fluids are calculated initially at 50 % of basal requirements for age and size. As previously described, supplementation with a combination of crystalloid, colloid, and blood products is the norm according to hemodynamic and intravascular volume status. In our experience, replacing fluid loss from the peritoneal dialysis catheter with saline during the first 48–72 postoperative hours decreases the need for repeated intravenous boluses. Fluid balance will be neutral or positive most of the time in the first 24–48 postoperative hours, with a goal to obtain an increased diuresis and negative fluid balance afterwards. CPB surgery increases measured resting energy expenditure and nutritional

demands, and a mismatch between caloric requirements and intake is common [51]. Hence, a nutritional strategy is an essential part of postoperative care in these patients. We start parenteral nutrition 24 h after surgical repair. A dextrose concentration of up to 20–25 %, with a protein intake of 3–3.5 g/kg/day and a fat intake of 3–3.5 g/kg/day, is used in neonates to achieve an anabolic physiology. These nutritional goals are adjusted according to age-appropriate needs and corrected depending on clinical and biochemical nutritional markers.

Hematologic Management

There are multiple factors contributing to an increased bleeding risk in these patients, including CPB circuit exposure and time, and dilutional coagulopathy as the prime volume is almost always larger than the estimated blood volume. Besides, these are extensive operations involving multiple suture lines. If there is persistent bleeding above 7–10 ml/kg/h, consideration for prompt surgical chest reexploration is mandatory. Proper treatment of medical postoperative bleeding requires an understanding of the most likely coagulation abnormalities following CPB. A more efficient, deficiency-directed transfusion practice with the help of thromboelastography or thromboelastometry can result in a reduced need for PRBC or plasma administration as opposed to platelets, fibrinogen concentrate, or cryoprecipitate during the postoperative period [52]. The use of the relatively new recombinant factor VIIa for the treatment of uncontrolled bleeding after CPB in neonates and children has shown to significantly decrease transfusion requirements. This potential benefit should be weighed against the lack of controlled trials and a disturbingly common incidence of thrombotic events [53, 54].

Renal Management

Aggressive diuretic treatment is essential to achieve a negative fluid balance during the first postoperative days. Furosemide and thiazides are the most commonly used diuretics. Furosemide is started within 6–12 h after repair. A continuous infusion will render a more consistent urinary output and less hemodynamic instability [55, 56]. Infusions of up to 0.4 mg/kg/h are common, and care should be taken when using higher doses given potential oto- and nephrotoxicities [57]. There is usually an inverse relationship between the peritoneal drainage volume and urinary output.

Neurologic Management

Lasting impairments in cognitive, motor, and expressive functioning have been reported in up to three-fifths of children who have undergone complex cardiac surgery during infancy [58]. The neurological outcome in these patients can be improved by a multimodality monitoring, combining venous oximetry, NIRS, transcranial Doppler, and electroencephalography [59].

Adequate sedation with narcotics and dexmedetomidine is a frequent combination in this setting. These authors have decreased our use of benzodiazepines, as dexmedetomidine seems to have potential neurologic and cardiologic advantages in comparison to benzodiazepines [60]. A disadvantage of long-term use of benzodiazepines is an increased risk of physical dependency and accordingly more often withdrawal symptoms after discontinuation [61].

Infectious Disease Management

At Children's Hospital of Pittsburgh, the authors use a third-generation cephalosporin with vancomycin on a routine basis until the chest is closed [62]. A first-generation cephalosporin is started afterwards until chest tubes are removed. Because of the increased risk of infection, central lines must be discontinued as soon as possible. Mediastinitis sprouts are seen eventually. In such a case a combination of wide-spectrum antibiotics including gram-positive coverage with adjustment pending on clinical response and sensitivity results, surgical exploration, and cleaning

of wound and sternum, together with a V.A.C.© system, is used for treatment.

Complications

Patients with D-TGA and VSD share similar potential complications with those with simple D-TGA. Additional problems include low cardiac output syndrome (LCOS), atrioventricular block, junctional ectopic tachycardia (JET), atrioventricular valve regurgitation, and residual VSD.

Particular postoperative problems for the Nikaidoh procedure include complete atrioventricular block, necessitating DDD pacing with an optimal AV interval to allow the best active (atrial) ventricular filling. Junctional ectopic tachycardia is not rare in this setting and should be addressed with an early stepwise approach described in detail elsewhere in this textbook [63]. Low cardiac output syndrome and ventricular dysfunction may require prompt and precise intervention with an early ECMO initiation strategy to support systemic circulation and allow for myocardial and multiorgan dysfunction recovery. Coronary ischemia is a dreaded complication. Caregivers should be suspicious whenever there are EKG signs of myocardial ischemia/necrosis and persistent elevation in postoperative troponin I levels [64] with low cardiac output syndrome or in the presence of ventricular arrhythmias. An aggressive diagnostic strategy including aortic root or selective angiography to assess the coronary circulation is warranted.

In patients with D-TGA and aortic arch obstruction, additional problems include LCOS, AV block or JET, and residual aortic arch obstruction.

Truncus Arteriosus

112

Steve Bibevski, Joshua Friedland-Little, Richard G. Ohye, Thorsson Thor, and Michael G. Gaies

Abstract

Truncus arteriosus is a rare anomaly that accounts for 0.4–4% of all cases of congenital heart disease. The condition is characterized by a single vessel arising from the heart, overriding the ventricular septum and giving rise to the systemic, coronary, and pulmonary circulations. Management is surgical, and is associated with excellent outcomes in the current era. In this chapter, we will review the molecular as well as the integrated physiology of truncus arteriosus, as well as review the clinically relevant aspects, including pathophysiology, classification, evaluation, surgical correction and postoperative care.

Truncus arteriosus is a rare anomaly that accounts for 0.4–4 % of all cases of congenital heart disease [1, 2]. The condition is characterized by a single vessel arising from the heart, overriding the ventricular septum and giving rise to the systemic, coronary, and pulmonary circulations. In this chapter, we will review the molecular and integrated physiology of truncus arteriosus, as well as the clinically relevant aspects, including pathophysiology, classification, evaluation, surgical correction, and postoperative care.

Embryology and Molecular Genetics

As described by Van Praagh and Van Praagh, truncus arteriosus is defined by two primary defects: complete absence of the pulmonary infundibulum and complete or partial absence of the aorticopulmonary septum [3]. The Van Praaghs emphasized the close embryologic relationship between truncus arteriosus and tetralogy of Fallot with pulmonary atresia (TOF/PA), noting the similarities of the outflow tracts and ventricular septal defects seen with both anomalies. Investigation into the genetic basis of these conotruncal anomalies has identified common molecular causes, confirming the Van Praaghs' pathological observations.

The embryologic origins of truncus arteriosus and the importance of neural crest cells to this process have been elucidated over the last several decades. Kirby and colleagues demonstrated that a specific population of neural crest cells in chick embryos migrate to the region of the aorticopulmonary septum, and that ablation of this region of the neural crest resulted in the formation of a common arterial trunk [4]. Subsequent investigation has identified genetic regulators of neural crest cell function and migration necessary for outflow tract septation, including Tbx3 and Pax3 [5, 6]. The genetic basis of truncus arteriosus has been further characterized with the discovery of DiGeorge syndrome (velocardiofacial syndrome), a monoallelic microdeletion of chromosome 22q11 that results in conotruncal heart defects, as well as hypoplasia of the thymus and parathyroid gland, craniofacial dysmorphisms, and developmental delay [7]. A 22q11 microdeletion is identified in 20–40 % of cases of truncus arteriosus, and is common in patients with other conotruncal anomalies as well [8, 9]. Tbx1, a T-box transcription factor located on chromosome 22q11, has been implicated in the development of DiGeorge syndrome [10, 11]. Tbx1 is an important regulator of the second heart field (SHF), a region of mesoderm lying posterior to the early embryonic heart responsible for contributing cells to both the arterial and venous poles of the developing heart tube. As reviewed by Parisot and colleagues, [12] Tbx1 is necessary for the proper development of the outflow tract and the pulmonary infundibulum. In addition, Tbx1 is a regulator of neural crest migration, further linking it to the process of outflow tract septation [13]. The development of the outflow tracts and the process of outflow tract septation are quite complex, and numerous other signaling pathways in the SHF have also been implicated, including the Wnt signaling pathway [14] and the sonic hedgehog signaling pathway [15, 16]. These findings have provided important mechanistic insights into the maldevelopment of the pulmonary infundibulum and the aorticopulmonary septum, the Van Praaghs noted it down as the primary anatomic defects characterizing truncus arteriosus.

Natural History

The prognosis of unrepaired truncus arteriosus is dismal. Mortality rates in the first year of life have been estimated at between 70 % and 85 %, with the majority of deaths occurring during infancy, secondary to severe congestive heart failure (CHF) [17, 18]. Sudden cardiac death has also been reported in preoperative patients with truncus arteriosus. This has been associated with significant truncal valve stenosis [18, 19]. The prevalence of coronary artery anomalies in truncus arteriosus along with the documentation of ventricular arrhythmia as a cause of death in preoperative patients has also led to speculation that myocardial ischemia may contribute to preoperative mortality [17, 20]. Patients who survive infancy generally develop severe pulmonary vascular disease early in childhood [17]. Reports of patients with unrepaired truncus arteriosus

surviving into the fourth decade of life exist, with survival attributed to either pulmonary artery stenosis or elevated pulmonary vascular resistance that limits the development of fatal heart failure [21].

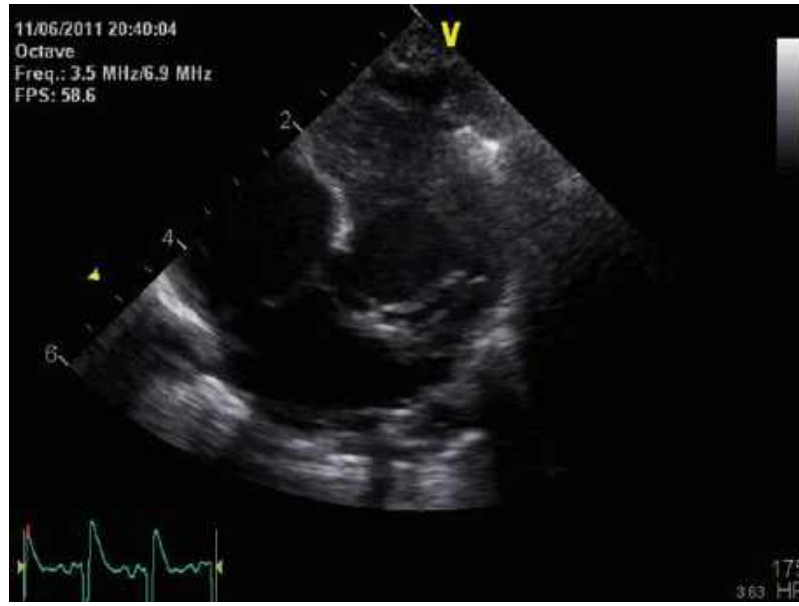
Physiology

Truncus arteriosus is a complete admixture lesion, with essentially equal saturations in the aorta and pulmonary arteries (although some streaming of blood from the right ventricle into the pulmonary arteries may lower the pulmonary artery saturation slightly). The single semilunar valve and outflow tract that characterizes truncus arteriosus supplies both the systemic and pulmonary vascular beds, which creates the pathophysiology of a complete admixture lesion. Relative blood flow, and thus oxygen saturation, is dependent on the relative resistances of each circulation. In the immediate perinatal period, pulmonary blood flow is limited by persistently elevated pulmonary vascular resistance (PVR), and patients with truncus arteriosus will frequently be cyanotic, with arterial saturations between 75 % and 80 % [22]. As pulmonary vascular resistance falls over the next few days to weeks, pulmonary blood flow and Qp:Qs increase. The excessive pulmonary blood flow results in reduced cyanosis, with arterial saturations frequently in the low 90 % range. The consequence of the significant pulmonary blood flow needed to achieve these elevated saturations is heart failure, with signs and symptoms of volume overload often appearing in the first week of life. Left-to-right shunting of blood from the common trunk into the pulmonary arteries occurs both in systole and diastole, increasing the Qp:Qs relative to other shunt lesions like an isolated large ventricular septal defect. In type 1 and type 2 truncus arteriosus (see Classification section), branch pulmonary artery stenosis is rare, and Qp:Qs is determined primarily by PVR [23]. Type 3 truncus arteriosus is more commonly associated with stenosis of the branch pulmonary arteries, and in these cases, Qp:Qs will be limited by the fixed obstruction, even in the absence of elevated PVR. Though much less common, main or branch pulmonary artery stenosis can also be seen in types 1 and 2 with considerably less left-to-right shunting. The development of CHF is accelerated by significant truncal valve insufficiency, if present. In most cases of truncus arteriosus, signs of CHF (i.e., cardiomegaly, pulmonary edema, tachypnea) are present by 2–3 weeks of life. As discussed above, the natural history of truncus arteriosus is dismal, with most patients dying in infancy.

Diagnosis

Truncus arteriosus is generally diagnosed in infancy, with a patient first coming to the attention of clinicians because of mild cyanosis. Typical physical exam findings for an infant with truncus arteriosus include tachypnea and diaphoresis, particularly with feeding. Hepatomegaly is generally present. Cardiac exam reveals an active precordium with palpable impulses frequently at the left lower sternal border, as well as the apex. High volume flow through a dysplastic truncal valve may result in a harsh systolic ejection murmur at the left upper sternal border, sometimes accompanied by a thrill. Truncal insufficiency, if present, results in a diastolic decrescendo murmur along the left sternal border. A diastolic rumble at the apex is present in infants with significant CHF. Systolic ejection murmurs radiating to the axillae and back may be noted with branch pulmonary artery stenosis. The presence of a prominent systolic ejection click at the left mid-sternal border further suggests the possibility of truncus arteriosus to the examiner. As would be expected, S2 is frequently single, but can also be narrowly split. This seemingly paradoxic finding is thought to be due to delayed closure of at least one leaflet of the truncal valve [23]. Peripheral pulses are often bounding due to the significant pulmonary arterial diastolic runoff. In the setting of interrupted aortic arch, lower extremity pulses can be normal with a widely patent ductus arteriosus, but will be diminished or absent if there is significant restriction to ductal flow.

Chest radiograph reveals cardiomegaly with increased pulmonary vasculature. The superior mediastinum is characteristically narrow due to the absent main pulmonary artery. There will



Video 112.1 Parasternal short axis view echocardiogram demonstrating a quadricuspid aortic valve

be evidence of a rightward aortic arch in approximately 20 % of cases. The electrocardiogram in patients with truncus arteriosus is nondiagnostic. The QRS axis will generally be normal for age in infancy, or slightly deviated to the right. There is frequently evidence of biventricular enlargement.

Echocardiogram is currently the gold standard for diagnosis of truncus arteriosus, and is sufficient to define the relevant anatomy for surgical planning. The parasternal short axis views allow evaluation of truncal valve morphology (Video 112.1 and Still Image 112.1), while apical and subcostal views will give the best assessment of truncal valve stenosis and insufficiency (Video 112.2). Characterization of the truncal valve function is essential using color and spectral Doppler to evaluate the degree of stenosis and/or insufficiency. In addition to evaluating the outlet ventricular septal defect (Video 112.3), a careful search for any additional ventricular septal defects is necessary. The origin of the right and left pulmonary arteries must be clearly established and can often be demonstrated via a parasternal view tilted anteriorly and superiorly (Video 112.4). Coronary artery anomalies including ostial anomalies, stenoses, and abnormal origins are sometimes associated with truncus arteriosus, and this anatomy must be fully delineated prior to surgical repair as it may impact operative technique when harvesting the pulmonary arteries [20]. A high takeoff of the left coronary artery is a well-described anomaly, and great care should be taken to obtain images from the long and short axes to rule out this possibility [24]. Finally, the aortic arch must be well seen in order to diagnose a possible interruption, with the necessary views obtained from the suprasternal notch. Type B interruption is most commonly associated with truncus arteriosus, but type A interruption has also been reported [25]. It is therefore essential to document integrity of the aortic arch through the aortic isthmus and proximal descending aorta.

With superior noninvasive imaging modalities providing much of the important data required for operative planning, the need for preoperative cardiac catheterization is limited to cases where there is concern about elevated PVR. Particularly in cases in which diagnosis has been made beyond the first month of life, there may be a role for the measurement of PVR and pulmonary vasoreactivity in the catheterization laboratory to determine a patient's surgical candidacy, but calculation of pulmonary blood flow is difficult due to complete admixture.

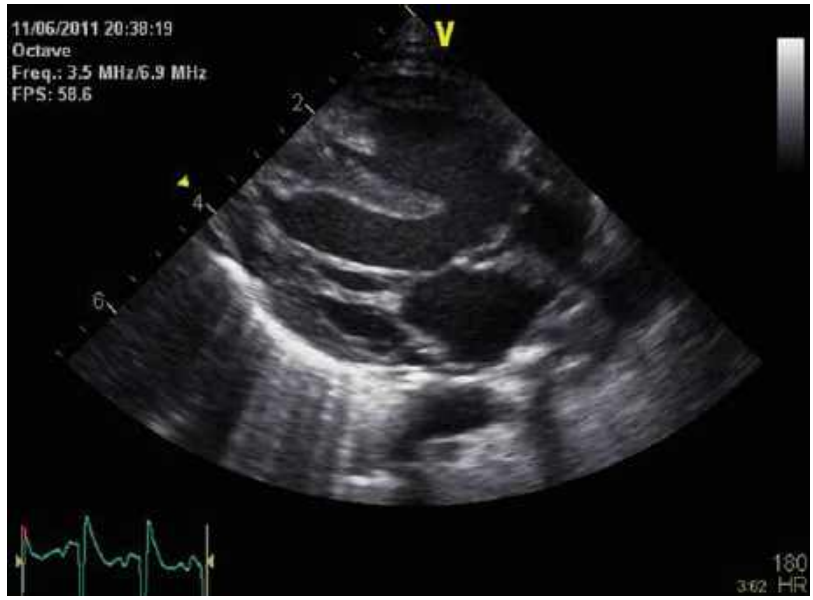
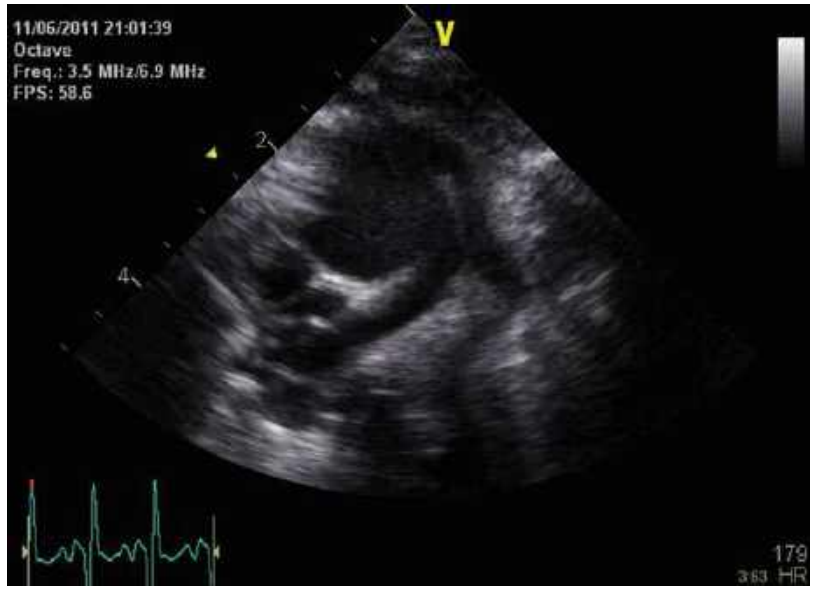
Anatomy

The anatomy of truncus arteriosus is best described and understood by failure of the pulmonary artery to separate from the aorta during development, leading to a large common arterial trunk as the outflow for both ventricles. The common trunk therefore supplies the systemic, pulmonary, and coronary arterial systems directly. Because there is no formal development of a pulmonary valve or pulmonary-ventricular

Video 112.3 Parasternal long axis view demonstrating the large ventricular septal defect





Video 112.4 Parasternal view tilted anteriorly and superiorly demonstrating the truncal anatomy

continuity, the branch pulmonary arteries arise from the common arterial trunk or its branches, in one of a multitude of variations described by multiple classification systems. The original scheme for classification was described by Collett and Edwards [26] in 1949 and has been used by the Congenital Heart Surgeons Society (CHSS) for description of patients entered into its database. The classification system described by Van Praagh [3] in 1965 has been utilized by other groups, as it recognizes the specific subset of patients with interrupted aortic arch. A limitation of both of these systems has involved the classification of those patients with interrupted arch that display features of both systems. Furthermore, the majority of patients fit into a category between type I and II which has been colloquially referred to as type 1.5. In addition, analysis of the CHSS

database reveals significantly different outcomes in patients with various features not well described by the current systems [27]. This has resulted in a recent attempt to introduce a simplified categorization for common arterial trunk into one of pulmonary or aortic dominance [28].

Classification

Collett-Edwards

Truncus arteriosus type I is characterized by origin of a single pulmonary trunk from the left lateral aspect of the common trunk, with branching of the left and right pulmonary arteries from the pulmonary trunk (Fig. 112.1) [26]. Truncus arteriosus type II is characterized by separate, but proximate origins of the left and right pulmonary arterial branches from the posterolateral aspect of the common arterial trunk (Fig. 112.2). In truncus arteriosus type III, the branch pulmonary arteries originate on either side of the common arterial trunk or aortic arch independent of each other, most often from the left and right lateral aspects of the trunk (Fig. 112.3). Type IV truncus arteriosus, originally proposed by Collett and Edwards as neither pulmonary arterial branch arising from the common trunk, is now recognized to be a form of pulmonary atresia with ventricular septal defect rather than truncus arteriosus.

Van Praagh

Type A1 is identical to the type I of Collett and Edwards. Type A2 includes Collett and Edwards type II and most cases of type III, namely, those with separate origin of the branch pulmonary arteries from the left and right lateral aspects of the common trunk (Fig. 112.4) [3]. Type A3

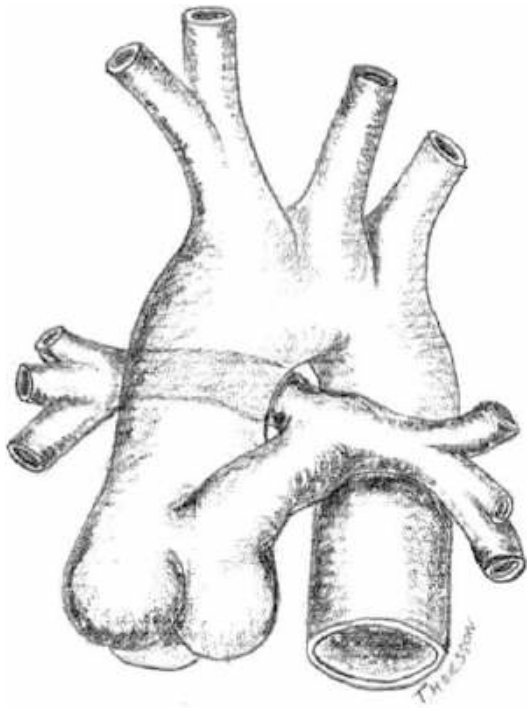


Fig. 112.1 Truncus arteriosus Type I characterized by origin of a single pulmonary trunk from the aorta with subsequent origin and branching of the pulmonary arteries from the pulmonary trunk

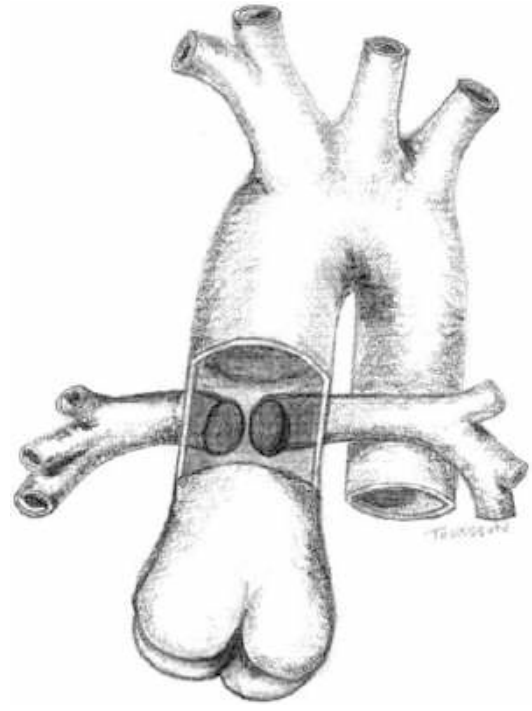

Fig. 112.2 Truncus arteriosus Type II demonstrating the separate, but proximate origins of the branch pulmonary arteries from the postero-lateral aspect of the truncus. There is a lack of a common pulmonary trunk prior to branching of the pulmonary arteries distinguishing from Type I

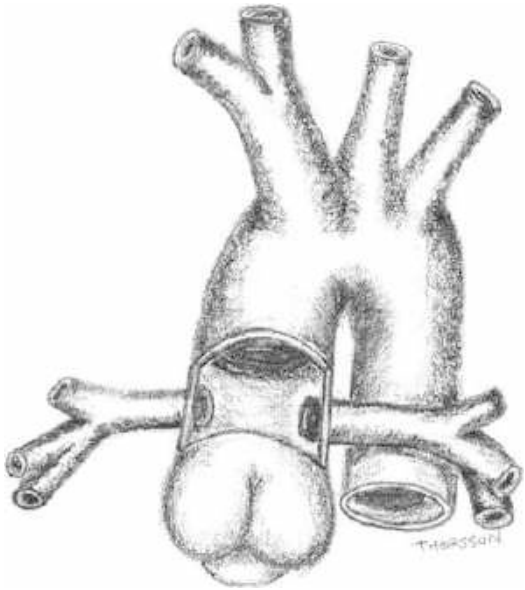

Fig. 112.3 Truncus Arteriosus Type III (Collett-Edwards) and Type A2 in the Van Praagh system is characterized by separate origin of the branch pulmonary arteries from the left and right lateral aspects of the common trunk

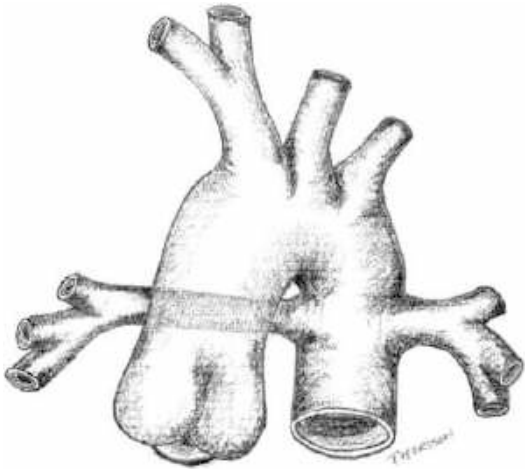

Fig. 112.4 Truncus arteriosus Type IV is characterized by origins of the branch pulmonary arteries from either side of the descending aorta. This subtype is no longer believed to be true Truncus Arteriosus, but instead represents pulmonary atresia with aorto-pulmonary collaterals

includes cases with origin of one branch pulmonary artery (usually the right) from the common trunk, with pulmonary blood supply to the other lung provided either by a pulmonary artery

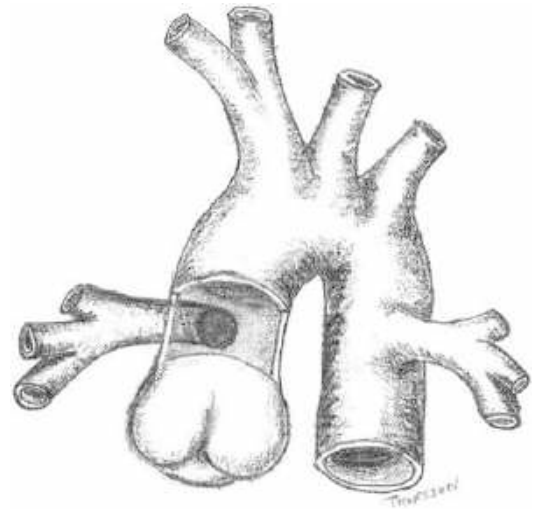

Fig. 112.5 Type A3 Truncus Arteriosus includes cases with origin of one branch pulmonary artery (usually the right) from the common trunk, with pulmonary blood supply to the other lung provided by either a pulmonary artery arising from the aortic arch, or by systemic to pulmonary collaterals

arising from the aortic arch (a subtype of Collett and Edwards type III) or by systemic to pulmonary arterial collaterals (Fig. 112.5). Type A4 is defined not by the pattern of origin of branch pulmonary arteries, but rather by the coexistence of an interrupted aortic arch (Fig. 112.6). In the vast majority of cases of type A4, which fall into the type I of Collett and Edwards, the pulmonary arteries arise as a single pulmonary trunk that then branches. In any of these patterns, intrinsic stenosis, hypoplasia, or both may be present in one or both branch pulmonary arteries, which may have an effect on management and outcome.

Simplified Categorization

In the new system promoted by Russel et al. [28] categorization is based on whether there is an aortic or pulmonary dominance. Pulmonary dominance was found when the aortic component of the trunk was hypoplastic and an arterial duct supplied the majority of flow to the descending aorta. In cases where the common trunk itself continues to supply the

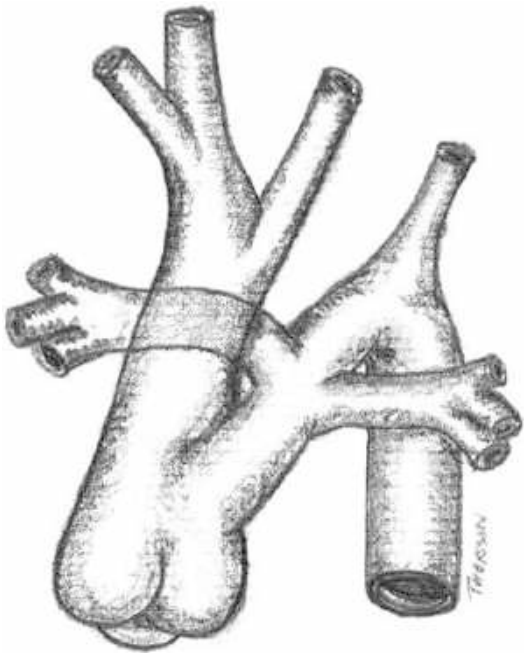

Fig. 112.6 Type A4 Truncus Arteriosus is defined not by the pattern of origin of the branch pulmonary arteries, but rather by the coexistence of an interrupted aortic arch

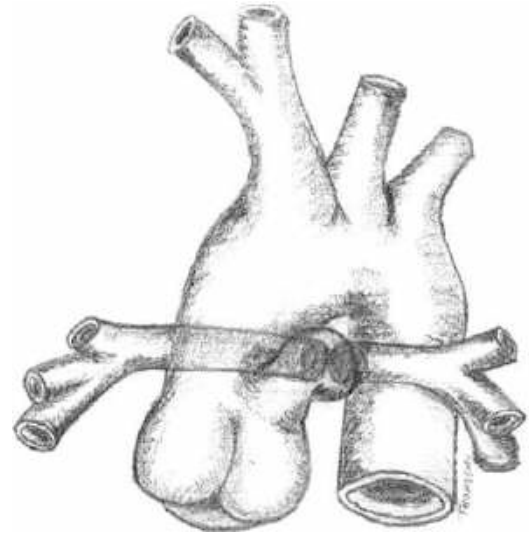

Fig. 112.7 The unofficial designation of "Type 1.5" is given to the most common anatomical arrangement seen in our practice which is between a Type 1 and Type 2 arrangement

brachiocephalic arteries, the pulmonary arteries arise close together from the dorsal surface of the trunk, and these patients are categorized as aortic dominant. The rarely reported observation of equally sized aortic and pulmonary components results in a third category of balanced arterial trunk. Despite the multiple classification systems however, our experience has demonstrated that the majority of patients fall into a 1.5 subtype (Fig. 112.7).

Associated Cardiovascular Anomalies

Various abnormalities may be associated with truncus arteriosus, some of which may have an impact on management and outcome. Variations in the coronary anatomy can add significant complexity, portend significantly higher risk in surgical repair, and are relatively common, ranging from 37 % to 49 % [29]. The orifice of either coronary can arise well above the coronary sinus and be quite proximate to the pulmonary orifice; therefore, injury to the coronary ostium during separation of the pulmonary artery branches from the common trunk is therefore a potential pitfall, if unsuspected [1, 20, 30–33].

Structural abnormalities of the truncal valve, including dysplastic and supernumerary leaflets, are common, and may result in significant valvar insufficiency [34, 35]. Regurgitation of the truncal valve has traditionally been considered a risk factor for poor outcome, and recent analysis of the CHSS data confirms this in a series of 572 patients where mortality for repair of truncus arteriosus with truncal valve repair versus isolated truncus repair was 30 % compared to 10 % [27]. Truncal regurgitation leads to ventricular dilation and low diastolic coronary perfusion, resulting in myocardial ischemia, while stenosis results in ventricular hypertrophy and poor coronary perfusion. These factors, combined with the large volume runoff into the pulmonary vascular bed, can result in significant myocardial ischemia.

Another anomaly commonly associated with truncus arteriosus is interruption of the aortic arch, most commonly type B. Based on the latest CHSS data analysis, the presence of an interrupted arch and truncal insufficiency portends the highest risk for mortality

following repair [27]. Other relatively common but minor associations include right aortic arch (18–36 %), left superior vena cava, aberrant-subclavian artery, and atrial septal defect [1, 36].

Preoperative Management

The standard of care for truncus arteriosus in the current era is complete repair in the neonatal period [37, 38]. This approach minimizes the volume overload due to the persistent elevation in pulmonary vascular resistance in the first week of life. Many patients with truncus arteriosus will require little medical management prior to surgery. As discussed above, mild cyanosis is frequently present at birth with oxygen saturations in the mid-70s to low 80s, and does not require intervention. Supplemental oxygen is not necessary, and may increase the volume overload due to its action as a pulmonary vasodilator. More severe cyanosis should alert caregivers to particular anatomic defects that restrict pulmonary blood flow, and/or raise the possibility of pulmonary disease. Pulmonary overcirculation generally occurs rather quickly, and infants may become tachypneic with mildly increased work of breathing. This degree of CHF is generally well tolerated, but if tachypnea or dyspnea appears to be progressive, noninvasive positive pressure respiratory support in the form of high flow nasal cannula or continuous positive airway pressure may be helpful. Gentle diuresis may be beneficial for patients with higher degrees of pulmonary blood flow. Unlike single ventricle patients in whom significant pulmonary overcirculation preoperatively generally comes at the expense of systemic underperfusion, two ventricle patients with truncus arteriosus generally demonstrate adequate systemic blood flow preoperatively, though measures of oxygen delivery help to clarify this issue.

For the approximately 10 % of truncus arteriosus patients with an interrupted aortic arch, maintaining the patency of the ductus arteriosus with prostaglandin E1 (PGE1) therapy is essential. The administration of intermittent aminophylline to infants receiving PGE1 infusion may reduce the risk of apnea [39]. In the absence of aortic arch abnormalities, a patent ductus arteriosus is uncommon in truncus arteriosus, and if present usually supplies a discontinuous pulmonary artery [22]. In the rare cases in which a patent ductus is identified without arch obstruction or discontinuous pulmonary arteries, the maintenance of the ductus is not necessary, and PGE1 infusion will only serve to worsen pulmonary overcirculation. Many centers avoid feeding neonates with ductal dependent left-sided obstructive lesions, and thus, truncus arteriosus patients with an interrupted arch will require parenteral nutrition. At our institution, we provide enteral feeds to all other patients with truncus arteriosus unless there are specific clinical contraindications such as intestinal abnormalities, sepsis, or low cardiac output states.

In the vast majority of patients with truncus arteriosus for whom surgery is planned in the neonatal period, we prefer to obtain central venous and arterial access in the umbilical vessels in order to spare the femoral vessels, as these may be needed later in life for diagnostic and interventional catheterization. Other venous access sites can be used according to institutional preference.

A preoperative evaluation for microdeletion of chromosome 22q11 is an important part of the diagnostic workup. Patients should be given irradiated blood products until the results of genetic testing are available.

Surgical Repair

Surgical management of truncus arteriosus has undergone significant evolution over the past 30 years. Complete correction was first performed in 1967, but involved staged repair with palliative pulmonary artery banding followed by complete repair performed at an older age. Currently, the majority of experienced centers, including our own, have maintained a policy of neonatal repair of truncus arteriosus, regardless of birth weight and demonstrated excellent results with this approach [37, 38].

Primary complete repair involves closure of the ventricular septal defect, separation of the pulmonary arteries from the common trunk with reconstruction of the right ventricular outflow tract using a conduit, and repair of the residual defect in the common trunk.

The repair is done via median sternotomy, with standard aortic and bicaval cannulation. Routine cardiopulmonary bypass under mild to moderate hypothermia is utilized, unless there is coexistence of an interrupted aortic arch, in which case the patient is begun on cooling for circulatory arrest. The pulmonary arteries are snared to prevent unnecessary runoff into the pulmonary vascular bed. The origins of the coronary arteries are confirmed to prevent injury during the harvesting of the pulmonary arteries. A left ventricular vent is inserted through the right upper pulmonary vein, and an antegrade cardioplegia needle is placed. In the presence of significant truncal valve insufficiency, retrograde or direct ostial delivery of cardioplegia may be required.

Once the cross-clamp is applied and the heart is arrested, the pulmonary arteries are separated from the common trunk. In true type I anatomy, the common pulmonary trunk may be easily divided from the common trunk. In other forms, visualization of the pulmonary artery origins may be facilitated by an anterior aortotomy or transection of the ascending aorta. Depending on the origins of the pulmonary arteries, they may be harvested together with a cuff of the common truck, or separately if they are remote. The defect in the common trunk is reconstructed with prosthetic material, such as a polytetrafluoroethylene (PTFE) patch, or a tissue patch. As our institution preferentially utilizes valved allograft conduits for the right ventricle-to-pulmonary artery reconstruction, an unused portion of the allograft is commonly used to close the defect.

In some instances, it may be necessary at this point in the operation to address any significant regurgitation or stenosis of the truncal valve. In general, a conservative approach to determining which patients require intervention should be undertaken. Preoperative gradients of up to 50 mmHg may be minimal after complete repair, due to the fact that both system and pulmonary circulations are traversing the truncal valve, as well as the increased flow related to the volume overload. If necessary, conservative commissurotomies can be performed. Truncal valve insufficiency should only be addressed if it is severe. The options for truncal valve repair for regurgitation are reviewed below; however, they should only be undertaken in the neonatal period when necessary. Moderate degrees of insufficiency will often be tolerated surprisingly well, and the options for replacement of the truncal valve as a neonate are limited. In the setting of a severely stenotic and/or insufficient valve, which is not amenable to repair or has failed repair, the only alternative may be replacement with an aortic allograft.

An infundibulotomy is next performed in the right ventricle, just below the truncal valve. Care must be taken to avoid injuring the truncal valve, as it often is located more inferiorly than it may appear externally when examining the truncal root. The ventriculotomy allows access to the ventricular septal defect, which is closed with a PTFE patch. An atrial level defect is closed at this time as well, via a right atriotomy. Once the atrial and ventricular defects are closed, the heart is de-aired and the cross-clamp removed.

In patients with both branch pulmonary arteries arising from the common trunk, the standard method of right ventricular outflow tract reconstruction involves removal of the central pulmonary arteries from the common trunk en bloc and placing a valved conduit from the right ventricle proximally to the central pulmonary arteries. In patients with branch pulmonary arteries arising distant from each other on the common trunk, or when one pulmonary artery arises from the common trunk and one from the underside of the aortic arch, the pulmonary arteries can be disconnected separately and anastomosed together before being connected to the conduit. The most common type of conduit used at our institution is a cryopreserved valved aortic or pulmonary allograft. Allograft availability can be limited and size matching can be challenging. We have therefore utilized bicuspidization of larger pulmonary allografts with very good mid-term results [40].

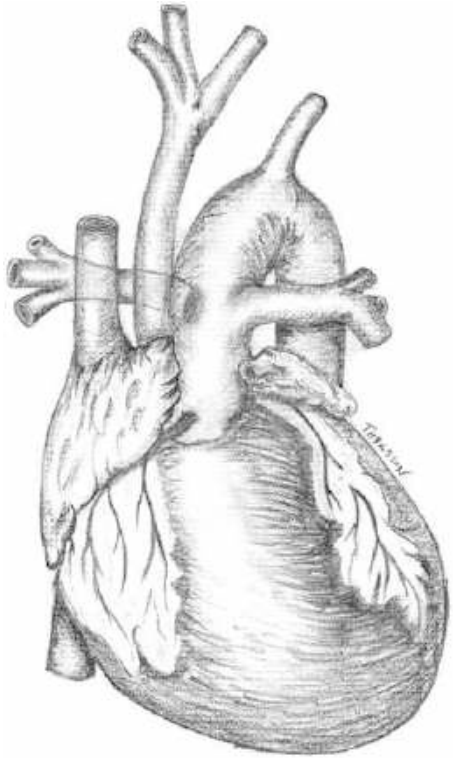

Fig. 112.8 Truncus arteriosus with interrupted aortic arch usually includes a Type B anatomy of the arch

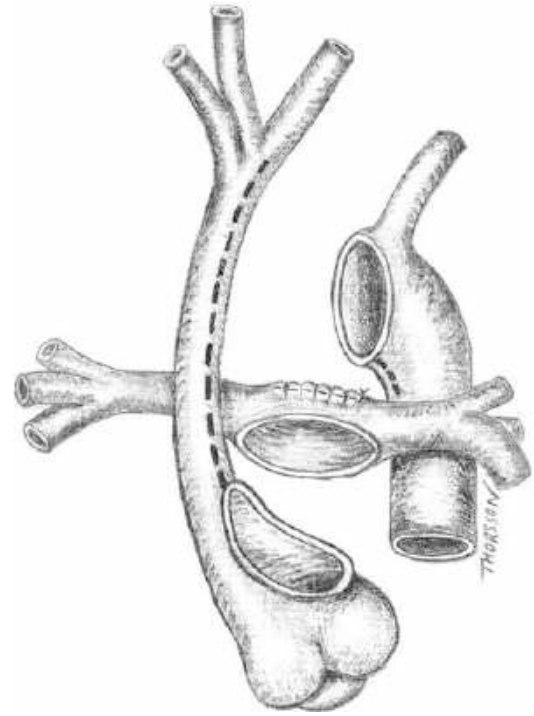

Fig. 112.9 In surgical correction of truncus arteriosus with interrupted arch, the proximal ascending aorta is spatulated superiorly along the medial aspect of the ascending aorta and into the base of the left carotid artery. The proximal descending aorta is also incised to enlarge the opening

Aortic allografts have the advantage of the curved portion of the arch, which can be advantageous for reaching the posteriorly located branch pulmonary arteries. Alternative forms of reconstruction include direct anastomosis of the pulmonary arteries to the right ventriculotomy, autologous flaps of pulmonary or aortic tissue augmented with synthetic patch material, or other valved conduits, such as bovine jugular vein [41–43].

Coexisting anomalies are repaired as appropriate, depending on anatomic features and the preference of the surgeon. One important associated anomaly that deserved special mention is interrupted aortic arch. The majority of interruptions are type B (Fig. 112.8). The portion of the ascending aorta distal to the origin of the ductus arteriosus and the pulmonary arteries is generally moderately hypoplastic. While the patient is cooling for circulatory arrest or regional cerebral perfusion, the ascending and proximal descending aorta, and the innominate, left carotid, and left subclavian arteries are mobilized. Once circulatory arrest or regional perfusion is established, all ductal is resected, and the branch pulmonary arteries are harvested from the common trunk. The proximal ascending aorta is spatulated superiorly along the medial aspect of the ascending aorta and into the base of the left carotid artery (Fig. 112.9). The proximal descending is also incised to enlarge the opening. The proximal descending aorta is then anastomosed to the distal most portion of the ascending aortotomy (Fig. 112.10). The remaining defect below this anastomosis is then augmented with a patch of pulmonary allograft (Fig. 112.11). As outlined above, the VSD is then closed and the right ventricular outflow tract is reconstructed.

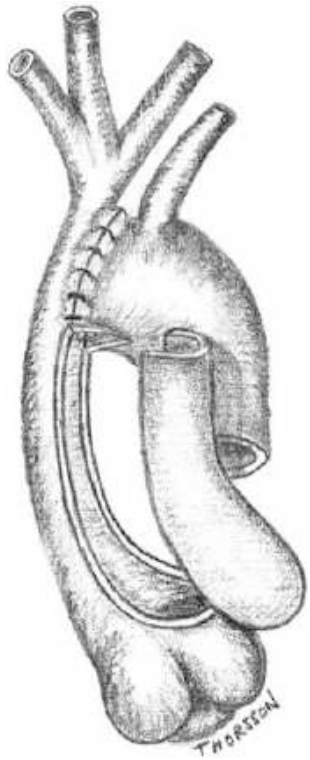

Fig. 112.10 The proximal descending aorta is anastomosed to the distal most portion of the ascending anatomy

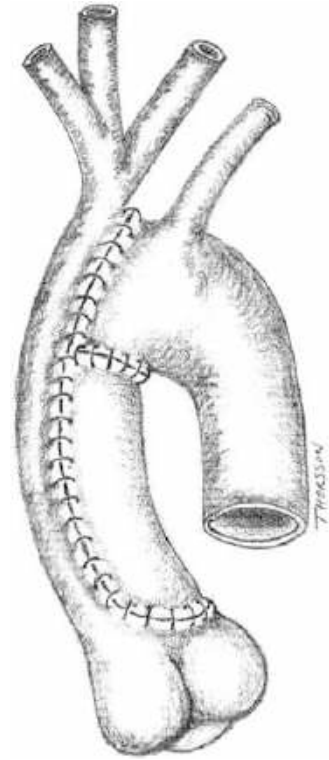

Fig. 112.11 The remaining defect below the anastomosis of the ascending and descending aortas is augmented with a patch of pulmonary allograft to complete the arch repair

In patients with severe truncal insufficiency, the truncal valve should not be ignored as recent data has suggested that failure to address truncal valve issues at the time of primary repair results in uniformly poor outcomes [27]. Conversely, repair of truncal valve insufficiency is associated with acceptable freedom from reoperation and good functional results [44]. Repair of the valve is preferred over replacement, given the obvious risks and frequency of truncal valve replacement. Numerous techniques of truncal valve repair have been described in the literature including suturing of leaflets together at the commissure [45], resection of malformed leaflets, extension of leaflets with pericardium [46], and resection of an entire cusp with recreation of a bicuspid valve or trileaflet valve in the case of quadri-cusp anatomy. In the latter technique, the entire leaflet cusp is excised through the annulus, being careful to spare the commissural support for the adjacent leaflets. The remaining defect is then primarily closed creating a trileaflet valve. If the leaflet to be excised is adjacent to a coronary ostium, the coronary orifice is mobilized as a button in the same fashion that is performed for an arterial switch operation. The button can then be reimplanted in an adjacent cusp. Care must be taken when resecting leaflets near the conduction tissue to avoid heart block.

Postoperative Care

Many of the immediate postoperative issues following complete repair of truncus arteriosus are typical of cardiac surgery in the neonate in general. Myocardial dysfunction and systemic inflammation postcardiopulmonary bypass should be anticipated, which may manifest as low cardiac output syndrome (LCOS) [47].

Patients typically require inotropic and vasopressor support during the first 24–48 h in the intensive care unit. Milrinone is commonly used to prevent development of LCOS in the immediate postoperative period [48]. Calcium chloride infusion may also be beneficial in cases of refractory hypotension due to the differences in calcium metabolism in the neonatal myocardium, particularly in patients with DiGeorge syndrome [49]. Relative adrenal insufficiency may contribute to inadequate cardiac output, and we use high dose hydrocortisone (2 mg/kg every 6 h) at our institution to limit the use of catecholaminergic medications in patients with refractory hypotension, weaning the steroids over several days [50]. Extracorporeal membrane oxygenation (ECMO) may be indicated in cases in which adequate cardiac output cannot be achieved despite maximal medical therapy.

A ventilatory strategy to maintain inflation at functional residual capacity utilizing the lowest possible mean airway pressure is desirable to avoid negative effects on right ventricular filling. Respiratory acidosis should be avoided due to its effects on the pulmonary vascular resistance, and a mild respiratory alkalosis may be beneficial if pulmonary hypertensive crises are suspected.

In addition to these standard postoperative concerns, there are several issues specific to truncus arteriosus repair that must be considered. The degree of truncal valve insufficiency is a key determinant of the patient's initial intensive care course. Moderate or severe insufficiency may compromise cardiac output, especially in those children with post-bypass ventricular dysfunction. Furthermore, patients who might require ECMO for low cardiac output syndrome are potentially unsupportable if there is significant truncal insufficiency. The right ventricle is hypertrophied and poorly compliant, and elevated filling pressures are generally necessary for adequate cardiac output. Some centers leave a small atrial communication at the time of surgery to augment systemic cardiac output in the presence of right ventricular dysfunction. If truncal valve insufficiency is significant, afterload reduction may be helpful to maximize cardiac output. As discussed above, injury to the left coronary artery is possible during separation of the pulmonary arteries from the arterial trunk, and coronary artery compression by the RV-PA conduit is possible as well. Inability to demonstrate flow in both coronary arteries on postoperative transesophageal echo (TEE), particularly in the presence of any regional wall abnormalities, should alert the ICU team about the potential of myocardial ischemia contributing to postoperative hemodynamic instability. The identification of residual ventricular septal defects on the postoperative TEE is also important, as significant left-to-right shunting may impede weaning from ventilatory support.

While postoperative pulmonary hypertension is not as prevalent in the current era of neonatal repair of truncus arteriosus as it was previously, our experience suggests that these patients are particularly prone to elevated PVR and paroxysmal pulmonary hypertension. Right ventricular function may be significantly diminished due to the effects of cardiopulmonary bypass and the right ventriculotomy, and even moderate elevation in PVR may not be well tolerated. An acute elevation in CVP with a drop in cardiac output, particularly in the setting of a stable left atrial pressure, should raise suspicion of a pulmonary hypertensive episode. In addition to a transthoracic left atrial catheter, a pulmonary arterial catheter is useful in cases where significant pulmonary hypertension is anticipated. The diagnosis of paroxysmal pulmonary hypertension can also be confirmed with echocardiographic analysis of tricuspid and pulmonic regurgitant jet velocities. If pulmonary hypertension is suspected postoperatively, acute management in the form of sedation and paralysis, supplemental oxygen, and mild hyperventilation is warranted. Patients may benefit from additional sedation before suctioning the endotracheal tube. Inhaled nitric oxide is the treatment of choice for persistent or severe pulmonary hypertensive episodes. Repeated episodes of pulmonary hypertension should raise the suspicion for residual anatomic lesions, including VSD or pulmonary artery stenosis.

Tachyarrhythmia, particularly junctional ectopic tachycardia (JET), is a common problem

encountered in the postoperative period following truncus arteriosus repair. Truncus arteriosus repair is a high risk operation for the development of JET, likely related to the VSD repair [51]. Junctional ectopic tachycardia may be poorly tolerated in the postoperative period, and often results in hemodynamic instability. Standard management including cooling, reduction of β-adrenergic stimulation, antiarrhythmic therapy, or overdrive pacing is indicated if JET or accelerated junctional rhythm results in hemodynamic compromise. At our institution we will frequently use vasopressin for hemodynamic support in order to reduce the use of catecholaminergic infusions. If the junctional rate can be lowered to a reasonable level, atrial pacing just above that rate can restore atrioventricular synchrony and often improve hemodynamics significantly. Ventricular arrhythmias are much less common following truncus repair and, if present, should raise the possibility of intraoperative coronary artery injury or coronary artery compression by the right ventricle-to-pulmonary artery conduit, particularly if accompanied by any regional wall motion abnormalities on echocardiogram. Electrolyte imbalances, especially low magnesium or potassium levels, should also be considered in the case of ventricular arrhythmias. Surgical heart block occurs in 3–5 % of cases [52]. Temporary pacing wires will generally be available, and dual chamber pacing may be performed until atrioventricular conduction has recovered or a permanent pacemaker is placed.

The postoperative management of truncus arteriosus with interrupted aortic arch involves all of the issues discussed above, with the additional concerns related to the arch repair. Patients should be carefully monitored for clinical evidence of residual arch obstruction, namely, a blood pressure gradient between upper and lower extremities or diminished lower extremity pulses. Multiple suture lines along the aortic arch entail a higher risk of bleeding, and hypertension should be aggressively treated in the postoperative period. The longer bypass, cross-clamp, and circulatory arrest times required for arch reconstruction may exacerbate the systemic inflammatory response and increase the likelihood of low cardiac output syndrome.

There are several manifestations of DiGeorge syndrome that may become clinically relevant in the postoperative period. Upper and lower airway anomalies, including subglottic stenosis, glottic webs, and laryngo-, tracheo-, or bronchomalacia, are relatively common in this population [53, 54], and may complicate attempts at extubation [49, 50]. Cleft palate is also common in the DiGeorge population, and may make a necessary re-intubation more difficult. Immune deficiency may be present in patients with a 22q11 deletion, with or without other manifestations of DiGeorge syndrome [55]. Blood transfusions pose an increased risk in this population, due to the potential for CMV disease, as well as transfusion associated graft versus host disease. For these reasons, if transfusion is required, irradiated blood is required and CMV seronegative blood should be considered until the results of genetic testing are known [56].

Results

Comparison of outcomes utilizing different techniques is difficult due to the progressive improvement in resources and methods over the last few decades. The results of complete repair have continued to improve since the earliest series in the 1970s where survival of 75 % was the standard [57–60]. Since that time, we and others have demonstrated that significantly better outcomes can be expected [37, 61–64]. Emphasis now focuses on long-term results related to truncal valve insufficiency [27, 45, 65, 66] and conduit restenosis [27, 61–63]. Recently, there has been renewed interest in reconstruction of the pulmonary outflow tract with direct right ventricle-to-pulmonary artery anastomosis utilizing various techniques with a goal of allowing for somatic growth and a decreased need for conduit replacement [67–70]. Current expected hospital mortality for neonatal repair of truncus ranges between 4.3 % and 17 %, with the majority of deaths occurring in complex truncus arteriosus or in

truncus arteriosus with severe truncal valve dysfunction [37, 38, 64, 71–73].

Rajasinghe et al. [64] have previously published long-term follow-up of patients undergoing truncus arteriosus repair. Patients were followed for up to 20 years (median 10.5 years). There were 23 post-discharge deaths, 19 of which occurred in the first year. Ten of the late deaths were related to reoperations. A significant independent risk factor for poor long-term survival was moderate to severe truncal valve insufficiency before repair. During the follow-up period, 107 patients underwent 133 conduit reoperations with a median time to conduit reoperation being 5.5 years. The only factor significantly associated with shorter time to conduit replacement was smaller conduit size at initial repair. In addition, 26 patients underwent 30 truncal valve replacements. Six patients required truncal valve replacement before any conduit-related reintervention, with two associated deaths. Actuarial freedom from truncal valve replacement among patients without previously repaired valves was 95 % at 10 years. At follow-up, all patients except three were in New York Heart Association functional class I.

In truncus arteriosus with interrupted aortic arch, late complications relate mostly to residual or recurrent obstruction. Bohuta et al. [25] reported their experience at the Royal Children's Hospital in Melbourne from April 1985 to August 2007 where 16 patients with TA associated with IAA underwent one-stage repair. There were two (12.5 %) early deaths and no late deaths at a median duration of follow-up of 18.2 years (range, 2.1–21.9 years). Thirteen patients underwent 25 surgical reoperations and five interventional procedures (three aortic arch balloon angioplasties and two pulmonary artery balloon angioplasties). Overall freedom from any reoperation was 69.2 % at 1 month, 54.5 % at 3 years, 30 % at 5 years, 11.1 % at 10 years, and 0 % at 15 years after the initial operation. Freedom from aortic reoperation was 76.9 % at 1 month, 72.7 % at 3 years, 70 % at 5 years, 66.7 % at 10 years, and 57.1 % at 15 years; while freedom from right ventricular-to-pulmonary artery conduit replacement was 84.6 % at 1 month, 63.6 % at 3 years, 40 % at 5 years, 11.1 % at 10 years, and 0 % at 15 years. Finally, freedom from truncal valve reoperation was 100 % at 5 years, 88.9 % at 10 years, and 85.7 % at 15 years.

For many patients, repair of truncus arteriosus in the first months of life has led to very good long-term outcome. Complex truncus arteriosus or truncus arteriosus with severe truncal valve dysfunction remains a challenging lesion for long-term management.

Double Outlet Right Ventricle

113

François Lacour-Gayet, Leo Lopez, and Eduardo M. da Cruz

Abstract

Double-outlet right ventricle is a complex congenital heart defect consisting of anomalous ventriculo-arterial connections with several "phenotypes" and associations. It is a conotruncal anomaly with a frequency of 0.5–1.5 % among all congenital cardiac defects and with a wide spectrum of anatomic forms depending on the location of the ventricular septal defect, the relationship between the great vessels and the ventricular cavities, and the presence of pulmonary outflow obstruction. This chapter discusses anatomical and functional classifications, pathophysiology, clinical presentation, and medical and surgical management of the double-outlet right ventricle.

Brief Historical Background

Although firstly described by Lev in 1972 [1], anomalies with a double-outlet right ventricle (DORV) pattern had already been published a few decades prior, albeit not recognized as such at that time, by Helen Taussig and Richard Bing, who defined the clinical, physiologic, and pathological findings of the "Taussig-Bing anomaly" [2]. Since then, multiple reference authors have described anatomical and functional characteristics, classifications, and therapeutic approaches [3–7].

Introduction

Double-outlet right ventricle (DORV) is an anomaly of ventriculo-arterial connections with several "phenotypes" and associations. It is a conotruncal anomaly with a frequency of 0.5–1.5 % among all congenital cardiac defects and with a wide spectrum of anatomic forms depending on the location of the ventricular septal defect (VSD), the relationship between the great vessels and the ventricular cavities, and the presence of pulmonary outflow obstruction. This wide variation has led to many controversies over the anatomic definition and the optimal surgical management. DORV is frequently associated with hypoplasia of one ventricle. The most complex forms remain a surgical challenge in terms of biventricular repair.

Anatomical Definitions

The anatomic definition of DORV has significantly evolved over time, resulting in noteworthy controversy owing to the heterogeneity of the multiple proposed perspectives. Some examples of the variable definitions follow: (a) Robert H. Anderson [3] champions the "50 % rule," which is the most commonly used definition and states that more than 50 % of each great vessel must arise from the right ventricle in a DORV; (b) Richard Van Praagh [4] defines DORV as fibrous discontinuity between the mitral and aortic valves because of persistent subaortic conus; (c) Yves Lecompte [5] defines DORV as malposition of the great vessels; and (d) François Lacour-Gayet [6, 7] supports the "200 % rule," viewing DORV from a surgical perspective and defining it as complete origin of both great vessels from the right ventricle.

Following Lev's definition [1], four *anatomic types* are usually described based on the location of the VSD [1], although the functional classification (see below) may be more adequate and practical:

- DORV with subaortic VSD
- DORV with doubly committed VSD
- DORV with subpulmonary VSD (Taussig-Bing anomaly)
- DORV with uncommitted or remote VSD

Associated anomalies are the rule:

Subvalvar or valvar pulmonary obstruction is the most frequent association and can be seen in the four types of DORV, although it is rarely combined with the Taussig-Bing anomaly. Pulmonary valve atresia can also occur albeit the definition is questionable as there is only a single outlet from the right ventricle. Nevertheless, two infundibular areas may be identified in these cases.

Subvalvar aortic obstruction occurs frequently, usually due to the presence of a subaortic muscular infundibulum with deviation of the conal septum into the subaortic region.

Aortic arch obstruction can also occur, most frequently in the setting of the Taussig-Bing anomaly in association with subvalvar aortic obstruction.

A *restrictive VSD* may be found and represents a major problem because this is equivalent to left ventricular outflow obstruction.

Multiple VSDs and "Swiss-cheese" interventricular septum can also be identified. *Atrioventricular valve malformations* such as straddling tricuspid and mitral valves can occur.

A *complete atrioventricular septal defect* usually with right isomerism and *total anomalous pulmonary venous return* represent probably the most complex form of DORV.

Left ventricular hypoplasia, usually associated to mitral valve atresia, may be part of the spectrum and is a contra-indication to bi-ventricular repair.

A large *left superior vena cava* without a bridging vein is frequent and has been considered as potentially associated with left ventricular hypoplasia.

Truncus arteriosus with complete origin of the truncal valve from the right ventricle may also be called by some a "double-outlet" right ventricle.

Pathophysiology and Functional Classification

The pathophysiology of DORV depends on the anatomic associations that may define different functional and clinical expressions, especially in terms of the position of the VSD relative to the great vessels and the presence of pulmonary stenosis (Fig. 113.1). Therefore, the spectrum of clinical presentations may vary from a situation of *increased pulmonary flow* (VSD physiology),

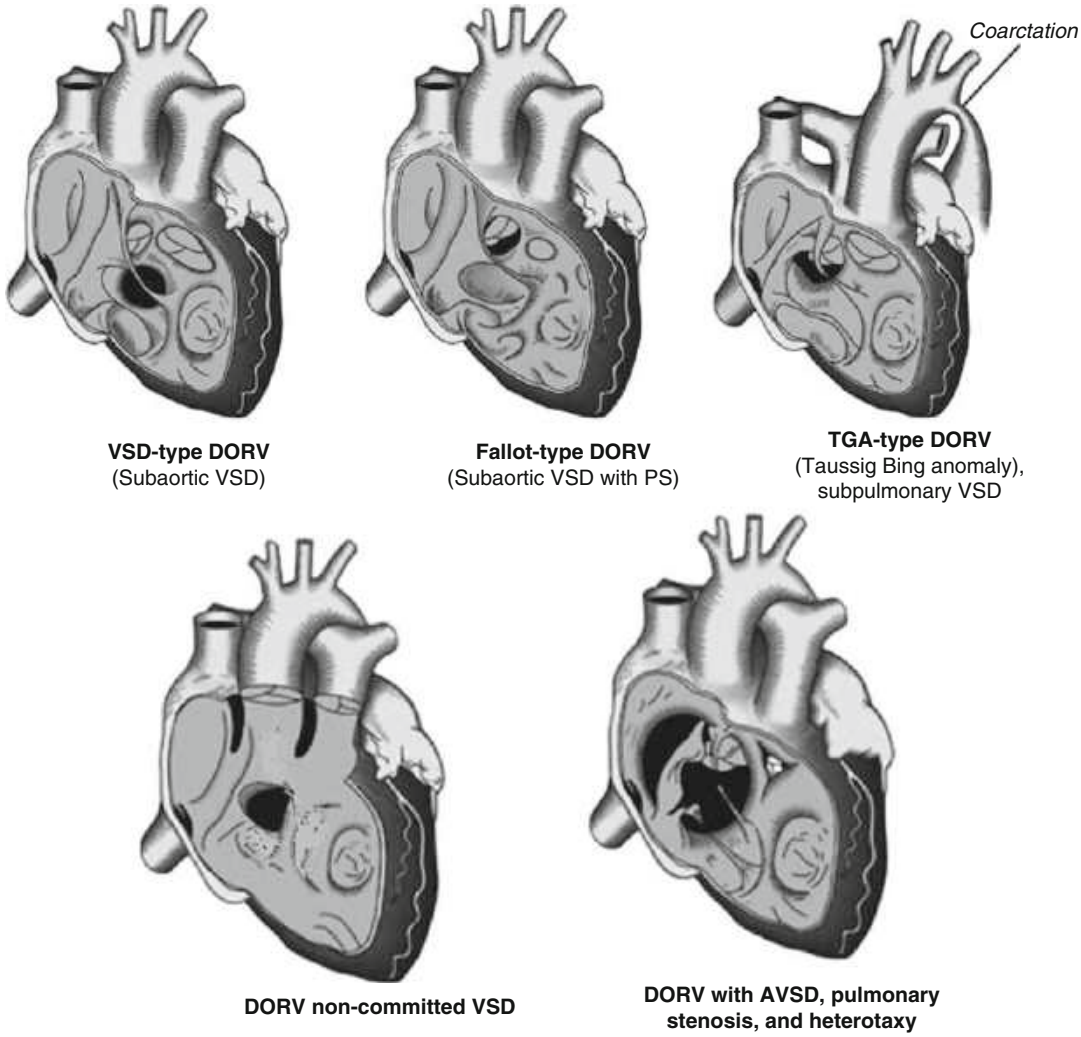

Fig. 113.1 The five types of DORV according to the functional classification

with absent subvalvular or valvular pulmonary stenosis, to a situation of *cyanosis* in the setting of pulmonary outflow tract obstruction (tetralogy of Fallot, DORV-AVSD-PS) or transposition of great vessels (Taussig-Bing) or single ventricle (DORV noncommitted VSD).

The spatial relationship of the VSD with the arterial outflow tracts and the possible association with pulmonary stenosis are the features which determine the various *functional types*, their usual clinical presentation, and, more importantly, the surgical approach. The following *functional classification* (Fig. 113.1) has been adopted by the Association for European Paediatric and Congenital Cardiology (AEPC), the European Association of Cardio-Thoracic Surgery (EACTS), and the Society of Thoracic Surgery (STS) [8–11]:

1. *VSD-Type DORV*

   This variant represents around 25 % of cases and includes DORV with a subaortic or a doubly committed VSD and no pulmonary stenosis. The pathophysiology is that of a VSD with a large left-to-right shunt and pulmonary hypertension. In more than one third of the cases [6, 7, 12], the VSD is restrictive. The great vessels do not always arise "200 %" from the RV.

2. *Fallot-Type DORV*

   This anatomic form is the most common, occurring in 66 % of cases, and it includes DORV with a subaortic or a doubly committed VSD and pulmonary stenosis. The pathophysiology is the equivalent to that seen in tetralogy of Fallot. It is often difficult to differentiate this type from a real tetralogy of Fallot as the overriding aorta may be related to the right ventricle in varying degrees. In nearly one fourth of these cases [6, 7, 12], the VSD is restrictive. The great vessels seldom arise "200 %" from the RV.

3. *TGA/VSD-Type DORV (Taussig-Bing Anomaly)*

   The pathophysiology of this anomaly is the same as for TGA with VSD [13, 14] (Fig. 113.2). Patients present with both cyanosis and congestive heart failure; there is no pulmonary stenosis and the VSD is rarely restrictive. Subaortic obstruction and aortic arch obstruction are frequently associated [15, 16]. The right ventricle is usually slightly small but not hypoplastic, unless there is an associated tricuspid stenosis [14]. The great vessels almost never arise "200 %" from the RV.

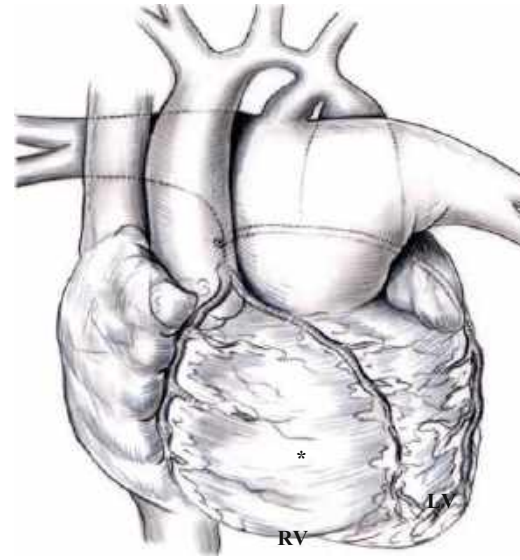

Fig. 113.2 *TGA-VSD-type DORV (Taussig-Bing anomaly)*. Notice the aortic arch obstruction, the important size mismatch between the PA and the aorta

4. *DORV with a Noncommitted VSD*

   In this anatomic form, the VSD is remote from the semilunar valves by a distance greater than a diameter of the aortic annulus [17]. The VSD is located below the septomarginal trabeculations [18] and is frequently in contact with the tricuspid annulus, [12, 19]. The great vessels arise "200 %" from the right ventricle. When there is no pulmonary stenosis, the pathophysiology is that of a single ventricle with unprotected pulmonary blood flow (Fig. 113.3). When there is pulmonary stenosis, the pathophysiology is that of a single ventricle with restricted pulmonary blood flow.

5. *DORV with Atrioventricular Septal Defect, Pulmonary Stenosis, and Heterotaxy Syndrome*

   The pathophysiology of this association is the same as in an atrioventricular septal defect with tetralogy of Fallot [7, 20]. The clinical presentation may be complicated by anomalies

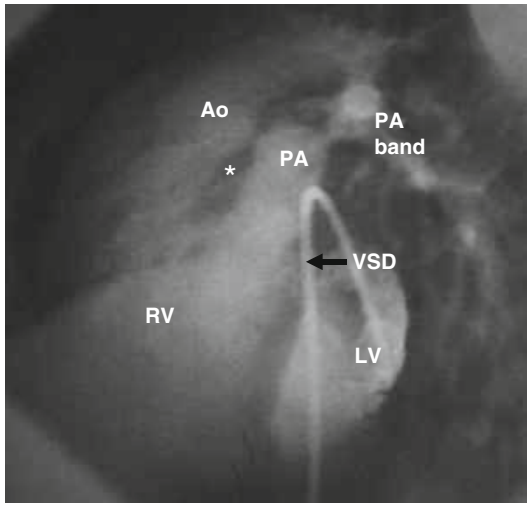

Fig. 113.3 Cardiac catheterization documenting a DORV with a noncommitted VSD (*filled arrow*). Both great vessels (*PA* pulmonary artery, *Ao* aorta) arise "200 %" from the RV. Notice that the conal septum (*) is part of the RV and unrelated to the ventricular septation

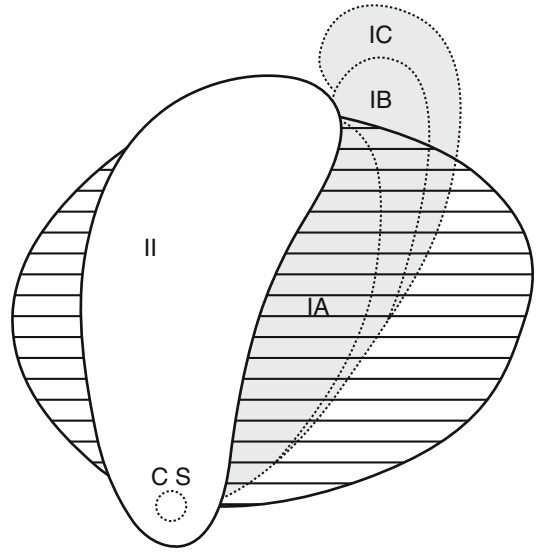

Fig. 113.4 Shape of the VSD in the following: IA, AVSD; IB, AVSD-Fallot; IC, AVSD-DORV; II, ostium primum patch (Roger Mee et al. Ann Thorac Surg 1986; 41:612–15)

associated with heterotaxy syndrome, which in these cases is usually right isomerism. Pulmonary stenosis is the rule and pulmonary atresia is also possible. The common atrioventricular valve is usually a Rastelli type C valve (the superior bridging leaflet has no attachments to the crest of the muscular ventricular septum). In most cases, the VSD is an atrioventricular septal defect type with significant superior extension towards the aortic valve [6, 7, 19–21] (Fig. 113.4). Total anomalous pulmonary venous return is a frequent association. Most cases are not associated with Down syndrome [20]. An intestinal malrotation is also a common finding and should be ruled out. In this form, the great vessels arise "200 %" from the RV.

Preoperative Evaluation

Clinical

The clinical presentation depends on the following morphologic and physiologic features:

- The position of the VSD relative to the great vessels
- The position of the great vessels
- The presence or absence of pulmonary outflow tract obstruction
- The presence or absence of aortic arch obstruction

Patients with left-to-right shunt physiology and unprotected pulmonary flow will present with symptoms and signs of cardiac failure, particularly when reaching the nadir of pulmonary vascular resistances over the several first weeks of life. Consequently, difficulty to feed and ultimately failure to thrive that may be refractory to maximal medical therapy will follow. In the association of left-sided obstruction, signs of compromised systemic perfusion and shock may be present, mostly in the case of ductal dependency. Patients with physiology like tetralogy of Fallot or Transposition of the great arteries will present predominantly with central and progressive cyanosis that depends on their capacity to ensure intracardiac mixing and on the degree of ductal dependency.

Evaluation of patients with DORV ought to be exhaustive and not exclusively cardiovascular; namely, it is important to evaluate the presence

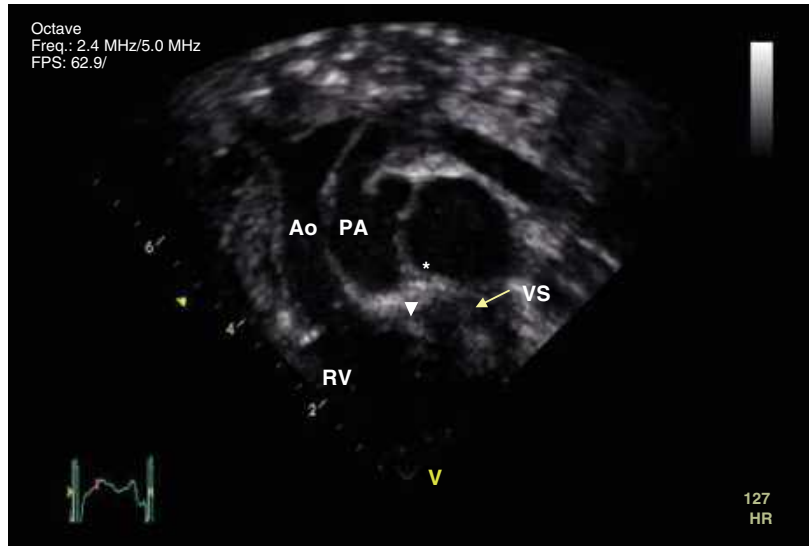

Fig. 113.5 DORV with a noncommitted VSD, transposed aorta, pulmonary stenosis (*), and a large conal septum (▼)

of syndromes or genetic anomalies like 22q11 deletion [30, 31]. Extra cardiac comorbidity should be ruled out, particularly in the presence of heterotaxy (intestinal malrotation, poly or asplenia, renal malformations, and other).

Chest X-Ray

The chest X-ray will reveal cardiomegaly and plethoric lungs in the setting of a subaortic VSD or subpulmonary VSD without pulmonary stenosis. When there is pulmonary obstruction, cardiomegaly is mild or absent, and the lung vascular markings may be normal or decreased depending on the severity of the stenosis.

Echocardiography

Echocardiography is the primary diagnostic tool for DORV. It must utilize the segmental approach in order to establish the diagnosis and provide a comprehensive description of all the morphologic and physiologic features of each particular case. Aside from the standard evaluation of any heart by echocardiography, the preoperative examination should focus on the following features:

- Ventriculo-arterial alignment – The spatial relationships between the ventricles and the semilunar valves and arterial roots are best evaluated with imaging and color sweeps in all views.
- VSD location and size – The classification system devised by Lev [1] should be utilized to describe the VSD location according to the semilunar valves (Fig. 113.5).
- Conal morphology and outflow tract obstruction - Conal morphology involves typically a double conus (Fig. 113.6). Obstruction of the coni are frequent; either involving the right conus (as in DORV-nc-VSD with PS) or the left conus (as in Taussig-Bing- Coarctation with subaortic obstruction). Rarely one of both conus could be absent. The degree of pulmonary or aortic outflow tract obstruction, when present, should be evaluated, and the gradient should be measured by Doppler interrogation [22].
- Relative sizes and spatial relationship of the arterial roots – Because both great arteries are aligned with the right ventricle, there is intrinsic malposition of the great arteries [23, 24]. The echocardiographic evaluation must determine whether the aorta is anterior or posterior to and to the right or left of the pulmonary artery. In addition, subvalvar or valvar obstruction often means that the affected semilunar valve and arterial root are smaller than the other semilunar valve and arterial root.

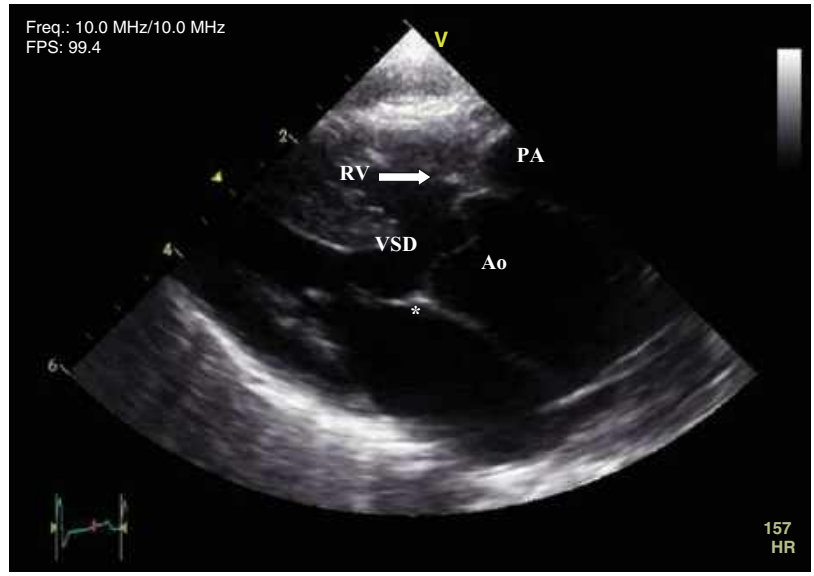

Fig. 113.6 Fallot-type DORV. The VSD is subaortic. Notice that the aorta is not fully arising from the RV and that there is a subpulmonary obstruction (*full arrow*). There is a mitral-aortic discontinuity (*)

- Aortic arch and pulmonary arteries – Similarly, subvalvar or valvar obstruction may result in small branch pulmonary arteries in the setting of pulmonary stenosis or some degree of aortic arch obstruction in the setting of aortic obstruction.
- Ventricular morphology and size – As discussed previously, DORV may be associated with hypoplasia of the left or right ventricle.
- Coronary artery anatomy – Because surgical repair may involve a right ventriculotomy or an arterial switch procedure, the coronary artery pattern must be determined prior to surgical intervention since abnormal coronary patterns may increase the surgical risk [25].
- Atrial morphology – The presence of an atrial septal defect must be determined by echocardiography. In addition, DORV is rarely associated with juxtaposition of the atrial appendages, so this must be excluded in the preoperative study.
- Systemic and pulmonary venous return – Especially in the setting of heterotaxy syndrome or right isomerism, the preoperative study must include comprehensive evaluation of the systemic and pulmonary veins.
- Atrioventricular valves and septum – Since straddling atrioventricular valves can occur in DORV [26], albeit rarely, a complete evaluation of the atrioventricular valves and their relationship to the VSD is warranted. In addition, DORV is occasionally associated with atrioventricular septal defect with Rastelli type C common atrioventricular valve, so this must be carefully evaluated when present.
- The distance between the anteroseptal commissure of the tricuspid valve and the pulmonary annulus should be calculated. When this distance is less than the diameter of the aortic annulus, a baffle patch rerouting the VSD to the aorta cannot be constructed [5].

The postoperative study must exclude all the possible sequelae and complications associated with DORV repair, and these include residual VSDs and residual aortic or pulmonary outflow obstruction.

Cardiac Catheterization

Cardiac catheterization (Fig. 113.3) is not always performed in neonates with DORV because echocardiography is quite good at providing a diagnosis and comprehensive description of the morphologic and physiologic features of each case. However, catheterization

is sometimes warranted in complex forms in order to fully delineate the systemic and pulmonary venous return as well as the coronary artery anatomy. In addition, it provides information regarding pulmonary pressures and the relative flow within and resistance of the pulmonary vascular bed. In older patients or in patients with significant residual lesions, this technique can be very useful, especially if transcatheter intervention can help to avoid a repeat operation.

Other

Magnetic resonance imaging [27–29], computed tomography, and three-dimensional echocardiography may be indicated in some cases. Noninvasive imaging technology continues to evolve and improve and may contribute to changes in the preoperative and postoperative approach to these lesions in the future. Since DORV can be associated with a 22q11 deletion [30, 31], evaluation of the patient's chromosomes is warranted as this abnormality can have a significant impact on the presentation and on the postoperative course and complications. The diagnosis of DORV is frequently made on prenatal diagnosis [32].

Preoperative Management

Preoperative medical management depends on the clinical presentation. In the neonatal period, there are three common scenarios:

1. *In the absence of pulmonary protection* (no valvular or subvalvular pulmonary stenosis), neonates present with the physiology of a large unrestrictive VSD. In the neonatal period, these patients are usually asymptomatic until the age of 3–6 weeks when they present in congestive heart failure, once the pulmonary vascular resistances reach their nadir. Medical treatment involves using loop diuretics, peripheral vasodilators and, in some institutions, digoxin which is controversial. Anemia must be prevented or treated if identified since it may increase the severity of the left-to-right shunt because of lower viscosity. If there are persistent signs and symptoms of heart failure, surgical intervention is indicated. Total repair is usually proposed. However, the patient's clinical status and the presence of associated extracardiac anomalies may require early palliation in the form of a banding of the pulmonary artery, prior to total repair.
2. *In the presence of valvular or subvalvular pulmonary stenosis*, the clinical status should be assessed once the ductus arteriosus closes. If the pulmonary obstruction is severe, patients become progressively cyanotic and may show ductal dependency and therefore prostaglandin dependency (PGE_1). In this case, patients should undergo placement of a modified Blalock-Taussig shunt, a ductal stent placement, or percutaneous dilatation of the pulmonary outflow tract (depending on the anatomy and institutional preferences and experience). On the other side of the spectrum, patients with mild pulmonary stenosis may need medical management similar to that needed for simple VSD physiology, although the obstruction in these patients tends to increase progressively over time, as the degree of pulmonary overcirculation decreases. These patients may also eventually develop a degree of stenosis that requires palliation.
3. *In the presence of associated complex anomalies*, treatment depends on the malformation complex. Total anomalous pulmonary venous return is a major associated lesion in DORV-AVSD-PS and should be repaired in the neonatal period [20, 33], in association with a Blalock-Taussig shunt. Rarely, the VSD could be restrictive in the neonatal period, requiring enlargement [7, 12] as a first palliative treatment.

Medical Interventions

Interventional catheterization may be useful. In patients in whom the intracardiac mixing is inadequate in spite of the VSD or in cases with

restrictive VSD, cardiac catheterization can be done to perform a Rashkind balloon atrial-septostomy during the neonatal period or first few weeks of life. Patients with DORV with transposition physiology and a subaortic VSD should undergo atrial septostomy if an aortic arch repair, and pulmonary artery band is the surgical procedure. Most centers will perform a complete repair of this type of DORV.

Surgical Management

Biventricular Repair

Provided that there are two viable ventricles, biventricular surgical repair is currently the best option even though it is more technically challenging than a cavopulmonary palliation [34–36].

1. *VSD-Type DORV*

   Patients with this type of DORV usually require a one-stage biventricular repair within the first 3 months of life. A prior pulmonary artery banding may be considered in selected cases [37], in the absence of flow restriction across the VSD. During the total repair, the VSD is baffled towards the aorta through the tricuspid valve, although a right ventriculotomy may be necessary. It appears in literature that VSD enlargements are required in more than one third of the cases [7, 12]. The frequent requirement for VSD enlargement and a right ventricular approach distinguishes this lesion from other anomalies requiring VSD repair.
2. *Fallot-Type DORV*

   Patients present like a tetralogy of Fallot and therefore surgical repair is very similar. Nevertheless, a modified Blalock-Taussig shunt may be considered in the neonatal period. The total repair consists in closing the subaortic VSD with a larger patch, and the right ventricular outflow tract obstruction is repaired accordingly. The VSD can be restrictive and may need to be enlarged in nearly one third of the cases [6, 7].
3. *TGA/VSD-Type DORV (Taussig-Bing Anomaly)*

   Neonatal total one-stage repair [14, 15] consisting in an arterial switch, VSD to PA baffle and aortic arch reconstruction when needed, is the best option [15, 16, 25]. The Kawashima operation [38] has been abandoned by most of the teams. A right ventriculotomy is often needed to achieve the anatomical repair. A previous palliation with PA banding with coarctation repair is rarely undertaken currently and is reserved to neonates with extracardiac disorders contraindicating surgery on cardiopulmonary bypass. It remains also an option in less-experienced centers, but it requires the absence of subaortic obstruction. The frequently associated subaortic obstruction needs to be corrected by division of the parietal band of the right ventricle and often by right ventricular outflow tract patch enlargement. The technical challenge of this neonatal arterial switch is due to the side by side relationship of the great vessels, the complex coronary anatomy, the associated subaortic obstruction, and a weight lower than 2.5 kg. Due to the frequent hypoplasia of the neo-pulmonary annulus, these patients are at risk for late right ventricular outflow tract obstruction [15]. Anomalies of the tricuspid valve and straddling of the mitral valve may complicate the repair.
4. *DORV with Noncommitted VSD*

   These patients have a remote VSD and the two great vessels are arising "200 %" from the RV [6, 7, 39]. This form illustrates, from a surgical standpoint, the "real DORV." Importantly, the VSD lies at a distance from both the aortic and pulmonary annulus greater than the aortic diameter [17]. Pulmonary blood flow obstruction and a restrictive VSD may also be present. In some instances, the VSD can be tunnelized easily to the aorta with minimal resection. In other cases, the VSD cannot be baffled to the aorta: because the distance between the tricuspid valve and the PA annulus is too short [5] or when the insertion of the baffled patch would imply to sacrifice part of the tricuspid valve or papillary muscle. In these cases, Barbero-Marcial [40] has proposed a multiple patch with reimplantation of the TV chordae on the

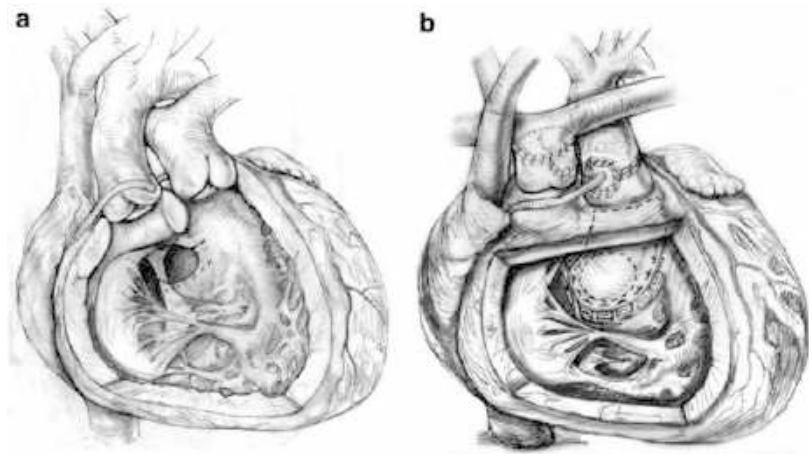

Fig. 113.7 DORV with a noncommitted VSD and a remote aorta (**7a**). The patch is tunnelizing the LV towards the pulmonary artery across the VSD. This technique will be associated with an arterial switch. The VSD needs to be enlarged in 75 % of the cases (**7b**)

patch. These authors have proposed another technique that respect the tricuspid valve and limit the size of the patch: the tunnelization of the VSD to the pulmonary artery associated with an arterial switch (Fig. 113.7a, b) [6, 7, 39].

There are different surgical options for these patients depending on the presence of a pulmonary obstruction and the possibility of constructing a tunnel between the VSD and the aorta. Biventricular repairs are challenging and reported by a few centers [6, 17, 39, 40]. In 75 % of the cases, the VSD is restrictive and should be enlarged at the time of repair [12, 19, 39] (Fig. 113.8).

I- In the Absence of Pulmonary Obstruction

In some instances, the VSD can be tunnelized easily to the aorta with minimal resection. The tunnelization from the left ventricle towards the aorta using a large patch or multiple patches [40] requires the resection of the parietal band. It may additionally require the reimplantation of the conal tricuspid papillary muscle on the baffle patch and a resection of the subaortic conus. When the VSD is very remote from the aorta, it is usually close to the pulmonary annulus. This allows a surgical repair like in the case of a Taussig-Bing anomaly, with a tunnelization of the VSD to the PA associated with an arterial switch (Fig. 113.7) [6, 7, 39].

II- In the Presence of Pulmonary Obstruction

This rare anatomical form raises the most difficult surgical issues.

When the right ventricular outflow tract obstruction is purely muscular, an arterial switch with VSD to PA baffle, and infundibular patch is a good option.

When the right ventricular outflow tract obstruction is valvular, a Rastelli [41]-type operation or a REV [42, 43] operation (Réparation à l'Etage Ventriculaire) is indicated when the VSD to aorta tunnel can be safely performed [5]. This requires closure of the pulmonary outflow and an RV to PA conduit (Rastelli) [41] or a Lecompte maneuver (REV) [42–44].

The Nikaidoh [45, 46] operation has not been reported successfully in DORV with noncommitted VSD. The double-root translocation technique was performed [47] in DORV noncommitted VSD. This complex technique requires longer follow-up.

5. *DORV with Atrioventricular Septal Defect, Pulmonary Stenosis, and Heterotaxy*

These patients are repaired like patients with a tetralogy of Fallot associated with an AVSD. [6, 7, 20, 33, 48, 49]. The right ventricular outflow tract is most often stenotic and sometimes atretic. For this reason, the repair is undertaken beyond the age of 6 months, requiring a previous modified

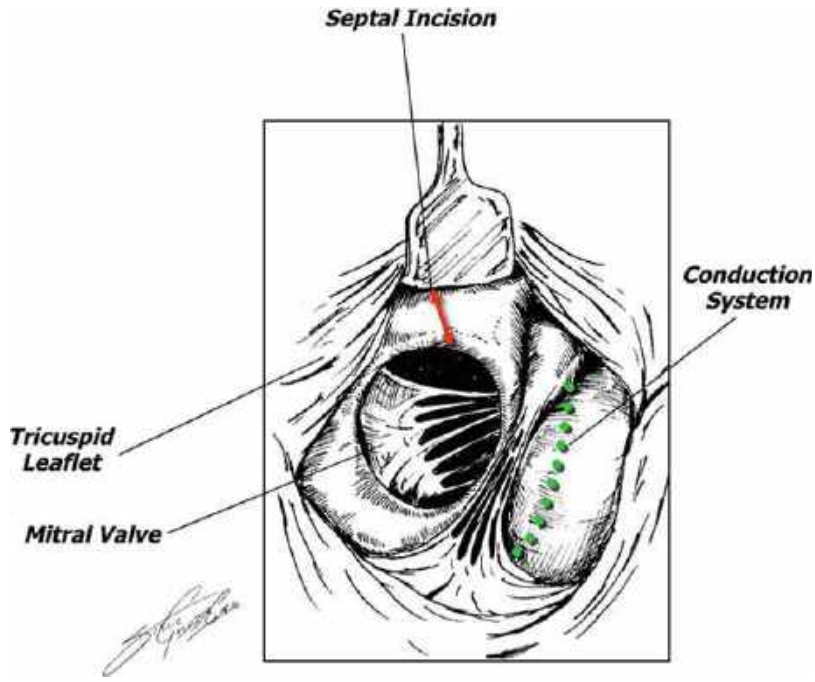

Fig. 113.8 The VSD could be restrictive in DORV. It is to be enlarged on its superior border. The conduction tissue is usually located on the inferior border of the VSD

Blalock-Taussig shunt if the cyanosis is severe. The AVSD is a Rastelli type C. The VSD has a superior component close to the aortic annulus [19, 20] (Fig. 113.4). The real challenge of this form is the association with a total anomalous pulmonary venous return that needs to be repaired in the neonatal period. As for the association AVSD-Fallot, efforts should be undertaken to maintain pulmonary valve sufficiency. Hence, the use of a valved conduit may be necessary. The patch required to baffle the VSD to the aorta may sometimes reduce the RV size, and one and a half ventricle repair may be needed or an RV-PA conduit may be required. These patients present frequently with an intestinal rotation that may require a Ladd procedure. This form of DORV clearly requires a technically demanding and challenging repair.

Univentricular Repair

The major controversy between biventricular and univentricular repair in some forms of DORV lies in the reluctancy of several teams to enlarge a restrictive VSD or to resect the conal septum. Nevertheless, recent reports [12] tend to prove that the enlargement of the VSD does not increase the risk of complete heart block nor does it impact on the long-term myocardial function.

Univentricular repair is *mandatory* in specific circumstances:

(a) Significant hypoplasia of one of the ventricles
(b) Severe atrioventricular valve straddling or overriding
(c) Multiple ("Swiss-cheese") ventricular septal defects
(d) Surgical learning curve

Also, the tunnelization to the aorta may sometimes reduce too much the right ventricular size, leading to a one and a half ventricular repair by associating a partial cavopulmonary connection. Some authors consider that in such cases, the total cavopulmonary connection is a better indication than the one and half ventricular repair.

Cardiac transplant may be contemplated as an alternative in exceptional circumstances.

Postoperative Management

Postoperative management varies depending on the anatomic and physiologic form and also on the type of intervention. Thus, principles discussed in specific chapters dedicated to the management of VSD, tetralogy of Fallot, and TGA with VSD are applicable to a great extent.

The most specific problems concern rhythm and conductive disturbances (persistent atrial tachycardia, ventricular ectopy, third-degree atrioventricular heart block), myocardial ischemic changes, and persistent subvalvular obstructions (secondary to a prolapse of the VSD patch onto the left ventricular outflow tract or to a VSD with restrictive dimensions), added to low cardiac output syndrome and postoperative bleeding.

Monitoring

Indwelling monitoring includes an arterial line (to be inserted on the right radial artery in case of associated coarctectomy), a central venous catheter, and a left atrial line. A transthoracic pulmonary catheter or a Swan-Ganz catheter may be inserted if the patient is considered at risk of developing acute pulmonary hypertensive spells. In small infants, a preoperative peripherally inserted central catheter (PICC) insertion may be considered. Also, whenever possible, mixed venous saturations should be monitored as serial samples or continuously.

Noninvasive monitoring consists of continuous EKG (rhythm pattern and heart rate monitoring), respiratory rate, and peripheral oxygen saturation (oximetry), as a minimal requirement. Tidal CO_2, transcutaneous CO_2, and near-infrared spectroscopy (NIRS) are also useful and routinely used in some institutions.

Atrial and ventricular pacing wires are requested as AV block and JET could occur with complex DORV repair.

Serial controls of markers of tissue perfusion are vital.

Sedation

Postoperative sedation after palliative interventions may be superficial although an adequate pain control ought to be ensured. Patients should be kept comfortable and free of pain and yet protecting their airways and breathing spontaneously, allowing early extubation. This can be achieved by associating non-opioid analgesia with low-dose morphine or fentanyl and benzodiazepines (in boluses or as a continuous infusion). Dexmedetomidine is a drug with great interest in this patient population for its anxiolytic effects and synergy with analgesics that maintain patients peaceful and comfortable without depressing their respiratory drive.

After total repair of a DORV, patients are maintained sedated and under analgesia for at least 12–24 h or until there is confirmation of a consistent hemodynamic stability and adequate tissue perfusion, with a combination of opioids and benzodiazepines to be titrated to the minimal efficient dose. Titration and length of treatment with these drugs also depends on the type of intervention and patients' characteristics: usually, a VSD closure or a Rastelli-type intervention progress more rapidly than an arterial switch with VSD closure and coarctectomy or than a REV repair. Delayed chest closure is also a factor that might determine the length and strength of sedation and analgesia. Muscle relaxants may be required, however should not be used systematically. Dexmedetomidine, propofol, ketamine, or clonidine drips may be useful in specific cases.

Fluid Management

Fluid management is based upon the type of intervention. Palliative surgery does not require fluid restriction unless the patient is deemed to be volume overloaded. Nevertheless, after total repair on CPBP, patients must be restricted to 50 % of their requirements on day 1, followed by 75 % on day 2 and 100 % from day 3. These recommendations must be individualized and adapted to the patient's hemodynamic, respiratory, and metabolic status.

Aggressive nutrition is a great benefit for these patients. Priority ought to be given to the enteral route whenever possible; whenever contraindicated, the early start of total parenteral nutrition is guaranteed.

Respiratory Management

After a total repair of a DORV, patients are very sensible to cardiopulmonary interactions. Provided an adequate and consistent hemodynamic stability and tissue perfusion are documented and in the absence of bleeding, neurologic, respiratory, or metabolic concerns, patients should progress towards spontaneous breathing and extubation as soon as possible. Sometimes, extubation is deferred by a systematic delayed sternal closure. All respiratory collateral complications (i.e., pleural effusion, atelectasis, or pneumothorax) should be aggressively managed.

Hemodynamic Management

Hemodynamic management also depends on the background defect and on the type of repair. Further details are discussed in the chapters related to the management of VSD, TGA with VSD, and tetralogy of Fallot, diseases that share pathophysiologic characteristics.

The usual drug combination consists of inotropics (dopamine; sometimes dobutamine, in some institutions) and systemic vasodilators, namely, phentolamine, phenoxybenzamine, sodium nitroprusside, and nitroglycerine; a reasonable alternative consists of the use of drugs with inotropic, vasodilator, and lusitropic effects – like milrinone – owing to the positive effects exerted not only on the systolic function and vascular reactivity but also on the diastolic function. A low-dose epinephrine may also be required. These authors advocate for low doses of epinephrine rather than higher doses of other inotropic drugs.

If the right ventricle is hypertrophic and poorly compliant, higher filling pressures may be required, and beta-blockers may be useful in order to decrease the cardiac rate therefore optimizing the ventricular filling (diastolic) time. Esmolol is, in this scenario, a good compromise since easy to titrate and its short half-life offers an advantage in patients who poorly tolerate it.

Loop diuretics as boluses or in a continuous infusion are usually initiated throughout the first day.

Patients who progress towards significant low cardiac output with tissue perfusion impairment and display unresponsiveness to medical therapy should promptly and proactively be supported by extracorporeal devices, mainly extracorporeal membrane oxygenation. In such cases, it is mandatory to exhaustively explore and treat patients for residual lesions.

Morbidity and Mortality

Morbidity and mortality of DORV repair depend on the anatomic associations, the surgical technique, and the general conditions of the patients and interrelated noncardiac anomalies. Patients with 22q11 deletions have a higher incidence of metabolic, respiratory, and infectious complications.

Mortality reported on literature varies from around 5 % in the "simple" forms with subaortic VSD to 10–15 % in Fallot-type repair or arterial switch with VSD repair. In DORV and noncommitted VSD, the recent introduction of the tunnelization to the pulmonary artery followed by arterial switch is associated with a mortality of 6 % [22, 39]. DORV-AVSD repair remains challenging with recently reported excellent results [22, 33].

Anatomic forms requiring a univentricular repair share the same morbidity and mortality as other anomalies with univentricular physiology.

Overall long-term survival is estimated around 80–85 %.

Conclusion

DORV is a complex heart defect with multiple facets and therapeutic options vary accordingly.

Currently, surgical results and overall long-term outcomes are good, although some anatomic forms require multiple re-interventions.

Congenital and Acquired Coronary Artery Anomalies in Newborns, Infants, Children, and Young Adults

114

Ali Dodge-Khatami, Constantine Mavroudis, and Carl L. Backer

Abstract

The incidence of coronary anomalies in the general population is 0.2 % to 1.2 %. In this chapter, the comprehensive nomenclature classification of the Society of Thoracic Surgeons (STS) Congenital Heart Surgery Nomenclature and Database Project will be used.

Coronary artery anomalies may be congenital or acquired and are associated with significant morbidity and mortality. The spectrum of congenital lesions includes anomalous pulmonary origins of the coronary arteries, anomalous aortic origins of the coronary arteries, single coronary artery, congenital atresia of the left main coronary, coronary artery fistulas, and intramyocardial courses. Acquired anomalies include coronary artery aneurysms, late postoperative obstructions in patients who had coronary artery surgical manipulations, and iatrogenic injuries that can occur in the catheterization laboratory or in the operating room. In this chapter, the anomalies described are those in hearts with concordant atrioventricular and ventriculoarterial connections. Coronary variations in complex

congenital heart diseases are not encompassed, nor are coronary artery lesions that are associated with initial operations for arterial switch, tetralogy of Fallot repair, and the various types of Norwood operations.

Keywords

Anomalous • Aortic origins • Congenital atresia • Coronary arteries • Coronary arteriovenous fistulas • Intramyocardial course • Left main coronary artery • Pulmonary origins • Single coronary artery • Surgical management

Historical Background/Introduction

Congenital and acquired coronary artery anomalies deviate from the standard anatomy of two separately originating right and left arterial blood vessels, the first branches of the ascending aorta, from their respective sinuses of Valsalva and patent, gradually branching, and evenly tapering vessels distally in a centrifugal fashion to perfuse all structures of the heart. The incidence of coronary anomalies in the general population is 0.2 % to 1.2 % [1]. Although coronary anomalies have been described since the eighteenth century with varying classifications, in this chapter, the comprehensive nomenclature classification of the Society of Thoracic Surgeons (STS) Congenital Heart Surgery Nomenclature and Database Project will be used [2].

Coronary artery anomalies may be congenital or acquired and are associated with significant morbidity and mortality, which can be sudden in onset. The spectrum of congenital lesions includes anomalous pulmonary origins of the coronary arteries (APOCA) including anomalous left and right from the pulmonary artery, anomalous aortic origins of the coronary arteries (AAOCA), single coronary artery, congenital atresia of the left main coronary (CALM), coronary artery fistulas, and intramyocardial courses (bridging). Acquired anomalies include coronary artery aneurysms, late postoperative obstructions in patients who had coronary artery surgical manipulations, and iatrogenic injuries that can occur in the catheterization laboratory or in the operating room. In this chapter, the anomalies described are those in hearts with concordant atrioventricular and ventriculoarterial connections. Coronary variations in complex congenital heart diseases are not encompassed, nor are coronary artery lesions that are associated with initial operations for arterial switch, tetralogy of Fallot repair, and the various types of Norwood operations.

Anomalous Pulmonary Origins of the Coronary Arteries (APOCA)

Anomalous pulmonary origins of coronary arteries (APOCA) include the most common type 1, anomalous left coronary artery from the pulmonary artery (ALCAPA), also known as Bland, White, and Garland syndrome [3], and type 2, anomalous right coronary artery from the pulmonary artery (ARCAPA).

Anomalous Left Coronary Artery from the Pulmonary Artery (ALCAPA)

Anomalous left coronary artery from the pulmonary artery (ALCAPA) is the most common anomaly of coronary origins and the most common cause of myocardial ischemia and infarction in infants and children resulting in 90 % mortality within the first year of life [4]. The clinical spectrum ranges from unspecific symptoms of global cardiac failure, sweating, tachypnea, poor feeding, and failure to thrive to angina, ventricular arrhythmia, and overt cardiogenic shock, all resulting from various degrees of myocardial ischemia.

The interplay between ductal patency and flow, pulmonary hypertension in the newborn period, and the degree and development of communicating coronary collateral arteries to provide retrograde perfusion from the right coronary artery to ALCAPA determines the onset of symptoms and severity of myocardial ischemia [5]. Although asymptomatic patients with large collateral vessels may survive into adulthood with a large right coronary artery providing rich, intramyocardial collaterals and restrictive retrograde flow into the pulmonary artery, they still are at an estimated 80–90 % risk of sudden death at a mean age of 35 years [6]. Therefore, even in asymptomatic patients, surgical therapy is justified as soon as diagnosis is made.

Clinical and Diagnostic Features

Patients with ALCAPA may present with angina pectoris and the signs and symptoms of congestive heart failure, which include sweating, dyspnea, and failure to thrive. A holosystolic murmur of mitral regurgitation is often heard because of ischemic and dysfunctional papillary muscles. Cardiomegaly is seen on chest x-ray, left-axis deviation and Q waves in the anterior leads are seen on electrocardiography [7], and the diagnosis can usually be confirmed by 2-dimensional echocardiography. Besides color flow Doppler demonstrating reversal of flow from the anomalous left coronary artery into the pulmonary artery constituting a left-to-right shunt, an enlarged, dilated right coronary artery, echodensity in the mitral valve papillary muscles and valve insufficiency [7], and a grossly hypokinetic and dilated left ventricle may also be noted. When necessary, magnetic resonance or computed tomography (CT) angiography can confirm diagnosis when the classic studies are inconclusive [8, 9] (Fig. 114.1) [10]. They will confirm the anomalous left coronary origin, as well as the typically enlarged right coronary artery, delayed passage of contrast medium with a characteristic blush from the anomalous left coronary artery into the pulmonary artery, and associated mitral valve regurgitation. Myocardial viability studies such as dobutamine-stress echocardiography, thallium CT myocardial perfusion imaging, or positron emission/fluorodeoxyglucose tomography scans may be used to assess hibernating myocardium [1, 11]. However, they are only relevant to influencing surgical strategy in patients with massive infarction or aneurysmal tissue, whereby coronary revascularization techniques may not be expected to improve myocardial function.

Decision Making/Surgical Management

Medical therapy does neither target the lesion or physiopathology, have an influence on survival, nor have a place in the current era of management for ALCAPA. Surgery is indicated at diagnosis. Medical therapy is therefore useful in maintaining patients with adequate tissue perfusion until urgent intervention is offered. The current ideal surgical option to achieve a definitive 2-coronary artery anatomy and physiology involves direct reimplantation of the anomalous left coronary into the aorta, transferring it with a button of pulmonary artery [12]. Even in the presence of a non-facing sinus origin of the ALCAPA, creative methods to extend the coronary artery button using the pulmonary artery wall [13, 14] or careful aortic flap creation (trap-door techniques) should always allow for reimplantation of the ALCAPA into the aorta [7–9].

Cardiac transplantation as a last-resort solution for ALCAPA patients with end-stage left ventricular failure from myocardial infarction [15] is reserved for patients with global myocardial necrosis as documented by viability studies, whereby no improvement can be expected after coronary revascularization.

In young adults, direct reimplantation may be technically more demanding owing to increased coronary artery friability, the potential for tearing, diminished elasticity for mobilization, and potential for stenosis owing to anastomotic tension [4, 16]. However, with increased experience, excellent results can be achieved [16].

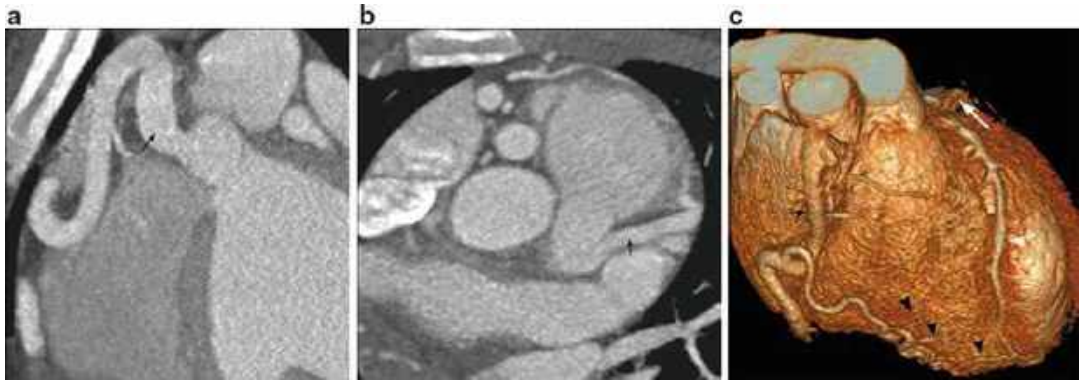

Fig. 114.1 Multidetector-row computed tomography (CT). (**a**) An oblique coronary image of coronary CT angiography shows a dilated right coronary artery (RCA, *arrow*) which is 1.0 cm in diameter, arising from the right aorta (Ao) sinus. (**b**) An axial image of coronary CT angiography clearly shows a dilated left main coronary artery (LMCA, *arrow*) originating from the pulmonary artery (PA). (**c**) The 3-dimensional volume-rendered image reveals multiple well-developed collateral arteries (*black arrowheads*) between the RCA (*black arrow*) and the left anterior descending coronary artery (LAD, *white arrowhead*); the LMCA merges with the pulmonary trunk. LCx = left circumflex artery (Reproduced with permission from Su CS, et al. J Chin Med Assoc. 2010;73(9):492–495 [10] Copyright Elsevier China © 2010)

When direct aortic reimplantation seems hazardous, coronary bypass may be more judicious, using the internal thoracic artery [17, 18].

Proper and thorough cardioplegia administration is a crucial point for myocardial protection. Backer, Mavroudis, and associates [9] describe their experience in 16 infants and children undergoing aortic reimplantation for ALCAPA, allowing maximal myocardial protection regardless of right coronary artery collateralization. After ligating the ductus arteriosus and snaring the pulmonary arteries, an initial dose of antegrade blood cardioplegia is initially dosed into the ascending aorta. Mobilized for maximum visibility, the pulmonary artery is transected below the bifurcation, and the ALCAPA button is excised (Fig. 114.2) [9]. Antegrade cardioplegia is dosed a second time while the ALCAPA orifice is occluded with a vascular clamp, after which the coronary transfer is performed into the aorta (Fig. 114.3) [9]. There was no operative mortality or need for a postoperative left ventricular assist device or extracorporeal membrane oxygenation (ECMO) in this series of patients [14].

Anomalous left main coronary artery from the pulmonary artery reimplantation will improve left ventricular function and mitral valve competency in the majority of cases. This recovery may take several weeks however. Mitral valve insufficiency results both from ischemic left ventricular dilation and from ischemic dysfunction of the papillary muscles [4]. Even severe mitral insufficiency has fully regressed after ALCAPA reimplantation and myocardial reperfusion so that most authors do not favor mitral valvuloplasty or ventricular wall resection at initial operation, even if the ventricular wall appears to be aneurysmal [19–23]. Conversely, with severe valve insufficiency and relatively preserved ventricular function, a minority of authors favor concomitant mitral valvuloplasty [6, 24–26] at initial ALCAPA surgery. This approach is advocated in older children rather than infants, as ischemic papillary dysfunction may already be irreversible [24, 25], mitral valve repair at the time of ALCAPA surgery enhances postoperative ventricular geometry, and more importantly late mitral valve replacement may be avoided [24, 25]. Huddleston and

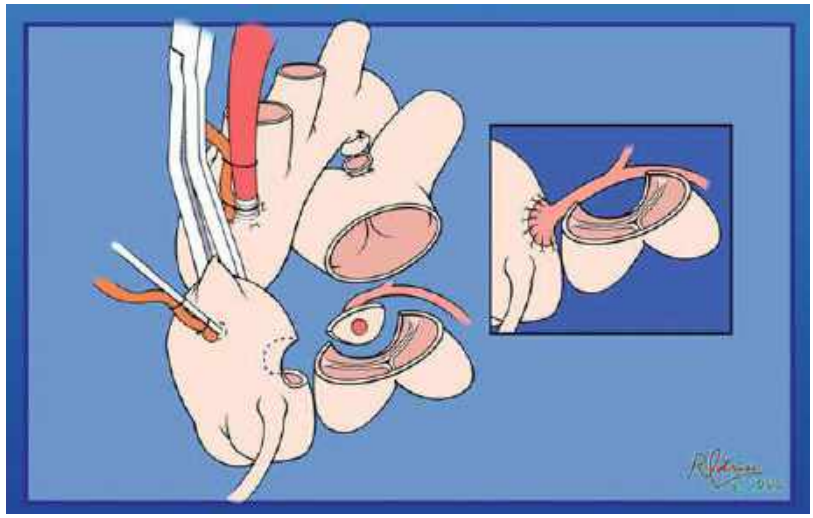

Fig. 114.2 Repair of ALCAPA: After the second dose of cardioplegia, an opening is created in the left posterolateral wall of the ascending aorta for implantation of the anomalous left coronary button, and the large button of coronary artery can then act as a *conduit* for the elongation of the left coronary artery. Once the anastomosis is created (*inset*), the aortic cross-clamp is removed, and both right and left coronary arteries are directly perfused (Reproduced with permission from Backer CL, et al. Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu 2000;3:165–172 [9] Copyright Elsevier © 2000)

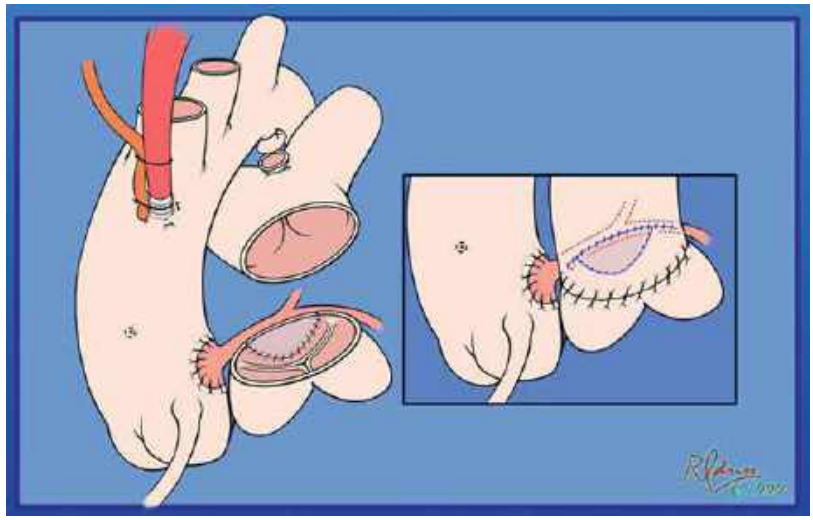

Fig. 114.3 The aortic cross-clamp is off. The posterior sinus of the pulmonary artery where the button was harvested is reconstructed with a patch of fresh autologous pericardium. The pulmonary artery is reanastomosed at the site of the transection (*inset*). This reconstruction of the pulmonary artery with the cross-clamp off helps to minimize the aortic cross-clamp time. In almost all instances, it is possible to perform the entire procedure with two doses of cardioplegia given in the sequence described (Reproduced with permission from Backer CL, et al. Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu 2000;3:165–172 [9] Copyright Elsevier © 2000)

associates [27] stress the importance of mitral valve function as an indirect sign of coronary patency as lack of improvement and recurring or worsening mitral insufficiency and/or left ventricular function as a sign of coronary stenosis, warranting cardiac catheterization to assess coronary patency, before attempting reoperation to target only the mitral valve [1].

Postoperative Management, Monitoring, and Complications

The principles of postoperative care, monitoring, and potential complications relating to patients after ALCAPA reimplantation are relevant and may be extrapolated to all coronary anomalies requiring reimplantation or repair of the coronary ostium, including ARCAPA, AAOCA, and CALM. Routine standard monitoring includes the usual central venous pressure and arterial pressure lines, eventually a left atrial line, and, very importantly, continuous ECG reading with attention to any ischemic changes (ST segment elevation or depression, unexplained and repetitive extrasystole, or new onset of any anomaly of conduction masking myocardial ischemia). Further monitoring includes serial cardiac enzyme evaluation (CK, CK-MB, troponin-I) specific to institution availability, whose trend in time may alert or reassure as to the state of myocardial perfusion, and serial evaluation of tissue perfusion and cardiac output markers (i.e., mixed venous saturation, lactate, NIRS). Serial 2-dimensional echocardiography allows for a good assessment of global and regional wall function, and again, the change in trend provides the most valuable information. Although controversial and not universal, many teams will empirically recommend therapeutic or low-dose intravenous heparin in the immediate postoperative period depending on the quality and technical ease of the coronary repair, overlapping with Aspirin (5 mg/kg, max 100 mg oral) for prophylactic antiplatelet treatment, ranging from 1 to 6 months depending on patient age at the time of surgery. Cardiac function is appropriately supported with various regimens of inotropes and afterload-reducing agents or may even require partial or full mechanical circulatory support with an intra-aortic balloon pump, ECMO, or a mechanical assist device, depending on the degree of perioperative circulatory insufficiency.

When present, signs of coronary insufficiency and resultant myocardial ischemia should promptly be evaluated with diagnostic coronary catheterization, selective multi-slice CT angiography, or MRI angiography, according to institution availability and rapidity regarding logistics. When present, any suboptimal repair should warrant immediate surgical revision with the goal of optimizing coronary flow.

Outcomes, Controversies, and Follow-Up

Operative mortality for ALCAPA aortic reimplantation is low, and late death is unusual [4, 7–9, 14, 16, 22–26]. Despite successful coronary artery reimplantation, poor preoperative left ventricular function, stunned myocardium, or malignant ventricular arrhythmias can prevent successful separation from cardiopulmonary bypass [4]. Mechanical support may be the only option to allow for survival in this setting, with encouraging mid- to long-term results [20, 24, 25, 27, 28]. However, the need for postoperative ECMO has been associated with a higher risk of reoperation for mitral valve repair or transplantation, as reported by Imamura et al. [28]. Although both antegrade and retrograde methods of intraoperative cardioplegia strategies combined with appropriate postoperative inotropic support should preclude the need for mechanical circulatory support [9], they should always be available in the modern surgical armamentarium when treating patients with ALCAPA [4]. Surgical complications include intraoperative coronary insufficiency owing to technical error and bleeding.

Risk factors that lead to postoperative mechanical support [20] or death after repair of ALCAPA include decreased preoperative left ventricular function [7, 21] and young age at

operation [7] and, for some, severe mitral insufficiency, although this has been refuted by others. Although younger patients present with more severe left ventricular failure, early surgery results in more rapid and complete recovery of myocardial function, as assessed by echocardiography [29–31]. Right coronary dominance has been positively correlated with survival [7], while left dominant or a balanced coronary circulation represents a risk factor for surgical mortality ($p < 0.01$) [7]. Elevated ST segments on electrocardiogram in more than two chest leads or more than one standard lead indicate acute myocardial infarction and correlate with lower perioperative survival ($p < 0.03$) [7].

Mild to moderate mitral insufficiency regresses after reperfusion and usually does not need to be addressed at the time of the first operation. Persistent, recurring, or worsening postoperative mitral insufficiency should warrant a cardiac catheterization to demonstrate coronary patency before reoperation on the mitral valve [27]. In patients with documented long-term patent coronaries, late death is rare [25], given that antegrade aortic reperfusion through a 2-coronary system practically eliminates the long-term risk of sudden death. Electrocardiography, Holter monitoring, stress-thallium scanning, and cardiac catheterization have all shown equivocal results as follow-up methods, often underscoring any remaining left ventricular dysfunction or recurrent coronary artery stenosis that may be apparent only under severe stress testing or by stress MRI [25]. Subsequently, close long-term follow-up of these patients by serial MRI [25, 32] is recommended to better understand the *corrected natural history*, which is the current expected goal after surgical correction of ALCAPA.

Anomalous Right Coronary Artery from the Pulmonary Artery (ARCAPA)

Anomalous pulmonary origin of coronary arteries type 2, or anomalous right coronary artery from the pulmonary artery (ARCAPA), is a very rare congenital anomaly, affecting 0.002 % of the population [33]. With increased awareness and improved imaging techniques, an increasing number of patients and small series of surgical repair are being documented [33–37] (Fig. 114.4) [38]. The vast majority of cases are reported in children, but isolated reports of neonates [37] and adults also exist [38–41]. Most patients are asymptomatic or have a benign murmur, but angina, congestive heart failure, cyanosis, palpitations, and even myocardial infarction with sudden death have been described. ARCAPA is rarely associated with complex heart disease, including tetralogy of Fallot and acquired pulmonary atresia [42] where it may be the only source of pulmonary blood flow (retrograde ARCAPA flow), and with aortopulmonary window [39]. Electrocardiogram findings are nonspecific, and echocardiography may be difficult, although abnormal diastolic flow in the pulmonary artery should raise suspicion. CT angiography and MRI are increasingly helpful in noninvasive imaging [40, 41]. Although it is often considered a benign lesion when presenting as an isolated defect, since there are many asymptomatic survivors in the adult age, there still exists a potential for sudden death and other cardiac events. Given the satisfactory advances achieved with standardized surgical technique and postoperative care, aortic coronary reimplantation is indicated at diagnosis of the anomaly with expected good outcomes [33–35, 40, 41].

Anomalous Aortic Origins of Coronary Arteries (AAOCA)

Introduction and Diagnosis

Anomalous aortic origin of the coronary arteries (AAOCA) represents one-third of all coronary artery anomalies [43]. All three coronary arteries may have abnormal origins, and every possible combination between the three coronary arteries has been reported. Most lesions are considered benign, except an aberrant origin of the left main coronary artery (LMCA) from the right aortic sinus of Valsalva (RASV), hitherto called *left from right*, and an aberrant origin of the right coronary artery (RCA) from the left aortic sinus

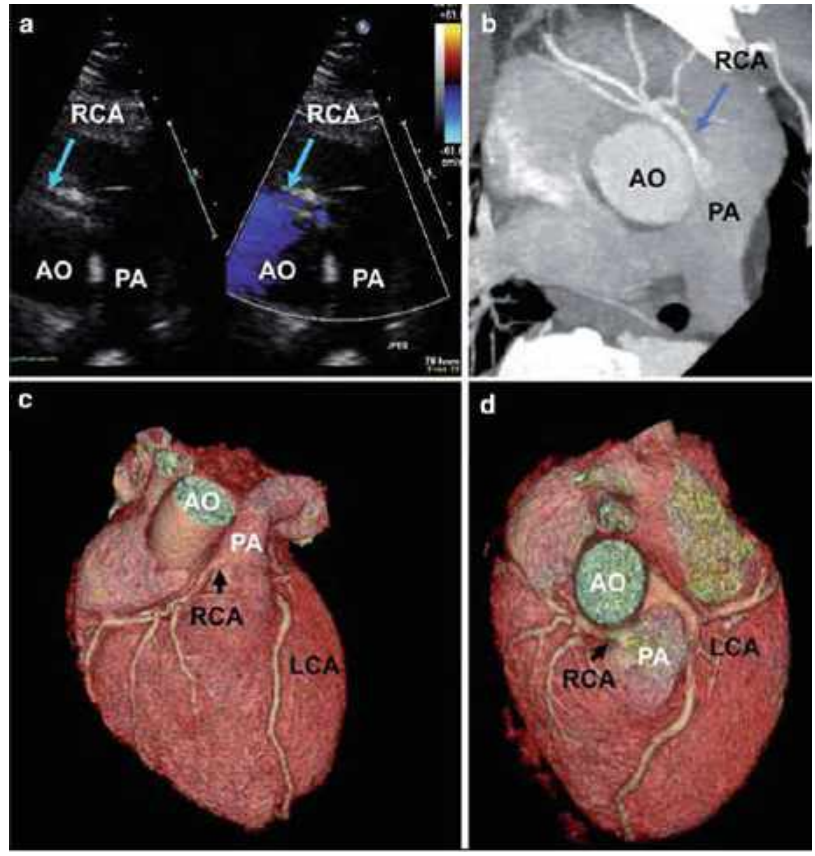

Fig. 114.4 Panel *A*: Echocardiographic shows suspicion of an abnormal right coronary artery. Panels *B–D*: Cardiac computed tomographic angiography confirmed an anomalous right coronary artery from the pulmonary artery (ARCAPA) (Reproduced with permission from Petersen JA, et al. Eur J Echocardiogr 2011;12(11):884 [38] Copyright Oxford Journals © 2011)

of Valsalva (LASV), hereafter called *right from left*, which are associated with cardiac symptoms and sudden death [44–54]. Symptoms and signs likely result from the course taken by the coronaries in relation to the great vessels and the potential for compression and low flow-induced myocardial ischemia and malignant arrhythmia, resulting in angina, syncope, and sudden death.

Although a chest x-ray and ECG are part of the standard work-up for patients with suspected AAOCA, they are often negative. Disappointingly, stress electrocardiogram, transthoracic or transesophageal echocardiography, and stress thallium are all fairly unreliable to detect ischemia. For screening purposes, newer imaging modalities such as coronary magnetic resonance angiography and multi-slice CT angiography are increasingly gaining ground, allowing for 3-dimensional reconstructions, and diminishing the need for ionized radiation and contrast medium [45]. Cardiac catheterization is indicated in any young patient with unexplained exertional syncope, dizziness, or angina.

Left Main Coronary Artery from Right Aortic Sinus of Valsalva

The LMCA arising from the RASV is associated with the highest incidence of symptoms and sudden death [41–51, 53, 54] and is the anomaly of aortic origin to take the most seriously, requiring urgent surgical correction upon diagnosis. The incidence of sudden death in untreated patients approaches 57 %, and up to two-thirds of these sudden deaths are related to exercise [43]. The spatial relation to the great vessels exists in 4 possible variations, either anterior to the pulmonary artery, posterior to the aorta, between the

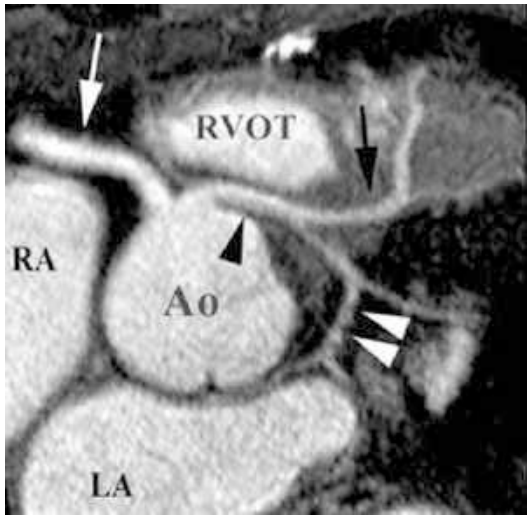

Fig. 114.5 AAOCA: *left from right*. Coronary magnetic resonance angiographic image with soap-bubble reconstruction. The left main coronary artery (*black arrowhead*) originates from the right sinus of Valsalva and courses within the upper ventricular septal myocardium, between the aortic root and the right ventricular outflow tract (RVOT, path no. 4). Both the left anterior descending (*black arrow*) and the left circumflex arteries (*double white arrowheads*) also have intramyocardial courses for their proximal portions. The right coronary artery (*white arrow*) has a normal course within the right atrioventricular groove. *Ao* aorta, *LA* left atrium, *RA* right atrium (Reproduced with permission from Angelini P, Flamm SD. Catheter Cardiovasc Interv 2007;69(7):942–954 [45] Copyright John Wiley and Sons © 2007)

great vessels, or through the conal septum beneath the right ventricular infundibulum (septal course). The risk of sudden death may be as high as 82 %, based on autopsy series, when the LMCA courses between the great vessels [43] (Fig. 114.5) [45]. In this configuration, the LMCA provides one or two branches to the proximal ventricular septum. However, the septal branches arise from the right coronary artery when the aberrant LMCA is posterior to the aorta.

The mechanism responsible for ischemia and sudden death is kinking of the slit-like coronary orifice at its origin by aortic root distension during diastole, effort-related stretching of the intramural LMCA segment, exercise-induced dilation of both the aortic root and pulmonary trunk with compression of the LMCA during its course between the great vessels, and spasm, torsion, or kinking of the LMCA by the intercoronary commissure [43]. With age, a higher incidence of atherosclerosis is reported, compared with age-matched controls, presumably owing to flow-induced jet lesions in the area of the coronary ostia. Most patients have a right dominant circulation with a small left coronary system. The presence of a left dominant coronary pattern has not been associated with increased risk of sudden death. When symptoms are present, patients are at higher risk of sudden death. Angina, congestive heart failure, syncope, and myocardial infarction should raise the suspicion of the anomaly and hopefully rapidly lead to a conclusive diagnosis and corresponding surgical intervention. In younger patients, syncope is more prevalent and the incidence of sudden death higher, while older patients (>30 years) present more commonly with angina and myocardial infarction [43]. In a postmortem study of United States military recruits undergoing basic military training between 1977 and 2001 (study population of 6.3 million, aged 17–35 years), 64 sudden cardiac deaths were identified. Almost two-thirds resulted from coronary artery pathology, of which more than half (54 %) were from anomalous aortic coronary origins [49]. In this cohort, compared with deaths resulting from acquired coronary artery disease, sudden death of cardiac origin was more likely associated with premortem chest pain and/or syncope induced by exercise in patients with congenital anomalous aortic coronary origin.

Right Coronary Artery from Left Aortic Sinus of Valsalva

Anomalous right coronary artery arising from the left aortic sinus of Valsalva (RCA from LASV) is more common than ALCA, reported between 0.26–0.6 % of postmortem studies and 0.2 % in angiographic series [54]. Anomalous RCA from LASV is no longer considered a benign lesion, as the potential risk for exercise-related sudden death exists in up to 25 % of cases [43, 45–50, 53, 54]. Symptoms include

angina, myocardial infarction, syncope, and high-grade atrioventricular block, most often induced during exercise or hypertensive crisis from presumable kinking and occlusion of the anomalous ostium within the aortic wall or by stretching of the coronary during effort-induced enlargement of the great vessel diameters [46–50] (Figs. 114.6 and 114.7) [45]. Mumtaz et al. reported a series of 15 patients with *right from left* presenting for surgical correction, of which all were symptomatic [44].

Anomalous Circumflex Coronary Artery from the Right Coronary Artery or Right Aortic Sinus of Valsalva (RASV)

This most common coronary variation is luckily also a benign one, reported in 0.2–0.71 % of cases [43]. The diagnosis is fortuitous, and symptoms of sudden death are rare.

Decision Making/Surgical Management

In all variations of anomalous aortic origins, with or without superimposed acquired atherosclerotic disease, surgery is always indicated at diagnosis in the presence of symptoms. In patients with *left from right*, prophylactic surgery is indicated, even in the absence of symptoms, to avoid risk of sudden death [43, 44, 46, 48, 50–53] (Fig. 114.8) [55]. When exercise-induced syncope, chest pain, or ventricular tachycardia is present, urgent surgery is warranted. In the asymptomatic patient with *left from right*, delaying surgery until 10 years of age is accepted by some, since sudden death has rarely been documented in children with this anomaly [50, 51]. If the parents or patient does not wish prophylactic surgery, avoidance of strenuous physical activity and competitive athletics is warranted [50, 51]. Surgical treatment is controversial [44, 46, 53] in asymptomatic patients with an aberrant *right from left*. With a negative thallium study or absence of atherosclerotic coronary lesions, no sudden death has been described. A multi-institutional registry is ongoing in an attempt to establish recommendations for these patients [56].

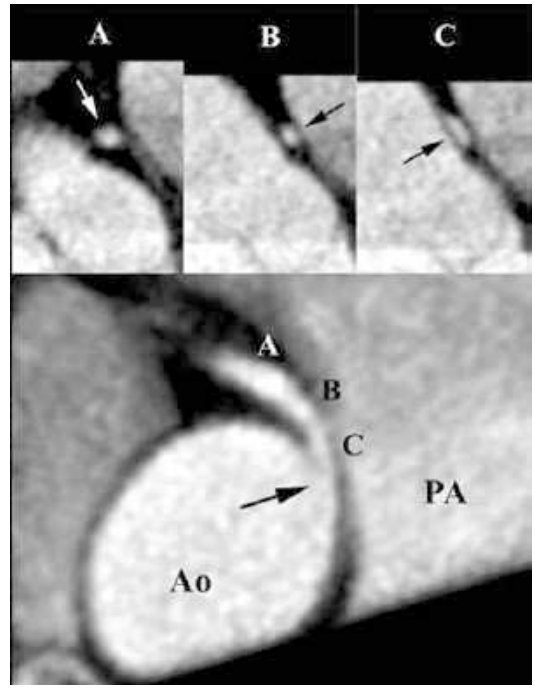

Fig. 114.6 *Right from left*: Sixteen-slice multidetector computed tomography (MDCT) demonstration of the intramural (aortic) origin of a right coronary artery (RCA) originating superior to the left sinus of Valsalva (right ACAOS, path no. 3). In the lower image (a multiplanar reconstruction through the proximal tubular portion of the ascending aorta and the proximal RCA), note the acute angulation of the RCAs origin (*black arrow*) from the tubular portion of the ascending aorta (Ao). The three images in the upper row are cross sections of the RCA that correspond to the lettered locations in the lower image. Each is approximately in a right lateral view. At point *A*, the RCA has a normal, round appearance (extramural); at point *B*, the vessel becomes oval in shape (intramural segment); at point *C*, the RCA becomes markedly eccentric and flattened as it nears its slit-like ostium. This example is the first published evidence of the potential of MDCT to describe the narrowing of the proximal ectopic segment, similar to the findings at intravascular ultrasound (IVUS) imaging. Because the aortic wall is poorly seen, MDCT images remain somewhat inferior to those of IVUS. Abbreviations: *Ao* aorta, *PA* pulmonary artery (Reproduced with permission from Angelini P, Flamm SD. Catheter Cardiovasc Interv 2007;69(7):942–954 [45] Copyright John Wiley and Sons © 2007)

For all AAOCA, the goal of surgery is to restore a normal anatomic position of the coronary

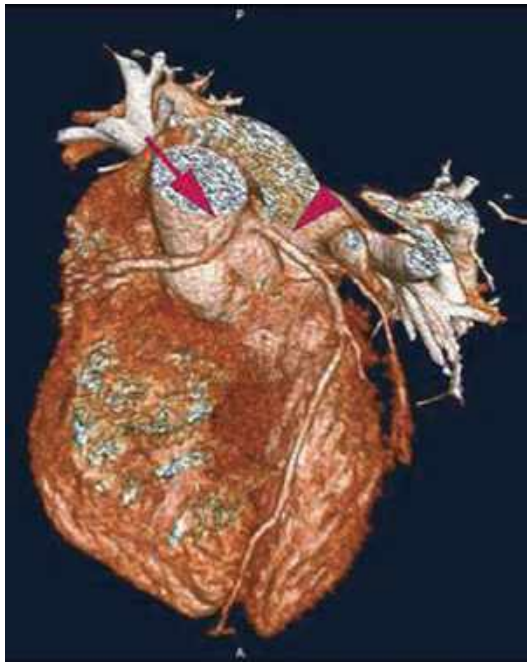

Fig. 114.7 *Right from left*: Three-dimensional volume-rendered reconstruction of multidetector computed tomography (MDCT) image in left anterior projection with steep cranial angulation, illustrating the same case of anomalous origin of the right coronary artery from the left sinus as shown in Fig. 6 (preaortic path, no. 3). Right ventricular outflow tract has been removed for better illustration. The left coronary artery (arrowhead) arises from a site located just above the left sinus of Valsalva, and the right coronary artery (arrow) arises next to the left ostium (Reproduced with permission from Angelini P, Flamm SD. Catheter Cardiovasc Interv 2007;69(7):942–954 [45] Copyright John Wiley and Sons © 2007)

ostium or to bypass a problematic proximal juxta-commissural or intramural course, with or without superimposed atherosclerotic lesions (Figs. 114.9 and 114.10) [55]. After coronary angiography, surgical correction is adapted according to the lesion at hand and includes unroofing and intimal tacking sutures, aortic reimplantation, or patch arterioplasty. The first attempts at surgical intervention targeted the distal patent vessel, using various classical bypass techniques with saphenous vein grafts or internal thoracic artery bypass grafting, rather than addressing the problem of origin, namely, the anomalous ostium or course. Although these techniques are still unavoidable in certain circumstances [46, 47, 50–52], they expose the patient to the usual problems of grafted coronary artery disease and potential reintervention [50]. Furthermore, the flow through the anomalous coronary is often normal at rest, so that competitive native vessel flow will jeopardize any type of bypass graft patency owing in the short- to mid-term [48, 50]. Although ligation of the proximal aberrant coronary concomitant to bypass grafting has been performed to avoid competitive flow [47, 52], ligation of any aberrant coronary artery is not favored. Instead, targeting the anomaly with unroofing and reimplantation with or without arterioplasty techniques is preferred [44, 53].

Outcomes and Follow-Up

Although the short-term follow-up of surgical repair for AAOCA is encouraging [46, 48, 50, 53], the durability of the repairs is still unknown [44, 50]. In shorter-term follow-up reports, ischemia has not been induced on stress testing, stress echocardiography, and even exercise-perfusion scanning [44]. Long-term issues may include coronary ostial stenosis after unroofing procedures, aortic valve competence from detachment of aortic valve commissures, and graft flow and patency in the case of bypass surgery. In a rare subset of patients, the results of these surgical techniques are in progress, as is optimal follow-up modality and frequency of follow-up, which await clearer guidelines [44, 53].

Single Coronary Artery

Single coronary artery is a rare coronary anomaly frequently associated with complex congenital heart disease and a reported incidence of 0.0024–0.066 % [57–61]. Patients with a single left or right coronary artery have antegrade flow to the entire heart in a centrifugal pattern from the aorta to the periphery, with a decreasing diameter of the vessel as it progresses distally toward the capillaries (Fig. 114.11) [58]. The most commonly associated concomitant congenital defects

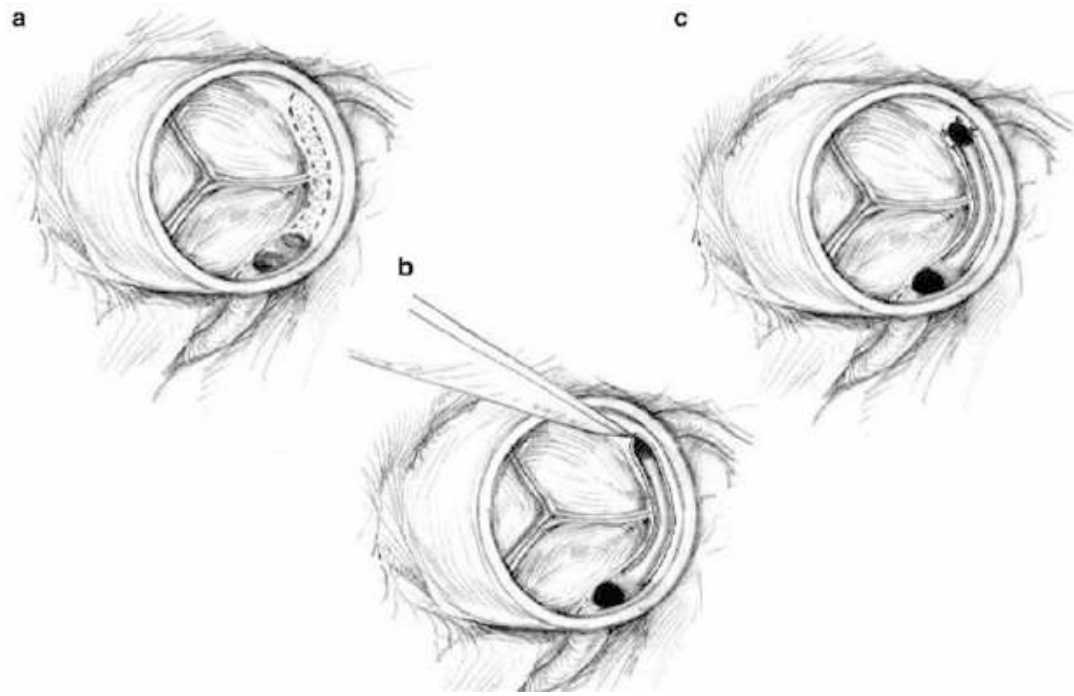

Fig. 114.8 *Left from right*: *A*, Transected aortic root demonstrates normal right coronary artery and abnormal intramural course of the left main coronary artery, which takes its origin from the right coronary cusp and traverses intramurally. *B*, The unroofing procedure is performed along the length of the intramural course. Dissection ends where an artery emerges from the aorta to supply the heart. *C*, The tacking sutures (8–0 Prolene) are placed at the neoorifice and serve to reattach the intimal layers, thereby preventing dissection and thrombosis. Abbreviations: *LCA* left coronary artery, *RCA* right coronary artery (Reproduced with permission from Mavroudis C, et al. Oper Tech Thorac Cardiovasc Surg 2010;15(1):18–40 [55] Copyright Elsevier © 2010)

associated include transposition of the great arteries, tetralogy of Fallot, truncus arteriosus, coronary arteriovenous fistula, endocardial fibroelastosis, and bicuspid aortic valve [62]. Overall survival is comparable with the general population. Patients may be asymptomatic or present with initial sudden death (23 %), and prognosis seems dependent on associated congenital heart defects [62]. The electrocardiographic pattern is nonspecific and may be normal, making coronary angiogram the gold standard diagnostic tool. Newer noninvasive imaging such as CT angiography allows very precise anatomic definition [58]. It remains unclear if superimposed atheromatous coronary disease is more prevalent in patients with single coronary artery [57–59, 63].

Successful treatment ranges from expectant medical management in the absence of an ischemic coronary syndrome to percutaneous coronary angioplasty or coronary artery bypass grafting when symptoms and signs related to myocardial ischemia are present [58, 59, 63], although long-term outcomes are unknown. Currently, the extant data are insufficient to recommend optimal surgical/interventional or follow-up strategies in this very rare coronary anomaly [59, 63].

Congenital Atresia of the Left Main Coronary Artery

Congenital atresia of the left main coronary artery (CALM) is an extremely rare congenital coronary anomaly, with less than 70 cases described in the literature. An association is

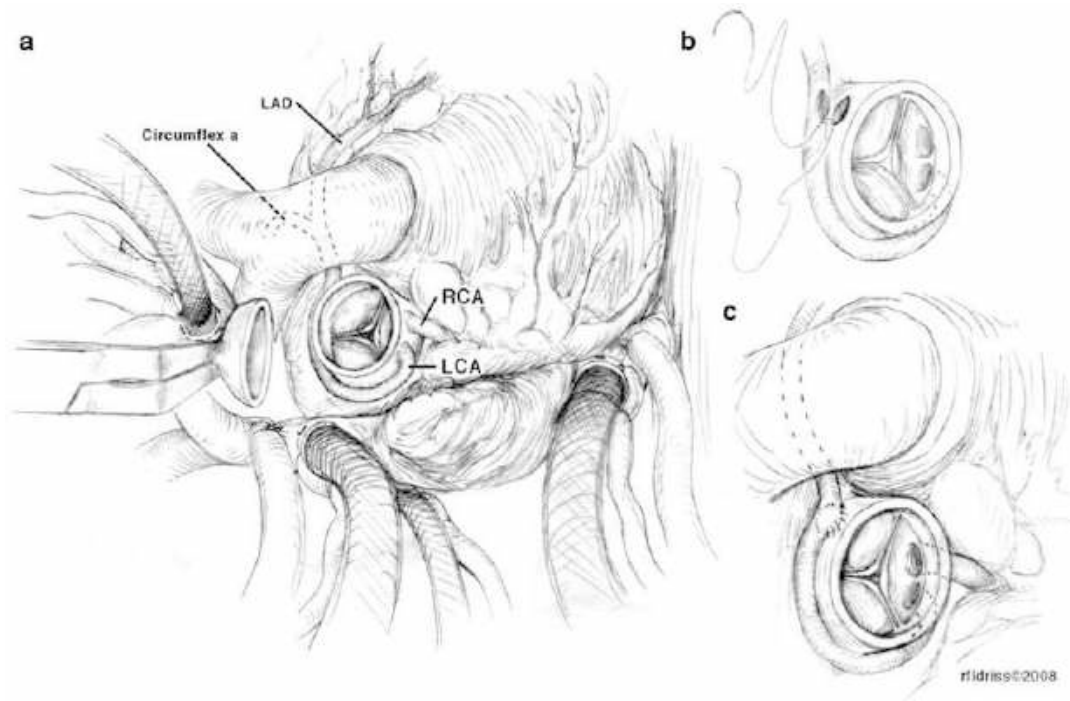

Fig. 114.9 *Left from right*. *A*, Anomalous origin and pathway of left main coronary artery. The origin is within the right coronary cusp adjacent to takeoff of the right coronary artery. The artery is elongated and courses to the right and posterior of aorta to emerge at the usual location and origin of the left main coronary artery near the left coronary cusp. *B*, It was decided here to perform side-to-side anastomoses for these abnormal coronary artery courses. *C*, This procedure succeeds in a neoorifice formation more closely related to normal coronary artery anatomy. Abbreviations: *LAD* left anterior descending coronary artery, *LCA* left coronary artery, *RCA* right coronary artery (Reproduced with permission from Mavroudis C, et al. Oper Tech Thorac Cardiovasc Surg 2010;15(1):18–40 [55] Copyright Elsevier © 2010)

found with mitral valve prolapse; supravalvar aortic stenosis, especially in Williams-Beuren syndrome; as well as ventricular septal defect and pulmonary stenosis [64–68]. ALCAPA and single coronary artery are the most important differential diagnoses but have different flow patterns. In CALM, a single right coronary artery perfuses the entire heart, but flow in the left anterior descending coronary artery as well as into the circumflex coronary artery is in a retrograde fashion (centripetal) and depends on collaterals from the right coronary artery (Fig. 114.12) [69]. Collateral channels are through the circle of Vieussens, which includes the conal artery, intraseptal coronaries, and apical-anterior and posterior ventricular anastomosis [64, 66]. The proximal left main trunk ends blindly, with no left coronary ostium. Contrary to single coronary artery, with congenital atresia of the left main, the left anterior descending and circumflex coronary arteries are located in their normal anatomic positions and branch out normally [66, 68].

The natural history is poor, as patients may initially present with sudden death [65] or after diagnosis, with or without medical treatment, have died while awaiting surgical repair [66, 68]. Clinically, patients with CALM present with symptoms in early infancy, including syncope, tachyarrhythmia, dyspnea, failure to thrive, and sudden death, similarly to ALCAPA. Survival into adulthood is rare, but possible and dependent on the degree of collateralization from the right coronary artery [69]. Left ventricular hypertrophy, increased oxygen demand, and superimposed atherosclerosis (present in 15 % of cases) all lead to

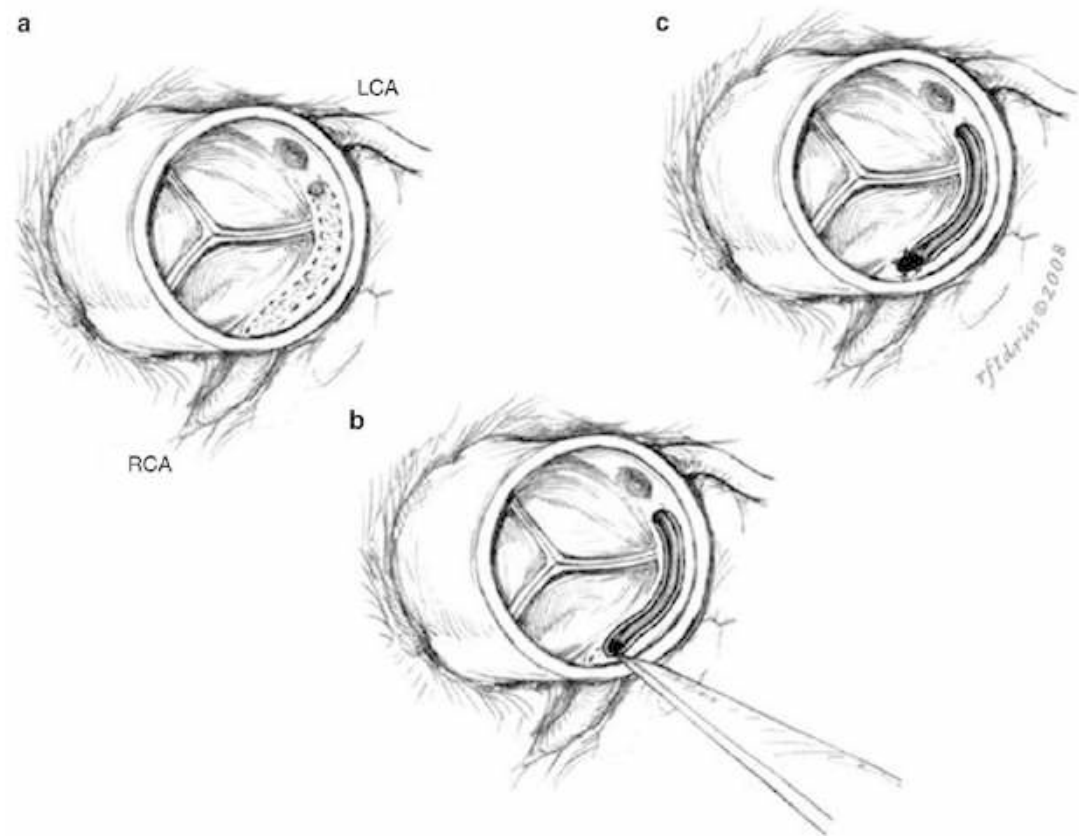

Fig. 114.10 *Right from left*: *A*, Transected aortic root demonstrates normal left main coronary artery and abnormal intramural course of the right coronary artery, which takes origin from the left coronary cusp, traverses intramurally (within wall of aorta) toward the right coronary cusp, and emerges to perfuse heart. *B*, Unroofing procedure performed along length of intramural course. *C*, Tacking sutures placed at the neoorifice, which serve to reattach the intimal layers, thereby preventing dissection and thrombosis (Reproduced with permission from Mavroudis C, et al. Oper Tech Thorac Cardiovasc Surg 2010;15(1):18–40 [55] Copyright Elsevier © 2010)

exercise-induced ischemia and ultimately to ischemia at rest [66]. Ischemia results from the lag in blood delivery to the left coronary system, as blood reaches the left anterior descending and circumflex coronary arteries in systole, rather than in diastole [66]. The electrocardiogram is nonspecific, with ischemia or myocardial infarction in the anteroapical leads, similar to ALCAPA. Likewise, the chest x-ray reveals cardiomegaly and pulmonary venous congestion. Viability studies for potential ischemia include stress thallium or PET, typically demonstrating perfusion defects of the anteroapical segments [65, 68, 69]. Although two-dimensional echocardiography may help in the diagnosis [68], definitive anatomic distinction between congenital atresia of the left main and ALCAPA is defined by coronary angiography [65–72], allowing for proper surgical corrective strategy. Angiographically, CALM and ALCAPA both reveal a solitary right coronary artery originating from the aorta with inability to inject into an obstructed left ostium and a left coronary artery filling retrograde via collaterals from the right coronary artery [65, 67, 69, 71]. However, with CALM, there is no shunt into the pulmonary artery and the left anterior descending and circumflex coronary arteries are anatomically situated normally. Distinguishing between CALM

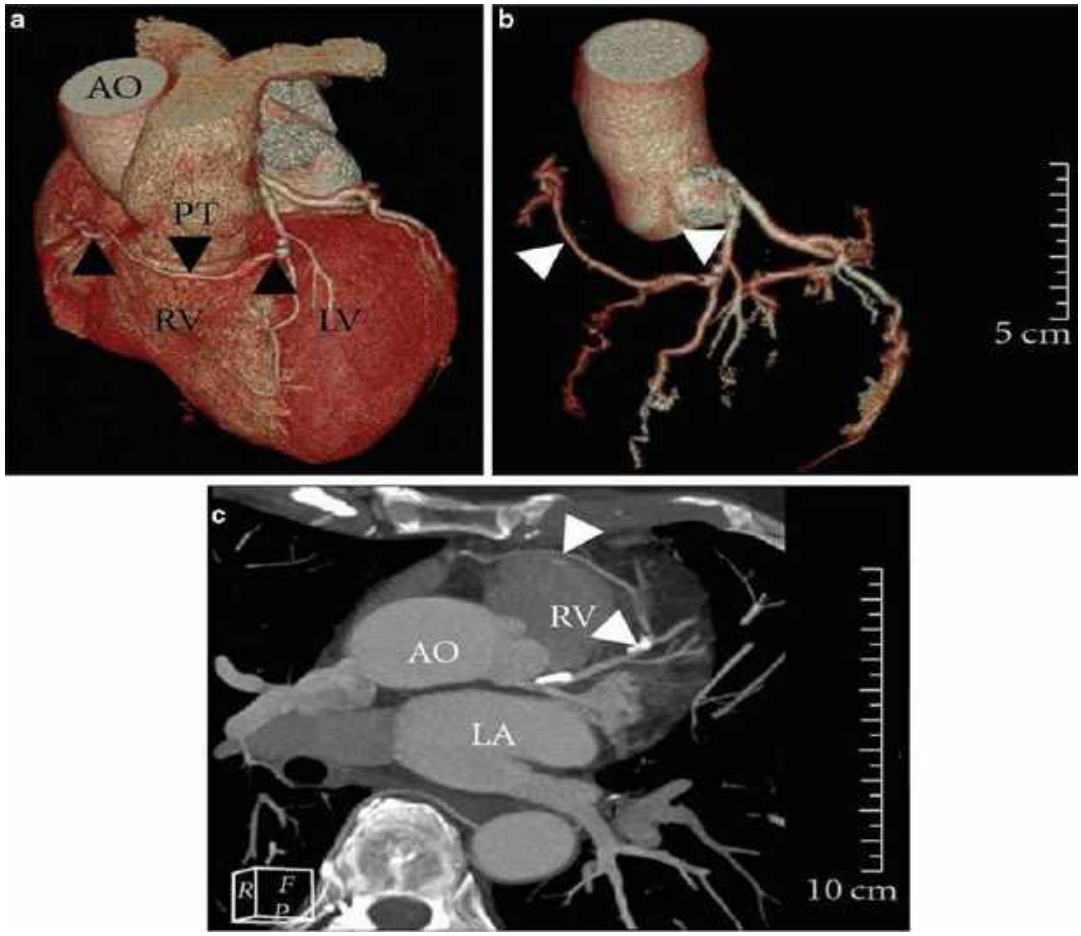

Fig. 114.11 Multidetector computed tomography image of a single coronary artery to illustrate the presence of an anomalous RCA originating from mid-LAD and coursing anterior of the aorta and pulmonary trunk. Volume rendering acquisitions (**a**)–(**b**) and multiplanar reconstructions (**c**) demonstrate the exact anatomic course of the anomalous vessel (*black arrowheads* in (**a**) and *white arrowheads* in (**b**) and (**c**)). (**a**) Overview of coronary vessel course in relation to the great arterial vessels aorta and pulmonary trunk; (**b**) coronary tree; (**c**) axial maximum intensity projection. Abbreviations: *Ao* aorta, *LA* left atrium, *RV* right ventricle, *PT* pulmonary trunk (Reproduced with permission from Gitsioudis G, et al. Case Report Med 2011;2011:108709 [58])

and ALCAPA is not always easy by angiography, especially if the ALCAPA has poor collateralization from the right coronary artery without the characteristic *blush* in the pulmonary artery [72]. However, there is no oxygen step-up from a left-to-right shunt in the pulmonary artery in CALM, which should be present in ALCAPA [72].

Surgery at diagnosis is mandatory, including classical bypass grafting of the left anterior descending coronary artery with saphenous vein or internal mammary artery [70, 71] or, more recently, by surgical ostioplasty using a patch of pulmonary homograft [73]. Surgical results depend on preoperative left ventricular function and degree of extant ischemia-induced damage. Follow-up includes angiography, with demonstrated ostial or graft patency and clinical improvement of ischemic symptoms. Long-term results are lacking in this very rare anomaly, which carries a lethal natural history if left untreated.

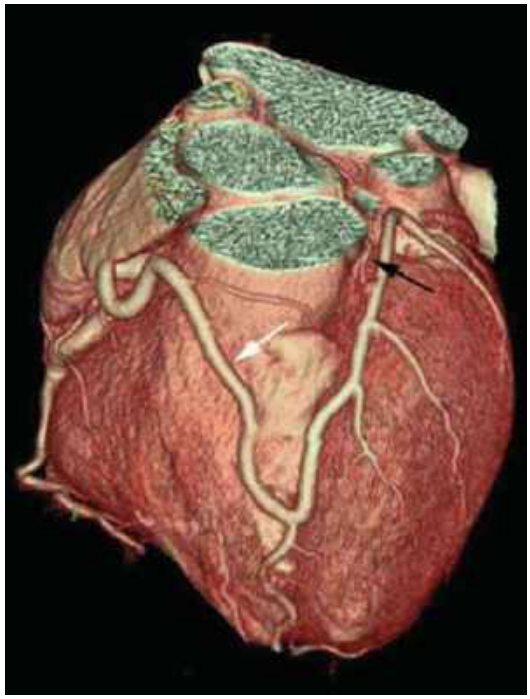

Fig. 114.12 Congenital atresia of the left main coronary artery (CALM), showing the acute marginal (*white arrow*) arising off the proximal right coronary artery and crossing anterior to supply the distal left anterior descending coronary artery. The proximal left anterior descending artery and circumflex fill retrograde. The embryonic small left main (*black arrow*) is visible on the left side of the aortic root (Reproduced with permission from Levisman J, et al. Coronary Arteriovenous Fistulas

Introduction and Pathophysiology

Coronary arteriovenous fistulas (CAVF) are anomalies of coronary inflow (origin) and outflow (drainage), are present in 0.2–2 % of the general population [74–76], are the most common hemodynamically significant coronary anomaly, and represent nearly half of all coronary anomalies [74, 75, 77]. Coronary arteriovenous fistulas may be isolated [74, 75, 78] or associated with other congenital heart defects, including tetralogy of Fallot, atrial septal defect, patent ductus arteriosus, ventricular septal defect, and superimposed coronary artery disease (35 %) [74, 78]. Approximately two-thirds are congenital, but acquired lesions are increasing, more readily recognized after trauma, Takayasu arteritis, cardiac surgery, in patients with indwelling transvenous pacemaker leads, postangioplasty, postendomyocardial biopsy in transplant recipients, or following interventional device closure of intracardiac defects [76, 79]. During fetal development, persistence of embryonic intramyocardial trabecular sinusoids and anomalous development of the intratrabecular spaces are believed to explain the congenital arteriovenous fistula.

Single fistulas are most common, ranging from 74 % to 90 % [52, 74, 75]. Multiple fistulas are present in 8–16 % [75, 78] of cases, and fistulas originating from both coronaries in 4–18 % [74, 75, 78]. Both the left anterior descending coronary artery (most common) and the RCA are sites of origin [78], and fistulas rarely arise from the circumflex artery [78, 79]. The most common drainage sites are the pulmonary artery and right ventricle (RV) [78, 79]. Owing to lower pressures, anomalous drainage into right heart structures is more prevalent (92 %), and drainage into higher pressure left heart cavities occurs in the remaining 8 % [52, 74, 75, 78, 79]. Coronary dilation is usual, although the extent to which the coronary of anomalous fistula origin enlarges is not related to shunt volume [76]. In surviving adults, congenital coronary fistulas are twice as prevalent in females than in males (70 % versus 30 %), as is aneurysmal formation (40 % females; 18 % males) [80]. Aneurysmal formation is significantly higher in the Asian population (65 %) compared with Caucasian patients (16 %) [80]. Nomenclature is descriptive and includes the vessel of origin and the chamber of drainage.

In younger patients with larger fistulas, symptoms are frequent and include angina, dyspnea, congestive heart failure, arrhythmias, and, more rarely, dizziness, palpitations, and fatigue [74, 75, 78, 79]. With smaller shunts, patients are usually asymptomatic in the first two decades of life [80]. Auscultation reveals a continuous machinery murmur at the second and third right

or left parasternal borders and may be confused with patent ductus arteriosus, ventricular septal defect and prolapse of the aortic valve cusp, or aortopulmonary window. Smaller coronary fistula may spontaneously close in rare cases [76, 78, 81]. More often, without surgery or intervention, patients with CAVF have shortened life expectancy. The onset of symptoms and complications in untreated patients typically begins by the second or third decade of life [74, 81], including myocardial infarction, bacterial endocarditis, aneurysm formation, and death. Angina is caused by coronary steal [52], ischemia, superimposed atherosclerosis, coronary thrombosis from turbulence and high flow, and critical coronary flow distal to the fistula. Congestive heart failure results from chronic volume overload. Aneurysmal dilation of the coronary artery may predispose to rupture, bleeding, and pericardial tamponade [82]. Rarely, sudden death may be the first manifestation of CAVF [76]. Bacterial endocarditis, coronary thrombosis with embolization, and pulmonary hypertension are the eventual results of long-standing left-to-right shunts, occurring more commonly in patients over 30 years of age.

Diagnosis

Cardiomegaly is frequent on chest x-ray, and a left-to-right shunt may reveal increased pulmonary vascular markings in 16.5 % [74]. Electrocardiographic changes are present in two-thirds of patients and include ischemia, chamber overload, infarction, and arrhythmias (premature ventricular ectopy [11 %], atrial tachycardia [5.6 %], anomalies of conduction [5.6 %]) [74]. Color flow Doppler echocardiography can define the exact anatomy in CAVF. However, cardiac catheterization is always performed either to allow for interventional device closure of solitary distal fistulas [76, 77, 79, 81]; to define multiple fistulas, hemodynamics, and the degree of left-to-right shunting [74]; and to plan surgical closure when device closure is deemed unfeasible. More recently, magnetic resonance imaging (MRI) angiography and 64-slice CT allow for precise anatomic delineation of coronary fistula origins and drainage sites and allow for surgical planning [76, 81].

Catheter-Based Intervention or Surgical Therapy

The goal of surgery or transcatheter device closure is to close the fistulous tract without compromising normal coronary flow (Fig. 114.13) [52, 75, 77]. In all symptomatic patients, fistula closure is indicated [74–78]. The timing and indications for surgery or intervention in asymptomatic patients remain controversial. Most surgical reports advocate early *prophylactic* closure, owing to near-zero morbidity and mortality in cases of isolated fistula [52, 75, 77, 79]. In cases with associated congenital heart defects, surgical mortality is determined more by the associated defects rather than the fistula per se, ranging between 2 % and 7 % [74–77]. Surgical techniques include patch closure or distal ligation, from the inside of a heart chamber at the site of drainage, which will always require cardiopulmonary bypass, or tangential arteriorrhaphy from the site of fistula origin. Cardiopulmonary bypass is rarely necessary if epicardial ligation or tangential arteriorrhaphy [52, 74] is anticipated, although having bypass standby is highly recommended. Internal closure in the right heart chambers may be done on cardiopulmonary bypass without cross-clamp or cardioplegia on a beating or fibrillating heart. Other possible techniques include ligation of the fistula and saphenous vein graft or left internal mammary artery bypass in case of compromised distal coronary artery flow or closure from within an aneurysm of a coronary artery fistula. More recently, transcatheter coil embolization closure is increasingly performed in cases with favorable anatomy, yielding excellent results [52, 76, 77, 81]. To date, no randomized studies have compared surgery with interventional techniques. No guidelines exist for a treatment algorithm depending on shunt size or anatomy, and

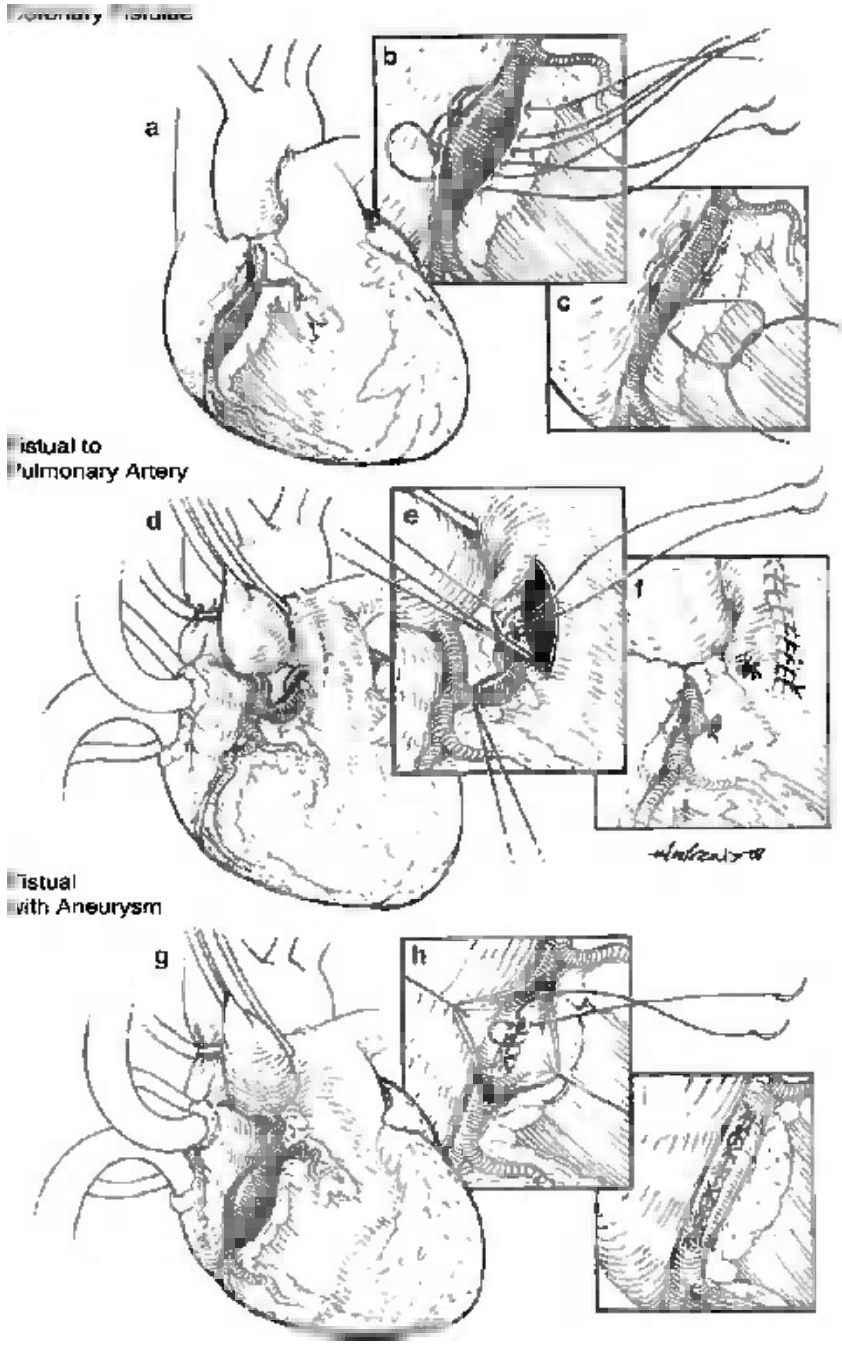

Fig. 114.13 Techniques to repair coronary artery fistula. *A* Coronary artery fistulas from the right coronary artery (RCA) to the right ventricle are shown, consisting of multiple openings. *B* Multiple horizontal mattress sutures are placed between the artery of origin and the heart. *C* The fistulous openings are obliterated while restoring the patency of the RCA. *D* Coronary artery fistula from the RCA to the pulmonary artery is shown. *E, F* The pulmonary artery is opened, the fistulous opening is identified, and the fistula is ligated from within the pulmonary artery under direct vision. *G* Coronary artery fistula from the RCA with an aneurysm is shown. *H* The aneurysm is opened and the fistula is repaired from within the aneurysm. *I* The aneurysm is plicated (Reproduced with permission from Urrutia S, et al. Ann Thorac Surg 1983;35(3):300–307 [74] Copyright Elsevier © 1983)

therapeutic strategies are currently based on individual case characteristics and institutional bias.

Intramyocardial Course of Coronary Arteries (Bridging)

The eventual mechanisms of ischemia in intramural (intramyocardial) segments of epicardial coronary arteries, also known as *bridging*, remain controversial [83–85]. Not all patients with bridging have systolic narrowing and ischemia or fixed coronary artery disease. Bridging is most commonly seen in the mid-segment of the left anterior descending (LAD), although it has been described in diagonal branches; the posterior descending artery of the right coronary artery (RCA); and the marginal arteries of the circumflex coronary [83–86]. The actual incidence of bridging is uncertain, with widely ranging estimates in the general population between 5.4 % and 85.7 % [83–87]. There is also great discrepancy between the reported incidence of autopsy and angiographic findings, ranging between 0.5 % and 85 % [83–87]. Bridging has been reported as an isolated finding or associated with hypertrophic cardiomyopathy, ischemic cardiomyopathy, idiopathic cardiomyopathy mitral valve prolapse, and muscular subaortic stenosis.

An overwhelming amount of angiographic and Doppler evidence has documented systolic narrowing of bridged coronary arteries, with turbulent flow through the bridge, potential intimal trauma, and possible platelet aggregation [83–87]. When present, ischemia-related symptoms occur after the third or fourth decade of life [83–85], including angina, ventricular septal rupture, conduction abnormalities, tachyarrhythmias, syncope, and sudden death [83–86]. In patients that have undergone a cardiac transplant with a graft that has an intramyocardial bridge, early death has been associated.

Diagnosis

Angiography and intravascular ultrasound (IVUS) are the diagnostic gold standards for bridging [85, 86, 88]. Significant *milking* effect is present when the coronary diameter is reduced by <70 % in systole and >35 % during mid-to-late diastole [86]. With IVUS, the *half moon* and early diastolic *finger tip* phenomenon are highly specific for a significant bridge; diameter narrowing in relation to delayed vessel relaxation, reduced antegrade systolic flow, and abrupt early diastolic flow acceleration [85, 86] may be accurately assessed.

Therapeutic Considerations (ICU)

Initial treatment for symptomatic bridging is medical [84–86]. Beta-blockers reduce tachycardia and prolong diastole by negative chronotropic and inotropic effects, thereby reducing external muscle compression [84–86]. Calcium channel blockers have also been used with success [86]. Nitroglycerine has been used in the symptomatic treatment of angina in bridging, but is no longer recommended, since ischemic symptoms may worsen [85]. With conduction disturbances and arrhythmia-induced syncope, pacemakers may be indicated.

Surgery

When symptoms are refractory to medical treatment, most surgeons agree to relieve documented angiographic systolic narrowing, although the indication and timing for surgery remains difficult, reserved for ischemia-induced symptoms refractory to medical treatment (Fig. 114.14) [88–90]. Surgical myotomy with unroofing a supracoronary bridge was initially performed, and later, bypass grafting distal to a bridge became more common. Both surgical myotomy and bypass grafting, with or without cardiopulmonary bypass, have relieved symptoms and restored normal electrocardiographic and angiographic findings at late follow-up [88–90]. Interventional percutaneous stenting of bridged vessels has been attempted, but with a high rate of in-stent stenosis and stent fracture, presumably owing to persistent external compression, and whose midterm efficiency is still doubtful [91].

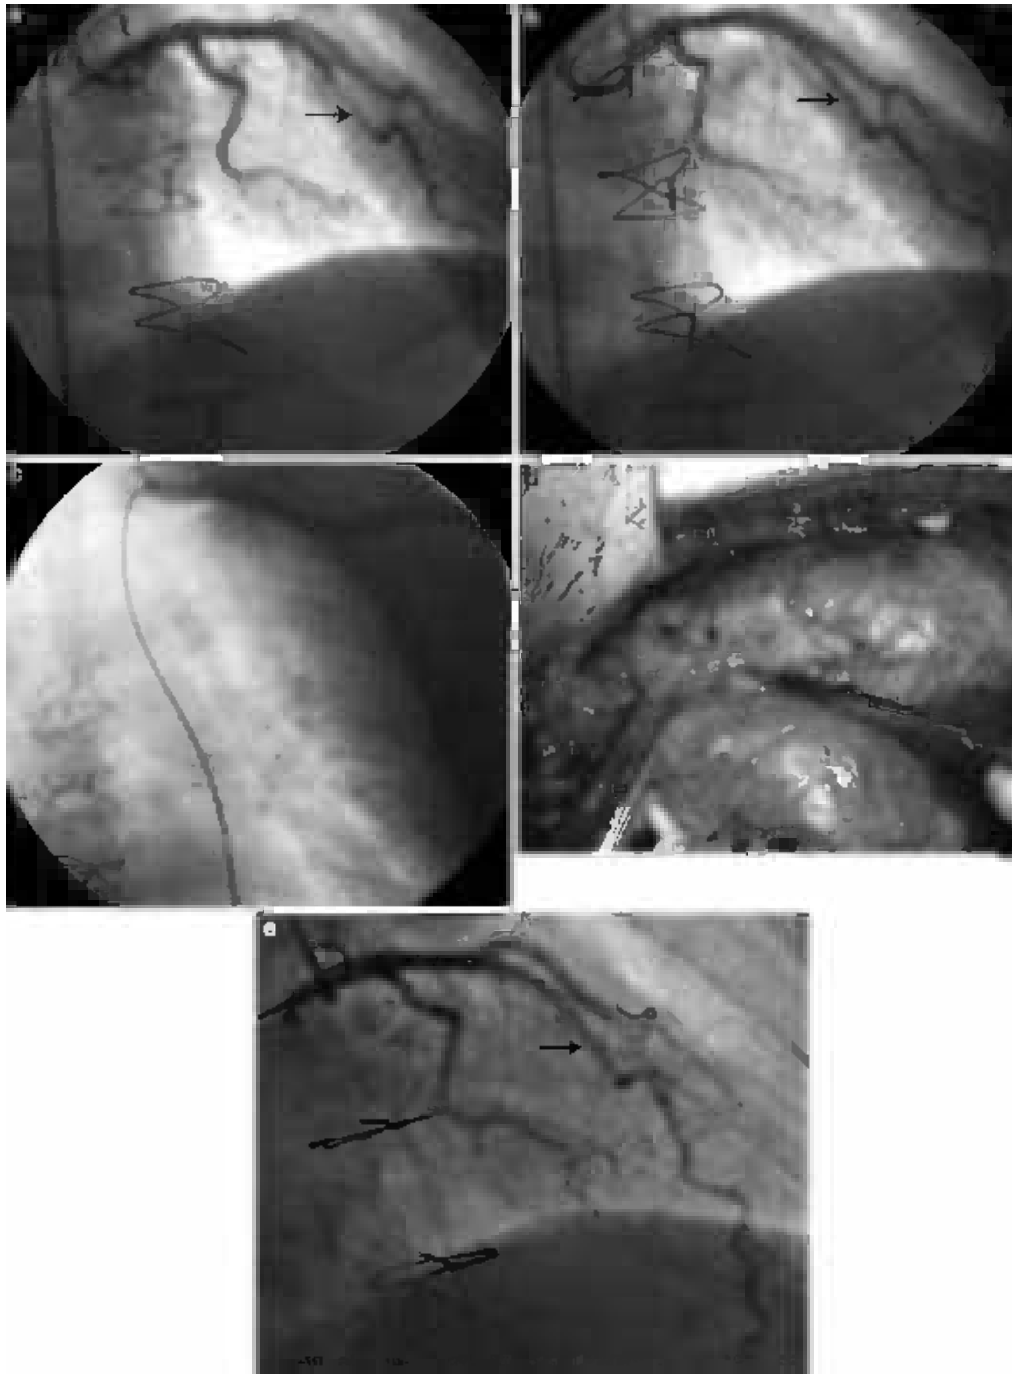

Fig. 114.14 Angiographic and surgical illustrations of coronary artery bridging. Repeat coronary angiography before myotomy shows systolic compression of the left anterior descending coronary artery (LAD) (**a**, *arrow*), almost complete recovery in the same area in diastole (**b**, *arrow*), and the left internal mammary artery (LIMA) graft occlusion (**c**). (**d**) (*arrow*), Intraoperative view reveals surgical dissection of LAD with myotomy. (**e**) (*arrow*), Follow-up angiography demonstrates complete relief of the narrowed LAD in systole (Reproduced with permission from Xu Z, et al. Abstract

Congestive heart failure is defined as the inability of the heart to meet the metabolic demands of the body or else to meet these demands only in the setting of an abnormally elevated filling pressure. The clinical presentation of a patient with heart failure is variable and depends on the degree of compensation. Heart failure is often a result of myocardial failure but may also occur in the presence of near-normal cardiac function under conditions of extremely high demand. Irrespective of etiology, the end result of heart failure is circulatory failure. This chapter will provide an overview of mechanisms, diagnostic tools, and management of cardiac failure.

Definition

Congestive heart failure (CHF), also called heart failure, cardiac failure, or congestive cardiac failure, is defined as the inability of the heart to meet the metabolic demands of the body; or else, the heart is able to meet these demands only in the setting of an abnormally elevated filling pressure. This definition also applies to the capacity of the heart to meet the requirements incurred by the growth process. The clinical presentation of a patient with heart failure can vary from a well-compensated state, which can be associated with minimal signs or symptoms, to the opposite side of the spectrum in patients with fulminant cardiogenic shock. Heart failure is often but not exclusively a result of myocardial failure. It may also occur in the presence of near-normal cardiac function under conditions of extremely high demand. Irrespective of etiology, the end result of heart failure is circulatory failure with altered tissue perfusion. The etiology of congestive heart failure in pediatrics varies with the age; congenital cardiac defects are usually responsible for the entity, but it may also relate to a number of acquired conditions.

Pathophysiology

Inadequate adaptation of the cardiac myocytes to increased wall stress in order to maintain adequate cardiac output is the inciting event in cardiac failure. The most important adaptations may be as follows:

- *Frank-Starling mechanism* is the ability of the heart to alter its contractility based on the degree of venous return. In the failing heart, increasing preload can increase stroke volume to maintain cardiac output [1–5].
- *Activation of neurohumoral systems*, including increased activity of the (1) sympathetic nervous system [6] and renin-angiotensin system (2) along with increased release of (3) vasopressin and (4) natriuretic peptides, act to maintain blood pressure and end-organ perfusion [7–9].
- *Myocardial remodeling* results in augmentation of contractile tissue (ventricular hypertrophy) [10, 11].

Frank-Starling Mechanism

- The Frank-Starling mechanism allows augmentation of cardiac output by the failing myocardium at the expense of elevated end-diastolic volume. As heart failure worsens, elevations in end-diastolic volume are associated with an increase in end-diastolic pressure resulting in pulmonary edema. Circulatory failure as a result of heart failure occurs when further increases in end-diastolic volume no longer result in increased ventricular performance and end-organ perfusion is inadequate. Figures 115.1, 115.2, and 115.3 display pressure-volume loops in different scenarios of cardiac failure, the effects of preload augmentation (Fig. 115.1) or decrease (Fig. 115.2), and the changes on the end-systolic pressure-volume relationships (Fig. 115.3) upon cardiac performance.

Neurohumoral Activation

Sympathetic Nervous System

Activation of the sympathetic nervous system results in increased release and decreased uptake of norepinephrine (NE) and, to a lesser degree, epinephrine resulting in vasoconstriction, so arterial pressure is maintained and end-organ perfusion preserved. This sympathetic stimulation also increases afterload and myocardial cytosolic calcium entry [6]. The increased calcium entry into the myocytes augments myocardial contractility (inotropy) while impairing myocardial relaxation (lusitropy). The combination of an increase in afterload and inotropy and impairment of myocardial lusitropy leads to an increase in myocardial energy expenditure and oxygen demand. Additionally, elevations in plasma norepinephrine are responsible for the downregulation of β_1-adrenergic receptors [12]. In children with

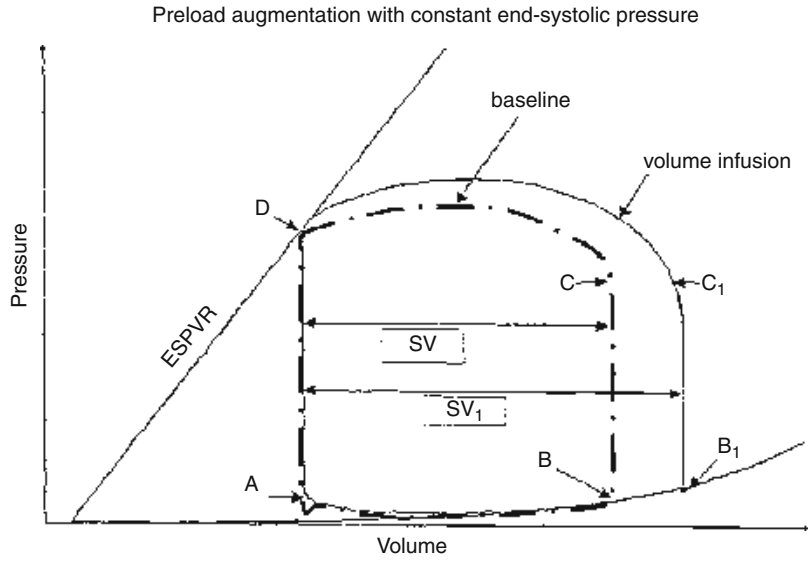

Fig. 115.1 Effect of preload augmentation on the pressure-volume loop. The infused volume raises end-diastolic volume (B–B_1). Stroke volume is increased by the difference between SV and SV_1. The end-diastolic pressure (D) does not change significantly in this scenario because of the effects of baroreceptor reflexes and other regulatory responses (Figure generated by the Heart Simulator, courtesy of mark Dickstein, MD, and Daniel Burkhoff, MD, Columbia University, New York, USA; with copyright permission from Elsevier Limited, Kidlington, Oxford, UK)

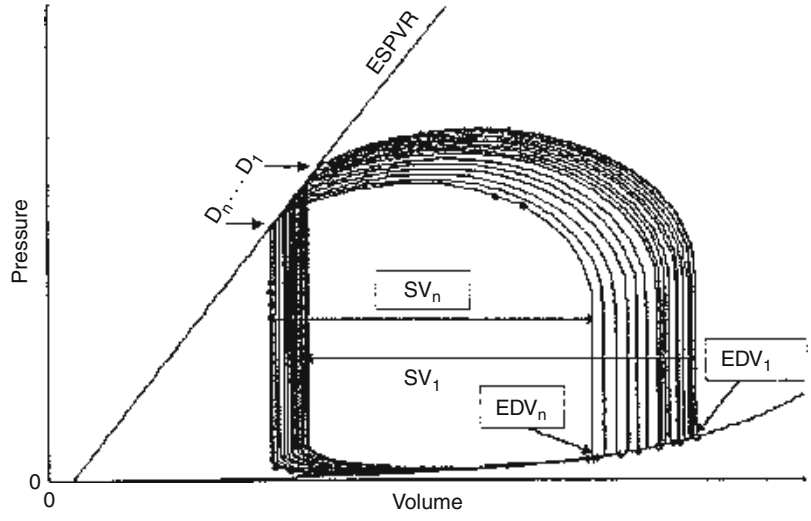

Fig. 115.2 Effect of decreasing preload on the pressure-volume loop. As volume is removed, successive loops move toward the left from the first loop to the nth loop. The nth loop has less end-diastolic volume (EDV_n) and stroke volume (SV_n) than the first loop. *Point D* represents end systole for each PV loop. The family of points $D_{1\ldots n}$ fall on a line that represents the end-systolic pressure-volume relationship (*ESPVR*). Therefore, it can be seen that the diastolic compliance relationship and the ESPVR define the limits within which the ventricle responds to changes in preload (Figure generated by the Heart Simulator, courtesy of mark Dickstein, MD, and Daniel Burkhoff, MD, Columbia University, New York, USA; with copyright permission from Elsevier Limited, Kidlington, Oxford, UK)

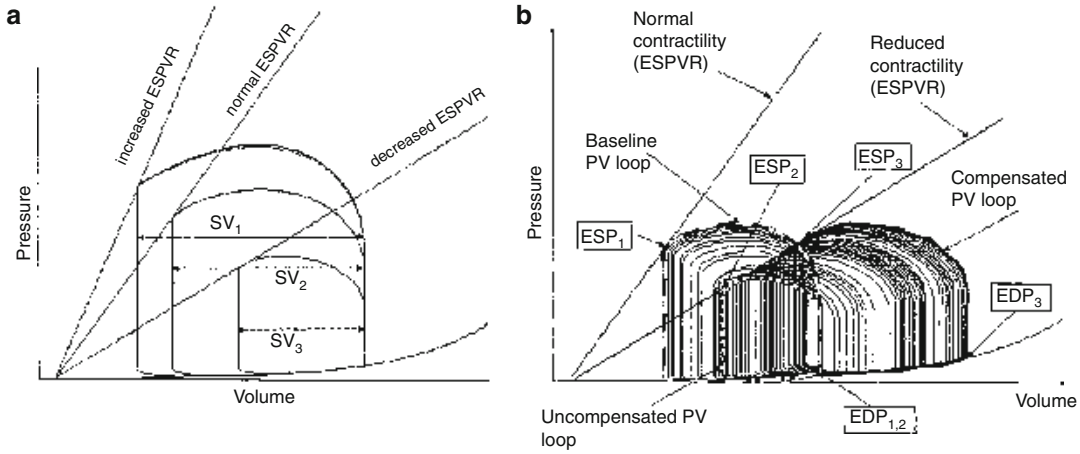

Fig. 115.3 Effect of changing the end-systolic pressure-volume relationship (*ESPVR*). (**a**) Pressure-volume (*PV*) loops are depicted with increased, normal, or decreased ESPVR (contractility), while all other variables (preload, afterload, heart rate) are held constant. The stroke volume (width of the PV loop) falls progressively (SV_1 to SV_3) with the reduction in ESPVR. Similarly, systolic pressure (height of the PV loop) decreases as ESPVR is reduced. (**b**) In vivo, PV relationships showing progressive reduction in ESPVR (contractility) followed by preload augmentation secondary to fluid retention. The initial progression of PV loops from "baseline" (*dashed PV loop*) to "uncompensated" (*dotted PV loop*) shows the reduction in stroke volume and end-systolic pressure (ESP_1 to ESP_2). Fluid retention (preload augmentation) leads to a series of PV loops from "uncompensated" to "compensated," resulting in an increasing stroke volume and end-systolic pressure (ESP_2 to ESP_3). This compensation is achieved at the expense of higher end-diastolic pressure (EDP_3) and volume (Figure generated by the Heart Simulator, courtesy of mark Dickstein, MD, and Daniel Burkhoff, MD, Columbia University, New York, USA; with copyright permission from Elsevier Limited, Kidlington, Oxford, UK)

a left-to-right shunt, the increase in afterload (systemic vascular resistance) worsens the left-to-right shunt, leading to an increase in the pulmonary to systemic flow ratio (Qp:Qs) and worsening symptoms of pulmonary overcirculation.

Renin-Angiotensin System

The activation of the renin-angiotensin-aldosterone system (RAAS) leads to increased circulating levels of renin, angiotensin II, and aldosterone. Release of these RAAS mediators occurs secondary to decreased perfusion and sympathetic stimulation of the kidney. Renin is responsible for cleaving angiotensinogen to form angiotensin I which via the actions of angiotensin-converting enzyme (ACE) forms angiotensin II. Angiotensin II is a potent vasoconstrictor, which enhances NE release and is associated with myocyte hypertrophy and cell death [13]. Aldosterone causes salt and water retention, resulting in increased preload, further increases in myocardial energy expenditure, and peripheral edema [7–9].

Vasopressin

Vasopressin is a pituitary hormone that is essential for the maintenance of normal plasma osmolality. Vasopressin levels are increased in heart failure and probably contribute to poor free water clearance (V_2 receptors) and systemic vasoconstriction via the V_1 receptors [14].

Natriuretic Peptides

Atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP) are released in response to changes in atrial and ventricular wall tension respectively as a result of volume/pressure expansion. Both peptides promote vasodilation and natriuresis, owing to reductions in cardiac preload and afterload. BNP produces afferent arteriolar vasodilation and inhibits sodium

reabsorption in the proximal convoluted tubule. BNP also inhibits renin and aldosterone release, is an important diagnostic tool, and has therapeutic implications discussed later in this chapter [15–17].

Myocardial Remodeling

Chronic neurohumoral activation eventually leads to increased myocardial volume and mass. This myocardial remodeling process is responsible for early adaptive mechanisms such as augmentation of stroke volume (Starling mechanism) and decreased wall stress (Laplace mechanism). However, persistent activation of neurohumoral systems is eventually harmful as maladaptive mechanisms such as increased myocardial oxygen demand, myocardial ischemia, impaired contractility, and arrhythmogenesis result. At the cellular level, chronic stimulation of the sympathetic nervous system results in myocyte hypertrophy, myocyte cell death, and eventually cardiac norepinephrine depletion [18]. For these reasons, the neurohumoral system is an important target of therapy resulting in improved long-term heart failure outcomes.

Etiology

Heart failure in children may result from varied etiologies that may depend on the child's age but are best classified by the time course of onset (acute or chronic) and mechanism of failure – systolic, diastolic, or a combination (Table 115.1).

Acute Heart Failure

One of the most common causes of acute cardiac failure in the pediatric population is myocarditis. Myocarditis is usually viral in origin, and patients

Table 115.1 Mechanisms of congestive heart failure

Systolic cardiac failure			Diastolic cardiac failure
Arrhythmias	Intrinsic heart disease	High-output failure	
Supraventricular tachycardia	Myocarditis (infectious, autoimmune)	Anemia	Infiltrative cardiomyopathy (amyloidosis, hemochromatosis, eosinophilic cardiomyopathy)
Bradycardia (complete heart block)	Ischemic heart disease (ALCAPA, Kawasaki's, transplant vasculopathy)	Thyrotoxicosis	Hypertrophic cardiomyopathy
Ventricular tachycardia (arrhythmogenic right ventricular dysplasia – ARVD)	Rheumatic heart disease	Arteriovenous malformations	Restrictive cardiomyopathy
	Valvular heart disease (endocarditis)	Sepsis	Systemic hypertension
	Toxin-induced (anthracyclines, carbon monoxide)		Heart transplant rejection
	Dilated cardiomyopathy (idiopathic, metabolic, postinfectious, genetic)		Sarcoidosis
	Congenital heart disease (right- or left-sided obstruction, chronic valvar insufficiency)		Endomyocardial fibrosis
	Myocardial non-compaction		
	Heart transplant rejection		

with fulminant myocarditis present in shock with rapid onset of hemodynamic deterioration. Endocarditis, rheumatic heart disease, and rarely trauma can result in severe valve injury which can present acutely in the intensive care unit.

Chronic Heart Failure

Patients with chronic heart failure can decompensate and present with signs and symptoms requiring intensive care management. Although it is not always possible to determine the cause, decompensated heart failure can be preceded by an acute infection, noncompliance with medical therapy, or onset of arrhythmias.

Systolic Heart Failure

Most forms of cardiac failure consist of a combination of systolic and diastolic failure. Systolic heart failure is defined by inadequate ventricular inotropy to meet the body's physiologic needs. Systolic heart failure occurs in the setting of myocarditis, dilated cardiomyopathy, ischemia (congenital coronary artery anomalies, Kawasaki's disease, posttransplant coronary vasculopathy, coronary injury after cardiac surgery), excessive pressure (left-sided obstructive lesions), or volume overload (long-standing valve insufficiency, intracardiac shunts). Inadequate perfusion of vital end organs results in presenting signs and symptoms such as mental status changes, poor end-organ function (kidney and liver), and vomiting or feeding intolerance.

Diastolic Heart Failure

Diastolic heart failure is defined by inadequate lusitropy, or abnormalities of ventricular relaxation. Isolated diastolic heart failure is rare and as mentioned above, usually occurs in combination with systolic heart failure. Restrictive and hypertrophic cardiomyopathies are common causes of diastolic heart failure while systolic function is initially preserved. Presentation of diastolic heart failure is related to the extent of elevation in atrial pressure as a result of ventricular stiffness. Elevated right atrial pressure results in jugular venous distention, hepatic congestion, and lower extremity edema. Elevated left atrial pressure is associated with pulmonary edema and orthopnea; exercise intolerance and dyspnea are common. Diastolic heart failure should not be confused with other causes of impaired ventricular filling such as constrictive or restrictive pericarditis, large pericardial effusions, mitral or tricuspid stenosis, or obstruction of systemic or pulmonary venous return. Despite their similar presentation to true diastolic heart failure, ventricular relaxation is usually normal in these settings.

Staging and Classification

The New York Heart Association (NYHA) classification is based on the relation between symptoms and the amount of effort required to provoke these symptoms.

NYHA Classification	
Class I	No limitations. Ordinary physical activity does not cause undue fatigue, dyspnea, or palpitations
Class II	Slight limitation of physical activity, comfortable at rest. Ordinary physical activity results in fatigue, palpitations, or dyspnea
Class III	Marked limitation of physical activity. Although comfortable at rest, less-than-ordinary activity leads to fatigue, dyspnea, or palpitations
Class IV	Symptomatic at rest. Discomfort increases with any physical activity

Because of the inability to use this classification in small children, R. D. Ross has proposed to grade the severity of heart failure in infants based on feeding, respiratory pattern, and clinical parameters [19]:

- Congestive heart failure (CHF) is present with a history of less than 105 ml/feed, respiratory rate greater than 50/min, an abnormal respiratory pattern, diastolic filling sounds, and hepatomegaly.
- Moderate to severe CHF is present when patients take less than 90 ml/feed or greater than 40 min/feed, have an abnormal respiratory pattern with a resting respiratory rate greater than 60/min, and have a diastolic filling sound and moderate hepatomegaly.

- Severe CHF is accompanied by a heart rate greater than 170/min, decreased perfusion, and severe hepatomegaly.

Clinical Features

History Upon Presentation

A comprehensive history may be as important as physical examination. In the infant, clinical history can reveal failure to thrive, poor feeding associated with diaphoresis, vomiting, increased work of breathing, and irritability. The older child can present with dyspnea, orthopnea, paroxysmal nocturnal dyspnea, poor appetite and growth, fatigue, or weakness.

The first manifestation of congestive heart failure is usually tachycardia unless the cause for CHF is related to bradycardia or atrioventricular conduction disorders. Signs of venous congestion are a common finding: left-sided heart failure presents with signs of pulmonary venous congestion, whereas right-sided heart failure presents with signs of systemic venous congestion. Because of the interventricular interactions, failure of one of the ventricles often affects the contralateral ventricle. A detailed discussion on this topic can be found in Chap. "► Cardiopulmonary Interactions."

Later stages of congestive heart failure are characterized by signs and symptoms of low cardiac output and altered markers of tissue perfusion, as patients progress toward lactic acidosis. As described above, congestive heart failure with well-balanced compensatory mechanisms (compensated congestive heart failure) will present with normal cardiac output, whereas congestive heart failure with deleterious or depleted compensatory mechanisms and low cardiac output is considered decompensated.

Physical Examination

Although some of the physical signs of heart failure described in this chapter can be seen in the compensated patient, the focus here will be on the expected features of a patient with decompensated or severe acute heart failure. Most common signs may be as follows.

Clinical findings may include central cyanosis, diminished pulse pressure, dusky discoloration of the skin with delayed capillary refill; reduced systolic arterial pressure, weak, rapid, and thready pulses, evidence of increased adrenergic activity (tachycardia, diaphoresis, pallor, peripheral cyanosis with pallor, and coldness of the extremities), tachycardia or arrhythmia, tachypnea, increased work of breathing, pulmonary rales over the lung bases (frequently accompanied by wheezing, especially in the infant), pleural effusions (usually bilateral) and/or ascites, jugular venous distention and peripheral edema (due to systemic venous hypertension), hepatojugular reflux, hepatomegaly (most reliable sign of cardiac failure in the infant), gallop rhythm, with a protodiastolic (S_3) and/or telediastolic (S_4) gallop (one of the earliest cardiac physical finding in decompensated heart failure), accentuated second heart sound if associated with pulmonary hypertension, cardiomegaly with a displaced apical impulse, systolic murmurs (mitral and tricuspid regurgitation murmurs are often present in patients with decompensated heart failure because of ventricular dilatation), and failure to thrive and cachexia (related to increased total metabolism secondary to augmentation of myocardial oxygen consumption and excessive work of breathing).

Laboratory Studies

The basic laboratory screening recommended in patients with cardiac failure are:

- *Complete blood count*: it is useful to assess anemia, which may cause or aggravate heart failure. Leukocytosis may result from stress or signal an underlying infection.
- *Electrolytes*: a number of tests may be required:
  - *Hyponatremia* reflects an expansion of extracellular fluid volume in the setting of normal total body sodium.

Table 115.2 Viral etiologies of myocarditis

Viral etiologies of myocarditis			
Coxsackie virus	Respiratory syncytial virus	Cytomegalovirus	Herpes virus (herpes simplex and human herpes virus 6)
Adenovirus	Mumps	Echovirus	HIV
Parvovirus B19	Rubella	Epstein-Barr virus	Parainfluenza
Influenza A virus	Varicella	Hepatitis C virus	Measles

  - *Hypokalemia* and *hypochloremia* can be the result of prolonged administration of diuretics.
  - *Hyperkalemia* can be the result from impaired renal perfusion and marked reductions in glomerular filtration rate (GFR) or from intracellular potassium release due to impaired tissue perfusion.
- *Renal function tests*: elevated BUN and BUN/creatinine ratios are seen in decompensated heart failure.
- *Liver function tests*: congestive hepatomegaly is often associated with impaired hepatic function, which is characterized by elevation of aspartate aminotransferase (AST), alanine aminotransferase (ALT), lactic dehydrogenase (LDH), and other liver enzymes. Hyperbilirubinemia is related to acute hepatic venous congestion and is common with severe right heart failure. Elevated alkaline phosphatase and prolongation of the prothrombin time can be seen. In children with long-standing heart failure and poor nutritional status, hypoalbuminemia results from hepatic synthesis impairment.
- *B-type natriuretic peptide*: BNP is a natriuretic peptide released in response to ventricular volume expansion and pressure overload. In normal individuals, BNP levels are elevated immediately after birth but fall to adult levels by 3 months of age [20]. In the setting of heart failure, BNP levels correlate closely with the NYHA classification of heart failure and with ventricular filling pressures [21–24]. BNP levels of more than 80 pg/ml have a good specificity and sensitivity in diagnosing heart failure [17].
- *CPK-MB, troponin I and T*: can be useful if the clinical scenario is suggestive of an ischemic process of with myocarditis.
- *Lactate*: elevated lactate is seen in patients with decompensated heart failure as a result of decreased tissue perfusion and/or decreased metabolism due to secondary liver dysfunction and can be a useful serologic marker for monitoring response to therapeutic interventions. Abrupt elevations on lactate levels may occur early in the process of decompensation and should motivate caregivers to aggressively treat patients, trying to reverse or to compensate the acute changes leading to the cardiac failure. Refractory and progressive lactic acidosis is one of the main markers used to decide the need for extracorporeal life support.
- *Infectious serologies*: viral infections are the most common cause of infectious myocarditis, but bacterial, rickettsial, fungal, spirochetal, and protozoal infections are other possibilities. The table below displays some of the viral etiologies of myocarditis (Table 115.2).
- *Metabolic work-up*: metabolic evaluation of a patient presenting with cardiac failure should be dictated based on patient age, history, and clinical suspicion:
  - Total carnitine level and an acylcarnitine profile can demonstrate carnitine transporter defects.
  - Urine organic and amino acids. Specifically, quantitative 3-methylglutaconic aciduria should be obtained in boys with clinical suspicion for Barth syndrome. This X-linked disorder is associated with dilated cardiomyopathy, failure to thrive, neutropenia, and muscle weakness.

  - Thiamine deficiency is a rare problem in developed countries but, when found, usually occurs in association with lactic acidosis and anemia.
- *Inflammatory markers*: C-reactive protein (CRP), erythrocyte sedimentation rate (ESR), and TNF-α are nonspecific but can be a supportive evidence of an acute inflammatory process and indicative of ongoing cardiac injury. The presence of autoantibodies (e.g., antimyosin) is a negative prognostic finding [25].
- *Endocrine work-up*: thyroid function tests – both profound hyper- or hypothyroidism – can cause heart failure.
- *Arterial blood gas*: usually reveal mild hypoxemia in patients who have mild-to-moderate heart failure. Severe heart failure often leads to severe hypoxemia or even hypoxia. Hypocapnia occurs in the early stages of pulmonary edema because of ventilation/perfusion (V/Q) mismatch, progressing to hypercapnia and respiratory acidosis, related to decreased vital capacity and poor ventilation.

Imaging and Other Studies

Chest Radiography

Chest x-ray may reveal cardiomegaly and alveolar edema with pleural effusions, and bilateral infiltrates in a butterfly pattern are the classic findings in the setting of heart failure. Other signs are haziness of hilar shadows, vascular redistribution, and thickening of interlobular septa (Kerley B lines). Nevertheless, patients with restrictive cardiomyopathy and venous obstruction may have a normal cardiac size.

Electrocardiogram

The electrocardiogram (ECG) may display a number of findings. Sinus tachycardia is a nearly universal finding in acute and decompensated heart failure. Heart rhythm can be abnormal secondary to cardiac dysfunction or electrolyte abnormalities. However, because an underlying primary arrhythmia (e.g., supraventricular tachycardia) may be the cause of heart failure, the heart rhythm at the time of presentations should be closely assessed. Heart block can occur as a result of the inciting event (e.g., in association with infectious myocarditis) or in association with medical therapies (e.g., digoxin, verapamil first-degree or higher levels of heart block, amiodarone-prolonged QTc). Congenital complete heart block is associated with eventual development of dilated cardiomyopathy and heart failure. The reported incidence of heart failure in this patient population has been variable and ranges from 6 % to 23 % [26–28]. Prolonged QTc and abnormal QT dispersion are commonly associated with cardiomyopathies due to repolarization abnormalities, and both have been noted to be markers for poor outcome [29, 30]. Left atrial enlargement and LV hypertrophy are sensitive for chronic LV dysfunction. In the setting of acute LV dysfunction, with the exception of sinus tachycardia, the ECG may be normal. In acute myocarditis, the classic ECG findings are low QRS voltages with T wave flattening or inversion. Prominent Q waves and ST segment abnormalities suggest myocardial ischemia (e.g., anomalous coronary artery).

Echocardiography

Transthoracic echocardiography can thoroughly assess both systolic and diastolic ventricular function. The presence and extent of valvular heart disease, structural congenital heart disease, LV wall thickness, chamber sizes, pericardial disease, regional wall motion abnormalities, and proximal coronary artery distribution and size can all be accurately determined in most children with echocardiography. Shortening fraction (SF) by M-mode and ejection fraction (EF) by M-mode or Simpson's biplane can be obtained. Mitral inflow Doppler, pulmonary venous Doppler, and tissue Doppler techniques can be used to assess left ventricular diastolic function. Transesophageal echocardiography

(TEE) is seldom necessary in pediatric patients as good-quality conventional transthoracic echocardiography is usually obtained. TEE imaging can be helpful when endocarditis is suspected, especially when there is concern about aortic root involvement. Caregivers must be cautious when requesting any diagnostic modality requiring anesthesia or sedation, mostly in patients with decompensated cardiac failure, since induction of anesthesia exposes patients to a high risk of cardiac arrest.

Cardiac Catheterization

Cardiac catheterization is often a necessary adjunct in the diagnostic approach to a patient with heart failure. Direct hemodynamic data in combination with angiograms clarifying structural anatomy can be essential in diagnosing and, in some cases, treating structural causes of heart failure. Despite advances in imaging technology, anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA) remains an elusive diagnosis by echocardiography in some situations and can be definitively identified in the catheterization laboratory. In idiopathic causes of cardiomyopathy, a myocardial biopsy can result in a definitive diagnosis. Viral myocarditis, metabolic storage diseases, infiltrative cardiomyopathies, and mitochondrial disorders among others can be diagnosed by biopsy. However, unfortunately nonspecific findings such as myocyte hypertrophy, abnormal nuclei, and fibrosis are common [31]. Endomyocardial biopsies are not without risk. Injury to the tricuspid valve, heart block, arrhythmias, cardiac perforation, and death, although rare, can occur.

Cardiac Magnetic Resonance Imaging

Cardiac MRI (cMRI) can be a useful noninvasive adjunct in select cases. Myocardial function including wall motion abnormalities as well as myocardial perfusion and viability can be determined with cMRI [32, 33]. Identification of myocardial non-compaction, arrhythmogenic right ventricular dysplasia, and constrictive pericarditis can be difficult diagnoses to make with echocardiography, but can be well defined by MRI.

Monitoring

Care of critically ill patients with CHF should start with the "C-A-B-D" (Circulation-Airway-Breathing-Drugs) principles, aiming to stabilize circulation as a priority. Once these goals are achieved, further management of the heart failure patient is optimized with the use of invasive and noninvasive hemodynamic monitoring strategies:

- Central venous pressure monitoring is necessary to accurately assess fluid status and to evaluate for alterations in the degree of restrictive physiology present. Patients in decompensated heart failure are highly dependent on adequate preload to maintain cardiac output. However, excessive fluid is counterproductive at some point and induction of diuresis may become necessary. An advantage of central lines if inserted in the upper segment of the body is to follow values of central mixed venous saturations as intermittent samples or continuously with specific technologies like the PediaSat Oximetry Catheter (Edwards Lifesciences, Irvine, CA, USA).
- Swan-Ganz catheters allow measurement of right atrial pressure, pulmonary artery pressure, pulmonary capillary wedge pressure, and mixed venous oxygen saturation, as well as the estimation of systemic and pulmonary vascular resistances and cardiac output and index. The use of these catheters is often not realistic in young infants, but transducing any central venous line could be used to trend the filling pressure of the right heart.
- Arterial pressure monitoring is necessary in patients with marked hemodynamic deterioration requiring intravenous support. Continuous arterial pressure readings allow titration of therapy to ensure adequate end-organ perfusion pressure.

- All patients with heart failure should be on constant telemetry in the intensive care unit. Heart rhythm abnormalities and alterations in heart rate must be rapidly assessed and treated.
- In patients who are critically ill and sedated, a Foley catheter can serve as a necessary means of obtaining precise measurements of urine output as a surrogate for renal perfusion.
- Near-infrared spectrometry (NIRS) is a useful noninvasive tool for assessing tissue oxygenation and regional perfusion in the intensive care unit. A study of abdominal site NIRS readings in infants and children requiring an intervention for congenital heart disease demonstrated good correlation with serum lactate and systemic mixed venous saturation [34].

Medical Treatment

Medical therapy of heart failure targets three main objectives:

1. *Preload reduction* results in decreased pulmonary capillary hydrostatic pressure and reduction of fluid transudation into the pulmonary interstitium and alveoli.
2. *Afterload reduction* obtained by decreasing systemic vascular resistance results in increased cardiac output and improved end-organ perfusion.
3. *Inhibition of both RAAS and vasoconstrictor neurohumoral factors* results in vasodilation, thereby increasing cardiac output and reducing myocardial oxygen demand.

Diuretics

Diuretic therapy is the cornerstone of heart failure treatment.

- *Loop Diuretics*
  Loop diuretics inhibit the $Na^+/K^+/2Cl^-$ cotransport system in the loop of Henle. The result is increased excretion of sodium, potassium, chloride, hydrogen, and water. Loop diuretics reduce preload through diuresis and by increasing venous capacitance. Furosemide is the most commonly used, but bumetanide has a higher bioavailability and may be more effective [35]. In patients with diastolic heart failure or restrictive physiology who are minimally fluid overloaded, aggressive diuretic use may be associated with hypotension and adverse outcomes, so careful titration based on cardiac output and central venous monitoring is essential.
- *Thiazides*
  Thiazides inhibit the Na^+/Cl^- co-transporter in the distal convoluted tubule resulting in increased sodium and chloride excretion. Hydrochlorothiazide, chlorothiazide, and metolazone are particularly useful in combination with loop diuretics in patients suffering from heart failure.
- *Potassium-Sparing Diuretics*
  The mechanism of action of spironolactone is to block aldosterone effect in the distal tubule and collecting duct. The association of a loop diuretic and spironolactone is useful to maintain serum potassium levels and avoid the need for potassium supplements. The RALES (Randomized Aldactone Evaluation Study) trial in adults demonstrated improved NYHA class and decreased mortality and hospitalization rate in patients with advanced heart failure treated with spironolactone [36]. Whether these findings would translate to the pediatric population is unknown.

Vasodilators

- *ACE Inhibitors*
  ACE inhibitors block the adverse effects resulting from the chronic activation of the renin-angiotensin system that occurs in heart failure. Prevention of the formation of angiotensin II and its subsequent vasoconstrictive effects and promotion of vasodilation via bradykinin result in reduced afterload and preload and improved stroke volume and cardiac output. Left ventricular remodeling is diminished by ACE inhibitor therapy. Prevention of the formation of angiotensin II results

in limitation of myocyte hypertrophy, fibrosis, and myocyte apoptosis that would otherwise occur [37]. Captopril rather than enalapril is preferred in neonates because of the delayed capacity of neonates to biotransform enalapril to enlalaprilat [38]. Studies consistently demonstrate that ACE inhibitors prolong survival and reduce morbidity in heart failure [39–41]. In children with a left-to-right shunts, ACE inhibitors reduce the Qp:Qs by decreasing systemic vascular resistance but are less effective in those with elevated pulmonary pressures [42, 43]. ACE inhibitors have also been demonstrated to be efficacious for valvar regurgitation in children [44]. Angiotensin receptor blockers (ARBs) inhibit angiotensin II and are especially useful in patients with heart failure who are otherwise intolerant of ACE inhibitors [45].

- *Sodium Nitroprusside*
  Sodium nitroprusside results in simultaneous preload and afterload reduction with a greater effect on afterload reduction through direct smooth muscle relaxation. Potency and rapidity of onset make it an ideal medication in critical situations, and dose should be titrated based on reduction in filling pressures and improvement in symptoms. Because it may induce precipitous falls in blood pressure, intra-arterial blood pressure monitoring often is recommended. By-products of nitroprusside include nitric oxide and cyanide. Prolonged use and use in those with hepatic dysfunction should be avoided due to increased risk of thiocyanate toxicity.
- *Nitroglycerin*
  Intravenous nitroglycerin provides rapid and titratable preload reduction by increasing venous capacitance. Its arterial vasodilatory effects result in afterload reduction as well. It is widely used in the adult population for patients with ischemic heart disease given its coronary vasodilatory properties and more sporadically used in pediatrics. Nitroglycerin may be useful in children who have had coronary reimplantation as a result of the arterial switch operation or ALCAPA repair, as it provides afterload reduction while decreasing myocardial oxygen consumption and providing coronary vasodilation and decreasing transmural tension. Nitroglycerin may reverse the coronary vasoconstrictive effects of endothelin-1 post-bypass in children undergoing cardiac surgery [46].
- *α-Adrenergic Blockers*
  Phenoxybenzamine, phentolamine, and nicergoline are potent vasodilators that have been used for the treatment of severe left ventricular failure. Although not widely used for heart failure, these drugs decrease peripheral vascular resistance, resulting in an increase in cardiac output and stroke volume. Combined use of phenoxybenzamine and dopamine has been shown to be beneficial in children with low cardiac output syndrome who are difficult to wean from cardiopulmonary bypass, by preventing the α-adrenergic action of dopamine and encouraging its β-adrenergic action [47].

Intravenous Inotropes

Inotropic support must be used judiciously and with caution in the setting of patients with heart failure. Although increased inotropy results in improved cardiac output and blood pressure, it comes at the expense of increased myocardial oxygen consumption and demand. The failing myocardium has a limited reserve, and complete hemodynamic collapse can occur as a result of high-dose inotropic support in this setting. For this reason, early and elective use of mechanical circulatory support should be considered in all patients with severe myocardial dysfunction that is refractory to medical therapy including low-dose inotropic support. Mechanical support is covered in detail elsewhere and will not be discussed in this chapter.

- *Dopamine*
  Effects of dopamine are dose dependent. As with other inotropic agents, moderate and high dosages are arrhythmogenic and may be counterproductive as a result of increased myocardial oxygen demand. Low dosages (0.5–3 μg/kg/min) cause stimulation of dopaminergic receptors within the renal and

splanchnic vascular beds, causing vasodilation and increased diuresis. Moderate dosages (3–10 μg/kg/min) cause stimulation of β-receptors in the myocardium, resulting in increased cardiac contractility (inotropy), blood pressure, and heart rate. High dosages (10–20 μg/kg/min) cause stimulation of α-receptors, resulting in peripheral and pulmonary vasoconstriction and therefore increased SVR and PVR.

- *Dobutamine*
  Dobutamine is a β_1-receptor agonist, with some β_2-receptor and minimal α-receptor activity. Intravenous dobutamine induces significant positive inotropic effects with mild chronotropic effects. It also induces mild peripheral vasodilation, decreasing SVR and PVR. The combined effect of increased inotropy with decreased afterload results in a significant increase in cardiac output.
- *Epinephrine*
  Epinephrine or adrenaline is a β_1-, β_2-, and α-receptor agonist that primarily exerts β effects at low doses (0.01–0.02 μg/kg/min) with α and β effects at higher doses. Vasodilation via β_2-receptor effect is seen in low doses, while at higher doses, positive inotropic effects, tachycardia, and mild increased blood pressure secondary to vasoconstriction result.
- *Norepinephrine*
  Norepinephrine or noradrenaline is an α- and β_1-receptor agonist, resulting in vasoconstriction and significant increases in afterload with subsequent increase in myocardial oxygen demand and reduced cardiac output.
- *Isoproterenol*
  Isoproterenol or isoprenaline is a β_1- and β_2-receptor agonist, induces increased inotropy and increased heart rate, but is potentially arrhythmogenic.

Phosphodiesterase Inhibitors

- *Milrinone and Amrinone*
  Phosphodiesterase inhibitors (PDEIs) increase intracellular cyclic AMP (cAMP) by inhibiting phosphodiesterase III. Increased cAMP results in improved calcium metabolism by the sarcoplasmic reticulum. The hemodynamic results of increased cAMP are positive inotropic effect, peripheral vasodilation, and improved myocardial relaxation (lusitropy). PDEIs do not cause tachycardia, and therefore, myocardial oxygen demand is not increased as with other inotropic agents. However, ventricular arrhythmias remain a side effect. Milrinone has been demonstrated to be useful in children with low cardiac output syndrome following cardiac surgery [48, 49]. As PDEIs are not dependent on adrenoreceptor activity, they are less likely to induce tolerance. Alternatively, tolerance to catecholamine-based inotropes can develop rapidly through downregulation of adrenoreceptors. In adult studies, oral milrinone therapy for heart failure was associated with worse outcome and increased mortality [50].

Oral Heart Failure Agents

- *β-Adrenergic Blocking Agents* (Metoprolol, Carvedilol)
  Ratio of β_1:β_2-receptors in the non-failing myocardium is approximately 3:1. Downregulation of β_1-receptors in the failing heart results in a ratio of 1:1. The beneficial effect of β-blockade is mediated primarily through inhibition of sympathetic system activation that occurs in heart failure but also reversal of adverse remodeling and upregulation of myocardial β-receptors. β-blockers improve symptoms, exercise tolerance, cardiac hemodynamics, LV ejection fraction, decrease mortality, and decrease myocardial oxygen consumption [51–53]. β-blockers are recommended for use in adults with stable heart failure resulting from left ventricular dysfunction. Data in children with heart failure show less evidence for their systematic use: only one randomized double-blind trial enrolled children with symptomatic systemic ventricle dysfunction and showed no clinical beneficial effect, probably because the events were rare and 20% of children had an non-LV

in systemic position [54]. β-blocker effectiveness for heart failure depends on the type of β-receptor activity present as well as α-blocking properties. Carvedilol, specifically is a β1- and β2-antagonist, is an α-blocker and has antioxidant effects, and is thus thought to have advantages over agents such as metoprolol – a pure β_1-blocker [55]. In children with left-to-right shunts and overcirculation, β-blocker therapy improves feeding, weight gain, and symptoms [56]. When initiating therapy, β-blockers should be started at a very low dosage and gradually increased to maximum therapeutic dosage with close monitoring according to heart rate and blood pressure [57].

- *Digoxin*
  Digoxin acts by inhibiting the Na^+/K^+–ATPase transport pump and inhibits sodium and potassium transport across cell membranes. This increases the velocity and shortening of cardiac muscle, resulting in a shift upward and to the left of the ventricular function (Frank-Starling) curve. The positive inotropic effect is due to an increase in the availability of cytosolic calcium during systole, thus increasing the velocity and extent of myocardial sarcomere shortening [58, 59]. Routine use of digoxin for pediatric heart failure is controversial. Adult studies demonstrate no mortality benefit but improved symptoms and decreased hospitalizations [60]. Digoxin toxicity can affect the gastrointestinal (nausea, vomiting), neurologic (headache, visual disturbances), and cardiac (heart block, arrhythmias) systems. Particular attention should be paid when digoxin is used in association with loop diuretics, as hypokalemia enhances digoxin intoxication.
- *Nesiritide*
  Nesiritide is a recombinant B-type natriuretic peptide used for symptomatic relief of acute decompensated heart failure in adults. In children with primary heart failure or low cardiac output after heart surgery, nesiritide has been associated with improved diuresis [61]. In children awaiting cardiac transplantation, nesiritide has been related to increased urine output without significant blood pressure change [62]. Pediatric data is still scarce.
- *Levosimendan*
  Levosimendan is a new calcium-sensitizing agent with inodilator properties. In children with low cardiac output post-cardiopulmonary bypass, levosimendan demonstrates trends toward improved hemodynamics with heart rate reduction, increase in mean arterial blood pressure, improvement of systolic and diastolic function, reduction in lactate, and reduced conventional inotropic requirement [63]. Levosimendan does not increase myocardial oxygen consumption and has also resulted in objective improvement in myocardial performance in children with end-stage or acute heart failure who are dependent on intravenous inotropic support [64].

Anticoagulation

Intracardiac thrombus and embolic events are a complication of heart failure in children. The protective effect of anticoagulation to prevent thromboembolic events is unclear with ongoing studies aimed at determining optimal therapy [65]. Risk factors to consider include severe left ventricular dysfunction and dilation, history of thromboembolism, and atrial fibrillation.

Nutrition

Growth failure is common in infants and children with significant heart failure due to increased metabolic demands. Infants suffering from heart failure require a higher caloric intake, about 140–160 kcal/kg of body weight, to ensure adequate weight gain [66]. In order to avoid volume overload, the concentration of the formula is increased (20–24 kcal/ounce of 0, 67-0, 8 kcal/ml) provided no osmotic diarrhea occurs. If the child is too sick to eat by mouth, gavage feeding should be instituted. In infants with severe heart failure or ductal-dependent circulation, enteric feeding should be carefully

monitored as mesenteric ischemia can lead to necrotizing enterocolitis. In this situation, parenteral nutrition is an alternative.

Outcome

The outcome of pediatric heart failure depends on the underlying diagnosis and the availability of appropriate medical and surgical treatment. Dilated cardiomyopathy is the most common form of heart muscle disease in children. The survival rate for this disease in children is highly variable, ranging from 40 % to 80 % at 5 years [67–70]. Myocarditis has generally had a better prognosis than idiopathic dilated cardiomyopathy even if mechanical circulatory support is necessary. Fifty to eighty percent of patients with viral myocarditis have been reported to have complete resolution of their cardiomyopathy within 2 years of their diagnosis [71–73]. Children with failed palliation of congenital heart defects present another group of patients that require management for heart failure. Systemic right ventricular failure, single ventricle failure, or post-cardiopulmonary bypass failure all present unique management challenges in the cardiac intensive care unit. New modalities of therapy have improved outcomes and survival in pediatric patients with heart failure. Mechanical circulatory support and heart transplantation are viable options in patients with end-stage heart disease or complex cardiac defects. These subjects are discussed in detail elsewhere in this text and therefore will not be addressed here, but nevertheless, are important and vital adjuncts when medical therapy fails.

Cardiomyopathies and Acute Myocarditis

116

Brian Feingold and Steven A. Webber

Abstract

Cardiomyopathies are a heterogeneous group of diseases caused by a functional abnormality of the cardiac muscle that are generally considered as primary or secondary, showing pathological myocardial involvement secondary to a systemic or multiorgan disease process. Both forms are commonly seen in children, although primary forms predominate. They may be caused by extrinsic or genetic factors. The incidence of cardiomyopathy varies widely according to patient ethnicity. Genetic testing plays an important role in the care of patients with cardiomyopathy and their families because it confirms diagnosis, may determine the appropriate care for the patient, and possibly delineates prognosis. Cardiomyopathies are associated with mechanical and/or electrical dysfunction that usually exhibit inappropriate ventricular hypertrophy or dilatation. Cardiomyopathies and myocarditis are significant contributors to end-stage heart failure in children, and the commonest indication for ventricular assist device support in childhood. Many cases may be unrecognized and go on to experience clinical recovery. Some may be misdiagnosed as sudden infant death syndrome. Others may present years later as chronic dilated cardiomyopathy with viral genome demonstrated in the myocardium but in the absence of active inflammation. This chapter will provide an overview of the child with new-onset or established cardiomyopathy.

Introduction

Cardiomyopathies are a heterogeneous group of diseases caused by a functional abnormality of the cardiac muscle. The definition and classification of cardiomyopathies was recently revised by an expert panel of the American Heart Association [1] following the initial classification by the World Health Organization in 1995 [2]. Cardiomyopathies were defined as "a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes that frequently are genetic" [1]. Cardiomyopathies are generally considered as primary (disease solely or predominantly confined to heart muscle) or secondary, showing pathological myocardial involvement secondary to a systemic or multiorgan disease process. Both forms are commonly seen in children, although primary forms predominate.

The incidence of cardiomyopathy varies widely according to patient ethnicity. Genetic testing plays an important role in the care of patients with cardiomyopathy and their families because it confirms diagnosis, it may determine the appropriate care for the patient, and possibly delineates prognosis.

Cardiomyopathies and myocarditis are significant contributors to end-stage heart failure in children, accounting for over 50 % of all pediatric heart transplants [3]. They are also the commonest indication for ventricular assist device support in childhood [4]. Pediatric cardiomyopathies have a reported incidence of 1.13–1.24 cases per 100,000 population in two large population-based studies [5, 6], though this is likely an underestimate. The true incidence of pediatric myocarditis is unknown. Many cases may be unrecognized and go on to experience clinical recovery. Some may be misdiagnosed as SIDS [7]. Others may present years later as chronic dilated cardiomyopathy with viral genome demonstrated in the myocardium but in the absence of active inflammation [8–10].

Management of the acutely decompensated patient with cardiomyopathy comprises the determination of the form of cardiomyopathy and of the most likely etiology (most commonly discerning between acute myocarditis and an acute presentation of dilated cardiomyopathy), management of acute heart failure and/or arrhythmias, and the estimation of prognosis and selection of patients for mechanical circulatory support and transplantation.

This chapter will provide an overview of myocarditis and the most common cardiomyopathies, namely, dilated, restrictive, and hypertrophic, as well as of the left ventricular non-compaction.

Dilated Cardiomyopathy and Myocarditis

Anatomic Considerations

Dilated cardiomyopathy (DCM) is characterized by dilation of one or both ventricles (most commonly the left ventricle) often with thinning of the left ventricle free wall. Varying degrees of hypertrophy may also be seen and left ventricular mass tends to be increased, even when the ventricular walls are thin. The left ventricle often takes on a globular shape and mitral regurgitation with annular dilation is frequently seen along

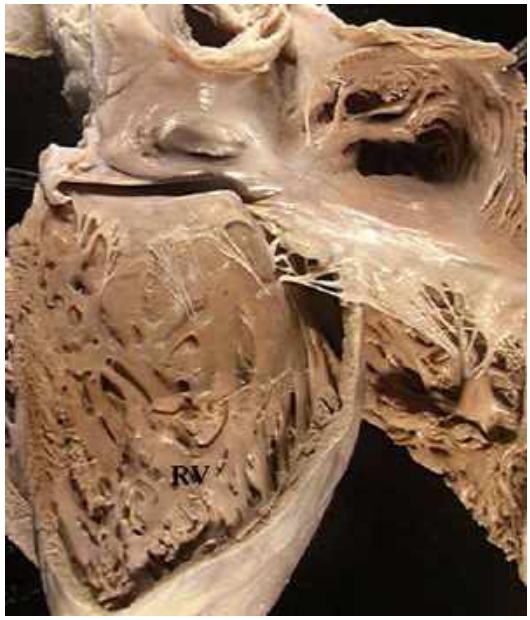

Fig. 116.1 Dilated cardiomyopathy with marked ventricular dilation and wall. Thinning *RV* right ventricle (Courtesy of William Devine, Department of Pathology, Children's Hospital of Pittsburgh)

Fig. 116.2 Echocardiographic findings of a dilated cardiomyopathy. Parasternal long axis view demonstrates severe left ventricular dilation in a child with idiopathic dilated cardiomyopathy. *LV* left ventricle, *LA* left atrium

with left atrial dilatation (Figs. 116.1 and 116.2). Left ventricular systolic function is usually globally depressed, though varying degrees of ventricular dyssynchrony may be observed, even in the absence of bundle branch block. In contrast, right systolic ventricular function is often only minimally decreased or normal. Right ventricular dilation, when present, may be due to myocardial involvement from the primary disease process or secondary to tricuspid regurgitation and pulmonary hypertension.

In contrast, patients with acute myocarditis often show only a poorly functioning left ventricle with minimal dilation, with or without regional wall motion abnormalities. There may be ventricular thickening secondary to myocardial edema, and left atrial enlargement may not be prominent, even when mitral regurgitation is present. These findings likely reflect the short duration of the disease process.

Etiology and Pathophysiology

Both acute myocarditis and DCM are characterized primarily by systolic ventricular dysfunction with resultant clinical signs and symptoms of heart failure. Diastolic dysfunction may also contribute to reduced myocardial performance in both settings, but particularly in acute myocarditis. In the latter, cardiac dysfunction may result from both direct viral invasion and myocyte lysis, as well as from the effects of myocardial inflammation. In clinical practice beyond the neonatal period, symptoms are most often associated with a presumed post viral lymphocytic infiltrates and autoimmunity. Adenovirus and enteroviruses (particularly Coxsackie B) are most frequent in children [11], although many other infectious and noninfectious causes have been identified including viral, bacterial, fungal, and protozoal infections, as well as drug toxicities, and various systemic disorders. The latter include Kawasaki disease and rheumatic fever.

Pediatric DCM encompasses a final common phenotype for a wide variety of etiologies. While the causes of most pediatric DCM are unknown, it is estimated that 30–40 % of DCMs are inherited [12, 13], mostly in an autosomal

dominant fashion. Mutations in genes encoding myocyte cytoskeletal proteins as well as genes encoding sarcomere proteins have recently been identified as etiologies for DCMs [14]. Other genetic causes include inborn errors of metabolism (e.g., mitochondrial transport chain defects) [15] and neuromuscular syndromes (e.g., muscular dystrophies). Also, the finding of viral genome in patients with DCM suggests that at least some DCMs may result from prior myocarditis (either apparent or clinically unapparent) [9]. Other acquired forms of DCM include medication related (e.g., anthracycline toxicity) and arrhythmia induced (e.g., chronic, incessant supraventricular tachycardia).

Clinical Presentation

Heart failure in children from any cause often presents somewhat insidiously, after repeated evaluation and medical testing for other, more common conditions. Neonates and infants often present acutely unwell, yet the diagnosis of a primary cardiac disorder may not be made on initial evaluation. It is not uncommon for cardiac disease to be considered only after ancillary studies fail to corroborate the presumed diagnosis or initial resuscitative attempts fail to improve the child's condition (e.g., shock due to sepsis). While much of the diagnostic difficulty results from the relative infrequency of primary cardiac disease in children, the inability of an infant or young child to verbally convey their symptoms also contributes. Also, the frequency with which young children experience nasal, respiratory, or gastrointestinal symptoms, particularly during winter and spring, often results in the initial symptoms of heart failure being attributed to these much more common maladies.

Infants with heart failure may present with a history of poor feeding, respiratory distress, listlessness, poor weight gain, or irritability. Common adult symptoms of paroxysmal nocturnal dyspnea and orthopnea are uncommon in pediatric patients. In older children, abdominal pain, anorexia, nausea, and vomiting are often observed and are likely due to liver capsule distention from hepatomegaly and/or intestinal venous congestion.

On physical examination, the child may appear anxious and sinus tachycardia is usually present. Sweating is common in infants. Elevation of the jugular venous pulse may be present but is difficult to identify in the infant and toddler. Pallor and cool extremities may be present and are often associated with poor peripheral pulses and prolonged capillary refill. Resting tachypnea and retractions (suprasternal, intercostal, and subcostal) are common. Unlike adults, crackles are exceedingly rare in infants and young children with heart failure, even when pulmonary edema is present. Wheezes are more likely to be present. While hepatomegaly is a common finding, it is often overlooked or underappreciated by the inexperienced practitioner. Periorbital edema (infants and young children) with or without ascites (older children) are more common than peripheral edema in children. Failure to thrive may also be evident, particularly with chronic heart failure.

The clinical distinction between acute, fulminant myocarditis and acute presentation of chronic DCM is often difficult. At the time of presentation, many will have a history of an intercurrent or recent viral illness. In fact, viral syndromes are so common in early childhood that the etiologic relationship to the onset of acute heart failure is often not clear. However, the distinction between myocarditis and DCM is crucial. Many patients with fulminant myocarditis will recover completely if able to be supported, whereas children with severely decompensated heart failure from DCM often will not recover without transplantation. Hence, the expectations from mechanical support (ECMO or ventricular assist device) and consideration for cardiac transplantation are directly impacted by the underlying diagnosis.

In many cases, clinical testing may help guide the diagnosis of acute myocarditis or acute presentation of DCM. The presence of marked cardiomegaly on chest radiograph and massive left-sided precordial forces on *ECG* suggest the underlying process occurred over some time, favoring a diagnosis of chronic DCM over

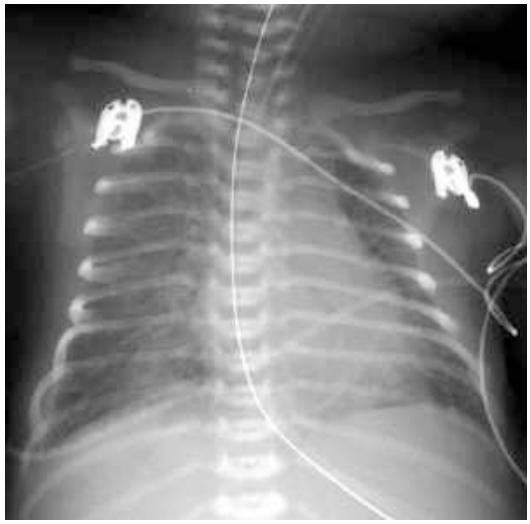

Fig. 116.3 Acute myocarditis. Chest radiograph shows a small heart with pronounced pulmonary edema

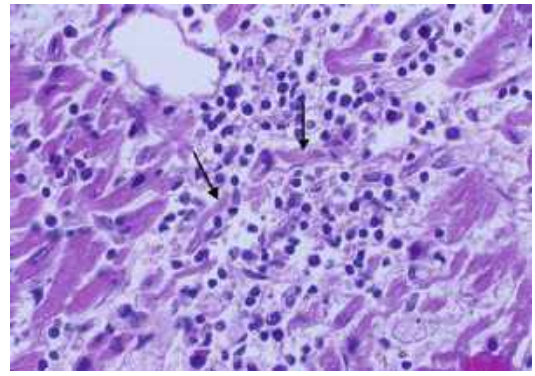

Fig. 116.4 Endomyocardial biopsy specimen showing lymphocytic infiltrate with myocyte destruction characteristic of acute myocarditis (*arrow*)

myocarditis. In contrast, absence of (or mild) cardiomegaly (Fig. 116.3) and globally diminished voltages on electrocardiogram are more typical of acute myocarditis. Frank myocardial infarction may sometimes be observed on the 12-lead ECG of children with acute myocarditis. Echocardiography is very useful in the evaluation of infants and children suspected to have either myocarditis or cardiomyopathy and should be performed in all patients in whom these diagnoses are considered. Endomyocardial biopsy can generally be performed safely in children over the age of 1 year [16] and should be considered in the diagnostic evaluation, particularly when trying to distinguish between myocarditis and DCM. Biopsy samples from the right ventricle can be analyzed by routine hematoxylin and eosin staining for lymphocytic infiltrates with myocyte necrosis (Fig. 116.4) consistent with a diagnosis of acute myocarditis [17] or for evidence of myocyte hypertrophy and/or interstitial fibrosis, favoring a diagnosis of DCM. A fresh-frozen sample should also be obtained for PCR analysis of common viral causes of myocarditis. Viral cultures of stool, urine, and respiratory secretions may contribute to the diagnosis, as may polymerase chain reaction analysis of blood, pericardial effusion, or cerebral spinal fluid. Viral titers (at presentation and during convalescence) are often performed but are generally noncontributory to the diagnosis of childhood myocarditis.

Diagnostic *evaluation for* inborn errors of metabolism is generally reserved for patients presenting with dilated or hypertrophic cardiomyopathies in the first year of life. The presence of severe acidosis, hypoglycemia, elevated lactic acid, deranged liver function tests, and hyperammonemia should all lead to rapid metabolic and genetic evaluation although all these may also be observed in the setting of cardiogenic shock from non-metabolic causes. A full description of the evaluation of infants suspected of having an inborn error of metabolism is beyond the scope of this chapter, but readers are referred to some excellent recent reviews [15, 18, 19].

Management of Dilated Cardiomyopathy and Myocarditis

The critically ill patient, who presents on the verge of hemodynamic collapse, requires aggressive therapy to augment oxygen delivery while minimizing consumption. Intubation with mechanical ventilation and sedation (± paralysis) is useful to eliminate the work of breathing while improving pulmonary edema as a result of positive pressure ventilation. The placement of central venous and arterial monitoring lines is

also facilitated by these maneuvers. In addition to being able to administer medications and monitoring hemodynamics, these lines serve to limit the need for repeated phlebotomy in infants and young children, in whom fear, agitation, and site availability are complicating issues. The use of pulmonary arterial catheters is less common in the pediatric age group than in adults and rarely improves management when it is apparent that pulmonary edema is of cardiac origin.

Intravenous diuretics are used to augment diuresis and improve congestive symptoms. Continuous infusions of furosemide have been used with success in pediatric patients when intermittent dosing has failed to result in adequate diuresis. Inotropes are used to augment cardiac function and output. Therapy often consists of low to moderate doses (2–5 μg/kg/min) of dopamine for renal perfusion and blood pressure support and milrinone (0.125–1 μg/kg/min) to diminish afterload and augment cardiac output. Augmented inotropy can be achieved with dobutamine (1–10 μg/kg/min), while further afterload reduction may be achieved with sodium nitroprusside (0.3–4 μg/kg/min), if blood pressure tolerates. Rarely do patients require support with infusions of high doses of epinephrine or norepinephrine. In these cases, except when pathology is believed to be rapidly reversible, serious consideration should be given to early institution of mechanical circulatory support. Caution must also be taken with regard to the arrhythmogenic potential of all inotropes, particularly with escalating doses. Appropriate monitoring is essential and care must be taken to aggressively correct all electrolyte disturbances, particularly hypo- or hyperkalemia and hypomagnesemia.

Only limited data exists regarding the use of nesiritide for the treatment of acute heart failure in the pediatric population. The authors' experience has primarily involved its use in children who were otherwise recalcitrant to diuretics [20]. With appropriate monitoring of blood pressure and serum sodium, no complications were noted and some success was achieved in inducing diuresis. Others have reported the use of nesiritide immediately after cardiac surgery, reporting no adverse hemodynamic effects or arrhythmias [21].

With stabilization and improvement in end-organ perfusion, gradual weaning of therapies is indicated. When oral medications can be safely tolerated and adequately absorbed, digoxin is often initiated, though of unproven benefit in pediatric patients. Intravenous diuretics are changed to oral forms and angiotensin-converting enzyme (ACE) inhibitors are begun for afterload reduction while weaning milrinone. Beta-blockers (other than as antiarrhythmic agents) have only a limited role in the ICU care of the child with DCM. Indeed, during acute deterioration requiring use of intravenous inotropes, beta-blockers will generally need to be withdrawn. Institution of beta-blockers for new-onset DCM is generally not performed in the intensive care unit, since any benefits (if they exist) are long term, and patients in the ICU are often hypotensive or being aggressively diuresed and vasodilated. Introduction of beta-blockers is part of the long-term management of chronic heart failure and is of unproven benefit (though widely performed) at this time [22]. Usually, beta-blockers are commenced after transition to oral diuretic therapy and once ACE inhibitor dosing is optimized. This generally occurs on the medical floors or in the outpatient setting.

When acute heart failure is unresponsive to aggressive medical management, institution of mechanical circulatory support must be considered. In general, ventricular assist devices are most appropriate when used as a bridge to transplantation, since prolonged periods of support may be required. Recovery from acute (including fulminant) myocarditis is often rapid, so ECMO or short-term use of VADs are more appropriate.

In acute myocarditis, therapy is primarily supportive. Only rarely is infection caused by a specific agent for which there is established antimicrobial therapy of proven efficacy. Intravenous immunoglobulin and corticosteroids have both been used [23], though there is no proof of their efficacy in randomized clinical trials. Steroids are contraindicated when there is evidence of active viral infection. More potent

immunosuppressive agents, including T-cell cytolytic agents and calcineurin inhibitors, have been used in some programs. There is no data to support a specific risk/benefit ratio, and most programs do not use these agents.

Avoidance of dysrhythmias is a key component in the management of all patients with acute and chronic heart failure. In addition to careful attention to maintaining normal serum electrolyte concentrations, control of supraventricular and ventricular tachyarrhythmias is important. Amiodarone is commonly used for treatment and prophylaxis of ventricular tachycardia, as well as for refractory atrial tachycardias.

The role of implanted cardioverter-defibrillators (ICDs) in the management of children and adolescents has not been as well defined as in adults. Evidence suggests children with DCM have a lower risk of sudden death as compared to adults with similar degrees of ventricular dysfunction [24, 63]. Nonetheless, in children with DCM, particularly those with evidence of ventricular tachycardia, ICDs have been utilized and are likely indicated in patients with syncope and aborted sudden death. Factors which may complicate placement of ICDs in children include greater risk of complications such as lead fracture (possibly due to growth or greater levels of activity in children as compared to adults); greater risk of inappropriate discharge due to ability to achieve higher sinus heart rates; and the inability to use endovascular leads in smaller children (<15 kg), necessitating epicardial lead placement [25].

Long-Term Outcomes

Traditionally, long-term outcomes in children with DCM was said to follow the "rule of thirds" with 1/3 improving, 1/3 remaining the same, and 1/3 demonstrating progressive deterioration in cardiac function. Recent population data from several groups has improved the understanding of the natural history of dilated cardiomyopathy. The National Australian Childhood Cardiomyopathy Study showed a 5-year freedom from death or transplantation of 63 % for children with dilated cardiomyopathy [26, 27]. The Pediatric Cardiomyopathy Registry showed a 5-year transplant-free survival of 54 % for dilated cardiomyopathy in North America [28, 29]. These data include outcomes for those followed with a diagnosis of dilated cardiomyopathy that may never have required intensive care. It is, therefore, of interest to note a recent important publication which focused on epidemiology and outcomes for new-onset heart failure from myocardial (nonstructural) disease. In a population-based study for the United Kingdom and Ireland, 82 % of children presenting with new-onset heart failure (most due to dilated cardiomyopathy) were in NYHA (or Ross) class III or IV and 41 % required mechanical ventilation during first admission. One-year transplant-free survival was only 66 % [30]. This is far worse than outcomes for new-onset heart failure in adults. Predictors of survival for dilated cardiomyopathy vary considerably between series. In a systematic review [31] and a recent publication of pediatric cardiomyopathy registry data [64], it was noted that the most consistent findings associated with improved outcome were younger age at diagnosis, better fractional shortening and ejection fraction at diagnosis, and presence of myocarditis.

In general, the outcomes of acute myocarditis in children are good. A number of studies have shown survival rates of between 75 % and 100 % for acute myocarditis in childhood [23], including fulminant cases that may require mechanical circulatory support. This emphasizes the benefit of knowing the diagnosis of myocarditis, since acute transplantation should be avoided even if mechanical support is required. This will provide the opportunity for cardiac recovery, as well as minimize the risks of transplantation during recent or active viral infection.

Hypertrophic Cardiomyopathy

Anatomic Considerations

In hypertrophic cardiomyopathy (HCM), it is most common for patients to show asymmetric hypertrophy of the interventricular septum, with

Fig. 116.5 Echocardiography showing asymmetric septal hypertrophy in a child with hypertrophic cardiomyopathy. *Arrows*: hypertrophic interventricular septum; *RA* right atrium, *LA* left atrium, *LV* left ventricle

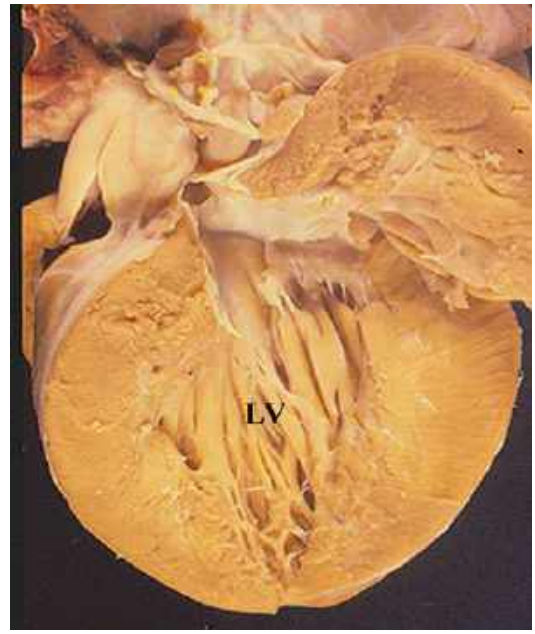

Fig. 116.6 Severe hypertrophic cardiomyopathy with concentric hypertrophy, secondary to Pompe's disease (glycogen storage disease type II) (Courtesy of William Devine, Department of Pathology, Children's Hospital of Pittsburgh)

varying degrees of obstruction to left ventricular outflow due to prominence of the subaortic septum and/or systolic motion of the anterior leaflet of the mitral valve (Fig. 116.5). Less commonly, children with HCM may demonstrate concentric left ventricular hypertrophy (Fig. 116.6). In infant presentation, involvement of both the left and right ventricles is common, and biventricular obstruction may occasionally be observed. Because ventricular hypertrophy may not be apparent until puberty, children with a family history of HCM in whom no genetic diagnosis/marker has been established should undergo serial evaluation with electro- and echocardiography before, during, and after puberty to assess for development of abnormal cardiogram and ventricular hypertrophy.

Etiology and Pathophysiology

HCM is most commonly an inherited disorder (autosomal dominant) with marked variability in clinical expression. Nearly all mutations identified to date are in ten genes which encode cardiac sarcomere proteins [32]. It is likely that many other disease-causing mutations have yet to be identified. When there is a known familial mutation, testing of relatives can rule out disease. However, in many families, no mutation is identified, or testing has not been performed. It is estimated that current screening panels for sarcomeric protein mutations reveal mutations in approximately 70 % of cases. Other causes of pediatric HCM include conditions associated with left ventricular hypertrophy such as glycogen or lysosomal storage diseases, mitochondrial defects, and Noonan, LEOPARD, and Beckwith-Wiedemann syndromes.

Patients with HCM generally have thickened left ventricle walls with normal or decreased cavity size, preserved or hyperdynamic systolic function. A subgroup with pronounced restrictive physiology and atrial dilatation has been reported [33]. In some cases, there appears to be overlap of phenotype with restrictive cardiomyopathy. Cases of classical hypertrophic and restrictive cardiomyopathy have been observed in different members of the same family, some due to cardiac troponin I mutations [34].

Heart failure symptoms are very rare in children and adolescents with hypertrophic cardiomyopathy, and they are most commonly

a result of diastolic dysfunction. The exception is the infant with severe disease, often with biventricular hypertrophy with or without outflow obstruction. These infants commonly present with heart failure. Metabolic and genetic work-up is warranted in these cases.

Syncope and aborted sudden death may be observed in patients with hypertrophic cardiomyopathy. The pathophysiology is often hard to define. Tachycardia and hypovolemia (e.g., due to dehydration and fever) may be poorly tolerated, and impaired myocardial perfusion, severe obstruction, inappropriate peripheral vasomotor tone, and atrial and ventricular arrhythmias may all contribute to syncope and mortality in HCM.

Clinical Presentation

Patients with HCM may present in the absence of symptoms (e.g., for evaluation of a murmur) or due to a family history. Progressive activity intolerance and syncope are also common presenting complaints; however, it should be noted that in clinical practice most children with these symptoms do not have cardiomyopathy. Infants who are affected may show tachypnea, hepatomegaly, and/or failure to thrive. In older children, chest pain may also be a symptom and suggests myocardial ischemia [32]. Unfortunately, it is not uncommon for sudden death (or aborted sudden death) to be the initial presentation of HCM in adolescents and young adults [35]. Undiagnosed HCM is a leading cause of sudden death in young, healthy individuals and athletes.

Management of Hypertrophic Cardiomyopathy

Most children with HCM are asymptomatic and thus do not often need admission to the ICU. While progression to end-stage heart failure occurs, the diagnosis is relatively rare in children, accounting for only 2.5 % of pediatric heart transplant listings in a recent analysis of over 3,000 pediatric transplant candidates from a large, multicenter database [36]. With advancing symptoms of heart failure, patients may be admitted to the hospital for treatment. Although so-called burned-out HCM occurs in children in which there is progressive systolic dysfunction and left ventricular dilation, heart failure from HCM results predominantly from diastolic dysfunction. Thus, many of the therapies employed in the treatment of heart failure from DCM are not useful or are only of limited benefit.

An ideal agent for management of heart failure due to HCM would possess positive lusitropic effects, enabling relaxation of the ventricular myocardium and thus achieving improved stroke volume at lower filling pressures. Unfortunately, this agent does not yet exist and therapies directed primarily at management of diastolic ventricular dysfunction are scant. Most common is the use of negative inotropic agents, such as non-dihydropyridine calcium channel blockers (e.g., verapamil) or beta-blockers (e.g., propranolol, atenolol). In the ICU setting, esmolol may be preferred due to its short half-life. Due to the exquisite sensitivity/dependence of the neonatal and infant heart to serum calcium levels, use of intravenous calcium channel blockers in infants less than 1 year of age is usually contraindicated. Milrinone, a phosphodiesterase-III inhibitor, possesses some positive lusitropic effect [37] and, thus may be of theoretical benefit in select patients with HCM and advanced heart failure symptoms in the absence of significant subaortic obstruction. Because milrinone can be arrhythmogenic, careful consideration must be given to balancing any potential benefits against the risks of induced tachyarrhythmias. Furthermore, vasodilatation may exacerbate any left ventricular outflow obstruction. Diuretics are often used in the outpatient setting for patients with congestive symptoms. These agents must also be used with caution in the setting of diastolic dysfunction as cardiac output and myocardial perfusion can be compromised with insufficient preload and again outflow obstruction may be increased.

The role of ICDs in the management of children with HCM is unclear. Data from a multicenter registry of pediatric and

congenital heart disease patients showed HCM was the second most common diagnosis for which subjects received an ICD [38]. In patients with HCM who experience syncope or aborted sudden death, implantation of an ICD is indicated. While the use of ICDs for primary prevention in patients with HCM is not fully established, a recent publication found a 3% annual rate of appropriate ICD discharge in children and adolescents who had at least 1 risk factor for sudden death such as extreme LV hypertrophy, family history of HCM related sudden death, or non sustained ventricular tachycardia [65].

Long-Term Outcomes

Although the natural history of HCM in adults is quite variable [32], survival tends to be worse the younger a patient presents. In particular, infants who present with heart failure have a poor prognosis. Patients who present older than 1 year of age are unlikely to die of progressive heart failure from HCM but may succumb to sudden death [39]. Sudden death predominates in adolescents and young adults with HCM and is thought to be more likely in those with a family history of sudden death or personal history of recurrent syncope, ventricular tachycardia, or massive left ventricular hypertrophy [35].

Hypertrophy often progresses (or may first become apparent) during periods of rapid growth (i.e., puberty), and, thus, patients with HCM should be monitored closely during adolescence. In a small percentage of patients there may be a regression of hypertrophy, with ultimate development of left ventricular dilation and poor systolic function. This so-called end-stage or "burned-out" HCM typically requires treatment for systolic heart failure much like DCM and may necessitate transplantation [40]. It is rare in childhood.

Knowledge of outcome in pediatric hypertrophic cardiomyopathy has recently been greatly advanced through analyses from the two large multicenter registries. In the National Australian Childhood Cardiomyopathy Study [27, 41], less than 10 % presented with heart failure, most presenting with a murmur or for family screening. A third of them were syndromic (mostly Noonan syndrome). Freedom from death or transplant was 83 % at 5 years and 76 % at 10 years. Presentation at one year was an important predictor of mortality. Annual mortality for patients presenting beyond this age was only 1.5 %. In the Pediatric Cardiomyopathy Registry [29, 42], survival for idiopathic cardiomyopathy ($n = 634$) was 82 % at 5 and 10 years for infantile presentation, and 94 % and 86 % at the same time intervals for presentation beyond infancy.

Restrictive Cardiomyopathy

Anatomic Considerations

Restrictive cardiomyopathy (RCM) is a very rare form of cardiomyopathy characterized by normal of decreased volume of both ventricles associated with atrial enlargement (often massive) and with normal LV wall thickness (Figs. 116.7 and 116.8). As mentioned earlier, there is some phenotypic overlap seen with hypertrophic cardiomyopathy, and mild left ventricular hypertrophy is sometimes observed. Systolic function is generally normal [1].

Etiology and Pathophysiology

Overall, RCM is a rare diagnosis, accounting for approximately 5 % of pediatric cardiomyopathies [5, 6]. The underlying cause(s) are generally unknown [43–45]. This is in contrast to adult patients with RCM, in whom infiltrative diseases such as amyloidosis and sarcoidosis are sometimes identified. While some children may present with familial forms, most cases are sporadic. Cardiac troponin I mutations have been reported as a cause of restrictive (and hypertrophic) cardiomyopathy [34]. The severe restrictive physiology leads to decreased cardiac output, elevated filling pressures, and atrial stretch which may lead to arrhythmias. Some patients

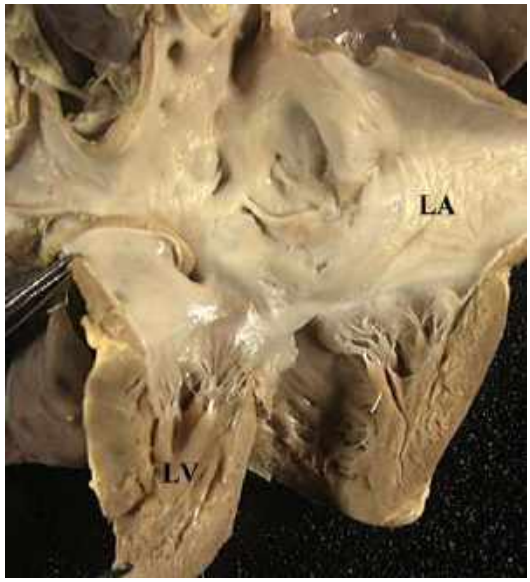

Fig. 116.7 Restrictive cardiomyopathy with small left ventricular cavity size and marked dilation of the left atrium. *LA* left atrium, *LV* left ventricle (Courtesy of William Devine, Department of Pathology, Children's Hospital of Pittsburgh)

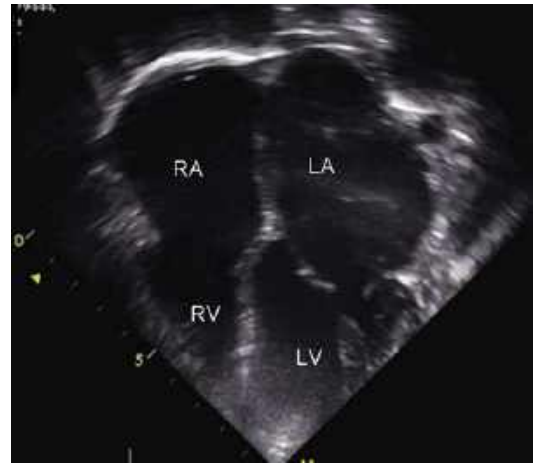

Fig. 116.8 Echocardiographic apical four-chamber view demonstrates small ventricular chamber sizes and biatrial enlargement typical of restrictive cardiomyopathy. *LA* left atrium, *LV* left ventricle, *RA* right atrium, *RV* right ventricle

demonstrate presumptive evidence of ischemia based on ST segment depression, especially during tachycardia. Elevation of pulmonary vascular resistance is frequently seen (even at presentation) and may contribute to right heart failure. Loss of systolic function is rare, although it is occasionally seen in advanced disease.

Clinical Presentation

Exercise intolerance, exertional angina, syncope, tachyarrhythmias, or sudden death may occur. Atrial tachycardias are not uncommon and likely result from severe atrial dilation due to poor ventricular compliance. These are poorly tolerated in the setting of diastolic compromise.

Much like those with HCM, children and adolescents with RCM often present incidentally for evaluation of a murmur or for follow-up of an atypical cardiac silhouette on chest radiography obtained for unrelated reasons. Patients may also present with symptoms of heart failure, angina, palpitations, or syncope. Syncope may be precipitated by atrial or ventricular tachycardia, both of which are poorly tolerated in the setting of limited ventricular compliance. Similar to HCM, sudden death is also not an uncommon presentation of RCM [44].

Management of Restrictive Cardiomyopathy

Therapeutic options for pediatric RCM are very limited. Many of the same physiologic considerations (and thus limitations in management) discussed for patients with HCM are also pertinent for those with RCM. Gentle diuresis is indicated if there is pulmonary venous congestion or pulmonary edema, but excessive diuresis may lead to reduction in cardiac output. Vasodilators may lead to hypotension, since augmented cardiac output may not occur when stroke volume is fixed. The role of beta-blockers is unclear. Slowing of the heart rate will prolong diastolic filling time but since stroke volume is relatively fixed, increasing heart rate may be an important mechanism for augmenting cardiac output.

Because short-term survival is poor after a diagnosis of RCM, many centers recommend

early evaluation for cardiac transplantation. Cardiac catheterization should be performed during the evaluation process because of the high likelihood of increased pulmonary vascular resistance. Hemodynamic assessment may also help with the distinction from constrictive pericarditis. Computed tomography is indicated if pericardial disease is suspected. Although secondary causes of RCM, such as amyloidosis and sarcoidosis, are exceedingly rare in children, biopsy should be considered in older children presenting with RCM to assess for these systemic diseases.

For patients managed out of hospital, implantation of an ICD in combination with antiarrhythmic agents may be considered, especially if prior near-syncope, syncope, or tachyarrhythmia has occurred.

Fig. 116.9 Left ventricular non-compaction cardiomyopathy. Pathologic specimen showing typical "spongiform" myocardium of the left ventricle (Courtesy of William Devine, Department of Pathology, Children's Hospital of Pittsburgh)

Long-Term Outcomes

Children with RCM have very poor prognosis in the absence of heart transplantation. Survival at 5 and 10 years after diagnosis was 39 % and 20 %, respectively, at Children's Hospital of Pittsburgh [43] and others have reported similar outcomes [46]. A minority of patients has been reported to survive upward of 8–12 years [45, 47–49]; however, strong, independent predictors of prolonged survival remain to be identified. The presence of symptoms at diagnosis did not correlate with survival in our cohort. Because excessive elevation in pulmonary vascular resistance may necessitate heart-lung transplantation, progressive elevation in pulmonary resistance should also lead to consideration of early transplantation.

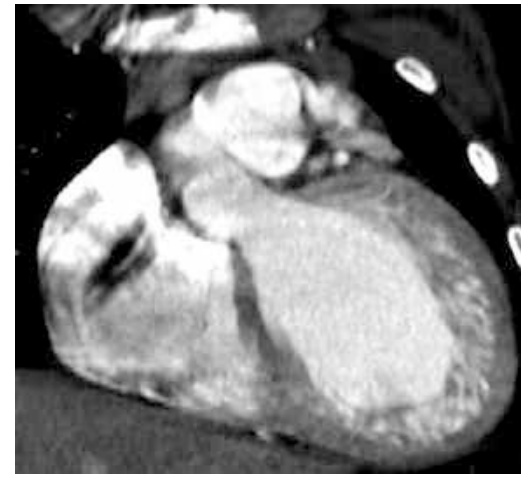

Fig. 116.10 Computed tomography showing intertrabecular recesses and dilation of the left ventricle in a teenager with non-compaction cardiomyopathy

Non-compaction Cardiomyopathy

Anatomic Considerations

In left ventricular non-compaction (LVNC) cardiomyopathy, the left ventricle shows prominent trabeculations and deep inter-trabecular recesses (Figs. 116.9 and 116.10). These findings are most commonly observed at the apex of the left ventricle but can be seen in an isolated fashion along the lateral wall. There is often dilation of the left ventricle with associated depressed systolic function. There may also be coincident ventricular hypertrophy, or at least lack of expected ventricular wall thinning for the degree of chamber dilation. Non-compaction can also occur in the setting of congenital heart disease, particularly hypoplastic left heart syndrome, ventricular septal defects, and pulmonary stenosis [50].

Etiology and Pathophysiology

LVNC has been increasingly diagnosed over the last 10 years. Previously, cases of LVNC may have been classified as HCM or DCM in part because of a lack of awareness of the diagnosis, limited resolution of earlier generations of echocardiography machines, and lack of standardized diagnostic criteria. LVNC may account for up to 9 % of pediatric cardiomyopathies [6]. It can occur in isolation or with other congenital cardiac disease and both sporadic and familial forms have been described [51]. When LVNC is inherited, X-linked inheritance appears to be most common, but autosomal dominant, recessive, and mitochondrial inheritance may also occur. Mutations in the *G4.5* gene at Xq28 (that encodes tafazzin) are responsible for X-linked LVNC [52] and also some other infantile DCMs, including Barth syndrome, which is characterized by cardiomyopathy (often with LVNC), intermittent neutropenia, peripheral myopathy, and growth delay [53, 54]. LVNC has been postulated to result from an arrest in early embryonic endomyocardial morphogenesis, resulting in a spongy meshwork of fibers and myocardial sinusoids [55]. Patients often have features most consistent with DCM, including symptomatic heart failure and arrhythmias, although some are found to have only asymptomatic LV dysfunction. Waxing and waning of ventricular function has also been described. Some series also report relative high prevalence of ventricular thrombosis and/or systemic embolic events, particularly in adults [56–58].

Clinical Presentation

Approximately half of children with LVNC who present for evaluation have signs and symptoms of heart failure. Others may come to evaluation incidentally for cardiomegaly on chest x-ray, abnormal ECG findings, or for assessment of a murmur. Patients may also present with arrhythmias. Most series show a tendency to progression in heart failure symptoms over time [58, 59], although a waxing and waning course is not rare. Presentation in infancy with heart failure due to severe systolic ventricular dysfunction is not unusual and some of these cases show marked improvement over time, though this may be transient.

Management of Non-compaction Cardiomyopathy

Discerning LVNC from the broader category of DCM can require a high index of suspicion. Echocardiographic diagnostic criteria have been described [60] and recently called into question [61]. Adjunctive imaging modalities such as CT or cardiac MRI may provide better diagnostic information [62] but are less readily accessible and may be impractical during the initial diagnostic evaluation of a critically ill child with heart failure. Genetic testing for mutations in the *G4.5* gene may help lead to a specific diagnosis, especially when the family history suggests X-linked inheritance.

Patients who manifest primarily with heart failure due to depressed systolic ventricular function are treated in a fashion similar to those with DCM. Therapy with diuretics and ACE inhibitors, with or without beta-blockers, are often employed during long-term follow-up. Although systemic embolism and arrhythmias (atrial fibrillation and ventricular tachycardia) are relatively common in the adult LVNC population, these are relatively rare in pediatric series. Ventricular ectopy may also be observed. Systemic anticoagulation is indicated when there is severe systolic ventricular dysfunction.

Long-Term Outcomes

Because of the relative infrequency of LVNC, the clinical course of children with this diagnosis is not as well characterized as in patients with DCM. Ichida and colleagues [59] report the longest follow-up in their series of patients with childhood LVNC (median 6 years, range 0–17 years) and described the development of ventricular dysfunction or death in 75 % of those

followed for ≥10 years. In another series, transplant-free survival in infants with LVNC and no congenital heart defect was 52 % at 3 years [50]. This was almost identical to transplant-free survival of 53 % among 29 subjects with LVNC in the National Australian Cardiomyopathy Study [27]. Although these studies of LVNC in childhood report median ages at presentation of between 3 months and 7 years [50, 58, 59], there are various reports in adults that describe initial diagnosis as late as 70–75 years [56, 57] with absence of depressed cardiac function in some cases. This suggests that LVNC may be more common than has been observed, with some having only the morphologic findings (deep trabeculations) without overt ventricular dysfunction until much later in life.

Conclusions

Cardiomyopathies and myocarditis are serious entities that may affect children at all ages. Early diagnosis and a precise etiologic data may prove useful in efficiently managing patients and optimizing prognosis.

Abstract

The causes of pulmonary arterial hypertension were reclassified according to a consensus at the Fourth World Symposium of Pulmonary Hypertension in Dana Point, 2008. This chapter will focus on category I pulmonary arterial hypertension that is divided into idiopathic pulmonary arterial hypertension, hereditary pulmonary arterial hypertension, and pulmonary arterial hypertension associated with other disease states such as a congenital heart defect or an autoimmune disorder. This chapter will also describe pathophysiological mechanisms of pulmonary arterial hypertension and emerging therapies.

Keywords

Classification • Pathobiology • Pathology • Pathophysiology • Pulmonary arterial hypertension

Introduction of Pulmonary Arterial Hypertension: Classification and Overview

The causes of pulmonary arterial hypertension (PAH) were reclassified according to a consensus at the Fourth World Symposium of Pulmonary Hypertension in Dana Point, 2008, and published by Simonneau and colleagues in 2009 [1]. This chapter will focus on category I PAH (Table 117.1) [2]. It is divided into idiopathic pulmonary arterial hypertension (IPAH), hereditary PAH (where there is a known gene mutation), and PAH associated with other disease states such as a congenital heart defect or an autoimmune disorder.

Insights into the pathophysiology of PAH have come from understanding mechanisms that lead to a similar pathology. For example, hypoxia-induced PAH is not category I, but many studies in hypoxic animals discussed in this chapter have provided important pathobiological information and are leading to novel therapies for PAH. Experimental and clinical studies now converge on the intersection and interactions between a genetic predisposition (mostly involving the BMPR2 signaling pathway), impaired metabolism, and a chronic

inflammatory state in the vessel wall (Fig. 117.1). These deranged processes culminate in an exuberant proliferative response that occludes the pulmonary arterial (PA) lumen and obliterates the most distal intra-acinar vessels. This chapter describes emerging therapies based upon preclinical studies that address these converging pathways (Table 117.2).

Relating Structure to Function in PAH Related to Congenital Heart Disease

In the neonate and very young infant, PAH is frequently encountered as a complication of certain types of congenital heart defects, those with either left-to-right shunts or common mixing lesions such as transposition of the great arteries. The heightened pulmonary blood flow and/or pressure and/or high oxygen saturation caused by the congenital heart defect induces structural remodeling of the vasculature. This is initiated by abnormal muscularization of distal pulmonary arteries (PAs) and medial hypertrophy of more proximal muscular PAs, and there is also a progressive reduction in arterial number [3] (Fig. 117.2). In older infants, in addition to these features, there is progressive neointimal formation caused by hyperplasia of vascular cells, and this leads to progressive obliteration of the lumen and plexiform lesions in the PAs, as described in detail below.

Rabinovich et al. previously related increased muscularization of distal arteries (that was called grade A) to high pulmonary blood flow and pulse pressure, whereas medial hypertrophy of muscular arteries (called grade B) was associated with high mean pulmonary arterial pressure, and reduced arterial number (grade C) reflected elevated pulmonary vascular resistance. Neointimal obliterative and plexiform lesions were associated with a progressive rise in resistance to pulmonary blood flow culminating in right-to-left shunting. The author showed that age at cardiac repair was a critical factor in the potential for hemodynamic improvement and (presumably) resolution of the vascular pathology. That is, infants repaired in the first 6 months of age had normal hemodynamics as assessed at cardiac catheter study 1 year later, whereas those repaired over 2 years of age usually had some impairment or even progressive pulmonary vascular disease, except if the pathology was limited to medial hypertrophy (grade B) [4–6]. A wedge angiogram [7] can be helpful in relating the extent of pulmonary vascular pathology to the calculations of pulmonary vascular resistance, and a frozen section can be valuable when the catheter data and the angiogram are borderline.

The endothelial cell (EC) is thought to be the orchestrator of the vascular pathology since this is the cell that senses environmental factors that predispose to pulmonary hypertensive changes. Early structural changes in pulmonary arterial (PA) ECs from patients with PAH are evident by electron microscopy [8] and associated with defective von Willebrand factor, a blood glycoprotein involved in coagulation [9] and fibrinolysis [10], as well as with reduced production of vasodilators and increased production of vasoconstrictors that also induce muscle cell (SMC) proliferation. Pulmonary arterial (PA) EC

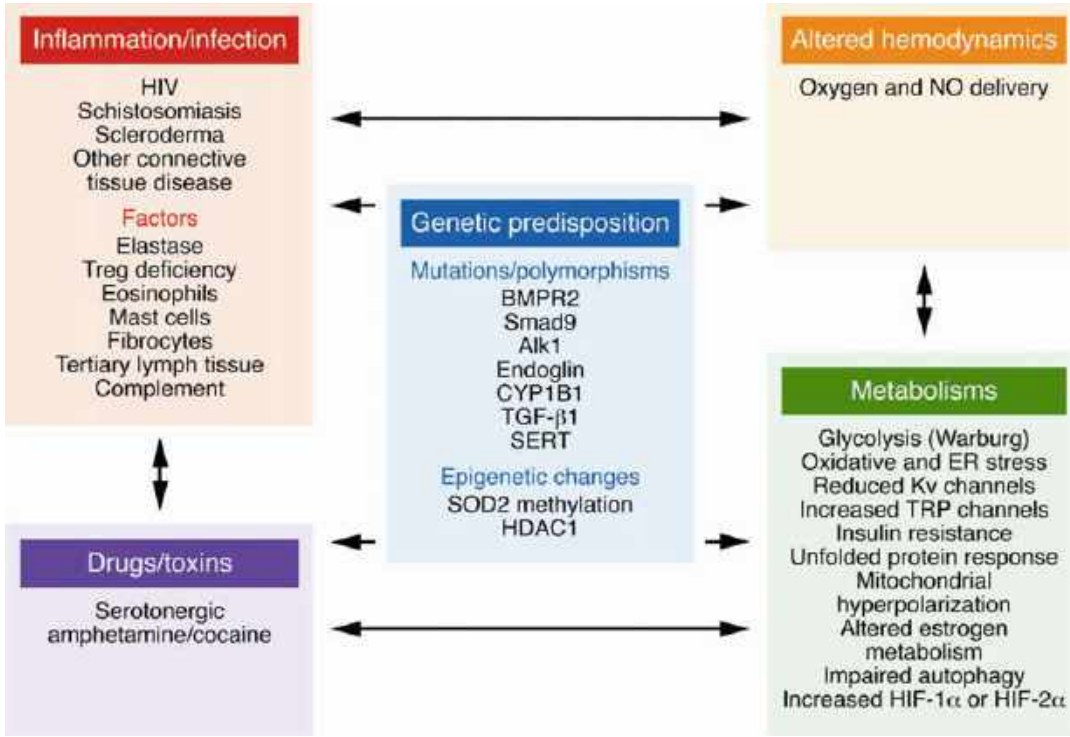

Fig. 117.1 Factors that converge in the molecular pathogenesis of PAH. This schema focuses on the interactions among inflammation, altered cellular metabolism, and genetic/epigenetic abnormalities in the pathogenesis of PAH

alterations precede the earliest vascular changes, i.e., muscularization of the distal arteries [11]. Cultured PA ECs release factors such as fibroblast growth factor (FGF)-2 that stimulate the proliferation of PA smooth muscle cells (SMCs) [12]. In PA ECs from patients with IPAH, an increase in Tie2 receptor activation has been related to release of serotonin and induction of SMC proliferation [13–15]. Reduced PAH PA EC signaling through the gene mutated in IPAH, bone morphogenetic protein receptor (BMPR)2, results in decreased production of apelin, a protein essential in EC recovery from injury and in the repression of SMC proliferation.

Muscularization of distal (alveolar duct and wall) PAs has been related to differentiation of pericytes into SMCs that subsequently proliferate [16] as well as to recruitment of fibroblasts that can also differentiate into SMCs [17]. Medial hypertrophy of the intra-acinar and pre-acinar muscular arteries and the obliteration associated with neointimal formation is thought to reflect increased proliferation and migration of smooth muscle-like cells. These cells express alpha-SM actin but are poorly differentiated [18] and may represent a specialized subpopulation of SMCs. Alternatively these SMC-like cells may have originated as stem cells or fibrocytes [19] or even from ECs or pericytes [20]. The loss of distal vessels could be due to alterations in ECs and/or pericytes resulting in their apoptosis or programmed cell death [21].

Development of the plexiform lesion is thought to be a late change. This structural abnormality is characterized by the formation of aberrant channels lined by endothelial-like cells (in that they maintain some markers of endothelium). These channels may be produced by clonal expansion of apoptosis-resistant ECs [22]. Those ECs may have originated from circulating

endothelial progenitor cells that accumulate at sites of endothelial denudation or injury and expand locally. Pulmonary artery ECs from patients with IPAH produce decreased amounts of nitric oxide (NO), a vasodilator and suppressor of SMC proliferation. Reduced NO can be a consequence of decreased endothelial nitric oxide synthase (the enzyme that generates it) or high arginase (the enzyme that degrades the substrate L-arginine) or both [23]. PA ECs from patients with PAH are highly proliferative in response to growth factors [24] and exhibit high rates of glycolysis [25] as a result of inappropriate sensing by hypoxia-inducible factor [26]. That is, they behave as if they are responding to a hypoxic stimulus. The PAH PA ECs are poorly differentiated as exhibited by impaired formation of endothelial tubular networks in culture [24].

There is also considerable thickening of the pulmonary adventitia and venous hypertrophy [27] in patients with PAH. Immunohistochemical studies revealed increased transforming growth factor (TGF)-β, matrix proteins (such as collagen, fibronectin, tenascin-C, and glycosaminoglycans) [18], in addition to macrophages, and T cells [28], as well as inflammatory mediators such as S100A4 (also known as metastasin 1 (Mts1)) [29] (Fig. 117.1) and fractalkine [30].

Counteracting the Pathology of PAH with "Vasodilator" Therapy

The attempt to reverse advanced pathology seen in category I patients with PAH with the vasodilator and anti-SMC proliferative agent prostacyclin was built on the observation that it was the deficient relative to the vasoconstrictor thromboxane [31]. While intravenous prostacyclin and analogues have often reduced the pulmonary vascular resistance (PVR) and improved quality of life and the survival of PAH patients [32], a recent meta-analysis has questioned the overall long-term benefit of this and other therapies for adults with PAH [33, 34]. The strategy of using endothelin (ET) receptor blockade was based upon studies in rats with that showed elevated levels of ET in association with hypoxia-induced pulmonary hypertension [35] and clinical studies showing increased ET in the lungs of PAH patients [36]. ET is a powerful vasoconstrictor that promotes SMC proliferation and inflammation. The two endothelin receptor subtypes, ET_A and ET_B, are found in smooth muscle cells of blood vessels and both can mediate vasoconstriction, but ET_B receptors on ECs induce vasodilatation and ET clearance particularly in microvessels. However, both the dual ET receptor antagonist [37] and a more selective ET_A receptor antagonist [38–41] show similar benefit. Reduced levels of lung NO synthase, the enzyme that generates NO [42], suggested that treatment with phosphodiesterase V inhibitors such as sildenafil would prolong the NO-mediated increase in cGMP, thereby maximizing the opportunity to dilate PAs [43, 44], and these agents appear to have further beneficial effects in improving cardiac function. Nitrites produce NO in the lung and can reverse experimental monocrotaline and

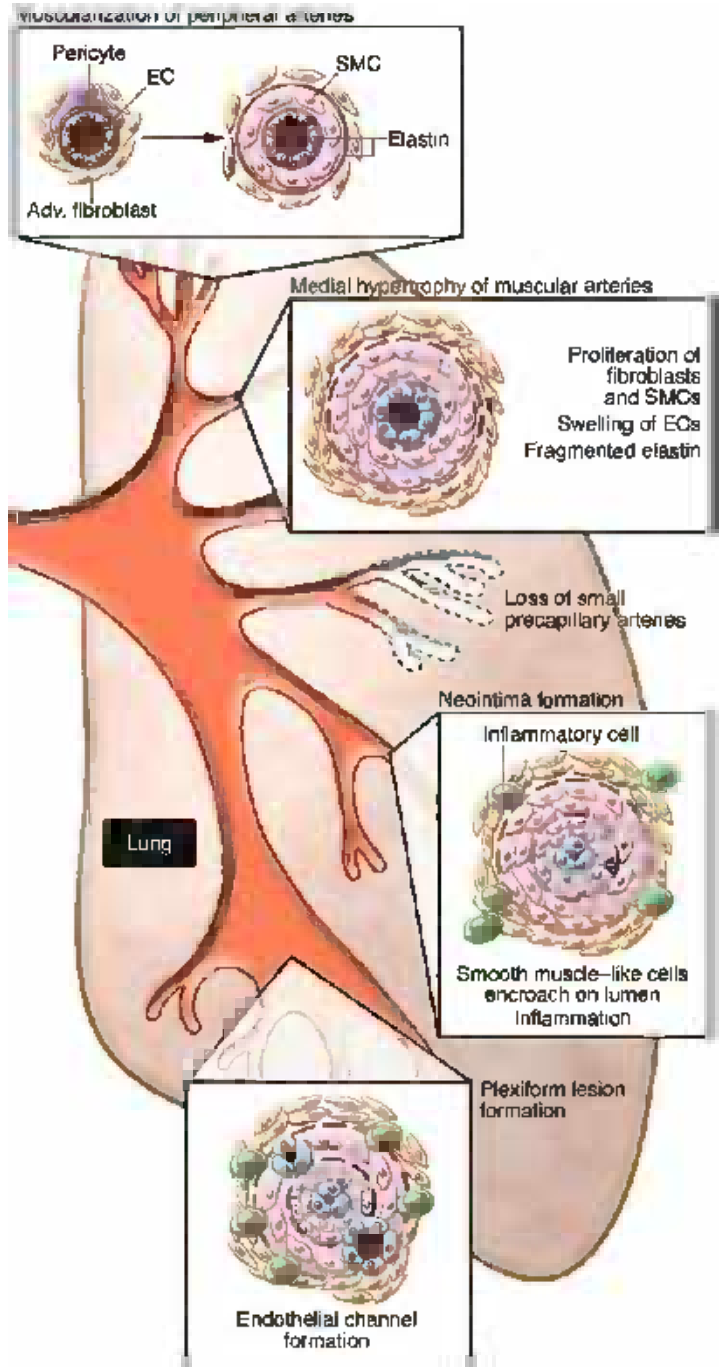

Fig. 117.2 *Schema illustrating the different vascular abnormalities associated with pulmonary hypertension*. This schema depicts the abnormalities throughout the pulmonary circulation consisting of abnormal muscularization of distal precapillary arteries, loss of precapillary arteries, thickening of large pulmonary arteries, and neointimal formation that is particularly occlusive in vessels <500–100 μM and plexiform lesions in these vessels

hypoxia-induced pulmonary vascular disease [45, 46].

Other vasodilators effective in reversing pulmonary hypertension in experimental rodents include adrenomedullin [47]. Vasoactive intestinal peptide is an important vasodilator and inhibitor of SMC proliferation in PAH, since transgenic mice that are null for vasoactive

intestinal peptide develop PAH with remodeled distal arteries, and both the hemodynamic abnormality and the pathology can be reversed with administration of vasoactive intestinal peptide [48]. Unfortunately an initial clinical trial has not proven successful.

Early studies in a congenital heart defect such as a ventricular septal defect with PAH had shown that placement of a PA band in infancy could substantially reverse the PA vascular pathology [49]. This author's group therefore investigated whether dropping the elevated pulmonary arterial pressure and resistance would be sufficient to reverse remodeling.

To this end, a single lung transplant was carried out in a normal rat, in which the donor lung came from a rat with severe pulmonary hypertension and vascular remodeling induced by the endothelial toxin monocrotaline. Placing the diseased lung in a normal animal was sufficient to induce regression of the pulmonary vascular abnormalities [50]. This was consistent with clinical studies showing regression of severe pulmonary vascular disease in the lung from a PAH patient that remained after single lung transplant [51]. In the latter studies, however, the regression could have also been induced by immunosuppressive agents that attenuate or reverse experimental PAH [52].

On the basis of these findings reconsideration has been given to agents that drop PA pressure by causing major cytoskeletal changes. Experiments using the rho-kinase inhibitor fasudil in rodents [53, 54] suggest that it should be developed for clinical use [55]. The systemic hypotensive side effects of fasudil may be reduced when it is administered via inhalation and will need to be addressed if these agents are to be useful in treating PAH patients for a prolonged period of time.

Bone Morphogenetic Protein Receptor 2 Signaling and Idiopathic PAH

In the year 2000, genetic studies showed that approximately 70 % of patients with a familial form of idiopathic (I) PAH [56–58] and 20 % of those with sporadic IPAH were heterozygous for a mutation in bone morphogenetic protein (BMP) receptor, type 2 (BMPR2). However, the penetrance of the mutation was low, in that 80 % of family members that carry the same mutation as affected family members never develop PAH. A recent study shows that expression of BMPR2 from the normal allele can distinguish unaffected from PAH-affected family members with a BMPR2 mutation [59], and there is also evidence that expression of a splicing variant, a short form of BMPR2 that is estradiol dependent, is greater in affected versus non-affected family members. BMPR2 is a member of the TGF-β superfamily of growth factor receptors [60, 61]. It is expressed ubiquitously and signals through multiple pathways, e.g., pSmad1/5 [62, 63] and p38 [64, 65], pERK, JNK, and Akt/PI3 kinase [66, 67]. Mutations in BMPR2 can affect the signaling mechanism and the interaction of the receptor with the cytoskeleton and with other molecules that affect gene regulation.

BMPR2 mutations have also been observed in 6–8 % in patients with PAH associated with a congenital heart defect causing a left-to-right shunt [68], and rarely BMPR2 mutations have been found in patients with PAH related to toxins such as fish oil and appetite suppressants, amphetamine, and cocaine [69, 70]. Independent of a mutation in BMPR2, IPAH patients have reduced expression or function of BMPR2 protein as do, to some extent, patients with APAH [71]. A reduction in a co-receptor, BMPR1A, has also been observed in patients with IPAH [15].

Mutations in other members of the TGF-β superfamily of receptors have been described in patients with PAH [72]. For example, activin-like kinase type 1 (ALK1) and endoglin are mutated in hereditary hemorrhagic telangiectasia with or without PAH [73, 74]. A microsatellite instability in TGF-β receptor 2, resulting in its reduced expression and function, has been observed in patients with IPAH [72]. However, it has also been shown that loss of BMPR2 is associated with an exaggeration in TGF-β signaling [75]. Consistent with this, a polymorphism causing an increase in TGF-β1 coupled with a mutation causing loss of BMPR2 increases the age of

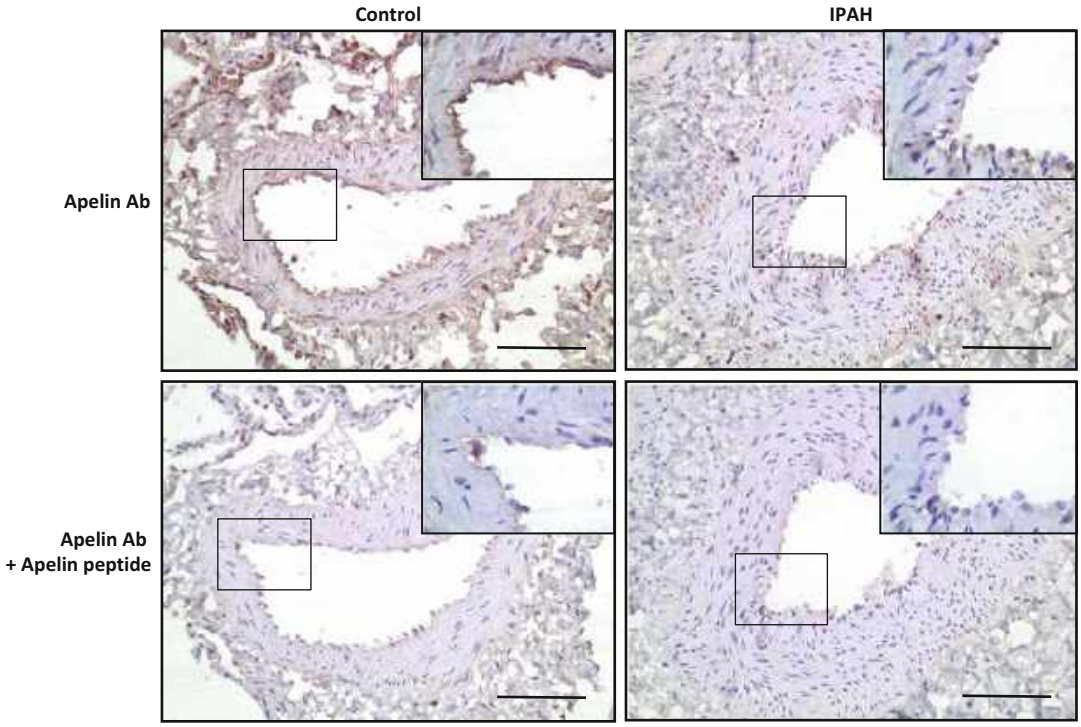

Fig. 117.3 *Decreased apelin expression in the endothelium of IPAH patients*. (**a**) IHC in serial lung tissue sections from representative unused donor control and IPAH patient lungs stained with Abs against apelin. Preincubation of Ab with apelin peptide was used as a specificity control. Higher-magnification endothelium in insets demonstrates greater apelin immunoreactivity in the control vessel. Scale bars: 100 μm. Original magnification, ×200 (insets, ×630). (**b**) BMPR2 protein levels in PMVECs from control and IPAH patients (Reproduced with permission from Ref. [1])

onset and the severity of PAH [76]. Thus, it appears that when BMPR2 is deficient, the dysfunction of alternative signaling pathways can lead to the development of PAH [65, 77, 78]. Also, while loss of BMPR1A, the co-receptor for BMPR2, was believed to contribute to the adverse pathology in IPAH patients [79], more recent experimental data suggest that loss of BMPR1A without concomitant reduction in BMPR2 may actually protect against abnormal muscularization and loss of PAs [80].

Thus, changes in the expression of BMPR2 and associated receptors, in the availability of ligands and concurrent abnormalities in downstream signaling events that influence gene expression, may all be required for the development of PAH [81] (Fig. 117.3). Consistent with this, the ALK-1-deficient mouse develops spontaneous (albeit mild) pulmonary hypertension whereas the BMPR2 heterozygote requires environmental perturbations such as hypoxia and serotonin or inflammation to bring out an exaggerated pulmonary hypertensive phenotype [82]. "Somatic" mutations in ECs from patients with pulmonary hypertension are described that may be related to chromosomal instability or DNA damage [83]. There is new evidence that, in response to loss of function of BMPR2, there is abnormal processing of microRNAs [84, 85], and this can alter the function of vascular smooth muscle cells [86]. Altered expression of microRNAs is observed in both experimental and clinical PAH [87].

Because of the pivotal role of BMPR2 loss of function in the disease process, a number of strategies have been tried to increase expression of

this receptor, either by gene therapy [88] or by improving trafficking of mutant receptors [89]. Since loss of BMPR2 leads to an adverse response to TGF-β signaling [90], therapies that inhibit the TGF-β receptor ALK5 have also been successful in experimental PAH [91].

How reduced BMPR2 function in ECs and SMCs leads to the pathobiology of PAH has been investigated by a number of laboratories. It was shown that reducing levels of BMPR2 by RNA interference in PA ECs renders them susceptible to apoptosis, and these cells also exhibit reduced migration and proliferation, features associated with impaired angiogenesis or repair of damaged blood vessels [92]. Work by our group showed that in PA ECs, BMPR2 activation leads to the formation of a complex between β-catenin and PPARγ that is essential in regulating genes that promote endothelial function such as apelin [93]. Circulating levels of apelin are reduced in patients with IPAH [94] and expression is reduced (Fig. 117.3), and apelin has autocrine effects in promoting PA EC survival and migration and paracrine effects in suppressing aberrant PA SMC growth. Mice with PPARγ deleted in ECs develop spontaneous PAH [95] that is reversed by treatment with apelin [93]. Our studies also showed the efficacy of using naturally occurring PPARγ adducts such as nitro-fatty acids (NO_2-FA) to rescue BMPR2 dysfunction. Both NO_2-FA and similarly reactive electrophilic keto-FA display nM affinities for PPARγ [96] and mediate distinctive patterns of PPARγ-dependent gene expression, in addition to their antioxidant properties related to activation of the transcription factor for these enzymes (Nrf2) and anti-inflammatory properties ascribed to inhibition of NFκB. Another transcription factor that has a beneficial effect in rescuing BMPR2 dysfunction in PA ECs appears to be Id1 [97].

Reduced BMPR2 also induces PA SMC proliferation [90, 98], in response to factors that normally suppress growth of these cells [99–101]. This may explain the exuberant proliferative response of the smooth muscle-like cells associated with PA occlusive neointimal changes. BMPR2 functions to repress signaling through potent growth factors such as PDGF [102] and perhaps EGF as well [103, 104]. It has also been shown that BMP4, a ligand of BMPR2, induces differentiation of fetal lung fibroblasts into SMCs and inhibits their proliferation [105], suggesting that lack of BMP4 interaction with BMPR2 might expand the fibroblast or myofibroblast population of cells accounting for the adventitial and medial thickening of the PAs in PAH.

The protective effects of BMPR2 in PA SMC are also mediated by PPAR-γ [102, 106]. PPAR-γ transcriptional activity leads to production of apolipoprotein (apo) E and with deletion of apoE develops PAH either when made insulin resistant [107] or with aging. In systemic arterial SMCs, apoE can repress proliferation by phosphorylating and internalizing the co-receptor of PDGF, namely, the LDL receptor-related protein 1 (LRP1) [108]. Repression of the PDGF receptor by imatinib (Gleevec) can reverse monocrotaline-induced pulmonary hypertension in rats [109] and may improve outcome in patients with end-stage PAH [110]. In addition to apoE, other transcriptional targets of PPAR-γ, such as adiponectin, [111] can sequester PDGF-BB [112] and repress PA SMC proliferation. We have shown that treatment of $apoE^{-/-}$ mice with the PPAR-γ agonist rosiglitazone reverses PAH in concert with raising adiponectin levels [107]. So it appears that while the antiproliferative effect of BMPR2 signaling in SMCs could be impeded in patients with a mutation or with impaired expression of BMPR 2, there is also the potential for rescue by activating downstream effectors such as PPAR-γ.

BMPs induce motility but suppress proliferation in a number of ways that may be independent of PPARγ. They interact with the receptor for advanced glycation end products (RAGE) [113] and they activate in tandem canonical and noncanonical Wnt signaling pathways. Induction of the canonical pathway is transient and necessary for the PA SMC to produce fibronectin and to activate the motility machinery through (integrin-linked kinase) ILK-1. This kinase mediates recruitment of a Wnt signaling protein called Disheveled as a platform for activation of the noncanonical Wnt pathway in which RhoA and Rac1 mediate contraction of the actin-myosin

cytoskeleton and extension of lamellipodia, enabling motility. If the activation of β-catenin is not transient, i.e., not interrupted when the noncanonical pathway is activated, then the PA SMC will proliferate, as is seen in disease [114]. In contrast to PA SMCs, in PA ECs BMPs need to simultaneously activate canonical and noncanonical Wnt signaling pathways so that both proliferation and migration can occur since both processes are necessary in vascular repair and regeneration after injury [115].

Other interesting targets of BMPR2 implicated in proliferation of PA SMC include osteoprotegerin [116] and tenascin-C [117]. Expression of osteoprotegerin is increased in pulmonary vascular lesions and in serum of patients with PAH, and osteoprotegerin can increase PA SMC proliferation and migration. Tenascin-C can cluster integrins and activate growth factor receptors in SMC and induce proliferation. We have shown that tenascin-C and osteopontin have similar functions in PA SMC, and circulating osteopontin levels are increased in PAH and indicate patients with more severe symptomatology [118].

Drugs and Toxins Induce PAH

The high incidence of PAH in patients taking appetite suppressants implicated serotonin-like compounds in the pathobiology [119, 120]. There are also additive adverse vascular effects related to a serotonin interaction with 17 β-estradiol, a compound increased in females [121]. Serotonin has similarities structurally and functionally to compounds such as cocaine and amphetamine, and greater abuse of these substances has been observed in IPAH patients versus those who have PAH associated with other conditions [122]. There is also an additive or synergistic interplay between HIV, cocaine abuse, and heightened activity of the potent smooth muscle cell growth factor, PDGF [123].

Serotonin Receptors and Transporter: Elevated serotonin levels and serotonin transport have been implicated in the pathology of experimental and clinical PAH, i.e., there is a gain-of-function polymorphism in the serotonin transporter in some populations of patients with PAH [124]. Serotonin causes increased vasoreactivity in rodents [125], and there is attenuated severity of pulmonary vascular disease in mice lacking the serotonin transporter gene [126]. Consistent with this, overexpression of the serotonin transporter in a transgenic mouse particularly when expressed in SMCs worsens hypoxia-induced PAH [127, 128]. Moreover, mice heterozygous for BMPR2 show increased sensitivity to the pro-proliferative effects of serotonin, and PDGF-mediated proliferation of SMCs is compounded by heightened activity of the serotonin transporter [129].

Serotonin stimulation of the serotonin transporter and the serotonin receptors induces genes critical to the PA SMC proliferative response [130], i.e., S100A4, a member of the S100 family of calcium-binding proteins [131] that induces both proliferation and migration of PA SMCs [131]. Expression of S100A4 is increased in neointimal lesions from patients with IPAH and PAH associated with other conditions. A mouse that overexpresses S100A4 can spontaneously (albeit rarely) develop similar pulmonary vascular pathology to that observed in IPAH patients [29] but does so consistently with concomitant infection with the murine gamma herpes (MHV-68) (the murine homologue of HHV-8) viral infection [132]. The latter study coupled with the increased incidence of PAH in patients with HIV underscores the importance of immune mechanisms and infection in the pathobiology of PAH [123].

Inflammation and Immune Mechanisms

Increasing attention is being focused on pulmonary vascular inflammation in the progression of PAH, particularly in association with genetic abnormalities [133]. Expression of HHV-8, associated with Kaposi sarcoma, was linked to IPAH [134], and the Kaposi sarcoma virus can stimulate lysosomal-mediated degradation of

BMPR2 [135]. The HIV-nef gene is associated with plexogenic pulmonary vascular lesions in HIV-infected patients and SIV-infected nonhuman primates [136]. In regions endemic for schistosomiasis, there is a high incidence of PAH. That is, roughly 10 % of patients with schistosomiasis develop portal hypertension and of those 10 % will have PAH. Chronic infection of mice with high-dose cercariae results in severe but spotty lung vascular remodeling [137, 138], with a relatively modest pulmonary hypertensive response, but treating the schistosomiasis induces regression of the pathology [137]. Allergic responses to ovalbumin or to aspergillus in mice result in pulmonary vascular remodeling, without PAH [139]. An IL-13-mediated increase in alpha resistin was implicated both in experimental allergic models and in experimental schistosomiasis [138] but also in scleroderma-associated PAH [140]. Mice lacking prostaglandin synthase develop intense pulmonary vascular remodeling following allergic inflammation with the house dust mite that can be reversed by administration of PGE2 [141].

The intersection of inflammation and genetic predisposition is seen in mice heterozygous for BMPR2, in that they develop exaggerated pulmonary hypertension in response to an inflammatory stimulus [142]. Chronic inflammation in experimental animals, induced by repeated injections of endotoxin [143] or tumor necrosis factor alpha [144], is known to cause pulmonary vascular changes, and complement appears to play an essential role [145]. In a rodent model of PAH where a VEGF receptor blocker was given, depletion of T cell subsets worsens the pathology [146]. This is attributed to unbalanced B cell activity resulting from impaired regulatory T cells (Tregs) [147]. In the athymic rat given the VEGF receptor blocker, reconstitution with Tregs was sufficient to rescue the PAH in association with inducing an elevation in BMPR2. Tertiary lymphoid tissue was described in patients with IPAH as evidence of altered immune regulation (Fig. 117.4) [148]. In keeping with this, circulating autoantibodies are prevalent in patients with both autoimmune and other associated forms of PAH and IPAH [149].

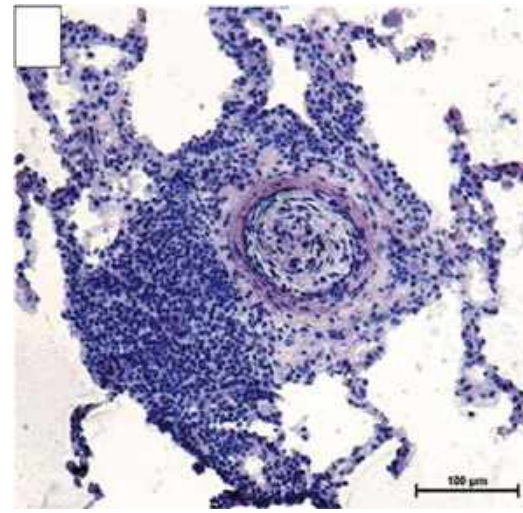

Fig. 117.4 *The lungs from patients with idiopathic pulmonary arterial hypertension (IPAH) show lymphoid follicles adjacent to remodeled vessels*. Hematoxylin and eosin (H&E) examination of sections of lung biopsy specimens from patients with IPAH shows lymphoid follicles close to remodeled vessels. Lymphoid aggregates were of various sizes and degrees of organization, from small lymphoid aggregates to large accumulations of lymphocytes resembling highly organized lymphoid follicles (**scale bar**, 100 µm) (Reproduced with permission from Ref. [170])

A number of observational studies in IPAH patients documented elevated circulating levels of cytokines and their receptors (reviewed in [150]), and experimental studies indicate an interaction with genetic factors. For example, in rodents dysfunction of BMPR2 signaling induces IL-6 [151], a cytokine that can cause severe pulmonary vascular disease in rodents [152] in association with SMC proliferation [153, 154]. Epigenetic factors appear to play a key role in inflammatory processes. In a calf model of chronic hypoxic pulmonary hypertension, activation of fibroblasts expressing elevated levels of cytokines was linked to increased histone deacetylase (HDAC-1), and inhibition of HDAC-1 reversed both the fibroblast phenotype and the pulmonary hypertension [155].

Recruitment of perivascular macrophages was shown to be critical in the development of hypoxia-induced pulmonary hypertension in experimental animals, and perivascular macrophages

are also abundant in the lung from patients with IPAH [156]. Mononuclear fibrocytes, cells that have features of fibroblasts and leukocytes [157], can migrate into the vessel wall through the angiomata in the expanding adventitia and could thus contribute to neointimal lesion formation. In fact, high levels of circulating fibrocytes are found in adults and children with PAH [158].

In T cells and in pulmonary vascular lesions from IPAH patients, increased nuclear expression of the transcription factor NFATc2 is observed [159]. This can lead to repression of Kv 1.5 channel expression and influx of intracellular calcium causing contraction and proliferation of smooth muscle cells. NFATc2 nuclear translocation can be inhibited by cyclosporine as well as by tacrolimus (FK-506). Recently it was shown that microRNA (MiR204) is reduced in PAH and low miR-204 increases the phosphatase Shp2 that activates nuclear translocation of NFATc [160].

Elastase Activity and PAH

Our previous studies applied electron microscopy to investigate the nature of endothelial and smooth muscle cell alterations in the pulmonary arteries in lung biopsy tissue from children with congenital heart defects and associated PAH. Ultrastructural evidence of fragmented elastin was striking particularly associated with modest pulmonary vascular abnormalities assessed on histological sections. This suggested that elastolysis may be an early feature of PAH [8]. Elevated serine elastase activity was subsequently documented in the monocrotaline as well as in other rodent models of PAH [161], and this led to the successful use of elastase inhibitors to prevent experimentally induced pulmonary vascular pathology [162, 163] (Fig. 117.5). The mechanism relating elastase activity to clinical PAH was further investigated in cultured PA smooth muscle cells. We showed that heightened activity of a serine elastase leads to the release of growth factors from the extracellular matrix [12], activation of matrix metalloproteinases, and induction of tenascin-C [103]. Elastin peptides (breakdown products of insoluble elastin) also promote SMC motility and recruitment of inflammatory cells by inducing fibronectin-dependent migration [164, 165] (Fig. 117.2). Subsequent studies showed that elastase activity might heighten cell survival signals in abnormally proliferating cells, and this led to the use of elastase inhibitors to reverse experimental, monocrotaline-induced pulmonary hypertension by inducing apoptosis of SMCs [166–168]. Regression of monocrotaline-induced PAH was subsequently also achieved by blocking a downstream effector of elastase, the EGF receptor that activates cell survival pathways [104]. In studies using either elastase inhibitors or EGF receptor blockers, we were able to show that there was regeneration of the distal vasculature. Similarly, others have shown that inhibition of the SMC survival gene survivin [169] was also successful in reversing experimentally induced PAH through SMC apoptosis.

Recently we identified that the PA SMC elastase in PAH is neutrophil elastase [170]. PA SMCs from mice that overexpress S100A4 have elevated levels of neutrophil elastase mRNA and protein as do PA SMCs from patients with IPAH (Fig. 117.5). Inhibition of elastase with the naturally occurring serine elastase inhibitor elafin attenuated the development of neointimal lesions in the S100A4 mice that are infected with virus.

K Channel Dysfunction, Mitochondrial Abnormalities, and PAH

Reduced expression and function of voltage-gated K^+ (Kv) channels, notably Kv1.5, is observed in PA SMCs from patients with IPAH as well as in APAH [171], and BMP2-mediated BMPR2 signaling has been directly related to expression of Kv channels [172, 173]. Reduced expression of Kv channels favors an influx of intracellular calcium and promotes vasoconstriction as well as cell proliferation. Kv channel openers like dichloroacetate (DCA) as well as gene transfer of Kv channels have been used as experimental strategies in animal models to prevent and reverse PAH [174–177] (Fig. 117.3). The fawn-hooded rat has abnormal

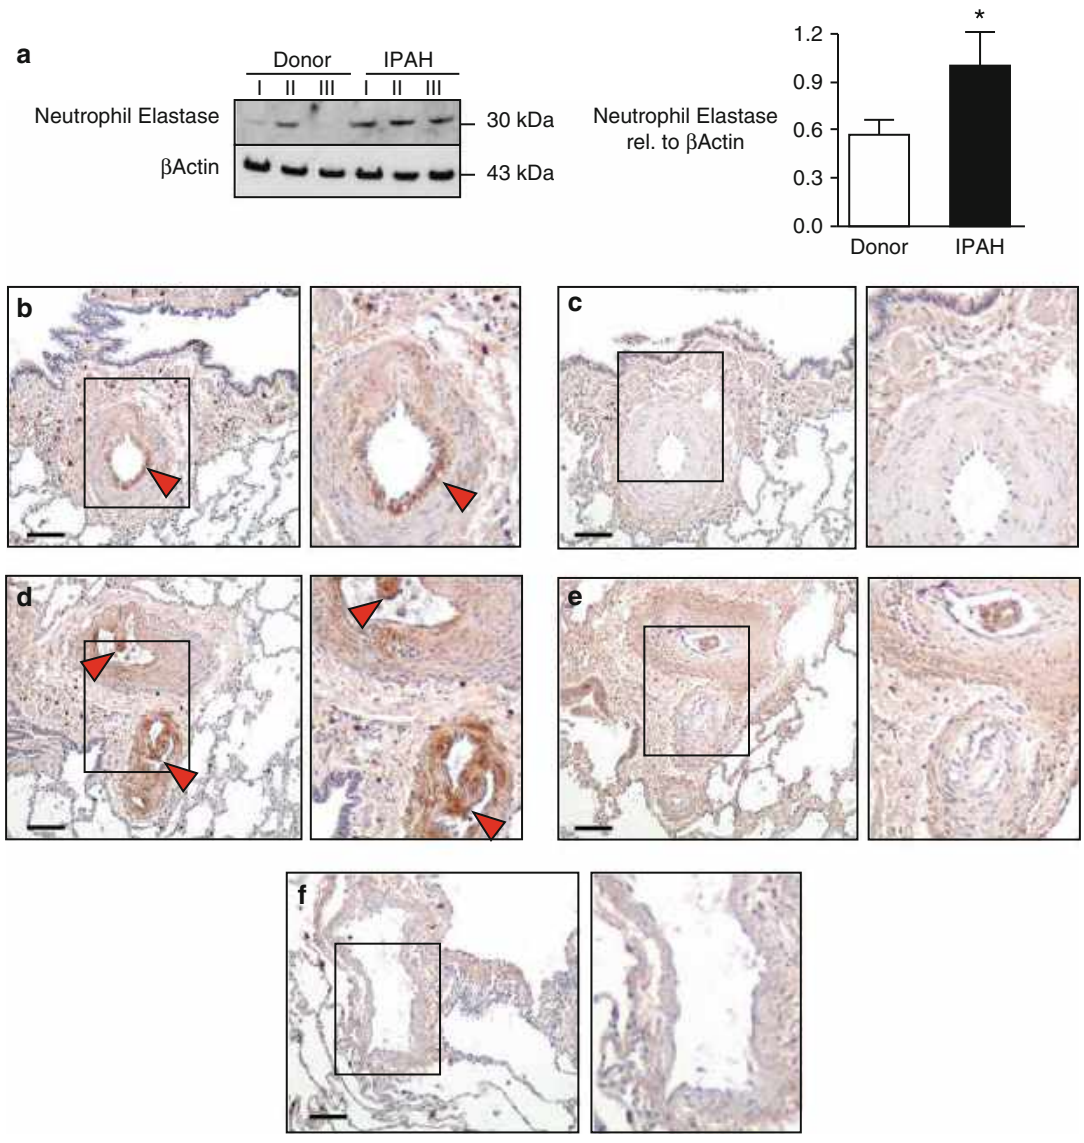

Fig. 117.5 *Heightened neutrophil elastase expression in cultured PA SMCs is localized to neointimal lesions in the lungs from IPAH patients*. (**a**) Western immunoblots on *top* and relative densitometry on the *bottom* comparing NE relative to β-actin in cultured PA SMCs isolated from three IPAH patients versus three unused donor lungs as controls. Bars represent mean of $n = 3$ per group, with $^*P < 0.05$ determined by *t*-test. Representative immunohistochemistry from one of five IPAH and one of four control lungs. Cells strongly expressing neutrophil elastase are apparent in the subendothelium and media of PAs with neointimal or plexiform lesions in the IPAH lung (**b** and **d**). Little immunoreactivity for NE was apparent in the PAs in the control donor lung (**F**). Background immunoreactivity is apparent using IgG as a control (**c** and **e**). *Arrowheads* point to regions of intense immunoreactivity. Marked areas are shown with twofold higher magnification, on the *right*. Scale bars, 100 μm (**b**–**e**) (Reproduced with permission from Reference [170])

oxygen-sensing in the mitochondria of SMCs, leading to reduced Kv channel function [26] as well as a defect in serotonin metabolism. This rat develops PAH in response to mild alveolar hypoxia at mile-high altitude. Hyperpolarized mitochondria cause normoxic stimulation of HIF-1α leading to reduced cytochrome *c* oxidase and superoxide dismutase levels and impaired Kv

channel expression and function (Fig. 117.2). Reversal of the mitochondrial abnormality can be achieved through the pyruvate dehydrogenase kinase inhibitor dichloroacetate, described above as reversing Kv channel dysfunction [26, 178]. In addition it is reported that the serotonin can, in signaling through the 5HT2A receptor, directly inhibit rat pulmonary artery voltage-gated K channels [179].

Mitochondrial Metabolism

Direct manipulation of mitochondrial metabolism in a manner that reverses mitochondrial hyperpolarization and Kv channel dysfunction has proven to be a promising strategy to prevent and reverse pulmonary vascular remodeling. For example, suppression of malonyl coenzyme decarboxylase suppresses experimentally induced hypoxia-mediated vasoconstriction and reverses chronic pulmonary hypertension [180].

Transient Receptor Potential (TRP) Calcium Channels

In addition to K channel dysfunction, activation of the transient receptor potential (TRP) calcium channels particularly TRP 3 and TRP 6 expression in PA SMC from patients with IPAH have been linked to the heightened proliferation observed in these cells [181]. Moreover, it was also shown that inhibition of protein kinase A or activation of cAMP might have a similar effect [182].

Stem Cells in the Pathobiology and Treatment of PAH

A major effort is being directed at understanding the mechanisms underlying pulmonary vascular regeneration and the beneficial or harmful role of progenitor cells in the hypertensive pulmonary vasculature. In the mouse model of PAH induced by monocrotaline, but not hypoxia, the recruitment of circulating stem cells appears to be protective [183]. Mesenchymal stem cells were engineered to prevent the development of experimental pulmonary hypertension in rodents as described in studies using the endogenous vasodilator calcitonin gene-related peptide [184]. Mesenchymal cells have also been delivered intratracheally to attenuate monocrotaline-induced PAH, but the mechanism is obscure [185]. In addition, these mesenchymal stem cells have been engineered to improve myocardial performance following injection into the right ventricles in rodent PAH models [186]. Endothelial progenitor cells (EPCs) transfected with eNOS not only prevent but also reverse PAH in rats by reestablishing connections between proximal and distal pulmonary arteries [187]. This strategy of genetically engineering endogenous EPCs to express eNOS has been recently embarked upon in a clinical trial in patients with advanced PAH. Non-engineered EPCs have been used to treat clinical PAH in a pilot study showing some short-term efficacy [188]. These results are at variance with studies indicating that EPCs may be the very cells that induce plexiform lesions in advanced PAH [24] and may be recruited by GM-CSF.

The Female Predisposition to Idiopathic Pulmonary Hypertension

Increasing effort is being directed at answering why the ratio of adult females to males affected with PAH (IPAH and many APAH conditions) is upwards of 2:1. Our group found that the incidence of metabolic syndrome was twice as high in women with PAH than in the general population [189]. Moreover, the presence of insulin resistance worsened by >50 % the event-free 6-month interval. There is an estradiol-mediated increase in the S100A4 receptor RAGE that has also been implicated in the metabolic syndrome. Only female S100A4 overexpressing mice appear to develop vascular remodeling either spontaneously or after infection with the virus MHV-68 [190]. A polymorphism in a cytochrome P450 enzyme leading to impaired metabolism of estrogen has also been linked to the female predisposition to develop PAH [191].

The Proximal Pulmonary Arteries and the Right Ventricle

Although the focus in understanding the mechanism of PAH has been on the small pulmonary arteries (<500 μM), there is evidence now that changes in impedance [192] resulting from stiffening of the more proximal PAs may also be a critical determinant not only of the pressure but of the ability of the right ventricle to function [193]. These studies also raise questions as to how BMPR2 mutations associated with PAH influence the remodeling pathology of the proximal PAs and of the cardiac myocytes and fibroblasts. A key factor in conferring vascular stiffness is the proportion and the assembly of elastin fibers. Mice with reduced expression of tropoelastin have pulmonary hypertension [194] and stiff pulmonary arteries and when there is degradation of elastin by elastase that will also impact PA stiffness.

Animal Models for PAH and Increased Pulmonary Blood Flow

118

Michael G. Dickinson, Beatrijs Bartelds, and Rolf M. F. Berger

Abstract

Pulmonary arterial hypertension (PAH), a progressive pulmonary vasoproliferative disorder, is characterized by the development of unique neointimal lesions including concentric laminar intimal fibrosis and plexiform lesions.

In PAH associated with congenital heart disease, increased pulmonary blood flow (i.e., systemic-to-pulmonary shunt) is an essential trigger for the occurrence of neointimal lesions and disease development. Although neointimal development is well described histopathologically, the pathogenesis of flow-induced PAH and its typical vascular lesions is largely unknown.

Animal models play a crucial part in giving insight in new pathobiological processes in PAH and possible new therapeutic targets. However, as for any preclinical model, the pathophysiological mechanism and clinical course have to be comparable to the human disease that it is supposed to mimic. This means that animal models mimicking human PAH ideally are characterized by (1) a hit resembling the human disease, (2) specific vascular remodeling that resembles neointimal development in human PAH, and (3) progressive disease development that leads to right ventricular (RV) dysfunction and eventually death.

Therefore, this chapter will discuss currently used animal models for pulmonary hypertension that are of interest for PAH in the pediatric population, specifically PAH associated with congenital heart disease.

Introduction

Pulmonary hypertension (PH) has been divided into five groups based on clinical parameters, histopathology, and therapeutic response according to the most recent Dana Point clinical classification update [1]. In this classification, group 1 comprises pulmonary arterial hypertension (PAH), a progressive and life-threatening pulmonary vasoproliferative disorder, which can occur idiopathically (iPAH) or can be associated with specific underlying conditions such as congenital heart defects (CHD) with a systemic-to-pulmonary shunt [1].

Regardless of the underlying cause, PAH is characterized by a characteristic form of pulmonary vascular remodeling, i.e., plexogenic arteriopathy (Fig. 118.1) [2]. While thickening of the media and adventitia layer of the pulmonary arterioles is seen in many forms of PH (e.g., PH associated with hypoxemia), PAH is characterized by the formation of complex cellular and fibrotic lesions with at the end of the spectrum the formation of concentric laminar intimal fibrosis and plexiform lesions (Fig. 118.1) [3, 4]. These neointimal lesions cause intraluminal obstruction characterized by apoptotic dysregulation and proliferation of endothelial cells, smooth muscle cells, fibrosis, and inflammation [3, 5].

Although neointimal lesions in PAH are well described histopathologically, the pathogenesis of neointimal development remains largely unknown. Clinical experience has shown that in patients with CHD who develop PAH, characteristic vascular lesions occur almost exclusively in defects associated with increased pulmonary blood flow, qualifying this increased flow as a trigger for the induction of neointimal development. In patients with increased pulmonary blood flow, additional increased pulmonary arterial pressure, as a second trigger, seems to accelerate this development of pulmonary vascular remodeling in PAH [6]. These observations indicate that besides flow certain additional triggers (e.g., increased pressure) are able to accelerate disease development.

PAH is considered irreversible when these neointimal lesions have formed, which results in increased pulmonary vascular resistance, increased right ventricular (RV) workload, and eventual death due to RV failure. Therefore, the complex pathogenesis of PAH needs to be further explored in order to identify potential therapeutic targets and improve future treatment possibilities.

During the past five decades, animal models have played a crucial part in this process and will continue to give investigators new insight for PH research in the future. This chapter will discuss currently used PAH animal models that are of interest for PAH, specifically PAH associated with congenital heart disease. Since increased pulmonary blood flow (i.e., systemic-to-pulmonary shunt) is regarded as a trigger for PAH development in this population, particular emphasis will be put on models with increased pulmonary blood flow.

Animal Models of PAH: General Concept

Animal models remain to play a crucial role in studying both new biomolecular pathways as well as investigating new treatment effects in PAH.

Clinical Classification Group	Characteristics of arteriopathy	Histological examples
1. Pulmonary arterial hypertension, Pulmonary veno-occlusive disease or pulmonary capillary hemangiomatosis	• Medial hypertrophy • Muscularization of arterioles • Cellular proliferation of intima layer • Concentric laminar intimal fibrosis • Plexiform lesions • Fibrinoid necrosis	2. PH due to left heart disease	• Medial hypertrophy • Muscularization of arterioles and veins • non-obstructive intimal fibrosis • moderate intima fibrosis veins	
3. PH due to lung disease or hypoxia	• Large arteries mostly normal • Medial hypertrophy • Muscularization of arterioles • similar changes to lesser extent in small pulmonary veins	
4. Chronic Thromboembolic PH (CTEPH)	• Mild medial hypertrophy • Eccentric intimal fibrosis • Recanalization of lumen • recent thrombi rare	
5. PH with unclear multifactorial mechanisms	• Muscularization of arterioles and veins (fibrotic lung disease, tumors) • non-obstructive intimal fibrosis (fibrotic lung disease, tumors) • vascular granulomas (sarcoidosis, tuberculosis) • enlargement of bronchial arteries (bronchiectasis)	
Adapted from Wagenvoort and Mooi

Fig. 118.1 Correlate of the Dana Point 2008 clinical classification with the characteristics of the pulmonary vascular arteriopathy. Group 1, PAH, is characterized by formation of plexiform lesions and concentric laminar intimal fibrosis. Typical examples of these lesions are presented in the right-sided column (Figure adapted from Mooi and Wagenvoort [2])

However, as for any preclinical model, the pathophysiological mechanisms and clinical course have to be comparable to the human disease that it is supposed to mimic. For PAH this means that an ideal model would include the following:

1. An initiation or trigger of pulmonary vascular remodeling that mimics the human situation (e.g., increased pulmonary blood flow)
2. Pulmonary vascular remodeling that represents plexogenic arteriopathy and includes the development of complex obliterative lesions of the small intra-acinar arteries and media hypertrophy of the smaller preacinar arterioles
3. A progressive disease development that leads to RV dysfunction and eventually death

In addition, the model has to be viable in an experimental setting regarding both functional (hemodynamic and histological assessments) and biomolecular analyses as well as having a workable period to disease progression.

To date no such ideal model for PAH exists. However, some recent animal models may resemble more closely both pathophysiological mechanisms and clinical course of human PAH compared to more historical animal models of PH.

Development of Pulmonary Vasculature: How Do Animals Compare to Humans?

In choosing a proper animal model for PH research, consideration first has to been given to possible anatomical and developmental differences between specific animals and humans. In humans the pulmonary parenchyma undergoes several

developmental stages of which only alveolar development and vascular maturation remain after birth. Comparable with humans, rats and mice have little alveolar development at birth, whereas, for instance, lambs have already well-developed alveoli at birth, making these species less suitable for studying perinatal changes in pulmonary blood flow and vascular remodeling [7].

Rat lungs on the other hand show quite similar alveolar and capillary surface developments after birth compared to humans [8]. Mice have less pulmonary blood vessel walls and more alveolar space compared to rats [8] which could possibly explain the mild forms of vascular remodeling in most murine PH models, as described below.

The pulmonary vasculature is lined by endothelial cells, which are the first structures to perceive changes in hemodynamic forces as increased blood flow or shear stress. The endothelium is the barrier between blood and the interstitium connected with surrounding vascular cell layers (e.g., smooth muscle cells, fibroblasts) and has an important function in controlling vasomotor tone, regulating permeability, maintenance of hemostatic balance, and immunity. There is increasing evidence that pulmonary vascular endothelial cells change in characteristics with size and location in the pulmonary vascular tree [9]. As the pulmonary vascular tree branches and the size of the pulmonary arteries decreases, the endothelial cell phenotype progresses from pulmonary artery endothelial cells towards pulmonary microvascular endothelial cells, which differ in their permeability and mechanistic properties [9]. These differences may reflect in the location specificity of the pulmonary vascular histomorphological changes observed in PAH. In the larger preacinar arterioles (100–500 μm), only increased medial wall thickness and intimal proliferation are observed, whereas complex neointimal lesions (e.g., laminar concentric intimal fibrosis, plexiform lesions) progressively develop in the normally nonmuscular arterioles (<100 μm), the so-called intra-acinar arteries (Fig. 118.2) [2]. It is debatable whether the most severe lesions, i.e., laminar concentric intimal fibrosis and plexiform lesions, are formed at distal dichotomous branching points [10] or at the branching points of supernumerary arteries [11]. For murine models, for instance, this is important to realize since there is still debate on whether or not mice even develop supernumerary arteries [7]. This may explain why to date it is so difficult to induce severe PAH in a mouse model, as discussed later [48].

Historical PH Models

Historically, the most widely used animal models of PH have been chronic hypoxia and the monocrotaline-induced PH rodent models. Although these models have added enormously to the understanding of the mechanisms of pulmonary vascular remodeling in PH, they are limited by the lack of typical complex vascular neointimal lesions and severe disease phenotype seen in PAH [12]. Still, these models form a basis for other newer animal models where multiple hits (triggers) result in characteristic pulmonary vascular lesions closely resembling human disease, e.g., the monocrotaline/increased flow model [13, 14] or the hypoxia/Sugen model [15]. Therefore, these historical PH models are briefly discussed below.

Chronic Hypoxia PH Model

The chronic hypoxia model is a widely used example for the investigation of PH in both large and small mammals, particularly rodents. As previously reviewed in greater detail by Stenmark et al. [12], rats, and to lesser extent mice, subjected to either chronic normo- or hypobaric hypoxia demonstrate muscularization of the precapillary arterioles, increase in mean pulmonary artery pressure, and RV hypertrophy. With the exception of fawn-hooded rats which develop severe PH after hypoxia exposure, most rodents only develop a moderate form of vessel muscularization after hypoxia exposure. Furthermore, this muscularization and the disease phenotype are reversible when normal oxygen levels are restored. Moreover, pulmonary neointimal lesions, typical for PAH, as well as apparent RV failure are not seen in the hypoxia-induced PH models [12].

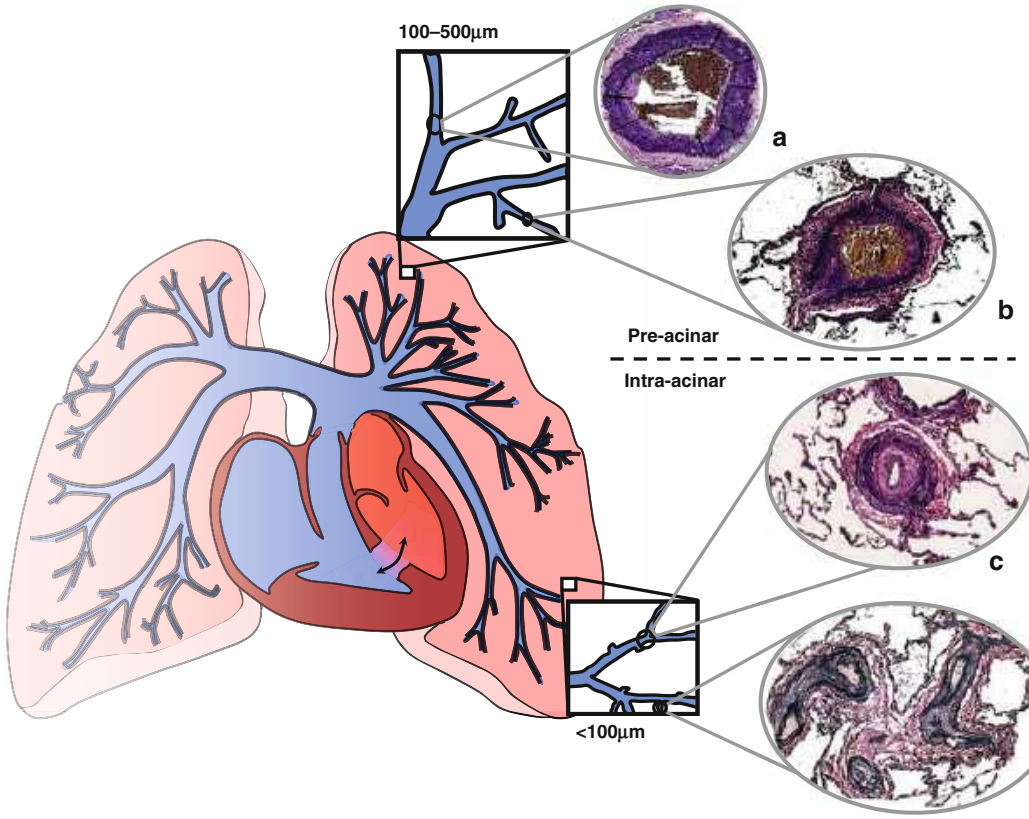

Fig. 118.2 Distribution of the specific lesions seen in pulmonary hypertension throughout the pulmonary vascular tree. The preacinar pulmonary arteries mainly display a phenotype of media hypertrophy (**a**) and neointimal formation (**b**), whereas the intra-acinar arteries have typical occlusive lesions such as concentric intimal fibrosis (**c**) and plexiform lesions (**d**)

Monocrotaline PH Rat Model

The effects of monocrotaline on the pulmonary vasculature have been extensively referenced [12, 16, 17]. In short, monocrotaline is a pyrrolizidine alkaloid that can be found in the plant *Crotalaria spectabilis*. Once activated to the toxic monocrotaline pyrrole by cytochrome p450, monocrotaline can induce pulmonary vascular injury characterized by vessel muscularization and arteritis in a dose-dependent matter, as first shown by Lalich et al. [18]. The rat is the most widely used animal for monocrotaline-induced PH due to its reproducibility and ease of manipulation. In mice, monocrotaline is less effective, as mice show little to no pulmonary vascular remodeling even after a tenfold dose. In rats, muscularization of the small intra-acinar vessels takes place 1–2 weeks after monocrotaline injection followed by RV hypertrophy in 3–4 weeks, depending on the dose used. However, the exact mechanism of monocrotaline-induced vascular remodeling is not known. It has been suggested that perivascular accumulation of inflammatory cells such as macrophages play a role in smooth muscle cell hypertrophy after monocrotaline injection. This concept is supported by the fact that therapy targeting monocyte chemoattractant protein-1 (MCP-1), a proinflammatory cytokine, attenuates muscularization of the small arterioles in monocrotaline-induced PH.

In addition to inflammation, it has been reported that early endothelial damage may

form the basis of monocrotaline-induced vascular remodeling since endothelial cell injury has been observed in early stages of vessel remodeling. However, the endothelial cell injury seen after monocrotaline injection is not followed by the typical endothelial cell proliferation as seen in neointimal lesions in human PAH. The lack of obstructive vascular remodeling with MCT-induced PH might explain the observation that almost every therapeutic intervention used in the monocrotaline model is able to either prevent or reduce pulmonary vascular remodeling and disease development [12, 16].

Increased Pulmonary Blood Flow and Vascular Remodeling

As stated above, in congenital heart disease (CHD) patients, increased pulmonary blood flow is a trigger for PAH-specific vascular remodeling. In patients with CHD associated with a pretricuspid shunt, where the vascular bed is solely subjected to increased pulmonary blood flow, but not to systemic pressure, 10–20 % of patients will develop progressive PAH and this usually requires 30–40 years to develop [19]. In contrast, in patients with unrestrictive posttricuspid shunts, in which the pulmonary vascular bed is subjected to both increased blood flow and systemic pressure, PAH develops, if left untreated, in virtually all patients and mostly within the first years of life. In other words, in patients with CHD, increased pulmonary blood flow is a trigger for PAH-specific neointimal development in a seemingly "susceptible" subset of patients, while second hits, such as increased pulmonary arterial pressure, can accelerate the development of pulmonary vascular remodeling in PAH.

Models of Increased Pulmonary Blood Flow

The role of increased pulmonary blood flow on vascular remodeling has been previously studied in experimental setting both in larger animals [20–23] and in rodents [24]. Various pathways that are known to play a role in human PAH have been studied in models of increased pulmonary blood flow. First, several studies have reported that systemic-to-pulmonary shunting in young lambs and piglets results in alterations of the endothelin pathway [21, 22, 25]. In these models, endothelin-1 and endothelin A receptor expression is first upregulated followed by increased endothelin B receptor expression after chronic (>8 weeks) shunting which were found on the smooth muscle cells of the pulmonary vessels [21]. Chronically increased flow has also been shown to increase endothelial nitric oxide synthesis (eNOS), but not inducible nitric oxide synthesis (iNOS), activity in lung tissue and pulmonary arteries subjected to increased flow [21, 22]. Interestingly, NO availability itself was reported to decrease after increased flow exposure, which has been suggested to be the result of peroxynitrite production that leads to scavenging of NO and decreased production of NO by eNOS. In addition to biomolecular investigation, several treatment effects have been reported in these models, including beneficial effects on pulmonary vascular resistance and vascular wall thickness after preventive treatment with PAH-specific drugs, i.e., endothelin receptor antagonists (ERAs) [26, 27], phosphodiesterase-5 inhibitors [26], prostacyclin, and inhaled NO [28].

In all models described above, increased pulmonary blood flow results in development of media hypertrophy of the pulmonary vessels (Fig. 118.3). Obliterative lesions of the intraacinar vessels or advanced plexiform lesions have not been found. Hence, although the hit is clinically relevant, i.e., (i) increased pulmonary blood flow, the pulmonary vascular remodeling is not representative for group I PAH (ii), which makes it difficult to extrapolate the therapeutic effects to human PAH where irreversible neointimal lesions form the basis of therapeutic targeting. A possible explanation for the moderate form of vascular remodeling is that in these larger rodent models the duration of shunting was not sufficient to produce complex lesions – weeks instead of months or years. Indeed, chronic (>a year) systemic-to-pulmonary shunting in both

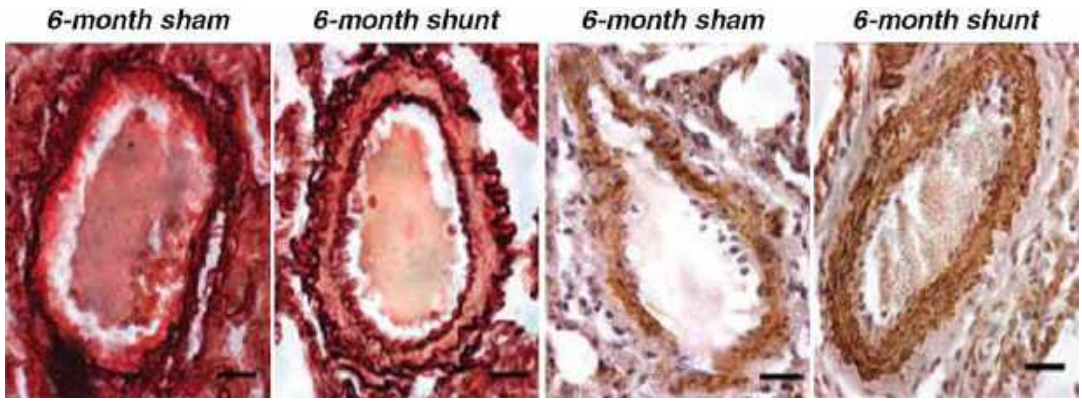

Fig. 118.3 Effects of increased pulmonary blood flow on the pulmonary vasculature in large animals. Pulmonary vascular histology in these models was dominated by medial wall thickness only; no advanced lesions were observed after 3 months of aortopulmonary shunting in piglets (Adapted from Rondelet et al. [21])

sheep and dogs has shown to result in plexiform-like lesions similar to human disease (Fig. 118.4) [29, 30]. A second possible explanation for the moderate form of vascular remodeling in many larger rodent models is that the shunt used in these models is a restrictive shunt [21, 25–28]. As mentioned above, only a limited proportion of patients with restrictive shunts develop advanced arteriopathy and only after several decades.

Several studies have shown that when either one lung (i.e., left pulmonary artery) [20, 31] or a single lobe [23, 32] is directly connected to the aorta, resulting in both high pulmonary blood flow in combination with (or) and high pressure, neointimal lesions comparable with human disease are seen to develop (Fig. 118.4). This confirms the clinical observation in CHD patients that increased pressure, as an additional hit, accelerates pulmonary vascular remodeling. Unfortunately, since extensive morphometric analysis was not conducted in these studies, it is difficult to interpret the exact magnitude of this remodeling.

Increased Pulmonary Blood Flow Combined with an Additional Trigger

A Second Hit Needed?

Okada and colleges were the first to show that combining vascular injury (via monocrotaline administration) with increased pulmonary blood flow (via an anastomosis of the left subclavian artery to the distal left pulmonary artery) results in an extended neointimal pattern of pulmonary vascular remodeling in the lung subjected to high flow after 5 weeks [13, 33]. In addition, increased pulmonary artery pressure and RV hypertrophy were reported. In this study either monocrotaline or anastomosis alone did not result in severe neointimal vascular remodeling. In a different model van Albada et al. have shown that when combined with monocrotaline administration, increased pulmonary flow via an aortacaval (av-) shunt results in (1) neointimal obliteration of the intra-acinar vessels staining positive for eNOS and smooth muscle actin, (2) increased systolic pulmonary artery pressure and RV hypertrophy, and (3) increased mortality after 5 weeks (Fig. 118.5) [34].

This data suggests that increased pulmonary blood flow, as a second hit in addition to MCT, is a prerequisite for the development of pulmonary neointimal lesions. Interestingly, in an experimental study Nishimura and colleagues showed that when monocrotaline was administered after av-shunt creation, pulmonary vascular remodeling was less pronounced, and the authors suggested a salvage effect of increased flow [35]. However, this is more likely to be explained by the fact that due to the increased blood flow through av- shunt, the concentration of monocrotaline pyrrole in the lungs was 2–3 times lower compared to nonshunted rats.

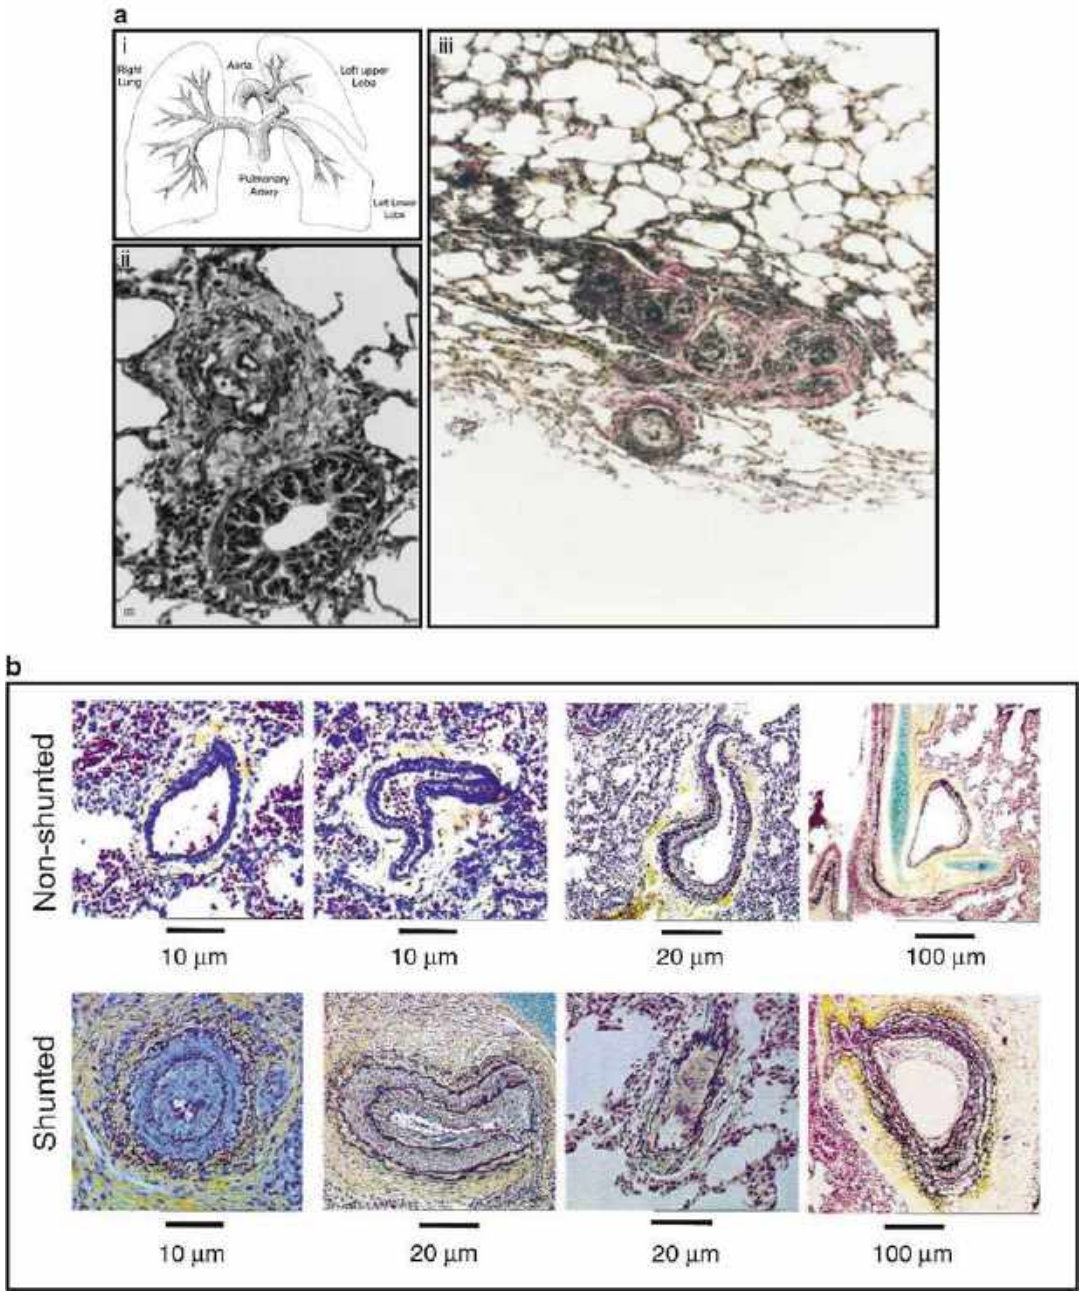

Fig. 118.4 Prolonged increased pulmonary blood flow in large animals mimics pulmonary vascular lesions in children with congenital heart defects: (**a**) A sheep model of increased pulmonary blood flow in the *left upper lobe* (**i**), induced intimal proliferation after 2 months (**ii**), but developed into more advanced lesions after 1.5 years (**iii**) (Adapted from Schnader et al. [30]). (**b**) Beginning of neointimal lesions and medial wall thickness observed in small intra-acinar vessels after 8 weeks due to an anastomosis of the *left lower lobe* directly to the aorta in pigs (Adapted from Bousamra et al. [32])

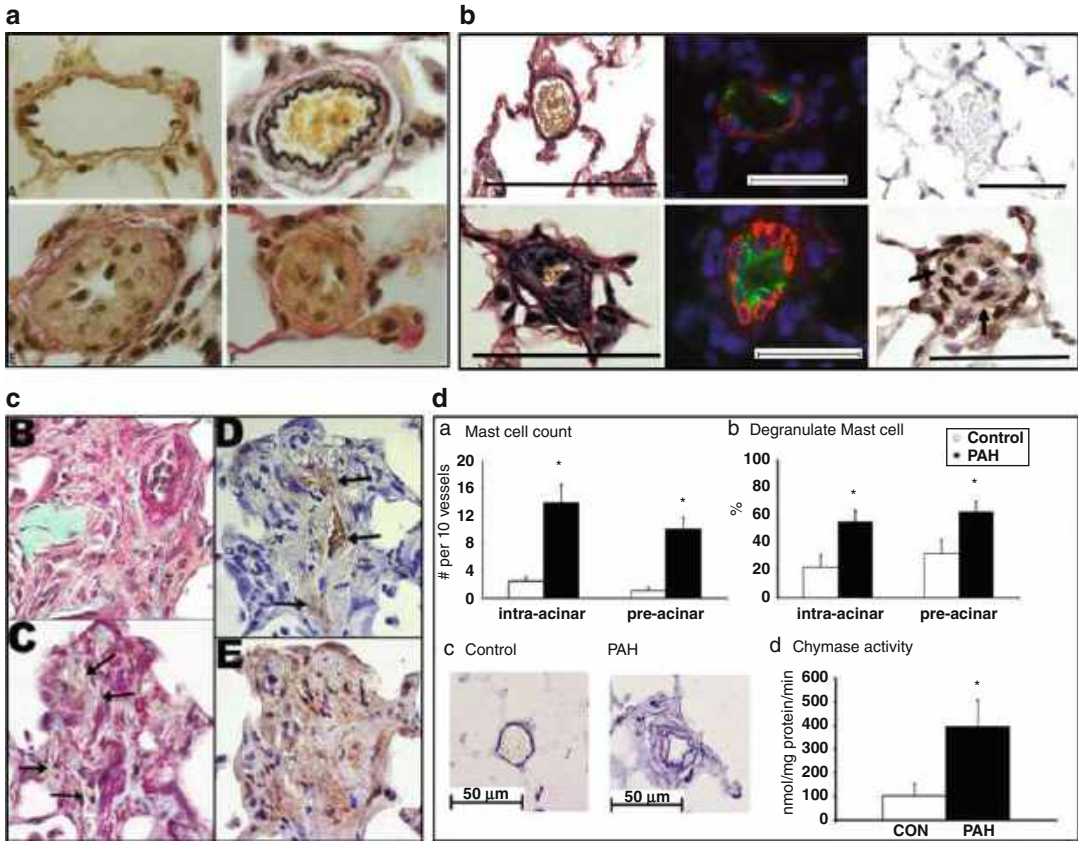

Fig. 118.5 Examples of extensive lesions resembling human PAH group 1 in "double-hit" models: (**a**) Extensive neointimal proliferation in the pulmonary vessels of rats subjected to a pneumonectomy combined with monocrotaline (Adapted from Okada et al. [13]). (**b**) Neointimal proliferation in intra-acinar vessels of rats with an aortocaval shunt combined with monocrotaline (*left*). Immunofluorescence staining shows proliferation of endothelial cells (*green*, vWF) and smooth muscle cells (*red*, α-SMA). Immunostaining shows increased expression of Egr-1 a putative inductor of advanced lesions (Adapted from Dickinson et al. [14]). (**c**) Typical examples of plexiform-like lesions in young rats subjected to a pneumonectomy and monocrotaline. These lesions stain positive for vWF (*top right*) and VEGFR-2 (*bottom right*) (Adapted from White et al. [38]). (**d**) Increased presence of mast cells around pulmonary vessels of rats with an aortocaval shunt combined with monocrotaline as well as increased chymase activity, one of the mast cell proteases (Adapted from Bartelds et al. [46])

Alternatively, the induction of the shunt may also activate genetic pathways that oppose previously activated pathways induced by monocrotaline [36].

Neointimal Lesions in Models with Increased Pulmonary Blood Flow

Are the vascular lesions seen in the "double-hit" models comparable with those in human disease?

In human PAH irreversible neointimal lesions are comprised of both ECs and SMCs with a reduction in apoptotic markers and increase in inflammatory cells [37].

In flow models, these obliterative lesions are comprised of cells that stain positive for the endothelial cell markers VEFG-R2 [38], eNOS [34], von Willebrand factor [14, 38], and CD31+ [39] and for SMCs staining positive for α-smooth muscle actin (Fig. 118.5) [14, 34, 38, 39]. Longitudinal studies using both the av-shunt and pneumonectomy/monocrotaline models have shown that these neointimal lesions start to form 1–2 weeks after increased pulmonary blood flow (Fig. 118.5) [13, 14, 38]. In these experimental

models the exact role of apoptotic or proproliferative state of these vessels during vascular remodeling is fairly unknown. In addition, questions still remain whether in the smaller pulmonary vasculature these occlusive lesions are most prominent (i.e., at branching points of larger arteries or at more distal locations).

Interestingly, White and colleagues have reported in their model that when monocrotaline administration is combined with unilateral pneumonectomy in younger rats, more complex plexiform-like lesions are formed (Fig. 118.5) [38]. The authors suggested that younger rats were more prone to vascular proliferation after injury. These plexiform-like lesions stained positive for vWF, VEGFR-2, and α-SMA and, as shown by microangiography, to be part of the pulmonary vasculature. However, with regard to this monocrotaline/pneumonectomy model, unlike the monocrotaline/av-shunt model, the possible effects of proliferation of lung parenchyma itself (up to 35 % due to pneumonectomy) have to be taken into consideration with this model, as previously shown [40].

Increased Pulmonary Blood Flow and Inflammation

Inflammation has been suggested to play a role in experimental PAH as well as in the development of flow-induced neointimal formation in PAH patients with systemic-to-pulmonary shunts [36, 41, 42, 46].

Proinflammatory cytokines and other inflammatory cells including mast cells [43, 46], macrophages, lymphocytes [41], and dendritic cells [44] have all been linked to either flow or nonflow PAH.

Accumulation of inflammatory cells in experimental PAH has also been linked to increased oxidative stress [44], which is also seen in pulmonary vessels of PAH patients [45].

In animal models of increased pulmonary blood flow, inflammation has also been suggested to play a role in neointimal development [36, 44, 46]. Clearly, the effect of monocrotaline administration in vascular inflammation has to be taken into account in these experimental models [16, 17], and questions remain whether inflammation can be seen as the additional trigger for neointimal development in the increased pulmonary blood flow/monocrotaline models.

Still, reducing inflammation such as recently shown by mast cell stabilization or inhibition of chymase can attenuate the development of pulmonary vascular remodeling [46, 47]. These results justify future exploration of the possible role of anti-inflammatory therapy for PAH.

In summary, in flow models that combine a trigger such as vascular injury (monocrotaline) with either pneumonectomy or an av shunt, increased pulmonary blood flow specifically induces severe pulmonary vascular remodeling including neointimal development, perivascular inflammation, and plexiform-like lesions that show remarkable similarities with human plexogenic arteriopathy (2) (Fig. 118.6). In addition, increased flow leads to more pronounced increases in pulmonary artery pressure, RV hypertrophy, and mortality (3).

Other Neointimal Models

Besides flow-associated PAH animals, other models (mostly rat and murine) have also been reported to develop specific obliterative lesions, some with great resemblance to neointimal lesions in human PAH.

Murine models are of interest since they allow researchers to investigate the relevance of single genes using genetic manipulation. The main disadvantage of murine models, however, is the mild degree of PH and RV dysfunction that usually are achieved in mice compared to other animal models [48]. In addition, possible differences in the vascular bed of mice and humans have to be taken into consideration when comparing these data, as described above.

Sugen/Hypoxia Rat Model

Vascular endothelial growth factor (VEGF) is a prosurvival growth factor and is known to play a critical role in normal lung development [49]. In both iPAH as well as PAH associated with

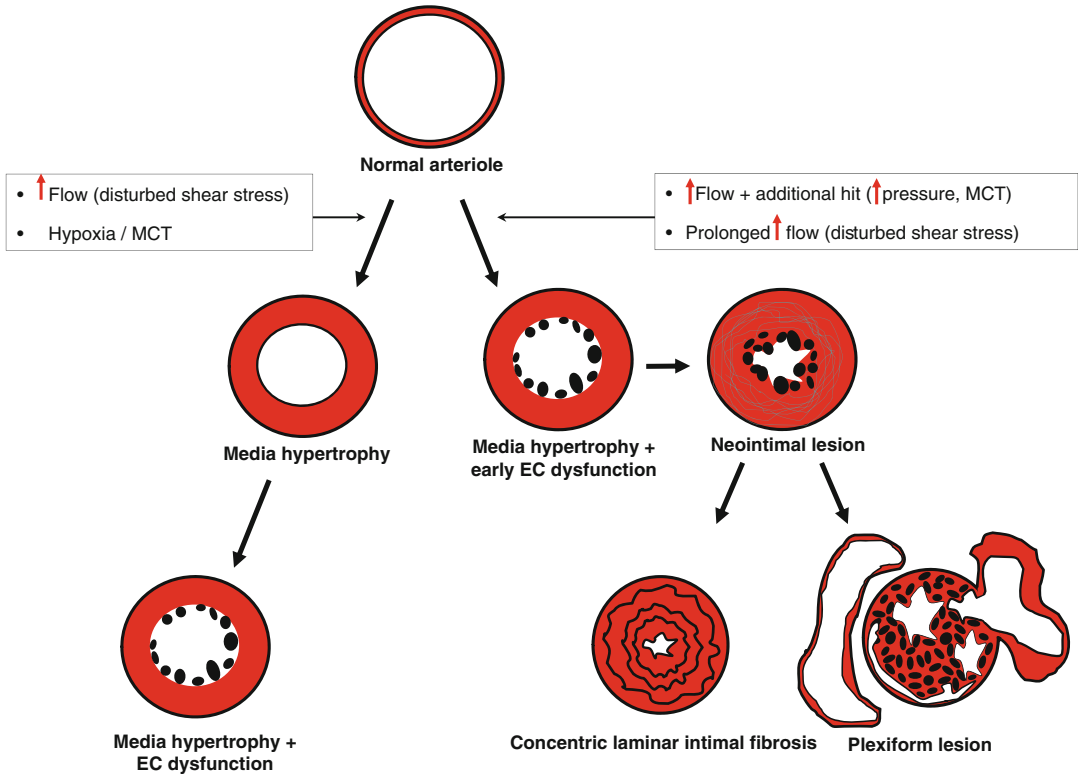

Fig. 118.6 Schematic representation of effects of increased flow on the development of pulmonary vascular lesions in PAH models. *Left side*: Triggers such as increased flow, monocrotaline, or hypoxia induce media hypertrophy and can induce endothelial cell changes. However, in most animal models, these hits alone do not trigger neointimal development within the time frame studied. *Right side*: Double-hit models progress from early endothelial cell activation via an initial hit, either increased pulmonary blood flow or monocrotaline, followed by a second hit, increased pressure, (prolonged) increased blood flow that combined triggers neointimal development in these animal models

congenital systemic-to-pulmonary shunts, VEGF is strongly expressed in plexiform lesions in end-stage disease [49]. However, the role of VEGF in pulmonary vascular remodeling in PAH remains unclear.

Taraseviciene-Stewart et al. have shown that by combining VEGF receptor 2 (VEGFR2) inhibition, using the compound Sugen 5416, with chronic hypoxia, results in PAH with characteristic obstructive neointimal lesions in the arterioles, increased mPAP, and right ventricular hypertrophy (Fig. 118.7) [15, 50]. Pulmonary vascular remodeling in this model is characterized by SMC proliferation, an initial endothelial cell apoptosis followed by endothelial cell proliferation that continues even after reexposure to normoxia (Fig. 118.7) [15]. In addition, when these rats are subjected to normoxia for a longer period of time (up to 14 weeks), more complex neointimal lesions are formed, showing similarities with human plexiform lesions (Fig. 118.7) [51]. However, unlike in irreversible human PAH, the survival rate of Sugen 5416/hypoxia rats has been shown to be close to 100 % even during long follow-up [51]. Apparently the degree and magnitude of arteriopathy in these rats is unable to induce RV failure, which raises the question whether the extent of arteriopathy is representative for the human setting.

Endothelial cell apoptosis could also play a major role in vessel occlusion in this model. Sakao et al. have shown that human pulmonary microvascular ECs (hPMVEC), when subjected to Sugen 5416, go into apoptosis and stimulate vascular SMC proliferation [5].

Despite these observations, it remains unclear how this characteristic arteriopathy develops in

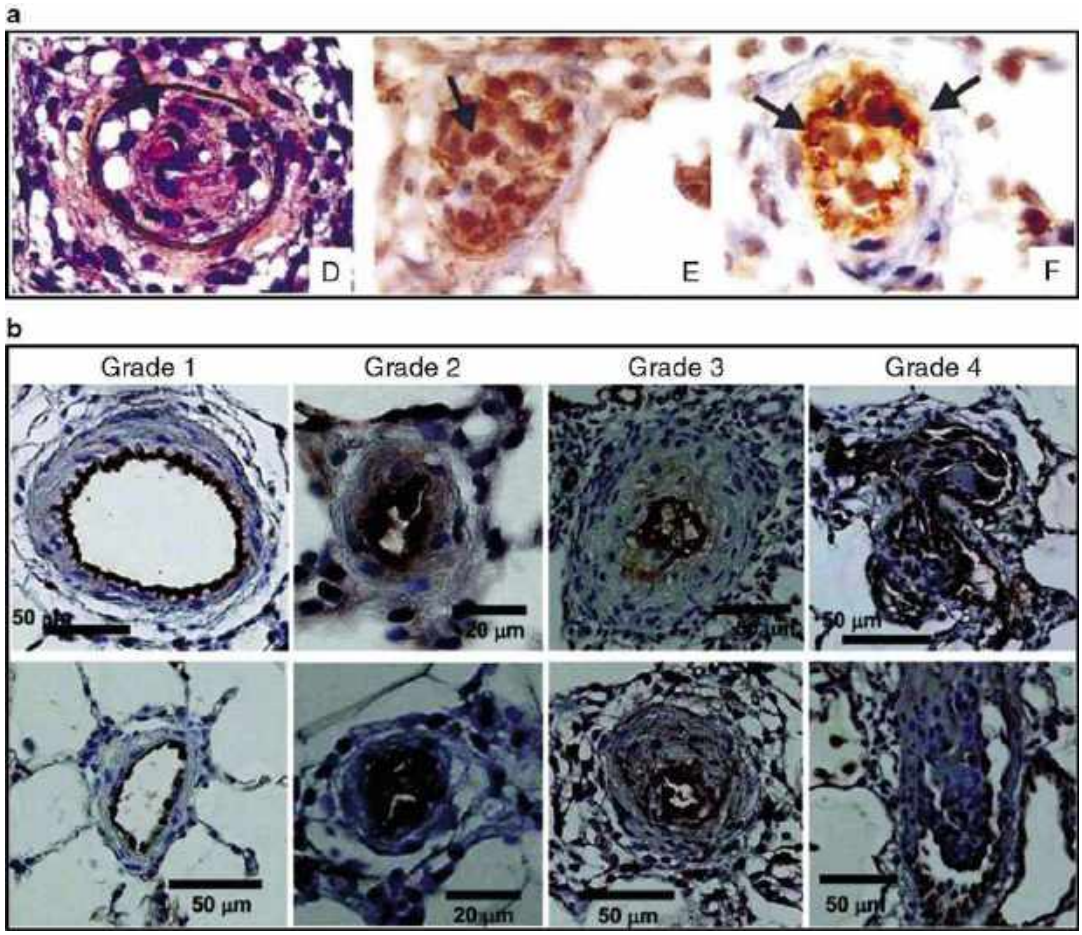

Fig. 118.7 Examples of advanced lesions observed in a model of inhibited angiogenesis combined with hypoxia (Sugen/hypoxia): (**a**) Rats treated a synthetic VEGF receptor antagonist and subjected to 3 weeks of hypoxia show lumen obliteration that stains positive for factor VIII and VEGFR-2 (Adapted from Taraseviciene-Stewart et al. [15]). (**b**) The severity of lesions increases in rats subjected to Su5416, 3 weeks of hypoxia, and subsequent normoxia. After 5, 8, and 13 weeks of normoxia, lesions progressed to plexiform-like lesions with both intraluminal cell proliferations as well as aneurysm like lesions (Adapted from Abe et al. [51])

the Sugen 5416/hypoxia rats. Sugen 5416 injection or hypoxia alone both do not result in obliterative lesions of the intra-acinar vessels indicating that also in this model additional triggers are needed to develop complex vascular lesions [15]. Unfortunately, little is known about the exact role of Sugen 5416 in this process of SMC and EC proliferation and vascular occlusion. For instance, besides VEGF-R2 inhibition, Sugen 5416 is also known for its inhibitory effect on other tyrosine kinases, making it possible that not only VEGF-R2 inhibition is the leading effect on vascular remodeling [52, 53]. It is therefore possible that other kinases also can play a role in the development of vascular remodeling in the 5416/hypoxia model. This raises the question whether the Sugen/hypoxia (normoxia) model of PAH is really ideal for biomolecular analysis of PAH. Indeed, Moreno-Vinasco et al have shown that when comparing gene expression of Sugen/hypoxia rat lungs with human PAH lung tissue, only one similar hit comes up (Fyn: a protein-tyrosine kinase oncogene) [54].

Endothelin-B Receptor-Deficient Rats

Ivy et al. have reported in rats that endothelin B (ETB) receptor deficiency combined with monocrotaline results in the development of neointimal lesions, increased RV hypertrophy and reduced cardiac output compared to monocrotaline alone [55]. The vascular lesions in this model are comprised of cells staining positive for both EC and SMC markers and show similarities with human PAH lesions as well as those in other PAH models. Also similar to other models is that this model also needs a double hit for neointimal lesions to develop. Still, when ETB receptor-deficient rats are subjected to hypoxia instead of monocrotaline [56], these neointimal lesions are not seen even though PH does occur, indicating that not all additional trigger induce the same magnitude of pulmonary vascular remodeling.

Although treatment effects have yet to be reported in this model, the current data suggests that the ETB receptor exhibits angioproliferative properties, when combined with the proper additional hit.

Bone Morphogenetic Protein Receptor 2 (BMPR-2) Gene Mutations

Germline mutations in the bone morphogenetic protein receptor 2 (BMPR-2) gene are known to play a role in the development of PAH [57].

In PAH patients BMPR-2 loss-of-function mutations have only been found in the heterozygous state. The heterozygous BMPR-2 knockout, however, showed only mild increased pulmonary artery pressure and pulmonary vessel muscularization at best [58].

A more recent work has focused on cell-specific BMPR-2 loss of function. SMC-specific loss of BMPR-2 shows a more profound vascular remodeling and increased RV systolic pressure, although neointimal lesions were not found [59, 60]. In contrast, endothelial-specific loss of BMPR-2 expression in mice resulted in pulmonary vascular remodeling consisting of proliferating α-SMA positive cells, in situ thrombosis, and perivascular macrophage and leukocyte infiltration leading to increased RV systolic pressure and RV hypertrophy [61]. Although the degree of vascular remodeling is not completely comparable with human PAH, these BMPR-2 models may provide a better understanding of the possible synergistic effects of genetic predisposition and environmental triggers that cause PAH.

Other models of potential interest are the Il-6 transgenic mice [62] and mice overexpressing a calcium-binding protein S100A4Mts [63]. Nevertheless, in both models disease penetrance is incomplete and a second hit is needed to develop pulmonary, non-neointimal vascular lesions.

Treatment Effects in Neointimal Animal Models

Currently PAH patients are treated, in addition to supportive medication, with either (1) calcium channel blockers or (2) one or a combination of the following agents: prostacyclin analogues, endothelin receptor antagonists, and phosphodiesterase-5 inhibitors. Despite improvements with these treatments, PAH still remains a fatal disease. The general thought is that this is related to the severity of pulmonary vascular remodeling, which is considered irreversible once neointimal lesions have formed. Therefore, future treatments should focus targeting on reversal of these so-called irreversible neointimal lesions, something that has not been accomplished so far.

In general – although some positive effects have been described (predominantly in prevention studies) – to date, no cure for animals with established advanced lesions has been found. Nevertheless, several interesting "proof of principle" studies may direct future research for development of novel therapies.

In monocrotaline/av-shunt rats, inhibition of the vasoconstrictor thromboxane, a key player of vascular remodeling in PAH, using the prostacyclin analogue treprostinil, resulted in a reduction in pulmonary artery pressure, although neointimal development was not reduced [64].

Similar resistance to vascular remodeling improvement was seen when using aspirin or iloprost [65], suggesting a vasodilatory effect rather than an antiproliferative effect of the drug.

Other studies have shown that ACE inhibition, using quinapril, attenuated neointimal formation of the intra-acinar vessels [47]. Also, when triptolide (a Chinese herb with anti-inflammatory and antiproliferative effects [66]) was administered to monocrotaline/pneumonectomy rats, neointimal formation, pulmonary artery pressure, as well as RV hypertrophy could be both attenuated and reversed [66]. However, the authors also described a mortality rate of roughly 30 % in the triptolide-treated group.

In the future, novel treatments in PAH may shift more towards targeting angiogenesis and inflammation. Indeed, in monocrotaline/flow models, simvastatin (also known for its anti-inflammatory properties) [39], mast cell stabilization (via cromolyn) [46], dehydroepiandrosterone (known to have antioxidant and anti-inflammatory effects) [67], rapamycin (an antiangiogenic agent) [68], and EPO (erythropoietin, known for endothelial repair by endothelial progenitor cell mobilization) [69] have shown to attenuate, or in part reverse [39, 68], neointimal formation and/or increased pulmonary artery pressure. However, caution is ought to be taken when directly extrapolating these data to the human setting as illustrated a recent randomized controlled trial in PAH patients, in which simvastatin as add-on therapy did not show a positive effect on 6 min walking distance [70].

Therapies in Models of Sugen + Hypoxia

Similar to the human setting, vascular remodeling seen in the Sugen 5416/hypoxia model has shown to be resistant to many drugs (Ca^{2+} channel receptor blockers, prostacyclin analogues, dual endothelin A/B ($ET_{A/B}$) receptor antagonists) currently used for the treatment of human PAH [50, 71].

Several other therapeutic treatments have been evaluated in this model. For instance, the caspase inhibitor Z-Asp-CH_2-DCB [15], the antineoplastic agent sorafenib [54], the bradykinin receptor 2 agonist B9972 [72], and simvastatin [50] all have shown to prevent the development of neointimal formation and severe pulmonary hypertension. However, similar to results from flow-PAH models, caution has to be taken when extrapolating these data to the human setting [70]. In addition, several other drugs including angiotensin-2 receptor blockers and angiotensin-converting enzyme inhibitors have shown to have no effect on prevention of pulmonary vascular remodeling [50, 73]. Also, to date no drugs have shown reversal of pulmonary vascular remodeling in this model, which as an intervention is more clinically relevant since most PAH patients present when vascular remodeling has already developed.

Other Interesting Pathways in Animal Models

Possible Novel Pathophysiological Pathways in PAH

The pathogenesis of the complex pulmonary vascular lesions is likely a multifactorial process, necessitating system biology approaches to indentify novel targets [74]. Using a microarray analysis, van Albada et al. showed that increased pulmonary blood flow specifically induced the expression WNT-signaling genes and several other transcription factors including activating transcription factor-3 and early growth response factor-1 (Egr-1) [14, 36]. Also, in the last years many new putative pathways have been discovered in non-neointimal models that could potentially affect PAH development. Examples are the PPAR gamma pathway in PAEC in mice [75], tyrosine kinase inhibitors in hypoxic PH or monocrotaline-induced PH [76], soluble GCs [77] and the possible role of microRNAs in PH [78]. Although promising pathways, their roles have yet to be established in more clinically relevant neointimal models of PAH.

Concluding Remarks

Pulmonary arterial hypertension is still a progressive disease with typical lesions characterized by neointimal formation, obliteration, and plexiform lesions. The pathogenetic mechanism underlying the formation of these progressive pulmonary vascular lesions is still poorly understood but might be the key to curative treatment. Animal models mimicking the human disease ideally are characterized by (1) a hit resembling the human disease (e.g., increased pulmonary blood flow), (2) the progression towards the characteristic pulmonary vascular remodeling that represents plexogenic arteriopathy and includes the development of complex obliterative lesions of the small intra-acinar arteries and muscularization of larger preacinar arteries, and (3) progressive disease development that leads to RV dysfunction and eventually death. Although no model to date is ideal, models showing the closest resemblance with human disease are those that use multiple triggers for disease development and result in neointimal lesions (Fig. 118.8). Since increased pulmonary blood flow is a known trigger for neointimal development and PAH associated with congenital heart diseases, flow-associated animal models that result in neointimal lesions are of particular interest for this patient population.

Using these more clinically relevant neointimal models, future studies should consider focusing their attention on the following: (1) the

Experimental model	Characteristics of arteriopathy	
Increased flow models: • short term or small systemic-to-pulmonary shunt in rats, pigs, sheep	• media hypertrophy and muscularization of arterioles	
Other models • hypoxic model rat /mouse • MCT model in rats	• media hypertrophy and muscularization of arterioles	**Media hypertrophy**
Increased flow models: • MCT + aortocaval shunt in rats • MCT + pneumonectomy • Chronic systemic-to-pulmonary shunt in rats, pigs, sheep, dogs	• muscularization + obliterative lesions (SMCs/ECs), perivascular inflammation. • neointimal proliferation of ateries; muscularization + obliterative lesions arterioles	Other models: • Sugen 5416 + chronic hypoxia • S100A4/Mts1 overexpression in mice • S100A4/Mts1 overexpression + YHSV-68in mice • IL6 overexpression + with hypoxia in mice	• muscularization + obliterative lesions (ECs) • muscularization + obliterative lesions (SMCs) + perivascular inflammation • obliterative lesions (ECs) + perivascular inflammation	**Obliterative lesion (neointima)**
increased flow models: • systemic-to-pulmonary shunt (prolonged increased flow + pressure) in dogs, sheep • MCT + pneumonectomy in young rats	• plexiform lesions with cellular vessel obstruction, dilatation and recanalization • perivascular proliferation with lesions containing ECs	
Other models: • Sugen 5416 / hypoxia + prolonged normoxia	• plexiform like lesions containing obliterative lesions (SMCs/ ECs and aneurysm like lesions	**Plexiform lesion**

Fig. 118.8 Summary of the main histopathological changes found in several experimental models used to study pathophysiological mechanism of PAH: (**a**) Models with only increased blood flow typically show only increased medial wall thickness in the time frame studied. (**b**) Double-hit models with histology resembling human pathology (e.g., increased flow + additional hit) typically progress into advanced neointimal lesions with obliteration of the vascular lumen within the time frame studied. (**c**) Severe prolongation of increase pulmonary blood flow can induce plexiform lesions, as is also observed in other double-hit models using experimental stimuli

exact localization of neointimal development in the vascular bed, (2) pathobiological pathways triggered by clinically relevant hits (i.e., increased pulmonary blood flow), and (3) novel therapeutic treatments that can reverse rather than prevent neointimal development. Using these methods, new pathways are deemed to emerge which may lead to new therapeutic targets for patients with PAH in the future.

Epidemiology of Pediatric Pulmonary Hypertension

119

Johannes M. Douwes and Rolf M. F. Berger

Abstract

Pulmonary hypertension (PH) is a rare condition. Data on adult PH patients is abundant, but data on pediatric PH are scarce. Nevertheless, in the past decade, increasing data concerning pediatric PH are becoming available, enabling this review of the epidemiology, characterization, and outcome of pediatric pulmonary hypertension.

PH is a condition that is associated with a variety of diseases. It is a rare condition in children with a complex and age-specific presentation. Transient forms of pulmonary arterial hypertension (PAH), i.e., potentially reversible PAH, specifically occur in children and form the largest group of pediatric PH. Advanced PAH in children is predominantly idiopathic or associated with congenital heart disease. Other forms of PAH seldom occur in children. WHO PH groups 2–5 are rare in childhood; however, they may be underreported.

The clinical presentation of pediatric PH is relatively nonspecific as it is in adults, with dyspnea on exertion as the most common presenting symptom. However, the clinical presentation of pediatric PH includes symptoms specific for children such as syncope. Pediatric PH frequently co-occurs with genetic and syndromal abnormalities, including Down syndrome. Right heart failure is less common in children despite a severe hemodynamic profile.

PAH is a detrimental disease with a poor prognosis. Outcome of pediatric PAH differs between patients with different types of congenital heart disease. In the last decades, new PAH-targeted therapies have been

developed, which have improved outcome in pediatric pulmonary arterial hypertension. However, currently reported survival rates vary and critical appraisal of patient populations, survival data, and proposed treatment approaches is necessary.

Introduction

Pulmonary hypertension, an increased pressure in the pulmonary artery, is a symptom of a variety of related diseases. Pulmonary hypertension is defined as a mean pulmonary arterial pressure equal to or more than 25 mmHg, measured during right heart catheterization [1]. Pulmonary hypertension can occur at any age, including childhood. However, the presentation of pulmonary hypertension and its associated diseases is age specific (Fig. 119.1) and may differ between children and adults [2]. This chapter will provide an overview of the currently known data concerning the epidemiology, characterization, and outcome of pediatric pulmonary hypertension.

Classification of Pulmonary Hypertension

Pulmonary hypertension can be clinically classified according to an internationally recognized classification. This classification was proposed and optimized during the successive World Symposium on Pulmonary Hypertension in Evian [3], Venice [4], and Dana Point [5]. It is currently known as the *Dana Point classification*, and will be reevaluated in Nice in 2013. The Dana Point classification includes five categories based on shared pathophysiological mechanisms: (1) *pulmonary arterial hypertension* (PAH), (2) pulmonary hypertension owing to left heart disease, (3) pulmonary hypertension owing to lung disease and/or hypoxia, (4) chronic thromboembolic pulmonary hypertension, and (5) pulmonary hypertension with unclear multifactorial mechanisms (Table 119.1) [5].

The characterization of PH according to this clinical classification is an essential part of the diagnostic workup of PH (Fig. 119.2) [1, 6, 7]. The treatment strategy and prognosis of pediatric PH largely depend on its subclass and associated conditions. It is therefore of utmost importance to correctly characterize the type of PH using a standardized diagnostic workup.

Although classifying PH by identifying associated conditions may seem rather straightforward, the characterization of pediatric PH is complex. Often, more than one associated condition can be identified, which leaves it to the clinician to determine the contribution of each condition to the PH and to decide on which condition therapy should be focused [8]. Therefore, elaborate specialist knowledge and experience with pulmonary hypertension in children is mandatory in the characterization of the disease, supporting the recommendations of the international guidelines to centralize the care for pulmonary hypertension patients in specialized referral centers [1].

PAH

PAH (group 1) distinguishes itself from the other four categories of the clinical classification by its characteristic pattern of pulmonary *vascular remodeling*, progressive nature, and response to specific medical therapy. The pulmonary vascular remodeling that is characteristic for PAH involves adventitial thickening, medial hypertrophy, and intimal proliferation, including the formation of concentric laminar intimal fibrosis and *plexiform lesions* [9–11]. The vascular remodeling leads to arterial wall thickening and occlusion of small distal pulmonary arteries. Together with several other mechanisms including vasoconstriction, inflammation, and thrombosis, the vascular wall thickening and occlusion will consequently increase pressure

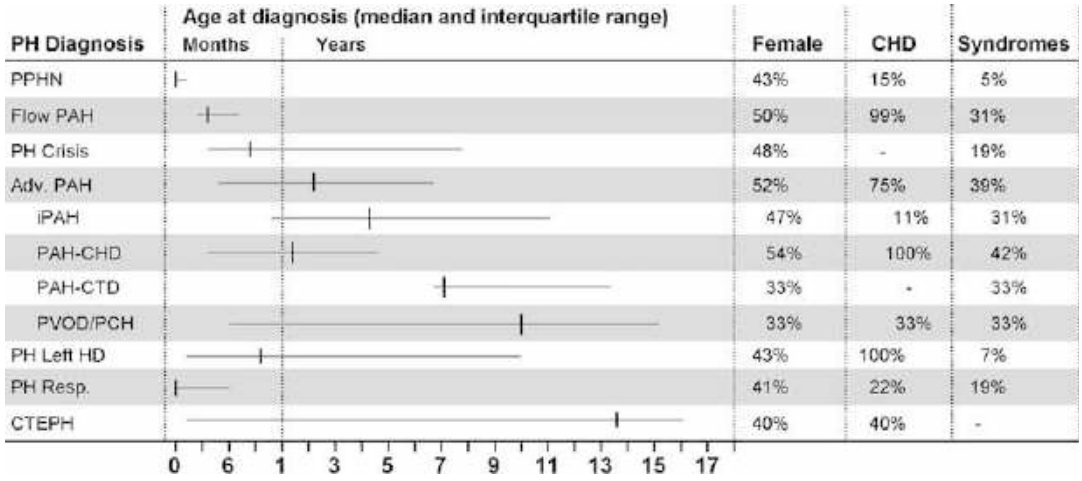

Fig. 119.1 *Age of presentation in pediatric PAH*. Graphical overview of the age at diagnosis for the different pulmonary hypertension diagnoses, and the percentage of females, congenital heart defects (CHD), and associated syndromal abnormalities (Syndromes) per diagnosis [2]. *PPHN* Persistent pulmonary hypertension of the newborn, *Flow PAH* flow-associated pulmonary arterial hypertension without increased pulmonary vascular resistance, *Adv. PAH* Advanced PAH, *iPAH* idiopathic PAH, *PAH-CHD* PAH associated with congenital heart disease, *PAH-CTD* PAH associated with connective tissue disease, *PVOD/PCH* Pulmonary veno-occlusive disease/pulmonary capillary hemangiomatosis, *HD* heart disease, *Resp* respiratory disease, *CTEPH* chronic thromboembolic pulmonary hypertension

and pulmonary vascular resistance. This increase in right ventricular afterload increases right ventricular workload, eventually resulting in right ventricular failure and death.

PAH can occur in association with several conditions, including *congenital heart diseases* (PAH-CHD), *connective tissue disease* (PAH-CTD), and portal hypertension. Furthermore, PAH can be hereditary (HPAH), either based on familial occurrence of PAH or based on genetic mutations [1]. Germ-line gene mutations have been identified in association with hereditary PAH: bone morphogenetic protein receptor type-2 (*BMPR-2*), activin-like kinase-1 (ALK-1), and endoglin mutations [12]. Furthermore, recently gene defects in members of the bone morphogenetic protein pathway (SMAD-family pathway) and a caveolin-1 mutation were reported in association with PAH [13, 14]. BMPR-2 is the most common germ-line mutation associated with pediatric PAH. A BMPR-2 mutation can be identified in 10–21 % of the pediatric IPAH/HPAH patients [2, 8, 15].

Finally, PAH can occur without any identifiable causes, which is classified as idiopathic PAH (IPAH). It is important to realize that one or more of the associated conditions included in the clinical classification may be present in PAH patients, although regarded to not sufficiently explain the PAH. In children, it is reported that in 25 % of the cases in which associated conditions could be identified, these were regarded not to be a sufficient explanation for the PAH [8]. In these cases, it is important to consider the possibility of concomitant intrinsic pulmonary *vascular disease*. Several authors have classified these patients accordingly as "idiopathic-like" PAH patients [8, 16].

IPAH and HPAH are often described together as IPAH/HPAH, because of similarities in presentation and plausible overlap between both disease groups. In 11–40 % of the patients thought to have IPAH, a PAH-associated gene mutation may be present, which would reclassify these patients as HPAH patients [5]. Furthermore, if no familial cases are present, IPAH and HPAH are indistinguishable without screening for known mutations. However, screening for mutations in PAH is not a standard practice, but should be considered with a family history of PAH [1].

Table 119.1 Clinical classification of pulmonary hypertension (Dana Point, 2008)[5]

1. *Pulmonary arterial hypertension (PAH)*	
1.1.	Idiopathic PAH
1.2.	Hereditary PAH (HPAH)
1.2.1.	BMPR-2
1.2.2.	ALK-1, endoglin (with or without hereditary hemorrhagic telangiectasia)
1.2.3.	Unknown
1.3.	Drug and toxin induced
1.4.	Associated with:
1.4.1.	Connective tissue disease
1.4.2.	HIV infection
1.4.3.	Portal hypertension
1.4.4.	Congenital heart diseases
1.4.5.	Schistosomiasis
1.4.6.	Chronic hemolytic anemia
1.5.	Persistent pulmonary hypertension of the newborn
1′. *Pulmonary veno-occlusive disease (PVOD) and/or pulmonary capillary hemangiomatosis (CPH)*	
2. *Pulmonary hypertension owing to left heart disease*	
2.1.	Systolic dysfunction
2.2.	Diastolic dysfunction
2.3.	Valvular disease
3. *Pulmonary hypertension owing to lung disease and/or hypoxia*	
3.1.	Chronic obstructive pulmonary disease
3.2.	Interstitial lung disease
3.3.	Other pulmonary diseases with mixed restrictive and obstructive pattern
3.4.	Sleep disordered breathing
3.5.	Alveolar hypoventilation disorders
3.6.	Chronic exposure to high altitude
3.7.	Developmental abnormalities
4. *Chronic thromboembolic pulmonary hypertension (CTEPH)*	
5. *Pulmonary hypertension with unclear multifactorial mechanisms*	
5.1.	Hematologic disorders: myeloproliferative disorders, splenectomy
5.2.	Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
5.3.	Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
5.4.	Others: tumoral obstructions, fibrosing mediastinitis, chronic renal failure on dialysis

Therefore, data concerning IPAH may frequently include HPAH patients, explaining the frequent combined analysis of both groups.

PAH-CHD

PAH-CHD is a progressive vascular disease associated with a broad variety of congenital heart defects. These congenital heart defects are associated with systemic to pulmonary shunts, including ventricular septal defect (VSD), atrial septal defect (ASD), and persistent ductus arteriosus (PDA), but also more complex lesions, such as atrio-ventricular septal defects and univentricular hearts [8, 17]. However, although PAH-CHD is predominantly *shunt* related, there is a small subset of patients with PAH-CHD associated with adequately repaired obstructive left heart disease, without shunts [2, 17].

In congenital heart defects with systemic to pulmonary shunt, the shunt causes increased pulmonary blood flow. The increased pulmonary blood flow induces vascular wall shear stress, leading to pulmonary vascular remodeling. When congenital heart defects are corrected at an early stage of the disease process, the vascular remodeling can reverse and thus the development of progressive PAH is prevented in most cases.

In contrast, when shunt defects are not corrected, PAH progresses into an advanced stage, which is considered irreversible. Furthermore, correction of shunt defects once PAH is irreversible may cause accelerated deterioration of clinical condition with worse outcome than when the shunt remains uncorrected [2]. Therefore, early correction of congenital systemic to pulmonary shunts, when the vascular remodeling is still reversible, is of major importance. However, the point of no return at which the pulmonary vascular remodeling becomes irreversible is difficult to determine. There is a gray area in which it is unclear whether the vascular remodeling is still reversible or not. In clinical practice, the pulmonary hemodynamic response to acute vasodilator challenge has been used to assess the reversibility of the vascular disease. Empirically, in patients with congenital heart disease, lack of acute response to vasodilator challenges is regarded as an indicator of irreversible disease [18, 19]. However, internationally accepted guidelines for assessing the vasodilator response for this purpose are lacking. Once the

[6]). *P(A)H* pulmonary (arterial) hypertension, *CXR* chest x-ray, *Dl CO* diffusing capacity of the lung for carbon monoxide, *CT* computed tomography, *HIV* human immunodeficiency virus

pulmonary vascular remodeling progresses into advanced irreversible disease, it is referred to as PAH-CHD.

The evolution of PAH-CHD and the age at which it presents itself depends on the type of shunt (Fig. 119.3) [20]. In patients with a shunt at pre-tricuspid level (for instance, atrial septal defects), there is an increased pulmonary volume load with a normal pressure load. From these patients, only 5–20 % develops advanced PAH, and usually not until the third to fourth decade of life [21, 22]. In patients with nonrestrictive shunts at post-tricuspid level, the increased pulmonary volume load is accompanied by an increased pressure load due to pressure equilibration over the shunt defect. In these patients, PAH usually develops more rapidly, during the first few years of life [20].

However, recently, there have been reports of pediatric PAH patients who developed persistent severe PAH associated with a post-tricuspid shunt already within the first weeks and months of life [8]. These patients have been referred to as accelerated PAH-CHD patients [2, 8]. In these patients, etiological factors in addition to the shunt defect are believed to be present, increasing the susceptibility for pulmonary vascular disease.

In uncorrected systemic to pulmonary shunts, the pulmonary vascular disease is progressive, steadily increasing the pulmonary vascular resistance. When the pulmonary vascular resistance exceeds the systemic vascular resistance, the shunt reverses to a pulmonary to systemic shunt with hypoxemia and cyanosis. This condition is referred to as the *Eisenmenger syndrome* [1].

Associated PAH

As stated previously, PAH can either be idiopathic, hereditary, associated with congenital heart disease, or associated with several other conditions. These conditions include connective tissue diseases, such as systemic sclerosis,

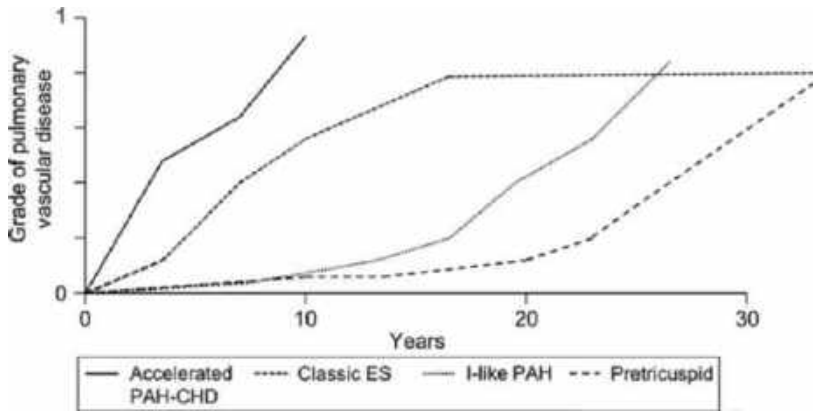

Fig. 119.3 *Development of PAH in congenital heart defects*. Illustration of the development of pulmonary vascular disease in patients with congenital heart disease, separated for the type of shunt. The image shows the variability in the evolution of pulmonary vascular disease based on the type of congenital heart disease. *Accelerated PAH-CHD* accelerated development of advanced PAH-CHD, *Classic Eisenmenger* development of Eisenmenger syndrome in patients with post-tricuspid shunt, *I-like PAH* idiopathic-like PAH, development of PAH in patients with small and initially restrictive shunts, *pre-tricuspid shunt* development of PAH in pre-tricuspid shunt patients (Adapted from van Loon et al. [20])

systemic lupus erythematosus, and mixed connective tissue disease [5]. Furthermore, PAH may be associated with HIV infection, portal hypertension, schistosomiasis, chronic hemolytic anemia, and can be drug or toxin induced [5].

Within the Dana Point classification, *pulmonary veno-occlusive disease* (PVOD) and pulmonary capillary hemangiomatosis (PCH) are classified distinct from but related to PAH. Both conditions share histopathologic changes, clinical presentation, and risk factors with PAH, but on the other hand differ in their response to treatment. In example, in PAH, vasodilators can provide successful treatment; however, in PVOD and PCH, they may cause deterioration of the patient's condition [23]. Therefore, PVOD and PCH are categorized as group 1′, a distinct category but not completely separated from PAH.

Transient PAH

In general, PAH (group 1 PH) is a progressive fatal disease. Transient PAH is a pulmonary vascular disease that is reversible or self-limiting, but nevertheless is classified in group 1, PAH, according to the current clinical classification. Transient forms of PAH are specific for the pediatric age group and do virtually not occur in adult patients.

Persistent Pulmonary Hypertension of the Newborn (PPHN) is a condition of the newborn characterized by pulmonary hypertension and reduced pulmonary blood flow [24]. In utero, the pulmonary vasculature is subdued to pulmonary arteriolar vasoconstriction and high pulmonary vascular resistance. Due to the high pulmonary vascular resistance, blood shunts from right to left through the foramen ovale and ductus arteriosus. After birth, in the normal lung, pulmonary vascular resistance drops due to lung inflation, nitric oxide release, and increased pulmonary oxygen tension, resulting in a dramatic increase in pulmonary blood flow, and cessation of right to left shunting. In PPHN however, pulmonary vascular resistance remains high, either due to maladaptation, underdevelopment, or maldevelopment of the pulmonary vasculature. In these cases, pulmonary vascular resistance and pulmonary arterial pressure do not decrease, the right to left shunts remain, and pulmonary blood flow will therefore be limited, causing respiratory distress, hypoxemia, and acidosis [24].

Therapy for PPHN includes treatment of underlying disorders, supporting the systemic and pulmonary circulation, optimizing oxygenation and medical therapy to establish pulmonary vasodilatation [24]. Despite therapy, overall mortality and morbidity in patients with PPHN is high (reported as 36 % and 65 %, respectively) [25]. However, if treatment is successful, PPHN fully resolves and is therefore regarded as a reversible or transient form of PAH.

Flow-associated PAH without increased pulmonary vascular resistance includes patients with a left to right shunt based on congenital heart defects, or in rare cases patients with increased pulmonary blood flow due to systemic arteriovenous blood vessel malformations or unilateral pneumonectomy (in whom there is an increased pulmonary blood flow due to redistribution of flow to the remaining lung). In patients with a shunt at pre-tricuspid level or a restrictive shunt at post-tricuspid level, pulmonary blood flow is increased. In normal subjects, the pulmonary circulation can accommodate up to five times the normal cardiac output, without an increase in pulmonary arterial pressure. Therefore, when PH is present in patients with increased pulmonary blood flow without a pressure equilibrating shunt, an abnormal pulmonary vascular response to increased flow should be considered. This may be a sign of intrinsic pulmonary vascular disease. In patients with nonrestrictive shunts at post-tricuspid level, an increased pulmonary blood flow is accompanied by pulmonary and systemic arterial pressure equilibration across the shunt defect. The pressure equilibration causes an increase in pulmonary arterial pressure and hence PH, although in the presence of low pulmonary vascular resistance.

Flow-associated PAH is an early stage of advanced PAH associated with congenital heart disease. In flow-associated PAH, vascular remodeling is likely to be present, due to shear stress of the increased pulmonary blood flow, but may be reversible when the heart defect is corrected. Whereas in advanced PAH, the vascular disease is irreversible, and will progress even after correction of the underlying heart defect. Early correction of the congenital shunt defect in the stage of flow-associated PAH with reversible vascular disease will prevent development of progressive PAH and will resolve the PH. Nevertheless, 3 % of the patients with previously closed systemic to pulmonary shunts were reported to develop PAH during follow-up, which might be due to late correction of the defect [26].

Group 2–5 PH

In PH owing to *left heart disease* (group 2), PH is caused by left ventricular or valvular dysfunction or total abnormal pulmonary venous return, leading to elevated left atrial and pulmonary venous pressures [5]. The elevated pulmonary venous pressure is transmitted to the lungs, causing increased pulmonary arterial pressure. In this condition, pulmonary vascular resistance initially is normal or near normal.

Group 3 PH is caused by alveolar *hypoxia* due to *lung disease*, impaired breathing, or chronic residence at high altitude [5]. The alveolar hypoxia leads to hypoxic vasoconstriction, increasing pulmonary vascular resistance and pulmonary arterial pressure. In childhood, pulmonary developmental disorders may not only cause alveolar hypoxia and hypoxic vasoconstriction, but also include lung hypoplasia and morphological vascular abnormalities with decreased total cross-sectional area of pulmonary vessels, contributing to the increased pulmonary vascular resistance and pressures [27].

Chronic *thromboembolic* PH (group 4 PH) comprises PH due to obstruction of pulmonary vessels by thromboemboli. And group 5 PH includes forms of PH for which the etiology is multifactorial or unclear [5].

A distinct presentation of PH is the acute pulmonary hypertensive crisis. Generally accepted criteria to define a pulmonary hypertensive crisis are lacking. However, it is often described as a rapid increase in pulmonary vascular resistance, with a pulmonary arterial pressure exceeding systemic blood pressure,

accompanied by right ventricular failure, and a decrease in systemic blood pressure [24, 28]. The acute increase in pulmonary vascular resistance is caused by pulmonary vasoconstriction, which can be triggered by hypoxia, hypercarbia, acidosis, or noxious stimuli [28]. Clinically, a PH crisis can typically be recognized by a fall in systemic output accompanied by signs of acute right ventricular failure, with or without cyanosis [2]. PH crisis can occur as a perioperative complication or as a complication of respiratory disease. Specific patient groups, including patients with congenital heart disease, and syndromal abnormalities, may have increased risk of developing PH crisis [2].

Incidence and Prevalence of Pediatric PH

Research covering PH mostly focuses on adult patients, and until recently, data on epidemiology of PH among children was lacking. In the past few years, national cohort studies and registry-based studies were conducted and enabled reports on epidemiology and characterization of pediatric PH. Epidemiologic data may be limited by selection bias. Registry studies in general cover a selected number of referral centers, whose data depend on referral patterns and the used inclusion criteria, whereas hospital registry studies can be hampered by possible coding errors. Van Loon et al. have addressed both issues for pediatric PH in 2011 [2].

The overall yearly incidence of all forms of pediatric PH in the national Netherlands registry was estimated as 64 per million children [2]. The overall incidence rate for pediatric PAH (excluding the transient forms of PAH) was estimated 3.0 cases per million children with a prevalence of 20 cases per million [2]. These numbers are comparable to the reported incidence and prevalence rates of PAH among adults, which have been estimated to range between 2.4–7.6 and 15–52 cases per million adults, respectively [29, 30].

PAH in children is most often caused by IPAH/HPAH or PAH-CHD [8, 17]. The estimated incidence rate of IPAH/HPAH is 0.5–0.7 cases per million children, with a prevalence of 2.1–4.4 cases per million children [2, 31]. This is lower than the reported incidence and prevalence rates of IPAH/HPAH among adults, in whom the incidence rate has been reported as 1.0–3.3 and the prevalence rate as 6.5–25 cases per million adults [29, 30].

The reported incidence rate of PAH-CHD in childhood is 2.2 cases per million children, with a prevalence rate of 15.6 million [2, 31]. In adults, the reported incidence and prevalence rates are lower for PAH-CHD (0.3–2.2 and 1.7–12 cases per million adults, respectively) [29, 30].

In children, PAH is reported to be idiopathic or hereditary in 46–70 % of the cases, making it the largest subgroup of PAH (Fig. 119.4) [8, 17, 32, 33]. PAH-CHD is the second largest subgroup of PAH in children, occurring in 24–37 % of the cases [8, 17, 32, 33]. Compared to the IPAH/HPAH subgroup, this percentage is lower than one would expect based on the prevalence numbers reported on both subgroups. This may be due to the origin of the data. The incidence and prevalence numbers originate from a national epidemiological study, whereas the percentages are reported by large referral centers for pediatric PAH. Incomplete referral of PAH-CHD patients to the referral centers and selection bias due to inclusion criteria of these studies may cause this disparity [2].

Pediatric PAH-CHD may present with a broad variety of congenital heart diseases, including isolated shunt defects, partially abnormal pulmonary venous return, complete atrio-ventricular septal defects, transposition of the great arteries without ventricular septal defect, truncus arteriosus, single ventricles, and complex combinations of the mentioned defects. Eisenmenger syndrome is reported in 57 % of pediatric PAH-CHD patients, which is comparable to adult PAH-CHD [8, 26].

PAH associated with conditions other than congenital heart disease is very rare in children [17, 33]. PAH associated with connective tissue disease accounts for only 2–5 % of all pediatric PAH cases [2, 8, 17, 32, 33]. Pulmonary vascular

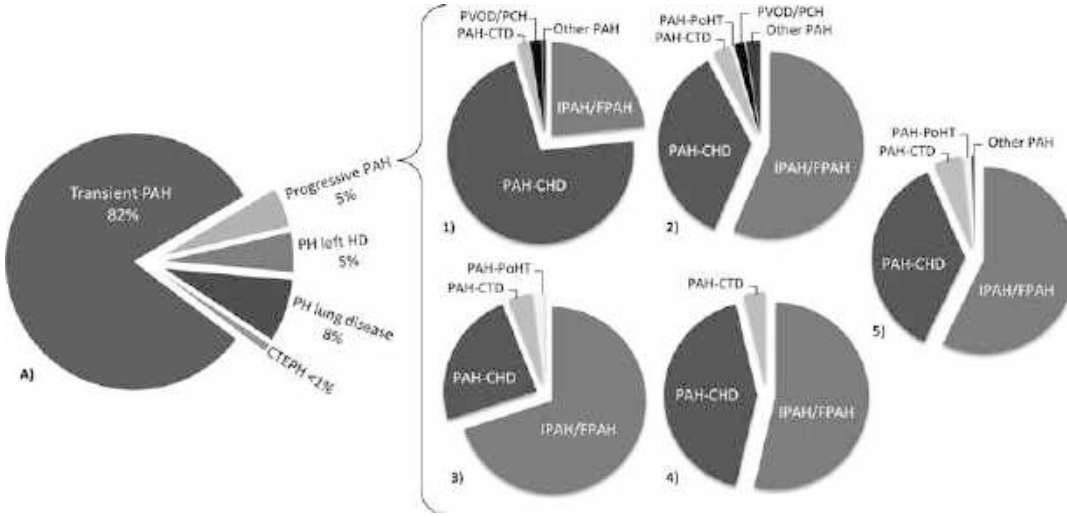

Fig. 119.4 *Characterization of pediatric PH*. Characterization of pediatric pulmonary hypertension, based on the most recent epidemiologic data. (*A*) and (*1*) van Loon et al. [2] (*2*) Berger et al. [17] (*3*) Fraisse et al. [32] (*4*) Van Loon et al. [8] (*5*) Barst et al. [33]. *PAH* pulmonary arterial hypertension, *HD* heart disease, *CTEPH* chronic thromboembolic pulmonary hypertension, *CTD* connective tissue disease, *PVOD/PCH* pulmonary vascular occlusive disease/pulmonary capillary hemangiomatosis, *PoHT* portal hypertension

occlusive disease or pulmonary capillary hemangiomatosis (PVOD/PCH) is reported in 2 % of cases [2, 17]. However, since diagnosis of PVOD/PCH is difficult and depends on post-mortal biopsy at autopsy, they may be underdiagnosed [23]. Therefore, the reported percentage may be an underestimation of the actual prevalence of the disease. PAH associated with chronic liver disease and portal hypertension is reported in 1–2 % of the pediatric PAH patients and PAH associated with HIV infection in 0–1 % of the cases [2, 17, 33]. Incidence and prevalence rates of these PAH subgroups are thus far not reported.

The distribution of associated conditions differs between children and adults with PAH. In adults, IPAH/HPAH is also the largest group, accounting for 43–58 % of cases; however, PAH associated with connective tissue disease is much more common among adults (15–35 %), whereas PAH-CHD is a smaller group in adult PAH (11–25 %) compared to children [29, 30]. In adult patients, both PAH associated with portal hypertension and with HIV infection are more common (10.4 % and 6.2 %, respectively) compared to PAH in children [29]. PAH is associated with drugs and toxins in 9.5 % of the adult cases of PAH, whereas the pediatric PAH registries report no patients with PAH associated with drugs and toxins [17, 29].

In pediatric PH, transient forms of PAH were reported to have the highest incidence rates [2]. PPHN is estimated to be responsible for 47 % of all cases of pediatric PH, occurring in 1–2 per 1,000 live births [2, 24, 34]. The incidence of PPHN is reported to be 30 cases per million children. PPHN may be associated with the development of progressive PAH at a later stage. A large international registry for pediatric PH reported 2 % of PH patients to have a previous history of PPHN. In these cases, PPHN either persisted or seemed to be resolved but subsequently recurred, after which PAH was confirmed [17]. Transient, flow-associated PAH without increased pulmonary vascular resistance is estimated to represent 34 % of all pediatric PH patients, with a reported incidence of 22 cases per million children.

In pediatric PH, 13 % of the cases are reported to be pulmonary hypertension classified within the groups 2–5 of the Dana Point Classification. However, since most referral centers and registry

studies focus on PAH and often even exclude the other groups of PH, there may be underreporting of these diagnoses. PH due to left heart disease is thought to represent the most frequent cause of PH among adults, but is reported to represent only 5 % of cases in pediatric PH [2, 5]. PH due to lung disease and hypoxia accounts for 8–11 % of the pediatric PH cases [2, 17].

Pediatric PH associated with lung disease and hypoxia results from obstructive or restrictive breathing disorders in 14–24% of cases, including laryngo-tracheomalacia, kyphoscoliosis, micrognathia and/or enlarged adenoid, tonsils or tongue [2, 17]. Residence at high altitude is reported to be responsible for 13 % and interstitial lung disease for 23 % of the cases [17]. Pulmonary developmental disorders are responsible for 58–76 % of the cases, including lung disease of prematurity (bronchopulmonary dysplasia), congenital pulmonary hypoplasia, and congenital diaphragmatic hernia [2, 17]. This is of special interest since pulmonary developmental disorders, such as bronchopulmonary dysplasia, have been reported to be associated with abnormal pulmonary vascular development [27]. Therefore, characterization of PH associated with pulmonary developmental disorders may differ from the group 3 PH in adult patients, and consequently, treatment cannot be extrapolated from adult treatment guidelines. Children with bronchopulmonary dysplasia and PH are at high risk of death, and the treatment approach is not yet clear [35]. Furthermore, the population of patients with PH and bronchopulmonary dysplasia is likely to increase due to improved neonatal care. Therefore, studies focusing on PH based on lung developmental disorders are a necessity.

Chronic thromboembolic PH (group 4) and PH with multifactorial causes (group 5) are very rare in children, representing less than 1 % of the cases of pediatric PH [2, 17]. PH crisis has been reported to occur most often in patients with preexisting PAH (14 % of progressive PAH and 17 % of flow PAH patients), either perioperatively or during respiratory tract infection. However, in rare cases, PH crisis may also occur during respiratory infection without a previous diagnosis of PH [2]. In 19 % of these cases, patients have a syndromal abnormality.

Clinical Presentation

Symptoms and Functional Status

The clinical presentation of pediatric pulmonary hypertension is nonspecific and age dependent. The most common presenting symptom is reduced exercise capacity presented by dyspnea during exercise (65–98 % of patients) [8, 17, 31, 32]. In young infants, a reduced exercise capacity can present with feeding problems and failure to thrive. Other symptoms include fatigue, cyanosis with exercise or at rest, cough, and chest pain. Signs of right ventricular failure are relatively rare in children with PH, which is in contrast to adult patients in whom signs of right ventricular failure are common [36]. Syncope as a presenting symptom is specific for pediatric pulmonary hypertension. Syncope is reported in 25–31 % of pediatric PAH patients, which is twice the percentage in adult patients and is most frequent in patients without a shunt defect [17, 31, 37]. There is often a long delay between onset of symptoms and diagnosis, which may be due to the low specificity of the presenting symptoms and the rarity of the disease. Because of the progressive nature of pediatric PAH, early identification and diagnosis of patients is important. Therefore, screening of patients belonging to high-risk groups based on underlying conditions or family members with PAH is advised.

The functional status of PAH patients, concerning exercise capacity and symptoms, can be classified using the World Health Organization (WHO) functional classification of pulmonary hypertension [1]. Generally, children with PAH present with WHO functional class II or III (72–80 % of cases), which is in contrast to adults who generally present in WHO functional class III [8, 17, 31, 32]. Nevertheless, a substantial group of pediatric patients can be classified in the advanced functional classes III and IV at

diagnosis, which is probably due to the delay between disease onset and diagnosis, underlining the importance of early diagnosis in pediatric PAH [8, 17]. In adult patients, treatment effect can be measured using changes in WHO functional class; however, in pediatric patients, the value of WHO functional class in assessing treatment effect is less clear.

A measurement of exercise capacity is the 6-minute walk distance, the distance a patient walks within 6 minutes under standardized conditions [1]. In adults, the 6-mininute walk distance is commonly used to assess exercise capacity and disease severity in PAH. However, in children, its value is limited since it is often not feasible, especially in the young children and children with syndromal abnormalities including mental retardation. Children also frequently lack the ability to focus during the examination.

Hemodynamic Profile

Severely increased pulmonary arterial pressure and pulmonary vascular resistance characterize the hemodynamic profile in pediatric PH. In pediatric patients, the right atrial pressure and cardiac index are generally preserved, which is in contrast to PH in adult patients [2, 17, 38].

The prevalence of acute pulmonary vasodilator response in children with PAH has been a topic of debate. It has long been assumed that children show more response to vasodilator challenge than adult patients, due to less extensive pulmonary vascular disease. The proportion of patients with an acute pulmonary vasodilator response was reported to be 42–56 % in children compared to 5–17 % in adult patients [7, 39–42]. However, in children, different response criteria were used instead of the internationally advised response criteria used in adult patients. A recent study directly comparing the proportion of acute responders in adult and pediatric patients using the same criteria showed that the prevalence of acute response in children is comparable to that in adults (8 % in children according to the current criteria) [42].

Comorbidities

Pediatric pulmonary hypertension frequently co-occurs with genetic disorders (17–43 % of cases; illustrated by Fig. 119.5), including specific syndromal, chromosomal, or genetic abnormalities and dysmorphism and/or mental retardation without a specified syndromal diagnosis [2, 8, 17]. Down syndrome is the most common concomitant syndrome (12–21 % of cases) and is reported to be more common in group 3 PH than in progressive PAH [2, 17]. Focusing on progressive PAH patients, trisomy-21 occurs most frequently within the PAH-CHD patient group [8]. Patients with Down syndrome are at higher risk for developing PH due to several potential causes for PH, including disordered breathing due to upper airway obstruction, congenital heart defects, sleep disordered breathing, silent aspiration, and pulmonary hypoplasia. Furthermore, Down syndrome patients have been suggested to have an increased susceptibility for intrinsic pulmonary vascular disease.

In addition to trisomy-21, several other syndromes have been reported to co-occur with PH, such as Noonan, Velocardiofacial, Jacobsen, 1p36 deletion, and neonatal onset multisystem inflammatory disease syndromes [8]. Furthermore, it is recognized that a substantial number of pediatric PH patients have clinical signs of syndromal disorders, such as dysmorphic features and/or mental retardation, which cannot be explained by a known syndromal diagnosis [8]. The frequent occurrence of syndromal and chromosomal abnormalities in pediatric PAH, especially those without a syndromal diagnosis, suggests the existence of still unknown genetic pathways involved in the disease process of PH.

Considering the age-specific forms of PAH, the complex presentation and the variety of associated conditions and comorbidities specific for pediatric PH, there is debate on whether the current classification of PH is suitable for pediatric PH. Several pediatric classifications have been proposed, but are not standard in the clinical care for children with PH [43, 44].

[8]). *PAH* pulmonary arterial hypertension, *CHD* congenital heart disease, *CTD* connective tissue disease, *RSH* disorders of respiratory system and/or hypoxia, *CTEPH* chronic thromboembolic pulmonary hypertension, *NOMID* Neonatal onset multisystem inflammatory disease

Outcomes

Pulmonary hypertension is a heterogeneous disease. The outcome of the different subgroups of pediatric pulmonary hypertension differs tremendously. In patients in the Dana Point groups 2–5, PH may resolve by treatment of the underlying disease.

In contrast, PAH (group 1) has no cure and outcome is therefore poor. In adult patients, the untreated median survival after diagnosis for IPAH/HPAH is estimated at 2.8 years [45]. Evidence-based reports on the untreated survival of pediatric PAH are lacking, but may be worse than in the adult patient group. The untreated median survival of pediatric PAH patients has been suggested to be 0.8 year, which has been reported following a study within the National Institutes of Health registry.

In the past decade, new medical PAH-targeted therapies have been introduced to treat PAH. Recently, three reports have described outcome and survival of pediatric PAH patients in the era in which PAH-targeted therapy has been available. There is a discrepancy between the survivals shown in these reports (Fig. 119.6). Comparing these studies, the 1-, 3-, and 5-year survival of pediatric PAH is in the range of 86–100 %, 71–88 %, and 66–72 %, respectively, for IPAH/HPAH and 87–96 %, 87 %, and 81 %, respectively, for PAH-CHD [33, 46–48]. In pediatric PAH, survival of IPAH/HPAH patients seems similar to PAH-CHD patients. However, within the PAH-CHD group, survival varies greatly, depending on the type of congenital heart defect. Patients with PAH-CHD persisting or recurring after shunt closure, and patients with accelerated PAH-CHD were reported to have significant reduced survival compared to patients with an uncorrected pre-tricuspid or post-tricuspid shunt [2].

Survival of pediatric PAH is reported to be improved after the introduction of PAH-targeted therapy, when compared to the predicted untreated survival [46]. However, data suggest that this improvement is more profound in

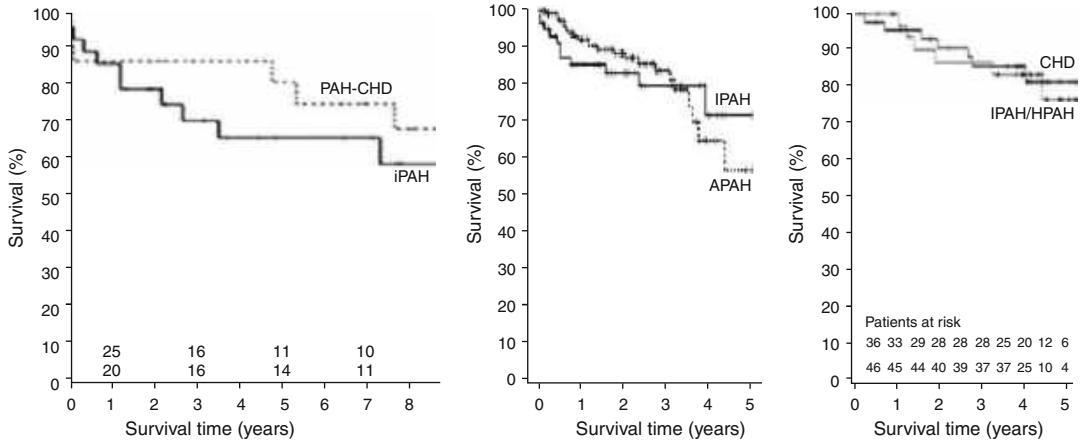

Fig. 119.6 *Survival of pediatric PAH*. Survival of pediatric pulmonary arterial hypertension patients in the era of PAH-targeted therapy (Adapted from (1) Van Loon et al. [46], (2) Haworth and Hislop [48], (3) Ivy et al. [47]), illustrating the variability in the presented survival rates for pediatric PAH. *IPAH* idiopathic pulmonary arterial hypertension, *HPAH* hereditary PAH, *PAH-CHD* PAH associated with congenital heart disease, *APAH* associated PAH including PAH-CHD, PH associated with respiratory disorders, and PAH associated with connective tissue disease, HIV infection, bone marrow transplantation, or metabolic disorders

prevalent cases than in incident cases, which underlines the importance of critical appraisal of the adult treatment guidelines when adapting them to the pediatric PAH population [46].

Conclusion

Pulmonary hypertension (PH) in children is a rare condition with a complex age-specific presentation, including age-specific diagnoses. The occurrence of transient forms of PAH, i.e., potentially reversible PAH, is specific for PH in childhood and the most frequently occurring subgroup of pediatric PH. Advanced pediatric PAH is predominantly idiopathic or associated with congenital heart disease. PH groups 2–5 are rare in children; however, they may be underreported.

The clinical presentation of pediatric pulmonary hypertension is nonspecific, which may explain the delay between onset of symptoms and diagnosis. Characteristics that are uniquely associated with pediatric PH, in contrast to PH among adults, include lack of right heart failure in most children despite a severe hemodynamic profile and the occurrence of syncope as a presenting symptom. Pediatric PH frequently presents with comorbidities such as Down syndrome, chromosomal disorders, and other undefined syndromal abnormalities. This observation suggests the existence of still unknown genetic pathways involved in the disease process of PH.

Outcome of pulmonary arterial hypertension is poor. Adult treatment guidelines have yielded improved outcome among children with PAH. However, a critical appraisal of treatment guidelines and development of new therapies is necessary in children.

Idiopathic Pulmonary Arterial Hypertension in the Pediatric Age Group

120

Usha Krishnan and Erika Berman Rosenzweig

Abstract

Idiopathic pulmonary arterial hypertension is a rare progressive disorder with a lethal outcome if not diagnosed and treated in a timely manner. Advances in treatment in the current era have increased the life expectancy for these patients and also improved the quality of life.

This chapter will review idiopathic and heritable pulmonary arterial hypertension in childhood, with a discussion about currently available medications and those undergoing clinical investigation.

Keywords

Pediatrics • Pulmonary arterial hypertension • Pulmonary vascular resistance • Right heart failure • Right ventricle

Introduction

Idiopathic pulmonary arterial hypertension (IPAH) is a rare progressive disorder with a lethal outcome if not diagnosed and treated in a timely manner [1]. In France, the incidence of PAH is estimated at 3.7 cases/million/year with 60 % being IPAH [2]. In the Netherlands, the incidence and point prevalence of IPAH was 0.7 and 4.4 cases per million children [3]. Prior to the current era, the median survival after diagnosis of IPAH was reported in the NIH Primary Pulmonary Hypertension Registry as 2.8 years in adults and only 10 months in children [4]. In the modern era, with early diagnosis and initiation of therapy, survival at 1, 2, and 3 years may be as high as 99 %, 96 %, and 84 % in children, with national registries reporting three survival of 73–85 % compared with 1-, 2-, and 3-year survival of 88 %, 76 %, and 63 % in adults [3–6]. Interest in finding newer therapies for PAH was prompted by the discovery of prostacyclin in 1976 and its subsequent use in patients since the early 1980s [4, 6]. This spanned a whole new field of translational research, with the quest for finding triggers for PAH at the molecular level and development of targeted therapies. Advances in treatment have not only increased the life expectancy for these patients but also improved the quality of life [3–10].

This chapter will review idiopathic and heritable pulmonary arterial hypertension in

childhood, with a discussion about currently available medications and those undergoing clinical investigation.

Definition and Classifications of Pulmonary Hypertension

PAH was defined at the 4th World Conference of Pulmonary Hypertension at Dana Point in 2008 as a mean pulmonary artery pressure (mPAP) $\geq$ 25 mmHg and normal pulmonary artery wedge pressure <15mmHg, for all age groups [9–11]. However, because the systemic arterial blood pressure in children is lower than in adults, it has been suggested that a systemic to pulmonary pressure ratio >0.4 should be considered indicative of PAH [12]. Adatia et al. have also suggested that in children being evaluated for surgery for congenital heart disease, a ratio of pulmonary to systemic mean pressures of >0.5 should be considered significant [13]. The Dana Point conference proceedings excluded the use of a threshold value of pulmonary vascular resistance (PVR) in the definition of PAH in adults; however, most pediatric PAH experts continue to consider PVRi >3 Wood units.m^2 as significant [11, 14, 15]. Pulmonary *arterial* hypertension occurs in the "precapillary" pulmonary vascular bed and therefore excludes forms of postcapillary PH, secondary to pulmonary venous obstruction, left ventricular diastolic dysfunction, and mitral stenosis. These disorders often have components of both Group I and Group III PAH as defined by the Dana Point classification (Table 120.1) [11].

At the Dana Point meeting in 2008, the classification of PAH underwent several modifications [15] with the identification of more mutations associated with PAH distinguishing *heritable* PAH (HPAH) from the idiopathic group (IPAH). IPAH and HPAH formed the top two categories in Group I PAH. Pulmonary veno-occlusive disease and pulmonary capillary hemangiomatosis, which share many similarities with Group I PAH but have subtle variations, have been separated out to Group I'. It is

Table 120.1 Updated World Health Organization clinical classification of pulmonary hypertension-Dana Point 2008 [15]

1. Pulmonary arterial hypertension
1.1. Idiopathic pulmonary arterial hypertension
1.2. Heritable
1.2.1. Bone morphogenetic protein receptor type 2
1.2.2. Activin receptor-like kinase type 1, endoglin (with or without hereditary hemorrhagic telangiectasia)
1.2.3. Unknown
1.3. Drug-and toxin-induced
1.4. Associated with
1.4.1. Connective tissue diseases
1.4.2. HIV infection
1.4.3. Portal hypertension
1.4.4. Congenital heart diseases
1.4.5. Schistosomiasis
1.4.6. Chronic hemolytic anemia
1.5. Persistent pulmonary hypertension of the newborn
1. Pulmonary venoocclusive disease or pulmonary capillary hemangiomatosis
2. Pulmonary hypertension owing to left heart disease
2.1. Systolic dysfunction
2.2. Diastolic dysfunction
2.3. Valvular disease
3. Pulmonary hypertension owing to lung diseases or hypoxia
3.1. Chronic obstructive pulmonary disease
3.2. Interstitial lung disease
3.3. Other pulmonary disease with mixed restrictive and obstructive pattern
3.4. Sleep-disordered breathing
3.5. Alveolar hypoventilation disorders
3.6. Chronic exposure to high altitude
3.7. Developmental abnormalities
4. Chronic thromboembolic pulmonary hypertension
5. Pulmonary hypertension with unclear multifactorial mechanisms
5.1. Hematologic disorders: myeloproliferative disorders, splenectomy
5.2. Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
5.3. Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
5.4. Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

important to do a complete diagnostic work-up and rule out all secondary causes before making a diagnosis of IPAH [16].

Despite the different clinical presentations, histopathologic changes in the lung vasculature are very similar for most forms of Group I PAH, and thus, similar treatment strategies have evolved over the past two decades. As more translational research focuses on alterations at the molecular level contributing to the pathogenesis of pulmonary arterial hypertension, the introduction of novel targeted therapies aiming at increasing the overall efficacy of treatment for pulmonary arterial hypertension is being developed.

Epidemiology and Etiology

Because PAH remains an "orphan" disease with multiple potential etiologies, registries have been developed to better describe the populations with PAH, categorize them into various etiologies, and study the frequency of each etiology [1, 15–19]. Two major registries describing adult populations are the French registry, which reported IPAH 39.2 %, familiar pulmonary artery hypertension (FPAH) 3.9 %, connective tissue disease (CTD) 15.3 %, and congenital heart disease (CHD) 11.3 %, while the REVEAL registry revealed estimates of IPAH 42.7 %, FPAH 2.7 %, CTD 25 %, and CHD 10 % [1, 16–18]. Similar registries in pediatric PAH would also be very important; however, due to the smaller number of patients overall, studies from national databases in countries with centralized care for PAH, as in the Netherlands and United Kingdom and from large centers in the USA, have been very helpful in estimating the prevalence of the disease [2–8, 14, 18–21]. These studies have estimated the prevalence of IPAH at 2.1–2.2 per million children. Since the availability of genetic testing is variable, an estimate of HPAH tends to not be uniform. Another issue with breaking down the etiologies of PAH in the pediatric population is the lack of consistent referral of children with CHD or CTD as well as with chronic lung disease to centralized referral centers for the management of PAH. However, unlike the adult population, where CTD is an important cause of PAH, in children, CHD is a more frequent cause. However, even this statistic will change for adults as more and more children with CHD survive into adulthood [3, 12, 14, 20, 21]. The mean age at diagnosis reported in the Registry to Evaluate Early and Long-Term PAH Disease Management (REVEAL) was 7 years, while the UK and French registries reported mean ages at diagnosis of 7.4 and 8.9 years, respectively [14–20].

Gender: The gender distribution in adults with IPAH is approximately 1.7–2.1:1 females/males. In children, this distribution has been more variable, with the ratio varying from 1.9:1 in the French and Swiss registries to 1.7:1 as reported by the UK group [20, 21]. When all etiologies of PAH are included, the female to male ratio gets closer to 1:1, as there seems to be no significant gender predominance for CHD with PAH. The REVEAL registry reported a 2:1 F/M ratio in children and a 4.1/1 in IPAH/HPAH adult patients [17, 18].

Genetics of PAH: The first report of familial primary pulmonary hypertension (PPH) was published as early as 1954 by Dresdale, and since then it has been increasingly evident that heritable PAH has a very strong association with germline mutations [22, 23]. HPAH has an autosomal dominant mode of inheritance with the defect in most cases localized to a region on chromosome 2 Q33 [22–25]. Intense research has focused on the transforming growth factor B (TGFB) family of receptors, particularly bone morphogenic protein receptor (BMPR2) in kindreds with HPAH [26–28]. Over 300 germline BMPR2 mutations have been identified in HPAH patients, with the mutations being usually similar within families. These mutations are located throughout the gene. BMPR2 mutations are seen in over 80 % of patients with HPAH, while the remaining may have mutations in other genes encoding the TGFB superfamily of receptors. Two of these, mutations of activin receptor-like kinase 1 (ALK 1) located in chromosome 12 and endoglin (ENG) on chromosome 9, have been

described in association with hereditary hemorrhagic telangiectasia (HHT) and HPAH [29]. Other loci, the SMAD8 gene on chromosome 13 and the CAV-1 gene, have also been reported [30]. BMPR2 mutations are potentially heritable regardless of whether they appear de novo or have been passed down in the family. Because of reduced penetrance, only about 20 % of people with a BMPR2 mutation detected develop the disease and presentation is variable even within a family carrying the mutation. It has also been seen that affected individuals in successive generations in a family pedigree with HPAH express the disease earlier and with earlier age of death. This is known as genetic anticipation and has been described in several other diseases like fragile X syndrome and Huntington's chorea [31]. Females have a greater incidence of HPAH, suggesting possibly that the male fetuses with the disease die in utero [31]. BMPR2 mutations are seen in 80 % of subjects with FPAH and 10–25 % of "sporadic" patients have de novo mutations. Individuals with a BMPR2 mutation have more severe disease associated with earlier presentation and mortality [32]. Genetic testing for BMPR2 mutations should be performed in all children with PAH and their healthy siblings. Because mutations within a given pedigree are constant, testing should start with the proband and family members should be tested for the mutation expressed in the index patient.

PAH in Childhood

IPAH may rarely present in the neonatal period or infancy and is initially treated as persistent pulmonary hypertension of the newborn (PPHN). When PAH persists beyond the first few weeks of life and there are no associated trigger factors that are seen with PPHN, caregivers must suspect an early presentation of IPAH. In these children, lung histopathology is very similar to that seen in IPAH at an older age [33].

The remainder of this chapter will focus on PAH beyond infancy. Though all of the five WHO groups of PAH are seen in childhood, majority of children present with either Group I or Group III chronic lung disease of infancy. Congenital heart disease and postcapillary pulmonary hypertension due to left heart disease should be ruled out before labeling a patient with IPAH, and these lesions will be discussed in another chapter. PAH secondary to connective tissue disease like systemic lupus erythematosus and scleroderma are important causes of childhood PAH, but their incidence is much lower than in adults. They are classified under WHO Group I PAH, because of similar histopathology and therapeutic approaches; however, patients with PAH secondary to collagen vascular diseases have a much lower responsiveness to acute vasodilator testing and worse prognosis.

The inclusion of exercise hemodynamic abnormalities in the definition of pulmonary arterial hypertension is important, since children with pulmonary arterial hypertension often have an exaggerated response of the pulmonary vascular bed to exercise and to hypoxia as compared with adults [14]. Children with a history of recurrent exertional or nocturnal syncope may have a near normal resting mean pulmonary artery pressure that markedly increases with exercise as well as with modest systemic arterial oxygen desaturations during sleep triggering PH crises [14].

Natural History of IPAH

The natural history of IPAH has changed in the past two decades beginning with the discovery and introduction of prostacyclins. Yung et al. reported that the 10-year survival for children was 78 % in the modern era. [6] The REVEAL study reported an overall survival of 91 %, 74 %, 65 %, and 59 % for IPAH/HPAH patients in the current era. They also analyzed data from 216 pediatric patients and reported a 5-year survival of 74 % and 71 % for IPAH and PAH secondary to congenital heart disease, respectively [9, 10]. The overall survival for Eisenmenger syndrome (ES) is better than IPAH with most ES patients surviving into their third–fourth decade [34, 35]. This is most likely due to the presence of a "pop-off" shunt. In contrast, prognosis for patients

with persistent PAH after shunt closure is poor and approximates that of an IPAH patient. Therefore, operability needs to be assessed carefully before considering closure [13, 36, 37]. For borderline patients, leaving a small 4–5-mm punch hole in the patch or creating an atrial shunt is often considered at the time of repair, with anticipatory management of PAH in the postoperative period.

Pathogenesis and Pathobiology of Pediatric PAH

Though the exact mechanism of PAH development has not been completely elucidated, endothelial cell dysfunction, with smooth muscle cell proliferation and dysfunction and altered apoptosis secondary to imbalance of vasogenic mediators, is considered to be the consistent common factor. A thorough understanding of the factors underlying the pathogenesis is the mainstay for developing targeted treatment modalities. As more and more factors involved in this complex process are uncovered, molecules targeting these individual pathways are concomitantly undergoing testing in animal and cellular models [38–40].

A: Vasoconstriction

Wagenvoort et al. suggested that "*primary pulmonary hypertension*" afflicts people with hyperreactive lung vessels with pulmonary vasoconstriction in response to specific triggers, resulting in the development of the characteristic vascular lesions of PAH [39]. Thus, initial treatment measures for this disease were based on this mechanism, i.e., finding the ideal pulmonary vasodilator. Despite PH being of multifactorial origin, vasoconstriction, cell proliferation and dysregulated growth, inflammation, and in situ thrombosis are all responsible in varying degrees. Imbalance in multiple circulating and tissue vasoactive mediators secondary to endothelial dysfunction leads to vasoconstriction. In young children, the pathobiology of PPHN suggests failure of the neonatal vasculature to relax after transition from fetal to the neonatal circulation. The lack of relaxation is accompanied by a reduction in arteriolar number and vascular surface area. As the baby gets older, if PPHN persists, these changes become fixed with a vasodilator-unresponsive component related to the development of thickened vascular media and adventitia [39]. In older children with IPAH, intimal hyperplasia and occlusive changes as well as typical plexiform lesions are found in pulmonary arterioles. In contrast to adults who have severe plexiform lesions and what appears to be "fixed" pulmonary vascular changes, children have more smooth muscle cell (SMC) hypertrophy, less intimal fibrosis, and fewer plexiform lesions. With increasing age, intimal fibrosis and plexiform lesions are more frequent. These observations may offer clues to the observed differences in the natural history and factors influencing survival in children with IPAH compared to adult patients. Three important pathways are thought to be responsible for vasoconstriction: the prostacyclin pathway, nitric oxide pathway, and endothelin pathway.

1. *Prostacyclin (PGI2) pathway*: PGI2, generated from arachidonic acid via the cyclooxygenase pathway, causes SMC relaxation and inhibits platelet aggregation via cAMP production. Thromboxane (TX) synthetase, which is derived from the same substrate as PGI2 synthetase, generates TXA2, which is a potent vasoconstrictor, and leads to platelet aggregation. In IPAH, the balance between PGI2 and TXA2 is tilted in favor of the latter [40, 41]. Thus, the use of epoprostenol (PGI2) leads to pulmonary vasodilation by correcting this imbalance.
2. *Nitric oxide (NO) pathway*: NO is synthesized in the endothelium by endothelial NO synthetase (eNOS). NO stimulates guanylate cyclase to produce cGMP, which has vasodilatory and antiproliferative properties [42]. The identification of this pathway has led to the use of inhaled NO (iNO) therapeutically in the treatment of PAH, as well as the development of other medications that lead to the release of endothelial cGMP. In various forms of PAH, there is reduced bioavailability of eNO, because of either reduced eNOS expression or secondary to oxidative free radical

production, which consumes eNO [43]. Asymmetric dimethyl arginine (ADMA), which is elevated in many forms of PAH, acts by the inhibition of eNOS and via direct effects on gene expression [44]. Increased expression of phosphodiesterase5 (PDE5) enzyme also degrades cGMP and leads to vasoconstriction. PDE5 inhibitors replenish cGMP and act as rescue agents preventing rebound PAH while weaning iNO and also act as potent pulmonary vasodilators [45].

3. *Endothelin-1 (ET-1) pathway*: ET-1 leads to vasoconstriction, fibrogenesis, and cell proliferation and acts via ETA and ETB receptors in the SMC. ET-1 levels are found to be increased in lung tissue and circulation in IPAH, APAH secondary to lung disease and thromboembolism as well as congenital diaphragmatic hernia patients. The ETB receptors on endothelial cells are involved with release of eNO and PGI2; however, there seems to be no added advantage to selective ETA inhibition, suggesting that the relative expression of the two receptors in disease states may play a role in the pathogenesis of PAH [46].

B: Endothelial Dysfunction

Endothelial dysfunction is an important factor mediating structural changes that occur in the pulmonary vasculature. The endothelium is vital for maintaining vascular tone, homeostasis, leukocyte trafficking, transduction of luminal signals to abluminal vascular tissues, production of growth factors, and cell signals with autocrine and paracrine effects and barrier function [47].

It is possible that there may be unknown "triggers" for endothelial activation in "genetically susceptible patients," which leads to apoptosis, destabilization of vascular intima, and endothelial proliferation leading to the classic plexiform lesions. Endothelial cell dysfunction leads to the release of *vasoproliferative* substances in addition to *vasoconstrictive* agents that results in the progression of the pulmonary vascular remodeling and progressive vascular obstruction and obliteration. Endothelial dysfunction causes release of chemotactic agents, leading to the migration of smooth muscle cells into the vascular wall resulting in medial hypertrophy and hyperplasia [47].

C: Cell Proliferation and Apoptosis

Many of the mediators described above also play an important role in cell proliferation and remodeling. Both endothelial and SMCs demonstrate mitochondrial abnormalities which lead to a shift in metabolism favoring glycolysis for ATP generation and possibly altering the apoptosis potential. Mutations in BMPR2 ALK-1 and endoglin lead to vascular remodeling and are potential pathways for therapeutic intervention. When loss of BMPRII is experimentally induced, PA endothelial cells and SMC are more susceptible to apoptosis, migration, and proliferation in response to TGF-β1 [48].

Growth factors: Several growth factors act as potent mitogens and chemotactic agents in PAH. Increased vascular endothelial growth factor (VEGF), TNF-α, platelet-derived growth factor (PGDF), and fibroblast growth factor (FGF) levels are implicated in PAH. Most of these growth factors act by activating tyrosine kinase receptors which initiates major signaling cascades within the cells, resulting in an antiapoptotic and pro-proliferative phenotype similar to that seen in malignant cells. Human trials using tyrosine kinase inhibitors are ongoing, with promising results in selected patient groups with severe PAH [49].

Apoptosis: The plexiform lesion forms a fascinating substrate for scientists studying the mechanism of vascular proliferation and remodeling. Selective apoptosis of endothelial cells results in unbridled proliferation of apoptosis-resistant precursor cells driven by changes in molecules like BMPR2, signaling factors (Notch-3, PPAR γ), and potassium and calcium channel derangements [50].

D: Inflammation and Thrombosis

Inflammation has long been implicated as a trigger in PAH as evidenced by an increase in cytokines, interleukins, and chemokines [51]. Endothelial dysfunction and inflammation

predispose to in situ thrombosis. Patients with IPAH have increased von Willebrand factor levels and increased platelet aggregation. The use of anticoagulants has been shown to reduce the incidence of thrombosis in both IPAH and chronic thromboembolic PH [7].

Right Ventricular (RV) Function in PAH

The RV works against increased afterload (due to increased pulmonary vascular resistance) as the pulmonary arterioles and arteries stiffen. Initially, as the RV dilates and the muscle hypertrophies, the systolic function is preserved: indeed, increased RV mass initially is a compensatory mechanism to improve its efficiency in pumping against the increased afterload. Over a period of time, the RV systolic and diastolic function gets compromised. As the RV dilates, tricuspid regurgitation increases because of annular dilatation and leaflet non-coaptation. As the hypertensive RV enlarges, hypertrophies, and eventually fails, the interventricular septum changes its shape, thickness, and motion. The left ventricle (LV) is significantly impacted by the changes in the RV, because of ventricular interaction. The two ventricles are separated by the interventricular septum and are housed within the common pericardial cavity, and the LV function is impacted by changes in the RV [52]. This phenomenon of ventricular cross talk can be harnessed to the patient's benefit by using medications like vasopressin and epinephrine in acute RV failure with preserved LV function. These drugs increase LV afterload, and increase LV contractility, and thus improve RV output. This effect is seen in postoperative patients, post heart transplant, as well as in IPAH with PH crisis [53].

Pathophysiology and Relation to Symptoms

There are significant differences in the hemodynamic parameters of pediatric patients with IPAH as compared with adult patients [8, 34]. Children with IPAH have a higher cardiac index than adults, with a mean CI of 3.4 L/min/m^2 reported from the TOPP study. The REVEAL registry analysis suggested that children tend to have a greater response with acute vasodilator testing than do adults (36 % using the modified criteria for vasoactive response in children) [10].

Dyspnea occurs during physical activity as a result of an inability to increase cardiac output in the presence of increased oxygen demands and is one of the commonest symptoms in children with IPAH. Syncopal episodes, which occur more frequently with children than with adults, are often post-exertional and imply a severely limited ability to increase cardiac output, leading to diminished cerebral blood flow. Peripheral vasodilatation during physical exertion possibly exacerbates this condition. In the TOPP registry, syncope was noted to be twice as common in children (25 % vs. 12 %) and is often the presenting symptom in children [34]. Though it occurs frequently in IPAH and in repaired CHD with PAH, it is unusual to find children with unrepaired CHD presenting with syncope, because of the "pop-off" provided by the ability to shunt right to left during crises [34]. Cyanosis at baseline or with exertion is commonly seen in patients with right to left shunts at baseline or shunts that reverse with exertion due to increased RV work. In IPAH, cyanosis can occur in the presence of an atrial shunt.

Patients with right ventricular failure (often a late presentation in children) develop peripheral edema as well as hepatomegaly. With progressive right heart failure, full-fledged anasarca with pleural effusions and ascites may develop. Intestinal wall edema may lead to malabsorption, resulting in severe protein deficiency (from reduced absorption as well as increased intestinal losses), and a protein-losing enteropathy-like state may result. This is often end-stage and rapidly results in death. Comorbidities like pneumonias and other systemic infections result in alveolar hypoxia leading to a downward spiral of pulmonary vasoconstriction and compromised cardiac output, resulting in cardiogenic shock and death. In addition to

RVH and RV dilatation, elevated RV end diastolic pressures lead to right atrial dilatation and atrial arrhythmias including atrial fibrillation as well as ventricular arrhythmias. The acidosis can make the arrhythmias worse and the loss of atrial kick in atrial fibrillation and flutter can lead to low cardiac output and death. Possible mechanisms for sudden death include ventricular arrhythmias, acute pulmonary emboli, massive pulmonary hemorrhage, sudden right ventricular ischemia, and acute increases in RV pressure leading to posterior septal bowing into the left ventricle leading to an acute drop in cardiac output and hypotension.

Diagnosis and Assessment of Childhood PAH

By definition, IPAH is a diagnosis of exclusion. Since there are multiple baseline systemic disorders that might lead to PAH, meticulous evaluation to diagnose potentially treatable conditions must be performed. This should include a detailed history and physical examination, laboratory tests, noninvasive imaging, and invasive hemodynamic studies. Tests should include evaluation for the end-organ effects of PAH and heart failure on the kidney, liver, and other organ systems. A detailed family history of pulmonary hypertension, congenital heart disease, rheumatologic disorders, other congenital anomalies, and unexplained deaths should be obtained. If the family history suggests FPAH/HPAH, careful screening of all first-degree relatives is recommended. All patients should ideally get genetic testing done. Other possible causes to be excluded are a history of using anorexigenic drugs and chemotherapy including the guanylate cyclase inhibitor dasatinib (which has recently been implicated in PH). A new pediatric functional classification has been proposed by the PVRI pediatric taskforce, which is based on the current WHO classification for adults, and takes into account age-related activity and exercise capacity (Table 120.2). This is subdivided for different age groups starting from 0 to 16 years [54].

Table 120.2 WHO Functional Classification in adults with PAH. http://www.ncbi.nlm.nih.gov/pmc/articles/PMC3161406/table/T2/. Copyright : © Pulmonary Circulation

Class	Symptoms
I	Patients with pulmonary hypertension but without limitation of physical activity. Ordinary physical activity does not cause undue dyspnoea, fatigue chest pain or near syncope
II	Patients with pulmonary hypertension resulting in slight limitation of physical activity. Comfortable at rest. Ordinary physical activity causes undue dyspnoea, fatigue, chest pain or near syncope
III	Patient with pulmonary hypertension resulting in marked limitation of activity. Comfortable at rest. Less than ordinary activity causes dyspnoea or fatigue, chest pain or near syncope
IV	Patients with pulmonary hypertension resulting in inability to carry out any physical activity without symptoms. These patients manifest symptoms of right heart failure. Dyspnoea and/or fatigue may be present even at rest. Discomfort is increased by any physical activity undertaken. Syncope or near syncope can occur

Physical Signs

General examination includes documentation (and follow-up of height and weight) to monitor growth as growth retardation may be an important sign of right heart failure as well as chronic disease. Tachycardia and tachypnea are important signs of cardiac failure. Oxygen saturations should be documented every visit and may be reduced if there is intracardiac right to left shunting. Jugular venous pulse amplitude and waveforms may be abnormally elevated in patients with IPAH and are better appreciated in older children. Ascites and peripheral edema can also occur in children with severe right heart failure.

The cardiac findings in children with PAH arise from elevated right atrial and right ventricular pressures. Palpation over the right sternal border is significant for a right ventricular heave. In children with large atrial septal defects, there is a prominent subcostal impulse secondary to RV volume overload. Auscultation findings include a normal first heart sound and a loud pulmonary component of the second sound with

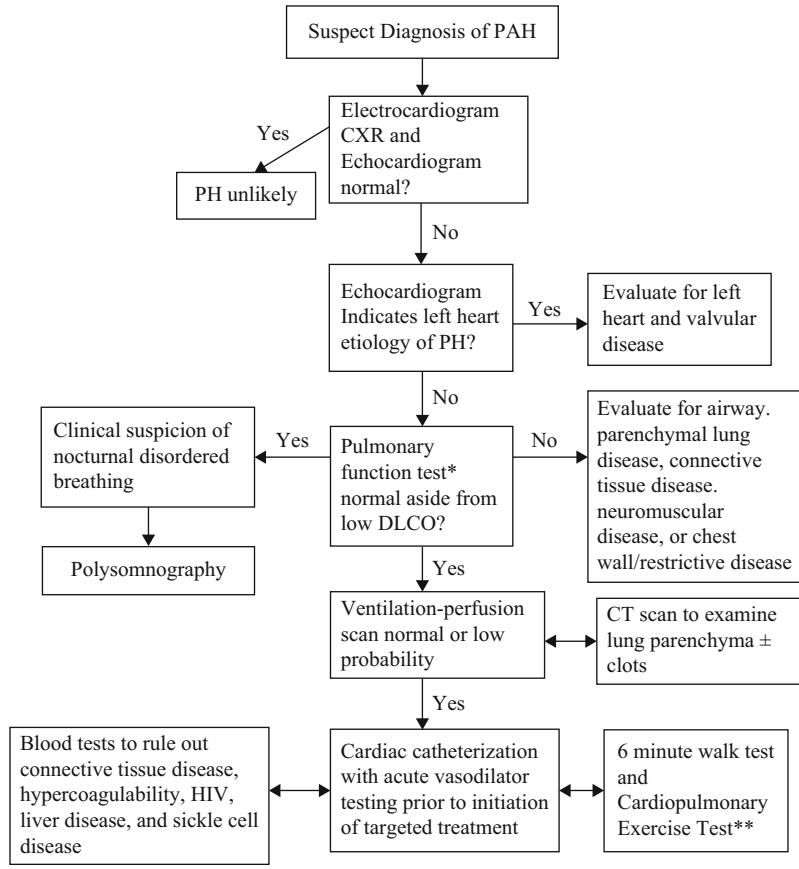

Fig. 120.1 Diagnostic work-up for pediatric pulmonary hypertension (From [55])

a widening of the second sound. In addition, there may be an S3 or S4 right ventricular gallop. Systolic ejection clicks and systolic flow murmurs may be audible over the dilated pulmonary artery. A holosystolic murmur of tricuspid regurgitation (TR) is heard at the right lower sternal border when there is significant TR present. A high-pitched early diastolic murmur of pulmonary regurgitation may also be audible in older children. In children with intracardiac shunts and severe PAH, shunt murmurs will not be audible due to the absence of a pressure gradient between the left and right heart. As expected, in children with persisting PAH after correction of intracardiac shunts, the physical examination is similar to patients with IPAH.

The recommended diagnostic work-up for children suspected of having IPAH is similar to that for adults (Fig. 120.1) [55]. Laboratory testing includes baseline chemistries, brain natriuretic peptide (BNP) or NT-proBNP (which is elevated in RV failure and is useful in follow-up), and tests to investigate other etiologies. In addition, it is important to evaluate for perfusion defects in the lungs (for thromboembolic PAH) with a nuclear ventilation/perfusion scan or CT angiography, sleep testing to rule out sleep disorders, and pulmonary function testing for reversible airway abnormalities as well as for follow-up evaluation.

Echocardiography in Pediatric Pulmonary Arterial Hypertension

Two-dimensional (2-D) and Doppler echocardiography has an important role to play in the

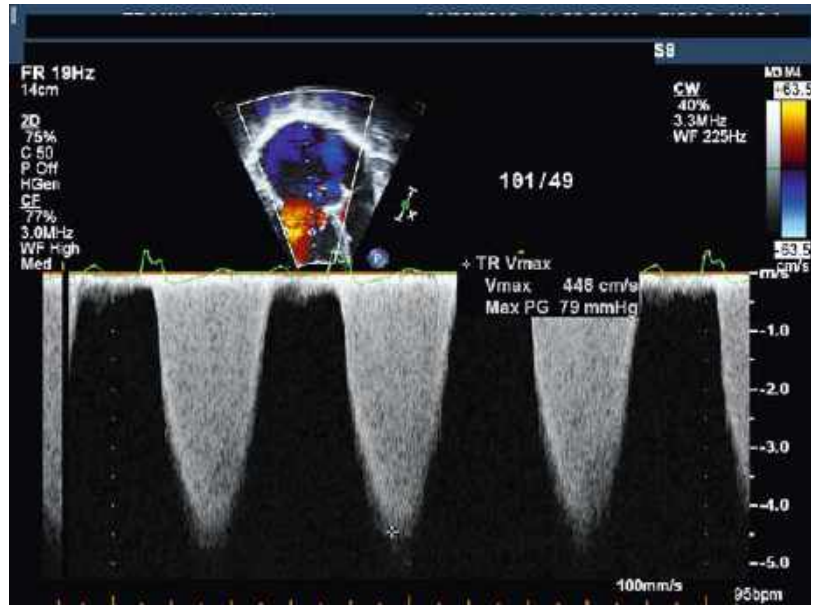

Fig. 120.2 Echo image showing measurement of TR gradient using the Bernoulli principle

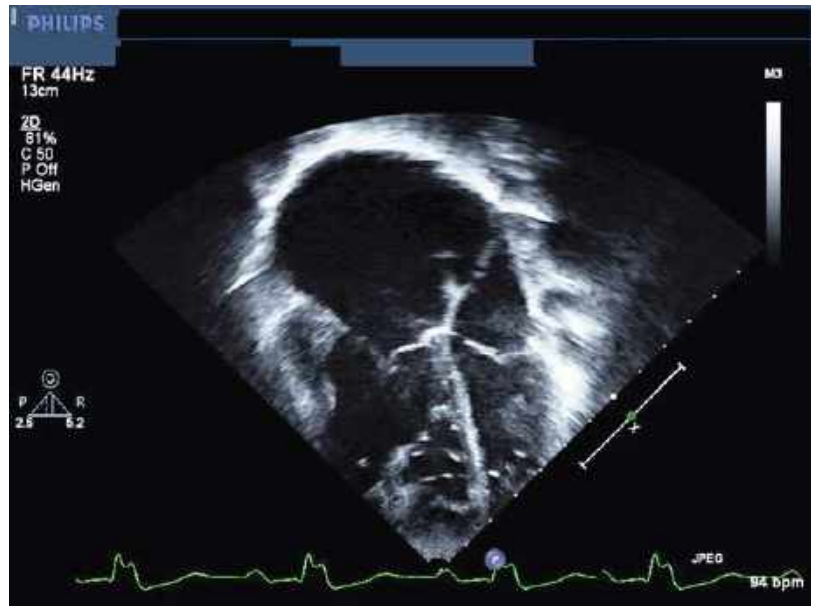

Fig. 120.3 Apical four-chamber image showing enlarged right atrium and right ventricle with atrial and ventricular septal bowing to the *left*

diagnosis and follow-up of patients with PAH. It is used to screen for the disease, rule out associated structural heart disease, determine heart function, and estimate the pulmonary arterial pressure (PAP) by Doppler.

The echocardiographic protocol suggested for an IPAH patient includes 2-D and M-mode evaluation for atrial and ventricular enlargement and ventricular hypertrophy. Ventricular septal flattening and posterior systolic bowing occur as the right ventricular pressure increases and then exceeds the left ventricular pressure (Figs. 120.2, 120.3) [56]. Consequently, with the septum bowing posteriorly, left ventricular (LV) size may be

reduced, but the left ventricular systolic function is usually preserved. A redistribution of left ventricular filling from early to late diastole, as demonstrated by tissue Doppler, reflects reduced compliance [56, 57]. Diastolic dysfunction of the ventricles can be quantified by mitral and tricuspid diastolic inflow velocities, pulmonary and systemic venous flow patterns, and tissue Doppler imaging of the mitral and tricuspid annulus and at the septum. Right ventricular systolic pressure can be determined by measuring the peak systolic pressure gradient from the right ventricle to the right atrium (calculated using the Bernoulli equation $P = 4v^2$ [2], where v is the maximum velocity of the TR jet measured by continuous wave Doppler) and adding the estimated right atrial pressure [56]. Using the TR jet velocity as an estimate of PASP can over- or underestimate the PAP and the clinician uses other features of the echocardiogram to support the diagnosis [57]. The estimation of RV function is challenging due to the complex geometry of the RV as compared to the left. Several measures have been described to estimate the degree of RV dysfunction including the Tei index (myocardial performance index), RV ejection fraction, RV fractional area change, and the tricuspid annular plane systolic excursion (TAPSE) [58–60]. When pulmonary regurgitation (PR) is present, the velocity profile across the valve can be used to estimate PA diastolic pressure.

Hemodynamics/Cardiac Catheterization

Right heart catheterization is the "gold standard" for diagnosis, estimation of severity, prognostication, and therapeutic decision-making [61]. Diagnostic catheterization should include acute vasodilator testing (AVT) with 40–80 parts per million (PPM) of iNO. For children, multiple experts recommend using the older definition for vasoresponsiveness: reduction in mean PA pressure and pulmonary vascular resistance of 20 %, with no change or an increase in cardiac output. The recent adult guidelines define AVT response as a drop in mean PAP by >10mm to <40 mmHg [12, 62, 63]. A lower MPAP/MAP and lower Rp/Rs ratio is considered a better prognostic index in children [62, 63]. Patients who do not manifest a response to AVT are unlikely to have clinical benefit from chronic oral calcium channel blockade therapy. Empiric calcium channel blockade therapy in patients who are AVT unresponsive is not recommended (Fig. 120.4).

Magnetic Resonance Imaging (MRI) and Computerized Tomography (CT) Angiography

MRI is a valuable tool and is useful in noninvasively assessing blood flow velocities, RV metabolic properties, and RV volumes, mass, and output in a serial manner [64]. Despite the need for general anesthesia in younger children, the absence of radiation and better safety profile of MRI contrast make it a very attractive modality [64]. High-resolution, thin-slice rapid CT scanning is used in PAH to rule out lung parenchymal disorders including interstitial lung disease, and CT angiography is increasingly used to rule out pulmonary embolism.

Cardiopulmonary Exercise Testing (CPET) and Six-Minute Walk Test (6MWT)

The six-minute walk test (6MWT) is useful to assess functional capacity and correlates with outcome in adults, but has not been validated in children with PAH. It is a useful test to follow up patients on therapy; however, in pediatrics, one must take into account the age, height, and weight while interpreting the results. Reliable CPET is usually possible in children over 7 years of age. Yetman et al. reported in a series of 40 children with PAH who underwent CPET that parameters like peak oxygen consumption (pVO2), anaerobic threshold, end tidal carbon dioxide, and change in ventilation per quantity of expired carbon dioxide (VE/VCO2) correlated with invasive measures of disease severity, including pulmonary vascular resistance [66, 67].

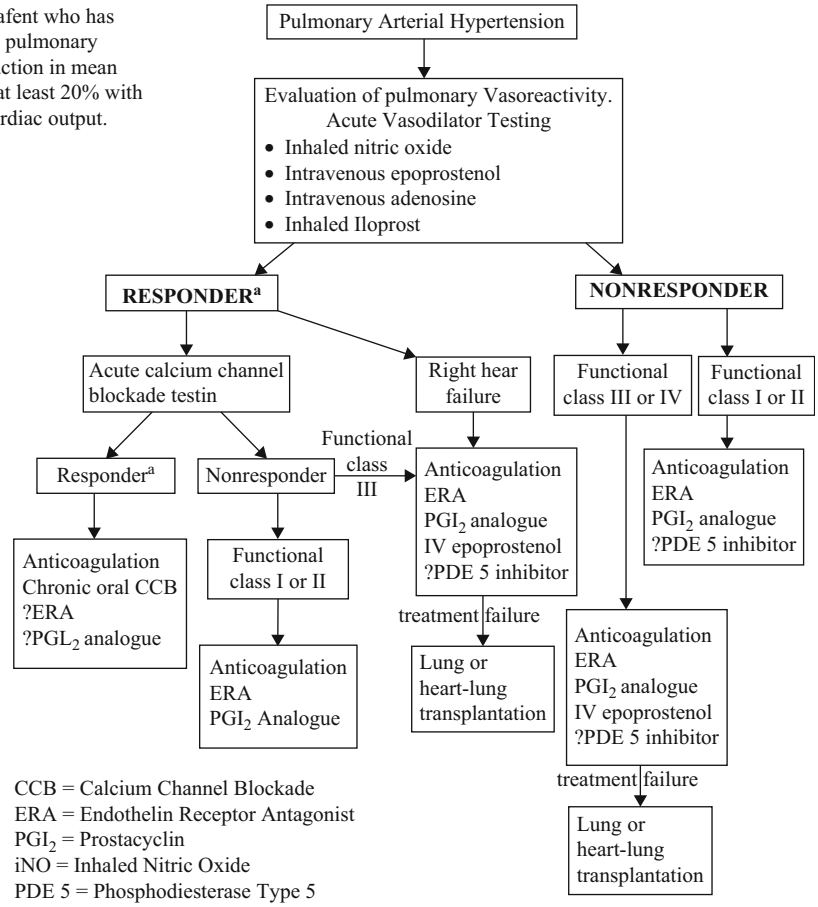

Fig. 120.4 This figure illustrates current treatment strategies for children with IPAH [68]

Treatment

Although there is no cure for PAH nor a single therapeutic approach that is uniformly successful, therapy has dramatically improved over the past several decades, resulting in sustained clinical and hemodynamic improvement as well as increased survival in children with various types of PAH [14, 20, 68, 69]. An overview of the current approach and guidelines for treatment is shown in Fig. 120.4 [68]. Noninvasive studies obtained prior to initiating therapy, as well as periodically thereafter, are useful in guiding changes in therapeutic regimens, particularly in light of recent advances with various novel therapeutic agents.

General Measures

The pediatrician plays an invaluable role in the care of children with pulmonary arterial hypertension. Since children often have a more reactive pulmonary vascular bed than adult patients do, respiratory infections resulting in alveolar hypoxia can result in PH crisis if not treated aggressively. Annual influenza and pneumococcal vaccination are recommended. Antipyretics should be administered for temperature elevations greater than 101 °F (38 °C) to minimize the consequences of increased metabolic demands on an already compromised cardiorespiratory system. Children may also require aggressive therapy, e.g., inhaled nitric oxide for acute pulmonary hypertensive crises occurring

with episodes of pneumonia or other infectious diseases. Patients may also require antitussive medications during upper respiratory infections. Decongestants with pseudoephedrine should be avoided as they may exacerbate the pulmonary hypertension. Diet and/or medical therapy should be used to prevent constipation, since Valsalva maneuvers transiently decrease venous return to the right side of the heart and may precipitate syncopal episodes.

Several goals of therapy for PAH include:

1. Improvement of hemodynamics
2. Improvement of symptoms and quality of life
3. Halt progression of disease
4. Reversal of established pulmonary vascular disease and cardiac hypertrophy (if possible)
5. Reduction of morbidity
6. Increasing life expectancy with the disease

Anticoagulation

Consideration of chronic anticoagulation in children with PAH is based on studies in adults with IPAH [4, 10]. The lung histopathology often demonstrates thrombotic lesions in small pulmonary arteries of adult patients with IPAH. Warfarin has been shown to be associated with improved survival in adult patients. Whether chronic anticoagulation is efficacious as well as safe for children with PAH remains to be determined. It is recommended to anticoagulate children who are hypercoagulable or with poor right ventricular function.

Calcium Channel Blockade

Calcium channel blockers are a chemically heterogeneous group of compounds that inhibit calcium influx through the slow channel into cardiac and smooth muscle cells. Chronic calcium channel blockade is efficacious for patients who demonstrate a robust response to AVT. In contrast, patients who do not respond acutely fail to respond to long-term calcium channel blockade [6, 10]. In general, these acute "nonresponders" will respond to long-term treatment with intravenous prostacyclin, i.e., epoprostenol, and may respond to other newer oral and inhaled treatments. As per the REVEAL registry, as well as in a study by Yung et al., significantly greater percentage of children than adults are acute "responders" and can be effectively treated with chronic oral calcium channel blockade. However, Douwes et al., who reported a comparison of three methods of evaluating AVT in 37 children and 62 adults, did not find a significant difference in vasoreactivity between the two groups. Further, they also found very low vasoreactivity in patients with CHD-APAH [6, 10, 12, 32]. For acute responders, most studies have used calcium channel blockers at relatively high doses, e.g., long-acting nifedipine 120–240 mg daily or amlodipine 20–40 mg daily; however, the optimal dosing for children with IPAH is uncertain.

Serial Reevaluations: Serial reevaluations, including repeat acute vasodilator testing, to maintain an "optimal" chronic therapeutic regimen is essential to the care of children with PAH. In these authors' experience, acute "responders" continue to do exceedingly well as long as they remain AVT responsive on repeat cardiac catheterizations. In contrast, children who no longer demonstrate acute vasoreactivity deteriorate clinically and hemodynamically despite the continuation of CCB therapy but will likely improve with chronic epoprostenol therapy similar to the experience with children who are "nonresponders."

Nitric Oxide

Nitric oxide activates guanylate cyclase in pulmonary vascular smooth muscle cells (SMC), which increases cyclic GMP leading to SMC relaxation [65]. iNO may also have antiproliferative effects on smooth muscle and inhibit platelet adhesion. It has been demonstrated to be safe and efficacious in the treatment of persistent pulmonary hypertension of the newborn [70, 71]. iNO is also used for AVT during right heart catheterization and for treating acute PAH crises in IPAH patients as well as following cardiac surgery.

Prostaglandins

The discovery of the role of prostacyclin in pulmonary vasodilation has revolutionized therapy for PAH. Indeed, the natural history of IPAH can be divided into two eras, the pre- and post-prostanoid eras with improvement in life expectancy and quality of life after the introduction of epoprostenol. Epoprostenol has been shown to improve hemodynamics, quality of life, and exercise capacity in patients with PAH. Chronic intravenous epoprostenol lowers pulmonary artery pressure, increases cardiac output, increases oxygen transport, and improves exercise capacity, hemodynamics, and survival in patients with IPAH [35, 72, 73]. These effects occur with long-term use even in patients unresponsive to AVT, suggesting that epoprostenol may cause pulmonary vascular remodeling in addition to its vasodilator properties. The epoprostenol dose (ng/kg/min) is titrated incrementally, with the most rapid increases occurring in the first few months after initiating therapy and slower thereafter. The dose needs to be increased possibly because of development of tolerance to the therapy. In the authors' institution, the mean dose at 1 year in children is closer to 50–80 ng/kg/min, but there is a significant patient variability of the "optimal" dose.

Because epoprostenol is chemically unstable at neutral pH/room temperature and has a short half-life (1–2 min), a continuous intravenous delivery system with cold packs is needed to maintain stability. An indwelling central venous line is necessary, with associated complications including thrombosis and line occlusion, local and systemic infection, and catheter breakage. In addition, pump malfunction may rarely lead to the administration of a sudden bolus of epoprostenol (leading to systemic hypotension) or the interruption of the medication which can cause severe rebound PAH. Therefore, a search for alternate routes of drug delivery has led to the clinical investigation of oral, inhaled, subcutaneous, and more stable and longer-acting intravenous prostacyclin analogues.

Prostacyclin Analogues

Oral Prostacyclin Analogue

Beraprost sodium is an oral prostacyclin analogue whose potency is approximately 50 % that of epoprostenol. It is approved for PAH treatment in Japan but is not approved for use in Europe and the United States [74].

Inhaled Prostacyclin Analogues

Inhaled iloprost and inhaled treprostinil are increasingly being used in patients requiring prostanoid therapy. They are an attractive option, because inhaled delivery may avoid the systemic side effects of intravenous epoprostenol use. Iloprost is a more stable synthetic analogue of prostacyclin, which acts through prostacyclin receptors on vascular endothelial cells. Iloprost has a short biological half-life, i.e., 20–25 min, and needs to be administered every 1–4 h depending on patient acuity. It has been used in neonates and infants with bronchopulmonary dysplasia and is thought to cause less V-Q mismatch than intravenous prostanoids [75, 76]. Inhaled treprostinil is longer acting and can be given on a 6 hourly basis with sustained effects. A recent study in children documented its use in children as young as 3 years with improvement in exercise capacity, BNP levels, and hemodynamics [74]. Longer-term studies are required in children to validate these preliminary findings.

Treprostinil sodium is a prostacyclin analogue with a neutral pH and longer half-life, is stable at room temperature, and shares the same pharmacologic actions as epoprostenol [77, 78]. It can be administered both intravenously and subcutaneously. Double-blind, randomized, placebo-controlled trials demonstrated improved exercise capacity, clinical signs and symptoms, as well as hemodynamic measurements in patients with pulmonary arterial hypertension including children [77, 78]. With subcutaneous administration, the risks associated with an intravenous line are minimized. Although no serious adverse events

related to subcutaneous treprostinil have been reported, discomfort at the infusion site has been noted. A recent study from France and Spain has described the use of subcutaneous treprostinil in very young children [79].

Endothelin Receptor Antagonists

Endothelin (ET)-1 is one of the most potent vasoconstrictors implicated in the pathobiology of PAH, and plasma endothelin-1 levels are increased in patients with IPAH and correlate inversely with prognosis. The oral nonselective endothelin receptor antagonist bosentan has been shown to improve exercise capacity, quality of life, as well as cardiopulmonary hemodynamics in patients with PAH [80, 81]. An open-label study of 19 children on bosentan, with Group I PAH and WHO functional class II and III, was performed with measurements of pharmacokinetic and hemodynamic parameters at baseline and 12-week follow-up [82]. Patients weighing 10–20 kg, 20–40 kg, and >40 kg received 31.25 mg qD, 31.25 mg BID, and 62.5 mg BID, respectively, for 1 month and then 31.25 mg BID, 62.5 mg BID, and 125 mg BID, respectively, for the remainder of the study. Hemodynamic improvement was demonstrated at 12 weeks and the drug was well tolerated. Risks associated with endothelin receptor antagonists include acute hepatotoxicity (dose related), teratogenicity, and possibly male infertility. Ambrisentan, a selective ET_A receptor blocker, which can be administered once a day, has been reported with less hepatotoxicity and was found to be efficacious in children with an acceptable safety profile [83].

Phosphodiesterase Inhibitors

Phosphodiesterase 5 (PDE5) inhibitors prevent the breakdown of cyclic GMP thereby raising cyclic GMP levels [84, 85]. PDE5 inhibitors are particularly beneficial in postoperative patients in preventing rebound PH at the time of iNO withdrawal. An early randomized double-blind crossover design study of patients with IPAH compared the efficacy of sildenafil with placebo. Exercise capacity increased by 44 % and there was an increase in cardiac index and there was improvement in the dyspnea and fatigue components of a quality of life questionnaire. A recent report analyzing low-, medium-, and high-dose sildenafil in children (STARTS1 study) suggests that long-term use of higher doses may be associated with mortality, and as a result, the European Medicine Agency recommends that lower doses be used in children [86]. This signal of increased mortality for high-dose sildenafil was not seen in CHD-APAH group. The doses of sildenafil approved in Europe are 10 mg TID < 20 Kg and 20 mg TID for children weighing > 20 Kg. In the USA, the FDA has warned against the use of sildenafil in children ages 1–17 year. Another PDE5 inhibitor, tadalafil has similar pharmacologic effects as sildenafil but is longer acting, requiring only once a day administration, and is approved for use in adults, but larger studies in children are awaited [87].

Novel Therapies, Ongoing Clinical Trials, and Investigational Drugs

Early development of targeted therapies for PAH was therapy based on "vasoconstriction" as the predominant mechanism for PAH. However, with increasing research in the last decade and increasing understanding of other pathobiologic mechanisms involved, multiple other molecules have been tried successfully in animal models and a few have undergone human trials [88, 89]. These medications target abnormal cell proliferation and growth, inducing apoptosis, reversing extracellular protein deposition, as well as reversing sustained vasoconstriction. Lessons learnt from cancer therapy have encouraged the use of multiple drugs earlier in the disease to stop the process as well as trying newer medications to stem the unbridled cellular proliferation, both at the smooth muscle cell level and the adventitia.

Reverse Sustained Vasoconstriction

Rho-Kinase Inhibitors

RhoA-/Rho-kinase signaling inhibits myosin-light-chain phosphatase which mediates actin-myosin dissociation and vasorelaxation and causes sustained SMC contraction at any given calcium level. Rho-kinase inhibitors like fasudil have been shown to significantly reduce PAP in animal models of PAH unresponsive to iNO and prostanoids [91]. However, these results have not been yet reproduced in human trials.

In experiments involving mice deficient in vasointestinal peptide (VIP) gene, there was overexpression of genes promoting vasoconstriction/proliferation and inflammation and underexpression of all vasodilator/antiproliferative genes noted. Treatment with VIP fully corrected the genotypic as well as the phenotypic abnormalities [92]. Adrenomedullin is also another potent vasodilator peptide, which works via the cyclic amp and NO-mediated mechanisms and has angiogenic, antiproliferative, anti-migratory, and anti-inflammatory properties [90].

Antiproliferative and Proapoptotic Drugs (Lessons Learnt from Cancer Therapies)

A tyrosine kinase inhibitor, imatinib, developed as a wonder drug for the treatment of chronic myeloid leukemia, has shown promise in selected adult patients with advanced PAH and WHO class 3 and 4 symptoms in studies from Europe. It acts by inhibiting the PGDF receptor on smooth muscle cells [49]. Sorafenib, a multikinase inhibitor, developed for renal carcinoma is currently undergoing human trials. As a note of caution, the tyrosine kinase inhibitor dasatinib has been implicated in causing PAH in some patients on the medications for their cancer.

Survivin is an inhibitor of apoptosis protein, widely present in cancer cells, has also been expressed in the PAs of patients with IPAH. Inhibition of survivin is now being investigated for cancer therapy and may also benefit PAH therapy down the line.

Gene Therapy

With the identification of an IPAH gene which codes for the BMPR2 protein, attention has focused on gene replacement therapy linked to the mutated 2q33 chromosome. With the rapid advances in genetics, gene therapy may hold the hope for very early detection and therapy before disease progression and perhaps even preempt the onset of disease in susceptible subjects carrying the genetic mutation.

Additional Pharmacotherapy

The treatment of heart failure with inotropes and digoxin, diuretic therapy, and supplemental oxygen is important in the management of these patients. The management of arrhythmias promptly is vital as atrial flutter or fibrillation often precipitates an abrupt decrease in cardiac output and clinical deterioration due to the loss of the atrial component. Ventricular arrhythmias may complicate RV failure and need to be treated appropriately.

Atrial Septostomy

Children with recurrent syncope in severe right heart failure have a very poor prognosis [1, 4]. In ES, cardiac output can be maintained because of right to left shunting, and syncope is rare. Increased survival has been reported in patients with IPAH with a patent foramen. Successful palliation of symptoms with atrial septostomy has been reported in several series. Patients with pulmonary arterial hypertension with recurrent syncope or right heart failure significantly improve clinically, as well as hemodynamically, following atrial septostomy [93, 94]. Atrial septostomy has also shown a survival benefit, i.e., survival rates at 1 and 2 years are 87 % and 76 %, respectively, compared with conventional therapy (64 % and 42 % at 1 and 2 years, respectively). Thus, although atrial septostomy does not alter the underlying disease process, it may improve the quality of life and represent an

alternative for selected patients with severe IPAH. However, this invasive procedure is not without risk; indications for the procedure include recurrent syncope or right ventricular failure despite maximal medical therapy, as well as a bridge to transplantation.

Lung Transplantation

A limited number of centers perform lung transplantation in children and the availability of suitable donors is limited. Currently, the overall 1-year, 5-year, and 10-year survival for lung transplantation for PAH patients is 64 %, 44 %, and 20 %, respectively [95]. For untreated Eisenmenger patients that had reached adulthood, the 5-year and 25-year survival is greater than 80 % and 40 %, respectively, as opposed to following lung transplantation (52 % and 39 %) [96]. Thus, transplantation should be reserved for WHO functional class IV patients with PAH who have progressed despite optimal medical therapy. Ideally, children should be listed when their probability of a 2-year survival without transplantation is 50 % or less. Although lung and heart/lung transplantation are imperfect therapies for pulmonary arterial hypertension, when offered to an appropriately selected population, transplantation may improve survival with an improved quality of life. The use of extracorporeal membrane oxygenation (ECMO) as a bridge to recovery (in acutely decompensated patients) as well as a bridge to transplant may also be a viable option in selected patients [97].

Conclusions

Recent therapeutic advances have significantly improved the prognosis for children with PAH. Chronic vasodilator therapy with CCB in "responders" to AVT and prostanoids or targeted oral therapy in "nonresponders" appears to be effective in children and improves survival, hemodynamics, and symptoms [2–6]. There are several new therapies undergoing clinical trials in adult patients with PAH. It is possible that early aggressive dual or triple therapy may improve the overall efficacy in treating a child's PAH. With increasing understanding of the mechanisms of the disease as well as the genetic factors involved, novel treatment strategies will continue to evolve and we will hopefully be able to prevent or cure this disease in the future.

Pulmonary Hypertension in Congenital Heart Disease

121

Prashant Bobhate and Ian Adatia

Abstract

The state of the pulmonary vascular bed impacts on the outcome of CHD. Both active vasoconstriction and pathological remodeling conspire to increase PVR. The combination of increased pulmonary blood flow and pulmonary artery pressure is a potent stimulator of pulmonary vascular disease. With the exception of a few high-risk malformations (e.g., d-TGA and VSD), permanent or progressive pathological changes seldom occur when malformations are corrected in the first 1–2 years of life. Patients with Eisenmenger syndrome were for a long time therapeutic orphans. However, the availability of orally administered therapies has resulted in the inclusion of patients with Eisenmenger syndrome in randomized controlled trials. New insights into pulmonary vascular biology, improved understanding of genetic predisposition, the development of therapies that engage novel pathways, and the improved delivery of medical and surgical care in underprivileged areas will, we hope, substantially reduce the medical burden caused by pulmonary vascular disease associated with congenital heart disease.

vascular disease • Pulmonary vascular resistance • Shone's complex • Single ventricle • World Health Organization classification of pulmonary hypertension

Introduction

Pulmonary hypertensive vascular disease (PHVD) associated with congenital heart disease (CHD) may represent the single most preventable cause of pulmonary vascular disease worldwide [1]. The pulmonary vascular bed plays a key role in the presentation and management of children with almost all forms of congenital heart disease. For instance, the onset of symptoms with breathlessness and failure to thrive from systemic to pulmonary shunt lesions coincides with the delayed postnatal decrease in pulmonary vascular resistance index (PVRI) that typically occurs at around 6 weeks of life. Children whose pulmonary vascular resistance does not undergo this characteristic change will present later in life with cyanosis and possibly an uncorrectable lesion. The timing of surgical correction and the staging of children with single ventricle lesions are dependent on the PVRI and rate of growth of the pulmonary vascular bed. In many congenital heart diseases, it is the pulmonary vascular resistance, which is the arbiter of symptoms, management decisions, and often outcome.

Definition of Pulmonary Hypertensive Vascular Disease Associated with Congenital Heart Disease

In patients with congenital heart disease, the pulmonary artery pressure alone provides an uncertain indication of the presence of PHVD and the inclusion of PVRI (or transpulmonary gradient divided by pulmonary blood flow indexed to body surface area) is extremely important. We favor a definition of PHVD associated with CHD as a mean pulmonary artery pressure >25 mmHg and a pulmonary vascular resistance index >3 Wood units × m^2 for biventricular circulations [2]. The concept of an increased PVRI together with an increased pulmonary artery pressure to define PVHD is crucial in the management of patients with post-tricuspid shunt lesions. For instance, a patient with a large ventricular septal defect (VSD) may have pulmonary artery pressures equal to systemic pressures by virtue of the physical connection between the two ventricles. However, if the PVRI is < 3 WU × m^2 or the patient has clinical signs of increased pulmonary blood flow, this patient requires timely and accurate closure of the VSD.

Subjects who have undergone cavopulmonary anastomoses for hearts without a dedicated subpulmonary ventricle may have an increased PVRI that responds to inhaled nitric oxide [3] despite a mean PA pressure > 25 mmHg. Therefore, following cavopulmonary surgery, we define PVHD as a pulmonary vascular resistance index >3.0 WU × m^2 or a transpulmonary gradient >6 mmHg even if the mean pulmonary artery pressure is <25 mmHg in [2].

The Eisenmenger syndrome occurs in patients with long-standing large systemic to pulmonary shunt lesions and advanced PHVD. The Eisenmenger syndrome was characterized by Dr. Paul Wood as pulmonary hypertension due to a high pulmonary vascular resistance (>10 WU × m^2) with reversed or bidirectional shunt at aortopulmonary, ventricular, or atrial level [4, 5].

Classification

PHVD associated with CHD is classified in Group 1 of the modified World Health Organization (WHO) classification of pulmonary hypertension most recently revised in 2009 and potentially scheduled for further refinement in 2013. The rationale for inclusion of pulmonary vascular diseases in Group 1 is based on a shared histology by light microscopy, including the hallmark feature of plexiform lesions in advanced pulmonary vascular disease (Fig. 121.1). However, the WHO classification presented at Dana Point is not readily applicable to the

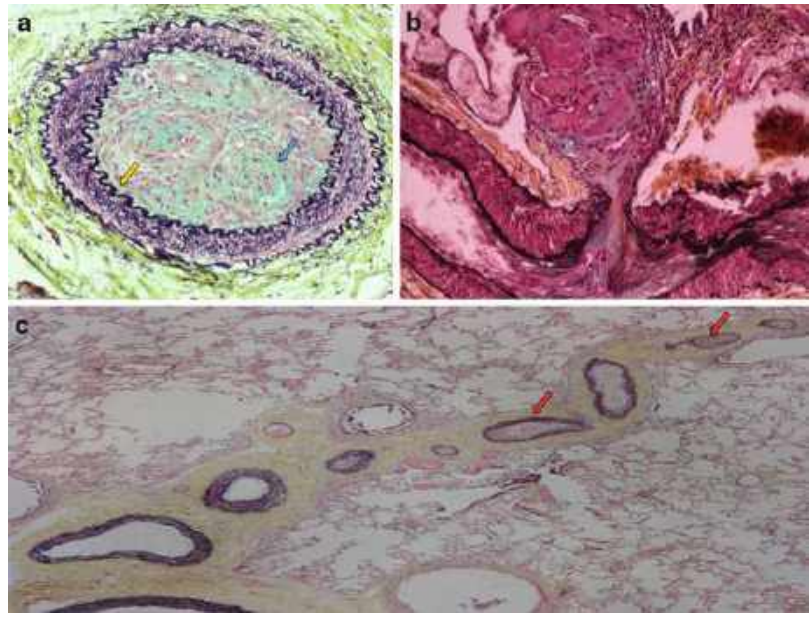

Fig. 121.1 Lung biopsy in a patient with congenital heart disease and advanced pulmonary vascular disease demonstrates classic plexiform lesions (*blue arrow*). On the *right*, the increased angiogenesis and proliferating blood vessels are seen in the plexiform lesion that disrupts the vessel wall. There is increased muscular medial thickness, elastosis of internal elastic lamina (*yellow arrow*), and complete occlusion of small pulmonary arteries (*red arrow*)

heterogeneity of PHVD encountered in pediatric practice and more inclusive classifications have been proposed such as the Panama Classification [2] (Tables 121.1 and 121.2) and that of van Albada and Berger [6] which provide a deeper and more refined description of the phenotypes encountered in childhood and, increasingly, in adult life. In addition, intriguing work by Lee et al. suggests that the proliferating endothelial cells in patients with PVHD associated with congenital heart disease are polyclonal rather than monoclonal as in idiopathic or heritable PAH. This raises the concept that phenotypes grouped by light microscopy may reflect rather different abnormalities of angiogenesis [7]. An additional difficulty in the application of the Dana Point classification is the arbitrary separation of pulmonary venous hypertension. In children with congenital heart disease, elements of pulmonary venous and arterial hypertension often coexist especially with left to right shunt lesions [8, 9].

Epidemiology

The prevalence of PHVD in European adults based on French and Scottish studies is estimated at 1.6–12.5 cases per million with approximately 50 % of cases due to CHD with reversal of shunt [10]. In a recent multicenter pediatric registry study, PHVD associated with CHD comprised 36 % of the patients and 53 % of cases were secondary to an unrepaired shunt lesion [11]. In the Netherlands, the incidence of PHVD associated with CHD was 4.2 % of all patients seen in the adult congenital heart disease program, with Eisenmenger syndrome accounting for 58 % of cases [12]. Although the greatest disease burden from PHVD associated with CHD is carried by populations in developing countries and underprivileged communities in the developed world, the incidence and prevalence of PHVD due to CHD in these areas is limited to rough estimates [1]. In Africa, the mean age of referral of children with CHD fortunate enough to see a pediatric cardiologist is 17 months and 5–10 % will have Eisenmenger syndrome at referral [13–15]. In China, a hospital-based survey revealed pulmonary hypertension in 6.6 % of all the patients admitted to a tertiary referral cardiac center from 1996 to 2005, of which 65 % had PHVD associated with CHD [16]. In India, 15 % (367/3790) of patients with CHD who had undergone cardiac catheterization over a 14-year period suffered from PHVD [17].

Table 121.1 Updated clinical classification of pulmonary hypertension (Dana Point 2008)

Category	Description
1	Pulmonary arterial hypertension (PAH)
1.1	Idiopathic PAH
1.2	Heritable
1.2.1	BMPR2
1.2.2	ALK1, endoglin (with or without hereditary hemorrhagic telangiectasia)
1.2.3	Unknown
1.3	Drug and toxin induced
1.4	Associated with
1.4.1	Connective tissue disease
1.4.2	HIV infection
1.4.3	Portal hypertension
1.4.4	Congenital heart disease
1.4.5	Schistosomiasis
1.4.6	Chronic hemolytic anemia
1.5	Persistent pulmonary hypertension of newborn
1	Pulmonary veno- occlusive (PVOD) and/ pulmonary capillary hemangiomatosis (PCH)
2	Pulmonary hypertension owing to left heart disease
2.1	Systolic dysfunction
2.2	Diastolic dysfunction
2.3	Valvular disease
3	Pulmonary hypertension owing to lung disease and/or hypoxia
3.1	Chronic obstructive pulmonary disease
3.2	Interstitial lung disease
3.3	Other pulmonary disease with mixed restrictive and obstructive pattern
3.4	Sleep disordered breathing
3.5	Alveolar hypoventilation disorders
3.6	Chronic exposure to high altitude
3.7	Developmental abnormalities
4	Chronic thromboembolic pulmonary hypertension
5.	pulmonary hypertension with unclear multifactorial mechanisms
5.1	Hematologic disorders: myeloproliferative disorders, splenectomy
5.2	Systemic disorders: sarcoidosis, pulmonary Langerhans cell histiocytosis, lymphangioleiomyomatosis, neurofibromatosis, vasculitis
5.3	Metabolic disorders: glycogen storage disease, Gaucher disease, thyroid disorders
5.4	Others: tumoral obstruction, fibrosing mediastinitis, chronic renal failure on dialysis

Table 121.2 Broad schema of 10 different categories of pediatric hypertensive vascular disease

Category	Description
1	Prenatal or developmental pulmonary hypertensive vascular disease
2	pediatric pulmonary vascular maladaptation
3	Pediatric cardiovascular disease
4	Bronchopulmonary dysplasia
5	Isolated pediatric pulmonary hypertensive vascular disease. (Isolated pediatric PAH)
6	Multifactorial pediatric pulmonary hypertensive vascular disease in congenital malformation syndromes
7	Pediatric lung disease
8	Pediatric thromboembolic disease
9	Pediatric hypobaric, hypoxic exposure
10	Pediatric pulmonary vascular disease associated with other system disorders

Development of the Pulmonary Vascular Bed

Complete development of human lung is not only limited to the intrauterine period but continues postnatally into early childhood [18]. The central pulmonary arteries up to the hilum develop from the sixth branchial arches. Three models have been suggested for the development of the distal pulmonary vascular bed or lung vascular morphogenesis. Model 1 describes central angiogenesis in the mouse with sprouting of arteries and veins from central vascular trunks and distal vasculogenesis with development of hematopoietic lakes in the mesenchyme [19, 20]. Model 2, using human fetal and embryonic tissue, proposes also distal vasculogenesis but with development of new vessels from endothelial cell precursors as the mechanism of lung vascularization [21]. Models 1 and 2 suggest that the developing blood vessels follow the scaffold of the developing airway. Model 3 in the mouse suggests distal angiogenesis as the process to develop lung vasculature with formation of new capillaries from preexisting ones and is of uncertain significance in humans [22].

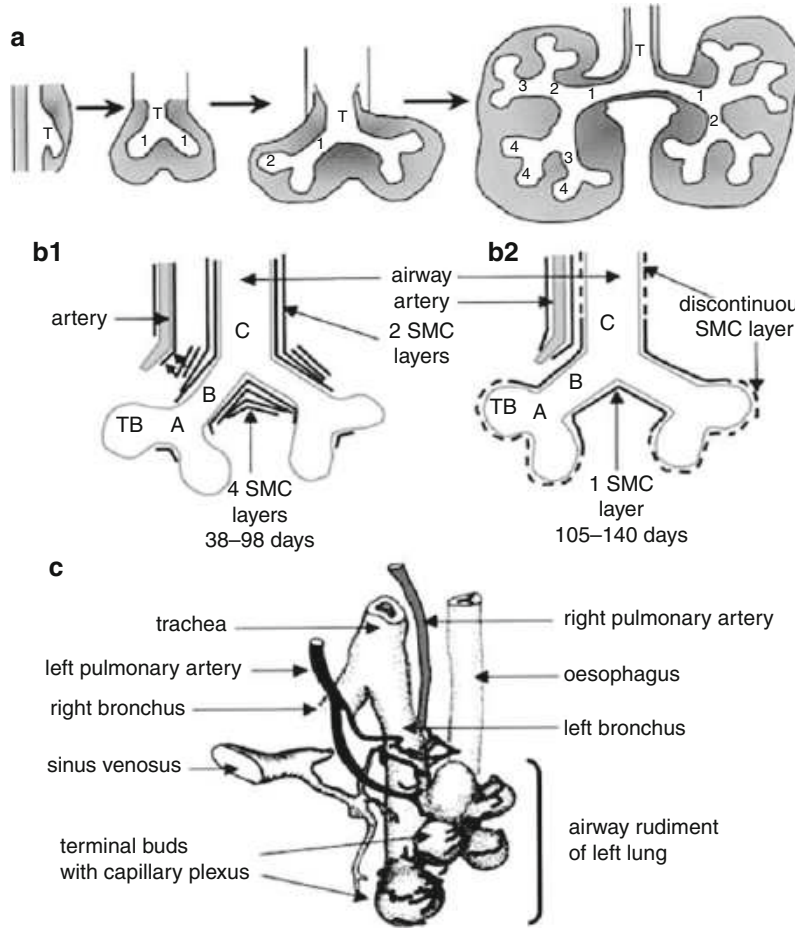

Fig. 121.2 (**a**) Diagram illustrating early airway branching into the mesenchyme based on serial sections from 28- to 47-day-old fetuses. A single diverticulum from the foregut, lying within the common mesenchymal sheath, divides to form the left and right lung buds. Each bud divides to increase the number of generations within an expanding mesenchyme. Generations are numbered from the hilum. T = trachea. (**b**) Diagram illustrating the arrangement of α-SM-actin-positive muscle cell layers around the peripheral airway and pulmonary arteries at two periods of development, 38–98 and 105–140 day of gestation. This is based on the observations on serial sections of these cases. *TB* terminal bud, *A, B, C* airway levels proximal to the terminal bud, *SMC*-α smooth muscle cell. (**c**) Drawing derived from a full serial reconstruction of the left lung bud at 38 day gestation, viewed from the *left side*, showing the airway branches and the accompanying pulmonary artery. The peripheral capillaries are clustered around each terminal bud. In addition, a mesenchymal sheath surrounds the lung bud and blood vessels; this is continuous with that of the trachea and esophagus (Reprinted with permission of the American Thoracic Society. Copyright © 2013 American Thoracic Society [21])

In humans, the intrapulmonary arteries appear to be derived from a continuous expansion of the primary capillary plexus by vasculogenesis [21] (Fig. 121.2). The arteries develop by continuous coalescence of endothelial tubes alongside the newly formed airway. The pulmonary arterial smooth muscle cells are derived from three sites in a temporally distinct sequence: the earliest from the bronchial smooth muscle, later from the mesenchyme surrounding the arteries, and last

from endothelial cells. Despite their different origins, all smooth muscle cells followed the same sequence of expression of smooth muscle-specific cytoskeletal proteins with increasing age. The order of appearance of these maturing proteins was from the subendothelial cells outward across the vessel wall and from hilum to periphery. The airways appear to act as a template for pulmonary artery development [21]. By term, the pre-acinar arteries are muscularized, the intra-acinar arteries are partially muscularized, and the more distal arteries remain nonmuscularized [21].

Hall et al. [23] have studied the development of the pulmonary veins in the human embryo and fetus. The pulmonary veins of the human embryo form initially by vasculogenesis from the splanchnopleural mesoderm and later growth in the intra-acinar region is by angiogenesis. Pulmonary venous smooth muscle is derived initially from undifferentiated mesenchymal cells. This differs from pulmonary arteries because there is no initial contribution from bronchial smooth muscle [23].

There is a gradual increase in pulmonary blood flow throughout gestation from 4 % of combined cardiac output to 8–10 % at term in fetal lambs [24]. The pulmonary blood flow in human fetuses estimated by echocardiography is 11–20 % of combined cardiac output at term [25, 26]. The human fetal pulmonary vascular bed is influenced by restriction at the foramen ovale and the ductus arteriosus especially in the presence of congenital heart disease, and decreased pulmonary artery size and reduced pulmonary vein flow have been described in fetal lung hypoplasia [27, 28].

Transitional and Postnatal Pulmonary Circulation

At birth the pulmonary artery pressure is close to the systemic pressure [29]. Within the first hours and days of life, pulmonary artery pressure decreases rapidly due to a combination of ductal closure, vessel wall remodeling, functional maturation of the endothelial cell, differentiation of smooth muscle cell, recruitment of lung vessels, and release of vasoactive mediators [29–34]. If successful transition occurs, the pulmonary artery mean pressure decreases to 10–20 mmHg and is similar to adult levels in the first 3 weeks of life [35]. The pulmonary arteriolar lumen increases in size, the endothelium flattens, and there is a decrease in the overlap of the smooth muscle cells. Peripheral extension of the smooth muscles occurs with muscularization of the intra-acinar arteries. An increase in number of both the arteries, as well as the alveoli, takes place. The alveolar arterial ratios decrease from 20:1 in the newborn to 10:1 by 4–5 years of age. In young children, total pulmonary vascular resistance index is similar to adults [36]. Yet despite this physiological adaptation, the ultrastructural appearance of smooth muscle cells does not closely resemble that of the adult until about 2 years of age [35, 37]. This may account for the lability of the neonatal pulmonary vasculature. The normal development of the pulmonary vascular bed is altered in neonates with a large left to right shunt and pulmonary hypertension. Children born with most forms of congenital heart disease (from VSD to aortic stenosis) have fewer pulmonary vessels than normal [18] (Fig. 121.3). If the defect remains uncorrected, further loss of vessels occurs with the development of obliterative pulmonary vascular obstructive disease [31]. There is, however, great variability in this rate of progression [38].

Pathophysiology

The currently accepted paradigm for the development of pulmonary vascular disease associated with congenital heart disease is that increased pulmonary blood flow and/or pressure conspire to trigger unfavorable vascular remodeling. Endothelial cell dysfunction, abnormal shear stress, circumferential wall stretch, and an imbalance in vasoactive mediators, involving the prostacyclin, thromboxane, endothelin, NO–cGMP, TGF β-1, VEGF, and FGF-2 pathways, promote vasoconstriction, inflammation, thrombosis, cell proliferation, impaired apoptosis, and fibrosis [39–52].

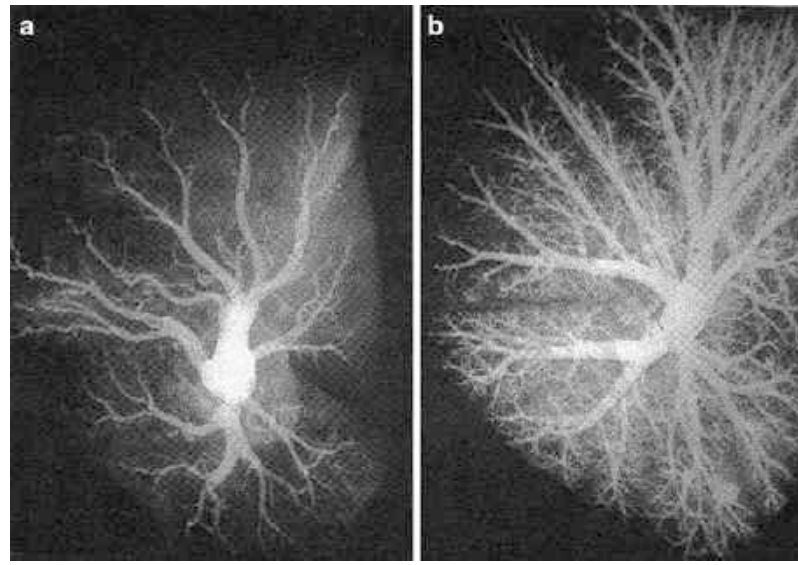

Fig. 121.3 Postmortem barium injection into the pulmonary vascular bed of a patient with a VSD (**a**) and without CHD (**b**). **a** demonstrates a marked reduction in small pulmonary vessels, loss of peripheral arborization, and reduced background haze compared with **b**

The Histology of Pulmonary Vascular Disease

Donald Heath and Jesse Edwards published the first systematic and now seminal description of pulmonary vascular remodeling due to CHD in 1958 [53]. They divided the histological progression from Grade 1–6 in increasing severity and presumed decreased likelihood of reversibility. Heath–Edwards (H–E) *Grade 1* change consists of medial hypertrophy, extension of smooth muscle into normally nonmuscular arteries, adventitial thickening, and fibrosis. *Grade 2* includes increased medial hypertrophy and cellular intimal proliferation in arteries <300 μm diameter. *Grade 3* changes include extension of cellular intimal proliferation into 300–500 μm diameter arteries, and intimal fibrosis in sub-300 μm vessels, resulting in widespread occlusion. In late stage 3, generalized dilation lesions are seen. The arteries in *Grade 4* show thinning of the media, generalized dilation, and plexiform lesions (Fig. 121.1). In *Grade 5*, medial fibrosis also is found. The rarely seen *Grade 6* indicates all of the changes from 1 to 5 plus necrotizing arteritis.

Rabinovitch, Haworth, and Reid developed a method of assessing the structure of the pulmonary vascular bed, which has provided additional information regarding the earliest changes associated with pulmonary arteriopathy. The morphometric approach quantifies the thickness of the arterial muscular coat, the degree of abnormal distal extension of smooth muscle, and the density of small pulmonary arteries relative to the number of alveoli [54–56]. Morphometric structural findings are graded as follows: *Grade A*, appearance of smooth muscle more peripherally than normal (into normally nonmuscular arteries) with or without modest medial hypertrophy (medial thickness less than or equal to 1.5 x normal); *Grade B*, distal extension of muscle plus medial thickness 1.5–2.0 x normal (mild), or greater than 2 x normal (severe); and *Grade C*, Grade B plus a decreased number of peripheral arteries relative to alveoli. C "mild" indicates a less than 50 % reduction in peripheral arteries, and "severe" denotes a reduction greater than 50 %. Morphometric analysis has contributed importantly to our understanding of pulmonary vascular remodeling by establishing that abnormal extension of smooth muscle and a reduction of small artery density are a hallmark of PVHD. Also, by quantifying early changes caused by increased flow and pressure (distal extension and mild hypertrophy), this analysis has enhanced our understanding of the evolution of pathological remodeling and the relationship to postoperative outcome. However, lung biopsy is infrequently used in the assessment of PHVD associated with CHD and reserved for

special cases. Nevertheless, the morphometric approach has emphasized that young age and preservation of small pulmonary arteries are the best indicators of good pulmonary hemodynamics postoperatively.

Development and Reversibility of Pulmonary Vascular Disease

Four variables are important in development of PVHD and whether or not PVHD will regress or progress after repair of a congenital cardiac shunt lesion [57].

1. The age of the patient at repair
2. The type of cardiac lesion
3. The PVRI at operation
4. Individual genetic, epigenetic, and environmental factors and comorbidities

Four clinical scenarios have been suggested in the paradigm of the development of pulmonary vascular disease.

1. An increased PA pressure (without an increase in flow) is a potent stimulator of vasoconstriction and medial hypertrophy, but irreversible pathological remodeling occurs slowly over years.
2. Increased PBF (without an increase in pressure) usually only causes significant vascular remodeling over many years in a minority of people.
3. Increased pressure and flow together are potent stimulators of vasoconstriction and may have pernicious effects on the pulmonary vasculature and more likely to promote high-grade lesions, than either alone.
4. Genetic, environmental, and concomitant comorbidities conspire with pressure and flow and influence the propensity to develop PHVD.

Early in the disease, in children under about 2 years of age, the abnormal pulmonary vascular remodeling is generally reversible if the congenital heart defect is repaired [58]. However, not all lesions have the same propensity to cause pulmonary vascular disease. For instance, pulmonary vascular disease may be advanced at birth and persist despite neonatal repair in patients with transposition of the great arteries emphasizing the importance of prenatal conditions (e.g., atrial septal or ductal restriction in utero) and developmental pulmonary vascular influences [27, 59–62].

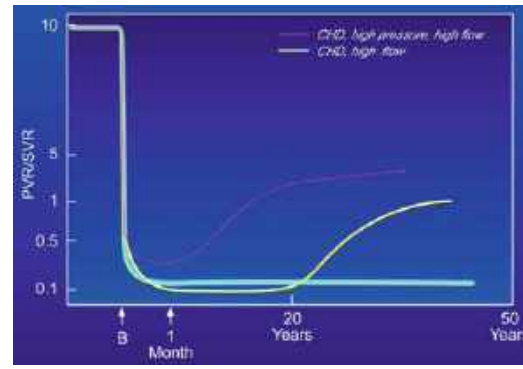

Fig. 121.4 Time course of change in the ratio of pulmonary to systemic vascular resistance with (**a**) normal pulmonary circulation; (**b**) high-pressure, high-flow congenital cardiac structural lesion (e.g., ventricular septal defect); and (**c**) high-flow congenital cardiac lesion (e.g., atrial septal defect) (Permission pending Kulik et al. Prog in Pediatr Cardiol 2009)

It is suggested that lesions with both a high flow and high pressure develop pulmonary vascular changes sooner and with more certainty than those with increased flow alone (Fig. 121.4). Yet clinical observations suggest that even with high flow and pressure lesions, there is variability in propensity to develop pulmonary vascular disease. Compare, for example, patients with transposition of the great arteries and a VSD or truncus arteriosus who develop severe pulmonary vascular disease during the first year of life (and inevitably if unrepaired) [38, 60, 63–65] with patients with an isolated large VSD or PDA, the majority of whom may develop pulmonary vascular disease over time but in whom it is unusual to do so before 2 years of age.

There is also a subset of patients with a small shunt from left to right who, nevertheless, develop pulmonary vascular disease of such severity that it is out of keeping with the anatomical size of the defect. There remains ongoing speculation as to whether those patients with small ASDs and pulmonary hypertension have an additional predisposition, which coupled with a small shunt promotes the development of

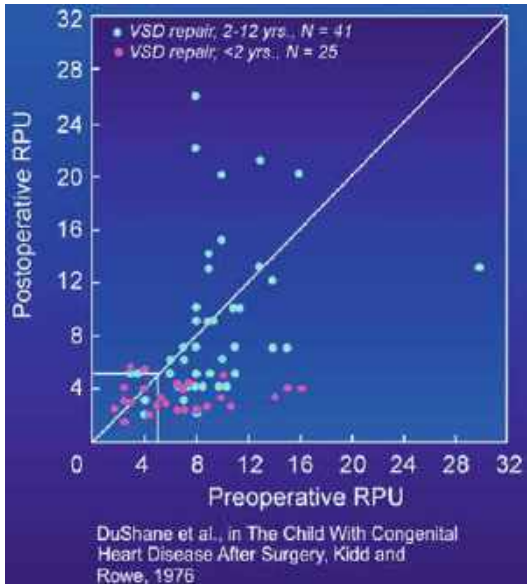

Fig. 121.5 Preoperative pulmonary vascular resistance (*RPU*), in patients with ventricular septal defect, tends to be higher in older patients and is less likely to fall after surgical repair (Diagram modified after DuShane JW, Krongrad E, Ritter DG et al (1976) The fate of raised pulmonary vascular resistance after surgery in ventricular septal defect. In: Langford Kidd BS, Rowe RD (eds) The child with congenital heart disease after surgery. Futura, Mt Kisco, N.Y., pp. 299–312. Rowe, 1976)

pulmonary vascular disease or whether they suffer from IPAH with an irrelevant shunt.

Few patients less than 1–2 years old have a severely elevated pulmonary vascular resistance (pulmonary to systemic vascular resistance (Rp:Rs) ratio of >0.75). On the other hand, older patients with severely elevated pulmonary vascular resistance index (PVRI) are at risk for sustained pulmonary hypertension, or a progressive increase in PVRI after repair [66] (Fig. 121.5). The exact level of PVRI that precludes safe closure of a defect is controversial and varies with each lesion. In the first US Natural History Study, patients with an Rp:Rs of <0.2 uniformly did well [67]. Closure of a VSD in the first two years of life, even when PVRI is markedly elevated, usually results in normal or near-normal pulmonary vascular resistance at follow-up [58, 68]. While an occasional older child or adult with substantially elevated PVRI has a marked fall after repair, most patients beyond the first few years of life with increased PVRI preoperatively have the same or increased PVRI postoperatively [66, 69–76]. Even if PVRI is normal at rest after closure of a high resistance VSD, it is well documented that abnormal responses to exercise and hypoxia persist and the pulmonary vascular resistance not only fails to decrease with exercise-induced flow but increases [77, 78]. However, it is worth noting that many of these studies predate improvements in preoperative treatments, cardiac surgical techniques, and postoperative care, and recent series may have improved results [79]. An elevated pulmonary vascular resistance of >7 WU × m^2 and age over 5 years were important risk factors for death on long-term follow-up over 30 years [76]. It is prudent to offer repair of a VSD or PDA in the first 2 years of life.

The risk of developing PHVD with an ASD is low especially in patients younger than 20 years old [80–82]. Asymptomatic ASDs are usually closed between 3 and 5 years. However, there are reports of infants with ASDs, often syndromic, who have increased PVRI and may not survive postoperatively [83, 84]. In a contemporary series of ASDs in children, only 2 % of 355 patients developed pulmonary hypertension. Following ASD closure, pulmonary artery pressures normalized by 16 weeks postoperatively in all patients [85]. Estimates of PVD in adults with ASD vary between 6 % and 15 % [81, 82, 86].

For patients with high, but not systemic-level pulmonary vascular resistance, we lack a sufficiently sensitive and specific method for determining who will respond favorably to operation. Wood, 50 years ago [4], suggested that surgical repair is indicated for those whose PVRI does not exceed 10 WU × m^2 and whose pulmonary to systemic flow ratio is at least 2:1. A contemporary approach to determining operative suitability is to consider the reactivity of the pulmonary circulation to vasodilators ([87] #2194, [88]). Some patients with Rp:Rs between 0.2 and 0.5 may have progression of pulmonary vascular disease on follow-up if they are older than 2 years at repair [67]. General guidelines suggest that if pulmonary vascular resistance can be decreased to 6–8

WU × m^2 and an Rp:Rs ratio of <0.3, a good outcome after repair of VSD can be expected. Thus, with rare exceptions, end-stage pulmonary vascular disease is preventable by early intervention to repair congenital heart defects in the first 2 years of life.

Genetic Differences

A genetic link between congenital heart disease and the propensity to develop PHVD is suspected from associations with trisomy 21 and the occurrence of PHVD in children with syndromic and unusual genetic defects. However, these children also have multifactorial problems that may contribute to PHVD [2, 12]. The BMPR2 mutation has been described in 6 % of a cohort of children with CHD [89].

A permissive genetic trait may account for the variability in expression of different degrees of pulmonary hypertension to similar stimuli. Du et al. reported a link between familial and acquired pulmonary hypertension [90], and molecular genetic contributions to abnormal septation, PDA, and ASD continue to be elucidated [91]. It is unknown currently how pulmonary vascular disease secondary to congenital heart is influenced by specific genetic factors.

Environmental Factors

High altitude has profound and fascinating effects on normal neonatal pulmonary vascular transition that is related not only to altitude but ancestry. Thus, ethnic groups with recent migration to high altitude have lower oxygen saturations and higher pulmonary artery pressures than those with a long ancestry of high altitude living such as native Tibetans or Andean residents. In addition the incidence of congenital heart disease increases at higher altitude, the ductus arteriosus is larger, and closure delayed, with a higher pulmonary to systemic blood flow ratio for any given pulmonary vascular resistance. Thus, operability assessment and management decisions are different at high altitude [92–96]. There is a suggestion that hypobaric hypoxia may protect against the development of PHVD associated with CHD.

Comorbidities

It is unknown how other factors common in children with limited access to medical care might exacerbate the pulmonary vascular disease from congenital heart disease. For instance, in a cohort of children with CHD evaluated in Africa, 53 % were anemic, 47 % underweight, and 33 % marasmic compared with a control group without congenital heart disease of whom none were marasmic and 14 % underweight [14]. Tuberculosis is more than twice as common in patients with congenital heart disease especially lesions with an increased pulmonary blood flow, and if treatment is available, the major morbidity is delay of cardiac surgery [97]. Tuberculosis may also mask the signs of congenital heart disease resulting in delayed referral for cardiac repair [98].

Human immunodeficiency virus infection is endemic in sub-Saharan Africa. Congenital heart disease affects 5 % of children in Uganda with human immunodeficiency virus compared with 2–3 % in developed countries [99]. Pulmonary hypertension indistinguishable from IPAH complicates the course of patients infected with human immunodeficiency virus. In addition infected children often have cor pulmonale [100]. It is unknown how concomitant human immunodeficiency viral infection or other infections such as malaria, which are more common in children with congenital heart disease, will promote or potentiate pulmonary vascular disease due to congenital heart disease [101]. Maternal health may also play a role in the susceptibility to congenital heart disease. It is estimated that each year there are more than 100,000 new cases of congenital rubella syndrome [102]. Up to 75 % of those affected will have congenital cardiovascular malformations (60 % will have a PDA). Maternal rubella infection can be eradicated almost by effective vaccination programs [102].

Natural History

Traditionally, it was believed that PVHD due to CHD has a more stable clinical course with better survival than patients with other etiologies of pulmonary hypertension. McLaughlin et al. reported 3-year mortality in patients with PAH CHD at 77 % as compared to 35 % with iPAH, 37 % with PAH–CTD, and 21 % in PAH–HIV [103]. However, on comparison with a healthy population, patients with Eisenmenger syndrome have limitation of functional capacity and reduced life span [104]. Oya et al. reported a survival of 98 % at 1 year, 77 % at 5 years, and 58 % at 10 years from diagnosis [105]. The prognosis also changes with complexity of congenital heart disease. Five-year survival in a patient with VSD and Eisenmenger is reported at 91 % compared to 67 % in patients with truncus and 34 % in single ventricle physiology [106]. Data from the European heart survey revealed an eight-fold increase in functional impairment (defined as WHO FC II or less) in patients with PVHD associated with CHD. It is six-fold higher in patients with unrepaired defects [107]. Full-time employment is variable with 53–57 % of the patients holding full-time jobs. Only 30 % of the patients with complex congenital heart disease held full-time jobs as compared to 80 % of the patients with VSD. Clinical deterioration occurs earlier in patients with complex congenital heart disease (18.6 ± 11.3 years) as compared to simple defects (26.7 ± 12.2 years) [106, 108]. With the advent of advanced therapy in patients with PAH, a similar 1- and 5-year outcome was demonstrated in patients with IPAH and PAH associated with CHD [109]. However, the use of targeted PH drug therapies in patients with Eisenmenger syndrome suggests improvement in functional capacity, baseline and exercise saturations, and even mortality [110–113].

Clinical Features of PVHD and CHD

The clinical assessment of the child with PHVD and CHD is aimed at differentiating those with reversible pulmonary vascular disease and, therefore, operable from those with irreversible or fixed disease. In cases that are not straightforward, it is important to put together all clinical information without undue reliance on one parameter. The age of the patients is very important as discussed above and, in general, all children under 2 years of age will have reversible disease and benefit from surgical repair. Some defects such as transposition of the great arteries, truncus arteriosus, aortopulmonary window, or aortic origin of a pulmonary artery often present with pulmonary vascular disease much earlier in the first 2 years of life than patients with simple shunts. Patients with simple post-tricuspid shunts usually present at 4–6 weeks of life with symptoms of increased pulmonary blood flow such as failure to thrive, feeding and breathing difficulty, and repeated respiratory tract infections. On clinical examination, these babies have cardiomegaly with left ventricle type of apex, loud pulmonary component of the second heart sound, presence of a third heart sound, and a flow murmur across the mitral and/or pulmonary valve. Clinical wisdom suggests that the mid-diastolic flow rumble across the mitral valve indicates a Qp/Qs of at least 2:1. As PHVD progresses, murmurs associated with the shunt become softer and shorter and murmurs associated with right ventricular and pulmonary artery dilation such as tricuspid and pulmonary regurgitation become more prominent. If the shunt is at pre-tricuspid level (ASD, partial anomalous pulmonary venous drainage without sequestration, systemic to right atrial shunt), it is difficult to differentiate clinically between dynamic and fixed pulmonary hypertension. A diastolic flow murmur across the tricuspid valve would indicate increased Qp:Qs and a murmur of tricuspid regurgitation would suggest the onset of PVHD. If the defect remains open, there is a variable and unpredictable period during which pulmonary blood flow decreases and paradoxically the child is less symptomatic and starts to gain weight.

With the onset of severe pulmonary vascular disease or Eisenmenger syndrome, there is reversal of shunt across the septal defect and progressive cyanosis, dyspnea on exertion, and

clubbing. The presence of cyanosis and clubbing of the toes but not the arms is pathognomonic of a PDA with reversal of shunt. Hemoptysis may occur secondary to rupture of bronchial collaterals, pulmonary thromboembolism, or in situ thrombosis in dilated pulmonary arteries [4, 11, 108, 114]. Long-standing cyanosis leads to a multiorgan syndrome including hematological manifestations of secondary erythrocytosis, thrombocytopenia, prolonged bleeding times, deficient clotting factors, and abnormal fibrinolysis. This compensatory erythrocytosis when severe can lead to hyperviscosity syndrome, the manifestation of which includes blurring of vision, headache dizziness, myalgia, and paresthesia. Other cerebral complications include cerebral abscess and stroke secondary to paradoxical embolism [108]. Progressive atrial and ventricular dilation lead to atrial and ventricular arrhythmias often associated with syncope or presyncope [108]. Sudden cardiac death although less common than in patients with IPAH has been reported in as many as 30 % of the patients. Other systemic manifestations of chronic cyanosis include hyperuricemia, gout, gallstones, and renal and hepatic dysfunction.

Electrocardiogram

Although nonspecific, ECG can provide useful clues regarding the hemodynamic status of the patient with CHD and PVHD. The presence of left atrial enlargement, left ventricular or biventricular enlargement (Katz-Wachtel phenomenon), and q waves in lateral precordial leads would suggest operability in post-tricuspid shunts, whereas presence of right atrial or right ventricular forces with absence of q waves in lateral leads would suggest inoperability (Fig. 121.6).

Chest X-Ray

A chest X-ray is easily available and provides much information on the ventricular volume loading and the pulmonary vasculature (Fig. 121.7) (Table 121.3).

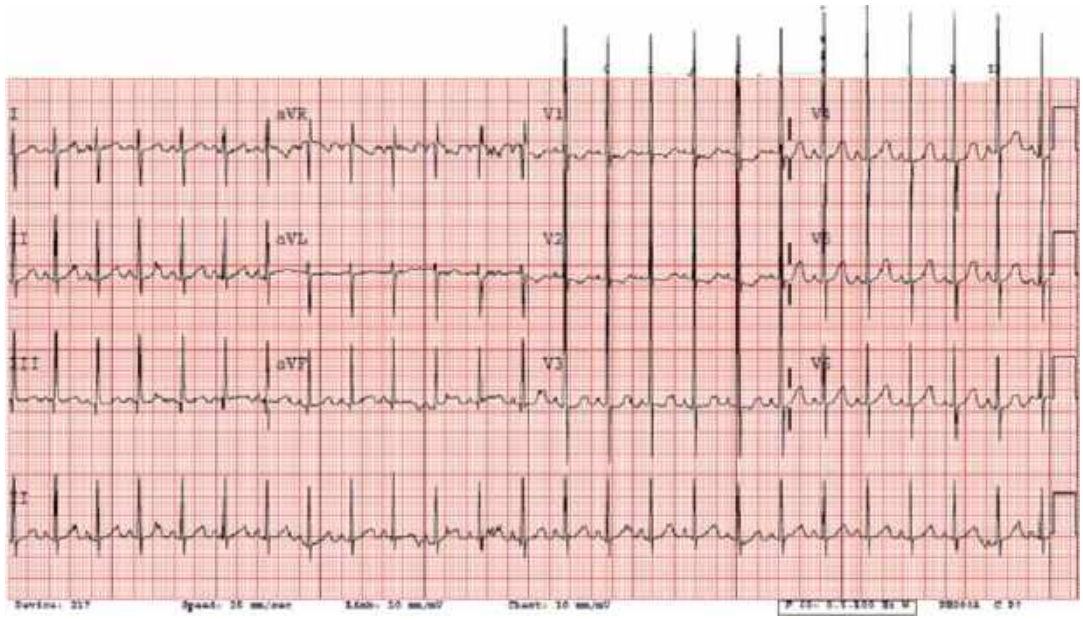

Fig. 121.6 ECG of the patient with VSD and pulmonary vascular disease, showing *right axis* deviation and right ventricular hypertrophy rather than LV predominance if the left to right shunt were large

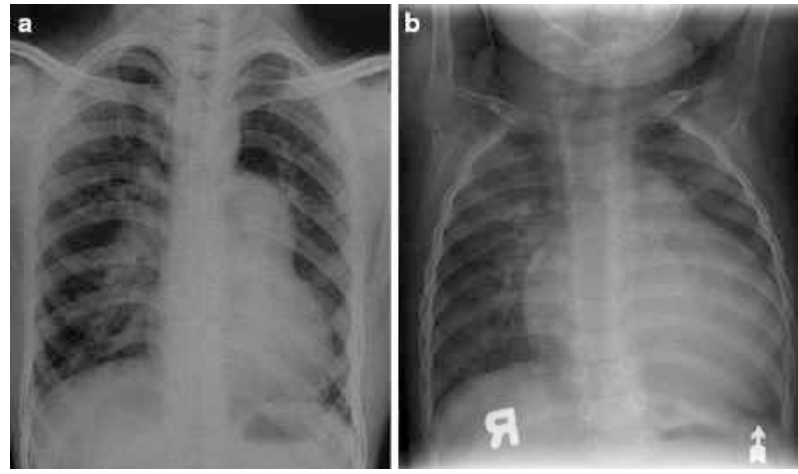

Fig. 121.7 (**a**) X-ray chest PA view of VSD and pulmonary vascular disease. There is no cardiomegaly, but aneurysmally dilated central pulmonary arteries and peripheral pruning. (**b**) X-ray chest of a patient with a large VSD with increased flow; note the cardiomegaly and pulmonary plethora

Table 121.3 Use of the chest X-ray to help in determining operability

	Features suggestive of operability	Features suggestive of inoperability
Cardiac size	Enlarged, predominant left ventricular enlargement in post-tricuspid shunt	No cardiomegaly, apex is right ventricular type
Atrial enlargement	Enlarged left atrium	Enlarged right atrium
Lung vascularity	Increased vascularity in the peripheral lung fields	Prominent main and hilar pulmonary arteries with peripheral pruning and oligemic peripheral lung fields

Echocardiography

Echocardiography may provide a detailed and extremely useful anatomic and hemodynamic insight into congenital heart disease and PHVD. However, this takes time, attention to detail, and a special interest. A detailed echocardiogram will permit a more focused approach to cardiac catheterization and should always be reviewed beforehand.

Echocardiography provides information pertaining to:

- Anatomic details of the lesion
- Assessment of shunt direction
- Assessment of pulmonary hemodynamics including pulmonary artery pressures, pulmonary vascular resistance, and pulmonary capacitance index
- Vasodilator testing
- Right ventricular and pulmonary artery coupling

Accurate determination of the anatomic details will help not only for the surgical management of the patient but also for hemodynamic assessment. Certain unusual causes of cyanosis, for instance, persistent left-sided SVC to the left atrium (Fig. 121.8), unfavorable streaming patterns, and pulmonary arteriovenous malformations (bubble study), are evaluated well by echocardiography. A thorough echocardiogram is useful and an essential prerequisite for planning further investigations and the approach to be adopted at cardiac catheterization. Echocardiography provides useful information about associated lesions, which may contribute to pulmonary hypertension, for example, obstruction to pulmonary venous drainage, mitral valve stenosis, and obstruction to the left ventricular outflow tract.

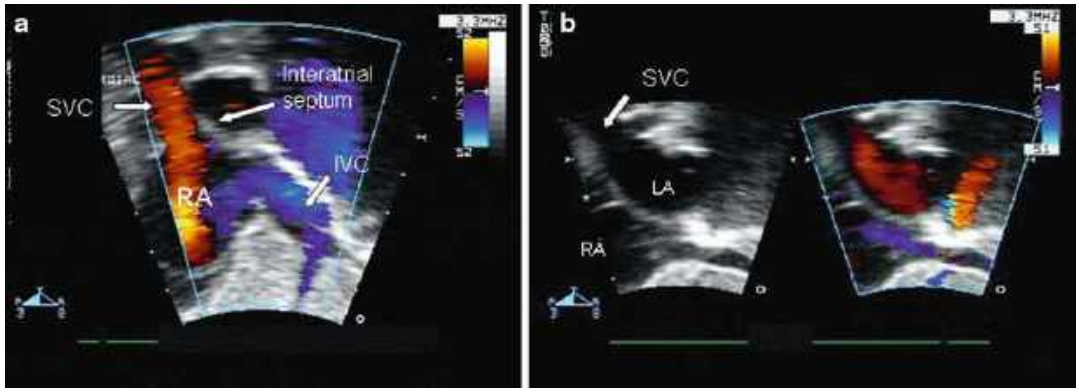

Fig. 121.8 Cyanosis does not always indicate pulmonary vascular disease. Echocardiography is useful to evaluate for unusual causes of cyanosis such as anomalous systemic venous drainage. Subcostal sagittal view, (**a**) showing normally draining SVC and IVC into the right atrium, in (**b**) the IVC drains into the right atrium but the SVC drains into the left atrium

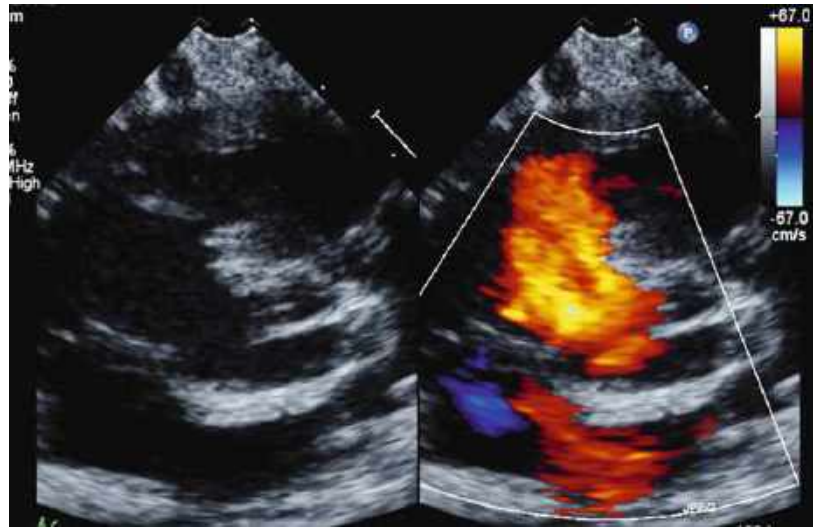

Fig. 121.9 Parasternal short axis view, showing a large perimembranous ventricular septal defect with a pure left to right shunt

Assessment of Shunt Direction

Direction of shunt flow can often give a fair estimate of the pulmonary hemodynamics. A pure left to right shunt across a large defect would indicate that the pulmonary vascular resistance is lower than the systemic vascular resistance (Fig. 121.9). However, the normal pattern of flow across the defect should be taken into consideration before reaching a conclusion. A large ASD would normally shunt from the left to right except during isovolumic contraction when the cephalic motion of the tricuspid valve with a larger surface area may transiently elevate the right atrial pressure. Similarly a large VSD usually shunts from left to right except during the phase of isovolumic relaxation. During this phase, the left ventricular pressure decreases more rapidly than the right ventricular pressure and leads to a transient right to left shunt. The presence of reversed or bidirectional shunt across an ASD, VSD, or PDA is ominous and may suggest the need for acute vasoreactivity testing (Fig. 121.10).

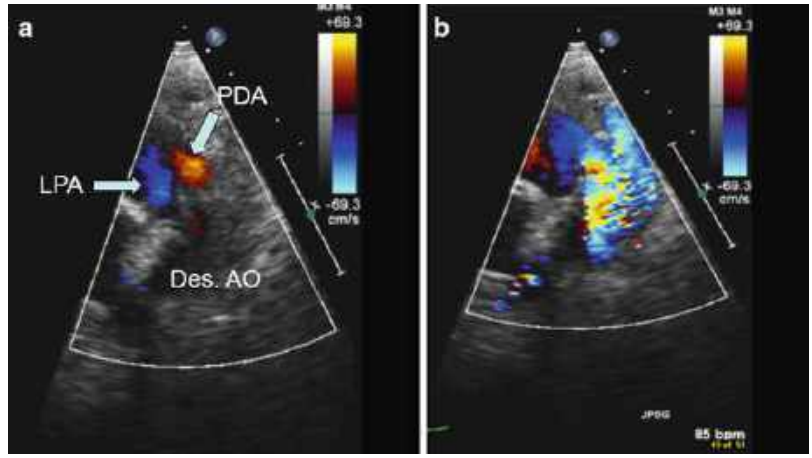

Fig. 121.10 Echocardiogram demonstrating bidirectional flow across a PDA suggesting the presence of an increased PVRI. With increase in pulmonary vascular resistance, there is bidirectional flow across the systemic to pulmonary shunt. (**a**) demonstrates left to right shunt across the patent ductus arteriosus (*PDA*) in systole, which changes to right to left in diastole (**b**)

Calculation of Ratio of Pulmonary Blood Flow (Qp) to Systemic Blood Flow (Qs)

Nonspecific information may be obtained from the left ventricular and left atrial size in post-tricuspid shunts. Enlargement suggests ongoing significant left to right shunting and low PVRI. However, one needs to rule out other causes of increased left heart volumes, anemia being the most common. The Qp:Qs may be derived using the continuity equation. Blood flow may be calculated by multiplying the velocity time integral (VTI) and the respective outflow tract area. Qp/Qs can be then represented as RVOT area X RVOT VTI/LVOT area X LVOT VTI. This equation however cannot be used for calculation in conditions where the shunt is distal to the ventricle (e.g., PDA or aortopulmonary window).

Estimation of the Pulmonary Artery Pressures: The pulmonary artery pressures may be accurately estimated by echocardiography providing there is sufficient tricuspid regurgitation (TR) or pulmonary insufficiency (PI) and a good angle of interrogation can be obtained. The pressure gradient between the right ventricle and the right atrium can be estimated from the peak velocity of the tricuspid regurgitant jet, according to the formula RVSP $= 4\ V^2$ + right atrial pressure. In absence of a right ventricular outflow tract obstruction or peripheral pulmonary artery stenosis, the right ventricular systolic pressure is equal to the pulmonary arterial systolic pressures [115]. The presence of a left ventricle to right atrial shunt may be confused with TR and lead to an erroneous diagnosis of increased right ventricular pressure. Right atrial pressure may be estimated from a number of indirect methods. IVC size and collapsibility hepatic venous Doppler, right atrial size, and E/E' ratio at the tricuspid valve can be used for estimating the RA pressures. However, none of these have been validated in pediatric population. Pulmonary arterial diastolic and mean pressures can be derived from the pulmonary regurgitation jet [116] (Fig. 121.11). Addition of the right atrial pressures to the end-diastolic pulmonary regurgitation (EDPR) gradient and peak pulmonary regurgitation jet would estimate the diastolic and mean pulmonary arterial pressures, respectively [117]. Continuous wave Doppler can be used to interrogate the pressure decrease across a VSD or PDA and estimate the pulmonary arterial pressures [118, 119]. This method is limited by the size of the shunt and interventricular dependence. Measurement of right ventricular systolic pressure from the VSD Doppler tracing has been validated for moderate-sized defects but not for very small or large defects. The septal position during systole and eccentricity index in parasternal short axis view can be used to

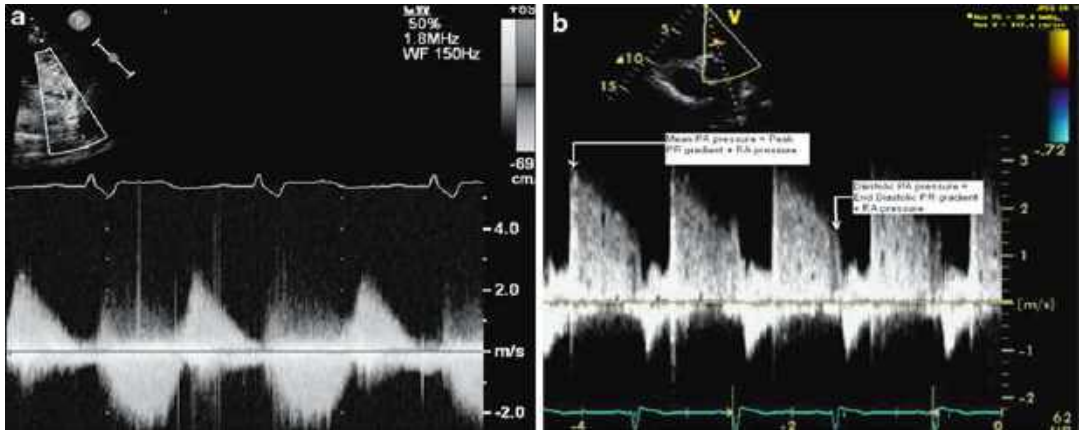

Fig. 121.11 Pulsed wave Doppler sampling the pulmonary regurgitation (*PR*) velocity. The mean pulmonary artery pressure (m PAP) may be estimated by adding the right atrial pressure to the early diastolic gradient. Similarly the diastolic pressures can be estimated by adding the right atrial pressure to the end-diastolic PR gradient (EDPR). Note that the end-diastolic pressure reaches the baseline in (121.11a), which would indicate low pulmonary vascular resistance. These estimates only hold true if the PR is mild to moderate

estimate the pulmonary arterial pressure. Normally the septum would be round and moving with the left ventricle. A flat septum would indicate that the right ventricular pressure is almost equal to systemic pressures, and bowing into the left ventricle would indicate suprasystemic right ventricular pressures. Pulmonary arterial acceleration time (PAAT), PA deceleration time (PAD), and the shape of the right ventricular outflow tract Doppler tracing have all been used to measure pulmonary artery pressure. The PAAT shortens with increase in pulmonary artery pressures and values $\leq$120 ms have correlated with elevated PAP. Three characteristic Doppler flow profiles have been described, the normal smooth round shape, the intermediate, and the triangular shape with progressive increase in PA pressures and decrease in capacitance [120] (Fig. 121.12). Tissue Doppler imaging has also been used to evaluate the pulmonary arterial pressures. In a recent study, it was noted that with progressive increase in the PA pressures, there is progressive increase in the time interval between the isovolumetric contraction and mitral systolic signal, with reciprocal changes seen in the time interval between the isovolumetric contraction and tricuspid systolic signal [121].

Vasodilator Testing

Although not ideal, echocardiography can be used for vasodilator testing prior to going to the cardiac catheterization laboratory. Administration of high-flow oxygen, inhaled nitric oxide, and sildenafil may be used. Quantification of pulmonary venous Doppler tracings before and after administration of high-flow oxygen has been useful in predicting operability in children with TGA/VSD or PDA [122]. In a case control simultaneous cardiac catheterization and echo study in patients with congenital heart disease, significant correlation was demonstrated in ratio of heart rate-corrected PAAT and RV ejection time before and after vasodilator testing [123].

Cardiac Catheterization: Children whose evaluation is uncertain by noninvasive investigation should undergo cardiac catheterization with a vasodilator challenge to assess operability. However, as with all investigations including echocardiography and cardiac MRI, if not performed with care and an understanding of the limitations, cardiac catheterization may provide misleading information without attention to the details, which follow.

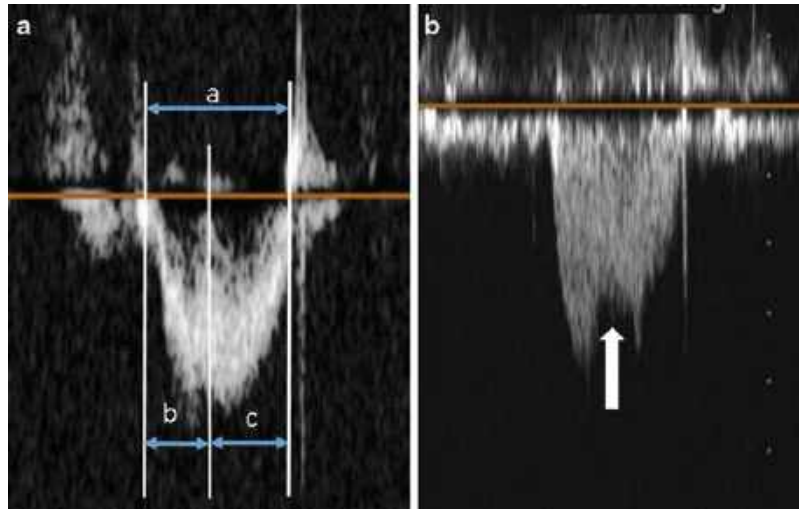

Fig. 121.12 Pulsed wave Doppler in the right ventricular outflow tract, right ventricular ejection time (*RVET*) is the time interval between the beginning and end of the ejection phase (**a**), the pulmonary artery acceleration time (*PAAT*) is the time interval between initiation of ejection and the peak velocity (**b**), and the pulmonary artery deceleration time (*PAD*) is the time interval between the peak velocity and the end of ejection to the end of systole (**c**). Presence of a notch (*white arrow*) during mid- or late systole would indicate elevated pulmonary vascular resistance

Anesthesia and Sedation

Arterial pH affects the PVRI. Acidosis whether due to hypercarbia or metabolic will increase the measured PVRI. Alveolar hypoxia will cause reflex vasoconstriction and increase PVRI. An arterial blood gas should be measured with each condition tested. The ratio of systemic to pulmonary vascular resistance will affect the Qp:Qs measured at cardiac catheterization and many anesthetic drugs decrease SVRI. Thus, all cardiac catheterizations are best performed with an unobstructed airway, adequate ventilation, and oxygenation. Discussion with anesthetic colleagues to forego the use of drugs, which decrease the SVRI or PVRI indiscriminately to avoid confounding the baseline hemodynamic measurements, is prudent.

Oxygen Consumption: Oxygen consumption (VO_2) should be measured directly. The assumption of VO_2 leads to errors in the calculation of flow by the Fick equation especially if tables are used that do not reflect the age of the patient or the conditions of cardiac catheterization (general anesthesia versus sedation, spontaneous versus mechanical ventilation [124–126]. If VO_2 is assumed, then tables which most accurately reflect the subject's age and testing conditions should be used. It is prudent also to calculate the vascular resistance using the highest and lowest assumed VO_2 as suggested by Lopes and present the data as a range [127]. Alternatively use of the ratio of PVRI:SVRI for decision-making removes the uncertainty of the VO_2 measurement. It is also important to remember that VO_2 cannot be measured accurately with an FiO_2 of 1.0 because most current techniques measure the VO_2 by comparing the difference in O_2 concentration between the inspired and expired gas. If the FiO_2 is 1.0, the difference becomes too small to measure with accuracy. Indeed, one should consider that VO_2 in 100 % oxygen might decrease by 20–30 % (if calculated from thermodilution in children without shunts) rather than assume the same VO_2 at baseline and in an FiO_2 of 1 [128]. It is probably more accurate to test with a FiO_2 between 0.4 and 0.7, which provides both the vasodilator effect of oxygen, as well as permitting accurate measurement of VO_2.

Blood Sampling and Pressure Measurements: The need for multiple pressure measurements and oximetry sampling sites may produce data that is remote both in time and the physiologic condition of the patient at baseline. One solution is to use multiple lines, for instance, the side arm of the sheath in the neck can be used to sample SVC saturation and pressure and then the pulmonary artery catheter does not need to be moved with each condition. An additional venous line to cross the atrial septum and an arterial line reduce further time delays or changes in hemodynamics due to multiple catheter manipulations. If there are multiple sources of pulmonary blood, obtaining a true pulmonary artery saturation may be impossible and pulmonary blood flow may be better assessed by MRI. The effect of streaming or obligate shunts may also confound interpretation of the data [129, 130]. Special approaches are required if there is unequal distribution of pulmonary blood flow and different pressures in each lung or lung segment as may occur after pulmonary artery banding with isolation of a lung or truncus arteriosus or pulmonary atresia with VSD and major aortopulmonary collaterals [131]. Quantification of flow by nuclear scan or MRI to each lung is then necessary.

Calculations of Flow and Resistance: By using the Fick equation, pulmonary blood flow (Qp), systemic blood flow (Qs), indexed pulmonary vascular resistance (PVRI), and indexed systemic vascular resistance (SVRI) may be calculated [132].

Prevention of Errors and Miscalculations in the Cardiac Catheterization Lab: Cardiac catheterization for evaluation of operability in congenital heart disease is prone to a number of errors. Measurement of VO_2 is detailed above. Obtaining an arterial blood gas sample prior to hemodynamic assessment will detect confounding factors such as hypoxia and acidosis, which independently affect the PVRI. Minimizing other sources of error includes avoiding undue delay in sampling from different chambers, avoiding diluted samples, carefully removing the air bubbles, and avoiding unnecessary delay of oximetric or blood gas analysis. In addition if cardiac catheterization is carried out with a $FiO_2 > 0.3$, then the dissolved oxygen in the sample must be included in the calculation to avoid underestimating the PVRI [132].

Vasoreactivity Testing

In patients with a PVRI of >6–8 WU m^2, it is current practice to attempt to differentiate the reversible component of the pulmonary vascular disease by administration of a vasodilator. An ideal drug to be used for vasodilator testing would have better pulmonary vasodilator effect than systemic, a short half-life, minimal side effects, be both easily and quickly administered, and would predict reliably the effect of surgical repair on long-term hemodynamics. General indicators of operability are baseline Rp/Rs < 0.33 [88] and PVRI < 6 WU × m^2 [79, 87]. A favorable acute vasoreactivity test would be a decrease in PVRI < 6 WU × m^2 or Rp/RS ratio < 0.3. A more stringent requirement would be a 20 % decrease in PVRI from baseline in addition to PVRI < 6 WU × m^2 or Rp/RS ratio < 0.3 with the acute vasoreactivity test. An algorithm to aid decision-making is presented in Fig. 121.13.

Pharmacological Agents Used for Vasodilator Testing: Currently the agents used are high concentrations of oxygen, inhaled nitric oxide, inhaled and intravenous prostacyclin and analogues, intravenous and orally administered sildenafil, intravenous adenosine, and recently inhaled milrinone and nitroglycerin. The role of 100 % oxygen as a pulmonary vasodilator, although frequently used in the decision-making about operability, is controversial. Initial studies performed at high altitude demonstrated a positive correlation between fall in pulmonary vascular resistance and postoperative outcomes [133, 134]. Studies at sea level have failed to reveal such a correlation [135]. Oxygen may increase the SVRI and increase left to right shunt and pulmonary blood flow and PVRI by this mechanism [136, 137]. However, once the defect is closed, changing SVRI will not affect the PVRI and may explain the unpredictability of decisions made based on the response to breathing 95–100 % oxygen [135]. Inhaled nitric oxide is an ideal agent

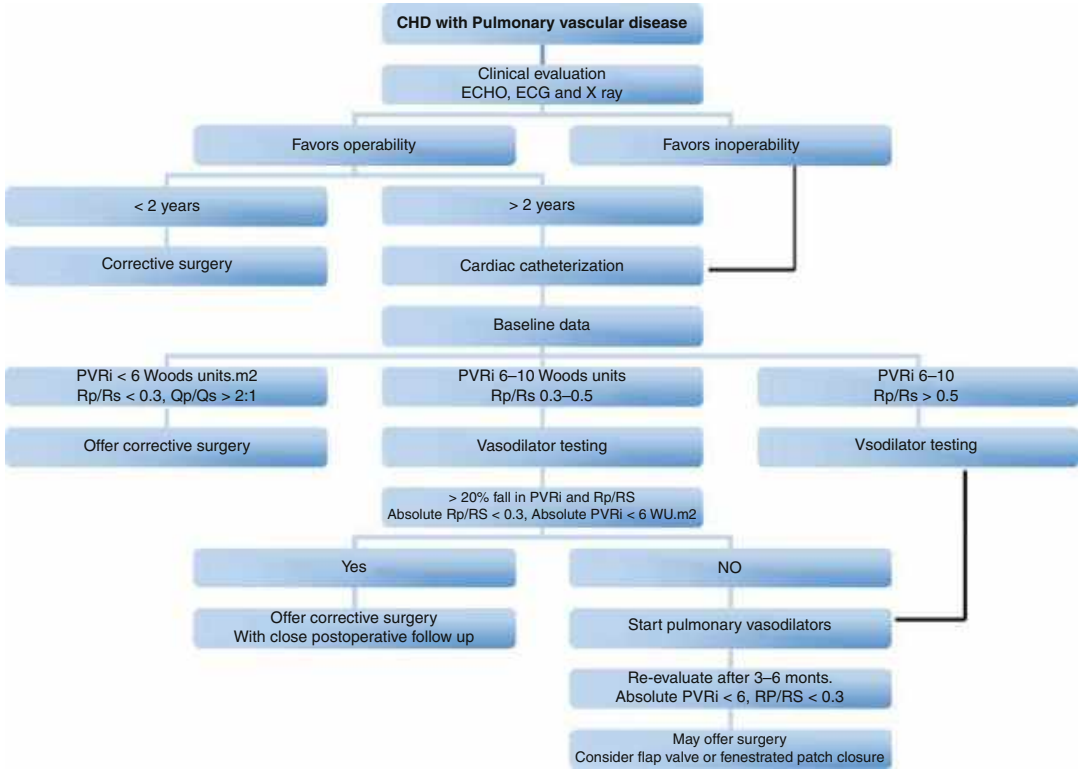

Fig. 121.13 Flow chart depicting an algorithm for evaluation and management of patients with PHVD and congenital heart disease

for vasodilator testing but is not always available or affordable. Inhaled NO selectively dilates the pulmonary vasculature, without significant systemic effects [88, 138–141].

Occlusion of Shunt: Temporary occlusion of a shunt in the cardiac catheter laboratory is the best means of demonstrating the short-term effect of shunt closure. Recent studies have demonstrated the usefulness of balloon occlusion of the PDA for hemodynamic assessment [142, 143]. The authors defined a favorable response to balloon occlusion as a decrease in pulmonary artery pressures of $\geq$25 % or decrease in diastolic pressures of $\geq$50 %. However, 2/16 responders continued to have elevated pulmonary artery pressures postoperatively, suggesting that interpretation of the results be done cautiously and individualized.

Pulmonary capacitance index (PCI) is calculated from the equation: pulmonary blood flow indexed to BSA/pulmonary artery pulse pressure and is useful in determining survival of adults with IPAH and in children with both IPAH and CHD [144–146]. However, there is no data as yet to support the use of PCI in decision-making around operability.

Magnetic Resonance Imaging (MRI)

MRI is a very useful tool to evaluate children with PVHD and CHD. Although pulmonary blood flow and oximetry may be determined by MRI, MRI cannot measure pressure [147, 148]. Pulmonary blood flow measured by MRI is accurate especially if there are multiple sources of pulmonary blood flow or indirect aortopulmonary collaterals. The combination of MRI and direct pulmonary artery pressure measurement may provide more information than either test alone.

Novel methods of determining operability may include blood sampling for circulating

endothelial progenitor cells [51, 52]. Although this technique has yet to be established in clinical practice.

Lung biopsy, as discussed above, may be appropriate in selected cases.

Pulmonary Hypertension Out of Proportion to the Congenital Heart Defect

Some children will have severe PHVD yet a relatively small defect anatomically. These cases have been described as "out of proportion pulmonary hypertension." Decision-making may be difficult in these cases as one weighs the pros and cons of closing the defect or treating them as patients with IPAH. The possibilities are that the defect was once much bigger and developed pulmonary vascular disease developed before the defect decreased in size. Alternatively the cardiac defect is irrelevant and the PVHD is due to coexistent idiopathic pulmonary hypertension. In pediatric practice, these children often have multifactorial disease and may have a syndrome with sleep disordered breathing, chronic aspiration, chronic lung disease and hypoxia, a history of prematurity, as well as a shunt lesion. An individualized approach to such patients is recommended as clearly the shunt is only one contributor to the PVHD.

However, there are patients with a small PDA, ASD, or VSD with advanced pulmonary vascular disease who will not benefit from closure; in fact right to left shunting across the defect may prevent syncope and contribute to prolonged survival [149]. The treatment of these patients will follow more closely the algorithms for idiopathic or isolated PAH.

Treatment of Patients with PHVD and CHD

Whenever possible patients with CHD with clear indications for surgical repair should be referred promptly. The management of patients with borderline hemodynamics or if there is uncertainty about the benefit of shunt closure is more problematic. The treatment of borderline patients with intravenous prostacyclin has been reported to be a means of improving the outcome of surgical closure of an ASD with high PVRI [150]. With the advent of oral pulmonary hypertension-specific drugs, the concept of treating patients with borderline hemodynamics with frequent reassessment is both appealing and widespread. Anecdotal experience is contradictory and definitive data is awaited to determine if this will prove to be a useful strategy.

Pulmonary Artery Banding

Pulmonary artery banding is a technique to protect the pulmonary vascular bed from excessive pressure and flow in patients who are at a high risk for primary repair or need time to mature before undergoing cavopulmonary anastomosis. However, interstage mortality is high for patients with biventricular correctable lesions [151, 152]. It has been described that pulmonary vascular disease, even plexiform lesions, may regress after banding [153, 154], but the use of pulmonary artery banding in patients with an increased PVRI has not found a routine place in therapy [155–157].

Fenestrated or Flap Valve Septal Defect Closure

A surgical technique described in principle in 1959 [158, 159] but which has seen a renewed interest recently is the unidirectional flap valve for ventricular or atrial septal defect closure. This technique, which permits intermittent right to left shunting and preserves left ventricular preload while the PVRI remains above systemic or if the right ventricle fails, appears to be useful especially if preoperative pulmonary vascular hemodynamics are borderline for shunt closure [160–164] (Fig. 121.14).

The palliative Senning or Mustard and more recently the palliative switch have provided long-lived freedom from cyanosis by improving

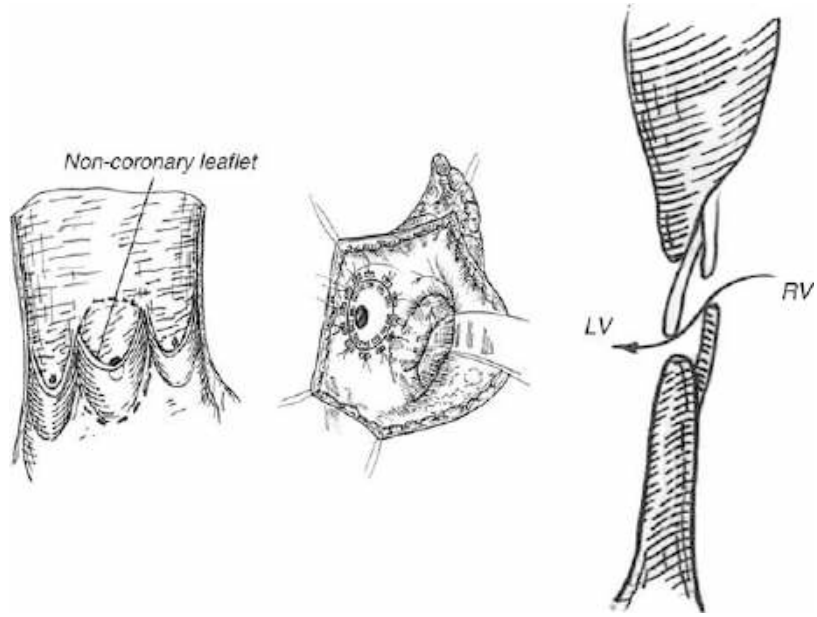

Fig. 121.14 Surgical approaches to a patient with increased pulmonary vascular resistance. Closure of the ventricular septal defect with a fenestrated patch or flap valve allows the right ventricle to decompress if the PVRI increases (Reproduced with permission from Zhang B et al. Ann Thorac Surg. 2007 Jun;83(6):2176–81)

streaming in children with transposition of the great arteries and ventricular septal defect with increased PVRI [165–167]. Recent reports suggest that that a palliative arterial switch with flap valve or fenestrated closure of the VSD may allow for later complete VSD closure [164, 168].

Medical Management of Eisenmenger Syndrome

Established Eisenmenger syndrome is a multiorgan disorder and requires a comprehensive approach to management including the timely and organized transition from pediatric to adult patient services. Until recently the management of Eisenmenger syndrome was supportive and consisted of general measures such as a prudent approach to exercise, remaining well hydrated in the presence of erythrocytosis, symptomatic use of oxygen, avoiding iron and folate deficiency, careful consideration of travel to high altitude, advice about contraception, and the dangers of pregnancy. Eisenmenger patients also require evaluation and management by experienced anesthesiologists when undergoing noncardiac procedures.

All of the PAH-targeted drug therapies have been used to treat patients with both Eisenmenger syndrome and patients with residual pulmonary vascular disease after repair. In general improvements in exercise capacity and tolerance and sometimes oxygen saturations have been demonstrated and perhaps survival [112, 169–171]. Children with Eisenmenger syndrome appear to have a less sustained response than adults [172].

Chronic Postoperative Pulmonary Vascular Disease

Chronic pulmonary vascular disease is an important cause of morbidity and mortality in children with congenital heart disease and accounts for 13 % of late sudden deaths in a cohort of children with CHD [173]. While many children with an Rp/Rs of around 0.5 respond well to shunt closure especially if performed early in life [174], it is often forgotten that even if pulmonary vascular resistance decreases to normal late postoperatively, the reactivity of the pulmonary vascular bed is abnormal and may not respond normally to

an increase in pulmonary blood flow with exercise [74, 77, 78]. Presumably this residual abnormality creates a susceptibility to environmental triggers of pulmonary hypertension they may encounter later in life. Children whose pulmonary hemodynamics does not normalize require close follow-up as pulmonary vascular disease may worsen after an asymptomatic period [67, 175–177].

The outcome for patients with repaired congenital heart disease who have progressive or severe residual pulmonary vascular disease is poor. Their survival is reduced compared with patients with idiopathic pulmonary arterial hypertension. Children with pulmonary vascular disease that continues to progress postoperatively have a similar physiology to patients with idiopathic pulmonary hypertension. However, postoperative patients have certain disadvantages due to the sequel of uncertain myocardial protection that is increasingly seen as diastolic heart disease. Tricuspid regurgitation and pulmonary regurgitation, although of little consequence in patients with a low pulmonary vascular resistance, become liabilities if the pulmonary vascular resistance is increased. Hislop and Haworth reported that children with postoperative pulmonary hypertension had a survival at 1 year of 88 % and at 3 years of 73 % [178]. In general, children with symptomatic and progressive pulmonary vascular disease after repair of congenital cardiac shunts appear to do worse than patients with Eisenmenger syndrome [12, 178]. However, many children with postoperative pulmonary hypertension have mild disease that remains static or slowly progressive and derive a great deal of benefit from shunt closure and are spared the sequel of chronic hypoxemia.

Drug Therapy in Chronic Postoperative Pulmonary Hypertension

Pulmonary hypertension-specific therapy has been reported to be beneficial in chronic postoperative pulmonary hypertension. However, it is as important to consider additional causes in this group of patients as with any other and includes evaluation for upper airway obstruction, residual postoperative shunts, valve dysfunction, pulmonary vein stenosis, or peripheral or proximal pulmonary artery distortion.

Symptomatic improvement in children with postoperative pulmonary vascular disease and improvement in a 6 min walk have been demonstrated with sildenafil [177, 179], bosentan [175, 176, 178, 180], inhaled iloprost [181], and intravenous prostacyclin [150] or combination therapy [178]. Once specific pulmonary hypertensive therapy is started, it is uncertain for how long therapy should be continued. We have seen normalization of residual postoperative pulmonary hypertension with sildenafil therapy, recurrence with cessation of treatment, and with a preserved response to reinstitution of sildenafil.

It remains to be seen if improved perioperative management and postoperative therapy with these agents will improve outcome. However, globally the focus of attention should be the early referral for accurate surgery of all children with reparable congenital heart disease. Globally, postoperative pulmonary vascular disease is, with few exceptions, a preventable disease.

Pulmonary Venous Hypertension

Pathophysiology

Pulmonary venous hypertension may be caused by increased pressure anywhere between the intraparenchymal pulmonary veins and the left ventricle. Pulmonary venous hypertension has different causes in children compared with adults. In adults the most common cause of pulmonary venous hypertension is left ventricular diastolic disease [182]. In children, congenital heart diseases [8] and acquired and congenital cardiomyopathies are the usual causes of pulmonary venous hypertension. However, left ventricular diastolic disease is emerging as an important cause of late pulmonary hypertension in the maturing population of patients with congenital

heart disease. Left ventricular diastolic disease is reported increasingly late after repair of aortic coarctation, ventricular septal defect (VSD) repair, cardiac transplantation, supra-annular mitral valve replacement, and in conditions such as Shone's syndrome that may require multiple operations [183–186].

Paul Wood described elegantly in the 1950s three important mechanisms in the pathophysiology of pulmonary hypertension secondary to mitral stenosis, which can be applied to most forms of pulmonary hypertension due to left heart disease [187–189]. Firstly, there is a passive rise in pulmonary artery pressure as downstream pressure increases to maintain left-sided preload and cardiac output. In this situation, the transpulmonary gradient (TPG) and pulmonary vascular resistance index (PVRI) are low (TPG < 10 mmHg, PVRI < 2.5–5 WU $\times$ m^2) and the pulmonary artery diastolic pressure is similar to the left atrial or, in the absence of pulmonary vein or mitral valve pathology, the left ventricular end-diastolic pressure [189]. Secondly, there is reflex vasoconstriction of the pulmonary arteries or veins or both, and the diastolic pulmonary artery pressure will be higher than the pulmonary vein, left atrial, or left ventricular end-diastolic (LVED) pressure depending on the site of the left-sided pressure increase. The TPG will be >10 mmHg and PVRI $>$ 2.5–5 WU $\times$ m^2. Thirdly, there may be fixed pulmonary artery or vein obstruction. Quite often a combination of all three mechanisms (passive, reflex vasoconstriction, and fixed) conspires to increase pulmonary artery pressure. Reflex vasoconstriction and fixed pulmonary vascular disease are distinguished from each other by the response to pulmonary vasodilators. Paul Wood demonstrated that in the presence of reflex vasoconstriction due to mitral stenosis an infusion of acetylcholine (an endothelium-dependent vasodilator) would cause both an increase in left atrial pressure and decrease in PVRI [189]. In contemporary practice, we use inhaled nitric oxide (NO), a short-acting pulmonary vasodilator, to reverse reflex vasoconstriction. In diverse forms of pulmonary venous hypertension, inhaled NO causes a decrease in TPG and PVRI with or without a decrease in pulmonary artery pressure depending on the exact cause of the pulmonary venous hypertension [140, 190–192]. Although testing with inhaled NO is very useful, it is not without risk in patients with pulmonary vein obstruction, mitral stenosis, or reduced left ventricular ejection fraction and may increase pulmonary vein, left atrial, or LVED pressures and precipitate pulmonary edema [140, 190, 193]. Thus, reflex vasoconstriction may be protective in some circumstances, and Paul Wood observed that patients with mitral stenosis and elevated PVRI had few symptoms of pulmonary edema [188].

If there is fixed pulmonary vascular disease, there will be little or no change in pulmonary artery hemodynamics in response to inhaled NO [138, 140].

Pathology of Pulmonary Venous Hypertension

The histopathology of pulmonary venous hypertension has been studied in children [194–197]. There is medial thickening of both pulmonary arteries and veins or so-called "arterialization" of the pulmonary veins. In patients over 18 months of age, there is intimal fibrosis of veins and arteries [194]. There is a correlation with medial thickness and preoperative pulmonary artery systolic pressure in children with pulmonary venous hypertension [194]. However, the medial thickening is not as marked as in patients with a VSD [194, 197]. Advanced lesions associated with pulmonary vascular disease of Grade 3 or 4, such as cellular intimal proliferation or plexiform lesions, were not seen in patients with isolated mitral stenosis or cor triatriatum [194]. This may reflect the histological correlate for the reversibility of pulmonary venous hypertension in general. Proliferation and dilation of lymphatics in interlobular septa and subpleural layers or lymphangiectasia is seen frequently especially in long-standing pulmonary venous hypertension and following in utero elevation in pulmonary venous pressure such as common pulmonary vein atresia, severely obstructed total anomalous pulmonary venous connection, and hypoplastic

left heart syndrome with intact atrial septum [194, 196, 198].

There is marked variability in the pulmonary artery response to pulmonary venous hypertension. There is heterogeneity in both the degree of reflex vasoconstriction and the reversibility of the pulmonary vascular disease after, for example, relief of the transmitral gradient in mitral stenosis. A permissive genetic trait may account for the variability in expression of different degrees of pulmonary hypertension to similar stimuli. Du et al. reported a mechanistic link between familial and acquired pulmonary hypertension [90].

Clinical Evaluation of Suspected Pulmonary Venous Hypertension

The history of an underlying condition that predisposes to pulmonary venous hypertension will be present often in children. Symptoms of pulmonary edema such as orthopnea or paroxysmal nocturnal dyspnea may be elicited in the older child or adolescent. Infants are tachypneic at rest and more so with feeding and may fail to thrive. The chest X-ray may show signs of pulmonary vascular congestion, pleural effusions, or Kerley B lines suggesting chronic pulmonary edema. High-resolution CT scan may show ground glass opacities and a mosaic perfusion pattern but can be challenging to interpret in children [199]. Echocardiography provides a great deal of useful information on systolic and diastolic function, structural anomalies, pulmonary venous flow, and left-sided valvar anomalies. A thorough and complete echocardiographic examination is essential prior to cardiac catheterization. It allows a more focused evaluation, which is essential to reduce the time spent on invasive investigation in fragile patients. Magnetic resonance imaging (MRI) provides excellent imaging of pulmonary veins and hemodynamic flow data but without pressure measurements and does not replace yet cardiac catheterization but augments it. However, in all neonates and infants and many older children, examination by MRI requires similar levels of sedation and anesthesia as required for cardiac catheterization and so may be associated with significant risk despite being a noninvasive test. Diastolic dysfunction and pulmonary arterial hypertension may coexist and cardiac catheterization may be required to distinguish between them. The essential measurements at cardiac catheterization are the TPG and pulmonary blood flow. An accurate TPG requires an accurate pulmonary artery occlusion pressure or capillary wedge pressure. Rich and Rabinovitch [182] have highlighted the difficulties in obtaining and interpreting the wedge pressure recently. Needless to say when evaluating patients with pulmonary venous hypertension, a single wedge pressure may be misleading and may be high, low, or normal in the presence of significant pulmonary vascular disease [200]. At times it is essential to measure pulmonary vein, left atrial, and left ventricular end-diastolic pressure to accurately delineate the cause of the pulmonary hypertension, especially in conditions with coexisting mixed arterial and venous disease. We advocate the simultaneous measurement of pulmonary artery diastolic and LVED pressure. In general this provides an unambiguous measurement from which to work towards a diagnosis.

Pulmonary hypertension may cause diastolic filling abnormalities in the left ventricle [201]. Therefore, at cardiac catheterization, cardiac output augmentation with exercise, [202], a vasodilator [203], or an inotrope [204] may be required. If a significant increase in cardiac output is unaccompanied by an increase in pulmonary capillary wedge pressure, the patient more likely has category 1 pulmonary artery hypertension. However, if the increase in cardiac output is accompanied by an increase in left-sided filling pressure, the patient is more likely to have category 2 pulmonary venous hypertension.

Pulmonary Venous Hypertension and Left to Right Shunts

Patients with large post-tricuspid left to right shunts (ventricular septal defect being perhaps the best example) have left atrial pressures ranging from normal to significantly elevated [8, 205–209]. Hoffmann and Rudolph reported

that in some patients left atrial pressure increased as pulmonary blood flow increased [8]. DuShane and Kirklin reported that in particularly symptomatic infants undergoing operative closure of large shunts left atrial pressure was elevated preoperatively and decreased promptly after shunt closure [9]. Pulmonary venous hypertension may contribute to active pulmonary vasoconstriction in patients with left to right large shunts and increased left atrial pressure, although increased wall stress in the large or small pulmonary arteries may also stimulate pulmonary vasoconstriction. Other experimental causes of reflex pulmonary vasoconstriction, which may be relevant to the child with a large left to right shunt, include pulmonary edema and pulmonary venous hypoxemia [210, 211].

Pulmonary Venous Hypertension in Hypoplastic Left Heart Syndrome

Pulmonary vascular changes from left atrial hypertension due to reflex vasoconstriction and restriction at the foramen ovale have a profound detrimental influence on the presentation and outcome of the hypoplastic left heart syndrome [212, 213]. Severe restriction or intact atrial septum is associated with profound cyanosis, pulmonary artery hypoplasia, lymphangiectasia, and a high mortality despite aggressive therapy [213–215]. In neonatal survivors, persistent pulmonary vascular changes may compromise subsequent palliation [216]. However, mild restriction at the foramen ovale may reduce pulmonary blood flow and systemic steal and permit a degree of preoperative stability. In the postoperative patient, an adequate atrial septectomy is extremely important to permit adequate oxygenation and progress to cavopulmonary anastomosis.

Pulmonary Vein Stenosis

Pulmonary vein stenosis may be associated with pulmonary hypertension. The condition may be either acquired following repair of anomalous pulmonary vein connections or from the development of diffuse fibrosis of the extraparenchymal pulmonary veins [217]. Pulmonary hypertension due to passive increase in pressure, reflex vasoconstriction, and pulmonary vascular changes with lymphangiectasia may all compromise survival. In general, with relief of obstruction and absence of recurrence, the pulmonary vascular changes are reversible. Immediately postoperatively, however, pulmonary vascular lability may be marked [192].

Pulmonary Hypertension and Mitral Stenosis

Pulmonary venous hypertension in mitral stenosis has been well characterized [187, 188, 218]. Paul Wood described reflex pulmonary vasoconstriction and he noted that patients with the least pulmonary edema symptoms had the highest pulmonary vascular resistance. Children with mitral stenosis have reactive pulmonary vascular beds [183, 191]. In general, pulmonary hypertension following relief of mitral valve stenosis whether by valve replacement or valvotomy results in a marked reduction in pulmonary artery pressure often to normal levels [188]. The rate of normalization is variable and may be immediate or delayed over months or years [188, 219–225]. In children normalization of pulmonary artery pressure post-mitral valvuloplasty or replacement is most likely to occur in patients with acquired mitral stenosis or isolated congenital mitral stenosis without additional left-sided obstructions or intracardiac shunts [195, 226–228]. In children, as in adults, diuretic therapy may result in a marked improvement in symptoms, mitral gradient, and pulmonary artery pressures (Fig. 121.5).

Thus, in children, as in adults, the best treatment for pulmonary hypertension is relief of the transmitral obstruction. However, the association with other cardiac anomalies, and the paucity of prosthetic options in small infants, often impacts significantly on the resolution of the pulmonary hypertension [183].

Although pulmonary hypertension is most often recognized with mitral stenosis, it can occur with mitral regurgitation [229].

Pulmonary Hypertension and Shone's Syndrome

In children with Shone's syndrome or variants [230] in whom mitral stenosis is just one of the factors contributing to pulmonary hypertension, regression may not occur despite relief of the transmitral gradient. Other anatomical factors that conspire to elevate left atrial pressure include residual left ventricular outflow tract obstruction, elevated LVED pressure due to a small hypertrophied left ventricle, endocardial fibroelastosis, and a small noncompliant left atrium that may be further compromised by the mitral prosthesis [183]. However, the long-term pulmonary vascular outcome of patients with Shone's syndrome and variants has been recorded imperfectly. Long-term outcome is affected by degree of residual mitral stenosis, left ventricular hypoplasia, and need for multiple surgical re-interventions, each of which leads to further left ventricular diastolic dysfunction. In children with Shone's syndrome suitable for biventricular repair, reported by Brauner et al., the baseline mean pulmonary artery pressure was 40 $\pm$ 3.5, with a peak systolic 60 $\pm$ 5 mmHg. Patients with the worst outcomes and all surgical deaths had severe pulmonary hypertension. Although in survivors pulmonary hypertension regressed in all but one patient [231]. However, a recent report with 5- and 10-year survival of 88 % and 83 % suggests that elevated pulmonary vascular resistance is not a major issue in mid-term survivors [232].

Pulmonary Hypertension and Left Ventricular Cardiomyopathy

Pulmonary hypertension occurring in the presence of reduced left ventricular systolic function with elevated left ventricular end-diastolic pressures has been described well and appears to be a powerful predictor of prognosis [182, 233]. An elevated pulmonary vascular resistance remains a risk factor after cardiac transplantation and most would recommend a pulmonary vasodilator test as part of the cardiac transplant evaluation in patients with cardiomyopathy and elevated pulmonary vascular resistance [203, 234, 235].

The presumed pathophysiology of pulmonary hypertension due to dilated and restrictive cardiomyopathies is described above. The response to inhaled nitric oxide has been described in children and in the presence of reflex pulmonary vasoconstriction decreases pulmonary artery pressure, transpulmonary gradient, and pulmonary vascular resistance [140]. Similar responses have been described in adults [236]. If cardiac output is limited by right ventricular output, pulmonary vasodilation may increase pulmonary blood flow and left-sided preload, and if left ventricular output cannot increase concomitantly, then LVED pressure will increase [140, 190, 236]. In these circumstances, concomitant inotropic, systemic vasodilation, or mechanical support may be required together with inhaled NO for a complete pre-transplant evaluation [203, 204]. Indeed mechanical support with assist devices and the use of inhaled NO and sildenafil may be necessary to prepare some patients for cardiac transplantation with elevated pulmonary vascular resistance [237–239].

The management of left ventricular systolic failure is not the focus of this discussion. However, one is approached often for advice regarding therapy for patients with concomitant pulmonary hypertension. In general, if the transpulmonary gradient or PVRI are not elevated, pulmonary vasodilator therapy is not indicated. If the transpulmonary gradient or PVRI is increased, then specific pulmonary vasodilator may be indicated but only after the safety of such therapy has been assessed with a short-acting agent or sildenafil in the cardiac catheterization laboratory. The precipitation of pulmonary edema is well described and may be fatal in some conditions with pulmonary venous hypertension [193, 240, 241].

However, sildenafil is emerging as a beneficial therapy in left and right heart systolic dysfunction [242, 243]. Sildenafil improves right heart afterload and increases cardiac index at rest and with exercise in patients with pulmonary hypertension and heart failure. In addition sildenafil improves right ventricular ejection fraction, ventilator efficiency, and peak oxygen consumption, all of which have been shown to predict prognosis in heart failure [242–244]. These effects are seen both acutely and with prolonged administration [245]. Prolonged therapy with bosentan and prostacyclin has been shown to be either ineffective or associated with an increased mortality in patients with reduced left ventricular systolic function [246, 247].

Left Ventricular Diastolic Disease

Pulmonary hypertension due to diastolic left ventricular disease has been reviewed recently [182, 248]. Outside of restrictive cardiomyopathies, severe pulmonary hypertension due to isolated left ventricular diastolic disease is not prominent in young children. However, it seems likely that with the emergence of childhood obesity, insulin resistance, systemic hypertension, survivors of left-sided congenital heart disease, and organ transplantation, diastolic heart disease will assume more prominence in pediatrics.

Aortic Stenosis and Pulmonary Hypertension

Pulmonary hypertensive vascular disease associated with aortic stenosis occurs secondary to left ventricular diastolic abnormalities resulting in increased left atrial and pulmonary venous pressures. The transpulmonary gradient is normal initially but with time increases and suggests the presence of either vasoconstriction and/or vascular remodeling [249, 250]. In aortic stenosis the left ventricle hypertrophies to lower wall stress and compensate for increased left ventricular afterload imposed by the aortic valve obstruction. However, over time the change in left ventricular wall remodeling unfavorably alters left ventricular filling characteristics through impaired relaxation in early diastole and decreased compliance or increased stiffness in mid- to late diastole leading to diastolic dysfunction [249, 251–253].

Pulmonary venous hypertension whether caused by aortic stenosis or mitral stenosis leads to upper lobe diversion of pulmonary blood flow demonstrated by nuclear lung scans and is reversible with therapeutic interventions that decrease left atrial pressure [254].

Pulmonary hypertension associated with acquired aortic stenosis was thought to be quite rare and related only to the severity of the aortic valve gradient or the presence of decreased systolic ventricular function [255]. However, subsequent studies have challenged previous understanding of both the prevalence of pulmonary hypertension in patients with acquired aortic stenosis as well as the mechanisms of the pulmonary hypertension [249, 256–259]. It has been suggested that diastolic and left atrial dysfunction may be as or more important than the degree of aortic stenosis or systolic ejection fraction. For example, the main determinant of pulmonary hypertension in both acquired [249, 252, 253, 260–262] and congenital aortic stenosis [263–268] may be the degree of associated left ventricular diastolic dysfunction and not the valve area or severity of aortic stenosis.

Left atrial dysfunction has been reported in patients with severe aortic stenosis and concomitant left ventricular dysfunction. Doppler-derived left atrial function parameters correlated with right ventricular systolic pressure irrespective of aortic valve area or gradient and were most impaired in patients with pulmonary hypertension. Left atrial function improved in patients whose pulmonary artery pressure decreased after aortic valve replacement [269].

NO–cGMP Pathway in Pulmonary Venous Hypertension

Pathophysiologic mechanisms and possible therapeutic strategies are suggested by the

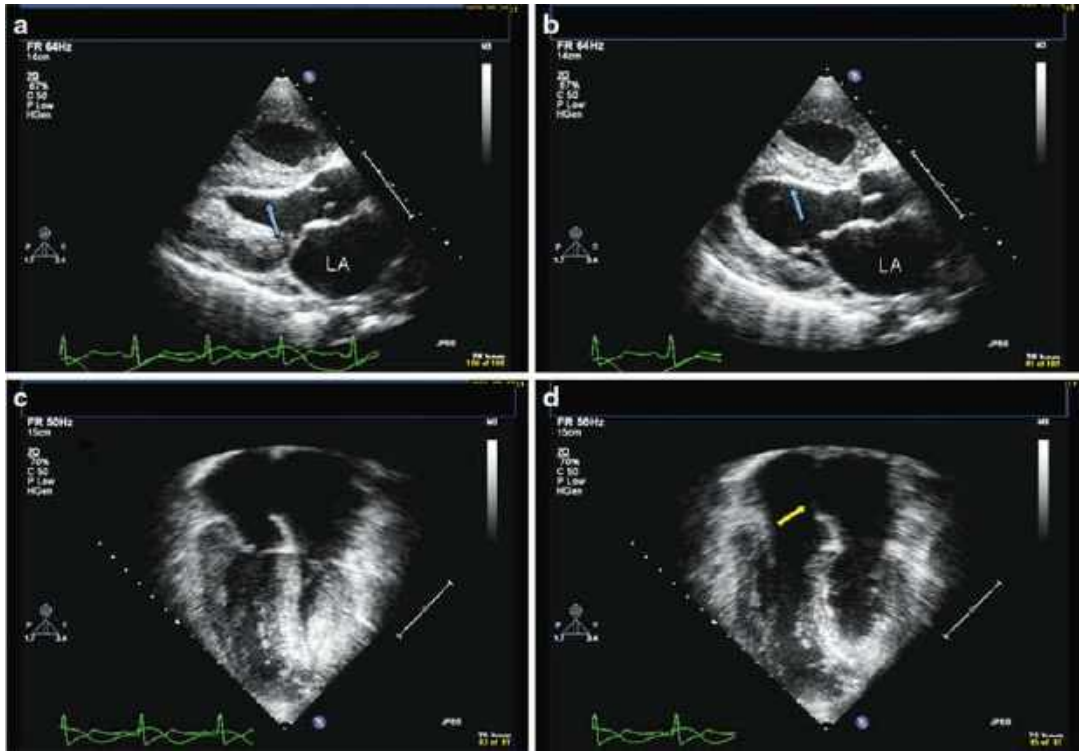

Fig. 121.15 Echocardiogram of parasternal long axis and four-chamber view in a patient with PHVD due to increased left ventricular diastolic pressures. The left ventricular cavity is small and lined by endocardial fibroelastosis. The LVEDp was 30 mmHg and the pulmonary artery pressures suprasystemic and only partially reactive to inhaled NO suggesting the presence of both reflex vasoconstriction and fixed disease. The left atrium is enlarged and the interatrial septum is bowing towards the right (*yellow arrow*) suggesting elevated left atrial pressures. This patient was 19 years old born with critical aortic stenosis and has undergone a Ross procedure. Late diastolic sequel of repaired congenital heart disease is an increasing problem in survivors of congenital left heart disease

downregulation of the NO–cGMP pathway in pulmonary venous hypertension, including pulmonary hypertension associated with aortic stenosis, recently reviewed by Lindman et al. [260]. For instance, Melenovsky et al. reported that phosphodiesterase type 5 inhibition may restore cGMP levels in pulmonary venous hypertension. Patients with systolic heart failure and increased pulmonary vascular resistance have preserved transpulmonary BNP uptake but diminished cGMP release that is reversible by acute phosphodiesterase type 5 inhibition. This study suggests that sildenafil restores sensitivity of pulmonary vasculature to endogenous cGMP-dependent vasodilators [270].

Congenital Aortic Stenosis and Pulmonary Hypertension

There are potentially important differences in the left ventricle and pulmonary vascular bed between acquired and congenital aortic valve stenosis (Fig. 121.15). For instance, most patients with acquired aortic stenosis or postneonatal onset of hemodynamic gradients have normal left ventricular size, and the pulmonary vascular bed has undergone normal postnatal remodeling. Rudolph reported that constriction of the ascending aorta in the fetal lamb led to not only left ventricular hypertrophy but also progressive decrease in left ventricular size [271]. Decreased

left ventricular size may impose additional diastolic abnormalities not seen in acquired aortic valve stenosis. In fetuses and newborns with critical aortic stenosis or aortic atresia, there is abnormal extension of muscle into peripheral, usually nonmuscular, pulmonary arteries. In addition the pulmonary veins become arterialized. These changes may be present in utero [268, 272–276] and prevent or delay or impair postneonatal pulmonary vascular adaptation and development. Although left-sided heart structures tend to grow and normalize by 1 year of life after neonatal successful aortic balloon valvotomy [277].

The outcome for neonates born with critical aortic valve stenosis has improved steadily and 5-year survival rates are between 77 and 85 % at 5 years [278–281]. However, compared with acquired aortic valve stenosis, there have been no studies which document systematically the prevalence or implications of pulmonary hypertension complicating congenital critical aortic stenosis.

In a report examining the risks of sudden unexpected death in children after balloon aortic valvuloplasty, 7 % (37/528) had pulmonary artery pressures >30 mmHg aged >30 days. Six children died suddenly at home and 1 of these had pulmonary hypertension although the cause of death at autopsy was sepsis [277]. Burch et al. described 4 children with persistent pulmonary artery hypertension (mean pulmonary artery pressures from 45 to 63 mmHg and left ventricular end-diastolic pressures of 26–40 mmHg) 4–12 years after treatment of congenital aortic valve stenosis in infancy. The cause of the pulmonary hypertension was considered to be due to left ventricular diastolic dysfunction [264]. Aota et al. described a child with Turner's syndrome and congenital aortic stenosis treated from birth who despite valvulotomy has pulmonary hypertension (mean pulmonary artery pressure 66 mmHg) at 5 years of age [268]. Pulmonary hypertension has been documented in 4 teenagers treated for congenital aortic stenosis in infancy who developed symptomatic diastolic dysfunction with mean pulmonary artery pressures ranging from 28 to 60 mmHg and left ventricular end-diastolic pressure 22–40 mmHg [267]. Interestingly echocardiographic evidence of left ventricular diastolic dysfunction is common in patients with biventricular circulation after fetal aortic valvuloplasty and persists in short-term follow-up. Left ventricular diastolic dysfunction in this unique population, as pointed out by the authors, may have important implications on long-term risk of left atrial and subsequent pulmonary hypertension [263].

Both aortic and mitral valve stenosis complicates mucopolysaccharidosis. In a study of 28 children with mucopolysaccharidosis aged 2–14 years old, pulmonary hypertension was present in 36 % and the cause of death in 2. This contrasts with adult disease where systolic dysfunction is a more frequent cause of death [282].

Left ventricular diastolic dysfunction persists late after repair of congenital aortic stenosis but measurements of pulmonary artery pressure were not reported [265, 266].

Pulmonary Vascular Disease and Cavopulmonary Surgery

Strategies to permit normal neonatal remodeling and subsequent protection of the pulmonary vascular bed from excess pressure and/or flow while providing sufficient pulmonary blood flow for somatic growth and development remain important principles in the management of all patients without a dedicated subpulmonary ventricle.

Patients with congenital heart disease who are born with a hypoplastic ventricle or in whom the heart cannot be septated (because of the position of the VSD, atrioventricular valve, or arterial outlet) are treated with superior and/or total cavopulmonary anastomoses (bidirectional Glenn or Fontan, respectively) [283]. After cavopulmonary surgery, systemic venous return drains directly into the pulmonary arteries and the pulmonary circulation is without a dedicated subpulmonary ventricle. The systemic and pulmonary circulations are then considered to be in series [284]. Pulmonary blood flow is dependent on the transpulmonary gradient and the kinetic energy imparted by systemic ventricular contraction [284, 285]. Measurements of transpulmonary

gradient and PVRI are important in the selection of patients with a single ventricle for cavopulmonary surgery and the measurements impact their survival [286, 287].

An increased pulmonary vascular resistance after cavopulmonary anastomoses is a significant but poorly understood clinical problem. There have been attempts to treat patients with borderline pulmonary hemodynamics with bosentan before cavopulmonary surgery [288].

However, less is known about the state of the pulmonary vascular resistance index after the operation and the impact of small increases in PVRI on functional outcome or as a cause of "Fontan failure." The exact mean pulmonary artery pressure or pulmonary vascular resistance that is abnormal after cavopulmonary surgery is unknown. A suggested definition is transpulmonary gradient >6 mmHg or PVRI >3 WU × m^2 [2]. There are difficulties estimating pulmonary blood flow and resistance after cavopulmonary anastomoses. These difficulties include measurements of pressure in a nonpulsatile system, sampling true pulmonary artery saturation in the presence of aortopulmonary collaterals, and the effect of venous collaterals or arteriovenous malformations that steal from the pulmonary circulation.

There is growing concern that late attrition after cavopulmonary anastomosis is related to increased pulmonary vascular resistance and that complications such as plastic bronchitis, protein-losing enteropathy, and decreased exercise tolerance may be due to abnormal pulmonary vascular bed [284, 285, 289–293].

Available evidence suggests that the pulmonary vascular bed is important in the outcome of patients undergoing cavopulmonary anastomosis. The evidence includes the paucity of patients with trisomy 21 [294] who survive cavopulmonary surgery, the unexpectedly poor outcome, and increased pulmonary vascular resistance in patients with a failing Fontan undergoing heart transplantation [295], and post-Fontan surgery small but important decreases in PVRI occur in response to NO [3].

Some case reports and the preliminary data from the Spanish registry suggest that select patients with increased PVRI are being treated with sildenafil and bosentan [291, 296]. Ovaert et al. suggested that bosentan improves exercise tolerance and oxygen saturation in select, but not all, patients with a failing Fontan [293]. A single dose of sildenafil improves VO2 and pulmonary blood flow in patients after the Fontan [290]. A randomized placebo-controlled double-blind crossover trial of 6 weeks of sildenafil therapy improved exercise tolerance and ventilatory efficiency but pulmonary vascular resistance was not measured [297].

Conclusion

In children pulmonary hypertension due to increased pressure between the intraparenchymal pulmonary veins and the left ventricle is more heterogeneous than in adults. In general, the pulmonary hypertension regresses if the left-sided obstruction or dysfunction can be adequately addressed. Diastolic dysfunction will likely become more common in pediatrics particularly in survivors of congenital heart surgery and post-organ transplantation.

Summary

The state of the pulmonary vascular bed impacts on the outcome of CHD. Both active vasoconstriction and pathological remodeling conspire to increase PVR. The combination of increased pulmonary blood flow and pulmonary artery pressure is a potent stimulator of pulmonary vascular disease. With the exception of a few high-risk malformations (e.g., d-TGA and VSD), permanent or progressive pathological changes seldom occur when malformations are corrected in the first 1–2 years of life. In privileged countries, early diagnosis and prompt and accurate surgical repair have decreased the incidence of problematic pulmonary vascular disease due to congenital shunt lesions. It remains a major challenge to deliver such care globally to all infants with congenital heart disease. Patients with Eisenmenger syndrome were for a long time therapeutic orphans. However,

the availability of orally administered therapies has resulted in the inclusion of patients with Eisenmenger syndrome in randomized controlled trials. New insights into pulmonary vascular biology, improved understanding of genetic predisposition, the development of therapies that engage novel pathways, and the improved delivery of medical and surgical care in underprivileged areas will, we hope, substantially reduce the medical burden caused by pulmonary vascular disease associated with congenital heart disease. Collaboration between the worldwide medical communities will be required to eradicate the suffering due to Eisenmenger syndrome. UNICEF reported in the State of the World's Children that "Attention to the youngest children is most needed where it is most difficult to guarantee: in countries where the seemingly intractable grip of poverty, violence and devastating epidemics seriously challenge parents' hopes and dreams for their children." This is germane to all illness with origins in childhood. Globally pulmonary vascular disease associated with congenital heart may represent the most preventable cause of pulmonary artery hypertension and the morbid and fatal sequelae [11].

Postoperative Pulmonary Hypertension in Children with Congenital Heart Disease

122

Dunbar Ivy and Eduardo M. da Cruz

Abstract

Pulmonary hypertension in the critically ill pediatric cardiac patient remains an important cause of morbidity and mortality. Although early surgery has markedly decreased the risk of a pulmonary hypertensive crisis, not all children throughout the world can benefit from this strategy. This chapter provides a summary of the main aspects to be taken into account in the management of acute pulmonary hypertension in the patient with cardiac disease.

Keywords

Adenosine • Congenital heart disease • Epoprostenol • Iloprost • Lung ventilation • Milrinone • Nitric oxide • Pulmonary hypertension • Sildenafil • Tadalafil • Treprostinil

Introduction

Pulmonary hypertension in the critically ill pediatric cardiac patient remains an important cause of morbidity and mortality [1–6]. Although early surgery has markedly decreased the risk of a pulmonary hypertensive crisis, not all children throughout the world can benefit from this strategy. Firstly, it is important to describe the current knowledge regarding the pathophysiology of pre- and postoperative pulmonary hypertension in the cardiac patient.

In the preoperative phase, the increase in pulmonary pressure associated with congenital heart disease is, in the vast majority, secondary either to an increase in pulmonary blood flow and pressure (left-to-right shunts) or to increased post-capillary pressures (left heart obstruction or left ventricular dysfunction either systolic or diastolic).

Albeit major advances in the understanding of the regulation of the pulmonary vascular bed and the pulmonary endothelial lesions leading to pulmonary vascular disease have been achieved, and despite the advances in surgical repair and the

discovery of potential therapies in the pre- and postoperative period, pulmonary hypertension still carries a significant mortality and morbidity in this population. The incidence of postoperative pulmonary hypertensive events has decreased from 31 % in the 1980–1984 era to 6.8 % in the 1990–1994 era and to 2.4 % in the current era [7]. This data reflects in part the improved understanding of the pathophysiology and the rapid translation of this knowledge into therapy. However, acute pulmonary hypertension after cardiac surgery remains a major contributor to hospital length of stay and need for prolonged mechanical ventilation.

Pathophysiology

It has been recognized for many years that the endothelium is vital for the maintenance of normal vascular function by regulating flow and low pulmonary vascular tone.

In congenital heart disease with significantly increased pulmonary blood flow or pulmonary venous hypertension, progressive anatomic and functional abnormalities of the pulmonary vascular bed occur. This state is characterized by progressive smooth muscle hypertrophy and hyperplasia, intimal proliferation, and finally plexiform arteriopathy. In addition, there are changes in the extracellular matrix and adventitia with synthesis and deposition of collagen and elastin. The role of hemodynamics in the development of pulmonary vascular disease has been clearly demonstrated (see ► Pathology, Pathobiology & Pathophysiology of Pulmonary Arterial Hypertension). Endothelial dysfunction occurs indeed before the onset of pulmonary hypertension or histological evidence of smooth muscle dysfunction.

Recently, several studies have focused on the endothelial dysfunction induced by increased pulmonary blood flow, such as encountered in many congenital heart diseases leading to increased pulmonary vascular resistance. Complex interactions between vasoactive substances produced by the vascular endothelium may in part explain the changes in pulmonary vascular tone. The cellular and molecular mechanisms underlying the pulmonary vascular remodeling in response to the mechanical stimulus of increased flow are however not completely understood. Shear stress has been shown to alter the production of vasoactive substances. Endothelial shear stress is directly proportional to blood flow velocity and is inversely proportional to the radius of the vessel. A high blood flow rate alters the mean shear stress and may directly damage the endothelial cell; this in turn may impair the balance between the vasoconstrictor and vasodilator effect, as well as promitotic and antimitotic functions, and lead to smooth muscle cell hypertrophy and proliferation. Cooper et al. [8] showed that in healthy adults, normal basal pulmonary vascular tone is in part related to nitric oxide production. This basal nitric oxide production may be increased in response to receptor-mediated stimulation, leading to further vasodilation; this function can be tested with acetylcholine. Nitric oxide dependence of basal pulmonary resistance has also been described in children. Thus, impairment of nitric oxide production, secondary to an injured endothelium, may contribute to the increased pulmonary vascular resistance as observed in infants and children with congenital heart disease. As a matter of fact, Celermajer et al. [9] demonstrated that in children with congenital heart disease and abnormal pulmonary hemodynamics, endothelium-dependent pulmonary artery relaxation is impaired and that this impairment may be one of the early events in the pathogenesis of pulmonary vascular disease.

Animal and human data strongly suggest that alterations in endothelin-1 (ET-1) metabolism, secondary to endothelial injury, also contribute to the development of pulmonary hypertensive disorders and their associated increased vascular reactivity [10, 11]. As shown by Fineman, lamb models with increased pulmonary blood flow secondary to experimentally created congenital heart disease also show alterations in the ET-1 cascade. ET-1 is a potent vasoactive peptide produced primarily in the vascular endothelial cell but also may be produced by smooth muscle cells. Two receptor subtypes, ET_A and ET_B, mediate the activity of ET-1. ET_A and ET_B receptors on vascular smooth muscle mediate

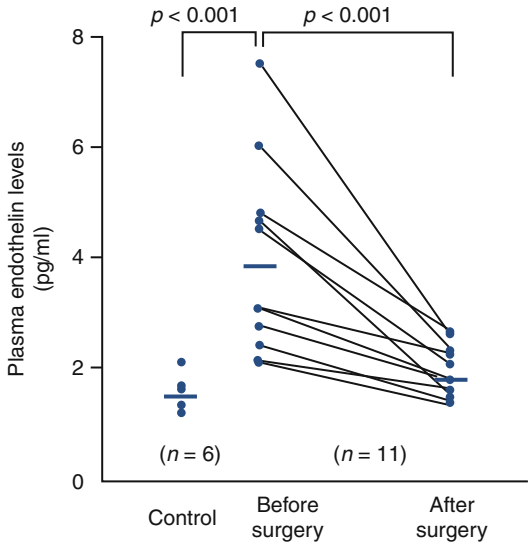

Fig. 122.1 Successful surgical repair decreases ET levels in patients with PAH caused by CHD [12]

vasoconstriction, whereas ET_B receptors on endothelial cells cause release of NO and prostacyclin and act as clearance receptors for circulating ET-1. At 4 weeks of age, lambs with increased pulmonary blood flow have increased plasma and lung tissue concentrations of endothelin-1 that is secondary to an upregulation of endothelin-converting enzyme. In addition, there is loss of ET_B receptor-mediated pulmonary vasodilation and augmented ET_A receptor-mediated vasoconstriction. This is associated with increased ET_A receptor gene expression and decreased ET_B receptor expression. Recent data have also demonstrated the emergence of ET_B receptor-mediated pulmonary vasoconstriction in these lambs at 8 weeks of age, suggesting a role for both ET_A and ET_B receptor-mediated effects in the pathophysiology of pulmonary hypertension.

Several human studies demonstrate increased ET-1 concentrations in patients with pulmonary hypertension, including children with congenital heart disease and increased pulmonary blood flow. In addition, patients with advanced pulmonary hypertension have an increase in plasma ET-1 concentrations which fall after surgery (Fig. 122.1).

Prostacyclin and thromboxanes are also potential actors in the changes of pulmonary vascular tone as their balance may be impaired in patients with congenital heart disease.

However, not all patients develop fixed pulmonary vascular disease or at least not within the same timing, and this may be related to a particular susceptibility to develop lesions or, even the opposite, to be protected from these events. Currently some studies are devoted to assess if there is genetic susceptibility. The recent publication of Levy et al. [13] suggests also the role of impaired endothelial cell apoptosis and inflammatory apoptosis in the pathogenesis of pulmonary vascular lesions.

The pulmonary vascular remodeling process is reversible in the early stages of the disease but may progress, with continuous stress, to smooth muscle cell proliferation in small arteries. As described before, it provokes changes in the extracellular matrix and adventitia with synthesis and deposition of collagen and elastin; this progression renders the vessels relatively unresponsive to vasodilators and may preclude corrective surgery.

The age at which congenital heart lesions cause irreversible pulmonary vascular disease varies. The consequences of increased pulmonary blood flow are more severe in the immature than in the mature animal. Endothelial cell morphology is modified as early as 2 months after birth in children with increased pulmonary blood flow. The development of irreversible lesions is also associated with the type of heart defect and it seems that a combination of high pressure and high flow causes a more rapid and more severe remodeling.

Thus, *surgical correction should be performed early in life* in children with a significant increase in pulmonary blood flow: before 2 years of age for ventricular septal defects and even earlier (<1 year or 6 months) for atrioventricular septal defects, transposition of the great arteries with ventricular septal defect or truncus arteriosus.

Besides the age effect, as mentioned above, individual susceptibility based on different genetic polymorphisms plays a major role, and research is currently directed to understand why two patients with the same malformation and hemodynamic profile will not develop pulmonary vascular disease at the same time.

Postoperative Pulmonary Hypertension: Cardiopulmonary Bypass and Ischemia-Reperfusion Injury

Reperfusion of tissues exposed to ischemia can lead to a cascade of events that produce cellular dysfunction and necrosis. This phenomenon has been implicated in the pathogenesis of some complications encountered after cardiopulmonary bypass. Cardiopulmonary bypass is known to induce a generalized inflammatory response with the systemic release of proinflammatory cytokines, the activation of the complement system, and endothelial dysfunction. This phenomenon is thought to be triggered by the exposure of blood to nonphysiologic surfaces and the development of ischemia-reperfusion injury. Endothelial cell dysfunction is common after cardiopulmonary bypass, and structural and functional damage to the pulmonary vascular endothelium has been demonstrated. During cardiopulmonary bypass, the lungs are hypoxic and ischemic, as the pulmonary circulation is excluded to abolish pulmonary venous return. It was long postulated that the lung was resistant to ischemia because of its dual pulmonary and bronchial blood supply and its direct source of oxygen from the alveolar space. However, bronchial flow is estimated at 0.5 % of the bypass flow, and indeed, it has been demonstrated that pulmonary vascular endothelial cells undergo ischemia-reperfusion injury. This phenomenon further aggravates the inflammatory response and subsequent lung damage as shown by a decrease in pulmonary endothelium-dependent relaxation after cardiopulmonary bypass. Lung injury following cardiopulmonary bypass is well described. Clinically, it is manifested as reduced oxygenation, reduced lung compliance, and most importantly increased pulmonary vascular resistance and augmented pulmonary vascular reactivity. Injury to the pulmonary vascular endothelium is considered to be a major factor. In fact, patients with preexisting pulmonary vascular endothelial dysfunction are at greatest risk for developing clinically significant bypass-induced lung injury.

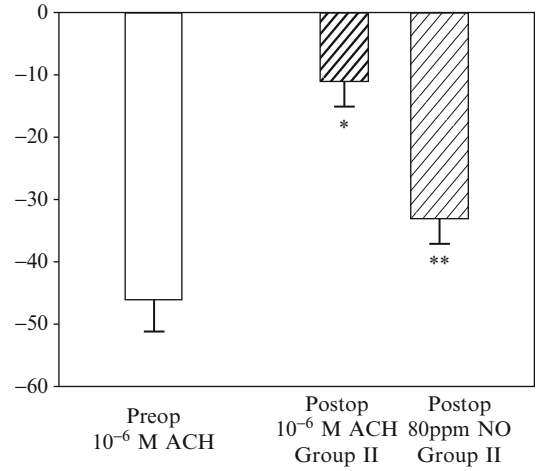

Fig. 122.2 Percentage change in pulmonary artery pressure with acetylcholine (ACH) in preoperative (preop) patients and postoperative (postop) patients. The vasodilating response to acetylcholine is attenuated in postop patients, but the capacity for vasodilation, as indicated by the response to inhaled nitric oxide (NO), is retained [14]

Both animal and isolated organ models of ischemia-reperfusion confirm pulmonary vasoconstriction and increased pulmonary vascular resistance after reperfusion. Wessel et al. ([14], Fig. 122.2) in children and Morita et al. [15] in an animal models showed that this might be related to a decrease in nitric oxide production.

A decrease in the output of nitric oxide from the vascular endothelium is due to either an enhanced inactivation of nitric oxide by free radicals (superoxide breakdown) produced in postischemic tissues or a decrease in endogenous nitric oxide production or combination of both. It has also been suggested that nitric oxide is a physiologically relevant scavenger of free radicals and may be considered as an important cytoprotective modulator.

Thus, nitric oxide may play an important role in mitigating the extent of ischemia-reperfusion injury. Moreover, its antiplatelet and leukocyte properties may be of major importance to prevent platelet aggregation and leukocyte sequestration during and after cardiopulmonary bypass. Several approaches may be adopted to overcome the decrease in nitric oxide availability: either to

increase production through the administration of its precursor L-arginine or citrulline or to substitute with intravenous NO donors, or inhaled NO.

In several animal and human studies, plasma ET-1 concentrations are consistently increased during and following cardiopulmonary bypass. In a study of children with congenital heart disease, the plasma concentration of ET-1 3 h after CPB correlated with the degree of post-CPB pulmonary hypertension, suggesting a role for ET-1 in the pathophysiology of cardiopulmonary bypass-induced pulmonary hypertension. In addition, several animal studies suggest that blockade of endothelin receptors attenuates post-CPB pulmonary hypertension and its associated altered reactivity. Thus, in lambs with preexisting pulmonary hypertension secondary to increased pulmonary blood flow, the increase in pulmonary vascular resistance following bypass was completely blocked in lambs pretreated with either dual or ET_A receptor antagonists. In addition, the augmented pulmonary vascular reactivity following bypass, which is responsible for the potentially life-threatening acute increases in pulmonary vascular resistance, was also completely blocked in those lambs pretreated with endothelin receptor antagonists. A recent study showed that ET_A blockers might have a place in the therapeutic armamentarium.

Taking the particular situation of congenital heart surgery, where preoperative endothelial dysfunction exists in many instances, further injury to the pulmonary endothelium due to ischemia-reperfusion may explain the increased pulmonary vascular resistance occurring in some patients postoperatively.

The pathophysiological events described above give a strong rational to support the use of the therapies discussed hereafter.

Diagnosis

Clinical

Clinical diagnosis is facilitated by the use of indwelling catheters allowing to continuously monitor pulmonary pressure and/or left atrial pressure. During a PH crisis, as the pulmonary pressures increase, patients may display signs of increased right heart preload (atrial pressure) and right heart failure, concomitantly with signs of abruptly decreased left heart preload with low systemic cardiac output. This may be aggravated by compression of the left ventricle by the right ventricle. At this point, there may also appear signs of ischemia by reduction of right coronary flow and patients may desaturate in the presence of right-to-left intracardiac shunts. Patients may also have arrhythmias, persistent hypoxia, or metabolic acidosis.

Chest X-Ray

Chest X-rays are unspecific for the diagnosis of acute pulmonary hypertensive spells although there can appear signs of decreased pulmonary vasculature. Yet, this technique may be useful to rule out triggering factors like volume overload and the presence of added pulmonary disease like atelectasis, pneumothorax, hyperinflation, or pleural effusions.

ECG

The ECG may be useful in patients who develop secondary arrhythmias or ischemic changes throughout a pulmonary hypertensive crisis. In particular, ST elevation with reciprocal ST depression in the inferior and precordial leads may be seen.

Echocardiography

Echocardiography undoubtedly remains the cornerstone technique to rapidly assess pulmonary hypertension and its impact on cardiac function in the intensive care setting [16], mostly in patients who do not have indwelling catheters. It is important to attempt to measure right heart pressures by tricuspid regurgitation, although the interventricular septal geometry may be suggestive of the degree of right ventricular pressure

Fig. 122.3 Echocardiography documenting severe PAH with a markedly enlarged interventricular septum in a long-axis view (*LV* left ventricle, *RV* right ventricle)

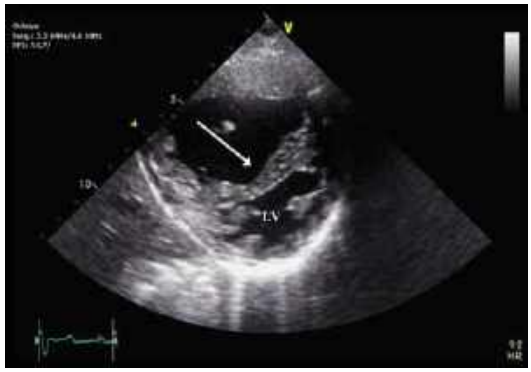

Fig. 122.4 Echocardiography documenting severe PAH with right-to-left shift (*arrow*) of the interventricular septum in a short-axis view (*LV* left ventricle, *RV* right ventricle)

(Figs. 122.3 and 122.4), unless there is a right outflow tract obstruction. Also, the presence of pulmonary regurgitation may allow a more comprehensive estimation of pulmonary diastolic and mean pressures. In patients with residual interventricular shunts, echocardiography may document the systolic pressure gradient and direction of shunt between the atria and ventricles (Figs. 122.5 and 122.6). In patients with pulmonary hypertensive spells, echocardiography is instrumental in assessing right and left ventricular function, the degree of intracardiac shunting if any, and also the presence of residual lesions that might be the origin of the spells. Last but not least, it allows follow-up of therapeutic efficiency.

Management of Pulmonary Hypertension After Cardiac Surgery

Probably the most important measures with these patients concern the *prevention* of pulmonary hypertensive crisis. Potentially malignant pulmonary hypertension spells are usually iso- or suprasystemic and may induce low cardiac output, hypoxia, acidosis, or cardiac arrhythmias.

Sudden pulmonary hypertensive crises may punctuate the postoperative course despite accurate surgery and are associated with significant mortality and morbidity. Even though it has been thought that this may become a relatively unimportant problem because of the recent progress in cardiac surgery, it seems that increased pulmonary vascular resistance after surgery remains a significant problem [17–20]. Potential therapeutic strategies for the treatment of acute pulmonary hypertension after cardiac surgery are summarized in Table 122.1 and will be discussed hereafter.

The primary aim is to decrease pulmonary vascular resistance and pressure and, if not possible, to avoid stimulation of the pulmonary circulation and support right ventricular function through the balance between pulmonary and systemic vascular resistances and maintenance of cardiac output.

Therapeutic Measures

Therapy should be individualized. The main measures concern analgesia and sedation, ventilation, and intravenous and inhaled drugs.

1. *Anatomic Considerations*
   First of all, residual anatomical problems should be excluded as this may be responsible for increased right ventricular pressure as in the case of residual shunts or right ventricular outflow tract obstruction. Thus, anatomic

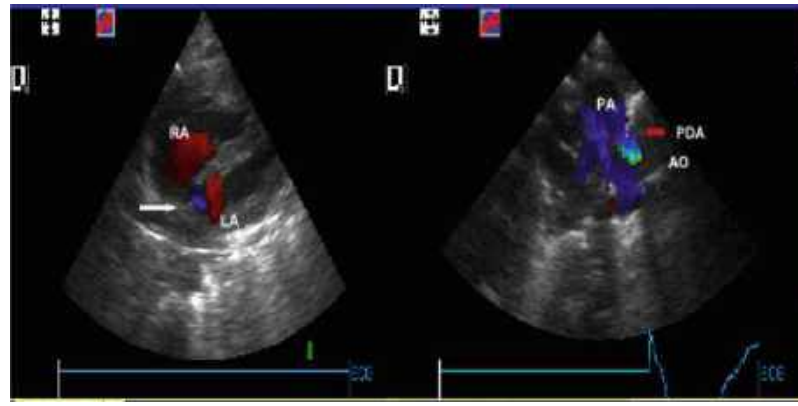

Fig. 122.5 Echocardiography showing severe pulmonary hypertension with a right-to-left shunt through the foramen ovale (*white arrow*) and the ductus arteriosus (*red arrow*)

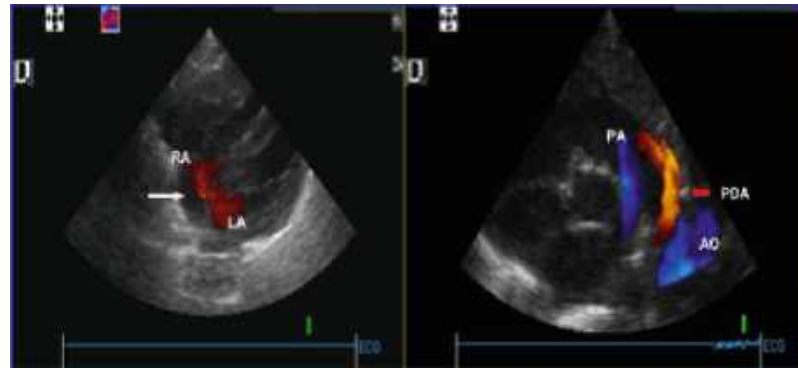

Fig. 122.6 Echocardiography showing significant improvement of pulmonary hypertension after treatment with inhaled nitric oxide, with a left-to-right shunt through the foramen ovale (*white arrow*) and the ductus arteriosus (*red arrow*)

investigations should be performed such as transthoracic or transesophageal echocardiography or catheterization particularly if a potential intervention is anticipated or the patient is not improving.

Anatomy is also important as some measures may help to maintain cardiac output through a right-to-left shunt used as a "pop off" for the right side. Preserving a calibrated atrial septal defect or fenestrated ventricular defect in the patch is a common measure, but some authors advocate the use of a valve patch when a ventricular septal defect is closed ("flap" fenestration of the VSD patch). This may be beneficial to maintain cardiac output but to the detriment of cyanosis. Oxygen delivery is maintained by increasing oxygen delivery. Delayed chest closure may be useful to decrease the constraints on a dilated dysfunctional right ventricle.

2. *Sedation and Analgesia*

Agitation and stress are potential triggers for pulmonary hypertensive crisis and should be avoided. Well-controlled analgesia and sedation should be guaranteed while ensuring spontaneous breathing in stable patients who would be candidates for extubation. However, unstable patients with frequently or poorly tolerated pulmonary hypertensive spells should be kept deeply sedated and eventually on muscle relaxants as required. This is usually achieved with a combination of opioids and benzodiazepines administered as continuous infusions and titrated to effect.

Table 122.1 Summary of therapeutic measures to treat acute pulmonary hypertension (Modified from [21])

Therapeutic approach to PAH	
• ENCOURAGE:	• AVOID:
– Anatomic investigations	– Residual anatomic defects
– Opportunities for right-to-left shunt as a "pop-off"	– Intact atrial septum in right heart failure
– Sedation/analgesia or anesthesia	– Agitation and pain
– Moderate hyperventilation	– Respiratory acidosis
– Moderate alkalosis	– Metabolic acidosis
– "Perfect" metabolic status	– Volume overload
– Adequate inspired oxygen	– Alveolar hypoxia
– Normal lung volumes	– Atelectasis or overdistension
– Optimal hematocrit	– Excessive hematocrit
– Inotropic support	– Low cardiac output and low coronary perfusion
– Vasodilators	– Vasoconstrictors/increased afterload
– Nutritional support	

Other alternatives are available and depend on specific institutional protocols: dexmedetomidine, propofol, and clonidine to mention some. The principle of using minimal efficient doses should be respected as much as possible.

3. *Ventilation and pH*

It is essential to adequately ventilate patients with pulmonary hypertension and to avoid overdistention or atelectasis, known to be potential triggers for increased pulmonary vascular resistance. It is important to remember that pulmonary vascular resistance is normal at normal functional residual capacity (Fig. 122.7).

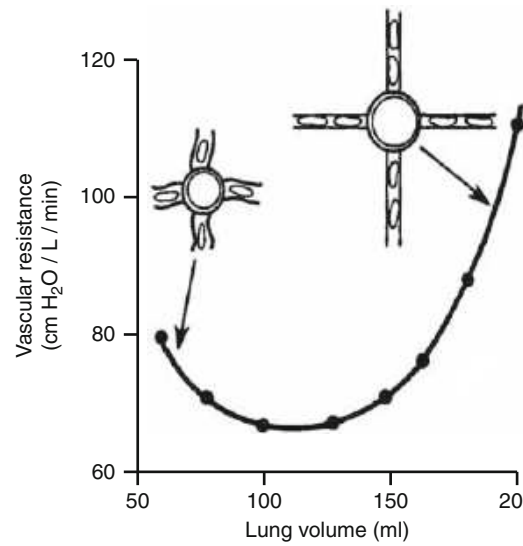

Fig. 122.7 Pulmonary vascular resistance rises in association with very large or very small lung volumes. Pulmonary vascular resistance is lowest at functional residual capacity [22]

Alkalosis induces pulmonary vasodilatation, whereas acidosis induces vasoconstriction (Fig. 122.8). It is known after the work of Chang et al. [24] that the triggers are mainly the pH (hydrogen ion concentration) and not the carbon dioxide levels (Fig. 122.9). The current approach is to maintain a normal or slightly alkalotic pH (as to avoid aggressive ventilation) and only in rare instances to raise pH over 7.5. Morris et al. [26] showed that hyperventilation to increase pH has some deleterious effects such as an increase in systemic vascular resistance that may not be tolerated in the postoperative period. Use of sodium bicarbonate or THAM may be considered in some patients in order to induce alkalosis without the potential deleterious effects of hyperventilation.

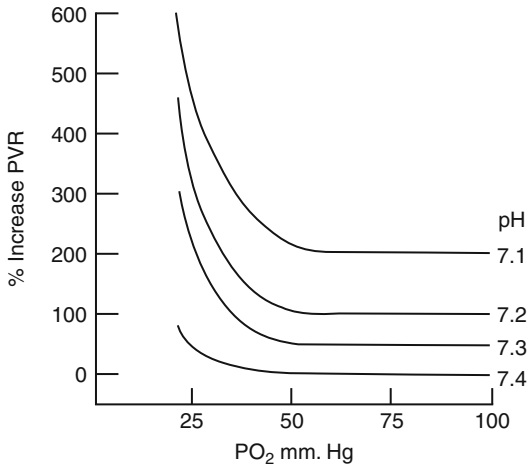

Fig. 122.8 The effects of pH and PO_2 on pulmonary vascular resistance [23]

4. *Oxygenation*
   It is well known that hyperoxia provokes pulmonary vasodilation and that hypoxia induces pulmonary vasoconstriction. It is therefore important to maintain an adequate oxygenation (PO_2 80–100 mmHg) during a pulmonary hypertensive crisis and with patients at risk to develop these problems. This is obtained with the administration of oxygen and again adequate ventilation ensuring a proper lung volume. However, the effect of oxygen seems not so clear in the setting of pulmonary hypertension after cardiac surgery as well as in the so-called fixed lesions. One must also remember that high levels of inspired oxygen may be deleterious and induce lung damage.
5. *Vasodilator Drugs*
   Pulmonary hypertension may be treated with intravenous or with inhaled vasodilators.

   Various intravenous vasodilators such as tolazoline, prostacyclin, phenoxybenzamine, phentolamine, and nitrodilators have been used in the past to reduce pulmonary arterial pressure. However, their lack of selectivity and inconsistent efficacy are a limiting factor; these drugs carry a risk of systemic hypotension among others, which may be undesirable after cardiac surgery.

   In this setting, there is a particular appeal in the therapeutic opportunities afforded by new strategies acting through a selective effect on the pulmonary vascular bed such as inhaled nitric oxide or inhaled prostacyclin.

   Inhaled nitric oxide (*iNO*) improves right ventricular systolic function by decreasing its afterload while increasing left ventricular preload, restoring aortic pressure and coronary perfusion [14, 27–31]. In patients with poor left ventricular function, iNO should be used cautiously since the preload increase may be deleterious.

   Wessel et al. [14] showed that pulmonary endothelial dysfunction was present after cardiopulmonary bypass; thus, the response to acetylcholine was attenuated, but the response to inhaled nitric oxide was maintained (Fig. 122.2). These authors hypothesized that a dysfunctional endothelium with reduced endogenous nitric oxide release may contribute to postoperative pulmonary hypertension. Journois and collaborators [30, 31] demonstrated that inhaled nitric oxide was a useful therapy for pulmonary hypertensive crises refractory to conventional treatment. According to Miller et al. [32, 33], even low doses of nitric oxide (2 ppm) appear to be effective in such patients (Fig. 122.10). Beghetti et al. [34, 35] showed that the effect of low-dose nitric oxide was maintained over several days at concentrations carrying little risks of toxicity. Nitric oxide has been used with success in several different congenital heart defects where increased pulmonary vascular resistance may complicate the postoperative course such as mitral valve stenosis, total anomalous pulmonary venous return, bidirectional Glenn anastomosis, and the Fontan circulation. It also appears useful after cardiac and/or lung transplant. However, a beneficial effect in patients with cavopulmonary anastomosis is not consistently reported and despite an increase in cGMP levels [36]. Inhaled nitric oxide augments right ventricular function after left ventricular assist device implantation, perhaps through an increase in pulmonary venous return and left atrial pressure, thus facilitating pump flow.

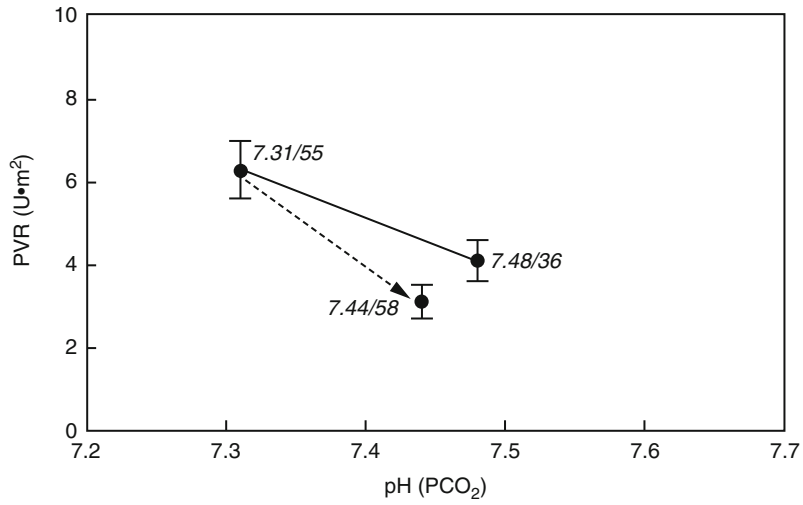

Fig. 122.9 Among 15 postoperative patients who were hypoventilated to a $PaCO_2$ of 55 mmHg, pulmonary vascular resistance increased. This was completely reversible using bicarbonate infusion without any change in Pco_2, supporting the widely accepted thesis that pH, not Pco_2, is the important determinate of pulmonary vascular resistance related to changes in ventilation [25]

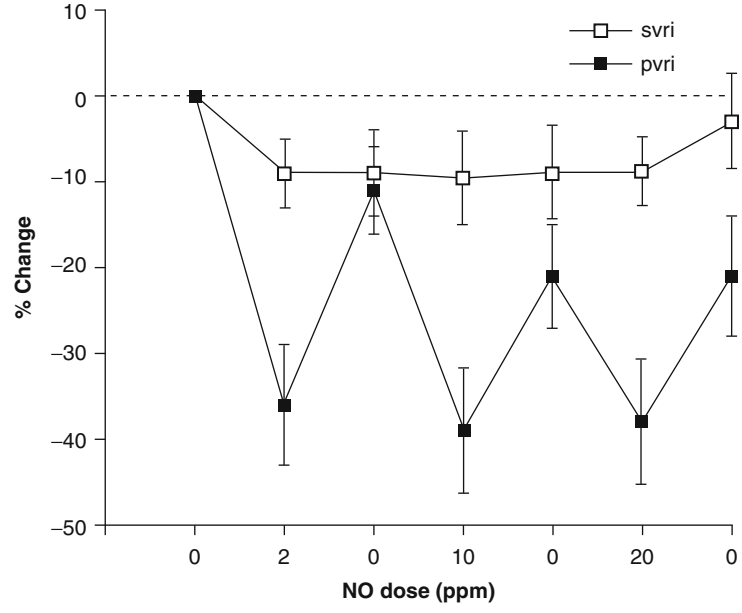

Fig. 122.10 Low doses of inhaled nitric oxide cause selective pulmonary vasodilation [32]

Patients who remain dependent on NO and have rebound pulmonary hypertension (Fig. 122.11) upon its withdrawal are candidates to therapy with sildenafil as a strategy to wean the NO [38].

Inhaled prostacyclin is increasingly used as delivered by aerosol and may overcome the necessity of a special device to deliver NO. Several series have been published with epoprostenol or iloprost (Fig. 122.12) [40–44] and prospective studies are underway, but one of the major problems is to define the dose to be delivered as well as the exact dose delivered when the drug is administered in ventilated patients.

Phosphodiesterase type 5 (PDE-5) inhibitors block the degradative action of PDE5 on cyclic GMP in the smooth muscle cells; PDE-5 is increased in PH. Specific PDE-5 inhibitors, such as sildenafil, promote an increase in cGMP levels and thus promote pulmonary vasodilation and remodeling [59–62].

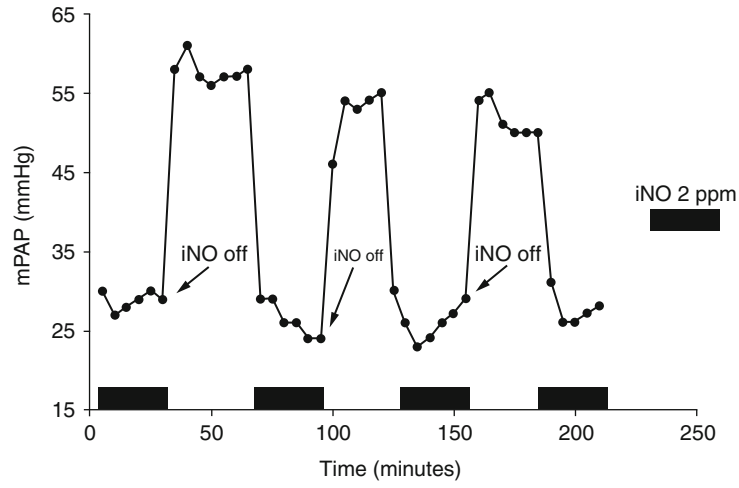

Fig. 122.11 Withdrawal of inhaled nitric oxide may lead to "rebound" pulmonary hypertension with a fall in systemic arterial pressure and rise in pulmonary artery pressure [37]

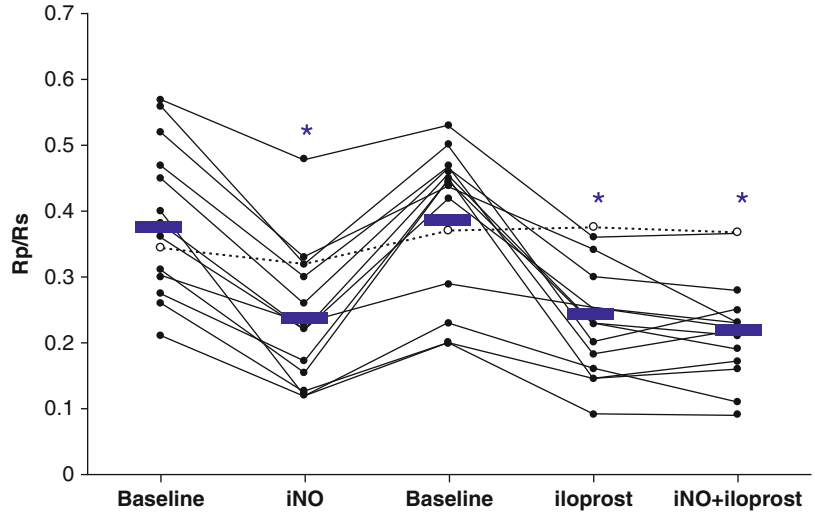

Fig. 122.12 Inhaled iloprost is a selective pulmonary vasodilator and has similar hemodynamic effects as inhaled nitric oxide [39]

Sildenafil is as effective a pulmonary vasodilator as inhaled NO. Sildenafil may also be useful in the setting of inhaled NO therapy withdrawal (Fig. 122.13) in postoperative pulmonary hypertension or in the presence of PH related to chronic lung disease [41–47].

Intravenous sildenafil has been shown to potentiate the increase in cGMP in response to NO in children with increased PVR related to CHD or in the postoperative state. Nevertheless, sildenafil infusion has been associated with increased intrapulmonary shunting and augmentation of hypoxemia related to ventilation/perfusion mismatch in the postoperative CHD patient [46, 47]. However, a recent study of intravenous sildenafil has shown improvement in oxygenation index in PPHN in patients treated with or without inhaled NO [48]. In a double-blind, multicenter, placebo-controlled, dose-ranging, parallel-group trial in postoperative pulmonary hypertension, one of three doses of intravenous sildenafil, or placebo, was given, for a minimum of 24 h. Although the sponsor terminated the study after 15 months owing to slow patient accrual, intravenous sildenafil reduced pulmonary

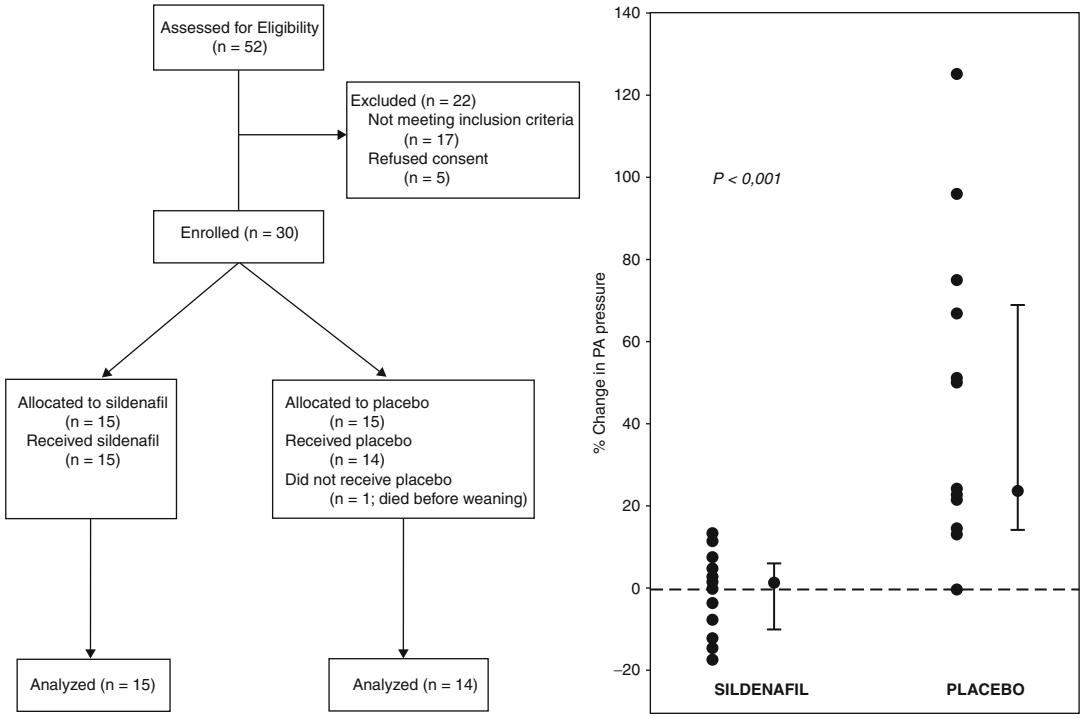

Fig. 122.13 In a randomized trial of sildenafil versus placebo during nitric oxide withdrawal, sildenafil blunted the rise in pulmonary artery pressure during nitric oxide withdrawal [45]

artery pressure and shortened time to extubation and intensive care unit stay in children with postoperative PH (Fig. 122.14) [49].

6. *Inotropic and Vasoactive Drugs*
   After surgical correction of patients with preoperative pulmonary hypertension or under significant risk for postoperative pulmonary hypertensive spells, most centers initiate milrinone [50–57] and a low dose (less than 5 μg/kg/min) of dopamine or dobutamine for right ventricular dysfunction. Low doses of epinephrine may be added for further inotropic effect.

   Right ventricular function may be compromised following congenital heart disease repair because of cardiopulmonary bypass and direct injury by the surgical procedure itself (Fig. 122.15). Increased pulmonary vascular resistance further compromises right ventricular function; as a result the right ventricle becomes dilated and induces an "intrapericardial tamponade" effect on the left ventricle. This in turn results in secondary diastolic dysfunction of the left ventricle which further reduces cardiac output leading to aortic hypotension and coronary hypoperfusion of the right ventricle.

   The effect of the usual inotropes such as epinephrine or dopamine on the right ventricle as well as the potential deleterious effect on the pulmonary vascular resistance is still matter of debate. It is anyway tempting and justified to use catecholamines in this setting trying to find a balance between the potential beneficial and the detrimental effects. Epinephrine can improve cardiac function but is known to be deleterious to the myocardium if used at high doses and for a prolonged period of time. However, it may still have a place at low dose. Norepinephrine through an increase in SVR may improve coronary perfusion and as such improve right ventricular function. The use of systemic vasoconstrictors is supported by an animal model of acute right heart failure,

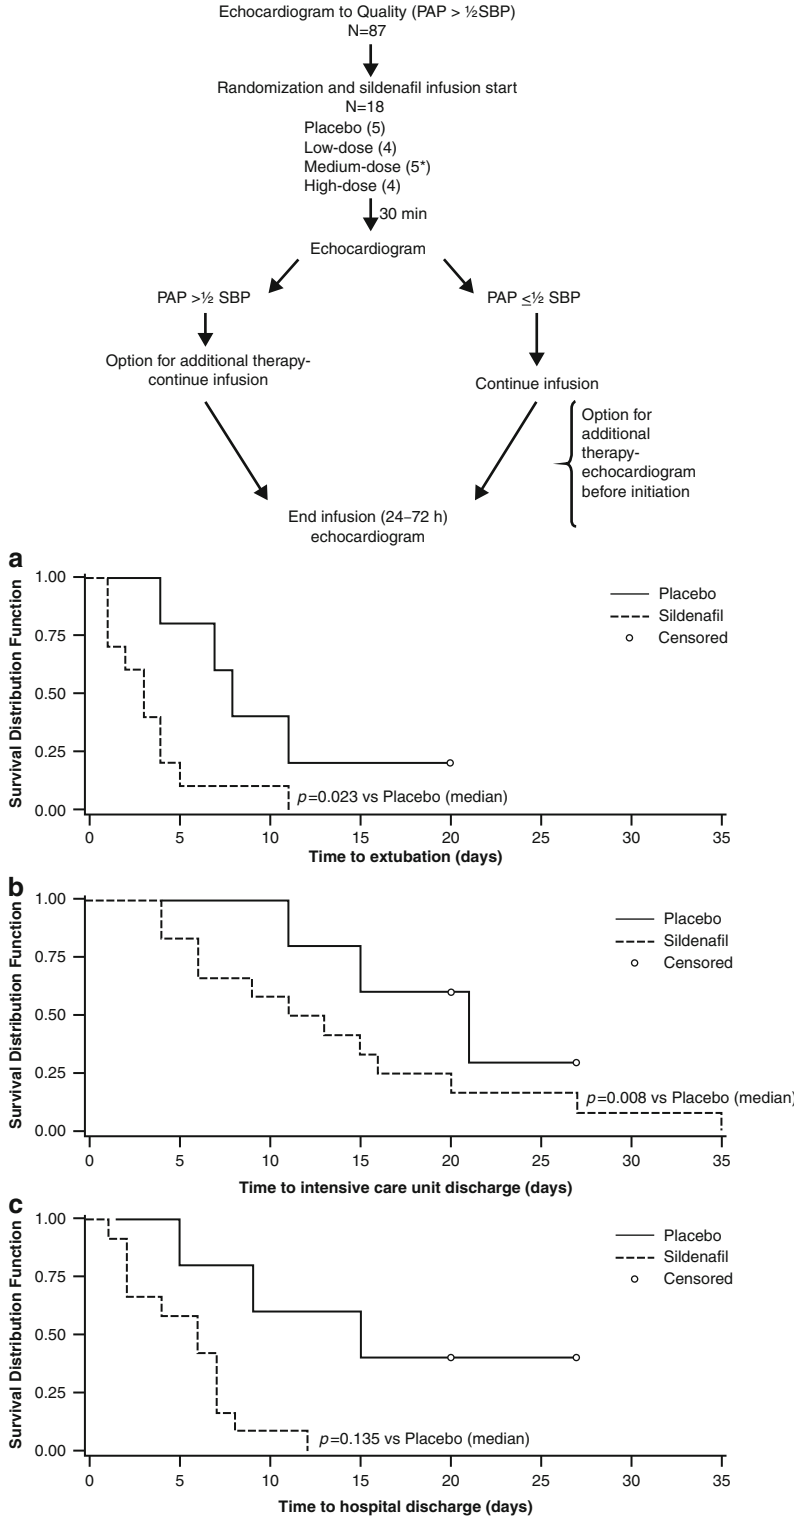

Fig. 122.14 Compared with placebo, intravenous sildenafil in a postoperative trial (*left*) improved survival and decreased time to extubation and time to intensive care unit discharge [49]

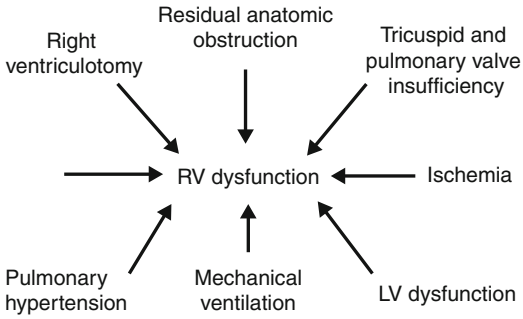

Fig. 122.15 Multiple mechanisms may contribute to right ventricular dysfunction in the postoperative congenital heart patient [10]

in which RV functional performance with increased cardiac output was achieved by administration of vasopressors, such as norepinephrine and epinephrine [58]. The virtues of these drugs should be balanced against their side effects.

The finality is that the perfect drug should improve myocardial performance and vasodilate the pulmonary vascular bed without inducing tachycardia and increasing oxygen consumption. Milrinone is a phosphodiesterase inhibitor that may have some of these properties and it is increasingly used in postoperative care. The role of type 5 phosphodiesterase inhibitors in the presence of pulmonary hypertension has a major interest, but type 3 inhibitors such as milrinone have been by far more studied and largely used in pediatric practice.

Some new therapies are under development. Nesiritide or natriuretic hormone shows some synergistic effect with nitric oxide and sildenafil, but so far the available data is not sufficient and further studies are required. The same principle applies to levosimendan, a calcium sensitizer that enhances contractility and has some vasodilatory properties without increasing myocardial oxygen consumption. Levosimendan has also been shown to have some pulmonary vasodilator effects in the presence of acute pulmonary hypertension, but so far data in children is scarce and further studies are also needed.

Conclusion

Management of pulmonary hypertension in the cardiac intensive care setting should be multifactorial and multidisciplinary as it remains challenging and still carries, even if decreased compared to the previous decade, a significant mortality and morbidity. An increased knowledge of the mechanisms as well as the introduction of new therapies has led to better prognosis. Appropriate therapy requires firstly the identification of the potential cause. Besides the pharmacological approach, caregivers should consider the creation of anatomic paths to decompress the right ventricle, as the final cause of death remains ventricular failure.

Vascular Rings and Slings

123

Carl L. Backer, Andrada R. Popescu, Jeffrey C. Rastatter, and Hyde M. Russell

Abstract

Since the mid-1940s, the phrase "vascular ring" has referred to congenital vascular anomalies of the aortic arch system that encircle and compress the esophagus and trachea causing various symptoms. The concept of vascular sling was described five decades later. The diagnosis of vascular ring or pulmonary artery sling should be suspected in any infant or child presenting with symptoms of respiratory distress, noisy breathing, or dysphagia. Suspicion of the diagnosis is often generated by the plain chest x-ray. However, the diagnosis is best established by CT imaging which accurately delineates the anatomy of the vascular ring and the associated tracheal pathology. All patients diagnosed with a vascular ring should have an echocardiogram because of the incidence of associated congenital heart disease.

Bronchoscopy should be performed in all cases to assess for additional tracheal pathology and to provide a clinical assessment of the degree of tracheomalacia and bronchomalacia. This chapter aims to overview the embryology, the anatomy and pathophysiology, the clinical presentation and diagnosis, and the management of the entities included in the spectrum of vascular rings and slings.

Keywords

Aberrant right subclavian artery • Anomalies • Aortic arch syndrome • Complete tracheal rings • Congenital • Double aortic arch • Esophageal stenosis • Innominate artery compression syndrome • Pulmonary artery • Pulmonary artery sling • Right aortic arch • Tracheal stenosis • Vascular malformations

Introduction

The phrase "vascular ring" was coined by Robert Gross in his classic paper in the *New England Journal of Medicine* from 1945 [1]. At that time, Gross described the first successful division of a double aortic arch. Within that article, Gross stated the following:

> A ring of blood vessels was found encircling the intrathoracic portion of the esophagus and trachea... The pathologic findings at once suggested that a division of some part of the *vascular ring* during life would have relieved the pressure of the constricted trachea and esophagus.

Since that time, the phrase "vascular ring" has referred to congenital vascular anomalies of the aortic arch system that encircle and compress the esophagus and trachea causing various symptoms. Figure 123.1 is an autopsy photograph of a child who died with a double aortic arch. The compression of the trachea and esophagus is quite apparent. In the current era, a child such as this would be diagnosed with a computed tomographic angiogram (CTA) as shown in Fig. 123.2. The ability in the current era to define the anatomy so precisely is a great aid to the surgeon in managing these patients. Gross was also the first to describe the other classic vascular ring, that is, the right aortic arch with retroesophageal left subclavian artery and left ligamentum arteriosum [1].

The surgical experience at Ann & Robert H. Lurie Children's Hospital of Chicago began with a case report by Willis J. Potts published in the *Archives of Surgery* in 1948 [2]. Potts reported two patients with double aortic arch. Potts also was the first to report successful repair of pulmonary artery sling [3]. This is a rare vascular anomaly where the left pulmonary artery originates from the right pulmonary artery and encircles the distal trachea en route to the left lung. In 1954, Potts reported intraoperative diagnosis and repair of a pulmonary artery sling in a 5-month-old infant with intermittent attacks of dyspnea and cyanosis. The repair was done through a right thoracotomy utilizing the Potts ductus clamps. Beginning with those two case reports, the series of children undergoing an operation for a vascular ring or pulmonary artery sling at Lurie Children's has grown dramatically as illustrated in Fig. 123.3. The total experience with double aortic arch, right aortic arch, and pulmonary artery sling is shown in Table 123.1. This experience forms the basis for this chapter. The classification of vascular rings used at Lurie Children's is based on anatomic and clinical features of the patients, in particular the location of the aortic arch(es). This classification scheme has been endorsed by the International Congenital Heart Surgery Nomenclature and Database Project for the Society of Thoracic Surgeons [4].

Clinical Presentation and Diagnosis

The classic presentation of a child with a symptomatic vascular ring is noisy breathing and a "seal bark" cough. Other frequent symptoms are wheezing, recurrent upper respiratory tract infections, dyspnea on exertion, and dysphagia. Apnea and apparent life-threatening events can also occur. Some children may have severe respiratory distress requiring intubation and ventilation. Dysphagia usually occurs in older children and is mostly a problem when taking solid foods. A classic symptom is that the child (because they have learned to chew their food very carefully) is the last to leave the table at dinner time. A table of symptoms leading to clinical presentation is shown in Table 123.2.

The diagnostic evaluation of a patient with a vascular ring should proceed in a stepwise fashion until adequate information has been obtained

Table 123.2 Symptoms leading to clinical presentation in patients with vascular rings[a]

	Double aortic arch (n = 80)[b]	Right aortic arch (n = 78)[b]
Stridor	46 (57%)	18 (23%)
Recurrent upper respiratory tract infections	22 (27%)	18 (23%)
Cough	17 (21%)	8 (10%)
Dysphagia	12 (15%)	12 (15%)
Respiratory distress	8 (10%)	13 (17%)
Ventilator preoperatively	7 (9%)	3 (4%)

From Backer et al. [5]
[a]More than one symptom occurred in many patients
[b]Our records did not provide symptoms for the earlier patients in the series

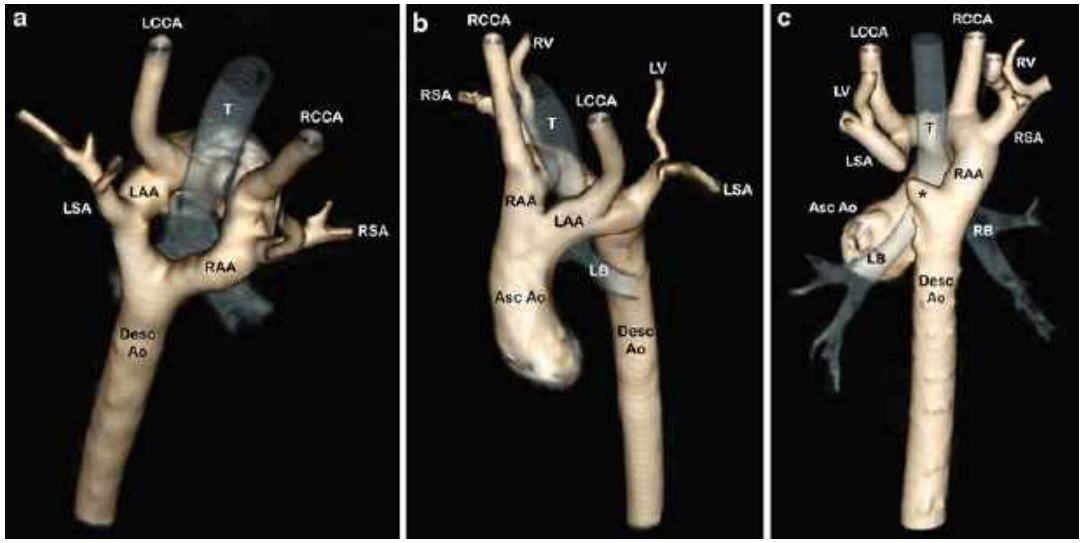

Fig. 123.4 (**a–c**) Contrast-enhanced CT angiograms with 3D multiplanar reformat of children with a double aortic arch. (**a**) Posterior view of balanced arches, (**b**) sagittal oblique view (same patient), and (**c**) posterior view of dominant right aortic arch with left arch atretic between the left subclavian artery takeoff and a small diverticulum (*asterisk) that extends off of the descending aorta. *Asc Ao* ascending aorta, *Desc Ao* descending aorta, *LAA* left aortic arch, *LB* left bronchus, *LCCA* left common carotid artery, *LSA* left subclavian artery, *LV* left vertebral, *RAA* right aortic arch, *RB* right bronchus, *RCCA* right common carotid artery, *RSA* right subclavian artery, *RV* right vertebral, *T* trachea

for the surgeon to intervene. These authors' diagnostic strategies have changed significantly over the past decade. The primary means of diagnosis in the current era is computed tomography (CT) [6]. With the newest generation of dual source CTs the evaluation can be completed in less than 1 s without the need for intubation and with a considerable reduction in radiation dose. The information obtained from a CT allows for precise planning of the surgical strategy. Examples of CT are shown in Figs. 123.4a–c (double aortic arch) and 123.5a, b (right arch).

The use of computed tomography has replaced barium swallow (Fig. 123.6) as the primary means of diagnosis. Some centers prefer magnetic resonance imaging (MRI), but this requires a longer time period to obtain and often needs sedation and intubation. MRI also does not give as clear a picture of the tracheal lumen. Other examinations that can lead to a strong suspicion

of a vascular ring include chest radiograph, bronchoscopy, and echocardiogram.

The chest radiograph is the most common place to start the evaluation. The chest radiograph will establish the location of the aortic arch whether it is a normal left aortic arch, a right aortic arch, or an indeterminate aortic arch (likely a double aortic arch). Some children who present primarily with noisy breathing or chronic cough will undergo bronchoscopy as their first examination. Bronchoscopic examination will show an extrinsic, often teardrop-shaped (often pulsatile) compression of the trachea. This leads to the suspicion of a vascular ring which can be confirmed by computed tomography. Initially, echocardiography was believed to be an excellent way to diagnose vascular rings. However, because structures that do not have blood passing through them are not visible with echocardiography, this has not become as important a diagnostic tool as was originally thought. However, an echocardiogram is highly recommended in all patients diagnosed

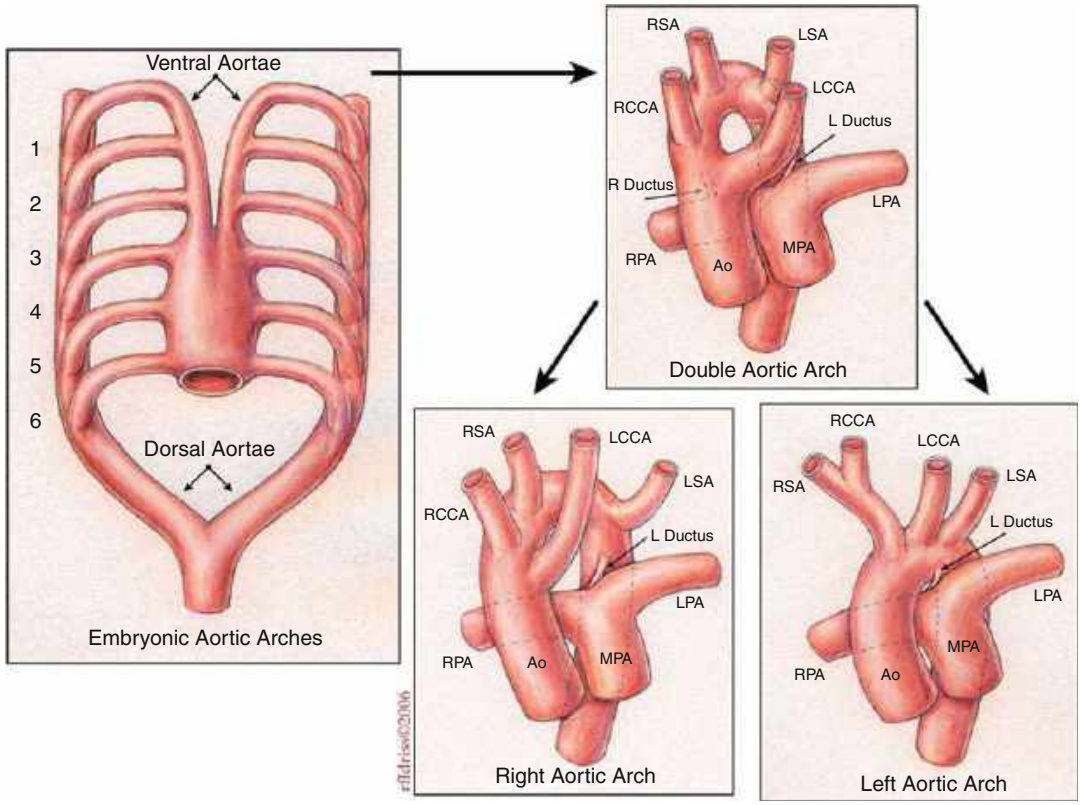

Fig. 123.7 Embryonic aortic arch development. Six pairs of aortic arches originally develop between the dorsal and ventral aorta. The first, second, and fifth arches regress. Preservation or deletion of different segments of the remaining arches results in either a double aortic arch, a right aortic arch, or the "normal" left aortic arch. *Ao* aorta, *CCA* common carotid artery, *L* left, *PA* pulmonary artery, *R* right, *SA* subclavian artery (Reprinted with permission from Backer CL, Mavroudis C, Stewart RD, Holinger LD. Congenital anomalies: vascular rings. In: Patterson GA, Cooper JD, Deslauriers J, Lerut AE, Luketich JD, Rice TW (eds): Pearson's Thoracic and Esophageal Surgery, Philadelphia, Church Livingstone Elsevier, 2008, 242–255)

with a vascular ring because of the 12 % incidence of associated cardiac pathology [5].

Embryology

The embryologic origin of vascular rings depends on varying involutions, regressions, and persistence of components of the embryonic arch system. The embryonic aortic arch system consists of a ventral and dorsal aorta connected by six primitive aortic arches (Fig. 123.7). In the development of the aortic arch, the first, second, and fifth aortic arches initially involute to form Edwards' classic aortic arch [7]. If the arch development arrests here, the patient will have a double aortic arch, a type of vascular ring. If the right fourth arch involutes, a normal left aortic arch is formed and the patient will not have a vascular ring. If the left fourth arch involutes and the right aortic arch remains patent, the patient will have a vascular ring malformation now referred to as a right aortic arch, retroesophageal left subclavian artery, and left ligamentum. There can be a great deal of variation within these major groupings depending on the positioning of the right and left carotid arteries, right and left subclavian arteries, and the location of the patent ductus arteriosus which later becomes the ligamentum arteriosum. As mentioned in the "Clinical Presentation and Diagnosis" section of this chapter, a number of these patients will have associated anomalies. Of particular importance is the 12 % incidence of

associated cardiac pathology. However, the most important association is that between pulmonary artery sling and tracheal stenosis secondary to complete cartilaginous tracheal rings. This is called the ring-sling complex [8]. In patients diagnosed with a pulmonary artery sling, two-thirds will have a tracheal stenosis caused by congenital cartilage tracheal rings. If starting with a diagnosis of tracheal stenosis, fully one-third of those patients will be found later to have a pulmonary artery sling.

Indications and Surgical Technique

The great majority of patients with a vascular ring will have clinical symptoms. Patients with clinical symptoms and a vascular ring or pulmonary artery sling require surgical intervention. The repair should be performed at the time of diagnosis to help avoid serious complications that occur from apnea, hypoxic episodes, or severe respiratory upper tract infections requiring intensive care unit admission. Other reported complications from unrepaired vascular rings include aortic dissection, aortic aneurysm, and catastrophic bleeding that can occur when patients have indwelling nasogastric tubes, indwelling endotracheal tubes, or tracheostomy tubes [9–12]. In the current era of imaging, patients are often referred when a vascular ring is discovered, but the patient appears to be "asymptomatic." Careful questioning of these patients often reveals symptoms related to their respiratory function and swallowing.

Double Aortic Arch

Infants with a double aortic arch tend to present earlier in life than patients with a right aortic arch. The great majority of these patients will have symptoms before 1 month of age. This is in contrast to patients with a right aortic arch where nearly 50 % do not have symptoms until after 1 month of age. There are three main anatomic types of double aortic arch. The most common is a dominant right aortic arch with a smaller left aortic arch (80 %) (Fig. 123.8). A dominant left

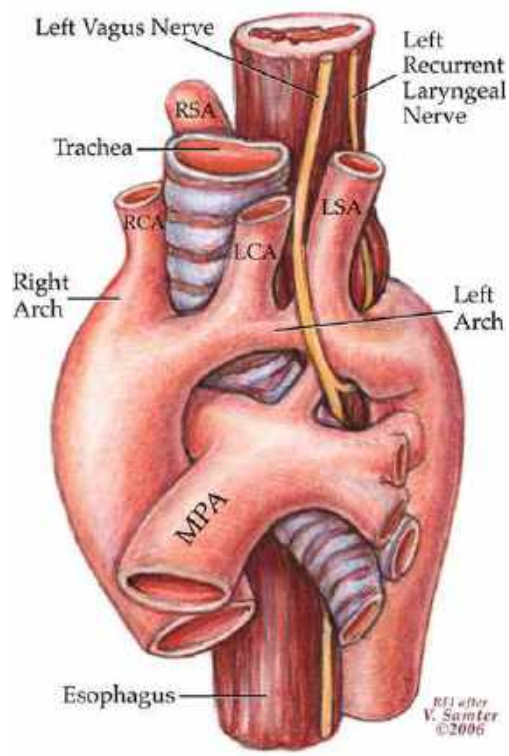

Fig. 123.8 Double aortic arch. Right (posterior) arch is dominant. The smaller left arch is patent. *LCA* left carotid artery, *LSA* left subclavian artery, *MPA* main pulmonary artery, *RCA* right carotid artery, *RSA* right subclavian artery (Reprinted with permission from: Backer CL, Mavroudis C, Stewart RD, Holinger LD. Congenital anomalies: vascular rings. In: Patterson GA, Cooper JD, Deslauriers J, Lerut AE, Luketich JD, Rice TW (eds): Pearson's Thoracic and Esophageal Surgery, Philadelphia, Church Livingstone Elsevier, 2008, 242–255)

aortic arch is found in 10 % of patients. "Balanced" aortic arches are found in the remaining patients (10 %) although these patients often have subtle signs that one arch is larger than the other, on CT imaging (Fig. 123.2). The most common approach to the double aortic arch is through a left thoracotomy using a muscle-sparing technique. However, for the patient with a dominant left aortic arch, an approach through a right thoracotomy is recommended. This emphasizes the importance of precise preoperative imaging using the CT scan. The chest is entered through the fourth intercostal space. The pleura overlying the vascular ring is opened. This opening in the pleura should be somewhat anterior rather than

posterior in order to avoid the thoracic duct. Careful dissection is performed to clearly identify all of the pertinent vascular structures. In particular, the recurrent laryngeal nerve must be carefully identified and carefully protected from injury. Some patients with double aortic arch will have atresia of the smaller arch at the distal portion of the arch. This occurs in approximately one-third of patients with a double aortic arch. The site of atresia is usually where the lesser arch inserts into the descending thoracic aorta. There are occasional patients who will have coarctation of one or both of the aortic arches.

The surgical intervention should be directed at dividing the smaller of the two arches at a site that does not compromise the flow of blood to the head vessels or lower body. The intended arch to be divided is temporarily occluded while the anesthesiologist carefully checks blood pressure and pulses above and below the site of the temporary occlusion. The use of pulse oximetry can facilitate this portion of the procedure. The arch is divided between vascular clamps, and the divided stumps are oversewn with polypropylene suture (Fig. 123.9). These authors recommend dividing only a portion of the arch and placing sutures on each side of the partially divided arch before completely dividing the arch. This helps ensure the arch does not slip out of the vascular clamp. The Potts ductus clamp which has small teeth to grip the arch is used in our practice. The oversewn arch should be reinforced with several interrupted prolene sutures. This helps to ensure prevention of catastrophic hemorrhage. When the stumps divide, they typically separate by 1–2 cm (Fig. 123.10). They may also disappear into the posterior mediastinum. Hence, precise hemostasis prior to clamp release is of paramount importance.

Some surgeons have reported thoracoscopic division of vascular rings using hemoclips [11–13]. This technique is not used at our institution. There is a risk of hemorrhage should a clip slip off a vessel when the vessel retracts. Hence, this technique is most applicable for those patients who have an atretic arch. However, our experience using a muscle-sparing thoracotomy has been that there is limited morbidity from the incision. The advantage of full exposure and

access to vessels should there be any bleeding outweighs the cosmetic advantage of the thoracoscopic approach.

At the conclusion of the operation, the mediastinal pleura is left widely open. This helps decrease the chance that recurrent scar tissue could form and cause recurrent stenosis in the area of the ring division. In these authors' practice, it has been noted that in several patients operated elsewhere who have had recurrence of their symptoms and at reoperation, it was noted that the pleura was closed at the initial operation. These patients developed significant scar tissue which was quite dense.

The operative repair is completed by dividing any adhesive bands surrounding the esophagus in the area of the divided vascular ring. Division of these small bands was emphasized by Gross in his earlier papers [1]. In the current era, all patients are drained with a small Silastic Blake drain (Ethicon, Inc., Somerville, NJ). These drains are very soft and well tolerated. They help ensure rapid diagnosis should there be any hemorrhage in the postoperative period and are also useful for demonstrating chylothorax prior to significant pleural effusion accumulation. The child is extubated in the operating room and monitored in the cardiac care unit for 48–72 h. It should be noted that many patients have residual tracheal and/or bronchomalacia following the operation. The parents are counseled that it may take up to 1 year for the child's noisy breathing to disappear as this malacia caused by the vascular ring resolves over a period of time.

Results

Since the first successful case performed at Ann & Robert H. Lurie Children's Hospital of Chicago in 1947 by Dr. Willis Potts, 145 patients have had repair of a double aortic arch. Mean age was 2.86 years and median age 1.17 years. There has been no operative mortality since 1952. Two patients have required a reoperation for recurrent symptoms. In both cases, this occurred from scar tissue that developed at the site of the divided posterior left arch. There has been a 2 % incidence of chylothorax. Several of these patients have been treated by rapid return to the operating room (3–5 days) for oversewing of a leaking lymphatic at the site of the dissection. This has improved the postoperative length of stay following this complication. In other patients, rapid resolution of the chylothorax has occurred with the adoption of a fat-free diet. This management has been facilitated by the use of the Blake drain at the time of the operation for monitoring the pleural fluid character.

Right Aortic Arch

These children typically present somewhat later in life than patients with a double aortic arch. Most of these patients develop symptoms between 1 and 6 months of age. The ring is anatomically "looser" as it is partially formed by the low-pressure pulmonary artery and the ligamentum which does not have blood flow. There are two primary branching patterns of the brachiocephalic vessels in patients with an aortic arch. The first is a retroesophageal left subclavian artery (Fig. 123.11) and the second is mirror-image branching (Fig. 123.12). Sixty-five percent of the patients have a retroesophageal left subclavian artery, and 34 % of the patients have mirror-image branching. With a retroesophageal left subclavian artery, the first branch off of the ascending aorta is the left carotid artery, the second branch is the right carotid artery, and the third branch is the right subclavian artery. The left subclavian artery originates from the descending thoracic aorta adjacent to the takeoff of the ligamentum arteriosum. It is the base of this left subclavian artery that is frequently formed by a dilatation referred to as "Kommerell diverticulum" [14]. The Kommerell diverticulum is a remnant of the fourth aortic arch. In patients with mirror-image branching, the first branch off of the ascending aorta is a left innominate artery that contains both the left carotid and the left subclavian arteries. The second branch is the right carotid artery. The third branch is the right subclavian artery. In these patients, the ligamentum

arteriosum either may insert into the descending thoracic aorta causing a vascular ring (Fig. 123.13) or may originate from the innominate artery, not causing a vascular ring (Fig. 123.14a, b). Right aortic arch is much more common in patients with tetralogy of Fallot and in patients with common arterial trunk. However, these patients do not appear to have an increased incidence of vascular rings because in many of these cases, the ligamentum originates from the innominate artery.

For patients with a right aortic arch and left ligamentum, the surgical approach is through a muscle-sparing left thoracotomy, again through the fourth intercostal space. The lung is retracted anteriorly and the pleura is opened. This incision should be relatively close to the vagus nerve, but not so close as to injure the vagus and left recurrent laryngeal nerve. Again, this will help avoid entry into the thoracic duct which is typically found in the more posterior mediastinum. The ligamentum is carefully dissected. The ligamentum can be divided either between silk ligatures reinforced with prolene suture or divided between vascular clamps with oversewing of the two stumps (Fig. 123.15a–c). Release of the ligamentum should lead to a separation of the two stumps of the ligamentum by 1–2 cm.

There is a subset of patients as mentioned earlier who have an origin of the left subclavian

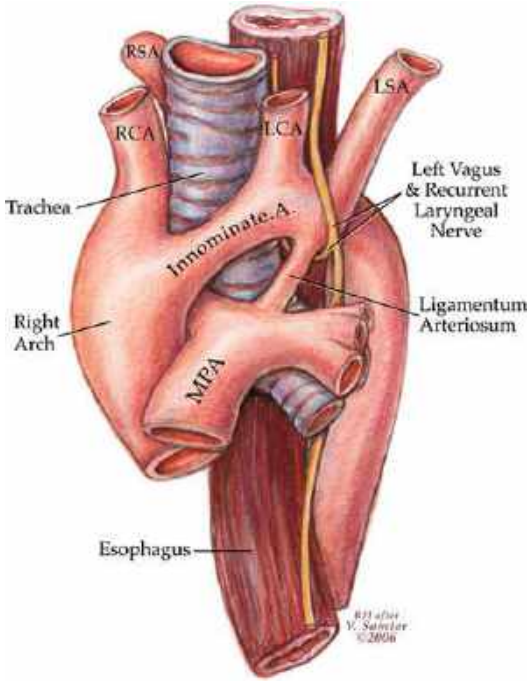

Fig. 123.13 Right aortic arch, mirror-image branching with ligamentum from innominate artery. In this case, a vascular ring is not formed. *Innominate A* innominate artery, *LCA* left carotid artery, *LSA* left subclavian artery, *MPA* main pulmonary artery, *RCA* right carotid artery, *RSA* right subclavian artery (Reprinted with permission. artery from a Kommerell diverticulum. A significant Kommerell diverticulum is defined as an aneurysmal bulging of the base of the subclavian artery which is more than 1½ to 2 times the size of the subclavian artery. In many of these patients, the Kommerell diverticulum is an independent cause of the compression of the posterior portion of the esophagus and trachea. This will be visible on the CTA (Fig. 123.5a, b) and on the preoperative bronchoscopy. Should there be a significant Kommerell diverticulum, resection of the latter and transfer of the left subclavian artery to the left carotid artery is recommended (Fig. 123.15a–c). This operation is clearly more complex than simple ligamentum division. The patient is given 100 units/kg of heparin prior to applying the vascular clamps. The base of the Kommerell diverticulum is occluded with a vascular clamp that also occludes a portion of the wall of the descending thoracic aorta (Fig. 123.15a). Flow to the lower body is maintained by assessing the lower extremity blood pressure with a test occlusion of the clamp. The left subclavian artery can be controlled by a small vascular hemoclip. The Kommerell diverticulum is resected (Fig. 123.15b). The stump on the aorta is carefully oversewn with running prolene suture in two layers. This is reinforced with multiple interrupted prolene mattress sutures prior to releasing the clamp. Staged oversewing and division techniques are recommended here to prevent slipping of the

(**b**) Resection of a Kommerell diverticulum through a left thoracotomy. There is a vascular clamp partially occluding the descending thoracic aorta at the origin of the Kommerell diverticulum. The Kommerell diverticulum has been completely resected. The clamp on the distal left subclavian artery is not illustrated. (**c**) The completed repair. The orifice where the Kommerell diverticulum was resected is usually closed primarily, or, as shown in the inset, the orifice can be patched with polytetrafluoroethylene if necessary. The left subclavian artery has been implanted into the side of the left common carotid artery with fine running polypropylene suture. Resection of Kommerell's diverticulum and left subclavian artery: transfer for recurrent symptoms after vascular ring division (Reprinted with permission. Eur J Cardiothorac Surg. 2002;221:64–69)

vessels through the clamps. The left common carotid artery is then identified in the posterior mediastinum. Typically, it lies in a space where the vagus nerve is anterior and the left recurrent laryngeal nerve as it recurs up towards the neck where it is posterior. It is in a plane between these two structures that the common carotid artery can be identified. The artery is encircled in a vessel loop and is pulled into the field. A vascular clamp is placed to completely occlude the artery. Arteriotomy is performed and an anastomosis to the left subclavian artery is performed with running prolene suture. The system is de-aired and the clamps are released (Fig. 123.15c).

Results

Since 1947, 153 patients have had division of the ligamentum for a right aortic arch and left ligamentum (mean age of 4.09 years and median age of 1.52 years). There has been no operative mortality since 1959. Two patients in our series have required reoperation for later resection of a Kommerell diverticulum. Sixteen patients from other institutions have undergone a reoperation for Kommerell diverticulum with left subclavian artery transfer [15]. Since 2001, 20 patients have had primary excision of a Kommerell diverticulum; 15 of these patients had simultaneous division and reimplantation of the left subclavian artery into the left carotid artery [16]. The mean age at operation in this group was higher than in the patients with only ligamentum division. These patients were 9 ± 6 years of age. There were no complications related to the subclavian artery transfer, and no patient had a recurrent laryngeal nerve injury. Two patients had a postoperative chylothorax. In all patients, there was resolution of their preoperative airway and esophageal symptoms.

Pulmonary Artery Sling

Pulmonary artery sling was first reported in 1897 as an autopsy finding in a 7-month-old infant who died of respiratory distress [17]. The left pulmonary artery originates from the right pulmonary artery and encircles the distal trachea coursing between the trachea and esophagus to the hilum of the left

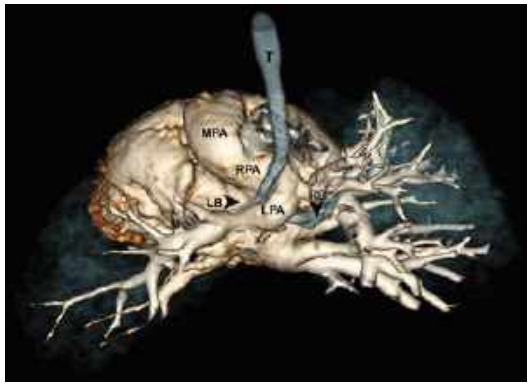

Fig. 123.16 Pulmonary artery sling. Contrast-enhanced chest CT angiography 3D multiplanar reformat. lung (Fig. 123.16). This left pulmonary artery acts as a sling applying pressure to both the right main bronchus and the lower portion of the trachea. In our series, there were several critically ill patients who presented with respiratory distress and required intubation. These patients were then diagnosed to have a pulmonary artery sling by echocardiography at the bedside. Other patients have presented with tracheal stenosis and the ability of the referring institution to only intubate the patient with a very small endotracheal tube. In our series of patients with pulmonary artery sling, 75 % have had tracheal stenosis secondary to complete cartilaginous tracheal rings. All patients with a diagnosis of pulmonary artery sling have had preoperative airway imaging with rigid bronchoscopy. Since the year 2000, all patients with pulmonary artery sling have had computed tomographic imaging of the chest with 3-dimensional reconstruction. Patients with pulmonary artery sling and complete tracheal rings are referred to as having the "ring-sling complex" [8].

The surgical repair of pulmonary artery sling should be undertaken as soon as the diagnosis is made because of the tenuous nature of the respiratory status in these children. One child in our series presented with an apneic episode with swallowing. The median age at surgery in our series is 3 months. Since 1985, 34 patients undergoing pulmonary artery sling repair at our institution have had this operation performed through a median sternotomy using cardiopulmonary bypass and mild hypothermia (Fig. 123.17) [18]. Associated intracardiac anomalies were repaired in seven patients. There have been no early deaths or complications related to the use of cardiopulmonary bypass. Median hospital stay was 24 days. The trachea repair has included pericardial patch tracheoplasty (n = 7), tracheal autograft (n = 10), tracheal resection (n = 4), and slide tracheoplasty (n = 5). There were four patients who had a severely hypoplastic or absent right lung. The primary technique of repair was to transect the left pulmonary artery at its origin from the right pulmonary artery and pass it through the mediastinum posterior to the trachea. The left pulmonary artery is then anastomosed to the main pulmonary artery anterior to the trachea (Fig. 123.18). In the four patients with a hypoplastic right lung, the left pulmonary artery was simply translocated anterior to the trachea during the tracheal repair [19, 20].

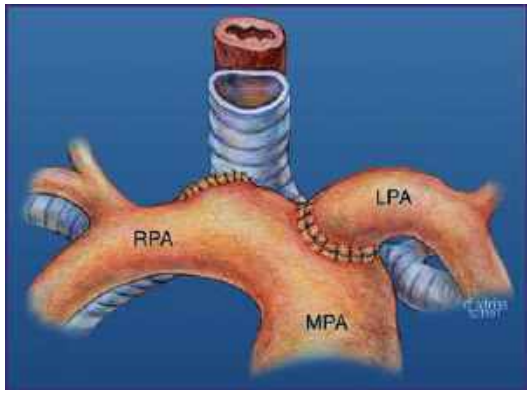

Fig. 123.18 Repaired pulmonary artery sling. The original origin of the left pulmonary artery has been oversewn. The left pulmonary artery has been reimplanted into the main pulmonary artery anterior to the trachea. *LPA* left pulmonary artery, *MPA* main pulmonary artery, *RPA* right pulmonary artery

The patency of the left pulmonary artery using this technique is 100 % with the mean percent blood flow to the left lung by nuclear scan being 41 % [18]. There were four late deaths in this series. Two were results of complications of tracheal surgery, one 6 months following pericardial patch tracheoplasty and the other nearly 2 years following graft tracheal surgery. One child died of biliary atresia 3 months after the operation, and one child died of pneumonia 6 years after the operation.

Complete Tracheal Rings

Our experience with the high frequency of tracheal stenosis in patients with pulmonary artery sling has led to a substantial experience in managing patients with tracheal stenosis secondary to complete cartilage tracheal rings. These patients frequently present with respiratory distress in infancy. Medical management of tracheal stenosis is associated with a 40 % mortality rate [21]. Patients are often referred when even the smallest endotracheal tube cannot be passed very far below the vocal cords. In all cases, the diagnosis is made by rigid bronchoscopy. In addition, CT is performed to find the extent of the tracheal stenosis. A total of 80 patients have now undergone repair of complete tracheal rings at our institution: pericardial tracheoplasty (n = 28), resection with end-to-end anastomosis (n = 14), slide tracheoplasty (n = 19), and free tracheal autograft (n = 19). Historically, the pericardial tracheoplasty was the first operation used to successfully treat patients with tracheal stenosis and was first performed by Farouk S. Idriss at our institution [22]. This was also the first use of cardiopulmonary bypass for tracheal repair in an infant.

Tracheal Stenosis Procedures

For the pericardial tracheoplasty, the patient is placed on cardiopulmonary bypass via median sternotomy incision. The aorta is retracted to the left. The anterior surface of the trachea is dissected. An incision is made through the anterior wall of the trachea throughout the length of the tracheal stenosis. An autologous pericardial patch is then anchored in place with interrupted absorbable sutures such as PDS or Vicryl (Fig. 123.19a, b). The pericardium is tacked to adjacent mediastinal structures to prevent tracheomalacia. Although our operative mortality with this technique was low, there was significant late mortality with a total mortality rate of 18 %. This was due to patch tracheomalacia, granulation tissue, and the need for a tracheostomy [23]. Other surgeons have reported excellent results with pericardial tracheoplasty [24].

In 1996, a technique called the tracheal autograft operation was introduced into practice at Lurie Children's [25]. In this procedure, the patient is again approached through a median sternotomy using cardiopulmonary bypass. The trachea is incised throughout the length of the tracheal stenosis. The midportion of the tracheal stenosis is resected, usually six to seven cartilage rings, and this piece is then used as a free tracheal autograft anteriorly. The two opened portions of the trachea are brought together posteriorly end-to-end. The autograft then either fills the space anteriorly or is augmented with a small piece of pericardium. This technique was performed in 20 patients, but the long-term mortality rate was 27 %. This was related to problems with

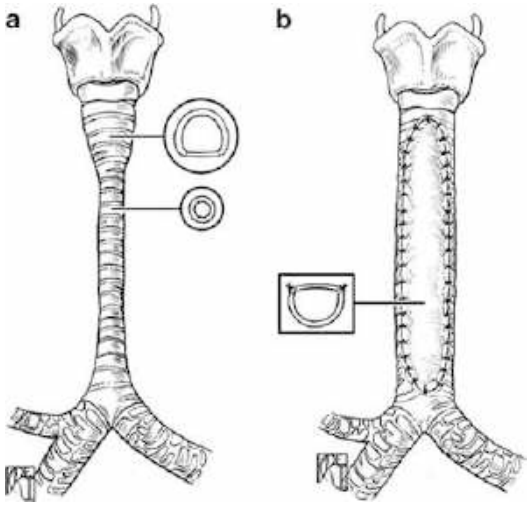

Fig. 123.19 Pericardial patch tracheoplasty technique. (**a**) Long-segment tracheal stenosis with complete tracheal rings. Note the absence of the membranous trachea. The trachea is incised anteriorly through the extent of the complete tracheal rings. (**b**) Completed repair with trachea patched anteriorly with autologous pericardial patch

granulation tissue, dehiscence in one case, and erosion of the posterior anastomosis into the carotid artery.

Tracheal resection has been performed with median sternotomy and cardiopulmonary bypass. The trachea is dissected and the area of the tracheal stenosis is carefully identified with flexible intraoperative bronchoscopy. The narrowed segment is sharply resected and a direct end-to-end anastomosis is performed with interrupted PDS suture. In this experience, there has only been one mortality using this technique in a very small infant. However, this approach is only applicable to patients with a short distance of tracheal stenosis, typically less than 1/3 of the trachea [26].

Since 2001, the slide tracheoplasty has been adopted as these authors' procedure of choice [27]. This operation has now been performed in 19 patients. There have been two deaths, one in a patient who had associated pulmonary atresia and the other in a patient with agenesis of the right lung. The slide tracheoplasty is performed with median sternotomy and cardiopulmonary bypass. The midportion of the tracheal stenosis is carefully evaluated with intraoperative flexible fiber-optic bronchoscopy. The trachea is transected in the midportion of the stenosis (Fig. 123.20a, b). Two incisions are then made in the upper and lower portions of the remaining trachea. The lower trachea is incised anteriorly and the upper trachea is incised posteriorly. These incisions can be reversed if the patient had a prior tracheostomy that needs to be encompassed in the repair. We then slide the two ends together and perform a running anastomosis with PDS suture (Fig. 123.20b, c). This is now our procedure of choice for patients with long-segment tracheal stenosis. These patients are extubated 1–5 days after the operation. They all have bronchoscopic evaluation prior to discharge from the hospital. The largest reported series are from Great Ormond Street and Cincinnati Children's Hospital. The authors from Great Ormond Street reported 84 patients with a mortality rate of 13 % [28]. Manning reported 80 patients with a 5 % mortality [29].

Innominate Artery Compression Syndrome

A small number of patients will have significant compression of the anterior portion of the trachea by the innominate artery as it crosses from left to right after originating from the ascending thoracic aorta. This is not a vascular ring per se, but an external tracheal compression. It is unclear why in some patients this causes significant compression of the trachea. In the authors' institution, the indications for operating on these patients are symptoms such as apnea or cyanotic spells and bronchoscopic evidence of compression of more than 80 % of the tracheal lumen. CT imaging is also used to make this diagnosis. This operation was originally described by Gross using a left thoracotomy at Boston Children's Hospital [30]. At our institution, we have used a small right submammary thoracotomy for this operation. The right lobe of the thymus is excised in order to identify the innominate artery. Excising the thymus may contribute to improving the room in the

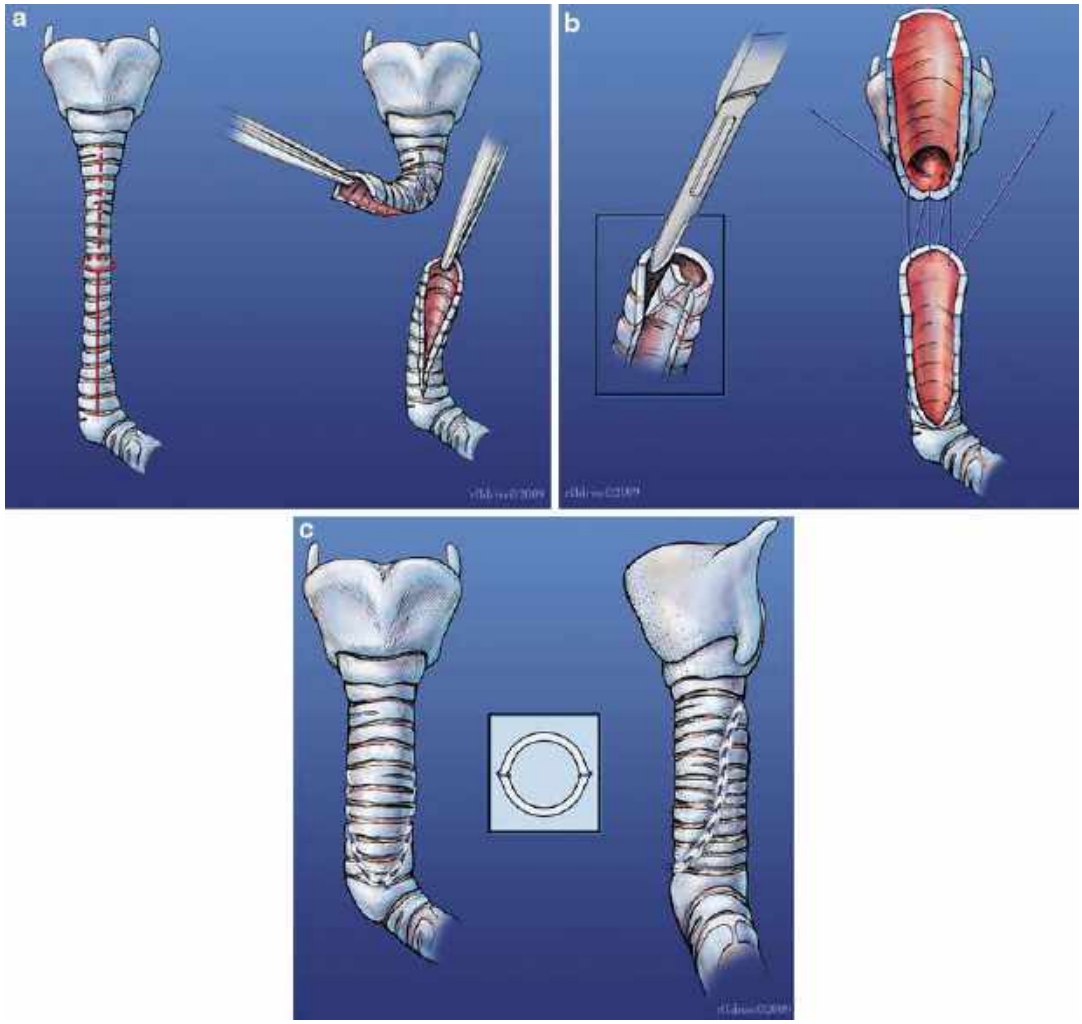

Fig. 123.20 Slide tracheoplasty; absent right lung. (**a**) The patient has been placed on cardiopulmonary bypass with mild hypothermia to 32 °C. The trachea is transected in the midportion of the tracheal stenosis. This site is determined either by external examination or by internal bronchoscopic findings. The inferior portion of the trachea is incised anteriorly, and the superior portion of the trachea is incised posteriorly. (**b**) The ends of the trachea are beveled as shown in the small inset. The anastomosis is performed with running 6.0 polydioxanone suture. The suture line is started superiorly (parachute technique) and finished inferiorly just above the carina. (**c**) Completed slide tracheoplasty. The everting running suture line helps to avoid the "figure of 8" configuration problem after the completed repair

mediastinum for the innominate artery. The innominate artery is then suspended to the posterior table of the sternum with three interrupted pledgeted sutures (Fig. 123.21). Confirmation of the results of the suspension is obtained by intraoperative bronchoscopy. The right radial pulse must be carefully monitored either with an arterial line, pulse oximetry, or blood pressure cuff to make sure that this vessel is not compromised. Currently, we have only been performing this operation on approximately one patient per year. Another operation that has been used at some institutions is to transect the innominate artery through a median

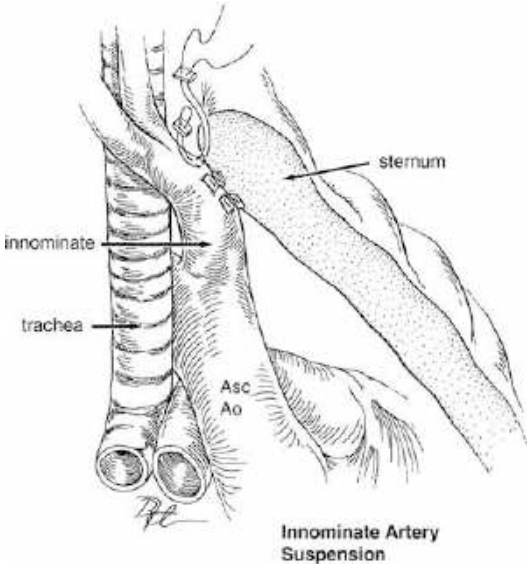

Fig. 123.21 Innominate artery suspension. The innominate artery is suspended to the posterior sternal table with interrupted pledgeted sutures. *Asc Ao*, ascending aorta (Reprinted with permission. sternotomy incision and reimplant it into the ascending aorta at a site more rightward and anterior so the trachea is not compressed [31]. We have not had experience with that procedure. In our series, only two patients have required reoperation for resuspension.

Aberrant Right Subclavian Artery

One of the most common vascular anomalies in humans is origin of the right subclavian artery from the descending thoracic aorta (Fig. 123.22). This occurs in 0.5 % of all humans [32]. Because it is so common in patients who have dysphagia, it has been blamed in the past for the swallowing symptoms. This has earned this anatomic malformation the label "dysphagia lusoria." In most cases, the aberrant right subclavian artery is actually a red herring and not the true etiology of the child's symptoms [33]. We have not operated on a child with this diagnosis since 1973.

Rare Vascular Rings

As mentioned in the "Embryology" section, there are many possible configurations of malformations depending on which portions of the aortic arch are deleted or remain present. One unusual combination is that of a left aortic arch with right-sided descending thoracic aorta. If there is a right patent ductus arteriosus or ligamentum arteriosum, a vascular ring is formed [34]. In most of these patients, a left aortic arch is actually a cervical arch resulting from persistence to the third rather than the fourth embryonic arch [35]. The cervical arch may independently compress the trachea in the absence of a right ductus. This is one of the few vascular rings best approached through a right thoracotomy rather than a left thoracotomy [36]. In the old literature, there are cues from the

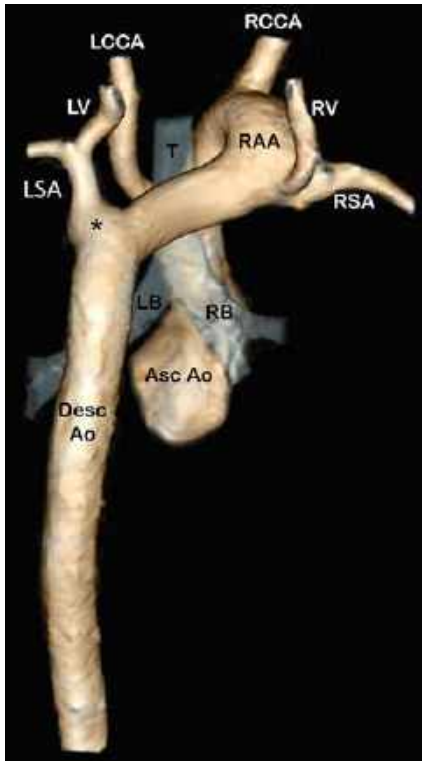

Fig. 123.23 3D MPR posterior view shows circumflex aorta in a 5-year-old child with a right cervical aortic arch, left ligamentum arteriosum (*), and retroesophageal left subclavian artery. The descending thoracic aorta crosses from right to left posterior to the trachea and superior to the carina. The posterior compression of the trachea is not relieved by ligamentum division. *Asc Ao* ascending aorta, *Desc Ao* descending aorta, *LB* left bronchus, *LCCA* left common carotid artery, *LSA* left subclavian artery, *LV* left vertebral, *RAA* right aortic arch, *RB* right bronchus, *RCCA* right common carotid artery, *RSA* right subclavian artery, *RV* right vertebral, *T* trachea

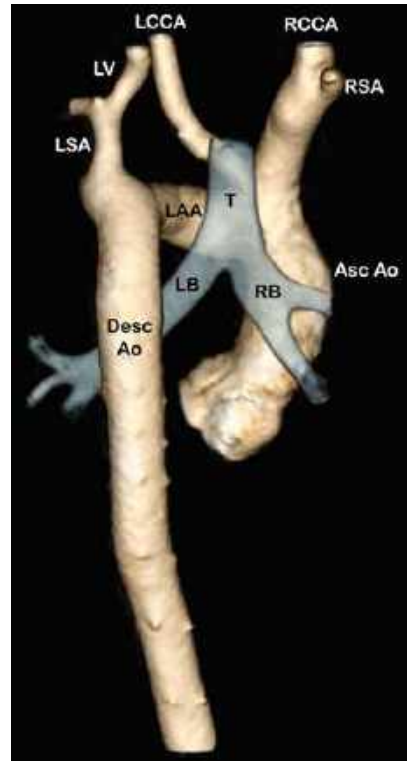

Fig. 123.24 Postoperative CTA 3D MPR posterior view shows circumflex aorta (as shown in Fig. 123.23) in a 5-year-old child. The transverse aortic arch is now anterior and to the left of the trachea. The anastomosis of the descending thoracic aorta to the transverse arch in this patient was widely patent and is off to the left of the trachea not compressing the trachea. *Asc Ao* ascending aorta, *Desc Ao* descending aorta, *LB* left bronchus, *LCCA* left common carotid artery, *LSA* left subclavian artery, *LV* left vertebral, *RAA* right aortic arch, *RB* right bronchus, *RCCA* right common carotid artery, *RSA* right subclavian artery, *RV* right vertebral, *T* trachea

chest x-ray that helped lead to this diagnosis. In the current era with computed tomographic imaging of all patients, this can be carefully planned prior to the operation, and the approach through the right thoracotomy will become more apparent. We reported a rare patient with a right aortic arch and a right ligamentum [37].

There is another group of patients with a rare vascular ring called a circumflex aorta. These patients have a right aortic arch, but the descending thoracic aorta traverses from right to left superior to the carina and independently compresses the trachea posteriorly (Fig. 123.23). Repair of this is done by an aortic uncrossing operation [38]. This operation is performed through a median sternotomy with cardiopulmonary bypass, deep hypothermia, and circulatory arrest. The aorta is transected on the right side just distal to the takeoff of the right subclavian artery. This portion of the aorta is then oversewn. The descending thoracic aorta is mobilized posterior to the esophagus and brought up anterior to the trachea and esophagus and then anastomosed to the side of the ascending aorta (Fig. 123.24). This completely relieves the posterior

compression. We have now performed this operation successfully in four patients; the mean age in that series was 3 years of age [39].

Conclusion

The diagnosis of vascular ring or pulmonary artery sling should be suspected in any infant or child presenting with symptoms of respiratory distress, noisy breathing, or dysphagia. Suspicion of the diagnosis is often generated by the plain chest x-ray. However, the diagnosis is best established by CT imaging which accurately delineates the anatomy of the vascular ring and the associated tracheal pathology. All patients diagnosed with a vascular ring should have an echocardiogram because of the 12 % incidence of associated congenital heart disease. Bronchoscopy should be performed in all cases to assess for additional tracheal pathology and to provide a clinical assessment of the degree of tracheomalacia and bronchomalacia. The common vascular rings are double aortic arch, right aortic arch with left ligamentum, and pulmonary artery sling. The surgical approach to double aortic arch is usually through a left thoracotomy although patients with a dominant left arch should be approached through a right thoracotomy. Patients with a right aortic arch and left ligamentum are approached through a left thoracotomy. Patients with double aortic arch and right aortic arch are treated by dividing the smaller of the two arches and/or the ligamentum. Patients with pulmonary artery sling are treated by median sternotomy with cardiopulmonary bypass for reimplantation of the left pulmonary artery anterior to the trachea and slide tracheoplasty if complete tracheal rings are associated. Innominate artery compression has been treated with a right thoracotomy and suspension of the innominate artery to the sternum. Close cooperation between the cardiothoracic and otolaryngology service is required to provide optimal care of these patients. There has been no operative mortality from an isolated vascular ring or pulmonary artery sling at Ann & Robert H. Lurie Children's Hospital of Chicago since 1959. Infants undergoing simple vascular ring repair have a 92 % incidence of freedom from respiratory symptoms at 1 year after the operation.

Acknowledgment The authors would like to thank Brian A. Reilly RT(R) for his help in preparing the CT images for this chapter.

Takayasu Arteritis

124

Eduardo M. da Cruz, Lorna Browne, Jeffrey R. Darst, Brian Fonseca, and James Jaggers

Abstract

Takayasu arteritis is the most common chronic idiopathic granulomatous inflammation of large arteries that produces a potentially life-threatening vasculitis of the aorta and its major branches. Its etiology is unknown.

Diagnosis in the early phase may be difficult and nonspecific, and consequently, patients may present later in life with symptoms of chronic ischemic changes in the affected vascular territories. Medical management is efficient in 2/3 of cases and complemented, as required, by palliative surgery or percutaneous vascular interventions. This chapter provides an overview of the diagnosis, classification, management, and outcomes of this devastating disease.

Aneurysm • Aorta • Arteritis • Chronic granulomatous disease • Hypertension • Inflammation • Large vessels • Takayasu arteritis • Vasculitides • Vasculitis

Introduction

Takayasu arteritis is the most common chronic idiopathic granulomatous inflammation of large arteries that produces a potentially life-threatening vasculitis of the aorta and its major branches [1, 2]. Nonetheless, Takayasu disease is a rare entity in pediatrics and as a matter of fact, published literature is rather scarce [3–5]. In pediatrics, the disease appears to be less specific than in the adult population and may therefore remain unrecognized in its early stage. It may present with fever, arthralgias and hypertension, and later narrowing of blood vessel lumen secondary to inflammation. Takayasu arteritis has a varied geographical incidence. Studies show that the disease is distributed all over the world and is not restricted to any specific ethnic group. The incidence in pediatrics is not well known; in adults, it is estimated around 2.6 cases/million/year in North America and 1 case/million/year in Europe overall [6–8]. Occurence is highest in the Far East and Africa [9]. Strong association with tuberculosis has been found in patients afflicted with Takayasu arteritis in those parts of the world. Lower rates are observed among white European and North American descendants. The only published data related to the incidence in children describes 30 % of the cohort as pediatric cases and an estimated incidence of 2.6/million in all ages [7]. The female-to-male ratio also varies considerably, ranging from 1.2:1 in Israel to 6.9:1 in Mexico [2, 10–12]. The peak incidence occurs in the third decade of life; however, the disease has been identified in patients as young as 6 months old [13]. Rare familial cases have been reported [14].

Brief Historical Background

Although Takayasu arteritis is a vascular disease, it was firstly described by Mikito Takayasu, a Japanese ophthalmologist [15]; at the 12th Annual Meeting of the Japan Ophthalmology Society held in 1908 in Fukuoka, Mikito Takayasu reported a case of a 21-year-old woman whose eyegrounds exhibited "coronary anastomosis," arteriovenous anastomosis around the papilla. This abstract was published in 1908 in the Proceedings of the Japan Ophthalmology Society. Other contemporary authors who described similar cases mentioned that the pulse could not be palpated in both radial arteries or in the left radial artery in their patients. Takayasu did not mention pulselessness in his patient in his presentation and indicated no abnormality in the medical examination. Soon afterwards, several cases were reported in Japan, including a report in 1939 by Yasuzo Shinmi who used the term "Takayasu's arteritis" for the first time. Takayasu arteritis has been well known in foreign countries since Kentaro Shimizu and Keiji Sano, Department of Surgery at Tokyo University, introduced this disease in the English literature as "pulseless disease." They described the clinical features of pulselessness, coronary anastomosis in retinal vasculature, and accentuated carotid sinus reflex

as the characteristic triad of this morbid condition in 1948. In addition, an introductory paper on the disease by Caccamize and Whiteman in the American Heart Journal contributed to the spread of information on Takayasu arteritis into Western countries. In 1963, Hideo Ueda, professor of Internal Medicine at Tokyo University, through studies of many cases of Takayasu arteritis, confirmed that it is due to aortitis involving the aorta, its main branches, pulmonary, and coronary arteries and called it "panaortitis syndrome." He suggested that it could be induced by an autoimmune mechanism [16]. Afterwards, he changed this name to "aortitis syndrome" because of potential misunderstandings whereby "pan" would be taken to mean the whole area of the aorta. In 1975, the research committee of the Department of Health and Welfare in Japan proposed the use of "Takayasu arteritis" in memory of the first reporter, Mikito Takayasu. Since then, multiple studies – particularly over the last two decades – have targeted tools for early diagnosis, the development of a reliable clinical classification and effective medical management to avoid progression towards a chronic phase.

Anatomy

Takayasu arteritis affects large arteries, mostly the aorta and its branches, as a vasculitic process. Vessel wall inflammation leads to concentric wall thickening, fibrosis, and thrombus formation. Affected vessels may become stenotic or develop aneurysms and vascular remodeling.

Pathophysiology

In Takayasu arteritis, progressive and sustained inflammation of involved vessels leads to stenotic lesions and aneurysm formation, with the subsequent hypoperfusion of the affected parenchyma. For this reason, Takayasu arteritis is also known as the "pulseless disease."

The cause of Takayasu arteritis is unknown, but immunogenetic factors appear to play a major role in pathogenesis. Takayasu arteritis has been reported in identical twins, leading to hypotheses of a hereditary basis for the disease. In Japan and Korea, Takayasu arteritis has been found to be associated with human leukocyte antigens HLA-A10, B5, Bw52, DR2, and DR4, although these associations have not been confirmed in Western studies. In North America, the disease has been found to be connected with HLA-B22 [17].

Infection has been often thought to play a triggering role. Tuberculosis has long been implicated, and viral infection has been investigated with no specific association demonstrated with the disease [18].

The *initial acute phase*, also called the *prepulseless* or *active inflammatory stage* of vasculitis, is characterized by the thickening of the aortic wall with or without alterations in the arterial lumen. Microscopic studies reveal panarteritis involving all layers of the artery, particularly in the media. The destruction of the elastic membrane and infiltration of all layers by lymphoid and plasma cells are pronounced. The intima is thickened due to proliferation of the endothelium as well as edema. This phase appears to have nonspecific and often unrecognized symptoms, namely, fever, headache, hypertension, muscle pain, arthralgia, weight loss, and night sweats, among others.

In the *second phase* of the disease, also known as the *chronic pulseless phase or sclerotic phase*, the progressive inflammatory process manifests through the formation of granulomas composed of macrophages, epithelioid, and giant cells.

In the final stage, the *pulseless end-stage sclerotic phase* demonstrates alterations in the arterial lumen and is characterized by stenosis seen in 90–100 % of patients, with occlusion or thrombosis, atypical coarctation, dilation, and/or aneurysms. Frequently, stenosis and obstruction predominate, but dilation and aneurysms are not rare [17].

Diagnosis

Clinical

The diagnosis of Takayasu arteritis currently remains a serious challenge for clinicians. Thus, diagnosis may be delayed by years. As described above, during the acute phase of Takayasu

arteritis, constitutional symptoms such as headaches, dizziness, fever, fatigue, weight loss, myalgia, arthralgia, abdominal pain, nausea, cough, lymphadenopathy, anemia, and transient skin rashes are prevalent. Due to the nonspecific nature of these signs, the diagnosis of the disease is difficult and frequently delayed for months to years. The most predominant symptom is hypertension (82.6 %), followed by headaches (31 %), fever (29 %), dyspnea (23 %), weight loss (22 %), vomiting (20.1 %), and abdominal pain (16.6 %) [2, 19, 20]. Interestingly, in South America, arthritis may be a more prevalent symptom (65 %) [4].

Patients may also present later in a "burnout" stage of the disease (1/3 of cases) [2], with signs of vascular sequelae rather than acute or active vasculitis.

In this late phase, presenting symptoms reflect chronicity with end-organ ischemia, infarction, and stroke. Manifestations result from chronic compromise of blood supply owing to vascular stenosis and ischemia. Clinical spectrum includes claudication and poor or absent arterial pulses in the affected territories (13 %), transient ischemic events, and abdominal angina. Secondary cardiac disease has been described in 19 % of the pediatric population [2, 19, 20] and relates to aortic dilatation, aortic insufficiency, congestive heart failure, myocardial ischemia, and arrhythmias. Aortic aneurysms, thrombus formation, and rupture are the common causes of death in Takayasu arteritis. Neurologic manifestations include headaches (31 %), seizures, visual disturbances, and stroke (17 %). Skin manifestations include nodules and rashes (rare) and there are no reports of skin ulcers in children. Lymphadenopathies are uncommon and retinopathy, though originally described by Takayasu, is rare [3, 21, 22].

Classification

The first proposed clinical classification of Takayasu arteritis based on vessel involvement was reported in 1978 by Ishikawa [23] in a cohort of 96 patients aged <30 years. Patients had to fulfill two major and one minor criteria, or one major and at least nine minor criteria (84 % sensitivity and 95 % specificity). Patients were compared with a limited control group of 12 individuals with other aortic diseases but not with a control group with inflammatory disorders.

Later in 1990, new criteria for the classification were developed and published by the American College of Rheumatology to simplify the clinical diagnosis. The study compared 63 patients with the disease versus 744 control patients with other forms of vasculitis. Six criteria were selected for the traditional format classification: onset at age ≤40 years, claudication of an extremity, decreased brachial artery pulse, >10 mmHg difference in systolic blood pressure between arms, a bruit over the subclavian arteries or the aorta, and arteriographic evidence of narrowing or occlusion of the entire aorta, its primary branches, or large arteries in the proximal upper or lower extremities. The presence of three or more of these six criteria demonstrated a sensitivity of 90.5 % and a specificity of 97.8 % [24].

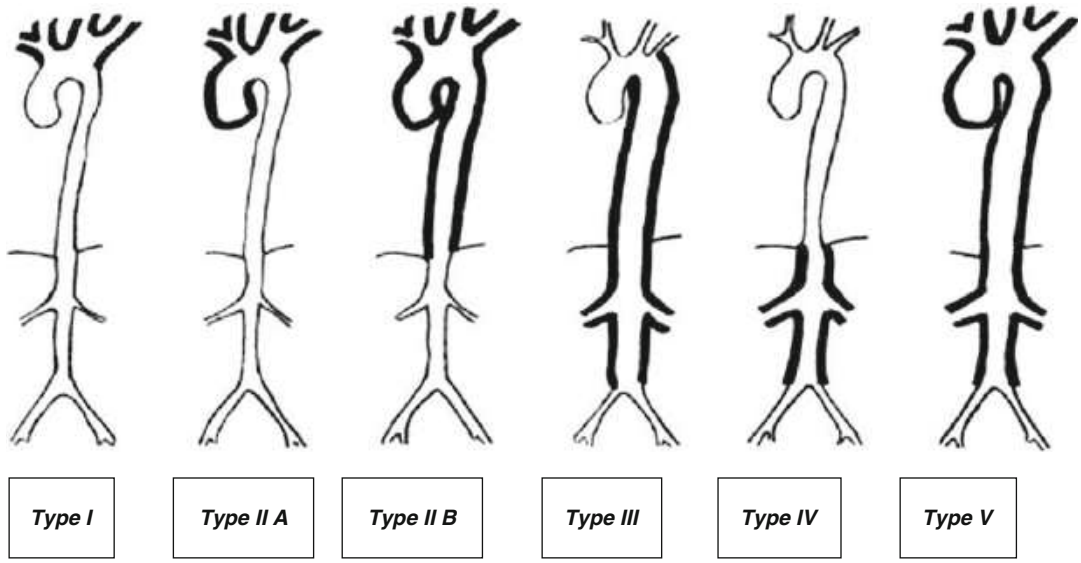
In 2007, the Pediatric Rheumatology European Society suggested consensus criteria for the classification of childhood vasculitis subtypes, including Takayasu arteritis, later endorsed by the European League Against Rheumatism [25, 26]. These criteria mandated the evidence of angiographic abnormalities (Fig. 124.1) and the presence of at least one of the following: decreased peripheral artery pulses or claudication of extremities, a blood pressure difference of >10 mmHg, bruits over the aorta or its major branches, and hypertension.

Laboratory

There are no specific laboratory markers for Takayasu arteritis, but classical inflammatory markers are usually tested.

Erythrocyte sedimentation rate (ESR) is elevated in 53 % of affected children and has been considered as the best marker for disease activity in adolescents [7, 23, 27]. However, as for other inflammatory indicators, normal values do not assure complete disease remission [28].

Other acute phase reactants have also been used as good activity markers, including



TYPE I	Branches from the aortic arch
TYPE II A	Ascending aorta, aortic arch and its branches
TYPE II B	Ascending aorta, aortic arch and its branches, thoracic descending aorta
TYPE III	Thoracic descending aorta, abdominal aorta, and/or renal arteries
TYPE IV	Abdominal aorta and/ or renal arteries
TYPE V	Combined features of types IIb and IV

Fig. 124.1 Classification of Takayasu arteritis and distribution of the cases for each type (From: Kalangos A, Christenson JT, Cikirikcioglu M, Vala D, Buerge A, Simonet F, Didier D, Beghetti M, Jaeggi E. Long-term outcome after surgical intervention and interventional procedures for the management of Takayasu's arteritis in children. J Thorac Cardiovasc Surg 2006; 132:656–664, with permission)

alpha-1 acid glycoprotein, C-reactive protein, electrophoretic alpha-2-globulin, tissue plasminogen activator, intercellular adhesion molecule-1, vascular cell adhesion molecule-1, E-selectin, platelet endothelial cell adhesion molecule-1, and haptoglobin levels. High CRP levels have been associated with a higher risk of thromboembolic complications [29, 30]. Platelets and procoagulatory markers may also be increased in Takayasu arteritis, suggesting a state of hypercoagulability and increased risk for thrombotic events [31, 32].

Imaging Techniques

Diagnosis and follow-up of children with Takayasu arteritis may require a combination of vascular imaging modalities: conventional angiography, magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA), CT angiography (CTA), echocardiography, and Doppler ultrasound. Distinct vessel wall techniques may include vascular ultrasound, gadolinium-enhanced MRA, and fluorodeoxyglucose positron emission tomography (PET). Conventional angiography and MRA are the most commonly utilized diagnostic tools. Sequential imaging evaluations have revealed disease progression (as determined by the presence of new vascular lesions) in over 60 % of patients with clinically stable profiles and normal ESR [28].

The thoracic and abdominal aorta are the most commonly involved vessels in children [3, 4, 22, 33]; diffuse aortic involvement is a key finding. Rosenthal and Morales reported 19 patients studied with conventional

angiography [12] or MRA [4], detecting 137 vascular lesions, mostly stenotic (53 %). Occlusion was documented in 21 %, dilatation in 16 %, and aneurysms in 10 % of patients. The most frequently involved vessels were renal (73 %), subclavian (57 %), and carotid arteries (52 %). The thoracic or abdominal aorta was affected in approximately 50 % of cases. The incidence of coronary lesions complicating Takayasu arteritis is relatively low; however, ischemia caused by coronary lesions is one of the major causes of death [34]. The literature regarding the incidence of coronary artery involvement is not consistent. One study found the incidence in an autopsy series to be 10.5 % (8/76 cases) [35]. Another study by Nagata above found high incidence of coronary artery pathology cardiac lesions in 91.5 % of cases: cardiomegaly in 81.7 %, aortic regurgitation in 14.6 %, and myocardial infarction in 12.2 % of 82 autopsy cases. Most (73 %) of these coronary lesions were ostial [36].

Conventional Angiography

Conventional angiography of the aorta and its branches used to be considered the gold standard imaging technique [37] but has largely become outdated, since it is invasive and exposes patients to significant radiation, the historical use of iodinated dye and its renal toxicity, and the risks of further ischemia when selectively catheterizing affected vessels. Additionally, intravascular injection of contrast does not provide information about the vessel wall characteristics. Unless percutaneous vascular intervention is anticipated, angiography ought to be avoided. Nevertheless, this needs to be counterbalanced with the need to definitely rule out and treat by percutaneous approach any significant coronary involvement with the exception of proximal ostial obstruction, since coronary ischemia can be one of the major causes of death in these subjects [38]. Surgical treatment would be recommended for patients with coronary ostial stenosis.

Magnetic Resonance Imaging (MRI) and Magnetic Resonance Angiography (MRA)

Magnetic resonance imaging (MRI) is a noninvasive, nonionizing technique that can provide dynamic images (cine MRI) in addition to static information regarding vessel wall thickening and inflammation.

Axial ECG-gated T1-weighted MRI sequences with breath-holding or respiratory compensation can detect relatively mild vessel wall thickening even before stenoses/aneurysms develop. Fluid-sensitive sequences (T2-weighted/STIR) with fat suppression can detect edema within the vessel wall thought to represent active disease. Active disease will also demonstrate arterial and periarterial gadolinium enhancement. 3D gadolinium-enhanced MRA further depicts vessel wall irregularities and has largely replaced conventional angiography, although because of the decreased spatial resolution of MRI/MRA, stenoses in small vessels may be overlooked (Figs. 124.2–124.6) [33, 39].

MRI/MRA is the preferred imaging modality for monitoring disease progression with new lesions demonstrating edema/enhancement likely representing areas of active disease [40].

CT Angiography (CTA)

CTA provides similar information to MRA but requires ionizing radiation and iodinated contrast material. Modern multidetector CTs can obtain angiographic images of the whole body in less than 1 s. The main advantage of CTA over MRI/MRA is improved spatial resolution and therefore better depiction of small vessel disease. CTA may also identify circumferential wall thickening and some degree of vessel wall enhancement; however, vessel wall tissue characterization is inferior to MRI; therefore, CT is less reliable in its ability to distinguish areas of active inflammation based on enhancement characteristics [7, 41].

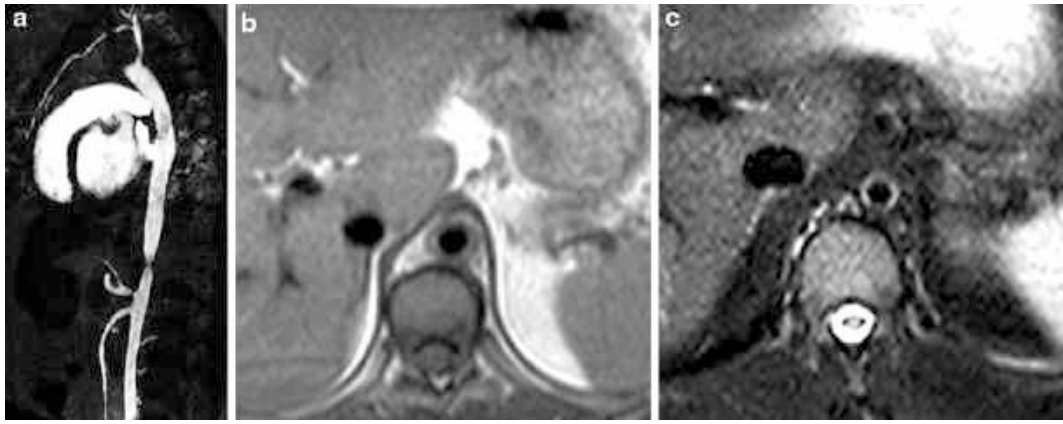


Fig. 124.2 MRI and MRA images of an 11-year-old male with active Takayasu arteritis. (**a**) Sagittal multiplanar reconstruction of gadolinium-enhanced 3D MRA demonstrating severely narrowed abdominal aorta and celiac artery origin with post-stenotic dilatation. (**b**) Axial ECG-gated T1-weighted image through the upper abdomen demonstrating severe narrowing of the aortic lumen with circumferential mural thickening. (**c**) Axial ECG-gated fat-suppressed T2-weighted image through the upper abdomen demonstrating increased T2 signal in the vessel wall

Echocardiography and Ultrasonography

Echocardiography and ultrasonography are inexpensive and non-irradiating tools that may be useful in establishing diagnosis even in a prestenotic phase with the evaluation of the extracranial vessels [42]. Echocardiography can aid in the evaluation of the ascending aorta and transverse arch. Duplex color-flow Doppler may reveal thickening of the intima, stenosis, and thrombi in the carotid, subclavian arteries, and the abdominal aorta and its branches (Fig. 124.6). Comparison of ultrasound with angiography has shown agreement on stenosis in 97 % regarding the common carotids, 95 % for the brachiocephalic trunk, and 97 % for the vertebral arteries [2, 42, 43].

Positron Emission Tomography (PET)

Fluorodeoxyglucose PET (18FDG-PET) assesses the increased glucose metabolism in inflammatory cells. There is a potential role for 18FDG-PET as a screening method for early Takayasu arteritis, particularly in patients with unspecific symptoms [44–46]. It may be that PET identifies more vascular regions affected by inflammation than MRA. However, these results are not exclusive or specific to vasculitis; also it cannot show changes in the structure or in the luminal blood flow.

Differential Diagnosis

Differential diagnosis of Takayasu arteritis includes coarctation of the aorta, Marfan syndrome, autoimmune disorders (primary and secondary vasculitis), infectious aortitis, other chronic granulomatous diseases (i.e., tuberculosis), fibromuscular dysplasia, and other causes of hypertension.

Medical Management and Decision Making

Therapy of Takayasu arteritis has the important goal of blunting the inflammatory process and preventing chronic vascular sequelae and multiorgan ischemia. Corticosteroids remain the mainstay of therapy, and immunosuppressive drugs are a second-line choice.

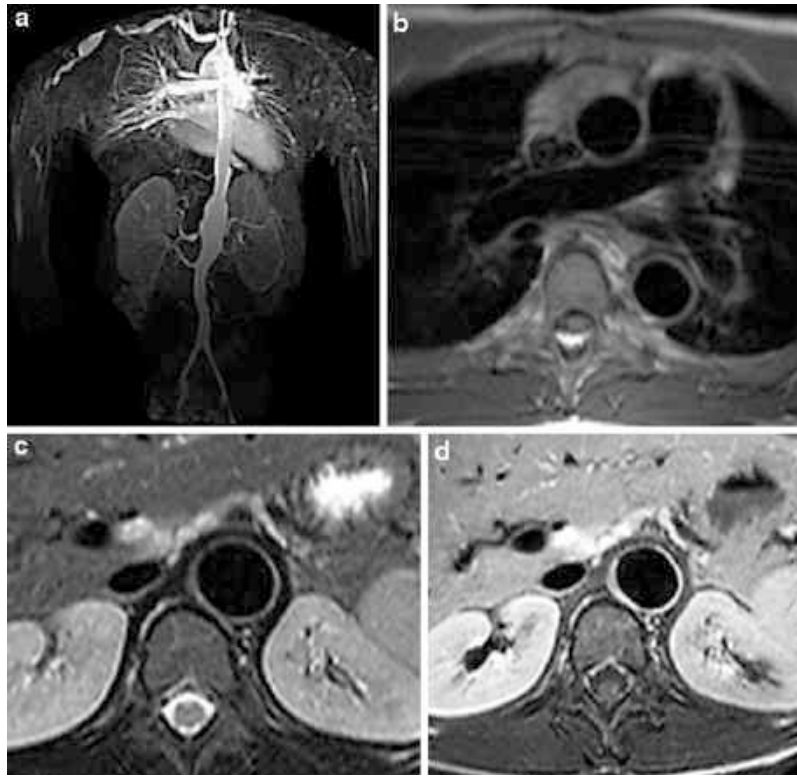

Fig. 124.3 MRI and MRA images of a 13-year-old male with active Takayasu arteritis. (**a**) Coronal multiplanar reformatted image of 3D gadolinium-enhanced MRA demonstrating fusiform aneurysmal dilatations of the abdominal aorta, and superior right renal artery, as well as alternating stenosis and aneurysms in the left subclavian artery resulting in "beaded" appearance. (**b**) Axial ECG-gated T1-weighted image through the descending thoracic aorta demonstrating circumferential mural thickening of non-dilated vessel. (**c**) Axial ECG-gated fat-suppressed T2-weighted image through the upper abdomen demonstrating increased T2 signal in the aneurysmal aortic wall. (**d**) Axial ECG-gated postcontrast T1-weighted image through the abdominal aortic aneurysm demonstrating circumferential enhancement of the thickened vessel wall

The treatment of Takayasu arteritis in the active phase consists of the control of inflammation with the use of steroids alone or in combination with other immunosuppressive agents. In the pulseless phase, aneurismal dilatation and multiple stenotic lesions with resultant ischemia in the cerebral, coronary, peripheral arterial, and renal territories could lead to severe physiologic consequences and require surgical or endovascular intervention.

Daily high-dose *prednisone* administration 1–2 mg/kg for 4–6 weeks is the accepted initial therapy with remission attained in 50 % of patients. High-dose therapy is subsequently weaned over 4–6 weeks while monitoring for signs of relapse. Forty percent of patients may relapse on steroid taper. In these patients or in patients with identified steroid-resistant disease, treatment with weekly intravenous *methotrexate* (adult dose 15–25 mg/week, pediatric 5–15 mg/m^2/week) or oral *cyclophosphamide* (1–2 mg/kg/day) has allowed achievement and maintenance of a stable remission [28]. *Cyclosporine* could be used as an alternative therapy offering an improved toxicity profile.

In approximately ¼ of the treated patients, remission is never achieved [28]. Treatment of glucocorticoid-resistant or relapsing Takayasu arteritis with *anti-TNF therapy* (etanercept and/or infliximab or tocilizumab)

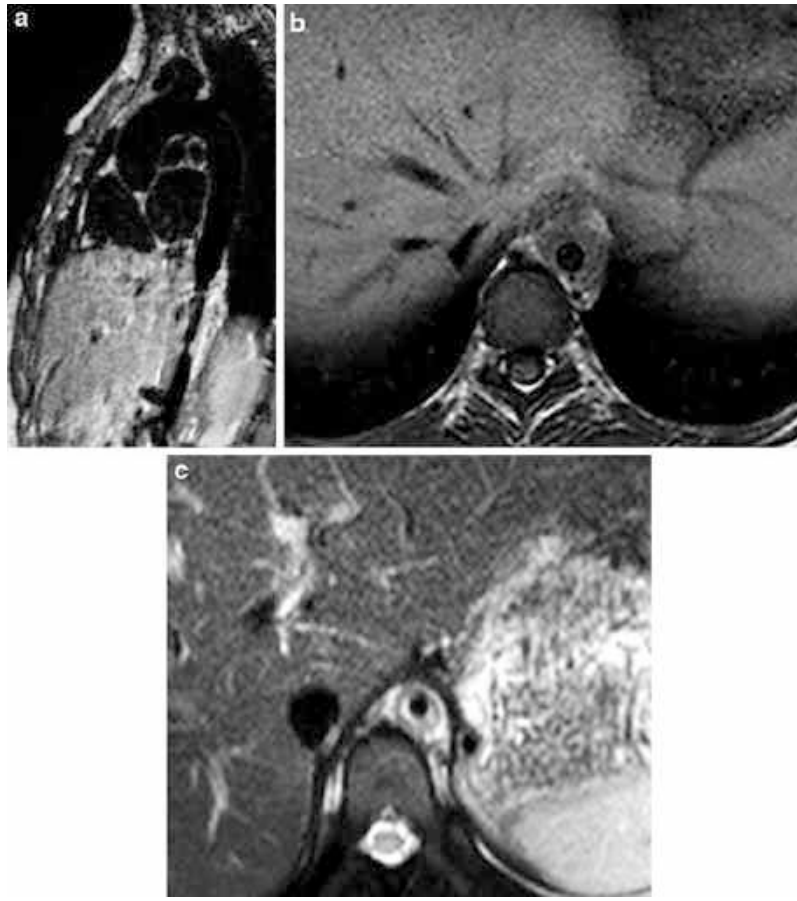

Fig. 124.4 MRI images of a 16-year-old female with active Takayasu arteritis who presented during the 3rd trimester of pregnancy. (**a**) Sagittal oblique ECG-gated T1-weighted image through the aorta demonstrating severe narrowing of the abdominal aorta just below the diaphragm. (**b**) Axial ECG-gated T1-weighted image through the aorta at the diaphragmatic hiatus demonstrating circumferential irregular thickening around the severely stenosed aortic lumen. (**c**) Axial ECG-gated fat-suppressed T2-weighted image through the upper abdomen at the diaphragmatic hiatus demonstrating increased T2 signal in the aneurysmal aortic wall and also in the periaortic fat

has demonstrated promising results. In one study, 14 of 15 patients with relapsing disease treated with anti-TNF therapy showed improvement, and four patients were able to achieve >50 % reduction in the glucocorticoid requirement. Sustained remission was reported in 10 of 15 patients, who were subsequently able to discontinue glucocorticoid therapy [47, 48]. *Mycophenolate mofetil* (MMF) is another agent used to treat individuals with glucocorticoid-resistant disease. MMF therapy has been seen to reduce clinical disease activity and to improve laboratory parameters in patients already treated with another immunosuppressive agent (methotrexate, azathioprine, or chlorambucil) who relapsed during steroid taper. MMF as a first-line immunosuppressive drug has also been shown in studies to be well tolerated for an average of 23.3 months in a dose of 2 g/day [49].

The use of intravenous immunoglobulin, recombinant IL-1 receptor antagonists, IL-4, and transforming growth factor is speculative as yet [50].

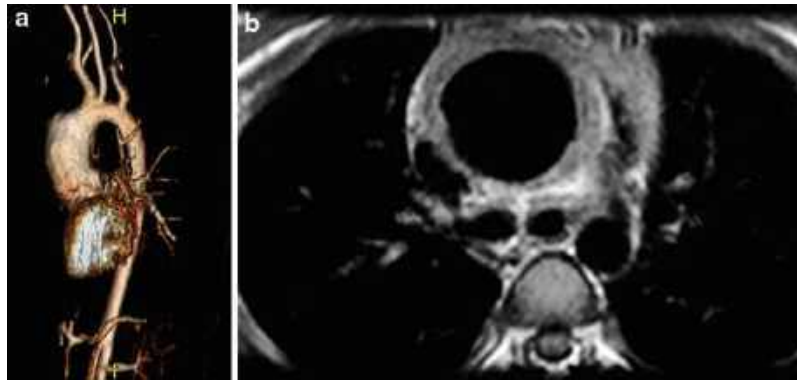

Fig. 124.5 MRI and MRA images of a 9-year-old female with Takayasu arteritis. (**a**) Volume-rendered image from 3D gadolinium-enhanced MRA demonstrating severe dilation of the aortic root and ascending aorta. (**b**) Axial ECG-gated T1-weighted image through ascending aorta demonstrating circumferential irregular wall thickening around the aneurysmal ascending aorta

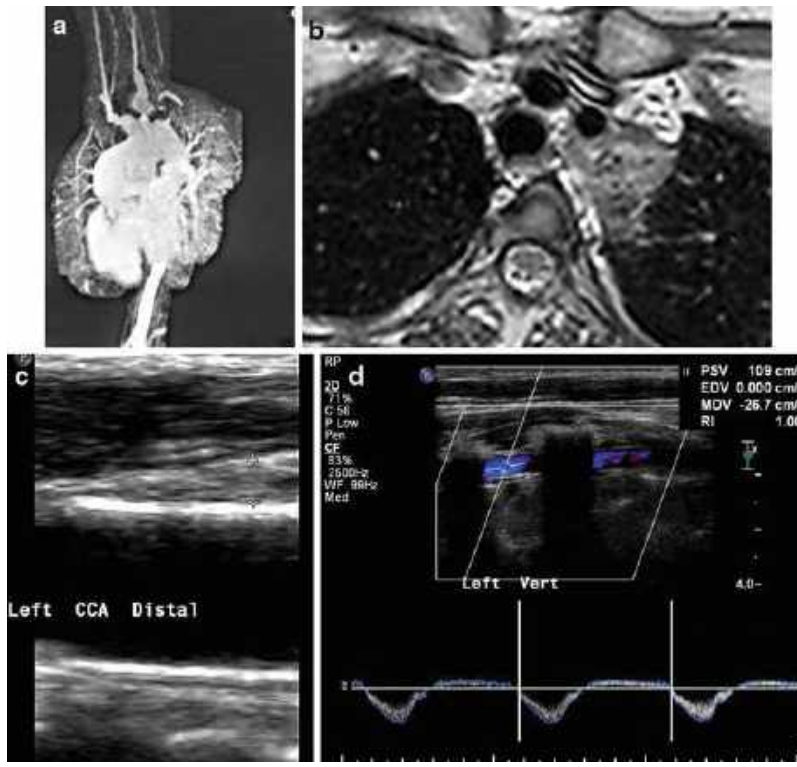

Fig. 124.6 MRI, MRA, and ultrasound images of a 13-year-old female with Takayasu arteritis. (**a**) Coronal oblique multiplanar reconstruction of the aorta demonstrating severe aneurysmal dilatation of the ascending aorta and multiple aneurysms and stenoses in the innominate artery and the left common carotid artery with occlusion of the left subclavian artery. (**b**) Axial ECG-gated T1-weighted image through ascending aorta demonstrating circumferential irregular wall thickening around the occluded proximal left subclavian artery. (**c**) Longitudinal ultrasound image demonstrating abnormal vessel wall thickening involving the mid- and distal right common carotid artery. (**d**) Longitudinal ultrasound image of left vertebral artery demonstrating reverse flow in left vertebral artery representing subclavian steal syndrome

Surgical and Interventional Management

Clinical presentation of Takayasu arteritis is multifaceted and patients with this disease require a coordinated multidisciplinary approach for optimal care and outcome. In the chronic phase, the objectives of the clinical treatment are not always achieved by medical therapy alone. Surgical and percutaneous interventions, including bypass procedures, graft and patch angioplasties, endarterectomy, percutaneous transluminal angioplasty, stent placement, aortic valve replacement, and aortic root repair, are frequently performed in the chronic phase. These interventions remain palliative with a rate of success between 56 % and 80 % [7].

Coronary artery involvement should be managed by interventional catheterization, unless the most proximal coronary ostium is involved. Surgical revascularization is best accomplished by non-arterial grafts, like vein grafts, because the risk or peripheral arterial grafts like radial and internal mammary artery may be involved in the process and the latter may have poor flow secondary to proximal subclavian artery stenosis.

Graft patency is likely to be worse than in patients with atherosclerotic disease.

Coronary artery-to-bronchial artery and coronary artery-to-pulmonary artery fistulas have been reported and may result in coronary artery steal phenomenon. These findings are usually treated by surgical ligation or percutaneous occlusion of the fistulous connection.

Aortic valvular regurgitation due to progressive aortic root dilation and resultant congestive heart failure may occur in patients with Takayasu arteritis. Surgical management of this condition may involve placement of a prosthetic valve but is often complicated by occurrence of prosthetic valve detachment or formation of a pseudoaneurysm at the suture line. Postoperative morbidity includes continued progressive dilatation of the aortic root. Hence, aortic root replacement with a composite graft for aortic regurgitation associated with aortitis is indicated in view of the propensity for development of prosthetic valve detachment [51]. Active inflammation confirmed in intraoperative specimens was found to be a significant risk factor for valve or graft detachment [52].

Diffuse, multifocal, and ostial vessel involvement in Takayasu arteritis makes the surgical revascularization with bypass grafting difficult and is also associated with a high rate of restenosis [53]. The percutaneous correction of vessel obstructions at multiple sites emerged as a viable alternative therapeutic possibility with no contraindications even in the presence of active arterial inflammation. Restenosis is a known complication of the percutaneous procedure, and repeated interventions are often required. A lower restenosis rate is observed when vascular interventions are performed in the stable stage and when post-interventional immunosuppressive treatment is implemented.

Takayasu arteritis can cause segmental dilation of the aorta and its major branches. Matsuura et al. [54] reported a series of 21 patients that underwent aortic arch repair for stenosis, aneurysm, and cervical occlusions. Because of the abnormal aortic wall, there is some risk of dehiscence of the prosthetic graft aortic anastomosis, but results are overall very good. Perioperative results have been good with both hemiarch replacement and total arch replacement. In this series, late cardiovascular events occurred in seven patients: five patients required aortic replacement for late dilatation of the residual aorta, and two patients required aortic valve replacement for recurrent aortic regurgitation after valve-sparing aortic root replacement.

Percutaneous balloon angioplasty of the aorta and stent implantation in children with Takayasu arteritis have been reported to normalize systolic and diastolic blood pressures with improvement in exercise tolerance and congestive heart failure and no complications up to 3 years follow-up [55, 56]. Short-segment stenoses were found to restenose less frequently than long-segment aortic stenoses. Percutaneous balloon angioplasty of renal artery stenoses in children with the disease has been found to be a safe procedure with a significant decrease in arterial blood pressure and decreased requirements for antihypertensives. However, a 25 % rate of restenosis has been seen on the 4–72 months follow-up [57]. The restenosis rates

have been improved by stent implantation. A possible alternative yet to be evaluated in a larger population of patients with Takayasu arteritis is the use of immunosuppressant-eluting stents (sirolimus, paclitaxel), which inhibit endothelial proliferation and endovascular inflammation and, thereby, decrease rates of restenosis.

Kalangos et al. [58] reported a series of surgical interventions for ten children (five boys and five girls; age, 12.7 +/− 2.6 years) with Takayasu arteritis. Two patients had disease confined to the thoracic aorta, four had disease confined to the abdominal aorta, and four had combined thoracoabdominal aortic disease. Steno-occlusive lesions were predominant in 92 % of cases. Seven patients were maintained on steroid therapy throughout the follow-up period. A common clinical finding was arterial hypertension, which was present in eight patients, with significant renal artery stenosis in six of them, five being refractory to medication. Eight children underwent reconstructive surgery. Eight children underwent complex surgical procedures, one patient had balloon dilatation of the renal and mesenteric arteries, and one patient had combined vascular surgery with percutaneous transluminal angioplasty. Overall, 24 grafts (polytetrafluoroethylene, Dacron grafts, and cryopreserved homografts) were implanted in various locations. There were no perioperative deaths. Arterial hypertension regressed in all patients, and cardiac function normalized in all four patients with dilative cardiomyopathy. Over a 20-year period, one patient presented with sudden death and two showed nonfatal disease progression, one of whom required surgical re-intervention. The occlusion rate was higher in Dacron grafts.

Management in the Intensive Care Unit

Takayasu arteritis patients are rarely admitted to the intensive care unit unless the admission is related to complications of the disease, such as dehydration, hemoptysis, neurological deficits, seizures, single or multiple vessel occlusions, extremity claudication, rupture of aortic aneurysm, severe systemic hypertension, congestive heart failure, angina, side effects of immunosuppressive agents, and post-interventional catheterization or surgery. Clinical management is symptomatic and requires individualization, focusing on the anticipation, prevention, and aggressive management of multiorgan compromise. Management of systemic hypertension requires great caution in order to protect the vascular territories affected by occlusive disease against further ischemia by lack of preload. This requires a certain permissive state of mind regarding the accepted blood pressure values.

Outcomes

Morbidity and mortality in patients with Takayasu arteritis are directly correlated with the vascular territories involved and the progressive course of the disease. The outcome also depends on the severity of hypertension [8]. Anti-inflammatory therapy can lead to dramatic clinical improvement. Currently, immunosuppressive agents added to corticosteroids can bring Takayasu arteritis into remission in majority of patients. However, significant morbidities are associated with these immunosuppressive therapies and are particularly seen in patients using high-dose steroids. New drugs that target intimal hyperplasia, as well as drug-eluting stents, deserve to be studied for possible utility as adjuncts to present treatments [59]. Persistent inflammation and endothelial dysfunction expose patients with Takayasu arteritis to the risk for premature atherosclerosis. Despite these potential life-threatening complications, 5–10-year survival rates have been reported to be 70–90 % [60]. Other studies, however, have reported mortality rates up to 35 % [4].

Conclusion

Takayasu arteritis is a severe granulomatous disease and a potentially life-threatening condition. Diagnosis may be difficult or delayed by lack of specificity of clinical presentation at the early

stages. In more advanced stages, patients present with hypertension and long-standing sequelae related to chronic ischemic insult to target organs. A thorough screening is required with the goal not only of confirming the diagnosis but also, very importantly, of blunting the inflammatory process and progression towards chronicity. Historically, angiography was required for the initial diagnosis, but other imaging modalities can now provide insight into the vasculitic process. Noninvasive imaging modalities are preferred methods for follow-up. Corticosteroids are the mainstay of therapy and may need to be combined with second-line alternatives for resistant cases.

Extracardiac Arteriovenous and Venovenous Malformations

125

Philippe Durand, Virginie Lambert, Augustin Ozanne, and Stéphanie Franchi-Abella

Abstract

An arteriovenous fistula is an abnormal connection between an artery and a vein in the absence of any intervening capillary bed; it may involve either the systemic or pulmonary circulation. As a result of the low resistance in the veins, a high-flow shunt occurs through such fistulas. The clinical consequence can be congestive heart failure that is variable in intensity and may be life threatening with circulatory failure refractory to medical treatment. The size of the fistula determines the magnitude of arteriovenous shunting and consequently the severity of cardiac failure. In childhood, the most common arteriovenous fistulas with associated cardiac manifestation involve the cerebral or hepatic circulation.

Extracardiac systemic arteriovenous fistulas are of importance to the pediatric cardiologist when they are hemodynamically significant and must be kept in mind, particularly in a patient with normal intracardiac anatomy who has signs of cardiac overload with hyperdynamic status and/or pulmonary hypertension of unknown origin. This chapter overviews the diagnosis, pathophysiology, clinical impact, and management of different types of arteriovenous fistulas.

Keywords

Arteriovenous fistula • Arteriovenous shunt • Cerebral arteriovenous malformation • Congenital portosystemic shunt • Congestive heart failure • Dural malformation • Embolization • Endovascular therapy • Giant cutaneous capillary hemangioma • Hemangioma • IHH • Infantile hepatic hemangioma • Pial arteriovenous fistula • Rendu–Osler–Weber syndrome • Vein of Galen aneurysmal malformation • VGAM • Volume overload

Introduction

An arteriovenous fistula (AVM) is an abnormal connection between an artery and a vein in the absence of any intervening capillary bed; it may involve either the systemic or pulmonary circulation. As a result of the low resistance in the veins, a high-flow shunt occurs through such fistulas. Whatever be the part of the body affected by the systemic AVM, the clinical consequence can be congestive heart failure that is variable in intensity. The heart failure can range from a well-tolerated mild cardiac overload to a dramatic life-threatening circulatory failure refractory to medical treatment (mostly affecting neonates or infants). The size of the fistula determines the magnitude of arteriovenous shunting and consequently the severity of cardiac failure [1]. In childhood, the most common AVM with associated cardiac manifestation involve the cerebral or hepatic circulation. Extracardiac systemic AVM are of importance to the pediatric cardiologist when they are hemodynamically significant (e.g., associated with a large left-to-right shunt). While rare, extracardiac AVM must be kept in mind, particularly in a patient with normal intracardiac anatomy who has signs of cardiac overload with hyperdynamic status and/or pulmonary hypertension of unknown origin. Most of these AVM are congenital, with a few known forms arising from genetic mutations like Rendu–Osler disease (*ENG*, *ACVRL1*) or capillary hemangiomas (RASA1).

Pathophysiology of Cardiac Failure: Overview and Pediatric Features

In animal models, chronic overload induced by surgical aortocaval or carotid-jugular fistula leads to congestive heart failure with significant left ventricular end-diastolic volume (LVEDV), while cardiac output, pulse pressure, and heart rate increase over time [2]. This can be demonstrated by catheter conductance as well as echocardiography studies. Moreover, intrinsic myocardial contractility is depressed but left ventricular performance is maintained (in compensated status) by chronotropic effect, Frank–Starling reserve, cardiac mass increasing, and left ventricular afterload reduction [2, 3]. The NO pathway may play a pivotal role in the pathogenesis of cardiovascular remodeling, contractile dysfunction, and beta-adrenergic hyporesponsiveness in some chronic volume overload rabbit or rodent models [4, 5]. However, the relative size of the AV shunt and difference in animal models clearly influence the degree of overload and ventricular failure [2]. As a result of the additional cardiac workload imposed by the shunt, myocardial metabolic demands are increased but the balance between

the increased oxygen demand and delivery may be compromised. Large arteriovenous shunts reduce the diastolic pressure within the aorta, leading to reduced coronary blood flow, which, coupled with the high ventricular pressure can promote myocardial ischemia. Moreover, once pulmonary vascular resistances exceed systemic vascular resistances, a right-to-left shunt occurs through the foramen ovale and the ductus arteriosus, mimicking persistent fetal circulation and resulting in hypoxemia and cyanosis [6]. The activation of myocardial-inducible NO synthase may also contribute to myocardial damage by depressing myocardial contractility and β-adrenergic hyporesponsiveness, as shown in experimental models of volume overload heart failure [5]. Cardiac failure, therefore, progressively worsens, leading to poor peripheral perfusion, lactic acidosis, and, ultimately, multi-systemic organ failure.

In utero, the fetus is, in theory, protected against the consequences of a high-flow shunt by its specific physiology. During the prenatal period, the pulmonary circulation is characterized by high vascular resistance and low blood flow. The ductus arteriosus allows right ventricular output to be diverted from the pulmonary to the systemic circulation, so that 10–25 % of the cardiac output reaches the pulmonary circulation under physiologic conditions between 20 and 38 weeks of gestation [7, 8]. Moreover, in cerebral arteriovenous malformation, the low-resistance utero-placental circuit protects the fetus by competing with and thereby diminishing flow through the low-resistance malformation [9]. Nevertheless, some cases of preterm congestive heart failure due to systemic AVM are described [10, 11] (Fig. 125.1) and pulmonary hypertension may be irreversible after birth despite successful embolization of the fistula, with anatomic evidence of pulmonary vascular abnormalities found in such cases [12]. Several experimental data showed that increased pulmonary blood flow and pulmonary hypertension in utero can alter the normal postnatal remodeling, preventing a fall in pulmonary vascular resistance, even after the cause of the pulmonary overflow is removed [13, 14]. One mechanism involved is that systemic arteriovenous fistulas, by increasing blood flow returning to the right atria, may overload the normal functioning of the three known fetal shunts, ductus venosus, foramen ovale, and ductus arteriosus, which become functionally restrictive [15]. Another pulmonary hypertension fetal model with high pulmonary blood flow, obtained by aortopulmonary shunt placement, provided convincing data for an alteration of the endothelin cascade by earlier upregulation of gene expression, contributing to vascular remodeling and enhancement of pulmonary vascular reactivity [16].

After birth, pulmonary vascular resistance dramatically falls, allowing a tenfold increase in pulmonary arterial flow [7]. Moreover, in cerebral malformations, after removal of the placenta, up to 80 % of cardiac output is directed to the low-resistance cerebral circulation, suddenly increasing the flow though the fistula and producing a massive left-to-right shunt [17]. The high-flow arteriovenous shunt leads to increased systemic venous return and enlarged right cardiac chambers [18]. As a result of increasing flow into the pulmonary circulation, a consequent increased volume load occurs in the left heart [1]. Both ventricles thus receive an increased preload which they must attempt to eject. The right ventricle must do so against increased afterload due to elevated pulmonary pressure, and becomes dilated, with resultant impaired diastolic filling and systolic contraction [17]. Right ventricular dilatation results in compensatory ventricular septal displacement to the left, which reduces both the end-diastolic left ventricular preload and cardiac output. Other major hemodynamic changes may stem from a lowering of peripheral resistance, and the subsequent compensatory increases in blood volume and cardiac output that maintain adequate perfusion of the remainder of the systemic vascular bed [19].

Diagnosis of AV Shunt-Associated Cardiac Failure

Clinical Features

When AVM are located in the brain, symptomatic newborn infants present with severe cardiorespiratory failure, including hydrops and renal failure,

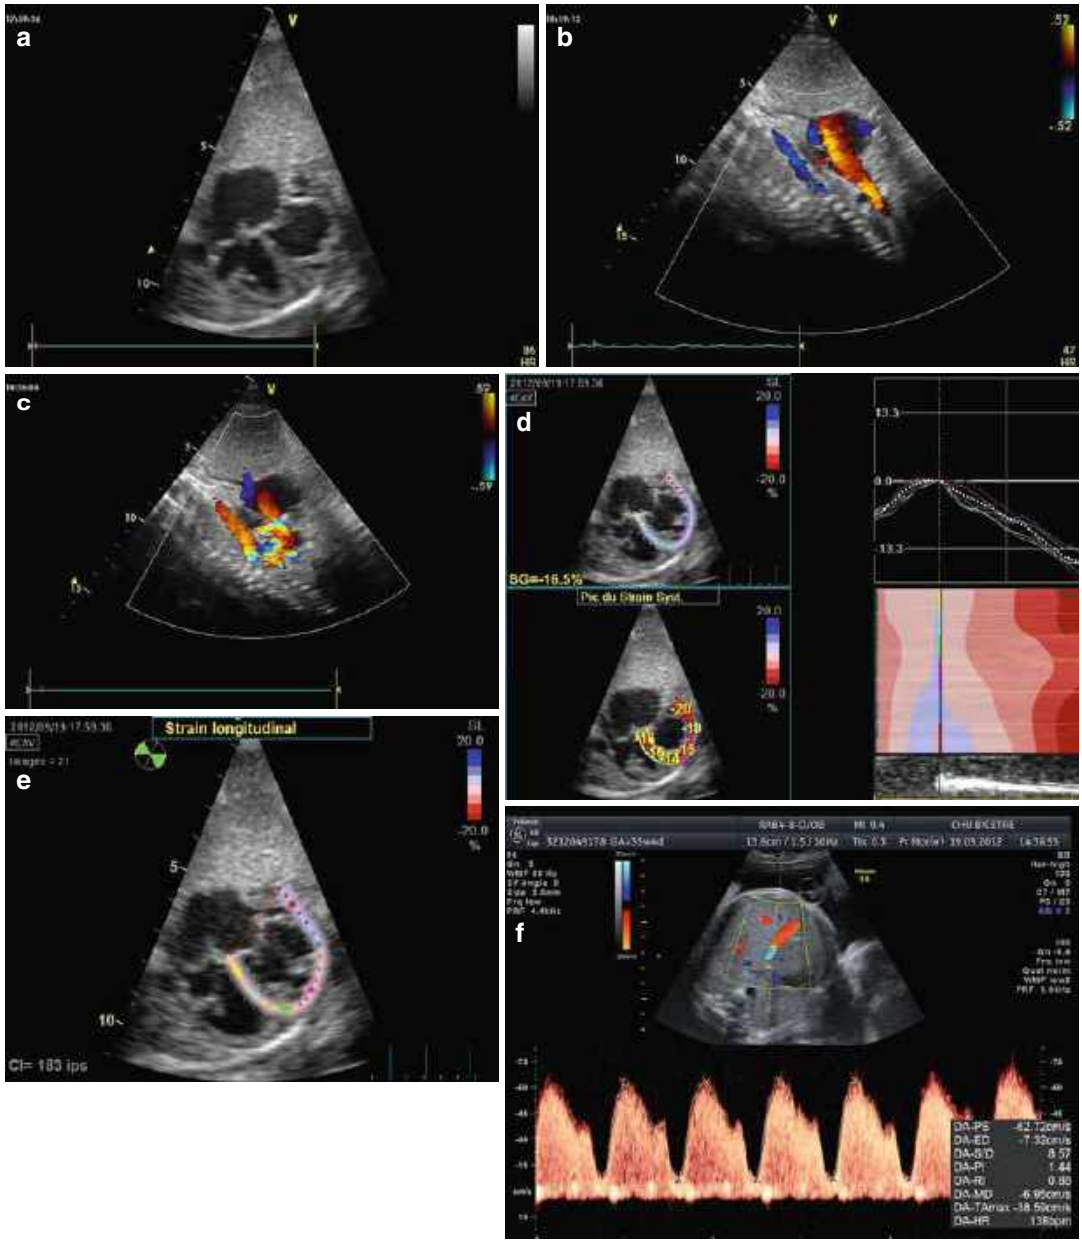

Fig. 125.1 Fetal heart echocardiography views in a case of VGAM at 34-week gestational age. (See the supplemental material in e Book section including video clip (Videos 125.1–125.9)): note the marked right chamber dilatation including superior vena cava with increasing cephalic venous return (**a**, **b**), color reverse flow into the aortic arch and descending aorta with diastolic flow into the supra-aortic vessels (**c**), and right ventricular dysfunction with reduced global strain rate (**d**, **e**) and biphasic flow pattern seen in the ductus venosus (**f**) (by courtesy Dr Stos, Centre chirurgical Marie Lannelongue)

which is secondary to flow reversal in the aorta. Usual signs of congestive high-output cardiac failure such as tachycardia, various degrees of respiratory distress, peripheral edema, and hepatomegaly are present. Cyanosis is often observed due to a right-to-left shunt through the patent ductus arteriosus or the foramen ovale. Most of these infants present with a bounding peripheral pulse

and precordium; a grade II or VI systolic murmur along the left sternal border; and a third heart sound, reflecting the high pulmonary flow and cardiac overload [1]. In contrast to neonates, patients presenting during infancy usually have smaller shunts and only mild cardiac manifestations.

Chest Radiography and ECG

When the fistula is large, the chest radiograph usually shows cardiomegaly with marked pulmonary vascularization. If pulmonary vascular resistance is elevated, pulmonary oligemia also may be present. In addition to signs of right or combined ventricular hypertrophy, the *ECG* often shows ST–T wave abnormalities as a reflection of myocardial ischemia and necrosis [1].

Echocardiography

Echocardiography combined with *Doppler* is the most appropriate investigation, providing an accurate, rapid, and noninvasive analysis of cardiac consequences of a systemic AVM (Fig. 125.2).

Two-dimensional echocardiography shows normal cardiac anatomy, thus excluding congenital heart disease, which is first suspected in newborn infants with severe cardiac failure. The short-axis ventricular view can describe the shape of the interventricular septum, based on right-to-left side motion, as follows: 1=normal, 2=intermediate, or 3=complete right-to-left shift with left ventricle collapse. With suprasternal views, the ascending aorta, arch arteries, innominate vein, and superior vena cava appear dilated in cerebral AVM [20]. Four-chambered views may

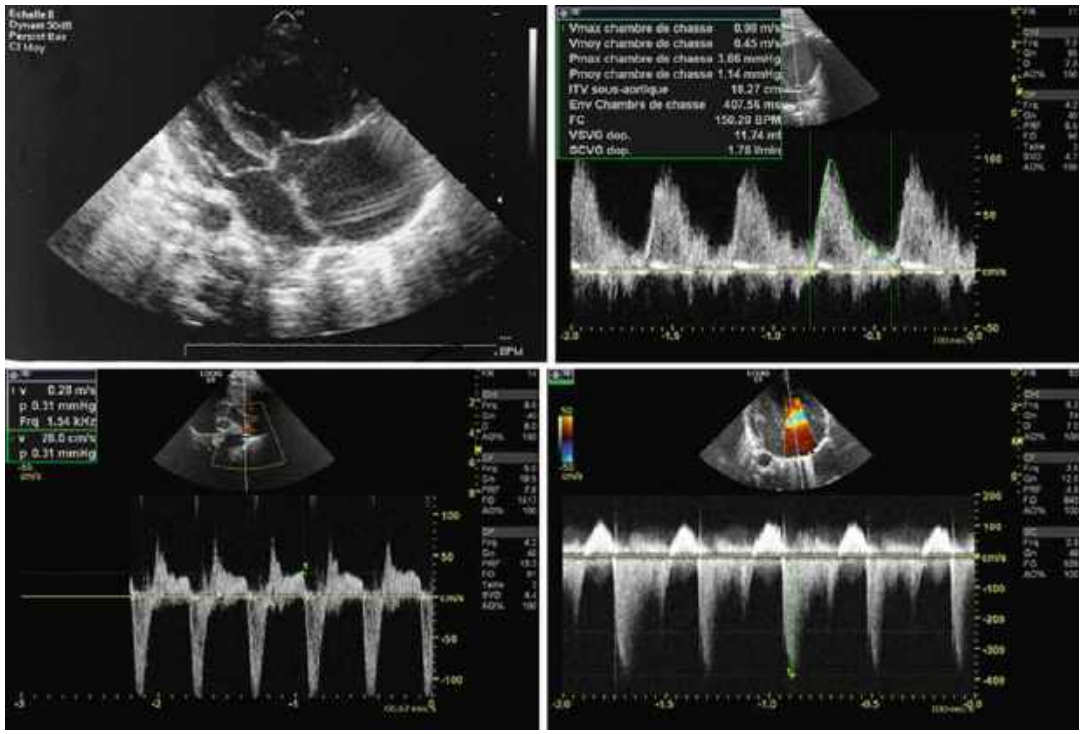

Fig. 125.2 Postnatal echocardiography view in a case of VGAM at day 3 (See the supplemental material in e Book section (Videos 125.1–125.9)): note the marked right chamber dilatation with severe systolic pulmonary hypertension (**a**), the high venous flow into the superior vena cava (630 ml/kg per min) (**b**), and the color reverse flow into the descending aorta (0.28 m/s) (**c**)

show the atrial septum bulging into the left atrium, and the foramen ovale may be seen flapping open, suggestive of right-to-left atrial shunting. *Cross-sectional echocardiography* shows dilated and hyperdynamic right and left ventricular chambers assessed by increased dimensions of the right and left end-diastolic diameters and increased left ventricular shortening fraction.

On *cardiac Doppler study*, elevated cardiac output associated with high-velocity flow in the superior vena cava indicates an intracerebral location of the AVM. Similarly, a high-velocity return into a markedly dilated hepatic vein is highly suggestive of a hepatic AVM [21]. Superior vena caval flow provides useful prognostic information [17, 22], and the ductal flow pattern and descending aortic flow reversal may be evident at the level of the insertion of the patent ductus arteriosus. A superior vena caval flow >400 ml/kg, a right-to-left shunt through the patent ductus arteriosus, and a diastolic (or continuous, if extensive, into systole) flow reversal into the descending aorta are associated with a poor prognosis in vein of Galen aneurysmal malformation (VGAM) [19, 22]. Pulmonary arterial pressures are estimated from the maximal velocity of the regurgitant tricuspid or pulmonary jet using the modified Bernoulli equation. Recently, the right myocardial performance index, or Tei index was proposed to quantify global (systolic and diastolic) ventricular function in infants with pulmonary hypertension [23].

Causes of Cardiac Failure

Table 125.1 summarizes the etiologies of AVM-associated cardiac failure in the pediatric population.

Table 125.1 Causes of extracardiac AV (or VV) shunt malformation potentially associated with Cardiac failure in neonates, infants, or children

Cerebral AV shunt (newborn)
– VGAM and dural AM (VGAD)
– Pial AV (including HHT and *RASA1* gene mutations)
– Carotido-cavernous fistula
Portosystemic shunt (children) and ductus venosus agenesia (newborn)
Hepatic hemangioma (newborn and infant)
– Focal or multifocal and diffuse
– Hemangioendothelioma type1 (benign or infantile hemangioma (IH))
– Hemangioendothelioma type 2 (angiosarcoma or HE kaposiform)
Giant cutaneous hemangioma (newborn and infant) (congenital (CH) or infantile (IH) forms)
– Limb
– Neck, cranial
– Chest
Non-cerebral AVM associated with HHT gene mutations and congestive heart failure, mostly liver (newborn, adult, children)
Traumatic arteriovenous fistulas (infant or children)

Cerebral AVM Shunt

Three types of cerebral vascular malformations are observed in children, in decreasing order of frequency. *Vein of Galen aneurysmal malformations* (VGAMs) are localized in the subarachnoid space and arise during the antenatal period. *Pial arteriovenous malformations* are localized in the cerebral parenchyma underneath the pia mater (pial AVM). They exceptionally occur during the antenatal period. *Dural malformations*, including dural sinus malformations associated with venous lakes, are localized deeply in the dura mater. They arise during the antenatal period and sometimes can resolve spontaneously before birth.

Vein of Galen aneurysmal malformations represent the majority of cardiac failure–associated AVM observed in newborns and infants. It is a choroidal type of AVM draining into the vein of Galen forerunner (see angioarchitecture in Fig. 125.3). Figure 125.4 provides a comprehensive natural history in neonates, infants, and children [24]. In contrast to the cardiac failure observed in large infantile hemangiomas, which occur in infancy at the proliferative stage of the disease, the congestive heart failure in VGAM may be present during the neonatal period. In most cases, there is a brief period of stabilization, after which the congestive heart failure worsens during the first 3 days of life, then stabilizes again,

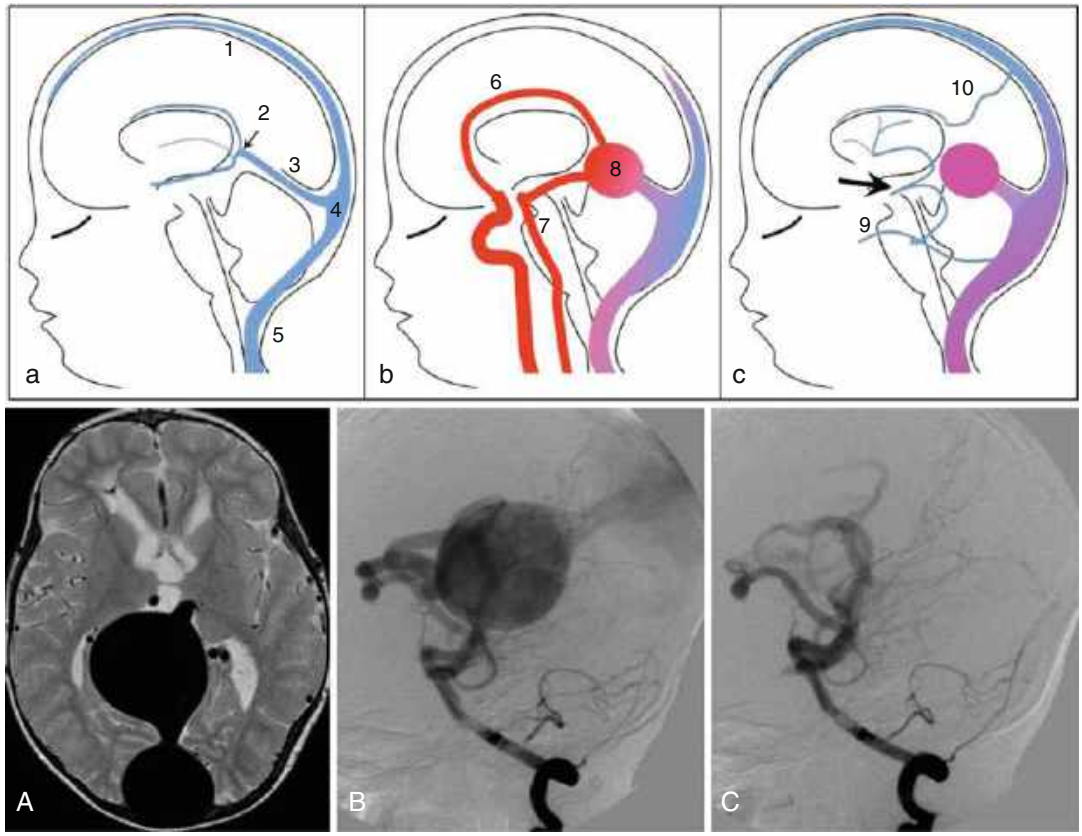

Fig. 125.3 *Top*. Normal venous angioarchitecture (**a**) and modifications observed in VGAM (**b**, **c**). Under normal conditions, the deep venous system drains into the great cerebral vein and then into the straight sinus, the confluence of the sinuses and the jugular veins (**a**, see Legend below). In the presence of VGAM (**b**), the deep venous system does not drain into the malformed great cerebral vein, which only receives malformed arterial afferents derived from the basilar artery and internal carotid arteries. The deep venous drainage (**c**) then involves alternative pathways via the superior petrosal sinus (*arrow*, characteristic "epsilon" appearance) or a falcorial sinus (10) to reach the superior sagittal sinus. *Below*. High-flow vein of Galen aneurysm malformation in a 5-year-old child. MR in axial view (**A**) shows the dilated vein of Galen (*empty arrow*). Left vertebral angiogram in lateral view before (**B**) and after (**C**) transarterial embolization with glue, showing near-exclusion of the malformation. Legend: *1*, superior sagittal sinus; *2*, great cerebral vein; *3*, straight sinus; *4*, confluence of sinuses; *5*, jugular vein; *6*, pericallosal artery (derived from the anterior cerebral artery); *7*, basilar trunk; *8*, vein of Galen malformation; *9*, superior petrosal sinus; and *10*, falcorial sinus

and improves with appropriate medical management. In the past, severe congestive heart failure in neonates requiring mechanical ventilation was considered to be associated with a very poor outcome [25]. In the authors' experience, none of the infants referred to our institution developed de novo cardiac failure after the third week of life [18] (Table 125.2). However, cardiac function may decompensate in the first weeks of life or recur later after seasonal infections or other concurrent diseases. Congestive heart failure never constitutes the presenting symptom in infants, nor does it worsen at that age if already present (Fig. 125.4). The degree of failure is variable from one child to another, but seems to be independent of the characteristics of the shunt. Some high-flow lesions are well tolerated, whereas apparently small shunts may lead to multiorgan failure. In the authors' series, all infants presented with clinical signs of severe cardiac failure at the time of admission; tachycardia, tachypnea, and hepatomegaly, and sometimes some degree of cyanosis

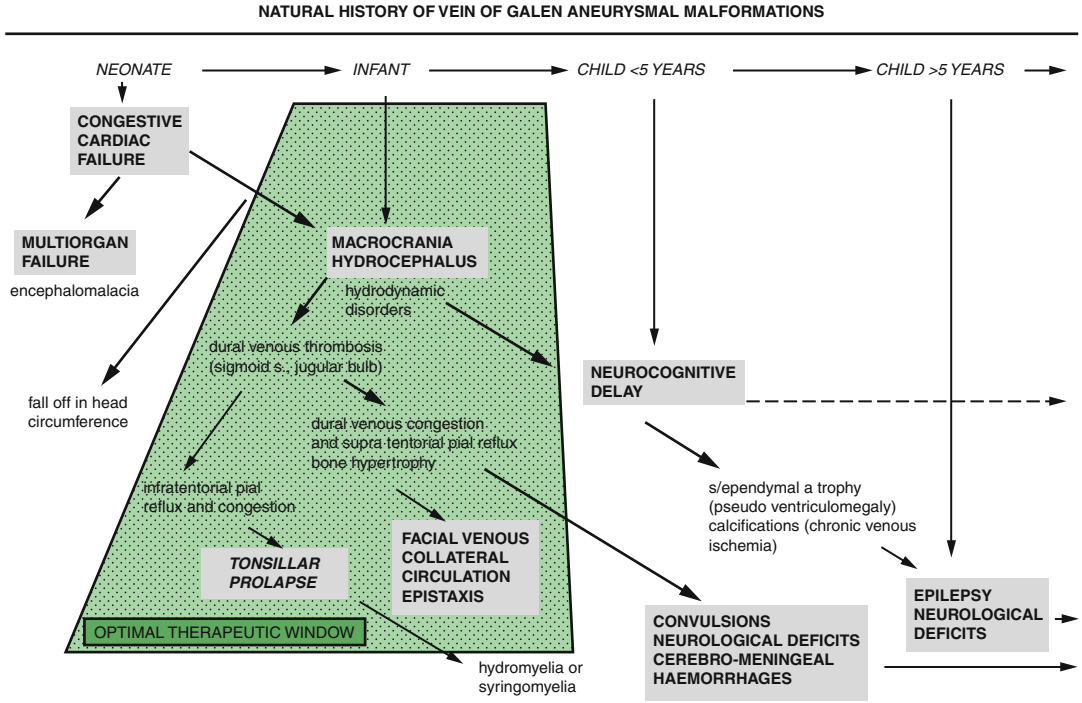

Fig. 125.4 Natural history of vein of Galen aneurysmal malformation in children (VGAM) (Lasjaunias, 2006 [24], with permission)

Table 125.2 Subgroup of neonates referred to the pediatric cerebrovascular referral center with VGAM-associated cardiac failure, Bicêtre Hospital, APHP France

Year	1987–2000 [18]	2001–2012
N=	24	43
Gestational age (weeks)	39	38
Birth weight (kg)	3.1	3.28

were present. Most patients had a cervical "dancing" carotid pulse with distended jugular veins and a cranial bruit. Every patient presented with a bounding peripheral pulse and precordium, a grade II or VI systolic murmur along the left sternal border, and a third heart sound [18, 26, 27].

Pial arteriovenous fistulas are rare lesional vascular anomalies that pose a high risk of intracranial hemorrhage across all age groups, including children. In the pediatric population, in particular, they may present with high-output cardiac failure [28], macrocrania, or seizures. An audible murmur or cranial bruit is occasionally heard, secondary to the high flow [29, 30]. Other posterior cranial fossa arteriovenous fistulas are very unusual causes of cardiac overload [30].

At echocardiography, it is worth noting that VGAM-associated congenital cardiac defects are unusual but have to be ruled out, especially aortic coarctation and sinus venosus septal defect [17, 31, 32]. Patel et al. have recently provided

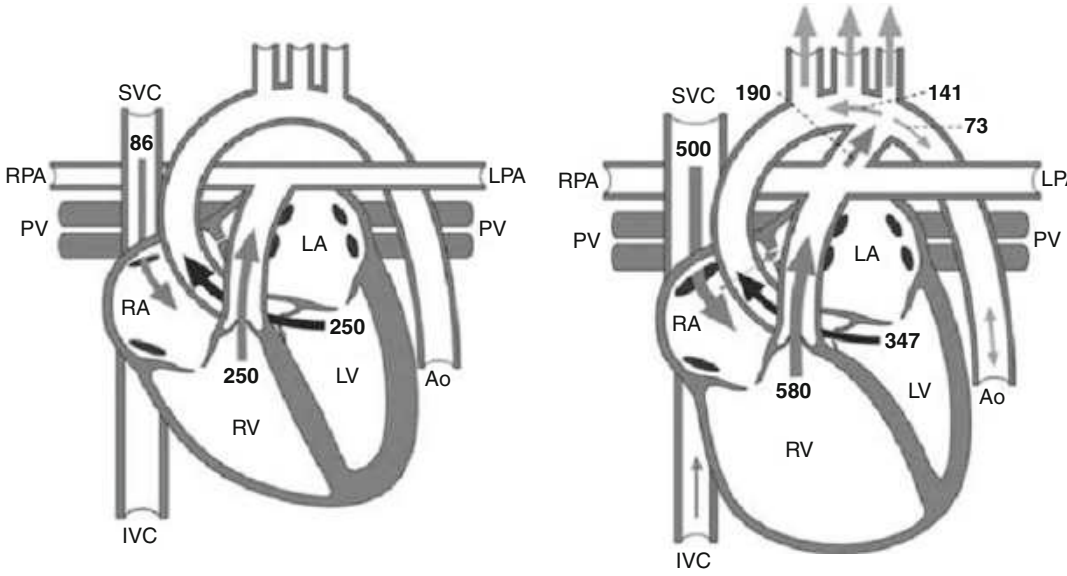

Fig. 125.5 Echo Doppler blood flow measurement in normal heart and a case of VGAM. All flows in ml/kg/min. In VGAM, note the high superior vena caval flows and ventricular outputs, the dilated right ventricle and leftward displacement of the interventricular septum, and the large right-to-left flow through a patent ductus which predominantly passes retrogradely up the aorta. Legend: *Ao* aorta, *IVC* inferior vena cava, *LA* left atrium, *LPA* left pulmonary artery, *LV* left ventricle, *RA* right atrium, *RPA* right pulmonary artery, *RV* right ventricle, *SVC* superior vena cava (Patel, 2007 [17], with permission)

a comprehensive echocardiographic assessment of the hemodynamics in VGAM presenting as cardiac failure in early infancy [17] (Fig. 125.5). On the basis of superior vena caval flows, it can be observed that over 80 % of cardiac output passed through the AVM, resulting in a significant reduction to lower body perfusion, with usual known clinical and biological markers of poor organ perfusion (lactic metabolic acidosis, acute kidney injury or failure, liver failure). Systemic perfusion is further reduced in diastole by a "steal" through the AVM that produces the characteristic reversed diastolic flow in the aorta (Fig. 125.2).

Cardiac catheterization is no longer necessary to establish the diagnosis or to evaluate the hemodynamic status. In historical studies in neonates with cerebral AV shunts, a small arteriovenous oxygen difference with a high blood systemic venous saturation in both internal jugular and right cavities suggested a left-to-right cerebral shunt (exceeding 80 %), right ventricular and pulmonary artery pressures were elevated in contrast to normal left atrial pressures, there was a low diastolic systemic pressure, and a high cardiac index. In most cases, angiograms revealed retrograde filling of the aortic arch and left carotid artery, and dilated brachiocephalic vessels with rapid return to the innominate vein and superior vena cava [19, 26, 27].

Congenital Portosystemic Shunts

Portosystemic shunts are a very unusual cause of congestive heart failure in children, in contrast to other frequent complications such as hepatopulmonary syndrome (hypoxemia), pulmonary artery hypertension, liver adenoma, or portosystemic encephalopathy. These shunts can be intrahepatic (between the portal vein and the inferior vena cava or hepatic vein) or extrahepatic (join the portal trunk directly to the inferior vena cava). The lack of complete resolution of ductus venosus, which normally involutes after a few days in term neonates, may give rise to these abnormal vascular communications [33]. In a recent clinical series of 22 children with a complicated congenital portosystemic shunt at a single institution, neonates

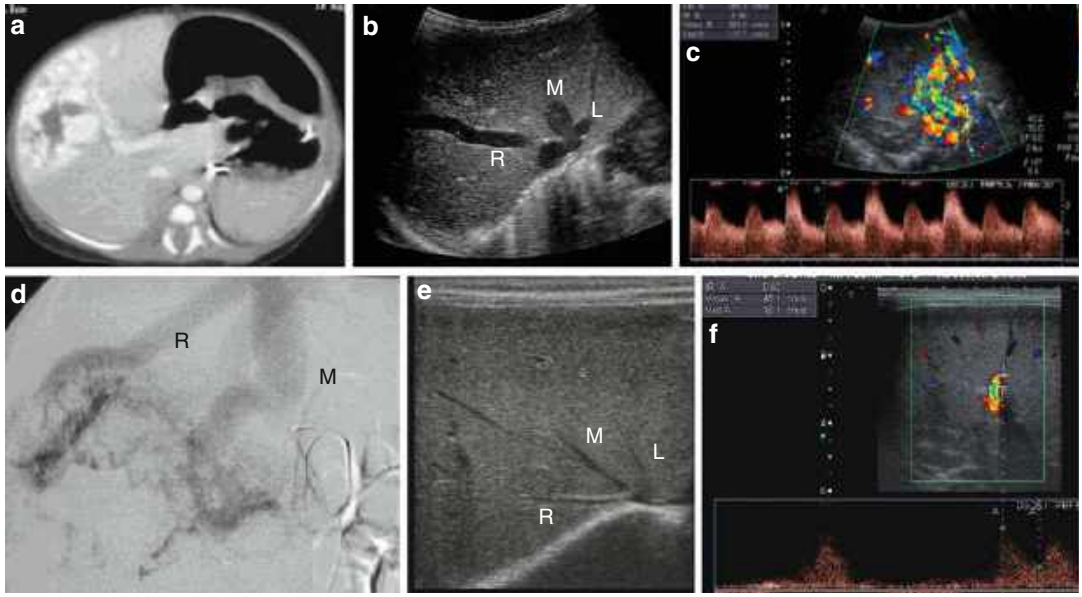

Fig. 125.6 A 1-month-old girl presenting with enlarged abdomen and heart failure and suprasystemic arterial pulmonary hypertension. (**a**) Computed tomography scan after contrast injection shows the focal hepatic hemangioma that strongly enhances. (**b**) Initial ultrasonography displays enlargement of the three hepatic veins (*L* left, *M* median, *R* right). (**c**) Color and pulsed-Doppler study shows numerous vessels within the mass and an elevated systolic speed of the feeding hepatic artery (about 260 m/s, normal <50 m/s). (**d**) Hepatic arteriography shows strong enhancement of the tumor with rapid opacification of right and median hepatic veins. Embolization of the feeding hepatic artery was performed with rapid and major improvement of the cardiac status. (**e**) Ultrasound performed a few days after embolization shows normalization of the aspect of the hepatic veins, and (**f**) normal systolic speed of the hepatic artery on Doppler study

presented with cholestasis, and 17 older children presented with liver tumors (13 cases), hepatopulmonary syndrome (2 cases), pulmonary artery hypertension (3 cases), portosystemic encephalopathy (3 cases), but heart failure was present only in one case. In the medical literature, pulmonary artery hypertension has been reported in at least 14 children with extra- or intrahepatic congenital portosystemic shunts, at a mean age of 7-1/2 years, the youngest age being 3 months [33].

Hepatic Hemangiomas

In the authors' experience, infantile hepatic hemangioma (IHH) is the most common benign liver tumor occurring prior to 1 year of age and probably the second most common cause, after VGAM, of AVM-associated high cardiac output failure during infancy. IHH exhibits a similar pattern of triphasic evolution of proliferation during the first weeks of life, plateau, and involution as seen in cutaneous infantile hemangiomas. It is expressed as GLUT-1 histological marker when liver biopsy is occasionally performed. Diagnosis is easily suspected because unique or multiple dome-shaped red–purple cutaneous hemangiomas are frequently associated, and abdominal ultrasound is strongly recommended in this setting (about 25 % of these children have liver involvement (Fig. 125.6)). Abdominal CT scan or MRI usually show a multifocal or diffuse form which is most likely to be associated with a more serious clinical course and have the highest mortality rate [34, 35] (Table 125.3). The HH present as solid, heterogeneous masses with a high signal on T2-W images and a low signal on T1-W images. Flow voids are frequently seen in relation to intralesional high-flow vessels, with a large porto-venous fistula associated in some cases [21, 33]. Consumptive hypothyroidism is involved in most cases of diffuse forms and has to be systematically ruled out

(high TSH level) [35, 36]. One-third to 55 % of infants with IHH develops heart failure, most commonly in diffuse forms of IHH [35–37]. Respiratory distress occurs in more than 30 % because of abdominal distention or compartmental syndrome [36, 37]. The hemodynamic profile is characterized by a marked cardiac index increase, up to 10 l/min/m^2, a decreased systemic vascular resistance, and in some cases a precapillary pulmonary arterial hypertension [38]. Prenatal diagnosis of HH in the focal form has been more recently reported in the literature, and it is now recognized as a possible cause of fetal cardiac failure [21, 35]. One retrospective series suggested that risk factors for severe HH that required urgent postnatal intervention (treatment of cardiac failure and or coagulation disorders) include fetal cardiomegaly or cardiac failure, large volume tumor exceeding 50 or 80 ml, or enlargement of more than two hepatic veins [21].

Table 125.3 Hepatic hemangioma and congestive cardiac failure in infancy. Liver hemangioma registry, Children's Hospital Boston

Type	Focal (n = 33)	Multifocal (n = 68)	Diffuse (n = 20)

Cardiomegaly	22 %	17 %	65 %
Heart failure	27 %	18 %	55 %

Adapted [35]

Giant Cutaneous Capillary Hemangiomas

Rapidly growing cutaneous hemangiomas associated with high cardiac output failure are a well-known complication of giant infantile hemangiomas (IHs) [39, 40]. The limbs, neck, face, or chest may be involved (Fig. 125.7). Congenital hemangiomas (CHs), a different but well-recognized clinical form of hemangiomas that arise in utero and present fully grown at birth, may either rapidly involute (RICH) or not involute (NICH) and may be of sufficient magnitude to produce life-threatening cardiac failure in the neonate. However, many CHs are uncomplicated and do not require active treatment during the neonatal period [41, 42]. Neither RICHs nor NICHs express GLUT-1, the specific marker of IHs [43]. In infantile hemangiomas that are associated with cardiac failure,

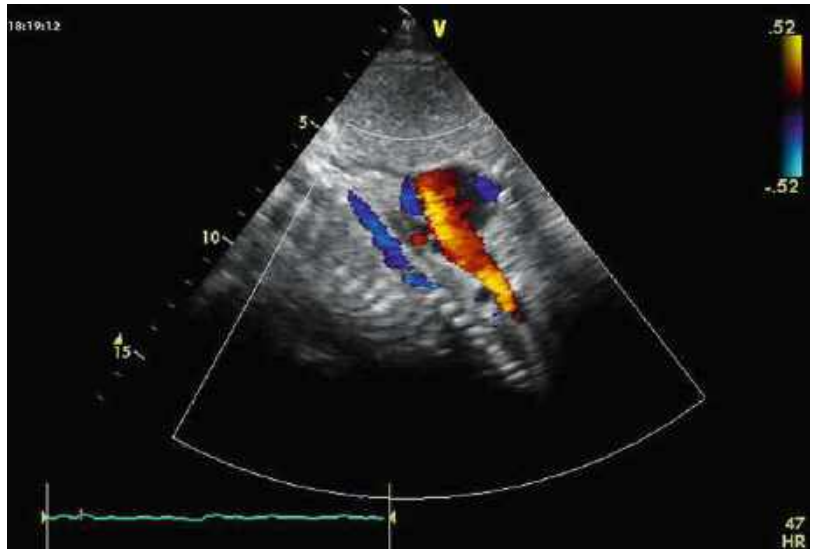
Fig. 125.7 Two examples of rapidly growing cutaneous hemangioma-associated cardiac failure in 2-month-old (**a**) and 3-month-old (**b**) infants

the use of propranolol to control the growth phase of IHs (1–3 mg/kg per day at starting doses) may contribute to improve symptoms of congestive heart failure promptly and dramatically [44, 45]. Other therapeutic options include steroids, embolization, or surgical resection. In CH with hemodynamic instability and congestive cardiac failure, the place of propanolol needs further confirmation [42].

Non-cerebral AVM Associated with HHT, Mostly Lung and Liver

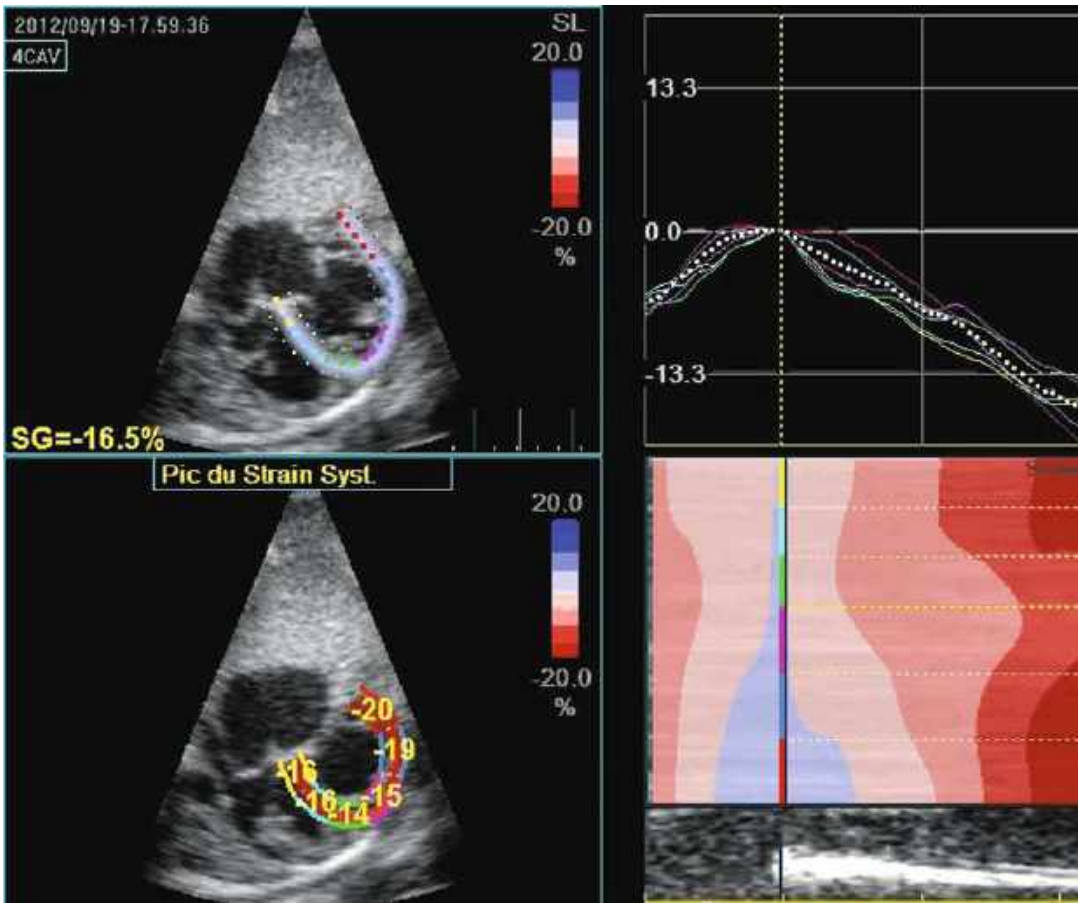
A clinical diagnosis of HHT (also known as Rendu–Osler–Weber syndrome) could be suspected according to the Curacao criteria, which include a history of recurrent spontaneous epistaxis; the presence of multiple skin telangiectasias at

Video 125.1



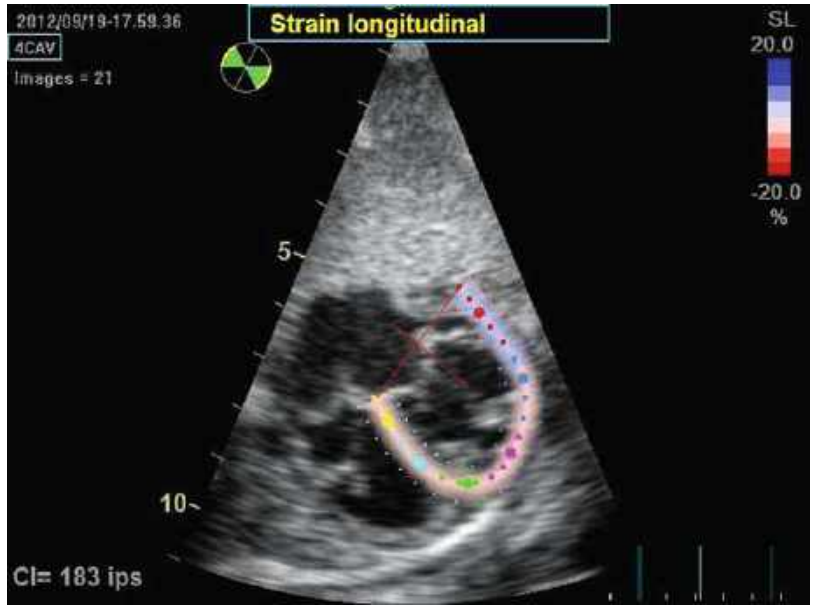
Video 125.2

Video 125.3



Video 125.4

Video 125.5



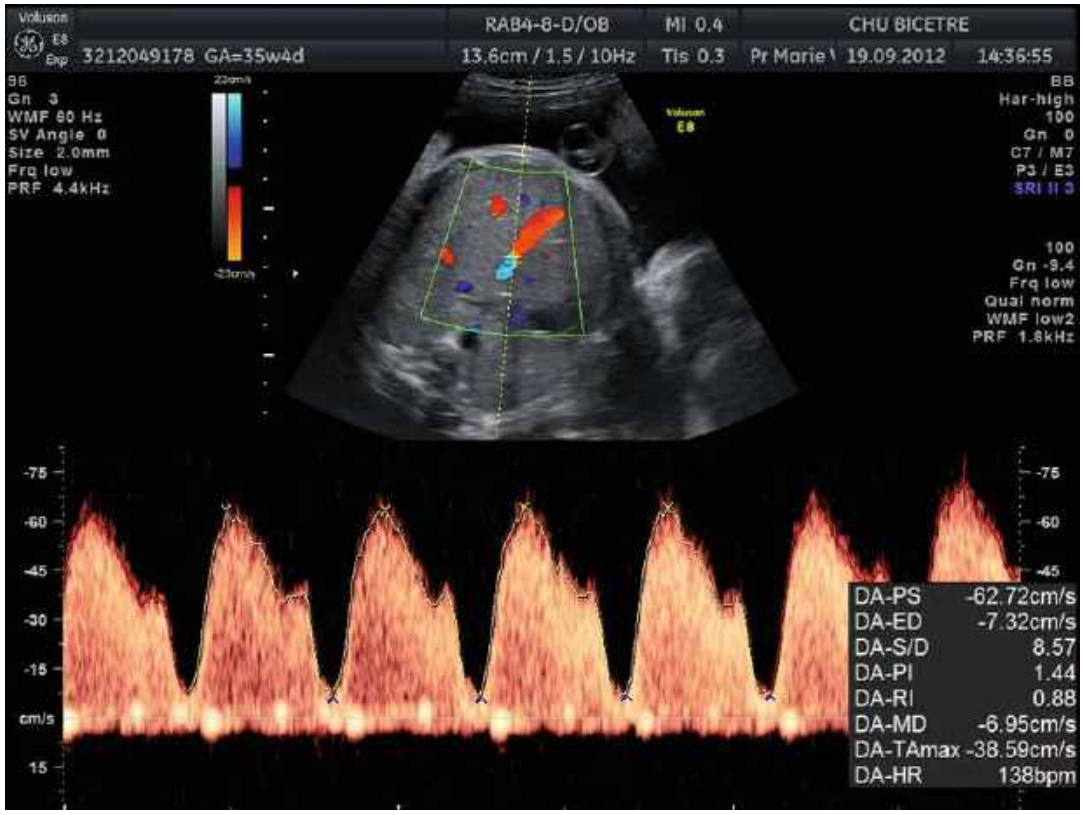
characteristic locations; a first-degree relative diagnosed with HHT; and the presence of visceral AVM. This condition is an autosomal dominant genetic disorder with an estimated prevalence between 1 in 5,000 and 1 in 16,000. Genetic mutations are identified in approximately 70 % to 90 % of cases of HHT and are found in either the endoglin gene (ENG) on chromosome 9 or the activin receptor-like kinase 1 gene (ACVRL1 or ALK1) on chromosome 12 (referred to as HHT1 and HHT2, respectively). In children with HHT, it was recently found that transthoracic contrast echocardiography (TTCE) has excellent sensitivity and negative predictive value for detecting definite pulmonary AVM that can cause right-to-left shunting leading to serious life-threatening complications like brain abscess, ischemic stroke, significant cyanosis, heart failure, or pulmonary hemorrhage. TTCE can be used as an initial screening tool and CT reserved only for those children with positive TTCE results or those with an intracardiac shunt in whom TTCE is non-diagnostic [46]. Congestive heart failure with high cardiac output and ventricular overload caused by intrahepatic arteriovenous shunting similar to that reported for symptomatic adult patients can occur in the neonatal period [47]. These severe neonatal cases were associated with missense mutations in the *ALK1* gene which are associated more commonly with liver AVM. It has been suggested recently that in cases of adult HHT associated with severe hepatic vascular malformations and high cardiac output, administration of bevacizumab (a VEGF inhibitor) was associated with a decrease in cardiac output and reduced the duration and number of episodes of epistaxis, and may avoid the need for alternative treatment such as embolization or liver transplantation [48].

Treatment of AVM-Associated Cardiac Failure

Amelioration of congestive heart failure symptoms and cardiac overload may be expected with either partial or complete occlusion of the AVM in some instances.

Nonspecific Medical Treatment

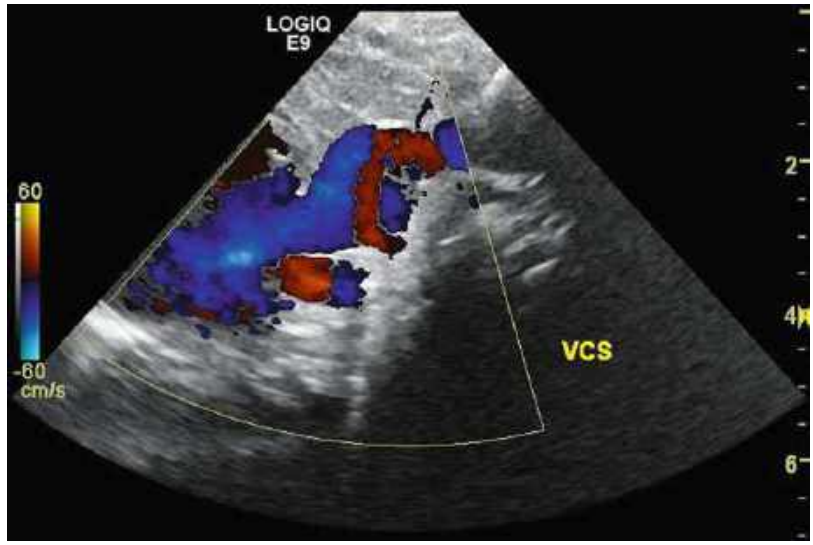
Medical management consists of diuretics (furosemide 2–6 mg/kg per day, spironolactone 3–5 mg/kg per day) to reduce the preload and improve symptomatic congestive heart failure, oxygen or nasal continuous positive pressure if

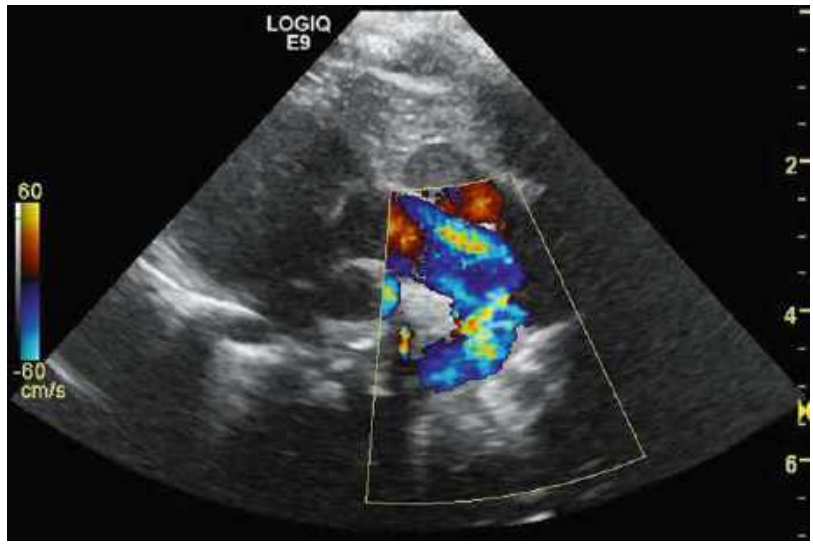


Video 125.6

Video 125.7

Video 125.8





Video 125.9

necessary, and continuous enteral feeding in cases of failure to thrive. In cases of tachycardia, some authors advocate digoxin use for its negative chronotropic effect in order to improve diastolic filling by decreasing the heart rate and increasing the duration of diastole. When circulatory failure (poor peripheral perfusion irrespective of blood pressure level, biological markers of organ failure) occurs (usually in the setting of vein of Galen aneurysm or hepatic hemangioma in the first weeks of life), mechanical ventilation is required in conjunction with opioids and/or benzodiazepines in order to lower oxygen consumption and reduce metabolic demand. Hemodynamic management is based on the echocardiographic findings as previously published [18, 22, 31]. An infusion of milrinone is started in patients with normal or relatively low cardiac output, poor peripheral perfusion or low urinary output, and severe right cardiac failure. Additional norepinephrine is added to restore right coronary perfusion

gradient and as such improve right ventricular function in cases of low blood pressure, especially when associated with oliguria. Other adrenergic agonists (dobutamine, dopamine, or adrenaline) should be used with caution in this setting because shortening of diastolic coronary filling time induced by tachycardia also worsens diastolic function and impairs cardiac output [31]. Additionally, in cases of suprasystemic pulmonary hypertension with right ventricular failure, PGE_1 infusion may be introduced early after birth to maintain or reopen the ductus arteriosus and discharge the right ventricle ("pop-off" effect) [17, 18]. Inhaled nitric oxide challenge failed to demonstrate any benefits in these setting in a few studies [18, 31]. However, these intensive care management strategies do not make sense if reduction or complete occlusion of the AVM cannot be obtained rapidly (see below). After a successful embolization procedure, medical treatment may be progressively decreased and stopped after the complete regression of symptoms. A regular cardiology follow-up, including clinical examination, ECG, and echocardiography, has to be organized with an end point of normalization of clinical status and echocardiographic parameters. Special attention should be given to cardiac output, cardiac chamber size, and pulmonary artery pressure. The introduction of a specific treatment may be discussed in cases of persistence of pulmonary hypertension.

Endovascular and Other Management Strategies

VGAM and Other Cerebral AVM

In most interventional neuroradiology teams, the endovascular procedure consists of catheterization via the femoral artery and a first transarterial occlusion session using glue (*N*-butyl cyanoacrylate). The goal for this first session is to reduce the shunt by at least a third, until significant hemodynamic improvement is achieved [9, 24, 49, 50]. The presence of brain damage or encephalomalacia is carefully assessed with brain MRI as soon as possible after birth and considered as a contraindication for an endovascular occlusion procedure. In these settings, the patient's eligibility is declined in accordance with these authors' policy [51]. If the treatment goal cannot be achieved in one session, the patient undergoes a second session of treatment on another day. After resolution of severe cardiac failure and pulmonary hypertension, weaning from intravenous cardiac medications, and discharge from the hospital, patients return for further treatment sessions at approximately 5–6 months of age, or earlier if failure to thrive persists [24, 51]. Conversely, in a few cases where improvement of the newborn cardiac function follows from medical management, the embolization procedure may be postponed until 5 months of age.

Hepatic Hemangiomas

Postnatal treatment for HH-associated cardiac failure remains controversial and may include medical supportive treatments for cardiac overload (digoxin, diuretics) or respiratory distress, and specific treatment to address the HH. The use of corticosteroids for the treatment of cutaneous IH has, until recently, been the de facto standard of care. In the past few years, the use of propranolol has changed the traditional treatment algorithm for patients with both cutaneous and hepatic IH (2–3.5 mg/kg body weight/day). However, in the event of severe life-threatening high-output heart failure associated with large shunts, embolization must be considered, although this procedure may not have an effect on the hemangioma volume per se. Other options include vincristine, interferon-α (rarely used because of neurotoxicity) and, again rarely, surgical resection in focal forms [34, 36, 45, 52, 53] (Fig. 125.6).

Primary and Secondary Cardiac Tumors

126

Rebecca S. Beroukhim and Tal Geva

Abstract

Cardiac tumors in children are usually histologically benign, although malignant cardiac tumors can occur. Diagnoses include rhabdomyoma, fibroma, myxoma, hemangioma, teratoma, papillary fibroelastoma, lipoma, malignant tumors, Purkinje cell tumor, and several additional rare tumors. This chapter reviews the incidence, classification, clinical manifestations, imaging characteristics, and management of the most common cardiac tumors found in children.

Keywords

Cardiac tumor • Cardiovascular magnetic resonance imaging • Carney complex • Fibroma • Gorlin syndrome • Hemangioma • Kasabach-Merritt phenomenon • Lipoma • Malignant cardiac tumor • Myxoma • Papillary fibroelastoma • Purkinje cell tumor • Rhabdomyoma • Teratoma • Tuberous sclerosis

Introduction

Cardiac tumors are a proliferation of tissue arising from various cellular precursors, including muscle (rhabdomyoma), fibrous (fibroma), vascular (hemangioma), fat (lipoma), nervous (paraganglioma), and ectopic (teratoma) tissues. Most cardiac tumors in children are histologically benign; however, primary and secondary malignant cardiac tumors also occur [1]. Because of the wide range in etiology and location (Fig. 126.1), each tumor carries a unique phenotype.

Accordingly, tumors can have variable clinical presentations, natural history, and treatment strategies.

Cardiac tumors in children are rare, with an incidence of up to 0.08 % in autopsy studies of children [2]. The advent of echocardiography has significantly improved detection rate, with a reported incidence of 0.32 % of first-time echocardiograms [2]. Of these, over 50 % of diagnoses are made at <1 year of age. The frequencies of cardiac tumors at Boston Children's Hospital from 1968 to 2010 are outlined in Table 126.1. Primary tumors of the heart are usually benign, and there is a low incidence of malignant primary tumors. However, approximately 1.6 % of malignant solid tumors in children have cardiac involvement from either distant metastasis or direct extension of the tumor into the heart [1].

Primary Benign Cardiac Tumors

Rhabdomyoma

Classification: Cardiac rhabdomyoma is a hamartoma of striated muscle that occurs within the heart. Gross pathology reveals a

Table 126.1 Frequencies of cardiac tumors at Boston Children's Hospital 1968–2010 [7]

Lipoma	3 (2)
Other[a]	15 (9)

[a]Other tumors include one foregut cyst, two papillary fibroelastoma, one inflammatory pseudotumor, one spindle cell sarcoma, one inflammatory myofibroblastic tumor, one plexiform neurofibroma, one pericardial cyst, two blood cysts, one Purkinje cell tumor, one paraganglioma, and three unknown or unclassified

circumscribed but not encapsulated mass that is millimeters to centimeters in size [3]. Multiple rhabdomyomas, often involving different cardiac chambers, are common. The tumors typically originate from the right or left ventricular myocardium, with intracavitary extensions that can result in inflow or outflow tract obstruction (Fig. 126.2). The cells contain large glycogen-rich vacuoles with a typical histologic appearance characterized by swollen myocytes and an almost "empty" cytoplasm with a centrally placed cytoplasmic mass and nucleus [3] (Fig. 126.3). The cells contain glycogen, and strands of cytoplasm extend to the periphery of the cell, giving the appearance of a "spider cell" [4]. Rhabdomyomas are associated with the tuberous sclerosis complex in a majority of newly diagnosed cases, including nearly all (95 %) patients with multiple tumors, and some (30 %) patients with solitary ventricular tumors [5]. The tuberous sclerosis complex is a dominantly inherited disorder affecting multiple organ systems, including the brain, skin, kidneys, heart, and other organs, and patients can have variable associated neurologic abnormalities including seizures and developmental delay. About 2/3 of newborns with a diagnosis of tuberous sclerosis have cardiac rhabdomyomas [6].

Incidence: Rhabdomyoma is the most common cardiac tumor diagnosed during fetal life and childhood, accounting for 61 % of all cardiac tumors in children (Table 126.1) [7].

Clinical Manifestations: Rhabdomyomas commonly present during fetal life or early childhood. The fetal presentation is usually that of a single or multiple cardiac masses detected on prenatal ultrasound, with or without fetal arrhythmia [8, 9]. The size and number of tumors are variable, ranging from small solitary tumors that grow proportionally with fetal size until ~30–32 weeks gestation, after which they remain stable, to multiple atrial and ventricular tumors that, in some cases, can cause hemodynamic compromise and fetal demise [8, 10, 11]. Causes of fetal hydrops and death have been attributed to obstruction to ventricular flow, arrhythmias, extrinsic compression of coronary arteries, and loss of functional myocardium [10]. A diagnosis of tuberous sclerosis can be inferred prenatally when cerebral masses are found by ultrasound or fetal brain MRI in a fetus with cardiac tumors, adding more certainty to the diagnosis of cardiac rhabdomyoma [8, 12]. Postnatally, rhabdomyomas may present as tumors that cause inflow or outflow tract obstruction, with clinically significant arrhythmias, or even sudden death [13]. Alternatively, they may present as an incidental finding in an asymptomatic infant or detected during evaluation for a suspected diagnosis of tuberous sclerosis [14].

Arrhythmias are commonly associated with the presence of cardiac rhabdomyomas [9]. In a recent review of 104 patients with rhabdomyomas, arrhythmias were present in 30 patients, including manifest pre-excitation, concealed accessory pathways, ectopic atrial tachycardia, and ventricular tachycardia [7].

Imaging: Echocardiography, either fetal or postnatal, is the primary diagnostic modality for evaluating cardiac tumors in children, including rhabdomyomas. When either multiple tumors are identified, or the patient has a confirmed diagnosis of tuberous sclerosis, a diagnosis of rhabdomyoma can be made by echocardiography alone [5]. The echocardiographic appearance of multiple rhabdomyomas is echo-bright masses within the ventricular myocardium (Fig. 126.4). Tumors can protrude into the ventricular cavities causing inflow or outflow obstruction. In the setting of a solitary tumor, cardiovascular magnetic

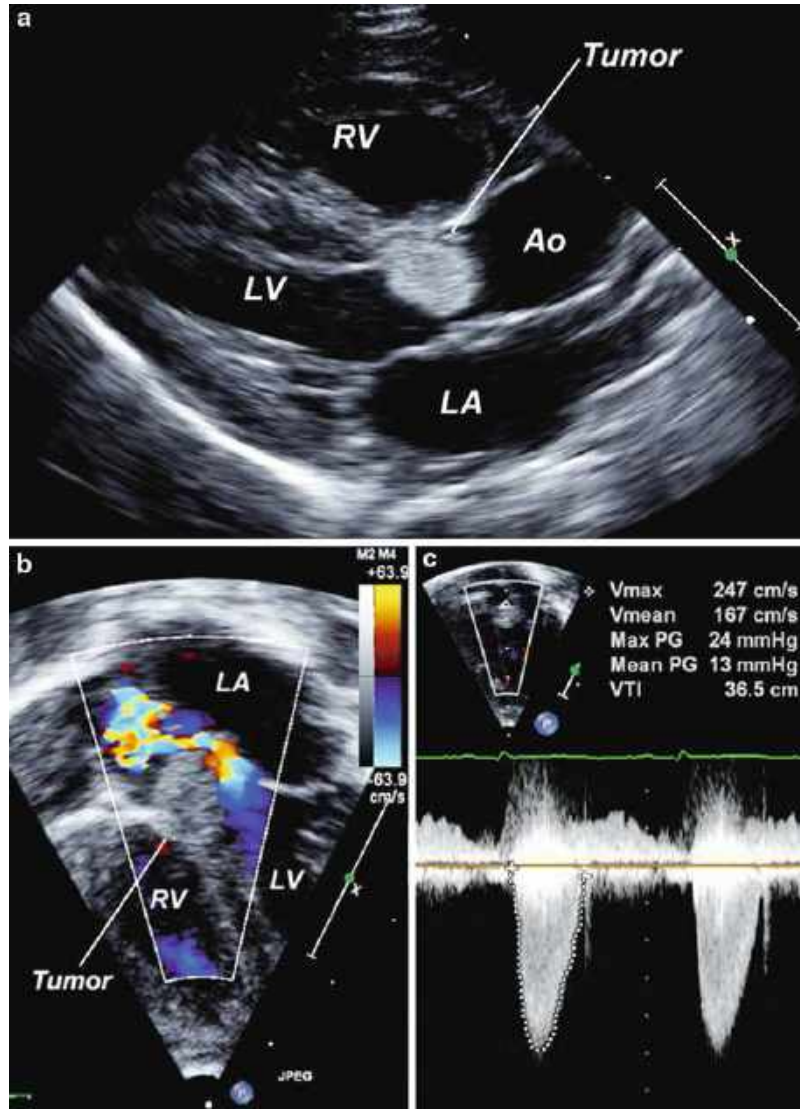

Fig. 126.2 Rhabdomyoma. Echocardiogram in a 3-month-old infant showing multiple tumors in the left ventricle, including one that caused left ventricular outflow tract obstruction. Because of significant left ventricular outflow tract obstruction, the tumor was resected with an uncomplicated postoperative course. Brain MRI was positive for multiple small subependymal nodules, and genetic testing confirmed TSC2 mutation characteristics of tuberous sclerosis

resonance imaging (CMR) can differentiate rhabdomyoma from other common tumors of childhood, including fibroma and hemangioma [15]. The imaging characteristics of rhabdomyoma by CMR include (1) intramyocardial or intracavitary location, attached to the myocardium; (2) hypointense on first-pass perfusion sequence; (3) isointense on myocardial delayed enhancement imaging; (4) mildly hyperintense on T2-weighted turbo spin echo imaging; and (5) homogenous appearance on all sequences (Fig. 126.5; Table 126.2) [15].

Management: The natural history of rhabdomyoma is regression over time, so that patients should be managed expectantly in the absence of severe cardiac symptoms, such as heart failure or arrhythmias [16]. In patients with severe outflow tract obstruction, resection has proven effective in reducing the degree of obstruction [14]. There is recent data that everolimus may be a novel drug therapy for the treatment of rhabdomyomas [17], with potential use in patients with large, hemodynamically significant tumors.

The arrhythmias that occur in patients with rhabdomyomas tend to resolve with tumor regression, so that medical management should be attempted before resorting to more invasive measures, such as catheter ablation or tumor resection [7].

Fibroma

Classification: Fibroma is a benign tumor of fibroblasts, composed of hyalinized collagen and elastic tissue [3, 18]. In children, the tumors are fibroblast-rich with possible mitotic activity; however in adults, the tumors are mostly acellular and composed primarily of collagen. Microsopic areas of calcification and regions of necrosis have also been observed [18]. Gross pathology reveals a well-circumscribed, unencapsulated solitary tan-colored mass ranging in size from 1 to 10 cm. On cut section, there is a classic "whorled" pattern.

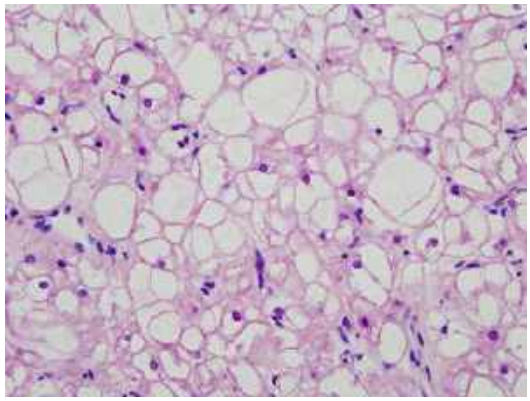

Fig. 126.3 Rhabdomyoma. Micrograph of rhabdomyoma histology demonstrating swollen myocytes with centrally placed nuclei

Incidence: Fibromas are the second most common tumor after rhabdomyoma, accounting for 14 % of cardiac tumors in children (Table 126.1) [7].

Clinical manifestations: Fibromas commonly present in the prenatal and pediatric population, but have been identified at any age including adults. Postnatally, symptoms include atrial and ventricular arrhythmias, congestive heart failure due to ventricular dysfunction or inflow/outflow obstruction, or sudden death [19]. About 1/3 of tumors are found incidentally in asymptomatic patients [18]. The incidence of fibroma in patients with nevoid basal cell carcinoma and Gorlin syndrome is higher than in the general population (~3 %).

Ventricular tachycardia is common among patients with fibromas and is often the presenting clinical manifestation. A recent series described

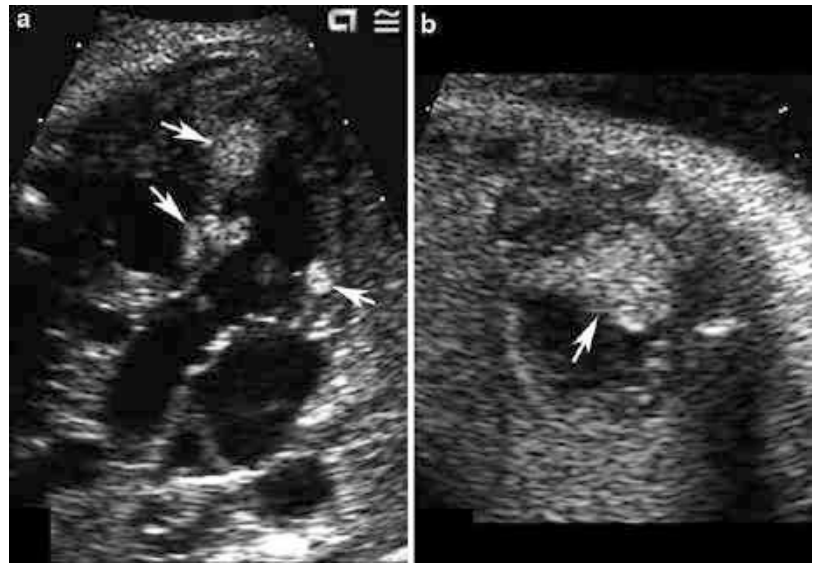

Fig. 126.4 Multiple rhabdomyomas. Fetal echocardiogram showing multiple rhabdomyomas at 29 weeks gestation. The patient was postnatally diagnosed with cortical tubers, subependymal nodules, and a mutation in the TSC2 gene. The father was subsequently diagnosed with the same gene mutation

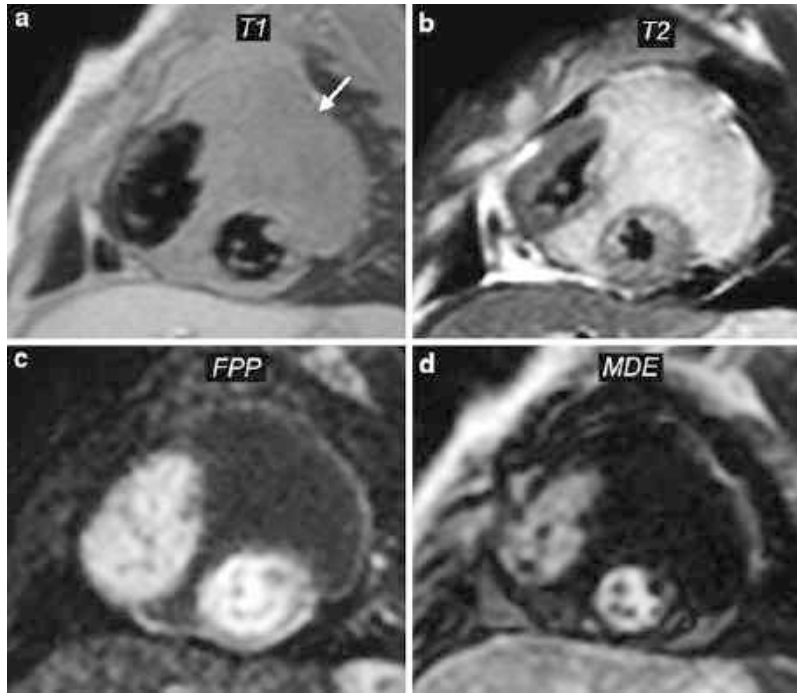

Fig. 126.5 Atypical solitary rhabdomyoma. Cardiovascular magnetic resonance imaging of atypical rhabdomyoma extending from the interventricular septum over the anterior-superior aspects of the left and right ventricular free walls (*arrow*). Imaging sequences as follows, with signal intensity compared to myocardium: (**a**) on T1-weighted turbo spin echo, the tumor is isointense; (**b**) on T2-weighted turbo spin echo imaging, the tumor is hyperintense; (**c**) on first-pass perfusion imaging, the tumor is hypointense; and (**d**) on myocardial delayed enhancement imaging, the tumor is isointense (Reproduced with permission [15])

67 % incidence of ventricular tachycardia in patients with fibroma [7]. In 13 of the 16 patients who underwent tumor debulking or resection and had follow-up data, none had recurrent ventricular tachycardia. Ventricular fibroma has a characteristic appearance on 12-lead ECG: inverted T wave in I and aVL or inverted T wave in leads I, aVL, and left-sided precordial leads (V1 through V6) (Fig. 126.6) [7].

The natural history of fibromas is that they generally do not shrink and in some cases can increase in size. In some cases tumor size does not change and as the patient grows the tumor appears smaller relative to body size. In patients with ventricular arrhythmias, there is data that the arrhythmias persist but may become less clinically significant [7].

Imaging: By chest radiography, fibroma may be evident as an abnormal ventricular contour with or without areas of calcification (Fig. 126.7). On echocardiography, fibromas are large, intramyocardial, echo-bright masses commonly involving the wall of the left ventricle or interventricular septum (Fig. 126.8). They have a homogenous appearance and may cause substantial hemodynamic compromise, including ventricular dysfunction and inflow or outflow obstruction. Because echocardiography has limited utility in distinguishing fibroma from other cardiac tumors in children, CMR is an important modality in the evaluation of fibroma. Its appearance is that of an intramyocardial tumor in the ventricular septum or free wall with a well-defined border and the following tissue characteristics: (1) strong hyperenhancement on myocardial delayed enhancement imaging, sometimes with a central hypointense (dark) core; (2) hypointense on first-pass perfusion

Table 126.2 Cardiovascular magnetic resonance imaging tumor diagnosis prediction table

Tumor type	Location	SSFP	T1	T1 + Fat sat	T2	FPP	MDE	Other
Fibroma	**Intramyocardial, ventricular septum or free wall**	–	±	±	±	**No**	++ **(well-defined border ± dark core)**	Can be in an atypical location
Rhabdomyoma	Intramyocardial or intracavitary, attached to myocardium	±	±	±	+	**No**	–	
Malignant	Infiltrative (defined below)[a]		±		±	Variable	± (if + then heterogenous appearance)	History of malignancy
Vascular[b]	Variable	±	–	–	+ (variable)	**Strong**	+ (variable and heterogenous)	Consider malignant tumor
Thrombus	**Mural or intraluminal**	–	–	–	–	**No**	—	MDE sequence, long inversion time
Myxoma	Typically left atrium but can be in any chamber	±	±	±	+	No	±	**Irregular, pedunculated, mobile**
Fibroelastoma	Pedunculated, mobile endocardial or valvular mass	–	–	–	–	No		
Pleuropericardial cyst	Right cardiophrenic angle	++	–	–	++	No	–	Smooth walled and well defined
Purkinje cell tumor	Ventricular myocardium		++	—	–	No		**Ventricular arrhythmia**
Teratoma	Intrapericardial (usually compressing SVC and/or RA)	±				No		Multilocular bosselated mass with solid and cystic areas
Lipoma[c]	Any chamber	–	++	—	±	No	–	

Reproduced with permission [15]

Bolded fields signify either strongly supportive of or necessary for diagnosis

Key: – denotes iso- or hypointense, ± denotes variable intensity, + denotes hyperintense, ++ denotes strongly hyperintense

[a]Infiltrative: (1) crossing an annular or tissue plane within the heart, (2) involving both cardiac and extracardiac structures, or (3) appearance of linear growth through a large vessel such as the superior or inferior vena cava

[b]Vascular refers to tumors with strong vascular supply, including hemangioma, malignant vascular tumors, and paraganglioma

[c]Lipoma was not tested as no cases of biopsy-proven lipoma were included

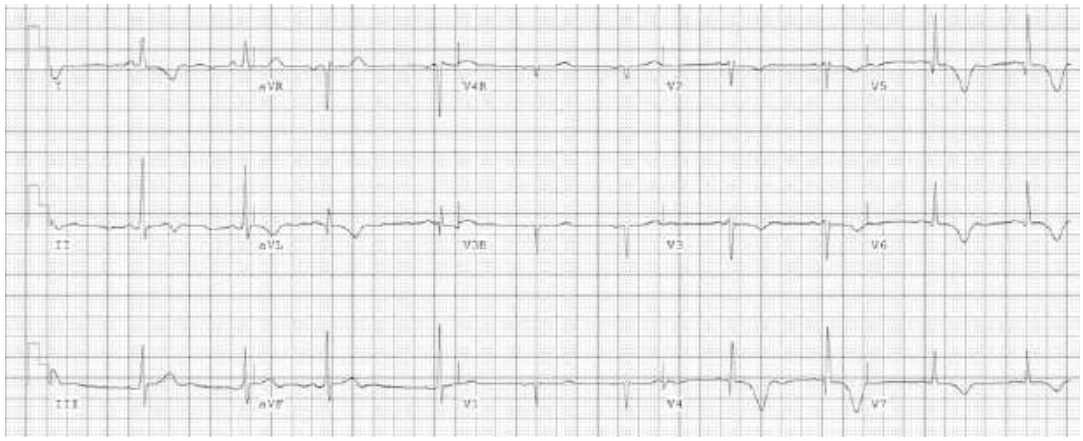

Fig. 126.6 Fibroma. Electrocardiogram of a 10-year-old boy who was incidentally found to have a left ventricular fibroma. Note the T wave inversions in leads I, aVL, and the left-sided precordial leads (V2 through V6)

Fig. 126.7 Fibroma. Chest radiograph of a patient with a left ventricular fibroma, demonstrating a bulge with coarse calcifications at the left ventricular apex

imaging; and (3) variable, heterogenous appearance on T1- and T2-weighted imaging (Fig. 126.9; Table 126.2) [15]. CMR images are particularly useful for planning surgical resection, as they give a spatial map of the tumor location as well as surrounding cardiac structures (including coronary artery relationship to the tumor).

Management: There are several approaches to the management of patients with fibroma. Because the tumor is not metastatic, management is directed at treatment of symptoms and local complications associated with the tumor. Patients who present with clinically significant arrhythmias or hemodynamic instability require appropriate medical management. Heart transplantation has been performed in patients with massive tumors in whom surgery was not considered feasible; however when possible, surgical debulking or resection of a fibroma is the treatment of choice. Postoperatively, most arrhythmias resolve [7]. Residual problems can include regional wall motion abnormalities at the site of resection and impaired valvar function requiring further surgical intervention [20].

Myxoma

Classification: Cardiac myxoma is a neoplasm of multipotent mesenchymal cells of endocardial origin, or myxoma cells [21]. The gross appearance is variable among different tumors. Pathologic examination reveals a white, gray-white, yellowish, or brownish mass measuring between 1 and 15 cm in dimension [22]. The mass is usually gelatinous, but can also have regions with a very hard consistency [23]. The surface may be lobular, smooth, or villous and frondlike [23]. The tumor is usually pedunculated with a short stalk, but may also be sessile [4, 21].

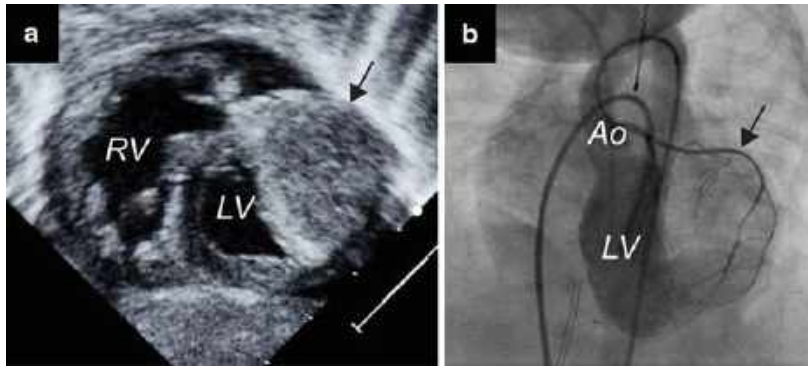

Fig. 126.8 Fibroma. Echocardiogram (**a**) and cardiac catheterization (**b**) of a fibroma in the anterolateral wall of the left ventricle. The mass effect of the tumor caused restrictive left ventricular physiology and moderate-to-severe mitral regurgitation. The patient also had several episodes of sustained ventricular tachycardia. The tumor was resected with no further tachyarrhythmias and good global left ventricular function in follow-up. There was a persistent regional wall motion abnormality at the prior tumor site

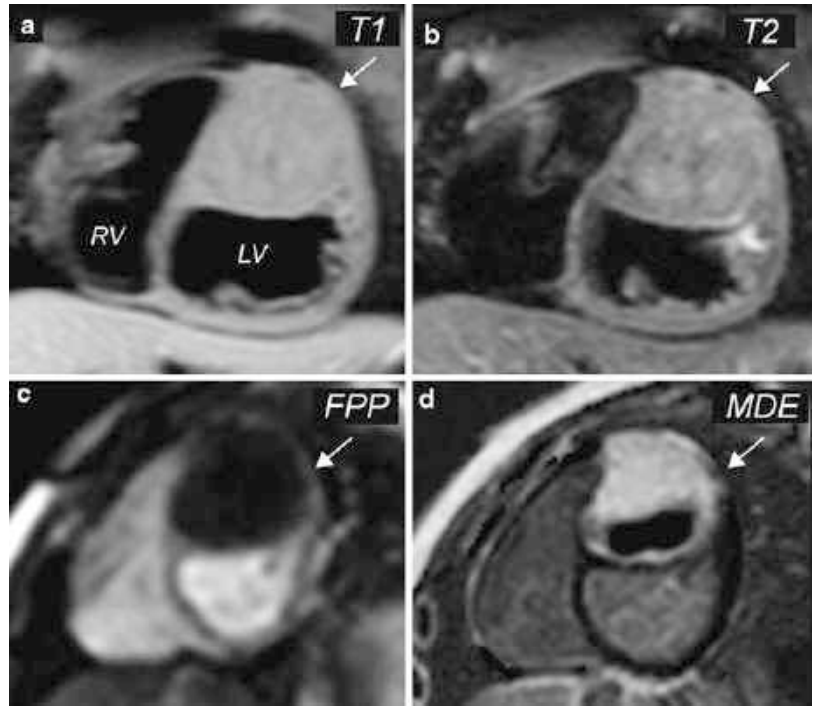

Fig. 126.9 Left ventricular fibroma. Cardiovascular magnetic resonance imaging of a large fibroma involving the anterior wall of the left ventricle. Imaging sequences as follows, with signal intensity compared to adjacent myocardium: (**a**) isointense signal on T1-weighted turbo spin echo, (**b**) slightly hyperintense signal on T2-weighted turbo spin echo, (**c**) strongly hypointense signal on first-pass myocardial perfusion imaging, and (**d**) strongly hyperintense on myocardial delayed enhancement imaging with a *central dark* core (Reproduced with permission [15])

About 75 % arise from the left atrium; the remainder arise from the right atrium, right or left ventricles, or from multiple chambers [22–24]. Of the left atrial myxomas, ~80 % arise directly from the fossa ovalis [21]. Focal areas of hemorrhage, calcification, fibrosis, and necrosis have been reported. Fibrosis and calcification are more commonly seen in older adults [21, 23]. On gross inspection, myxomas may be covered by thrombus [24]. In one of the largest series of myxomas, 64 % were deemed histologically "active," or with a dense myxoma cell population, compared to 36 % that were "inactive," or with sparse cell concentration and

calcification or ossification. In that cohort of cases, all recurrences (5 %) occurred in tumors that were "active" with poorly differentiated cells [21]. While cardiac myxomas are considered histologically benign, they can either recur locally after resection or embolize throughout the arterial tree and cause stroke or local growth and aneurysms, particularly within the central nervous system [21, 24].

Incidence: Cardiac myxoma is the most common primary cardiac tumor in adults (typically appearing between 30 and 60 years of age). The tumor has also been found in children as young as 2 months [22, 25]. In the Boston Children's Hospital series, myxoma accounted for 8 % of all cardiac tumors in children (Table 126.1) [7]. There is a slight female predominance [21–23].

Clinical Manifestations: It is important to note that there are no pathognomonic signs in the clinical presentation of myxoma and that symptoms depend on location, size, and mobility of the tumors [21, 24]. In fact, there are no symptoms in around 10 % of cases, with variable modes of presentation in the remainder. The following triad of symptoms has been described in some patients with cardiac myxoma: (1) *obstructive symptoms* due to valvular obstruction; (2) *systemic emboli*, commonly involving the central nervous system, but also in other locations along the arterial bed such as the aortic bifurcation, retinal arteries, and coronary arteries. Cerebral emboli may lead to fusiform aneurysms of the cerebral arterial system; and (3) nonspecific *constitutional signs* including myalgia, muscle weakness, arthralgia, fever, weight loss, anemia, and elevated sedimentation rate. The constitutional symptoms are thought to be related to an immunologic response to the tumor. Smooth-surfaced myxomas are more likely to present with constitutional symptoms, whereas friable, irregular, or villous tumors tend to embolize [21, 22, 24]. There is no significant association between the size of the tumor and the presence or absence of clinical symptoms.

About 10 % of patients with myxomas have the Carney complex, which is a neuroendocrine-cardiac syndrome characterized by (1) familial recurrent myxoma; (2) pigmented skin lesions, schwannomas, and multiple recurrent mucocutaneous myxomas; and (3) various endocrinal overactivity and neoplasms [26]. About 67 % of patients with Carney complex have cardiac myxomas [26]. Mutations in the gene-encoding PRKAR1α have been identified most commonly in patients with Carney complex, which functions as a tumor suppressor gene [26].

About 2/3 of the patients have abnormal findings on electrocardiogram. The most common finding is left atrial enlargement, followed by ST segment abnormalities, ventricular hypertrophy, microvoltage, and extrasystoles. Atrial arrhythmias are rare [21].

Imaging: Chest radiograph findings vary depending on the size and location of the tumor and may include left atrial enlargement, pulmonary vascular congestion, enlarged pulmonary artery, cardiomegaly, and pleural effusions. Intracardiac calcifications are commonly found [23].

Echocardiography is the screening modality of choice for identifying a myxoma. The classic appearance is that of a pedunculated left atrial myxoma that moves in and out of the mitral valve orifice during the cardiac cycle (Fig. 126.10).

Indications/Utility of CMR in Myxoma: Cardiac myxoma has the following appearance on CMR imaging: (1) irregular border, pedunculated, and mobile; (2) hyperintense on T2-weighted turbo spin echo imaging; (3) hypointense on first-pass perfusion; (4) heterogeneous enhancement (iso- or hyperintense) on myocardial delayed enhancement imaging; and (5) location in any cardiac chamber (commonly left or right atrium or atrial septum) (Fig. 126.11; Table 126.2) [15].

Management: The treatment of choice is prompt surgical removal to avoid complications of tumor embolization or sudden death [21, 22, 24]. Tumor resection is generally straightforward, particularly in the setting of a pedunculated tumor, and resection has been shown to carry a low operative mortality [21, 24]. Full thickness excision of the tumor base is recommended to avoid local recurrence, which is reported in ~5 % of cases [21, 24].

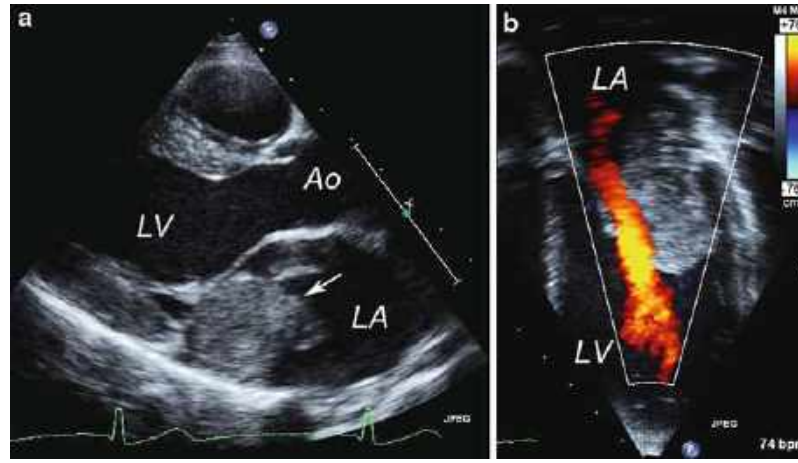

Fig. 126.10 Myxoma. Echocardiogram of a left atrial myxoma in the parasternal (**a**) and apical (**b**) views with prolapse into the mitral valve orifice during diastole. The patient was asymptomatic with left ventricular hypertrophy on ECG. The tumor was surgically resected with a good postoperative outcome

Valvuloplasty or valve replacement may be indicated if a valve has sustained significant damage from the tumor [22, 24]. The most frequent postoperative complication is early transient arrhythmias [21].

Hemangioma

Classification: Vascular tumors of the heart fall into several categories with different biologic behavior, ranging from benign to malignant. Because of historical variations in the nomenclature of vascular tumors, the International Society for the Study of Vascular Anomalies was developed in 1996 [27]; in spite of this, misclassification of vascular tumors is common [28]. The recommended grouping of anomalies is listed in Table 126.3. Classification is based on the pathologic appearance as well as various immunohistochemical markers.

Cardiac hemangiomas (congenital, infantile, and intramuscular) are comprised of a proliferation of endothelial cells of blood vessels and are histologically the same as hemangiomas in other regions of the body [29]. Intramuscular hemangiomas are composed of vascular channels interspersed between muscle bundles of myocardium [29]. Because the different subtypes of cardiac hemangioma are difficult to distinguish without histology, and because of problems with misclassification in the literature, differences in appearance and natural history of the subtypes of cardiac hemangioma have not been well delineated. In general, they may involve the endocardium, myocardium, or epicardium and can develop in any location within the heart [29, 30]. On gross pathology, they appear red and hemorrhagic [31].

There is no known association between cardiac hemangioma and hereditary hemorrhagic telangiectasia, which is a genetic disorder that leads to vascular malformations within the skin, mucous membranes, and some internal organs. A previously described case is likely attributed to a vascular malformation in the heart [32].

Kaposiform hemangioendothelioma of the mediastinum with cardiac involvement has been reported in the literature [33]. This patient presented as a fetus with pericardial effusion, and postnatally had the classic presentation of Kasabach-Merritt phenomenon (thrombocytopenia secondary to platelet trapping). Angiosarcoma and lymphangiosarcoma are discussed under the heading "Primary cardiac malignant tumors."

Incidence: Hemangioma is an uncommon cardiac tumor in children, accounting for 4 % of cases in the Boston Children's Hospital series (Table 126.1) [7].

Clinical presentation: Cardiac hemangiomas can present at any age, but are more commonly found prenatally, in neonates, and in children [30]. Clinical presentations vary according to

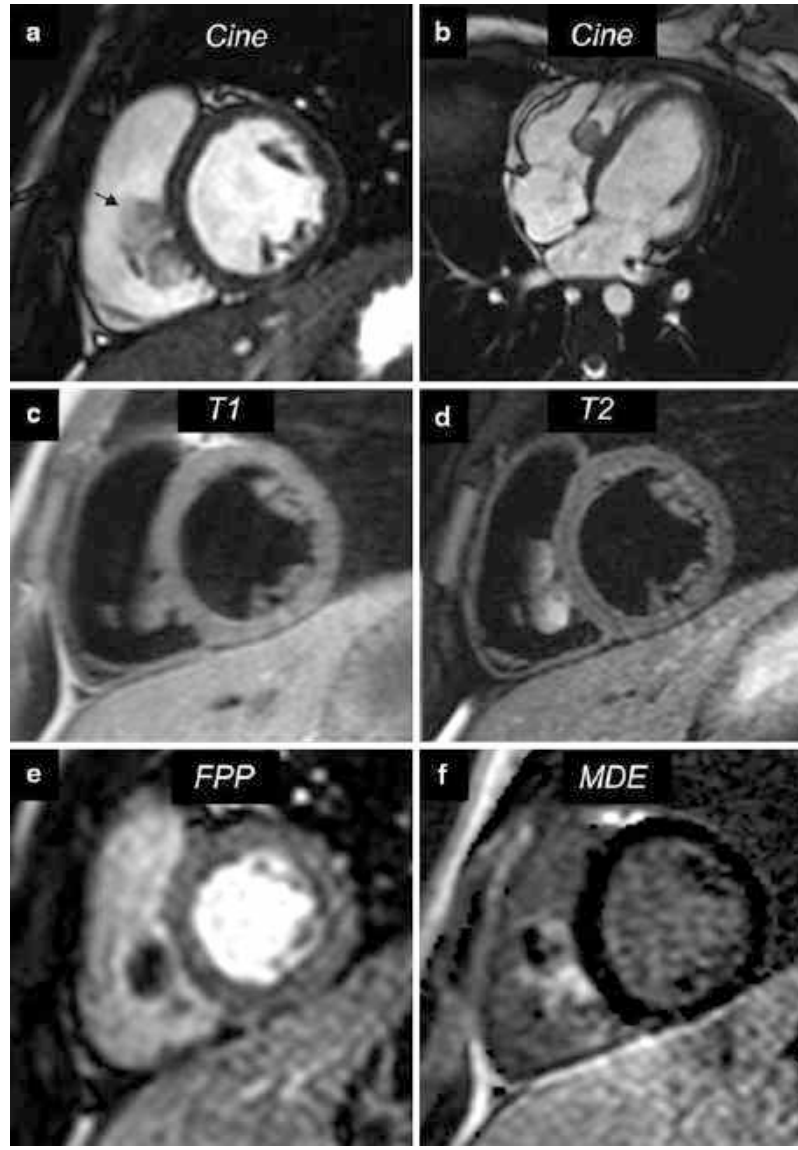

Fig. 126.11 Myxoma. CMR imaging of a myxoma in a 17-year-old boy with history of chest pain and palpitations. Imaging sequences as follows: (**a, b**) on cine imaging the tumor is in the right ventricle, attached to the interventricular septum; (**c**) on T1-weighted turbo spin echo imaging, the tumor is isointense relative to myocardium; (**d**) on T2-weighted turbo spin echo imaging, the tumor is hyperintense relative to myocardium; (**e**) the tumor is hypointense on first-pass perfusion imaging; and (**f**) the tumor is hyperintense on myocardial delayed enhancement imaging

patient age and anatomic location. Prenatally, they present as a cardiac mass during routine obstetric ultrasound examination. Neonatal hemangiomas commonly cause pericardial effusion and tamponade [34], and patients may also present with arrhythmias, syncope, congestive heart failure, and sudden death [30, 35]. Most cases in older children and adults are asymptomatic and discovered incidentally [30].

Imaging: Hemangiomas diagnosed in the neonatal period commonly arise from the right atrium, but are much less likely to involve the right atrium when found in an older child [34]. Echocardiography is useful in documenting the presence and location of the tumor and occasionally demonstrates vascular channels within the tumor (Fig. 126.12). However, CMR imaging is diagnostically more useful in distinguishing vascular from nonvascular tumors because of the presence of avid perfusion on first-pass perfusion imaging. Imaging characteristics of vascular tumors by CMR include (1) strongly positive first-pass perfusion; (2) variable, often weak enhancement on myocardial delayed

[a]List of vascular tumor types from Dr. John Mulliken, Boston Children's Hospital (personal communication)
[b]Note there are two types of congenital hemangiomas: (1) RICH (rapidly involuting congenital hemangioma) and (2) NICH (non-involuting congenital hemangioma)

enhancement imaging; and (3) variable location (Fig. 126.13; Table 126.2). Note that imaging sequences currently available by CMR do not allow reliable distinction among benign vascular tumors, malignant vascular tumors, vascular malformations, and other tumors with rich vascular supply [15].

Management: Historically, cardiac hemangiomas have been unpredictable in their natural history. Because noninvasive imaging cannot reliably identify which tumors have malignant characteristics, surgical resection is recommended and usually has a favorable outcome [36]. When technically feasible, the tumors are completely resected with minimal evidence of recurrence in follow-up. Occasionally, the tumors are not completely resectable and may recur locally. Operative complications include tumor embolization, local damage to the heart or associated valves, arrhythmias, and sudden death [30].

Intrapericardial Teratoma

Classification: Intrapericardial teratomas belong to the family of germ cell tumors, comprised of benign or malignant tumors derived from primordial germ cells [3, 37]. The gross appearance is an encapsulated, lobulated, cystic mass with fluid-filled cavities of various sizes intermingled with solid areas [38]. Tissue is derived from all three germ cell layers and can include neuroglia, cartilage, bone, smooth muscle, skeletal muscle, liver, intestine, pancreas, and glandular tissue [39, 40]. About 15 % are classified as malignant based on the histologic characteristics [41].

Clinical presentation: Prior to the era of fetal echocardiography, most patients presented in the newborn period with clinical symptoms of respiratory distress, cyanosis, and congestive heart failure related to pericardial effusion and/or cardiac compression from the tumor [42]. Since the first prenatal diagnosis was reported in 1983, numerous fetal cases have been described with a mean age at diagnosis of 28 ± 5 weeks gestation [43]. The tumors are commonly missed at second trimester ultrasound examinations, and grow rapidly between 20 and 40 weeks gestation when cellular differentiation occurs [37, 42, 44]. By the third trimester, almost 50 % of fetuses develop pericardial effusion, hydrops, or tamponade [41, 43]. A high maternal serum alpha-fetoprotein has been reported in these pregnancies [45]. Beyond the perinatal period, patients may present with recurrent pericardial effusion [46]. Rarely are teratomas discovered incidentally in an asymptomatic adult [38].

Incidence: Intrapericardial teratoma is a rare cardiac tumor in children, accounting for 2 % of all tumors in the Boston Children's Hospital series (Table 126.1) [7].

Imaging: By echocardiography, intrapericardial teratoma is a large, echo-bright mass usually located adjacent to the right atrium with cystic components. There is classically a fibrous attachment to the aorta, through which courses the source of blood supply. Rarely, the tumor attaches to the pulmonary trunk or present as an intracardiac mass [3, 41]. As with other tumors, the clinical signs relate to the size and location of the tumor. Commonly tumors will cause extrinsic compression of the right atrium and/or superior vena cava, which may be associated with low cardiac output, pericardial effusion, and fetal hydrops. Imaging characteristics of intrapericardial teratoma by CMR include the following:

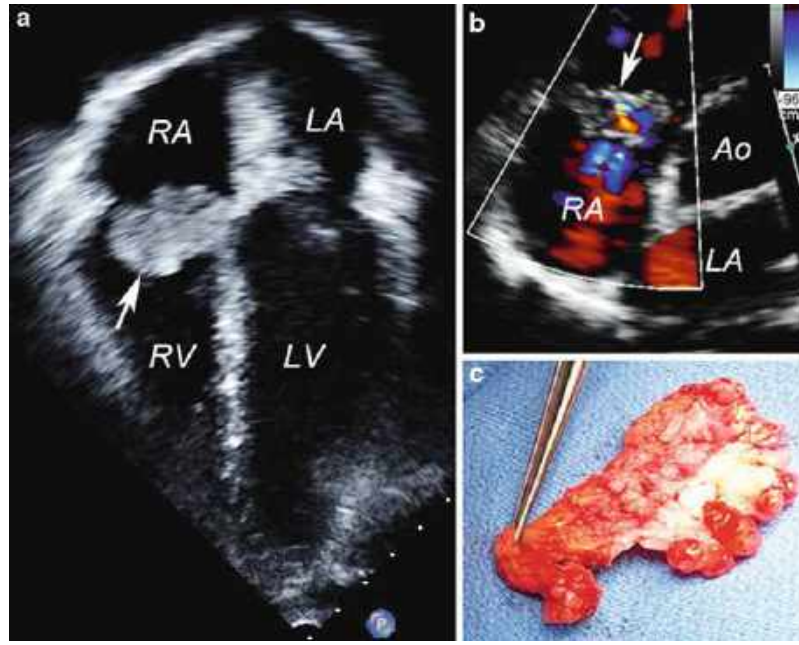

Fig. 126.12 Hemangioma. Echocardiogram and gross appearance of a hemangioma involving the anterior tricuspid valve leaflet. The tumor is attached to the anterior tricuspid valve leaflet in the apical view (**a**), has some vascular spaces with low velocity flow by color Doppler imaging in the parasternal short axis view (**b**), and the gross appearance is red and hemorrhagic (**c**). The appearance by CMR imaging is shown in Fig. 126.13

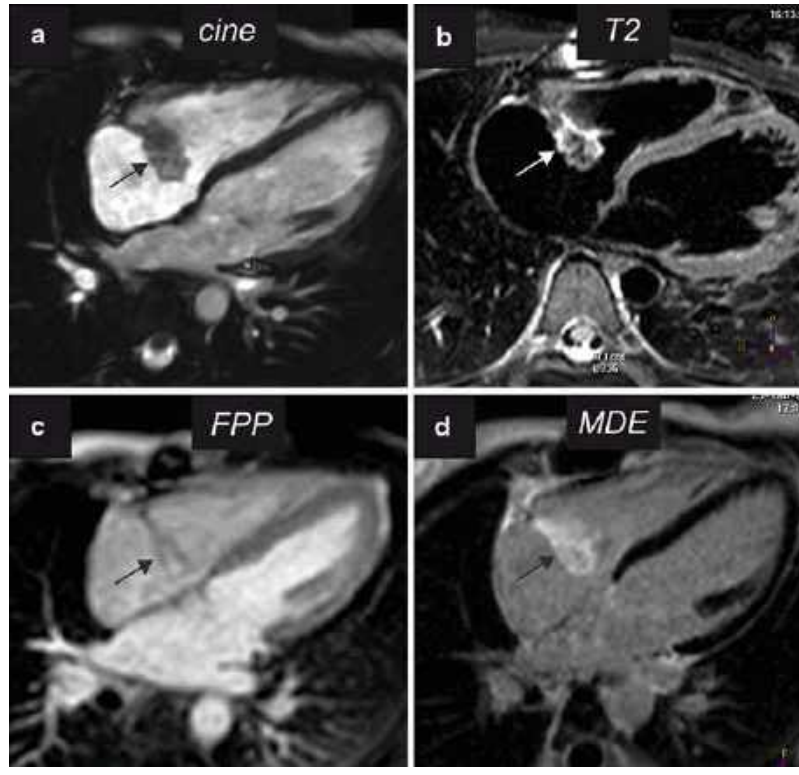

Fig. 126.13 Hemangioma. CMR imaging of a hemangioma involving the anterior leaflet of the tricuspid valve. Imaging sequences as follows, with signal intensity compared to adjacent myocardium: (**a**) hyperintense signal on cine steady-state free precession imaging; (**b**) hyperintense signal on T2-weighted turbo spin echo imaging, with dark vascular spaces within the tumor; (**c**) hyperintense signal on first-pass perfusion imaging, similar to the blood pool; and (**d**) hyperintense signal on myocardial delayed enhancement imaging. The echocardiogram and gross histology are shown in Fig. 126.12

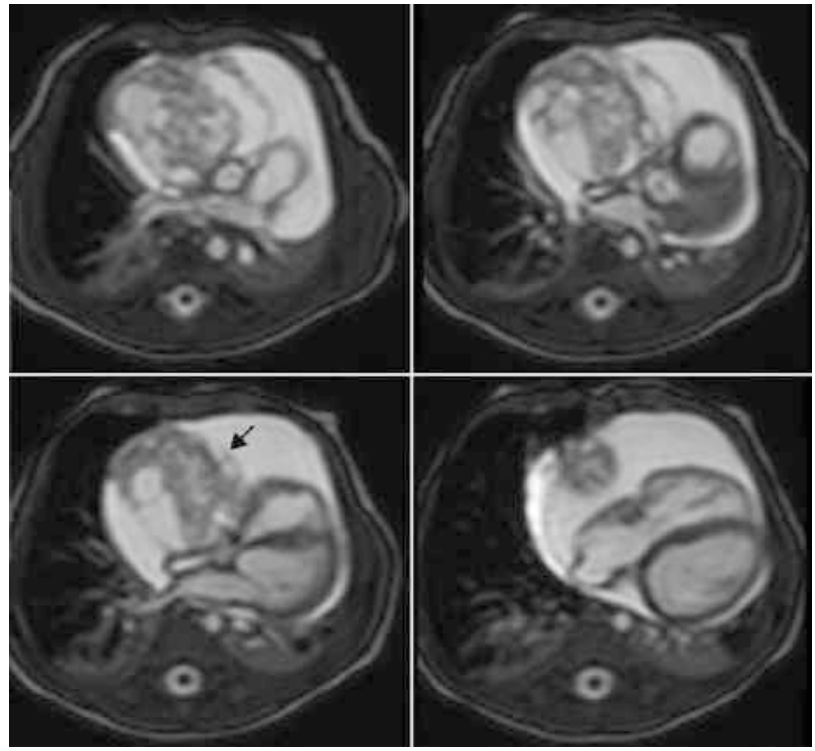

Fig. 126.14 Teratoma. CMR imaging of an infant with a large intrapericardial teratoma. On cine steady-state free precession imaging in the axial plane, note the presence of a large, cystic, intrapericardial tumor, associated compression of the superior vena cava and right atrium, and a large pericardial effusion

(1) intrapericardial, often compressing the superior vena cava and/or right atrium; (2) multilocular, bosselated mass with solid and cystic areas; and (3) hypointense on FPP (Fig. 126.14; Table 126.2) [15].

Management: For prenatally diagnosed intrapericardial teratomas, management depends on the presence or absence of hydrops. In the fetus with hydrops, pericardiocentesis is recommended to reduce the risk of in utero fetal demise and allow for lung development [37]. In cases of rapid reaccumulation of pericardial fluid, creation of a pericardioamniotic shunt has been described with variable results [37, 44]. If hydrops is absent, the pregnancy can be carried to term, with prompt early postnatal resection. Some authors recommend delivery by cesarean section to reduce the risk of respiratory complications and cardiac compression during vaginal delivery [37, 44, 47]; however, others suggest pericardiocentesis before vaginal delivery [45]. Postnatal resection within the first few days of life is recommended to address cardiorespiratory symptoms and to decrease the chance of malignant metastasis [37, 41]. Postnatally, unresected teratomas can grow rapidly in size, but resected teratomas have a favorable outcome [3]. Most surgeries can be performed without the use of cardiopulmonary bypass, unless the tumor has invaded the aorta or an adjacent cardiac structure [41, 47]. In a review of prenatally diagnosed intrapericardial teratoma, the overall hospital mortality, including fetal demise, was 16/38 or 42 % (13 deaths, 1 death after fetal surgery, 1 tumor recurrence causing death, 1 termination) [43]. Fetal hydrops was associated with a higher rate of mortality, and within that subset, pericardiocentesis was associated with a lower rate of mortality (0/15 nonsurvivors had pericardiocentesis, compared to 10/22 survivors) [43].

Malignant Cardiac Tumors

Classification: Primary and secondary cardiac malignancies are exceptionally rare in the pediatric population and are typically associated with

Table 126.4 Malignant cardiac tumors[a]

Tumor type	Primary	Secondary
Angiosarcoma [51, 72, 73]	✓	✓

Neuroblastoma [72]		✓

[a]Partial list

a very poor prognosis. In a series of 3,641 children with solid malignancies, Chan et al. reported 59 patients (1.6 %) with cardiac involvement. Of those, 45 had distant metastasis to the heart, and 14 had direct extension of the tumor into the great veins and/or cardiac chambers [1]. Examples of primary and secondary cardiac tumors are outlined in Table 126.4 (list may not be all-inclusive). In children, sarcomas are the most common type of primary malignant cardiac tumor, accounting for ~75 % of cases [48].

Clinical Presentation: The clinical presentation of a malignant cardiac tumor relates to tumor size and location. Symptoms are generally nonspecific and vary from a heart murmur in an asymptomatic child to fevers, lethargy, lightheadedness, dyspnea, heart failure, arrhythmia, stroke, and sudden death [48–52]. Because most malignant cardiac tumors in children have metastasized from another location, patients will often have a prior history of malignancy.

Imaging: CMR imaging characteristics of malignancy include the following: (1) history of extracardiac malignancy; (2) infiltrative appearance, defined as (a) crossing an annular or tissue plane within the heart, (b) involving both cardiac and extracardiac structures, or (c) appearance of linear growth through a large vessel such as the superior or inferior vena cava; and (3) variable appearance on cine steady-state free precession, T1-weight turbo spin echo, T2-weighted turbo spin echo, first-pass perfusion, and/or myocardial delayed enhancement imaging. If hyperintense on myocardial delayed enhancement imaging, the appearance is heterogenous (Table 126.2) [15].

Management: Management of cardiac malignant tumors is dictated by the primary tumor. In general most malignant cardiac tumors are fairly aggressive with a poor prognosis, and treatment is palliative in nature [51]. In some cases surgical resection with chemotherapy or heart transplantation is offered [15, 48–50, 53]. For patients with symptomatic effusions associated with a malignant cardiac tumor, pericardiocentesis or pericardial window can be a temporizing palliative measure.

Papillary Fibroelastoma

Classification: Papillary fibroelastoma is a primary valvular tumor, originating from cardiac valvular endocardium. The tumor contains fibrous tissue, elastic fibers, and smooth muscle [54]. They measure from millimeters to centimeters in dimension and can arise from either the atrioventricular valves or semilunar valves [4]. On the mitral and tricuspid valves, the tumors usually occur on the atrial aspect of the valve; whereas they may occur with equal frequency on either the ventricular or arterial side of the semilunar valves [4]. The tumors may also have attachments to the chordae tendineae, papillary muscles, or ventricular endocardial surface [55]. The gross appearance is that of filiform threads attached to the endocardium, either sessile or connected to a short pedicle. When suspended in water, they may have the appearance of a sea

anemone [4]. On histology, the strands have a central core of collagen that is continuous with the valve leaflet. The core is surrounded by a myxomatous matrix, with an outer layer of elastin [4]. It has been suggested that this lesion is a hamartoma of subvalvar apparatus (as its histology similar to that of normal chordae tendineae) versus a proliferative response to mechanical injury [4].

Clinical Presentation: Given its rare occurrence in children, the clinical presentation of papillary fibroelastoma is limited to case reports. It can present either as an incidental finding in an asymptomatic patient or varied presentations including right heart obstruction, myocardial infarction, cardiac failure, and embolic events (including stroke and neurologic symptoms associated with tumor embolization) [54–56].

Incidence: Papillary fibroelastoma in children is extremely rare, with two cases in the Boston Children's Hospital series (Table 126.1) [7]. There is speculation that the incidence is higher in environmentally polluted areas [57].

Imaging: By echocardiography: one or several round, homogenous, echogenic masses attached to a valve [54, 56]. The appearance has also been described as multiple masses attached to thin stalks, similar to a string of beads [55]. By CMR, characteristics include a pedunculated, mobile, endocardial or valvular mass. Other imaging characteristics have not been well defined [15].

Management: The standard treatment for papillary fibroelastoma is surgical excision. In some cases, only surgical debulking is possible without causing valve incompetence [55]. In those cases with significant valve destruction, valve replacement is required [56].

Lipoma

Classification: Cardiac lipomas are fatty tumors that originate from the subendocardium (50 %), subepicardium (25 %), or myocardium (25 %) [58]. Gross histology demonstrates mature adipose tissue intermixed with the surrounding tissue, such as myocardium, with a surrounding fibrous capsule [59, 60]. In neonates and children, lipomas have been found in various locations including the right atrium, mitral and tricuspid valves, and epicardial location [58, 60–62]. In adults, the most common locations are the right atrium, left ventricle, and interatrial septum [61].

Clinical Presentation: Because of their slow growth, lipomas may reach considerable size before causing clinical symptoms. A full spectrum of signs and symptoms has been reported, from asymptomatic patients in whom the tumor was found incidentally to syncope or sudden death from coronary artery obstruction [59, 63]. They may be clinically silent, embolize, and cause neurologic symptoms or arrhythmias, or cause a ball-valve obstruction similar to myxomas [64]. Most lipomas are asymptomatic, and some have been found incidentally at autopsy [60]. Signs and symptoms, when present, depend on the size and location of the tumor [58, 61].

Incidence: Cardiac lipoma in the pediatric population is extremely rare, with several case reports in the literature. In the adult population, they are the second most common primary cardiac tumor after myxoma, accounting for 8.4 % of cases [65].

Imaging: Chest radiography may show an irregular cardiac border or cardiomegaly depending on the location and size of the tumor [60, 62]. By echocardiography, lipomas present as an echo-bright mass in any cardiac location. Depending on the size and extent of tumor involvement, they may cause inflow or outflow obstruction, or valvular damage [61]. Some intracavitary lipomas appear mobile, raising concern for possible tumor embolization [65]. CMR imaging is useful in distinguishing lipoma from other tumors because of its ability to characterize fat. CMR characteristics of lipoma include (a) high signal intensity on T1-weighted turbo spin echo imaging and (b) low signal intensity on T1-weighted turbo spin echo imaging with fat suppression (Fig. 126.15; Table 126.2) [15].

Management: The long-term prognosis of asymptomatic lipoma is thought to be favorable [65]. However, they should be surgically resected if causing symptoms or if there is the potential for embolization causing clinical symptoms [64–66].

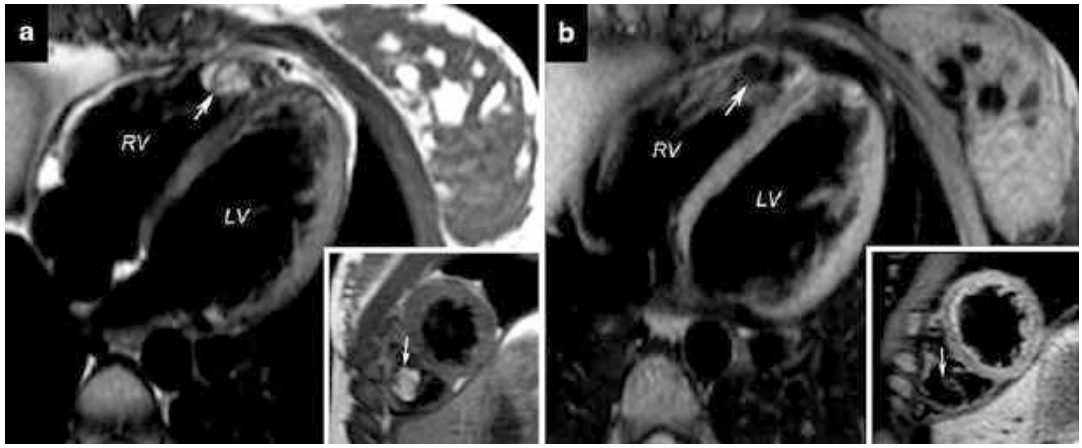

Fig. 126.15 Lipoma. Cardiovascular magnetic resonance imaging of a 16-year-old with a lipoma of the right ventricular apex. On T1-weighted turbo spin echo imaging, the tumor is hyperintense (**a**); and on T1-weighted turbo spine echo imaging with fat suppression, the tumor is hypointense (**b**). The patient had a history of palpitations with no documented evidence of arrhythmias

Apical ventricular lipomas present a surgical challenge because of difficult access to the tumor from standard operative exposure [65, 66]. If the tumor has infiltrated through the atrial or ventricular myocardium, resection may involve partial resection of atrial or ventricular wall [60, 62]. Incomplete surgical resection may result in recurrence [65].

Purkinje Cell Tumor

Classification: The lesions are characterized by the presence of yellow nodules with histiocyte-like cells that are large and spherical and contain lipid droplets ("foamy" appearance) [67]. The cells are derived from altered cardiac myocytes that have lost all contractile elements [67]. The lesions most commonly occur in the left ventricle, but have also been associated with the atria and all four heart valves [68]. The gross appearance of the heart is that of gray-white discoloration of the epicardium or endocardium with small nodules on or near the cardiac valves [67, 69]. Other names for this disorder include myocardial hamartomas, arachnocytosis of the heart muscle, isolated cardiac lipidosis, infantile cardiomyopathy with histiocytoid reaction, infantile xanthomatous cardiomyopathy, lipid histiocytosis, focal myocardial degeneration, idiopathic infantile cardiomyopathy, and focal lipid cardiomyopathy [67, 69].

Clinical Presentation: This tumor classically presents in infants and young children from 6 to 24 months of age, but has been described in older children as well [67, 70]. There is a female predominance [69]. The presentation is that of severe, incessant, and often fatal, supraventricular and/or ventricular cardiac arrhythmias that fail to respond to standard medical therapy [69]. Occasionally this presents as sudden death and is only discovered after an extensive, detailed autopsy with histologic analysis of the myocardium [70]. Digoxin and verapamil are considered dangerous drug therapy, with 5/10 patients in one series having rhythm degeneration to ventricular fibrillation after digoxin [69]. It is thought that the tumors are a focus for abnormal or enhanced automaticity, or that they distort conduction patterns and facilitate reentry [68].

Incidence: Purkinje cell tumor is rare, accounting for a single case in the Boston Children's Hospital series (Table 126.1) [7].

Imaging: Most patients do not have any form of structural heart disease [69]. Because of the microscopic size of the tumors, the echocardiogram may appears normal except for the common occurrence of biventricular dysfunction [69].

By CMR, the lesions have tissue properties of fat: (1) increased signal intensity on T1-weighted turbo spin echo imaging and (2) decreased signal intensity on T1-weighted turbo spin echo imaging with fat suppression [15].

Management: Arrhythmias are often refractory to medical treatment, and the disease is fatal without surgical resection [67, 69, 71]. In some patients, the tumors are too extensive for complete surgical resection; in those cases, cryoablation may be useful in the unresectable areas [68]. However, automatic internal cardiac defibrillators or heart transplantation have also been reported in difficult cases [68].

Prevention of Infective Endocarditis in Patients with Congenital Heart Disease

127

Sylvie Di Filippo

Abstract

Infective endocarditis is still a life-threatening event that may significantly impair long-term prognosis of patients with cardiac disease. The profile of infective endocarditis has changed over the past two decades with decreasing cases in rheumatic cardiac disease and increasing cases in patients who survive with congenital heart disease. Given high rates of morbidity and mortality of infective endocarditis episodes, antibiotic prophylaxis has long been recommended for high-risk groups. Guidelines have serially changed over years. The most recent revised recommendations significantly differ from previous guidelines and give new insights into the prophylaxis of infective endocarditis. Emphasis has shifted to oral activities and particularly on teeth brushing. Both buccal and skin hygiene may present the greatest threats for individuals at risk of infective endocarditis. Significant limitations in both at-risk patients and procedures result in a potential and substantial change in clinical practice and raise concerns about the safety and reliability of these new recommendations for patients with congenital heart disease.

Introduction

Infective endocarditis (IE) is a life-threatening complication that may impair significantly the long-term prognosis of patients with cardiac disease. The profile of IE has changed over the recent decades with fewer cases of rheumatic fever and increasing survival of patients with congenital heart disease (CHD). Facing the high rates morbidity and mortality and based on previous experimental studies, antibiotic prevention of IE has long been recommended for at-risk groups. Serial revised guidelines for prophylaxis were published over the years. The most recent recommendations differ dramatically from previous guidelines and provide new insights in the management of IE prophylaxis [1]. Emphasis is put on oral activities, in particular teeth brushing; both buccal and skin hygiene may be the greatest threat for individuals at risk for infective endocarditis. Significant limitations in both at-risk patients groups and procedures result in a potential and substantial change in the practice of clinicians [2] and raise concerns about the safety and reliability of these new recommendations for patients with CHD.

Incidence and Epidemiology

The incidence of infective endocarditis is reported to vary from 1.5 to 6 cases per 100,000 persons per year in adults. The percentage of IE in congenital heart diseases has increased relatively with the decrease in rheumatic fever [3]. IE is supposed to be much less frequent in children. However, more complex surgical CHD procedures with implanted material and prosthesis and/or residual lesions are likely to result in ongoing IE occurrence. Moreover, more children can currently reach adulthood even with complex CHD, and the cohort of patients with CHD is increasing.

Therefore, the relative incidence of IE is likely to maintain or even increase in pediatric and adult patients with CHD. IE diagnosis or sequelae are reported to account for 4–5 % of inhospital admissions of patients with CHD and 2.3 % frequency of adult-onset IE in adults with CHD. As a result, IE represents a lifelong risk in these patients. Various factors may impact on the level of risk, like the type of underlying cardiac disease, the presence of prosthetic material, and the microbial causal agent.

Prognosis of Infective Endocarditis

Despite improvement in early diagnosis, management, microbial diagnosis and therapeutics, and even surgical techniques, the morbidity and mortality rates of IE are still significant [4]. The mortality varies from 10 % to 15 %. Therefore, IE represents a life-threatening ongoing complication that may impair long-term outcomes of patients with CHD [5].

Data from literature have shown IE to be less severe in children. This might be due to the higher proportion of right-sided IE in patients with CHD, in particular with VSD-located infection [6–9].

In a recent review about IE in CHD, Knirsch et al. reported a 10 % overall mortality, 14 % surgical mortality, and recurrence less than 3 % [10]. Besides early mortality and morbidity, IE may also impact on long-term functional status of patients with CHD, considering that many of them were asymptomatic before IE occurred [11]. In the long-term experience with IE in adult and pediatric CHD patients, more than 50 % of deaths in this cohort can be directly related to IE; others are due to either IE sequelae management or to CHD outcomes itself regardless of IE episodes [4].

Pathogenesis

Three major components must interact to result in IE:

1. The underlying cardiac lesion and endocardial damage
2. The circumstances leading to significant lesions of the mucosa susceptible to cause bacteremia
3. The volume of the microbial inoculum and the virulence of the bacterial agent

The key factor for IE to develop is firstly endocardial damage. This lesion allows fibrinogen deposits, platelet aggregation, and thrombi formation. Interactions with circulating pathogen agents may promote microbial adherence to thrombi resulting into the development of the IE specific lesion, the so-called vegetation. The prosthetic surface is particularly exposed to fibrinogen binding and also promotes turbulence of blood flow and endothelial injuries, making prosthetic materials to be at high risk for IE.

Facing prognosis and morbidity and also considering high costs for management of IE, prophylaxis has long been recommended, in an attempt to minimize IE incidence.

Guidelines have been published and revised over years, to define:

1. The underlying CHD level of risk
2. The at-highest-risk procedures and events
3. The protocols for antibiotic prevention of IE

The above aspects therefore aim to identify "who" should benefit from prophylaxis, "when" to adequately apply prophylaxis, and "how" to administrate such prophylaxis. Nevertheless, IE still occurs, raising the question of whether noncompliance or lack of efficacy (or both) should be incriminated. No randomized study has been conducted until now, to elucidate whether or not IE prophylaxis should be applied, and if yes to whom and when it should be applied. Lockhart et al. [12] conducted a prospective comparative study designed to compare subjects who received amoxicillin before tooth extraction and subjects who had no antibiotics or were given placebo before dental procedure. The authors showed that bacteremia was less frequent in the amoxicillin group (33 %) than in the placebo group (84 %), but this result does not demonstrate that IE would have occurred. The recommendations were based on experimental animal studies that previously demonstrated the efficacy of antibiotics to prevent infective endocarditis when administered before bacteria inoculation [13] and also on medical practice and experience [14]. Conversely, most of published data reported that IE can still occur although prophylaxis had been applied according to current recommendations. Thus, recommendations for IE prophylaxis have lightened dramatically over years. Based on case–control studies, expert opinions, and daily practice, the last 2007 published revised American Heart Association guidelines result in drastic reduction and limitation of cardiac diseases and procedures where IE prophylaxis should be indicated [1].

Rationale for Revised Recommendations for IE Prophylaxis

The main key points that led to the new expert consensus in the field of IE prophylaxis are as following:

- First, IE occurs rarely and is unlikely to impair significantly the overall prognosis of patients. The number of treated IE to number of cases undergoing prophylaxis ratio is far too low to support routine prevention of IE: "Prophylaxis may prevent an exceedingly small number of cases of IE, if any, in individuals who undergo a dental, GI tract, or GU tract procedure." However, no mention exists about the costs due to IE management (hospitalization, antibiotics, techniques for anatomic and microbial diagnosis, iterative surgeries, long-term follow-up, management, and complications) and about patients' vital and functional prognosis. The low cost of prophylaxis has to be weighed against high costs of IE diagnosis and treatment.
- The second and most important point is that procedures are unlikely to cause IE compared to daily activities and poor patient hygiene. Moreillon et al. [15] assessed the theoretical cumulative bacteremia resulting from daily oral activities like toothbrushing or chewing and concluded that 1-year everyday bacteremia is six million times greater than a dental extraction. Thus, it is not clear whether daily activities related bacteremia could reach the cutoff inoculum volume to seed the cardiac tissue [16].
- Another point is that some patients may undergo dental procedures, whereas the underlying cardiac disease has not been recognized

before. In Di Filippo et al. report of IE in CHD, such cases were observed in patients whose underlying disease was mostly minor valvular lesions like bicuspid aortic valve or mitral valve prolapse. These patients with unrecognized CHD accounted for about 15 % of the cases.

- Lastly, experts have argued that side effects of antibiotics include microbial-induced resistance and anaphylaxis. However, no report has been published regarding resistance due to one-dose amoxicillin, and no case has been reported about death due to antibiotic-induced anaphylaxis, whereas mortality due to IE is still significant and widely reported.
- Finally the revised recommendations were also based on the lack of a controlled randomized study to prove IE prophylaxis efficacy. The number of patients necessary to conduct a controlled randomized trial to assess IE prophylaxis effectiveness has been estimated to reach more than 6,000 patients per group, which discouraged centers to initiate such a study [14, 17].

Therefore, new recommendations conclude that "maintenance of optimal oral health and hygiene may reduce the incidence of bacteremia from daily activities and is more important than prophylactic antibiotics for a dental procedure to reduce the risk of IE" [1].

Table 127.1 Cardiac conditions for which prophylaxis with dental procedures is recommended

Cardiac valvulopathy in a cardiac transplant recipient
Congenital heart disease[a]
Congenital heart defect completely repaired within the previous 6 months with prosthetic material or device, whether placed by surgery or by catheter[b]
Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or device (which inhibit endothelialization)
Unrepaired cyanotic congenital heart disease, including palliative shunts and conduits
Previous infective endocarditis
Prosthetic cardiac valve

Prevention of infective endocarditis [published correction appears in Circulation. 2007;116(15): e376–377]. Circulation. 2007;116 (15):1745

[a]Except for the conditions listed, antibiotic prophylaxis is no longer recommended for patients with any other form of congenital heart disease

[b]Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure

Underlying Congenital Cardiac Disease

In previous recommendations, CHDs were classified into high-, moderate-, or mild-risk groups. Recent guidelines resulted in the following: (1) drastic reduction of target CHD for IE prophylaxis; (2) suppression of the CHD classification into at-high, at-moderate, and at-mild risk for IE, assuming that only patients ranging in the previously named "high-risk" group should apply as in Table 127.1. The other CHDs, previously ranging in the at-moderate or at-mild risk should no longer be targets for IE prophylaxis [1, 18, 19]. It is well understood that surgical repair may nullify the lifetime risk of IE provided that neither residual lesion nor prosthetic material is present. In fact, only few CHDs can be completely cured; some kind of residual lesion often persists (residual shunt, valve anomaly, to mention some) or prosthetic materials are implanted (valve prosthesis, tubes, anastomosis, patches). Considering that high velocity and turbulent flow are more likely to generate endothelial lesions and promote IE, risk varies consecutively according to the underlying cardiac lesions, although guidelines do not retain anymore importance to this assessment. Lastly, some IE episodes have been reported in patients who underwent interventional procedures and raised the question whether these cases should receive prophylaxis.

Regarding cyanotic unrepaired or palliated CHD, there is a common consensus for IE

prevention, as well in the group of patients who had experienced a previous IE episode. These CHD are considered at highest risk for IE.

IE prevention is no longer recommended in repaired CHD in the case of no residual lesion [1]. Nonetheless, prophylaxis should be applied within the first 6 months after repair, allowing for endothelialization to develop, in particular after patch closure of a VSD. However, any residual shunt or any associated lesion such as aortic insufficiency will justify lifelong IE prophylaxis, considering that endothelialization could not occur. This assessment seems to be in discrepancy with the same native unrepaired lesion, i.e., VSD or aortic regurgitation.

Knirsch et al. aimed to estimate the mean frequency of repaired and unrepaired CHD in a series of IE patients [10]. The author showed that IE is a lifetime risk for repaired, non-operated and palliated CHD. Aortic and mitral valves are the most frequent targets for IE, including unoperated and non-hemodynamically significant valvulopathies. If unrepaired, VSD is the most frequent CHD associated with IE. The cumulative incidence of IE over a 25-year follow-up after surgical repair (or interventional procedure) and according to the CHD is as follows: 1.3 % for tetralogy of Fallot, 2.7 % for VSD, 2.8 % for primum ASD, 3.5 % for coarctation of the aorta, 13 % for aortic valve stenosis, and 0 % for ostium secundum ASD, PDA, and pulmonary valve stenosis. A 30-year follow-up demonstrated a cumulative IE incidence of 4.0 % for transposition of the great arteries, 5.3 % for pulmonary atresia with intact ventricular, and up to 6.4 % for VSD [20]. Risk is evidently enhanced by any prosthetic material and devices.

Procedures

An endocardial lesion is the primary target for microbial adherence. Therefore, any cause of significant bacteremia will potentially be the initial factor for IE to occur. Horder [21] observed in 1909 a link between mouth infection and infective endocarditis. Tooth extraction was later shown to induce bacteremia. Moreover, the microbial agents susceptible to cause IE belong to the *Streptococcus* group from oral origin. Indeed, any procedure that could potentially cause bacteremia was thought to represent a potential route of entry. A dental procedure was the leading target for antibiotic prophylaxis, as animal experiments demonstrated the effectiveness of antibiotics in preventing the development of infective endocarditis after experimental inoculation of bacteria [13]. Based on these experimental studies and on common practice of patients who were diagnosed with IE within several weeks after unprotected dental procedure, protocols for prevention of IE have long been applied to minimize risk and prevent bacteremia and subsequent development of IE.

IE can occur despite the fact that a protocol for IE prevention had been applied, but most of the time detailed data about antibiotic administration are lacking. Imperiale et al. showed that only 13 % of patients who experienced IE after unprotected dental procedure had applied prophylaxis compared to 63 % of matched controls who had no IE [22]. Conversely, not only dental procedures but also any other procedures susceptible to damage of the mucosa were supposed to carry on the same risk. In particular digestive, urinary, or bronchial procedures were also included in prior IE prophylaxis recommendations.

On the basis of a Cochrane review that showed little evidence to support the published guidelines [23], revisited guidelines have completely changed previous assessments. Indeed, no randomized controlled trial exists to demonstrate the efficacy, reliability, and safety of antibiotics for the prevention of IE. Such a study is still questionable because of ethical issues and too high number of enrolled patients per group. It is known that bacteremia is more likely to result from daily activities like chewing and brushing teeth using devices for water irrigation, than from dental procedures [16]. Experts have pointed out oral hygiene to be the most important endpoint for bacterial prevention of IE.

Clinical reports and series often fail to prove the link between IE and previous procedures.

The causative event can be retrieved in only one third of the cases. Even in cases of close temporal association between a precedent event or procedure and onset of IE, it is still hardly possible to determine whether bacteremia was induced by the procedure or by other daily activities or poor oral hygiene [14].

The new guidelines recommend prophylaxis for any procedure that may alter the gingival tissue and the periapical region or induce perforation of the oral mucosa, i.e., biopsies, suture removal, placement of orthodontic bands, teeth extractions, and periodontal procedures, but not local anesthetic injections, dental radiographs, placement of removable prosthodontic or orthodontic appliances, and placement or adjustment of orthodontic brackets [1].

Regarding any other nondental procedure, prophylaxis is no longer recommended [1]. Therefore, digestive endoscopic manipulations or procedures on the respiratory tract do not require antibiotics administration, even in at-high-risk groups, unless ongoing tissue infection is recognized. This assessment also includes skin tissue and the American Heart Association guidelines provide advice against body piercing, but no clear recommendation. For patients with the highest risk of IE who undergo a procedure that involves infected skin or musculoskeletal tissue, the therapeutic regimen administered for treatment of the infection should contain an agent active against *Staphylococcus* and *beta-hemolytic Streptococcus* [24].

Guidelines are currently focusing on daily mouth and skin hygiene. In a double-blind, placebo-controlled study, Lockhart et al. assessed bacteremia in 290 subjects randomized to either toothbrushing or single tooth extraction with amoxicillin prophylaxis or single tooth extraction with identical placebo [25]. Cumulative incidence of endocarditis-related bacteria from blood draws was 23 %, 33 %, and 60 % for the toothbrushing, extraction-amoxicillin, and extraction-placebo groups, respectively ($p < 0.0001$). Culture positivity was lower in patients receiving amoxicillin. The authors concluded that toothbrushing might be the highest at-risk circumstance for IE.

Unanswered Questions and Concerns

Due to lack of evidence, all the recent recommendations are class IIa and level of evidence B or C. Provided that no randomized controlled study is currently available, the level of evidence of this new recommendation is not stronger than before.

Underlying CHD

Native unrepaired CHD such as left to right high-velocity shunts or mild mitral and/or aortic valvulopathies are no longer targets for IE prophylaxis. Nevertheless, IE can occur in patients with such underlying CHD, as widely reported in the literature. Knirsch and Nadal reviewed the clinical entity of CHD-associated IE between 1960 and 2007, considering reports of more than 25 IE cases, and provided information on cardiac diagnoses and procedures performed.

VSD is the most frequent unrepaired CHD associated with IE [26] and accounted for 30 % of the cases of IE in CHD [4]. Most of these cases were small and hemodynamically insignificant VSDs, with or without associated aortic regurgitation. The incidence of IE in unrepaired VSD is 1.5–2.4 per 1,000 patient-years. The natural history of VSD shows that the estimated lifetime risk for IE at age 30 years is 9.7 % and by the end of life is 12 % [27].

Bicuspid aortic valve has long been considered an at-risk CHD. The prevalence of this anomaly is 0.5–2 %. Complications of bicuspid aortic valve may increase over time with aortic stenosis and mostly aortic insufficiency. Recent estimates of endocarditis in bicuspid aortic valve are around 0.3–2 % per year [28].

Isolated persistent ductus arteriosus frequency is about 1 in 2,000 full-term infants. Most patients are asymptomatic and the left to right shunt is usually nonsignificant [29]. However, common practice has long recommended closure of PDA because of a lifetime risk of IE. Percutaneous closure of PDA has become the leading therapeutic option for infants and children with hemodynamically nonsignificant PDA.

Patients with mitral valve prolapse (MVP) have a three- to eightfold higher risk of developing infective endocarditis, with an estimated incidence of about 0·02 % per year [30]. Endocarditis occurs in MVP at a rate of 0.1 cases/100 patient-years [31]. With the improved resolution and sensitivity of newer generations of echocardiograms, clinicians often face the dilemma of the patient with MVP and "trivial" or "minimal" mitral regurgitation, making decision for prevention of IE a matter of debate. Recent criteria from the American Heart Association guidelines may help to decide, since valve prolapse of 2 mm or more above the mitral annulus is required for diagnosis [32]. This change has effectively lowered the prevalence of MVP from 4 % to 8 % of the general population down to 2–3 %.

Recent guidelines for prevention of IE published by the American Heart Association in 2007 [1] do not consider native unrepaired cardiac lesions at risk of IE. In particular, prophylaxis is no longer recommended in patients with MVP, bicuspid aortic valve, PDA, and VSD. Nevertheless, IE can occur in these patients and are reported in all published series. This discrepancy probably contributes to clinicians being concerned about fully following or not these guidelines. Some would continue prevention in patients they feel to be at significant risk.

Procedures

Streptococcus and Staphylococcus are the two main microbial agents responsible for IE in CHD, coming from either the oral cavity or skin. Daily buccal activities are considered as the current leading causes of bacteremia. However, this concept of cumulative bacteremia has not been currently supported by any experimental study; studies have not shown that everyday bacteremia can reach and exceed the theoretical bacterial inoculum volume cutoff needed to induce infective endocarditis. Moreover, no mention is provided about the bacterial virulence that would lessen the threshold of at-risk bacteremia nor the immunosuppressive status of the patient. It is commonly admitted that the skin may be widely colonized by commensal but also pathogenic *Staphylococcus* agents [33]. Any cutaneous damage including a tattoo or body piercing may therefore induce bacteremia, even in the absence of proved tissue infection. The level of cutaneous risk might be underestimated by the new guidelines, regarding the frequency of *Staphylococcus* IE.

Clinicians' Behavior

Facing these new recommendations, Pharis et al. assessed the impact of the 2007 American Heart Association endocarditis prophylaxis guidelines on clinician practice in a multicenter cross-sectional Web-based survey sent to Canadian, Australian, New Zealand, and American pediatric and adult congenital heart disease cardiologists in 2008 [2]. The response rate was 55 %. Cardiologists were divided between recommending prophylaxis and not for perimembranous VSD status post-surgical patch closure with no residual shunt 3 months postoperatively." The greatest proportion of cardiologists discontinued prophylaxis for "small muscular VSD, no previous endocarditis," and "small audible patent ductus arteriosus." Twenty-eight percent of the clinicians felt that the new guidelines leave some patients at risk. Therefore, although the 2007 guidelines have resulted in changes in endocarditis prophylaxis, a wild heterogeneity has been observed among cardiologists who are in charge of these patients. These results show that many of them feel concerned about the safety of these recommendations, facing the severity and life-threatening risk of IE. As claimed by Weaver, "Lack of evidence is not necessarily equivalent to lack of benefit" and "If prophylaxis is futile, why select high-risk patients for prophylaxis?" [34, 35].

Protocols for Antibiotic Prophylaxis

The current recommended protocols for antibiotic prophylaxis have been also lightened (Table 127.2). An oral single dose of antibiotic should be administered 30–60 min before

Table 127.2 Antibiotic regimens for patients at high risk of infective endocarditis undergoing dental procedures

Route of administration	Agent	Dosage	
		Adults	Children
IM or IV	Ampicillin	2 g IM or IV	50 mg per kg IM or IV
	Or cefazolin (Ancef, brand not available in the United States) or ceftriaxone (Rocephin)	1 g IM or IV	50 mg per kg IM or IV
IV or IM (in patients allergic to penicillin or ampicillin)	Cefazolin or ceftriaxone[a]	1 g IM or IV	50 mg per kg IM or IV
	Or clindamycin (Cleocin)	600 mg IM or IV	20 mg per kg IM or IV
Oral	Amoxicillin	2 g	50 mg per kg
Oral (in patients allergic to penicillin or ampicillin)	Cephalexin (Keflex)[a, b]	2 g	50 mg per kg
	Or clindamycin	600 mg	20 mg per kg
	Or azithromycin (Zithromax) or clarithromycin (Biaxin)	500 mg	15 mg per kg

Adapted with permission from Wilson W, Taubert KA, and Gewitz M, et al.; for the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee; Council on Cardiovascular Disease in the Young; Council on Clinical Cardiology; the Council on Cardiovascular Surgery and Anesthesia; and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Prevention of infective endocarditis [published correction appears in Circulation. 2007;116(15):e376–377]. Circulation. 2007;116(15):1747

IM intramuscularly, *IV* intravenously

[a]Cephalosporins should not be used in patients with a history of anaphylaxis, angioedema, or urticaria after taking penicillin or ampicillin

[b]Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage

Table 127.3 Summary of major changes in the updated American Heart Association (AHA) guidelines for prevention of infective endocarditis

Antibiotic prophylaxis is no longer recommended for patients with any form of congenital heart disease except those listed in *Table* 127.1
Antibiotic prophylaxis is not recommended based solely on an increased lifetime risk of infective endocarditis
Antibiotic prophylaxis is recommended only for patients with conditions listed in *Table* 127.1 who are undergoing dental procedures that involve manipulation of gingival tissues or periapical region of teeth or perforation of the oral mucosa
Antibiotic prophylaxis is recommended only for patients with conditions listed in *Table* 127.1 who are undergoing procedures on the respiratory tract or infected skin, skin structures, or musculoskeletal tissue
Antibiotic prophylaxis solely to prevent infective endocarditis is not recommended for patients undergoing gastrointestinal or genitourinary tract procedures
Prophylaxis for infective endocarditis is not recommended in patients undergoing ear or body piercing, tattooing, vaginal delivery, or hysterectomy
Recommendations for prophylaxis of infective endocarditis should be limited to patients with conditions listed in *Table* 127.1

AHA American Heart Association

Prevention of infective endocarditis [published correction appears in Circulation. 2007;116(15):e376–377]. Circulation. 2007;116(15):1748

invasive procedures, only in patients of the high-risk group for dental at-risk procedures. In case the dose cannot be given before, it should be done within 2 h following the procedure [33]. First-line antibiotics are focused on Streptococcus infection and amoxicillin is the recommended first option (50 mg per kg in children, 2 g in adults). In case of allergy, a macrolide should be chosen for oral

medication (azithromycin or clarithromycin 15 mg per kg in children, 500 mg in adults) and cefazolin or ceftriaxone (50 mg per kg in children, 2 g in adults) if the patient is unable to take oral medication [1]. For specific skin-related procedures, the regimen should mostly focus against *Staphylococcus aureus* microbial agent. Severe anaphylactic events have not been reported nor have single dose of antibiotics induced resistance (Table 127.3).

Conclusion

Congenital heart disease patients are specifically exposed to IE risk. According to recent revised guidelines, some unrepaired native congenital heart defects are no longer a target for IE prophylaxis. Recommendations emphasize daily oral activities and poor buccal and skin hygiene as the leading causes of IE. In light of these substantial changes in endocarditis prophylaxis for pediatric and adult congenital disease patients, cardiologists raise unanswered questions about to whom and when to apply prophylaxis. Further studies are required to elucidate and assess the consequences and impact of the new guidelines on CHD patient outcomes.

Diagnosis and Management of Infective Endocarditis

128

Michael G. W. Camitta, Joseph W. St. Geme III, and Jennifer S. Li

Abstract

Although infective endocarditis is a relatively uncommon diagnosis in the pediatric population, it carries a high rate of morbidity and mortality. Endocarditis is increasing in frequency and changing in epidemiology due to the improvement in surgical outcomes for complex congenital heart disease, increasing survival of very low birth weight infants, and advances in invasive medical technology. It is now primarily a nosocomial disease, which is complicated by increasing bacterial resistance patterns. Effective detection of the signs and symptoms of infective endocarditis is the key to prompt diagnosis and treatment in order to improve associated patient outcomes. Detection requires a high level of diagnostic suspicion along with a team approach to care with pediatric cardiology, cardiothoracic surgery, and infectious disease consultation.

Introduction

Infective endocarditis (IE) denotes infection of the endocardial surface of the heart and implies the physical presence of microorganisms in the lesion. Although the heart valves are most commonly affected, the disease may also occur within the heart in the location of congenital septal defects or on the endocardial surface in areas of turbulent flow. Extracardiac infections of arteriovenous or arterio-arterial shunts (patent ductus arteriosus), infection related to structural aortic arch anomalies, and infections of prosthetic materials such as vascular occluders and stents can also be included in this definition due to similar clinical manifestations. Unfortunately, variability in the clinical presentation continues to make the diagnosis of IE clinically challenging. The Duke criteria for the diagnosis of infective endocarditis have been developed [1] and modified [2]. These criteria (Tables 128.1 and 128.2) have been validated in multiple studies and have been shown to be superior to other criteria for the diagnosis of IE in the pediatric population [3–5].

Despite improvements in diagnosis and treatment, IE continues to be associated with high morbidity and mortality. There are several reasons for this persistent morbidity and mortality. Pediatric patients with IE are increasingly complex. In developed countries, the improved survival of children with congenital heart disease has led to a shift in the underlying condition for IE from rheumatic heart disease to congenital heart disease. In addition there has been an increase in antibiotic resistant organisms. Targeted antibiotic treatment is the ideal approach to the pharmacologic management of IE. Prevention of IE remains the standard of care, though practices in prophylaxis have been shown to vary widely. Successful management of IE is dependent on the close cooperation of cardiologists, cardiothoracic surgeons, infectious disease specialists, primary care providers, and patients themselves.

The true incidence of IE is difficult to determine because the criteria for diagnosis have changed and the methods of reporting vary in different series [6, 7]. An analysis based on strict case definitions often reveals that only a small proportion (~20 %) of clinically diagnosed cases are categorized as definite. IE occurs less commonly in children than in adults, with an estimated incidence of 1 case per 1,280 pediatric admissions per year [8] versus approximately 1 case per 1,000 adult hospital admissions per year. However, the incidence of IE in the pediatric population has increased over the past 20 years [9] potentially in part because of the improved survival of higher-risk neonates. IE is associated primarily with nosocomial bacteremia in the setting of underlying structural congenital heart disease or in the context of invasive procedures or vascular devices [10, 11].

Table 128.1 Definition of infective endocarditis according to the modified Duke criteria

Definite infective endocarditis
Pathologic criteria
1. Microorganisms demonstrated by culture or histologic examination of a vegetation, a vegetation that has embolized, or an intracardiac abscess specimen; or
2. Pathologic lesions; vegetation or intracardiac abscess confirmed by histologic examination showing active endocarditis
Clinical criteria
1. 2 major criteria; or
2. 1 major criterion and 3 minor criteria; or
3. 5 minor criteria
Possible infective endocarditis
1. 1 major criterion and 1 minor criterion
2. 3 minor criterion
Rejected
1. Firm alternate diagnosis explaining evidence of infective endocarditis; or
2. Resolution of infective endocarditis syndrome with antibiotic therapy for $\leq$4 days; or
3. No pathologic evidence of infective endocarditis at surgery or autopsy, with antibiotic therapy for $\leq$4 days; or
4. Does not meet criteria for possible infective endocarditis, as above

Adapted from Li et al. [2]

Predisposing Conditions

Congenital Heart Disease

The incidence of IE in unrepaired congenital heart lesions has become rare due to surgical advances that have enabled the correction or

Table 128.2 Definition of terms used in the modified Duke criteria for the diagnosis of infective endocarditis

Major criteria
Blood culture positive for IE
Typical microorganisms consistent with IE from 2 separate blood cultures:
Viridans streptococci, *Streptococcus bovis*, HACEK group, *Staphylococcus aureus*; or
Community-acquired enterococci, in the absence of a primary focus
Microorganisms consistent with IE from persistently positive blood cultures, defined as follows:
At least 2 positive cultures or blood samples drawn >12 h apart; or
All of 3 or a majority of ≥4 separate cultures of blood (with first and last sample drawn at least 1 h apart)
Single positive blood culture for *Coxiella burnetii* or antiphase I IgG antibody titer >1:800
Evidence of endocardial involvement
Echocardiogram positive for IE (TEE recommended in patients with prosthetic valves, rated at least "possible IE" by clinical criteria, or complicated IE [paravalvular abscess]; TTE as first test in the other patients), defined as follows:
Oscillating intracardiac mass on valve or supporting structures, in the path or regurgitant jets, or in implanted material in the absence of an alternative anatomic explanation; or
Abscess; or
New partial dehiscence of a prosthetic valve
New valvular regurgitation (worsening or changing of a preexisting murmur not sufficient)
Minor criteria
Predisposition, predisposing heart condition or injection drug use
Fever, temperature >38 °C
Vascular phenomena, major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway lesions
Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor
Microbiological evidence: positive blood culture but does not meet a major criterion as noted above or serologic evidence of active infection with organism consistent with IE

Adapted from Li et al. [2]

palliation of nearly all of these defects. The most common repaired congenital heart lesions predisposing to IE in children include aortic valve stenosis, pulmonary atresia, tetralogy of Fallot, complete atrioventricular canal defect, d-transposition of the great arteries, and coarctation of the aorta [12, 13]. Unlike most other congenital defects, secundum atrial septal defects and pulmonary valve stenosis are not associated with an increased risk of IE [12]. IE in the absence of underlying congenital heart disease has been reported to be the cause in 8–10 % of pediatric cases [4]. There has been an increase in the incidence of fungal endocarditis which appears to be related to prolonged use of broad spectrum antibiotics, central venous catheters, and improved survival of sick premature neonates [14, 15]. The emerging importance of nosocomial IE in industrialized nations has influenced the microbiology of IE, with an increasing prevalence of *S. aureus* and a decreasing prevalence of viridans streptococci among US tertiary care centers [16]. In children, nosocomial IE in the absence of structural heart disease most often affects the mitral or aortic valve [9, 17, 18]. *S. aureus* is a unique pathogen because of its virulent properties, potential to cause protean manifestations, and its ability to cause IE on architecturally normal cardiac valves [19].

Prosthetic Heart Valves

Presence of a prosthetic valve is an important risk factor for IE in adults, with IE occurring in 1–4 % of prosthetic valve recipients in the first year following valve replacement and in approximately 1 % of recipients annually thereafter [20, 21]. While prosthetic valves are used less frequently in children, mechanical aortic valve replacement is associated with a significant increase in the incidence of IE [12].

Injection Drug Use

Injection drug use is a common predisposing factor for IE in adult patients less than 40 years of age, with *S. aureus* being the predominant organism. The yearly prevalence of injection drug use in children aged 12–17 is 0.11 % in comparison to 0.29 % for adults between the age of 18 and 25 [22]. The incidence of IE in

adult intravenous drug users may be 30 times higher than that in the general population [23]. Tricuspid valve involvement is noted in 78 %, mitral in 24 %, and aortic in 8 % of drug abusers with IE [24]. More than one valve is involved in approximately 20 % of cases, and some of these infections are polymicrobial [25, 26].

Pathophysiology

The endothelial lining of the heart and the cardiac valves is normally resistant to infection with bacteria and fungi. In vitro observations and studies in experimental animals have demonstrated that the development of IE requires the simultaneous occurrence of several independent events, each of which may be influenced by a host of separate factors [27–30]. The valve surface must first be disrupted to produce a suitable site for bacterial attachment. Surface changes may be produced by a variety of local and systemic stresses such as turbulent blood flow in incompletely repaired congenital heart disease or local catheter-induced trauma to the endocardium or valve tissue. These alterations result in the deposition of platelets and fibrin and formation of a so-called sterile vegetation, the lesion of nonbacterial thrombotic endocarditis (NBTE). Bacteria must then reach this site and adhere to the involved tissue to initiate infection. Transient bacteremia can occur when a mucosal surface heavily colonized with bacteria is traumatized.

Vegetations often prevent proper valvular leaflet or cusp coaptation, resulting in valvular incompetence and congestive heart failure. Vegetation growth may result in leaflet perforation that can manifest as acute congestive heart failure [31]. Patients with mitral or tricuspid valve vegetations may develop chordal rupture when infection progresses beyond the valve orifice. Extension of infection may also occur into surrounding structures such as the valve ring, the adjacent myocardium, the cardiac conduction system, or the mitral-aortic intravalvular fibrosa [32]. Rarely, cavitation of periaortic abscesses may occur into the adjacent aortic wall, resulting in the formation of a diverticulum or aneurysm. Even more rarely such aneurysms may perforate into surrounding structures, resulting in aortic-atrial or aortic-pericardial fistulae [33].

Clinical Presentation

History and Physical Examination

Children with IE typically have an indolent presentation, with generalized symptoms such as prolonged fever with rigors and diaphoresis, fatigue, arthralgias, myalgias, and weight loss [34]. Occasionally, children will present acutely ill with a more fulminant course and require urgent intervention. Although the virulence of the infecting organism can influence the acuity of the presentation, the interval from onset of infection to onset of symptoms is usually short. Symptoms in staphylococcal IE may even begin within a few days of the onset of infection.

The symptoms and signs of IE are protean, and essentially any organ system may be involved (Table 128.3). Four processes contribute to the clinical picture: (1) the infectious process on the valve, including the local intracardiac complications; (2) septic or aseptic embolization to virtually any organ; (3) constant bacteremia, often with metastatic foci of infection; and (4) circulating immune complexes and other immunopathologic factors [29, 35]. As a result, the clinical presentation of patients with IE is highly variable, and the differential diagnosis is often broad (Table 128.4). The prevalence of nonspecific symptoms may result in a delay in diagnosis or an incorrect diagnosis of another systemic illness.

Findings classically associated with IE such as low-grade fever, malaise, and peripheral stigmata from long-standing IE are less prevalent in patients currently presenting with IE, reflecting a higher incidence of nosocomial IE and more effective diagnostic modalities nowadays. Fever is usually present in the current era, but may be absent (5 % of the cases), especially in the setting of congestive heart failure, immunosuppressive therapy, or previous antibiotic therapy [36, 37]. Congestive heart failure has been reported in 10–20 % of pediatric cases of IE [38–40].

Malignancies	Paraneoplastic syndromes
	Cardiac myxomas
	Carcinoid tumors
	Highly vascular tumors

Audible heart murmurs occur in a majority of children with endocarditis related to valve destruction, associated with congenital heart disease, and as non-related innocent murmurs. The classic "changing murmur" is less common and has been reported in 21 % of pediatric IE cases [38]. Although valvular regurgitation is the most important hemodynamic complication of IE, hemodynamically significant valvular obstruction requiring surgery may occur, even without a prior history of valvular stenosis [41]. IE in patients with congenital heart disease palliated with a systemic to pulmonary shunt can present with cyanosis due to shunt obstruction, without a change in character of the murmur.

The classic peripheral manifestations of endocarditis are much less common in pediatric patients than in adults. Splinter hemorrhages are linear red to brown streaks in the fingernails or toenails. They are a nonspecific finding and are often seen in the elderly or in people experiencing occupation-related trauma. Petechiae from local vasculitis or emboli are found after a prolonged course and usually appear in crops on the conjunctivae, buccal mucosa, palate, and extremities. These lesions are initially red and nonblanching but become brown and barely visible in 2–3 days. Osler nodes are small, painful, nodular lesions usually found in the pads of fingers or toes and occasionally in the thenar eminence. They are 2–15 mm in size and are frequently multiple and evanescent, disappearing in hours to days. Osler nodes are rare in cases of acute IE. Furthermore, they are not specific for IE, sometimes occurring in systemic lupus erythematosus, marantic endocarditis, hemolytic anemia, and disseminated gonococcal infection and in extremities with cannulated radial arteries [42]. Janeway lesions are hemorrhagic, macular,

painless plaques with a predilection for the palms or soles. They persist for several days and are thought to be embolic in origin and to occur with greater frequency in staphylococcal IE. Roth spots are oval, pale, retinal lesions surrounded by hemorrhage and are usually located near the optic disk. They may also be found in anemia, leukemia, and connective tissue disorders. Splenomegaly is more common in patients with IE of prolonged duration. Splenic septic emboli are common during IE, but localized signs and symptoms of splenic involvement are absent in approximately 90 % of patients with this complication [43].

Complications of Infective Endocarditis

Abscess in or adjacent to the valve annulus is often heralded by the appearance of first or second degree heart block and/or fever that persists despite appropriate therapy. Pericarditis is rare but, when present, is usually accompanied by myocardial abscess formation as a complication of staphylococcal infection. Myocarditis may occur as a result of coronary vasculitis or embolic coronary occlusion or from the effects of microbial toxins or immune complex deposition.

Major embolic episodes occur in approximately one-third of cases [38–40]. Splenic artery emboli with infarction may result in left upper quadrant abdominal pain with radiation to the left shoulder, a splenic or pleural rub, or a left pleural effusion. Renal infarctions may be associated with microscopic or gross hematuria, but renal failure, hypertension, and edema are uncommon. Retinal artery embolus is rare with one reported pediatric case [44] and may be manifested by a sudden complete loss of vision. Pulmonary emboli can be a complication of right-sided IE. Coronary artery emboli usually arise from the aortic valve and may cause myocarditis with arrhythmias or myocardial infarction.

Neurologic manifestations occur in 10–15 % of pediatric cases, especially in staphylococcal IE [39, 40]. Stroke is the most common neurologic complication of IE. Patients with mitral valve IE have a greater risk of stroke than patients with aortic valve IE [45]. The development of clinical neurologic deterioration during IE is associated with a two- to fourfold increase in mortality in adults. Mycotic aneurysms of the cerebral circulation occur in 2–10 % of the cases. Other features include seizures, severe headache, visual changes (particularly homonymous hemianopsias), choreoathetoid movements, mononeuropathy, and cranial nerve palsies.

Patients with IE may have symptoms of uremia. In the pre-antibiotic era, renal failure developed in 25–35 % of the patients, but presently fewer than 10 % are affected. Renal disease can present as transient renal insufficiency or glomerulonephritis and is reported to occur in 2–5 % of pediatric IE [39, 40]. Renal failure is more common with long-standing disease but is usually reversible with appropriate antimicrobial treatment alone.

Septic arthritis has been reported in a small percentage of pediatric cases of IE [38, 40].

Diagnosis

Laboratory Studies

Blood Cultures: The blood culture is the single most important laboratory test performed in a diagnostic workup for IE. Bacteremia is usually continuous and low-grade; therefore, cultures do not have to be drawn at the time of fever spikes or chills. Based on adult studies, in approximately two-thirds of cases all blood cultures will yield positive results [46]. Two blood specimens will be sufficient to detect the etiologic agent more than 90 % of the time. The sensitivity of blood cultures for the detection of streptococci is particularly affected by receipt of prior antibiotic therapy and is also affected by the culture media employed [47]. Continuous monitoring blood culture systems (e.g., BACTEC, BacT/ALERT) are significantly more sensitive than conventional methods [48]. Blood culture media containing neutralizing resin particles have been especially helpful in improving the detection of staphylococci from patients receiving antimicrobial therapy at the time of culture [49].

On the basis of these studies, the following procedures for culturing blood are recommended. At least three blood culture sets should be obtained in the first 24 h. More specimens may be necessary if the patient has received antibiotics in the preceding 2 weeks. Blood cultures drawn within 4 h may yield equal results to those drawn 12–24 h apart; however, more positive cultures are required for a diagnosis of IE when drawn at shorter intervals. In general, culture of arterial blood offers no advantage over use of venous blood. At least 1–3 ml of blood per bottle should be drawn in infants and young children and 5–7 ml in older children.

The interpretation of positive blood cultures requires consideration of the isolated organism and the likelihood of that organism as a cause of IE. The following organisms are considered to be likely causes of IE when isolated from 2 or more blood cultures: *S. aureus*, viridans streptococci, enterococci (if acquired in the community and not nosocomially), and Group G streptococci. False positive results are likely to be present when organisms such as *Propionibacterium spp.*, *Corynebacterium spp.*, *Bacillus spp.*, and coagulase-negative staphylococci are recovered from a single blood culture or a minority of blood culture results. However, since these organisms are also capable of causing IE, it is important to determine if there is persistent bacteremia present as opposed to contamination with skin flora. Persistent bacteremia is likely if (1) positive cultures with organisms likely to cause IE are obtained from 2 samples collected >12 h apart or (2) if all of 3 or a majority of 4 or more separate blood cultures are positive and if the first and last samples are collected at least 1 h apart [1].

Other Blood Laboratory Tests: The utility of other blood tests in the diagnosis of IE is limited. Hematologic parameters are often abnormal in IE, but none is diagnostic. Anemia is frequently present, especially in subacute cases. This anemia usually has the characteristics of anemia of chronic disease, with normochromic, normocytic indices, but can present as hemolytic anemia. Thrombocytopenia and leukocytosis can be seen, sometimes with a high percentage of immature neutrophils (left shift). A significant number of patients have elevation of nonspecific acute-phase reactants such as erythrocyte sedimentation rate, C-reactive protein, procalcitonin, and immunoglobulins. A positive result on assay for rheumatoid factor is found in 40–50 % of adult cases, especially when the duration of the illness is greater than 6 weeks [33]. Hematuria can develop with associated proteinuria, red blood cell casts, hypocomplementemia, and renal insufficiency [34].Circulating immune complexes and mixed-type cryoglobulins are detectable in most adult patients with IE but also constitute a nonspecific finding [50].

Culture-Negative IE: Blood cultures fail to isolate an etiologic agent in 5–7 % of cases [34, 51]. Culture-negative IE is most often associated with antibiotic use within the previous 2 weeks. If blood cultures are negative in definite or possible IE, microbiologic considerations include *Bartonella*, *Coxiella*, *Brucella*, *Legionella*, *Chlamydia* species, and non-*Candida* fungi [52].

Diagnosis of these organisms requires special culture techniques or measurement of specific antibody titers.

Imaging

Echocardiography: Since its first use in the diagnosis of IE in 1973, echocardiography has become paramount in the process of evaluating IE [53]. It is of crucial importance in detecting vegetations, echogenic distinct masses from the adjacent valve with independent motion from the valve itself. Vegetations have characteristic findings of a shaggy dense band of irregular echoes in a nonuniform distribution on one or more leaflets (Fig. 128.1). Echocardiography may not only confirm the presence of vegetations in the setting of bacteremia, but it also provides important hemodynamic information regarding ventricular function and an estimate of the degree of valvular regurgitation (Fig. 128.2).

Transthoracic echocardiography (TTE) should be performed in all patients in whom IE appears to be a reasonable diagnosis. TTE is not, however, an appropriate screening test in the evaluation of febrile patients in whom IE is

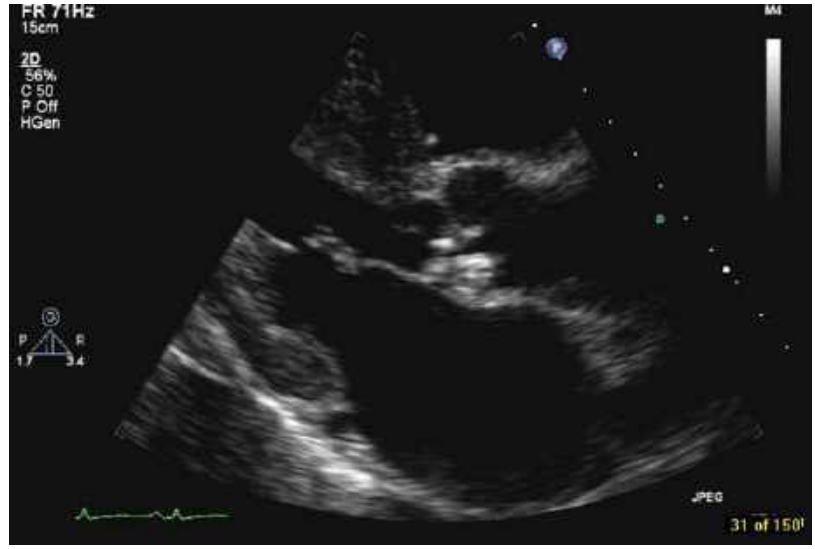

Fig. 128.1 BMP – multiple vegetations on the aortic valve seen by transthoracic echocardiogram

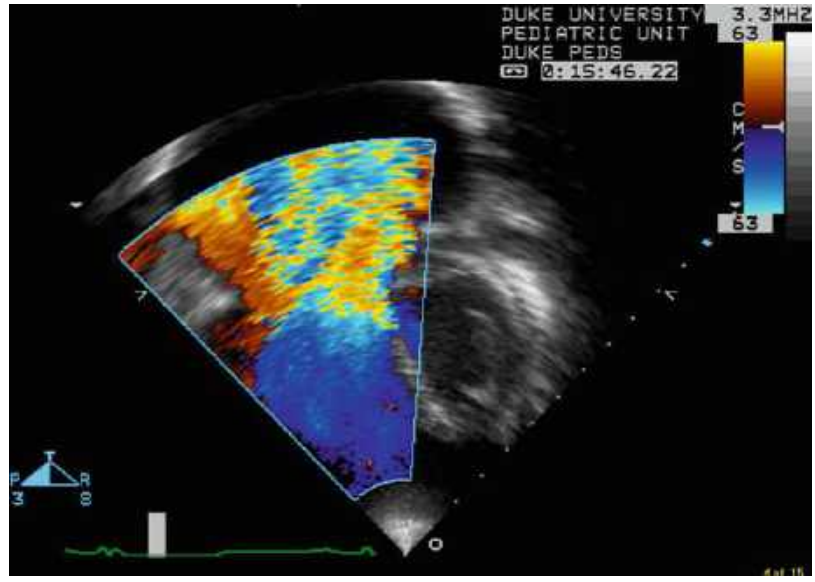

Fig. 128.2 BMP – free tricuspid insufficiency secondary to damage to the valve leaflets from endocarditis

unlikely on clinical grounds or in bacteremic patients with organisms that rarely cause IE, particularly if there is another obvious focus to explain the clinical syndrome [54]. TTE has a reported sensitivity of up to 97 % for detection of vegetations in children with IE [55]. One important consideration in children with congenital heart disease is that the echocardiogram be performed in a pediatric echocardiography laboratory and evaluated by a pediatric cardiologist due to the presence of underlying cardiac structural abnormalities. Technically inadequate studies are not of any value in the detection of vegetations. Although still controversial, certain characteristics of vegetations have been suggested to be prognostic of the risk for complications such as embolization or the need for surgery [56, 57]. In general, decisions about surgical intervention should be based on findings on the echocardiogram along with clinical parameters.

Transesophageal echocardiography (TEE) has significantly altered the diagnostic approach to

Fig. 128.3 BMP – vegetation prolapsing through the mitral valve seen by transesophageal echocardiogram

patients with suspected IE (Fig. 128.3). TEE has been demonstrated to be more sensitive than TTE in adults [58]; however, children often have more clear echocardiographic windows by TTE, generally obviating the need for further imaging. TEE is useful in children with poor TTE imaging, with a negative TTE and a high index of suspicion for IE to more precisely define the site of infection, to evaluate prosthetic valve function, and to evaluate for perivalvular abscess [59, 60].

Electrocardiography: An electrocardiogram should be part of the evaluation of a patient with suspected IE since the development of a new arrhythmia has been reported in 5 % of cases of endocarditis in patients with congenital heart disease [40]. The presence or new appearance of heart block is important evidence of extension of infection to the valve annulus and conduction system [61]. A new prolongation of the PR interval in a patient with IE is highly diagnostic of the presence of a ring abscess.

Other Imaging Modalities and Tests: Computed tomography and magnetic resonance imaging of the heart have become more prevalent in pediatrics, though the utility of these techniques in detection of IE in this population has not been evaluated. Labeled white blood cell, antibacterial antibody, and platelet studies have also shown promise in experimental IE [62–64]. Cardiac catheterization is not used in children, as the anatomic information provided by echocardiography in young patients is usually adequate to establish need for surgical repair or valve replacement [36].

Diagnostic Criteria for IE

IE is typically a syndrome diagnosis based on the presence of multiple findings rather than a single definitive test result. Practical and logical case definitions for IE are important for both clinicians and researchers who study this complex disease. Accurate identification and classification of patients with IE are important in defining natural history, complications, epidemiology, and treatment outcomes.

Early diagnostic criteria developed by Petersdorf and Pelletier in 1977 and von Reyn and colleagues (Beth Israel criteria) in 1982 have been supplanted by the Duke criteria [1], which were first proposed in 1994. Direct comparisons of the Duke and Beth Israel criteria have now been carried out in 11 major studies, involving nearly 1,400 patients. Multiple studies have demonstrated the superiority of the Duke criteria for the diagnosis of IE in children [3, 4].

Modifications of the Duke criteria have recently yielded more specificity to the schema [2]. The modified Duke criteria for the diagnosis of IE are provided in Tables 128.2 and 128.3.

Treatment

General Guidelines

Current recommendations include consultation of an infectious disease specialist in any complex case of IE or when there is any uncertainty in the diagnosis or therapy. Following the diagnosis of IE antibiotics should be administered in a dose designed to give sustained bactericidal serum concentrations throughout much of or the entire dosing interval. Certain general principles have been accepted that provide the framework for the current recommendations for treatment of IE (Table 128.5). Guidelines for outpatient parenteral antibiotic therapy for IE in adults as well as general guidelines for outpatient parenteral antibiotic therapy in all age ranges have been published [65, 66]. Pediatric outpatient parenteral antibiotic therapy has been demonstrated to be successful, to have a relatively low risk of complications, and to have a low rehospitalization rate mostly related to issues with vascular access [67]. Patients selected for outpatient therapy should have responded clinically to inpatient therapy, with negative blood cultures, no evidence of intracardiac complications, and stable hemodynamic parameters. Patient's families need to be compliant and capable of managing the technical aspects of intravenous therapy. Such patients require careful, regular monitoring in association with a home healthcare service and prompt access to medical care [34].

The American Heart Association has issued treatment guidelines for children [34] and more recently updated specific treatment guidelines based on the microbiologic etiologic agent [52]. General therapeutic considerations are summarized in Tables 128.6–128.9 [34, 52, 87]. It is important to remember that antibiotic doses in children are calculated per kg but should not exceed the maximum published adult dosage.

Table 128.5 Important considerations for the antibiotic treatment of IE

A prolonged course of therapy is necessary in order to eradicate microorganisms growing in valvular vegetations
Bactericidal, rather than bacteriostatic, antibiotics should be chosen to decrease the possibility of treatment failure or relapses
Parenteral antibiotics give a more sustained level of antibiotic activity and are therefore recommended over oral drugs
Synergistic antibiotic combinations can produce a more rapid bactericidal effect than some single agent regimens

Medical Therapy

Staphylococci: Most *Staphylococcus aureus* isolates produce a β-lactamase and are therefore highly resistant to penicillin G. The term methicillin-susceptible *S. aureus* (MSSA) implies that the organism is susceptible to some beta-lactam antibiotics (but not penicillin or ampicillin). The drugs of choice for native valve MSSA are semisynthetic, β-lactamase-resistant penicillins such as nafcillin or oxacillin (Table 128.6). The addition of gentamicin for the first 3–5 days is optional, as it may increase the killing of the staphylococci and facilitate clearance of bacteremia, though it may increase rates of nephrotoxicity and ototoxicity. In patients without a history of type 1 penicillin-allergic reactions, a first-generation cephalosporin such as cefazolin is indicated with or without gentamicin for the first 3–5 days. Vancomycin (with or without gentamicin for the first 3–5 days) is the drug of choice for patients with methicillin-resistant *S. aureus* (MRSA) infections and for those with MSSA infections and severe allergies to β-lactams. However, vancomycin is an inferior drug in the treatment of MSSA IE, predominantly because of its slow bactericidal activity and poor tissue penetration [69].

Coagulase-negative staphylococci are usually methicillin-resistant. Due to cross-resistance, cephalosporins should not be used in these patients. Vancomycin is usually administered for at least 6 weeks with or without gentamicin for the first 3–5 days.

Staphylococcal prosthetic valve IE (PVE) is associated with high mortality and requires

Table 128.6 Antimicrobial therapy for endocarditis caused by Staphylococci (Adapted from references [34, 52, 68])

Organism	Antimicrobial agent	Dosage per kg per 24 h	Maximum daily dose	Frequency of administration	Duration, week
Staphylococcus-methicillin sensitive					
Native valve	Nafcillin or oxacillin	200 mg IV	12 g	Q 4–6 h	6
	Plus optional				
	Gentamicin	3 mg IM or IV	Based on serum concentrations	Q 8 h	3–5 days
Native valve β-lactam allergic	Cefazolin	100 mg IV	6 g (children) 12 g (adolexcents)	Q 8 h	6
	Plus optional				
	Gentamicin	3 mg IM or IV	Based on serum concentrations	Q 8 h	3–5 days
	or				
	Vancomycin	40 mg IV	Based on serum concentrations	Q 6–12 h	6
Prosthetic valve	Nafcillin or oxacillin	200 mg IV	12 g	Q 4–6 h	6–8
	or				
	Cefazolin	100 mg IV	6 g (children) 12 g (adolexcents)	Q 8 h	6–8
	or				
	Vancomycin	40 mg IV	Based on serum concentrations	Q 6–12 h	6–8
	Plus				
	Rifampin	20 mg IV or PO	900 mg	Q 8 h	6–8
	Plus				
	Gentamicin	3 mg IM or IV	Based on serum concentrations	Q 8 h	2
Staphylococcus-methicillin resistant					
Native valve	Vancomycin	40 mg IV	Based on serum concentrations	Q 6–12 h	6
	Plus optional				
	Gentamicin	3 mg IM or IV	Based on serum concentrations	Q 8 h	3–5 days
Prosthetic valve	Vancomycin	40 mg IV	Based on serum concentrations	Q 6–12 h	6–8
	Plus				
	Rifampin	20 mg IV or PO	900 mg	Q 8 h	6–8
	Plus				
	Gentamicin	3 mg IM or IV	Based on serum concentrations	Q 8 h	2

aggressive management. Treatment for MSSA PVE is with nafcillin or oxacillin, in combination with rifampin for 6–8 weeks and gentamicin during the first 2 weeks. For MRSA PVE, vancomycin is used in combination with rifampin for 6–8 weeks, and gentamicin is added during the first 2 weeks. In order to minimize resistance to rifampin, this antibiotic should be added only after antibiotics active against staphylococci, such as a β-lactam or vancomycin and an

Table 128.7 Antimicrobial therapy for endocarditis caused by viridans group Streptococci, *Streptococcus bovis*, and other non-enterococcal Streptococci (Adapted from references [34, 52, 68])

Organism	Antimicrobial agent	Dosage per kg per 24 h	Maximum daily dose	Frequency of administration	Duration, week
Streptococci-penicillin susceptible (MIC $\leq$ 0.12 μg/mL)					
Native valve	Penicillin G	200,000 U IV	24 million units	Q 4–6 h	4
	or				
	Ceftriaxone	100 mg IV	4 g	Q 24 h	4
	or

Streptococci-relatively penicillin resistant (MIC > 0.12–0.5 μg/mL)					
Native valve	Penicillin G	300,000 U IV	24 million units	Q 4–6 h	4
	Or				
	Ceftriaxone	100 mg IV	4 g	Q 24 h	4
	Plus				
	Gentamicin	3 mg IM or IV	Based on serum concentrations	Q 8–24 h	2
Native valve β-lactam allergic	Vancomycin	40 mg IV	Based on serum concentrations	Q 6–12 h	4
Prosthetic valve	Penicillin G	300,000 U IV	24 million units	Q 4–6 h	6
	or				
	Ceftriaxone	100 mg IV	4 g	Q 24 h	6
	or				
	Vancomycin (β-lactam allergic)	40 mg IV	Based on serum concentrations	Q 8–12 h	6
	Plus				
	Gentamicin	3 mg IM or IV	Based on serum concentrations	Q 8–24 h	6

aminoglycoside, have been started and the infection burden of bacteria is significantly reduced. In some cases, MRSA resistant to aminoglycosides (reported to be decreasing in frequency [70]) can be treated with fluoroquinolones, depending on the results of susceptibility testing. Daptomycin is a lipopeptide antibiotic that is bactericidal and has been shown to be effective in treatment of

Table 128.8 Antimicrobial therapy for endocarditis caused by enterococci on native or prosthetic valves (Adapted from references [34, 52, 68])

Organism	Antimicrobial agent	Dosage per kg per 24 h	Maximum daily dose	Frequency of administration	Duration, week
Enterococci nonresistant

	Imipenem/ cilastatin	60–100 mg IV	4 g	Q 6 h	≥8

staphylococcal endocarditis in adults [71]. Daptomycin clearance is reported to be increased in younger children suggesting that higher dosages are necessary to achieve the same drug concentrations as in adults [72, 73]. However, experience with daptomycin in children is limited, and thus, a safe pediatric dose has not been established [74]. Staphylococcal PVE IE has been reported to have a very high mortality in adults even with aggressive medical therapy [75]. For this reason early surgical valve replacement is often considered. *S. aureus* prosthetic valve IE has been reported to cause a high incidence of intracerebral hemorrhage in adults [76], and thus, the risks of continuing anticoagulation need to be carefully considered.

Viridans group streptococci, Streptococcus bovis, and other non-enterococcal streptococci: The treatment for endocarditis due to viridans streptococci is based on the in vitro penicillin minimum inhibitory concentration (MIC) of the isolate (Table 128.7). Streptococci with a penicillin MIC $\leq$ 0.12 μg/ml are considered highly susceptible and are usually treated with penicillin G or ceftriaxone for 4 weeks. Comparable cure rates can be achieved with a combination of penicillin or ceftriaxone with low-dose gentamicin for 2 weeks. A cure rate of 98 % has been reported with these regimens in adults [77, 78], but there are no published data on the efficacy of ceftriaxone for the treatment of IE in children. Cefazolin or other first-generation cephalosporins may be substituted for penicillin in patients whose penicillin hypersensitivity is not of the immediate type. Vancomycin is recommended for patients allergic to β-lactams.

When IE is due to streptococcal strains with a penicillin MIC $>$ 0.12 μg/ml and $<$0.5 μg/ml, combination therapy with penicillin for 4 weeks and low-dose gentamicin for the first 2 weeks of treatment is recommended. In patients allergic to β-lactams, a 4-week course of vancomycin is recommended. When native valve or PVE IE is due to streptococcal strains with a penicillin MIC $>$0.5 μg/ml or nutritionally variant streptococci (now classified as *Abiotrophia* species), the regimen for penicillin-resistant enterococcal IE is recommended (Table 128.8).

For highly penicillin-susceptible streptococci PVE (MIC $\leq$ 0.12 μg/ml), penicillin G for 6 weeks and gentamicin for 2 weeks are usually indicated. When PVE is due to relatively penicillin-resistant streptococci (MIC $>$ 0.12 to 0.5 μg/ml), penicillin G is recommended for 6 weeks and gentamicin for 4 weeks.

Enterococci: IE caused by enterococci is usually associated with *E. faecalis* and occasionally with *E. faecium*. Enterococci are increasingly resistant to most classes of antibiotics, making treatment difficult (Table 128.8). Due to a defective bacterial autolytic enzyme system, cell

wall-active agents are bacteriostatic against enterococci and should not be given alone to treat IE. When used in combination with gentamicin, penicillin G and ampicillin facilitate the intracellular uptake of the aminoglycoside, resulting in a bactericidal effect against enterococci. Before embarking on therapy, susceptibility of the enterococcal isolate should be determined for penicillins, vancomycin, and aminoglycosides. For strains with intrinsic high-level resistance to penicillin (MIC >16 μg/ml), vancomycin is indicated. Vancomycin is synergistic with aminoglycosides, particularly gentamicin. When high-level resistance to aminoglycosides is detected (500–2,000 μg/ml for gentamicin), the combination with cell wall-active agents is no longer synergistic, and therefore, treatment with an aminoglycoside is not recommended. Limited data are available to guide therapy in these difficult cases; however, some experts will attempt high-dose ampicillin combined with imipenem or ceftriaxone for 8–12 weeks.

IE caused by vancomycin-resistant enterococci (VRE) is difficult to treat. Most vancomycin-resistant strains of *E. faecalis* and some vancomycin-resistant strains of *E. faecium* are susceptible to achievable concentrations of ampicillin. In such cases the recommended therapy is ampicillin or penicillin combined with gentamicin. Even when enterococci are considered resistant to ampicillin, higher doses can be used in order to achieve sustained plasma levels of more than 100–150 μg/ml with some treatment efficacy and little toxicity. In 1999, the FDA approved quinupristin/dalfopristin (QD) to treat infections associated with vancomycin-resistant *Enterococcus faecium* bacteremia when no alternative treatment is available. However, QD alone is unlikely to be curative in VREF IE because it is not usually bactericidal against *E. faecium*. Endocarditis models suggest that the association of QD with ampicillin may be beneficial. It is important to note that *E. faecalis* is not susceptible to QD. In 2000, the FDA approved linezolid to treat infections associated with vancomycin-resistant *E. faecium*, including cases with bloodstream infection. However, linezolid is bacteriostatic against VRE and therefore should not be used if other options are available. Newer agents such as daptomycin, telavancin, and dalbavancin may be useful in such cases based on experimental models, but clinical experience is lacking. Unfortunately, case reports of pediatric patients with enterococcal resistance to daptomycin are already emerging [79].

Gram-Negative IE: Though less common than gram-positive infection, gram-negative endocarditis has been increasing in frequency over the past two decades [80, 81]. HACEK organisms, including *Haemophilus* spp. (*H. parainfluenzae, H. aphrophilus*, and *H. paraphrophilus*), *Actinobacillus actinomycetemcomitans, Cardiobacterium hominis, Eikenella corrodens*, and *Kingella kingae*, are recognized in children but are uncommon. These organisms have fastidious growth characteristics, and thus, standard culture incubation for 2–3 weeks is recommended for cases in which IE is suspected and the initial blood cultures are negative. Third-generation cephalosporins are recommended for the treatment of HACEK IE (Table 128.9), with a duration of 3–4 weeks for native valves and 6 weeks for PVE [82]. HACEK isolates are typically susceptible in vitro to fluoroquinolones, aztreonam, and trimethoprim-sulfamethoxazole. However, since clinical data are still lacking, these agents should be reserved as an alternative therapy in patients who cannot tolerate β-lactams.

Other gram-negative bacteria are an infrequent cause of IE in children and are most often nosocomially acquired. Treatment of organisms such as *Pseudomonas aeruginosa, Escherichia coli*, and *Serratia marcescens* should be individualized based on antimicrobial susceptibility of the specific isolate [34]. Empiric therapy with an extended-spectrum penicillin/β-lactamase inhibitor or cephalosporin together with an aminoglycoside is recommended until final culture testing is completed. Total duration of therapy should be 6 weeks and should be implemented in consultation with and infectious disease specialist.

Fungal IE: The incidence of fungal IE has increased significantly in the past decade, in most cases due to *Candida* species or *Aspergillus* species. Though current recommendations

Table 128.9 Antimicrobial therapy for HACEK, gram-negative, culture-negative, and fungal endocarditis on native and prosthetic valves (Adapted from references [34, 52, 68])

Organism	Antimicrobial agent	Dosage per kg per 24 h	Maximum daily dose	Frequency of administration	Duration, week
HACEK	Ceftriaxone	100 mg IM or IV	4 g	Q 24 h	4 (native)–6 (prosthetic)
	or				
	Ampicillin-sulbactam	300 mg IV	12 g	Q 4–6 h	4–6
	or				
	Ciprofloxacin	20–30 mg IV or PO	1.2 g	Q 12 h	4–6
Other gram negatives					
Empiric therapy	Extended-spectrum penicillin plus β-lactamase inhibitor (piperacillin-tazobactam)	200–300 mg IV	16 g	Q 6–8 h	6
	or				
	Cephalosporin (ceftazidime)	90–150 mg IV	6 g	Q 8 h	6
	Plus				
	Gentamicin	3 mg IM or IV	Based on serum concentrations	Q 8 h	6
Directed therapy	Tailored to the resistance profile of the individual organisms				
Culture negative					
General approach	Ceftriaxone	100 mg IM or IV	4 g	Q 24 h	6
	Plus				
	Gentamicin	3 mg IM or IV	Based on serum concentrations	Q 8 h	2–6
Suspected Staphylococcal IE add	Ampicillin-sulbactam	300 mg IV	12 g	Q 4–6 h	6
Suspected MRSA	Vancomycin	40 mg IV	Based on serum concentrations	Q 6–12 h	6
	Plus				
	Gentamicin	3 mg IM or IV	Based on serum concentrations	Q 8 h	2–6
Suspected fastidious organism	Consider doxycycline and ciprofloxacin with an infectious disease consultation				
Fungal					
Primary therapy	Liposomal amphotericin B	Use with pharmacy and infectious disease consultation			
	Plus optional				
	5-fluorocytosine	Use with pharmacy and infectious disease consultation			
Suppressive therapy	Fluconazole	6–12 mg IV or PO	400 mg	Q 24 h	Indefinite

strongly favor a combined medical-surgical approach, the introduction of new fungicidal agents may reduce that need. Any documented or suspected case of fungal IE requires an infectious disease consultation.

A mainstay of antifungal drug therapy is liposomal amphotericin B for at least 6–8 weeks. This agent is much less toxic than routine amphotericin B, which produces multiple side effects, including fever, chills, phlebitis, headache, anorexia, anemia, hypokalemia, renal tubular acidosis, nephrotoxicity, nausea, and vomiting. Depending on the isolate, some experts recommend the addition of 5-fluorocytosine or rifampin to amphotericin B, as these drugs may act synergistically to potentiate fungal killing. In patients who are unable to undergo surgery, after an initial course of amphotericin B, an azole is often used for long-term suppressive therapy. The role of newer antifungals such as posaconazole and caspofungin in the treatment of fungal IE remains unclear. Caspofungin appears superior to amphotericin in the clearance of Candida spp. from the bloodstream; however, its efficacy in the treatment of endocarditis is not known.

Culture-Negative IE: Due to the substantial issues in treatment decisions, consultation with an infectious disease specialist is recommended. The primary considerations for therapy are directed against staphylococci, streptococci, enterococci, and the HACEK organisms (Table 128.9). An initial approach is to use ceftriaxone and gentamicin. A β-lactamase resistant penicillin such as ampicillin-sulbactam should be added if there is a high suspicion of staphylococcal IE. Vancomycin should be substituted in penicillin-allergic patients and when suspicion of MRSA is high. If clinical improvement occurs, some authorities recommend discontinuation of treatment with the aminoglycoside after 2 weeks. The other agent(s) should be continued for a full 6 weeks of treatment. Patients who are at risk of unusual causes of IE such as *Coxiella*, *Bartonella*, *Legionella*, and *Brucella* can be empirically started on doxycycline and ciprofloxacin; however, these pathogens require targeted therapy which should be undertaken in consultation with an infectious diseases specialist.

Table 128.10 Indications for surgical intervention in cases of endocarditis

Clinical features	Refractory congestive heart failure
	More than one serious embolic episode
	Uncontrolled infection
	Physiologically significant valve dysfunction
	Ineffective antimicrobial therapy
	Resection of mycotic aneurysms
	Most cases of prosthetic valve IE
	Most cases of IE on prosthetic material in repaired CHD
	Significant worsening of cyanosis in patients with cyanotic CHD
Echocardiographic features	Valve dehiscence, rupture, perforation, or fistula
	Perivalvular or myocardial abscesses
	Persistent large vegetations after a systemic embolic episode
	An increase in vegetation size after 4 weeks of antimicrobial therapy
	New heart block
	Large (>10 mm) anterior mitral valve vegetations
	Acute aortic or mitral insufficiency with signs of ventricular failure
	Shunt or conduit obstruction in repaired or palliated CHD

Surgical Therapy

Valve replacement has become an important adjunct to medical therapy in the management of IE and is now used in at least 25 % of the cases. The generally accepted indications for surgical intervention during active IE are listed in Table 128.10. Of particular importance to pediatric patients with palliated CHD is development of aortopulmonary shunt obstruction and infected prosthetic material such as in right ventricle to pulmonary artery conduits. The hemodynamic status of the patient, not the activity of the infection, is the critical determining factor in the timing of cardiac valve replacement. Surgery should not be delayed because a full course of antibiotic therapy has not been completed or the patient is still bacteremic. Indeed, the incidence

of reinfection of a prosthetic valve after surgery is below 1 %. Thus, when CHF is diagnosed in patients with aortic valve IE or persists despite therapy in mitral valve IE, surgery is indicated. Although not systematically studied, most experts recommend continuation of antibiotic therapy postoperatively for 2–6 weeks when surgery is undertaken with active IE [83].

Most patients with PVE (except those with late disease caused by penicillin-sensitive viridans streptococci) require valve replacement. Similarly, valve replacement is necessary in a significant proportion of patients with IE on native valves after a medical cure, particularly with aortic valve involvement, which is more likely to be hemodynamically significant.

Medical therapy alone can be considered even in the face of the listed risk factors if there are significant comorbid conditions such as CNS bleeding. The morbidity and mortality of surgery must be carefully considered when patients are at high risk of bypass complication.

Acute Rheumatic Fever and Chronic Rheumatic Disease

129

Bo Remenyi and Jonathan Carapetis

Abstract

Rheumatic heart disease, a sequel of acute rheumatic fever, remains the most common cause of acquired heart disease worldwide and today it is a disease of poverty. This chapter describes the epidemiology, pathogenesis, clinical manifestations, diagnostic criteria, and management principles of acute rheumatic fever. Chronic rheumatic heart disease, its clinical manifestation, and medical and surgical management are also presented.

Keywords

Acute rheumatic fever • Aortic regurgitation • Aortic stenosis • Aortic valve • Arthritis • Chorea • Erythema marginatum • Jones criteria • Mitral regurgitation • Mitral stenosis • Mitral valve • Myocarditis • Penicillin • Pericarditis • Rheumatic fever • Rheumatic heart disease • Streptococcal infection • Subcutaneous nodules • Tricuspid valve • Valvulitis

Introduction

Acute rheumatic fever (ARF) is a delayed autoimmune reaction that typically follows a group A streptococcal throat infection. It is a multiorgan disease that affects the skin, joints, subcutaneous tissue, brain, and the heart. The residual damage from acute cardiac inflammation, rheumatic heart disease (RHD) is the only long-term sequel and responsible for the mortality and the majority of morbidity relating to ARF. Despite the virtual disappearance of ARF/RHD from the developed world, its human, social, and economic costs continue to burden many low- and middle-income countries.

Epidemiology

Acute rheumatic fever (ARF) and rheumatic heart disease (RHD), once very common pathologies in North America and Europe, are now rarely seen by physicians who practice among affluent populations. In developing nations, ARF remains the predominant cause of acquired heart disease in young adults and children. In developed countries, the incidence of ARF began to decline in the nineteenth century and preceded the availability of penicillin [1]. The decline was attributed to decreased crowding, better personal hygiene, improved nutrition, and overall improved living standards [1]. With the introduction of penicillin in the mid-twentieth century, the incidence of ARF further declined, and in many places it is now virtually nonexistent. Low- and middle-income countries and some indigenous populations of the developed world continue to struggle with the scourge of ARF and its long-term consequence [2]. A conservative estimate of 15 million people that are affected worldwide by RHD is likely to represent the tip of the iceberg [2]. The true prevalence of RHD would be several times that if subclinical or echocardiographically diagnosed disease is included, although the significance of these manifestations remains unclear [3–6]. Children and adolescents aged between 5 and 15 years of age are at the greatest risk of a primary episode of ARF [7]. While a primary episode of ARF is rare beyond the fourth decade of life, the peak prevalence of RHD is between 25 and 45 years of age [7]. This difference between the peak incidence of ARF and the peak prevalence of RHD reflects the cumulative effect of primary as well as recurrent episodes of ARF. Although there is no established gender difference for ARF, in most populations RHD occurs 1.5 to 2 times as commonly in females compared to males, which may be due to increased exposure to streptococcal infections (related to child-rearing), lack of access to preventive medications, different host susceptibility, or other factors yet to be determined.

Pathogenesis

The association between ARF and group A B-hemolytic streptococcal upper respiratory tract infections is well established [1]. However, the exact pathogenesis of ARF remains incompletely understood. The classical disease model is based on a complex interaction between the susceptible host, a virulent bacterium, and an environment conducive to bacterial infection. The current hypothesis attributes the delayed autoimmune reaction of ARF to molecular mimicry between the host and the streptococcus [8]. Certain streptococcal proteins (e.g., M protein and *N*-acetylglucosamine) share homologous sequences with human tissues such as myosin, tropomyosin, keratin, and laminin. As a result, the immune reaction that occurs in response to the group A streptococcal (GAS) infection can lead to the formation of cross-reactive antibodies in susceptible hosts. These antibodies can then attach to native laminin in valvular endothelium and to other tissues. This then allows the entry of primed T cells, B cells, and macrophages and triggers an autoimmune reaction [9].

Not all hosts are susceptible and it is thought that only 3–6 % of any population is at risk of developing ARF [10, 11]. Genetic predisposition to ARF has been linked to human leukocyte antigen (HLA) class II alleles [12, 13].

Some HLA alleles are associated with increased susceptibility, these appear to be different in different populations, while others appear to be protective against ARF [12, 13]. Polymorphisms in the TNF-alpha and mannose-binding lectin genes have also been implicated [13]. High-level expression of a particular alloantigen present on B cells, D8-17, has been reported to occur in patients with ARF with mid-level expression in unaffected family members and low-level expression in the general population, implying that it may be a possible marker of susceptibility [14].

M protein on the surface of the bacterium has been linked to the virulence of GAS. Historically it was thought that only certain strains or M types of GAS were rheumatogenic and hence had the ability to trigger ARF. Today, in developing country settings with numerous circulating M (or *emm*) types potentially linked to ARF, it is hypothesized that the serotype-specific association with ARF pathogenesis may not apply and that strains from any *emm* type may possess or acquire rheumatogenic potential [15, 16].

In temperate climates there is a very strong epidemiological association between GAS pharyngitis and ARF [1]. In some tropical settings, however, pharyngeal carriage rates of GAS may be low and symptomatic pharyngitis uncommon despite very high incidences of ARF [17]. In these settings, the upper respiratory tracts of children are more often colonized by groups C and G rather than group A streptococcus [15, 17], while the main source of GAS may be skin infections [13]. The strains that inhabit these skin lesions appear to overlap with the strains that have been documented to cause pharyngitis and have been linked to ARF [15]. Moreover, it has been demonstrated that groups C and G streptococci are capable of exchanging virulence determinants with GAS [18]. Studies from tropical countries where ARF remains endemic have challenged the current model of pathogenesis, the quintessential requirement of a GAS upper respiratory tract infection to be present for ARF to be triggered. However, the potential role for GAS skin infections and groups C and G streptococci in the pathogenesis of ARF is yet to be proven.

A conducive environment appears to be another important factor in the pathogenesis of ARF. Factors such as overcrowding, poverty, poor hygiene, and poor access to health care all have been linked to increased prevalence of ARF, probably linked to increase transmission of bacterial infection from person to person [19].

Clinical Manifestations of ARF

Diagnostic Criteria

The diagnosis of ARF relies on clinical criteria as there are no specific tests that confirm or rule out the diagnosis. In 1944 in the United States, Jones and colleagues established clinical diagnostic criteria for ARF which still bear his name today [20]. Over the latter part of the twentieth century, the Jones criteria were revised, modified, and updated. On each occasion the criteria were changed to become more specific and less sensitive for ARF. The changes to the Jones criteria were appropriate for industrialized countries given the rapid decline of ARF over that period of time. In 2001 the World Health Organization (WHO) further clarified the updated Jones criteria with regard to the diagnosis of ARF recurrences [21, 22]. Today the application of the revised Jones criteria may not be appropriate to populations where ARF remains endemic, because it may lead to underdiagnosis, with potential devastating consequences. Australia, a country where ARF remains endemic among its indigenous population, further modified the Jones criteria to increase the sensitivity for their high-risk population [23]. The WHO and the Australian diagnostic criteria are shown in Tables 129.1 and 129.2.

Evidence of Streptococcal Infections

For the diagnosis of ARF to be confirmed, there is a requirement for evidence of antecedent streptococcal infection, with the exceptions of two clinical manifestations that often have a delayed presentation: chorea and low-grade carditis [21]. There is a latent period of 1–5 weeks in between

Table 129.1 2003 WHO criteria for the diagnosis of acute rheumatic fever (based on the 1992 revised Jones criteria) [21]

Diagnostic categories	Criteria
Primary episode of ARF	Two major or one major and two minor manifestations **plus** evidence of a preceding group A streptococcal infection[a]
Recurrent attack of RF in patient **without** established RHD	As above
Recurrent attack of RF in patient **with** established RHD	Two minor manifestations **plus** evidence of a preceding group A streptococcal infection
Rheumatic chorea	Other manifestations or evidence of group A streptococcal infection not required
Insidious onset rheumatic carditis	Other manifestations or evidence of group A streptococcal infection not required

a group A streptococcal infection and the onset of ARF [24]. As a result most individuals with ARF do not have a positive throat swab culture or a rapid antigen test. Serological evidence remains the gold standard. When serology is performed too early in the course of the illness, it may be negative and will be required to be repeated in 10–14 days. The two most commonly utilized tests are antistreptolysin O (ASO) and anti-DNase B (ADB) titers. Only 80 % of patients with ARF show an immunological response to a single streptococcal antigen [25]. When reactions to multiple antigens are tested, it improves detection of antecedent streptococcal infection to 92–98 % in patients with ARF [25]. ASO peaks at 3–6 weeks, and anti-DNase B peaks at 6–8 weeks into the illness and is likely to stay elevated longer. Whenever possible the reference range for abnormal titers should be age-specific and based on data from local populations of healthy people without a recent GAS infection [22, 26]. Levels indicative of a recent streptococcal infection based on USA [22] and Fiji [26] data for children are shown in Table 129.3.

Major Manifestations

Arthritis

Arthritis (hot, red, tender, and swollen joints) is the most common presenting symptom of ARF. It typically affects the large joints (knees, ankles, hips, and elbows) in an asymmetrical fashion. The classical pattern is migratory and fleeting, one joint becoming inflamed as the other one subsides. The presence of polyarthritis is required to meet WHO diagnostic criteria for a major manifestation of ARF. In Oceania, monoarthritis and polyarthralgia are frequent presentations and local guidelines are modified and recognize these as major manifestations (Table 129.2) [23, 27]. Individual joints remain inflamed for

Table 129.3 Suggested upper limits of normal serum streptococcal antibody titers in children and adults: a comparison of data from USA [22] and Fiji [26]

	USA [22]		Fiji [26]	
	ASOT	Anti-DNase B	ASOT	Anti-DNase B
5–15 year	>320 IU/ml	>240 IU/ml	>276 IU/ml	>499 IU/ml
>15 years	>240 IU/ml	>120 IU/ml	N/A	N/A
15–24			>238 IU/ml	>473 IU/ml
25–34			>177 IU/ml	390 IU/ml
>35			>127 IU/ml	265 IU/ml

1–5 days and maximum severity is usually reached on day 2. If untreated, the process of migratory arthritis subsides within 2–4 weeks and generally resolves without any chronic consequence. The arthritis of ARF is exquisitely painful and can be out of proportion with the clinical signs. Signs and symptoms are very responsive to NSAIDs, and caution must be exercised not to initiate such therapy too early as it may abate the full manifestation, thus impeding the ability to make an accurate diagnosis.

Carditis

Acute rheumatic carditis is the only serious or potentially life-threatening manifestation of ARF, and it is the only manifestation that has a long-term sequel. It occurs in 30–80 % of patients during the first episode and is more common and severe with ARF recurrences [28–30]. While traditionally rheumatic carditis is described as a pancarditis affecting the pericardium, myocardium, and endocardium, the predominant manifestation is valvulitis [31].

Valvulitis most commonly affects the mitral and aortic valves and manifests as regurgitation. Less commonly the tricuspid and very rarely the pulmonary valves can be affected but almost never in isolation. Typically valvulitis is evident at the time of presentation; however, on occasion it can be low grade and its onset may be delayed by 2–6 weeks [32]. Hence, repeated clinical and/or echocardiographic examinations may be required. Moreover, individuals with low-grade carditis may have delayed presentation and hence have normal streptococcal titers. Traditionally the diagnosis of valvulitis relied on the presence of a pathologic murmur in patients with suspected ARF [22]. With the advent of modern echocardiography, it is now clear that auscultation is insufficiently sensitive and specific [33, 34]. However, subclinical carditis (echocardiographic evidence of mild but significant regurgitation of the mitral or aortic valve without an associated clinical murmur) is not universally accepted as a major manifestation of ARF. Some guidelines, including those in Australia and New Zealand, accept subclinical valvulitis as a major manifestation (in Australia this is restricted to individuals who come from populations with an ARF incidence >30/100,000). The 1992 updated Jones criteria and the 2003 WHO criteria both require a clinical murmur to be evident. However, WHO guidelines consider isolated echocardiographic findings to be consistent with "indolent carditis" even in the absence of any other manifestation of ARF or evidence of antecedent streptococcal infection (Table 129.1). WHO recommends that individuals with such echo findings should be classified as having "probable RHD" and until proven otherwise should be offered secondary prophylaxis for ARF [21].

Valvulitis during the first presentation of ARF is often mild (Fig. 129.1, Videos 129.1 and 129.2), and the majority of patients with mild disease will have no detectable disease within 5–10 years providing appropriate measures are instituted to prevent a recurrence [35–37]. The 5–10 % of children who present with severe carditis have significantly worse outcomes and many will require cardiac surgery and/or succumb (Fig. 129.2, Videos 129.3 and 129.4) [38, 39].

Pericarditis is rarely if ever an isolated cardiac manifestation of ARF [40]. It commonly presents with chest pain, typically sharp or pleuritic, and may be alleviated by sitting up and leaning forward. It is often associated with friction rub, a squeaky, scratching, or grating sound on

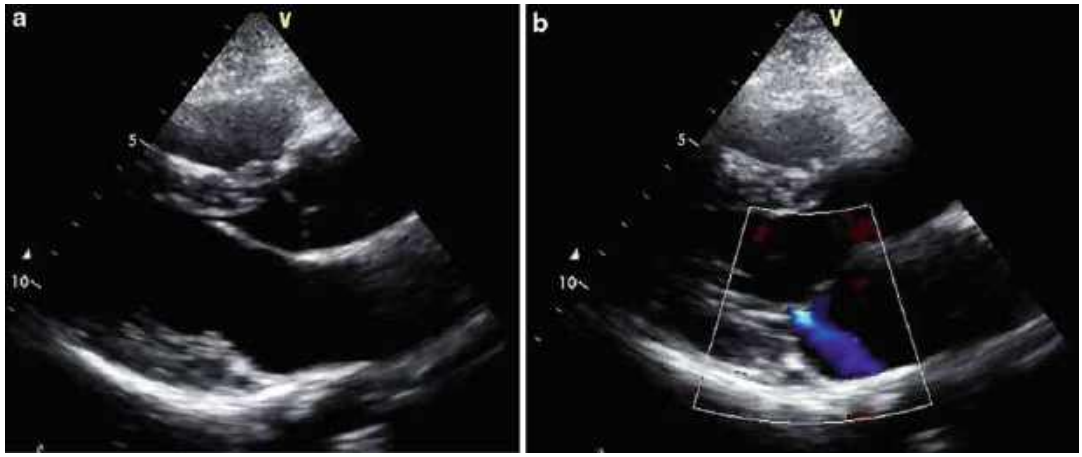

Fig. 129.1 Echocardiographic images depict mild valvulitis in an 8-year-old boy with acute rheumatic fever. (**a**) 2D imaging demonstrates normal thin mitral valve leaflets with normal mobility. (**b**) Color-Doppler imaging demonstrates mild mitral valve regurgitation

Video 129.1 Echocardiographic images depict mild valvulitis in an 8-year-old boy with acute rheumatic fever. 2D imaging demonstrates normal thin mitral valve leaflets with normal mobility

auscultation, and it may obscure a coexisting valvular murmur. Muffled or distant heart sounds are often indicative of a pericardial effusion that can be confirmed on echocardiographic examination.

Myocarditis. In the echocardiographic era, clinically significant myocarditis in the absence of severe valvulitis has not been clearly documented [31]. In the pre-echocardiographic era, myocarditis was a recognized cause of mortality during the acute phase of illness [41], but pathologists may have been misled by the relative lack of deformity of the valves, universally present in the chronic phase of illness, which led to severely dilated left-sided chambers, rather than a myocarditis process. The microscopic findings of Aschoff bodies further supported their hypothesis [42] as did immunological studies that demonstrated cross-reactivity between antistreptococcal antibodies and myosin [43]. In the current era, using very sensitive markers such as troponin and creatinine kinase, biochemical studies have failed to demonstrate myocardial necrosis during an episode of ARF [40, 44]. The cardiac function on echocardiography frequently is hyperdynamic rather than depressed. If impairment of cardiac contractility is present, it is

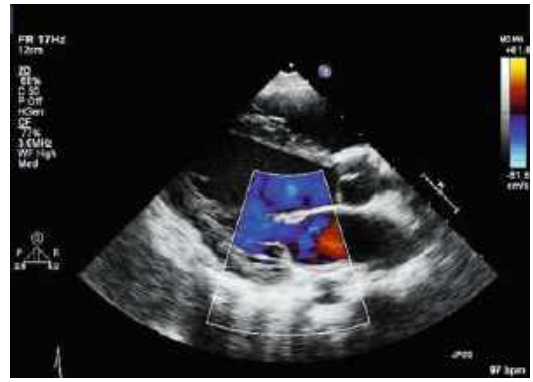
Video 129.3 Echocardiographic images depict severe acute rheumatic heart disease in a 12-year-old girl who required emergency cardiac surgery. 2D imaging demonstrates flail posterior leaflet



Video 129.4 Echocardiographic images depict severe acute rheumatic heart disease in a 12-year-old girl who required emergency cardiac surgery. Color-Doppler imaging demonstrates severe mitral valve regurgitation

always in the setting of severe valvular dysfunction and recovery can be expected following surgical correction of valvular dysfunction [45, 46]. Therefore, modern studies do not support the presence of clinically significant primary myocarditis in the setting of ARF [31, 47].

Chorea

Sydenham's chorea may be the sole manifestation of ARF and does not have a requirement of evidence of antecedent streptococcal infection. It commonly presents following a prolonged latent period of 1–6 months. By that time streptococcal titers have often normalized and other manifestations, if initially present, resolved. It occurs in 10–25 % of cases of ARF and has a strong female predominance [30, 48]. It is characterized by involuntary, semi-purposeful, jerky, uncoordinated movements predominantly of the hands, feet, tongue, and face. The abnormal movements disappear during sleep. It may only affect one side of the body (hemichorea). Manifestations may be subtle and a teacher may describe a child with chorea as clumsy with poor handwriting. More stereotypical manifestations include "milkmaid's grip" (irregular repetitive squeezing of the examiners hand), "spooning" (flexion of the wrist and extension of the metacarpal pharyngeal joints when hands are extended), "pronator sign" (turning outward

of the arm and palms when arms are extended above the head), and "bag of worms sign" (inability to maintain the protrusion of the tongue with jerky speech). Chorea is a self-limiting illness and the majority of patients will recover within 6 months without any treatment, though recurrence of chorea is frequent during subsequent episodes of ARF and occurs in a quarter of all patients [48]. More recently, associated behavioral abnormalities, particularly emotional lability and obsessive–compulsive symptomatology, have been recognized as significant findings in patients with chorea and may persist after the movement disorder has subsided [49].

Erythema Marginatum

Erythema marginatum is a rare but highly specific manifestation of ARF. It occurs in about 3–4 % of cases but is almost never reported in dark-skinned people [30, 50]. It is a nonpruritic, macular or papular, erythematous rash with a pale center and rounded or serpiginous margins. It is evanescent (appears and disappears within hours). It is characteristically accentuated by heat and it can quickly disappear in cold air-conditioned settings. Lesions occur predominantly on the trunk or proximal extremities and almost never on the face.

Subcutaneous Nodules

Subcutaneous nodules are rare but highly specific signs of ARF. They occur in less than 2 % of cases [30, 51]. They consist of firm, round, and highly mobile painless nodules that occur around bony prominences such as elbows, wrists, and spinous processes of vertebra. They are 0.5–2 cm in size and occur in crops. They tend to occur early in the course of the illness, 1–2 weeks after onset, and last only a few weeks or a month. They resolve with no long-term sequel and are strongly associated with the presence of rheumatic carditis.

Minor Manifestations

Arthralgia without any objective signs of inflammation is a very common manifestation of ARF. It affects joints in the same distribution as arthritis (large joints in an asymmetrical and often migratory manner). If arthritis is present as a major manifestation, arthralgia cannot be considered an additional minor manifestation in the same person.

Acute-phase reactants (CRP and ESR) are almost always elevated in ARF to levels above 30 mg/L and 30 mm/h, respectively. CRP rises and falls quickly while ESR can remain elevated for many months. Repeated measurements, particularly of CRP, may help to track the course of the illness.

Fever is a very common manifestation of ARF; however, its presence is not essential for the diagnosis to be made. It is often low grade [51] and might be masked by premature administration of NSAIDS.

A **prolonged PR interval** (or first-degree heart block) on an electrocardiogram is a nonspecific manifestation of ARF and it is present in up to a third of patients. The normal PR interval is age related. Rarely more advanced heart blocks such as second or third degree can develop [50]. The majority of conduction defects resolve within a few weeks of onset, so a repeat ECG 6–8 weeks after onset that demonstrates resolution of the conduction can help to confirm the diagnosis in uncertain cases. Prolonged PR interval is not a reflection of the severity of carditis and it is not associated with long-term conduction defects. If carditis is present as a major manifestation, then a prolonged PR interval cannot be considered an additional minor manifestation in the same person.

Investigations

It is recommended that all patients with suspected ARF should have the following investigations whenever possible: white blood cell count, ESR, CRP, blood cultures (if febrile), electrocardiogram, chest X-ray (if respiratory or cardiac symptoms), and an echocardiogram. If available antistreptococcal serology, both antistreptolysin O and anti-DNase B titers, should be performed to confirm antecedent

Table 129.4 Differential diagnoses of common major presentations of ARF

Presentation		
Polyarthritis and fever	**Carditis**	**Chorea**
Septic arthritis (including disseminated gonococcal infection)[a]	Innocent murmur	Systemic lupus erythematosus
Connective tissue and other autoimmune disease[b]	Mitral valve prolapse	Drug intoxication
Viral arthropathy[c]	Congenital heart disease	Wilson's disease
Reactive arthropathy[c]	Infective endocarditis	Tic disorder[d]
Lyme disease[e]	Hypertrophic cardiomyopathy	Choreoathetoid cerebral palsy
Sickle cell anemia	Myocarditis: viral or idiopathic	Encephalitis
Infective endocarditis	Pericarditis: viral or idiopathic	Familial chorea (including Huntington's)
Leukemia or lymphoma		Intracranial tumor
Gout and pseudogout		Lyme disease[e]
		Hormonal[f]

[a]Gonorrhea should be actively sought in all sexually active cases. Tests for gonorrhea include polymerase chain reaction (*PCR*) of joint aspirate, endocervical PCR (gonococcal and chlamydia) and microscopy, culture and sensitivity, or urine/self-collected vaginal swabs in cases where endocervical PCR is not possible
[b]Includes rheumatoid arthritis, juvenile chronic arthritis, inflammatory bowel disease, systemic lupus erythematosus, systemic vasculitis, and sarcoidosis
[c]*Mycoplasma*, cytomegalovirus, Epstein–Barr virus, parvovirus, hepatitis, rubella vaccination, *Yersinia* spp., and other gastrointestinal pathogens
[d]Possibly including *PANDAS* (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection)
[e]Lyme disease has not been confirmed in Australia or New Zealand
[f]Includes oral contraceptives, pregnancy (chorea gravidarum), hyperthyroidism, hypoparathyroidism (Source: Reproduced with permission from Carapetis J, McDonald M, Wilson N [87] Acute rheumatic fever. Lancet 366:155–68)

streptococcal infection. If the first one is within normal range, then repeat titers are required 10–14 days later.

The differential diagnoses for ARF are listed in Table 129.4. Based on the clinical manifestation of ARF, additional target investigations may be necessary and may include the following: repeated blood cultures for suspected endocarditis; joint aspirates (microscopy and culture) for suspected septic arthritis; serology and autoimmune markers for undifferentiated arthritis; and copper, ceruloplasmin, antinuclear antibodies, and drug screen for choreiform movements.

Management of Acute Rheumatic Fever

Acute Management

Acute management of ARF is supportive as no treatment to date has been demonstrated to impact on the likelihood of development, persistence, or progression of carditis. The management principles are summarized in Table 129.5.

Eradication of Streptococcus

Eradication of streptococcus is recommended at time of diagnosis of ARF. A single dose of intramuscular penicillin or alternatively a 10-day course of oral penicillin or erythromycin is sufficient (Table 129.5). If an intramuscular dose is given, then it can be viewed as the first dose of secondary prophylaxis (Table 129.5); see section below.

Bed Rest

In the pre-penicillin era, prolonged bed rest in sanitoria was associated with shorter duration of carditis, fewer relapses, and less cardiomegaly [52]. Today, restricted activity and bed or chair rest is only recommended for those with moderate to severe rheumatic carditis or symptomatic arthritis. In this setting ambulation should be gradual and as tolerated until the serum CRP and ESR levels normalize or dramatically reduce.

Aspirin

Aspirin and potentially other nonsteroidal anti-inflammatory agents provide rapid symptomatic relief of arthralgia and arthritis. However, anti-inflammatory agents should not be introduced too

Table 129.5 Management principles of ARF

General management	
Whenever possible admit to hospital to allow for appropriate investigation, speedy diagnosis and patient education.	
Secondary prophylaxis (and treatment for episode of ARF)	
Benzathine penicillin G IM (gold standard)	– 900 mg (1,200,000 U) ≥20 kg (every 28 days)
	– 450 mg (600,000 U) <20 kg (every 28 days)
Penicillin V PO (second line)	– 250 mg twice daily, children
	– 500 mg twice daily, adolescents and adults (10-day course for treatment of streptococcal infection)
Erythromycin PO (only if allergic to penicillin)	– 20 mg/kg twice daily, children
	– 500 mg twice daily, adolescents and adults (10-day course for treatment of streptococcal infection)
Arthritis	
Paracetamol or codeine until diagnosis confirmed as anti-inflammatory medications can mask the full manifestation	
Aspirin (first line)	Children: 50–60 mg/kg/day given in 4 divided doses (increasing to 80–100 mg/kg/day if needed)
	Adults: 4–8 g given in 4 divided doses
Naproxen (alternative first line)	Children: 10–20 mg/kg/day given in 2 divided doses
	Adults: 1,000 mg in given in 2 divided doses
Chorea	
Usually self limiting and in most cases no treatment required	
If medication initiated therapy should continue 2–4 weeks following the cessation of chorea	
Carbamazepine (first choice)	6–20 mg/kg/day in 3 divided doses (max 1,500 mg/day)
Valproic acid (teratogenic effects)	15–20 mg/kg/day in 3 divided doses (max 2,000 mg/day)
Carditis/cardiac failure	
Bed or chair rest only if moderate to severe carditis	
Symptomatic management of heart failure –fluid restriction, diuretics, vasodilators,and inotropic and intensive care support as required	
Valve surgery for intractable heart failure	

early in patients with arthralgia or monoarthritis as it might mask the development of polyarthritis and may cloud the diagnosis of ARF. In such cases, if required, paracetamol or codeine may be used as analgesics.

Aspirin has been demonstrated to allow rapid normalization of fever and inflammatory markers (ESR and CRP) and resolution of heart block [53]. However, to date it has not been demonstrated to alter the evolution or resolution of valvulitis [53–55]. Over 40 years ago, a number of small randomized trials compared aspirin to no treatment. There was an overwhelming belief at that time that aspirin had a beneficial effect. As a result crossover from no treatment to treatment was frequent. Without an intention-to-treat analysis, and with uncorrected baseline differences and subjective end points (presence or absence of cardiac murmur), it is difficult to draw any meaningful conclusions from those studies [53–56]. As a result, today the use of aspirin for valvulitis remains nonevidence based [56]. Nevertheless, pediatric cardiologists around the world continue to use aspirin (and in many cases glucocorticoids – see below) in the setting of mild, moderate, and severe carditis [21, 57]. These treatments must be carefully weighed against the potential side effects (salicylate toxicity and gastrointestinal irritation). It is recommended that the starting dose be 50–60 mg/kg/day in divided doses, increasing if necessary to control symptoms to a maximum of 80–100 mg/kg/day. If high doses are used, serum salicylate levels (taken 6 h post dose) should not exceed the target range of 20–30 mg/100 dL to avoid toxicity. Duration of therapy should be based upon the clinical response and normalization of acute-phase reactants [21]. It is not

uncommon for relapses of joint symptoms to occur during or after weaning of anti-inflammatories, in which case the medication can be restarted or the dose increased for 1–2 weeks further, before attempting weaning again. Experience has grown with alternative anti-inflammatories, particularly naproxen and ibuprofen, and these are considered acceptable alternatives to aspirin [58]. Naproxen has the added advantage of being better tolerated in children and requiring only twice-daily dosing [58].

Glucocorticoids

In the setting of rheumatic valvulitis, use of glucocorticoids remains controversial and not evidence based. Two meta-analyses have failed to demonstrate a benefit of glucocorticoids compared to placebo or to salicylates in improving the short- or longer-term outcomes of valvulitis [56, 59]. All studies were performed over 40 years ago in the pre-echocardiographic era and the medications studied are no longer in common usage today. Despite the lack of evidence, many clinicians treat cases of severe carditis (causing heart failure) with glucocorticoids in the belief that they may reduce the acute inflammation and avoid the need for valve surgery at least in the short term. Potential benefits of this treatment should be carefully balanced against the possible adverse effects, including weight gain, gastrointestinal bleeding, fluid retention, and susceptibility to infections. If used, prednisone or prednisolone is recommended at doses of 1–2 mg/kg per day (maximum, 80 mg). Glucocorticoids often are required only in the short term for approximately 2–3 weeks then the dosage can be tapered by 25 % per week. While reducing the steroid dosage, a period of overlap with aspirin could be considered to prevent a rebound of disease activity [21].

Diuretics and Vasodilator

The majority of patients with heart failure due to severe valvular regurgitation can be successfully medically managed using supportive measures, fluid restriction, diuretics, vasodilators, and when required inotropic support.

Cardiac Surgery

In the majority of cases, cardiac surgery can be safely deferred until active inflammation has subsided [38], but occasionally a life-saving emergency operation is needed [60, 61]. When cardiac tissues are inflamed and friable, repair can be technically difficult, and reports suggest a high requirement for late reoperations even in highly experienced hands [61]. The alternative surgical option is mechanical valve replacement [60].

Antiepileptics

The majority of cases of chorea are self-limiting and do not require treatment. If medication is required, carbamazepine or sodium valproate can be used as first line agents (Table 129.5) [62]. Neuroleptics (haloperidol) or benzodiazepines may also be used; however, they have sedative side effects.

Long-Term Management of ARF

Secondary Prophylaxis

The fundamental principle of long-term management of patients with ARF is to prevent a recurrence of ARF and hence worsening of heart disease. Secondary prophylaxis in the form of 4-weekly intramuscular benzathine penicillin G injections has been demonstrated to be cost-effective at preventing recurrences. Secondary prophylaxis is best delivered as part of a register-based control program [21]. Long-acting intramuscular penicillin is superior to oral penicillin and remains the treatment of choice [63]. Recurrence rates using 3-weekly injections are lower than less frequent injections; however, this regimen is often difficult to administer in endemic settings. Moreover, recurrence rates on regimens of 4-weekly injections are low [64], so it seems most prudent to recommend 3-weekly injections only for patients who have breakthrough recurrences on 4-weekly dosing. Patients with proven penicillin allergy should be prescribed erythromycin. Patients with RHD require long-term secondary

Table 129.6 Suggested duration of secondary prophylaxis by the WHO [21]

Category of patient	Duration of prophylaxis
Patient without proven carditis	For 5 years after the last attack or until 18 years of age (whichever is longer)
Patient with carditis (mild mitral regurgitation or healed carditis)	For 10 years after the last attack or at least until 25
More severe valvular disease	Lifelong
After valve surgery	Lifelong

prophylaxis even if they had undergone cardiac surgery. The recommended treatment duration and drug doses are summarized in Table 129.6.

Sore Throat Management

Individuals with ARF are at an extremely high risk of a further episode. To further minimize the risk of a recurrence, patients should be encouraged to seek prompt medical care in an event of a sore throat. Based on the structure of health-care facilities, it may be appropriate to treat all patients with a past history of ARF/RHD with a 10-day course of oral or a single dose of intramuscular penicillin (dosage as per streptococcal eradication protocol in Table 129.5). Alternatively if facilities allow, then await throat culture results prior to the commencement of treatment. It is well established that treatment within 9 days of onset of pharyngitis markedly decreases the risk of developing ARF [65].

Prevention of Infective Endocarditis

Patients with RHD are at an increased risk of bacterial endocarditis. This risk may be reduced by exercising meticulous skin and dental hygiene. The American Heart Association no longer recommends antibiotic prophylaxis for bacterial endocarditis prior to dental and surgical procedures that are likely to result in significant bacteremia in patients with RHD [66]. However, data from Australia confirm that RHD is an important risk factor for endocarditis in both indigenous and nonindigenous patients [67], so Australian recommendations continue to support prophylaxis in RHD patients. The procedures that require endocarditis prophylaxis and the recommended antibiotics and their dosages are detailed in Section 18.

Chronic Rheumatic Heart Disease

The majority of patients with mild to moderate carditis at first presentation and who are highly compliant with secondary prophylaxis will have no detectable disease within 5–10 years [36, 37]. Those with moderate to severe valvulitis at first presentation and those who experience ARF recurrences will frequently progress to chronic rheumatic heart disease and suffer its complications.

Mitral Regurgitation

Mitral regurgitation (MR), in isolation or in combination with the aortic regurgitation (AR), is the most common manifestation of RHD in children. Acutely, it is the result of annular dilation, chordal elongation or in extreme cases chordal rupture. The primary chords that attach to the leaflet tips elongate and allow the free edges of the leaflet to approach or to override the plane of the annulus and result in abnormal coaptation and valvular regurgitation. It can affect either the anterior or the posterior mitral valve leaflet or both. With time, scarring and fibrosis of the leaflet apparatus results in restricted movement of the leaflets (Fig. 129.3, Videos 129.5 and 129.6). As the disease progresses, the leaflets thicken, harden and calcify, and take on a rigid and immobile appearance and may gradually progress to valvular stenosis.

Clinically mitral regurgitation is characterized by a pansystolic murmur that is loudest at the apex and radiates to the axilla. Markers of severe disease include increased precordial activity, displacement of the apical impulse, and the presence of a mid-diastolic flow murmur (Carey Coombs murmur). Congestive cardiac failure and pulmonary edema are signs of advanced decompensated disease.

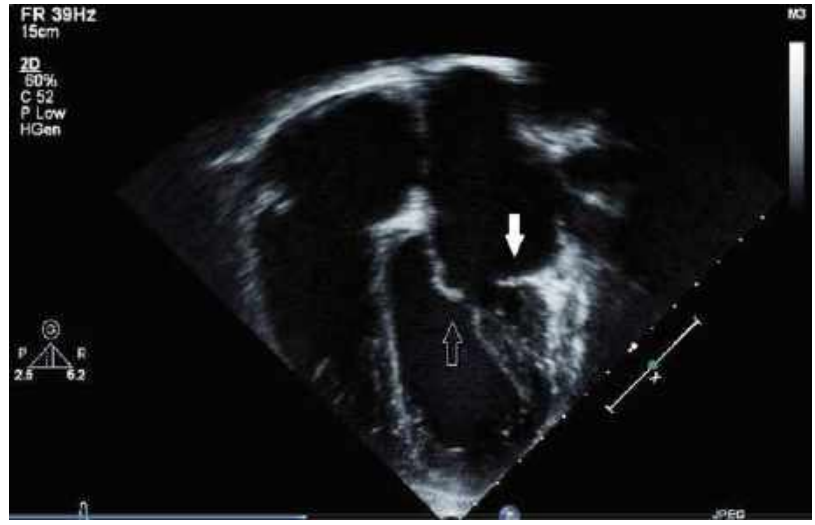


Fig. 129.3 Echocardiographic images depict morphologic changes of the mitral valve apparatus that are characteristic of rheumatic heart disease. The anterior mitral valve leaflet is thickened; the chordae are shortened resulting in restriction of the leaflet (*black arrow*). The posterior valve leaflet is rigid and immobile (*white arrow*)

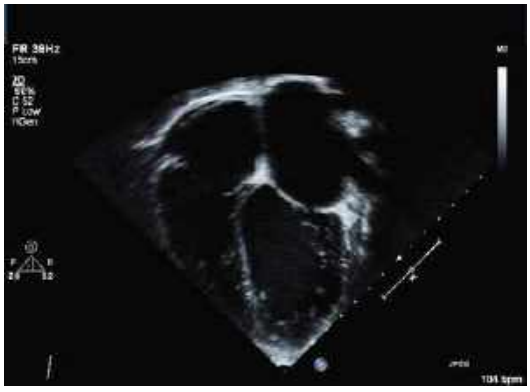
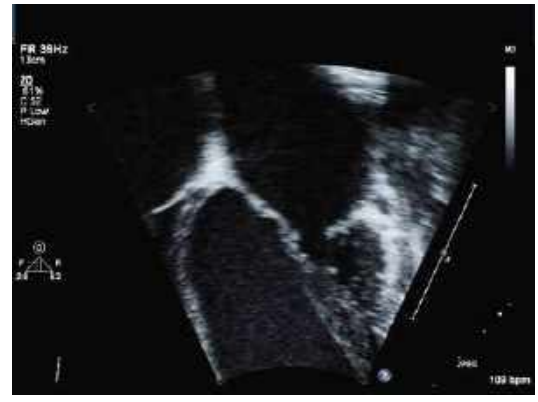


Video 129.5 Echocardiographic images depict morphologic changes of the mitral valve apparatus that are characteristic of rheumatic heart disease. The anterior mitral valve leaflet is thickened; the chordae are shortened resulting in restriction of the leaflet (*black arrow*). The posterior valve leaflet is rigid and immobile (*white arrow*)



Video 129.6 Echocardiographic images depict morphologic changes of the mitral valve apparatus that are characteristic of rheumatic heart disease. The anterior mitral valve leaflet is thickened; the chordae are shortened resulting in restriction of the leaflet (*black arrow*). The posterior valve leaflet is rigid and immobile (*white arrow*)

Children and adolescents with mild to moderate MR are generally asymptomatic. Even those with severe chronic compensated MR frequently remain in New York Heart Association (NYHA) class I. On careful questioning, however, many will reveal subtle symptoms such as an inability to keep up with peers. As the disease progresses reduced exercise tolerance, dyspnea, and congestive cardiac failure may ensue.

Aortic Regurgitation

Rheumatic aortic regurgitation (AR) most commonly coexists with mitral regurgitation; however, in 5 % of patients, aortic valve disease may be isolated [68]. The early disease process is characterized by leaflet prolapse resulting in a loss of the height of the cusp tissue and commissures [69]. With time the leaflets thicken and retract and the leaflet edges roll, giving rise to

Fig. 129.4 Echocardiographic images depict severe chronic rheumatic heart disease in a 5-year-old boy who experienced recurrent episodes of acute rheumatic fever. Images depict mild aortic regurgitation and mixed mitral valve disease – severe mitral regurgitation and severe mitral stenosis. (**a**) Parasternal long-axis view. (**b**) Apical two-chamber view

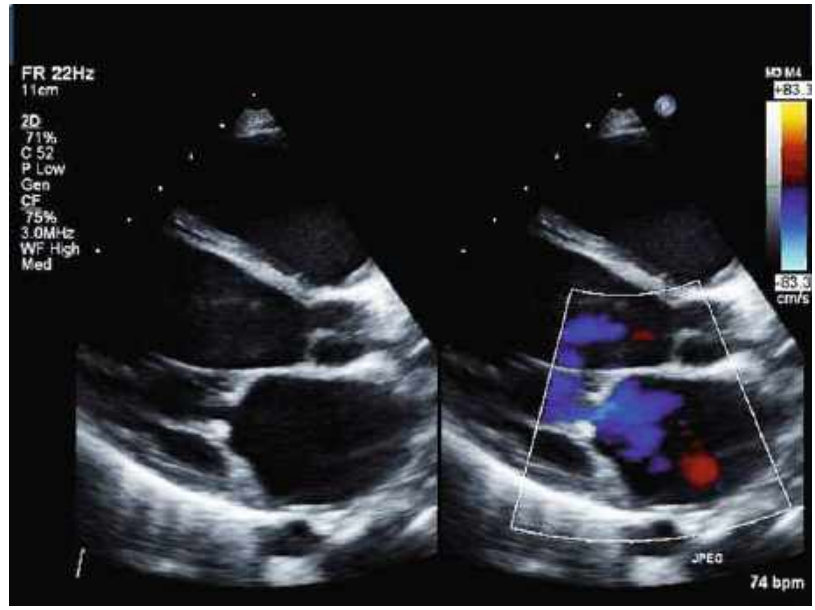
central coaptation defect. Leaflet thickening, commissural fusion, and later calcification all restrict the mobility of leaflets and may eventually lead to stenosis of the valve.

AR is characterized by a high-pitched, decrescendo murmur that is best heard at the left sternal border with the patient leaning forward in full expiration. Signs of clinically significant AR include the following: increased precordial activity, displaced apex beat, wide pulse pressure (elevated systolic and low diastolic pressure), and bounding or water hammer pulse. Signs of very advanced disease include head nodding with the time of the heart beat, pistol shot sound over the femoral artery, and pulsatility of the capillary nail beds and uvula.

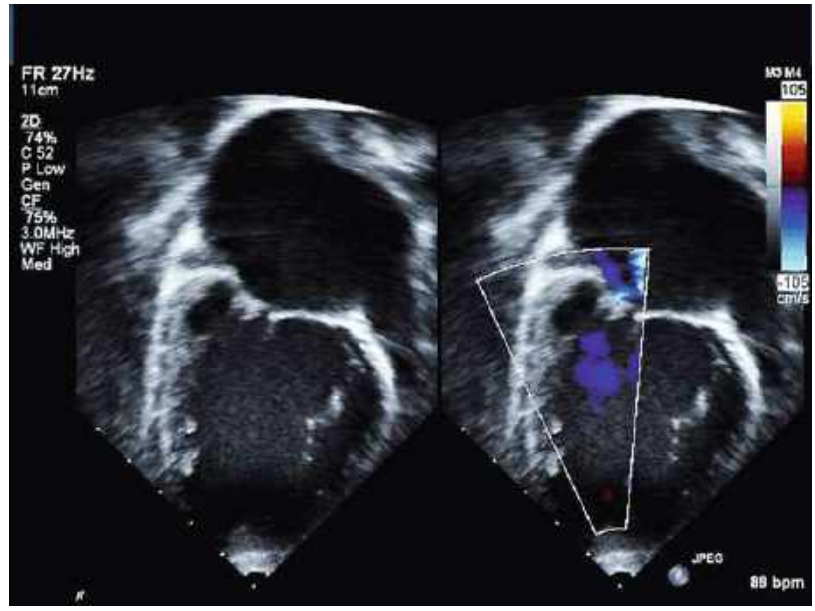
Severe chronic aortic valve regurgitation is generally well tolerated by most children. Gradual impairment of exercise tolerance and dyspnea on excretion and later at rest may develop.

Mitral Stenosis

RHD is responsible for over 95 % of mitral stenoses (MS) worldwide [70], and it is 2 to 3 times more common in women than men. In most instances patients with mitral regurgitation, over the course of decades, progress to mixed then pure mitral stenosis (MS) (Fig. 129.4, Videos 129.7 and 129.8) [41, 71]. In some regions of the world where ARF remains



Video 129.7 Echocardiographic images depict severe chronic rheumatic heart disease in a 5-year-old boy who experienced recurrent episodes of acute rheumatic fever. Images depict mild aortic regurgitation and mixed mitral valve disease – severe mitral regurgitation and severe mitral stenosis. Parasternal long-axis view



Video 129.8 Echocardiographic images depict severe chronic rheumatic heart disease in a 5-year-old boy who experienced recurrent episodes of acute rheumatic fever. Images depict mild aortic regurgitation and mixed mitral valve disease – severe mitral regurgitation and severe mitral stenosis. Apical two-chamber view

hyperendemic, this progression has been demonstrated to be more rapid, and severe MS can develop in children as young as 5–10 years of age. This very aggressive form of MS is often referred to as "juvenile" or "malignant mitral stenosis" [72]. However, not all individuals start with evidence of clinical mitral regurgitation. Studies from the pre-penicillin era demonstrated that patients without any evidence of carditis (no clinical murmur) during the first episode of ARF progressed to MS even in the absence of a recurrence of ARF [71]. This suggests that the first episode of carditis may sometimes be subclinical, and without penicillin, a slow and gradual progression of disease can allow the development of MS [71].

Rheumatic MS is the result of gradual fusion, thickening, shortening, and calcification of the chords, commissures, and the leaflets. This fibrotic process eventually interferes with the function of the valvular apparatus and results in MS.

On auscultation, the murmur of mitral stenosis is a low-pitched, diastolic rumble heard best at the apex, with the patient in the left lateral position. The duration of the murmur correlates with the severity of the lesion. The diastolic rumble may be preceded by an opening snap. A loud second heart sound and a right ventricular heave are indicative of severe MS with pulmonary hypertension.

Mild to moderate MS is very well tolerated in children. Many patients, however, present with advanced symptomatic disease or complications of RHD (infective endocarditis, pulmonary hypertension, or congestive cardiac failure), often without a clear history of ARF.

Aortic Stenosis

Predominant aortic stenosis (AS) is rare in children and adolescents with RHD. More commonly aortic lesions are mixed (stenotic and regurgitant). Over the course of decades, regurgitant aortic valve leaflets thicken, fibrose, and calcify and commissures fuse, resulting in stenosis of the valve.

Clinically it is characterized by an ejection systolic murmur best heard at the right upper sternal edge radiating to the neck. It is considered to be clinically significant when associated with a narrow pulse pressure, palpable suprasternal, or right parasternal thrill and/or left parasternal heave.

AS is generally well tolerated in young people. Symptoms such as angina, syncope, dyspnea on exertion, and heart failure are indicative of severe or critical AS.

Tricuspid Valve

Tricuspid regurgitation in the setting of RHD is often functional and is the result of advanced left-sided pathology and pulmonary hypertension. Organic tricuspid valve disease that results from direct rheumatic inflammation is less common and almost always coexists with mitral and/or aortic valve involvement [73]. Like the mitral regurgitation, tricuspid valve regurgitation can also progress to stenosis.

The pansystolic murmur of TR is loudest at the left lower sternal border. When severe it may be associated with an enlarged, often pulsatile liver and a raised jugular venous pressure. Symptoms however are generally related to associated mitral and aortic valve disease.

Pulmonary Valve Involvement

Pulmonary valve involvement is extremely rare but has been reported in very severe cases of RHD when all four valves were affected [68]. Like with tricuspid valve disease, the mechanism is likely to be functional rather than the result of direct rheumatic involvement.

Investigations

Echocardiography in RHD

In patients with a past history of ARF and known RHD, serial echocardiography is very useful in assessing disease progression. The severity of regurgitation and stenosis can be evaluated and graded using standard methods [74, 75]. Each cardiac valve should be carefully assessed. Left ventricular dimension and function should be measured and tracked with time as indications for surgery often rely on these measurements [76]. It is important to note that in the setting of significant mitral and/or aortic regurgitation, fractional shortening or ejection fraction are poor surrogates for cardiac contractility due to altered loading conditions and may underestimate cardiac impairment. Load-independent measures, such as stress velocity index, correlate more closely with the state of cardiac contractility in these circumstances [77].

Echocardiographic evaluation of the morphology of the valvular apparatus is of great

Table 129.7 Grading of mitral valve characteristics form the echocardiographic examination

Grade	Mobility	Subvalvular thickening	Leaflet thickening	Calcification
1	Highly mobile valve with only leaflet tips restricted	Minimal thickening just below the mitral valve leaflets	Leaflets near normal in thickness (4–5 mm)	A single area of increased echo brightness
2	Leaflet mid and based portions have normal mobility	Thickening of chordal structures extending up to one third of the chordal length	Mid-leaflets normal, considerable thickening of margins (5–8 mm)	Scattered areas of brightness confined to the leaflet margins
3	Valve continues to move forward in diastole, mainly from the base	Thickening extending to the distal third of the chords	Thickening extending through the entire leaflet (5–8 mm)	Brightness extending into the mid-portion of the leaflets
4	No or minimal forward movement of the leaflets in diastole	Extensive thickening and shortening of all chordal structures extending down to the papillary muscles	Considerable thickening of all leaflet tissue (>8–10 mm)	Extensive brightness throughout much of the leaflet tissue

Source: Reproduced with permission from Wilkins G, Weyman A, Abascal V, et al. [78] Percutaneous balloon dilatation of the mitral valve: an analysis of echocardiographic variables related to outcome and the mechanism of dilatation. Brit. Heart J. 60:299–308

importance as it can affect the nature and timing of cardiac intervention. The Wilkins score gives a guide to the suitability of the mitral valve's morphology for percutaneous balloon mitral valvotomy. It is based on the degree of (1) valve calcification, (2) leaflet mobility, (3) leaflet thickening, and (4) disease of the subvalvular apparatus (Table 129.7) [78]. Patients with a score of <9 and only mild mitral regurgitation have the best outcomes and hence patients with high scores should generally be referred for cardiac surgery [78]. Accurate morphological assessment of a regurgitant valve also helps to guide the nature and timing of cardiac surgery as those with favorable anatomy for repair may benefit from early surgical intervention.

Echocardiography can be useful in determining the etiology of valvular pathology. The World Heart Federation recently developed an evidence-based guideline for echocardiographic diagnosis of RHD in patients without a prior history of ARF to facilitate decision making, rapid case identification, and enrolment onto secondary prophylaxis programs [79].

Electrocardiography

In those with established RHD, serial electrocardiography is recommended to detect arrhythmias or document the cardiac rhythm. An electrocardiogram may also demonstrate atrial or ventricular enlargement or right ventricular hypertrophy due to pulmonary hypertension.

Exercise Testing

Exercise testing in the setting of RHD is reserved for those patients with equivocal symptoms.

Chest X-Ray

A chest X-ray in cases of advanced disease may demonstrate an enlarged cardiac silhouette, pulmonary venous congestion, or interstitial edema.

Management of Chronic RHD

Medical Management of Chronic Valve Disease

Patients with asymptomatic chronic RHD generally do not benefit from cardiac medications such as ACE inhibitors, diuretics, or vasodilators [76]. This is regardless of the severity of disease, providing they are in a well-compensated asymptomatic state. One exception is severe asymptomatic AR, where there is some evidence to suggest that ACE inhibitors can help maintain the compensated phase of chronic severe AR and therefore delay the need for surgical intervention [80].

In patients with symptomatic valvular disease, cardiac medications (ACE inhibitors, vasodilators, diuretics) have only a temporizing role to optimize hemodynamic profile prior to surgery. In this setting, there may be a requirement to combine medications with bed rest, fluid restriction, and inotropic and/or intensive care support.

Patients with MS and MR are prone to developing atrial fibrillation; however, it is relatively rare in children.

Surgical Management

Indications for cardiac surgery in children are derived from adult data, as there is a paucity of pediatric studies that help to guide surgical decision making. Recommendations are summarized in Table 129.8. Any child with symptomatic valvular heart disease should be referred for cardiac surgery. In addition, asymptomatic children with abnormal cardiac function, pulmonary hypertension (right ventricular systolic pressure >50 mmHg), atrial fibrillation, or with a dilated left ventricle should also be considered for cardiac surgery. Despite technological advancements, basic m-mode measurements are still used to help guide surgical decision making in asymptomatic patients with severe valvular disease. In adolescents and adults, an LVESD >40 mm with severe MR and LVEDD >70 mm with severe AR have been identified as cutoff values when cardiac surgery is recommended [76]. For younger children such cutoff values have not been defined; however, evidence of left ventricular dilation should be based on Z-scores (measurements indexed to body surface area and expressed as standard deviates). Asymptomatic patients with severe MS and who have suitable valvular morphology should be considered for percutaneous balloon valvotomy. Those who are not suitable for a percutaneous procedure should only be consider for cardiac surgery if symptomatic or if significant pulmonary hypertension exists (right ventricular systolic pressure >50 mmHg) [76]. Tricuspid valve disease alone is rarely, if ever, an indication for surgery in the setting of RHD. However, tricuspid valve repair may be required when aortic and/or mitral valve surgery is performed. RHD commonly manifests as mixed valve or multivalve disease. However, currently there are insufficient data available to make any specific recommendations in those settings. Generally clinical symptoms and the nature of the predominant lesion should dictate timing of cardiac intervention; however, consideration should be given to an earlier intervention.

Comparative studies have demonstrated that mitral valve repair is superior to mechanical valve replacement in adult patients. Repair is associated

Table 129.8 Indication for surgical or percutaneous intervention

Valve lesion	Indication for surgery
Severe mitral regurgitation	• NYHA class II–IV symptoms
	• Marked ventricular enlargement
	• Enlarged LVESD Z-score
	• Absolute LVESD >40 mm
	• Ventricular dysfunction – EF <60 %
	• Pulmonary hypertension – >50 mmHg
	• Consider early repair in those with favorable anatomy and high likelihood of successful repair
Severe mitral stenosis	If anatomy suitable and associated regurgitation is less than moderate, then percutaneous balloon mitral valvotomy is indicated when:
	• NYHA class II–IV symptoms
	• Pulmonary hypertension >50 mmHg
	• MVA <1.5 cm^2 or a valve area index <0.6 cm^2
	Indication for surgically valvotomy are:
	• NYHA class II–IV symptoms
	• Pulmonary hypertension RV systolic pressure >50 mmHg
Severe aortic regurgitation	• NYHA class II–IV symptoms
	• Marked ventricular enlargement
	• Enlarged LVEDD Z-score
	• Absolute LVEDD >40 mm
	• Ventricular dysfunction – EF <55 %
Severe aortic stenosis	• NYHA class II–IV symptoms
	• Ventricular dysfunction – EF <55 %

with improved survival, better preservation of cardiac function, and lower thrombotic, embolic, and hemorrhagic event rates [81]. However, questions have been raised over the durability of repair in young rheumatic patients [82, 83]. Despite this, whenever technically possible, mitral valves should be repaired in children as it avoids the need for anticoagulation, and its related complications are appallingly high in regions where RHD is most prevalent [84]. Individuals with RHD frequently reside in settings that are characterized by poverty, overcrowded housing, high rates of infectious diseases, poor access to medical care, low levels of literacy, and often poor adherence to long-term treatment regimens such as anticoagulation monitoring. Complications include infective endocarditis and embolic and hemorrhagic events (particularly cerebrovascular events or stroke), all of which are often fatal or cause significant and permanent disability. However, if repair is not possible, then a mechanical valve replacement is the next choice. In children and adolescents, bioprosthetic valve replacement in the mitral position should be avoided whenever possible as it is associated with a high valve failure rate [85].

Data from centers that excel in RHD surgery suggest that durable aortic valve repairs are also feasible in young rheumatic patients [69]. However, the international pool of surgeons who can perform satisfactory aortic valve repair remains limited. Alternatives to aortic valve repair are mechanical valve replacement, bioprosthetic valve replacement, or Ross procedure (pulmonary autograft for the aortic valve with homograft replacement of pulmonary valve). Durability of bioprosthetic valves in the aortic position is also limited [86]. In addition redo operations are often technically demanding following homograft and autograft placement. When required, tricuspid valves can generally be repaired.

Kawasaki's Disease

130

Shinichi Takatsuki, Marsha S. Anderson, and Tsutomu Saji

Abstract

Kawasaki disease was first described in 1967 by Tomisaku Kawasaki and is now recognized as the leading cause of acquired heart disease among children. Kawasaki disease is an acute febrile illness affecting primarily infants and young children and rarely teenagers. Although the disease is self-limited, coronary artery abnormalities have been reported in approximately 20–25 % of untreated patients. The diagnostic criteria include a history of 5 or more days of fever and at least four of five principal clinical features. Although the etiology remains unknown, standard therapy consists of high dose, single infusion of intravenous immunoglobulin and oral acetylsalicylic acid. This regimen was studied in patients presenting in the first 10 days of illness and was found to reduce the risk of coronary abnormalities to 5 %. Approximately 10–15 % of IVIG-treated patients are initial IVIG nonresponders and are at increased risk of developing coronary artery abnormalities. In patients who develop coronary aneurysms, approximately 50 % of the lesions may remodel within 1–2 years after the illness. Patients with giant aneurysms are at the greatest risk to develop secondary thrombotic occlusion. Long-term follow-up studies in Kawasaki disease patients are still ongoing. However, studies have shown prolonged endothelial dysfunction even in children without any evidence of coronary abnormalities. Therefore, until further data become available, many experts recommend long-term cardiology follow-up even in patients without a history of coronary involvement.

Introduction

In 1961, Dr. Tomisaku Kawasaki saw a 4-year-old boy with a 7-day history of high fevers, cracked lips, conjunctival injection, rash, erythema and edema of the palms and soles, and a swollen cervical lymph node. In 1967, he described 50 children with these clinical features in a Japanese journal (published in English in 1974) and referred to the disease process as mucocutaneous lymph node syndrome [1, 2]. Currently, Kawasaki disease is recognized worldwide and described in children of all races and ethnicities.

The association of Kawasaki disease with cardiac complications was first described in 1968 in Japan [3]. Although Kawasaki disease is a self-limited vasculitis of medium-sized arteries, the hallmark of this disease is the coronary artery abnormalities that develop in approximately 20–25 % of untreated patients [4–6]. In developed countries, Kawasaki disease has surpassed acute rheumatic fever as the most common cause of acquired heart disease among children [7]. In addition, Kawasaki disease is now reported as a potential risk factor for adult ischemic heart disease and sudden death in early adulthood [8]. Despite over 40 years of Kawasaki disease research, there is no specific diagnostic test for Kawasaki disease, and the diagnosis remains a clinical one.

Epidemiology

Kawasaki disease is most common in young children aged 6 months to 5 years, with a peak incidence in children at 1 year of age. It is less common in children less than 6 months of age and adolescents, but there is an increased risk of coronary artery abnormalities in children with Kawasaki disease in both of these age groups. Some adult cases have been reported, but these are extremely rare [9, 10]. Overall, 80 % of Kawasaki disease cases occur before 5 years of age.

Kawasaki disease is overrepresented among Asian populations, especially among Japanese. Children of Asian heritage, who were born in the United States, also have the same elevated risk. The highest incidence is reported among Japanese children and is estimated at 184 per 100,000 children less than 5 years of age [11]. In the United States, the incidence for African American, Hispanic, and Caucasian children is 16.9, 11.1, and 9.1 per 100,000, respectively, whereas the incidence among American-Indian and Alaskan native children is only 4.3 per 100,000 children [12].

Kawasaki disease is more common in boys, who are affected 1.5 times more often than girls. The recurrence rate has been reported to be approximately 3 % in Japan [13]. Although there is no evidence for person-to person transmission, there may be a genetic predisposition to developing Kawasaki disease. Japanese children, whose parents had Kawasaki disease, have an increased risk of developing the disease, are more likely to have a severe course, are more likely to have a recurrence, and have a higher incidence of coronary artery aneurysms [14]. Siblings of patients have a tenfold greater risk of acquiring Kawasaki disease than children in the general population [15]. In the case of twins, when one twin has Kawasaki disease, the risk of the other twin acquiring Kawasaki disease is 13 % [16]. Kawasaki disease is seen year around, but distinct seasonal variation has been reported with peak occurrence in the spring and winter months in Japan [17].

Etiology

The etiology of Kawasaki disease remains unknown. Many agents have been investigated as potential causes of Kawasaki disease and etiologies proposed include an infectious trigger, host immune response, and genetic predisposition.

Infectious Agents

Several clinical and epidemiologic observations suggest that Kawasaki disease is triggered by

an unknown infectious agent, for the following reasons. First, the winter/spring seasonality peak seems to imply a recurring infectious vector. Second, epidemic outbreaks of Kawasaki disease with geographic clustering have been reported in Japan and the United States [18, 19]. In Japan, outbreaks are described starting in one geographic area and then spreading throughout the country. Third, Kawasaki disease has a peak incidence in children younger than 5 years of age, with fewer cases seen in children less than 3 months of age, suggesting protective transplacental antibodies. Although epidemiologically Kawasaki disease seems to behave as an infectious disease, conventional bacterial and viral cultures and serologic investigations have failed to identify an etiologic agent. Historically, many infectious agents have been studied in children with Kawasaki disease including *Yersinia pseudotuberculosis*, *Rickettsiae*, *Leptospira*, *Chlamydia*, *Adenovirus, Measles virus, Parvovirus B 19, Epstein-Barr virus*, *Cytomegalovirus*, *Retroviruses*, *NL63 (New Haven Coronavirus)*, and *Mycoplasma pneumoniae*, but none have been confirmed as an etiologic agent.

Host Immune Response: Superantigens

A possible superantigen etiology has also been proposed based on some clinical and immunologic similarities of Kawasaki disease to staphylococcal toxic shock syndrome and streptococcal toxic shock syndrome. Superantigen production has been associated with both toxic shock syndromes and, like Kawasaki disease, both have clinical manifestations that include fever, conjunctival injection, oral mucosal changes, extremity changes, rash, and subsequent desquamation of the hands and feet. Immunologic evidence of a superantigen etiology includes reports of T-cell receptor V-beta skewing in Kawasaki patients [20–22]. However, other studies have not detected V-beta skewing, so this remains controversial [23, 24]. A few studies have isolated superantigen-producing *Staphylococcus aureus* from Kawasaki disease patients [25, 26]. However, these findings have not been confirmed by others [27, 28], and a prospective multicenter study with Kawasaki patients and controls showed no significant differences in isolation rates of superantigen-producing *S. aureus* in the Kawasaki patients as compared to controls [29]. Therefore, there is ongoing controversy regarding the superantigen theory as the etiology of Kawasaki disease.

Genetics

The increased incidence of Kawasaki disease among Asians raises the possibility of a genetic predisposition to Kawasaki disease [30]. A genetic influence is suspected that increases likelihood of acquiring Kawasaki disease. In addition, genetic polymorphism may increase the tendency to develop coronary artery abnormalities. Previous study has shown that certain genetic polymorphisms including CD40 ligand gene and inositol-trisphosphate 3-kinase C are associated with an increased susceptibility to Kawasaki disease and to development of coronary artery abnormalities [31, 32].

Diagnosis

There is no specific diagnostic test for Kawasaki disease; therefore, the diagnosis of classic Kawasaki disease is based on clinical criteria. Other symptoms, clinical signs, and/or laboratory findings are sometimes helpful in making the diagnosis (Table 130.1) [33]. Early diagnosis and treatment is essential, as late diagnosis of Kawasaki disease (after the tenth day of the illness) has been associated with increased risk of coronary artery aneurysm formation [34, 35]. The differential diagnosis of Kawasaki disease includes measles, rubella, scarlet fever, toxin-mediated staphylococcal diseases, staphylococcal scalded skin syndrome, Stevens Johnson syndrome, juvenile rheumatoid arthritis, leptospirosis, rickettsioses, Rocky Mountain spotted fever, and viral exanthems.

Table 130.1 Clinical and laboratory features of Kawasaki disease (Modified from guideline in American Heart Association and American Academy of Pediatrics)

Classic clinical criteria	
Fever	Persisting fever at least 5 days (in presence of ≥4 principal criteria, diagnosis can be made on day 4 of illness) Presence of at least following four principal features
Changes in extremities	Acute: Erythema of palms, soles; edema of hands, feet Subacute: Periungual peeling of fingers, toes in weeks 2 and 3
Polymorphous exanthem	
Bilateral bulbar conjunctival injection without exudate	
Changes in lips and oral cavity	Erythema, lips cracking, strawberry tongue, diffuse injection of oral and pharyngeal mucosae
Cervical lymphadenopathy	>1.5 cm diameter, usually unilateral Patients with fever at least 5 days and <4 principal criteria can be diagnosed with Kawasaki disease when coronary artery abnormalities are detected by echocardiography or angiography
Other clinical and laboratory findings	
Cardiovascular findings	Congestive heart failure, myocarditis, pericarditis, valvular regurgitation Coronary artery abnormalities Aneurysms of medium-sized noncoronary arteries Raynaud's phenomenon Peripheral gangrene
Musculoskeletal system	Arthritis, arthralgia
Gastrointestinal tract	Diarrhea, vomiting, abdominal pain
Hepatic dysfunction	Hydrops of gallbladder
Central nervous system	Extreme irritability Aseptic meningitis Sensorineural hearing loss
Genitourinary system	Urethritis/meatitis
Other clinical findings	Erythema, induration at BCG inoculation site Anterior uveitis (mild) Desquamating rash in groin
Laboratory findings in acute phase	Leukocytosis with neutrophilia and immature forms Elevated erythrocyte sedimentation rate Elevated C-reactive protein Anemia Abnormal plasma lipids Hypoalbuminemia Hyponatremia Thrombocytosis after week 1 Sterile pyuria Elevated serum transaminases Elevated serum gamma-glutamyl transpeptidase Pleocytosis of cerebrospinal fluid Leukocytosis in synovial fluid

Principal Symptoms

The diagnosis depends on a history of 5 or more days of fever and at least four of five principal clinical features (characteristic eye changes, mucous membrane changes, extremity changes, rash, and cervical adenopathy). Fever is present in >95 % of patients during the acute phase. Classically, the fever is high and spiking, and usually persists for more than a week if not

Fig. 130.1 Conjunctival injection

Fig. 130.2 Oropharyngeal changes (swollen, fissured, and cracked lips)

treated. Conjunctival injection is seen in 90 % of Kawasaki disease patients; it is characteristically bilateral, bulbar, and nonpurulent (Fig. 130.1). Anterior uveitis and iridocyclitis have been reported within the first week of illness [36]. Oropharyngeal changes are seen in 90 % of patients and involve the lips, tongue, or pharynx. The lips may become swollen, dry, fissured, or cracked; peeling or bleeding may be observed (Fig. 130.2). Diffuse erythema of the oropharyngeal mucosa may be seen, but pharyngeal exudates and ulcers are not associated with Kawasaki disease. A strawberry tongue (similar to scarlet fever) is described in 77 % of patients. The extremity changes include erythema of the palms and/or soles and/or swelling (indurative edema) of the hands and feet, which can be painful. Extremity changes are present during the acute phase in 75 % of patients. A polymorphous exanthem occurs in 90 % of patients. The lesions vary in appearance but are typically not vesicular or bullous. The most common presentation is a nonspecific, diffuse maculopapular eruption (Fig. 130.3) which is often most prominent on

Fig. 130.3 Maculopapular rash

the trunk. Cervical lymphadenopathy is the least commonly observed of the principal clinical features (70 %); the observed lymph node (1.5 cm or larger in diameter) is typically nonsuppurative, tender, is usually unilateral, and is more commonly seen in older children. Clinically, the adenopathy usually appears to be a solitary node; however, ultrasound evaluation has shown there may be a cluster of nodes. In some patients, there is marked erythema of the skin overlying the node, appearing like bacterial adenitis. Although not part of the diagnostic clinical criteria, many patients with Kawasaki disease may be toxic and irritable during acute phase. Infants less than 6 months of age, who are at the highest risk for development of coronary lesions, may display subtle clinical signs and are more likely to have incomplete Kawasaki disease. In the subacute phase (10–15 days after the onset of the illness), desquamation and peeling of the skin usually begin in the periungual region and may extend to include the palms and soles in about 70 % of patients (Fig. 130.4).

Other Significant Symptoms or Findings

Noncardiac Symptoms and Findings

A unique manifestation of Kawasaki disease is induration and erythema which may develop at

Fig. 130.4 Desquamation of hands seen in the subacute phase

Fig. 130.5 Erythema at the site of BCG inoculation

the site of a previous Bacille Calmette-Guérin (BCG) inoculation (Fig. 130.5). This is seen most commonly in infants who develop Kawasaki disease within 1 year after the inoculation [37]. The gastrointestinal features of Kawasaki disease include diarrhea, vomiting, abdominal pain, and paralytic ileus. Hydrops of the gallbladder diagnosed by ultrasound is well described. Large or small joint arthritis and arthralgia are noted in 30 % of patients [38]. Large joint arthralgia and arthritis (especially of knees and ankles) occur within 2–3 weeks of the start of the illness. In contrast, small joint arthritis usually occurs early in the illness. Transient unilateral peripheral facial nerve palsy has been reported rarely [39].

Cardiac Symptoms and Findings

Cardiovascular manifestations are the leading cause of long-term morbidity and mortality. The cardiovascular abnormalities consist of tachycardia, cardiac murmurs, gallop rhythm, electrocardiogram changes (including PR-QT prolongation), abnormal Q waves, low voltage, ST-T changes, and arrhythmias. Rarely, a systolic murmur may indicate mitral regurgitation is present. Resting tachycardia out of proportion to fever is commonly seen in Kawasaki disease and likely reflects underlying myocarditis. Myocarditis is also suggested by a gallop rhythm on cardiac auscultation and confirmed by depressed myocardial contractility on echocardiography. The electrocardiogram (EKG) is usually normal with the exception of tachycardia, but abnormalities may suggest cardiac complications. Nonspecific ST-T changes and low-voltage QRS complexes may be seen in pericarditis. EKG changes indicative of ischemia or arrhythmias on a rhythm strip may be observed. Echocardiographic findings seen in Kawasaki disease may include pericardial effusion, mitral or aortic regurgitation, dilation of the coronary arteries, and/or coronary artery aneurysms. Echocardiographic findings are not part of the formal diagnosis of Kawasaki disease.

Laboratory Findings

Laboratory findings are nonspecific since there is no specific diagnostic test for Kawasaki disease. During the first week there is typically leukocytosis with a left shift, mild anemia (normocytic, normochromic), high erythrocyte sedimentation rate, and/or high C-reactive protein. In addition, hypoalbuminemia and mild to moderate increase in serum transaminases are common. Sterile pyuria may be present during the acute phase, which may sometimes be associated with clinical urethritis. Pleocytosis of mononuclear cells in the cerebrospinal fluid is common [40]. The platelet count is usually elevated by the second or third week of the illness. These laboratory findings typically improve after therapy with intravenous immunoglobulin.

Incomplete (Atypical) Kawasaki Disease

About 10 % of patients do not fulfill the criteria for the diagnosis of complete Kawasaki disease [41]. These patients are classified as having

"incomplete" Kawasaki disease (formerly called "atypical" Kawasaki disease). Patients with incomplete Kawasaki disease have the same or a higher risk of coronary artery abnormalities (as patients with complete Kawasaki disease), therefore making it important to diagnose these patients. Incomplete Kawasaki disease is diagnosed more commonly in patients less than 6 months of age; these patients are at the highest risk for development of coronary abnormalities. Children in this age group may have subtle or transient signs, making the diagnosis difficult. Incomplete Kawasaki disease should be considered in patients with persistent fever, even if the clinical presentation does not fulfill classic Kawasaki disease criteria. In such cases, laboratory and echocardiographic evaluations, as well as exclusion of other possibilities in the differential diagnosis, can be helpful to assess the patient.

Figure 130.6 shows an algorithm developed by the American Heart Association for evaluation of suspected incomplete Kawasaki disease [33]. This algorithm incorporates use of supplemental laboratory tests and echocardiography to assist in making the diagnosis. According to the guideline, infants $\leq$6 months old with $\geq$7 days of fever without other explanation should undergo laboratory testing and, if evidence of systemic inflammation is found, an echocardiogram, even if the infants have no clinical criteria. If the echocardiogram is positive, treatment should be given to children within 10 days of fever onset and those beyond day 10 with clinical and laboratory signs of ongoing inflammation.

Cardiovascular Complications

Cardiac complications include coronary abnormalities (Figs. 130.7–130.10), systemic arterial aneurysms, myocarditis, congestive heart failure, pericarditis with pericardial effusion, mitral or aortic valve insufficiency, arrhythmia, and myocardial infarction. Coronary artery aneurysms, thrombosis, or myocardial insufficiency are the leading causes of morbidity and mortality in Kawasaki disease.

Coronary Artery Abnormalities

Coronary artery abnormalities include dilatation (ectasia), stenosis, and aneurysms. Coronary artery abnormalities appear in 20–25 % of untreated patients with Kawasaki disease [4–6]. Randomized, placebo-controlled studies found that if treated during the first 10 days of the illness (with intravenous immunoglobulin and aspirin), the risk of coronary artery abnormalities decreased to 3–5 % [42]. Several studies have identified risk factors for coronary artery abnormalities in Kawasaki disease including male sex, age less than 1 year, high C-reactive protein, high erythrocyte sedimentation rate, high white blood count, low albumin, low hemoglobin concentration, and low platelet count [43, 44]. The original echocardiographic criteria established by the Japanese Ministry of Health defined abnormal coronary arteries as having intraluminal diameters greater than 3 mm in children younger than 5 years, greater than 4 mm in those older than 5 years, lumen diameter greater or equal to 1.5 times the size of an adjacent segment, or if the coronary lumen is clearly irregular. However, coronary artery size in normal children correlates linearly with increasing body surface area. Therefore, body surface area adjusted coronary dimensions, termed z-scores, are thought to be better for the evaluation of coronary artery abnormalities [45]. The z-score system is used only for the left main coronary artery, proximal left anterior descending coronary artery, and proximal right coronary artery. Coronary artery dilatation or aneurysms are usually classified as follows: mild dilatation is characterized by a coronary artery intraluminal diameter of up to 5 mm (small aneurysms); moderate dilatation is characterized by diameters of $>$5 mm and up to 8 mm; and giant aneurysms are characterized by intraluminal diameters that exceed 8 mm [33, 45].

Giant aneurysms occur in about 1 % of patients and can cause serious morbidity or mortality in the acute, convalescent, and remote phases. Thrombosis is the most common complication associated with giant aneurysms in the acute phase, although rupture has been reported rarely. Later, stenotic lesions may develop as a consequence leading to

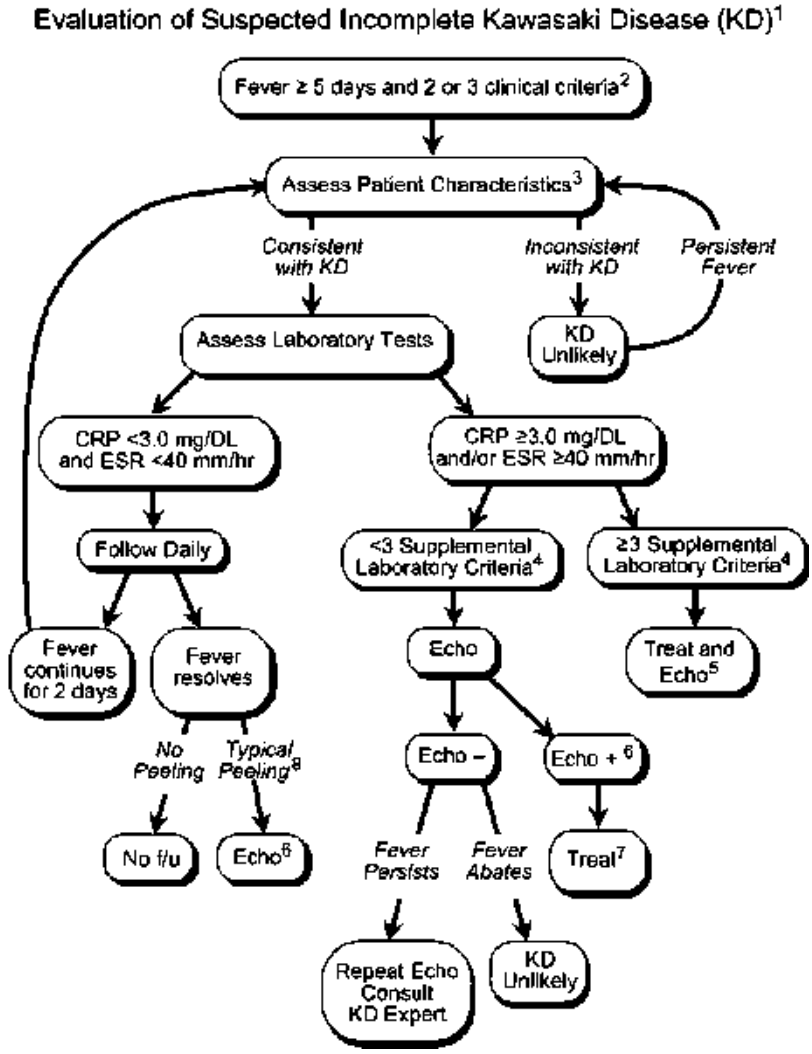

Fig. 130.6 Diagnostic algorithm for incomplete Kawasaki disease (from guideline in American Heart Association and American Academy of Pediatrics). [1]Bilateral nonprulent conjunctivitis. [3]Nonspecific exanthema. [4]Supplemental laboratory criteria include albumin ≤3.0 g/dL, anemia for age, elevation of alanine aminotransferase, platelets after 7 days of illness ≥450,000/mm^3, white blood cell count ≥15,000/mm^3, and urine with ≥10 white blood cells per high-power field. [5]Uncommon in schoolchild. [6]Echocardiogram is considered positive if any of three conditions are met: *z*-score of left descending coronary artery or right coronary artery ≥2.5, coronary arteries meet Japanese Ministry of Health criteria for aneurysms, or ≥3 other suggestive features exist, including perivascular brightness, lack of tapering, decreased LV function, mitral regurgitation, pericardial effusion, or *z*-scores in left descending coronary artery or right coronary artery of 2–2.5. [7]CAA; echocardiography (LAD). [8]Typical peeling begins under nail bed of fingers and then toes. [9]CAA; angiography (LAD). myocardial ischemia or myocardial infarction in either the convalescent phase or many years later (remote phase).

The in-hospital mortality rate for children with acute Kawasaki disease is 0.17 % in the United States [46]. The peak mortality occurs 15–45 illness days when both coronary vasculitis and hypercoagulability (due to marked elevation of the platelet count) may occur [47]. Physicians should recognize that patients with coronary

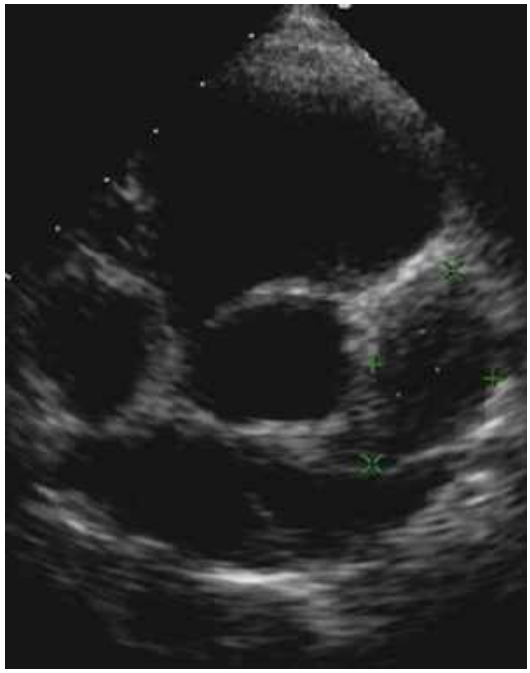

Fig. 130.7 CAA; echocardiography (LAD)

Fig. 130.9 CAA; angiography (LAD)

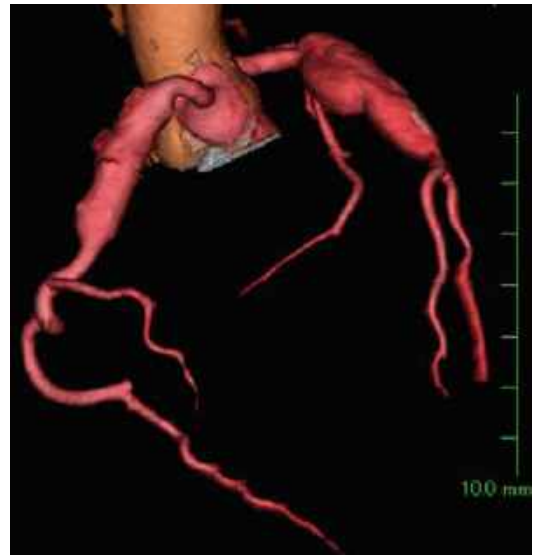

Fig. 130.10 CAA; 3D CT (RCA and LAD)

artery aneurysms also remain at increased risk for myocardial infarction or cardiac sudden death in adulthood.

Echocardiography is a noninvasive imaging method that is recommended and widely available for the routine assessment of cardiac complications due to Kawasaki disease. Angiography may be utilized for evaluation of suspected thrombosis or stenosis. Two-dimensional echocardiographic evaluation should focus on left ventricular wall motion, regurgitation of mitral and aortic valve, pericardial effusion, and coronary artery morphology (including the left main coronary artery, left

anterior descending coronary artery, proximal left circumflex coronary artery, and proximal right coronary artery). Increased echogenicity or brightness of the coronary arteries has been described. Echocardiography is recommended at the time of diagnosis, at 1–2 weeks after diagnosis, and at 6–8 weeks after diagnosis. In Japan, clinical assessment is also performed at 6 months after the diagnosis (in the United States, imaging is not routinely performed at 6 months). More frequent echocardiographic evaluation may be needed in children at higher risk for coronary artery abnormalities or those with poor cardiac function during acute phase. After discharge, follow-up echocardiography can identify the progression or regression of coronary abnormalities.

Recently, multidetector computed tomography (MDCT) scans and magnetic resonance angiography (MRA) have been useful in the diagnosis of coronary aneurysms, occlusions, and stenoses [48, 49]. Three-dimensional CT can visualize the aneurysm at distal coronary artery. The advantage of 64-slice MDCT is to detect coronary stenosis with high sensitivity and specificity, but the presence of calcifications and the high-radiation dose are problems. Likewise, MRA also can detect distal coronary stenosis, but it requires anesthesia in children.

Myocardial infarction is the main cause of death in patients with Kawasaki disease. Thromboembolic occlusion of coronary aneurysm or stenotic lesion leads to myocardial infarction and sudden cardiac death in children and/or young adults. Around 2–4 % of patients with giant coronary aneurysms develop myocardial infarction within first year after the diagnosis [50, 51]. The diagnosis of myocardial infarction is suggested from the patient's symptoms and confirmed by electrocardiography, echocardiography, and biochemical data (e.g., troponin). Rarely, patients with giant coronary aneurysms may be asymptomatic despite ischemia. The obstruction in two or three vessels including the left main coronary artery is high risk of sudden death. To mitigate or prevent thrombosis, most patients with giant coronary aneurysm receive anticoagulant and/or thrombolytic medications.

Other Cardiac Complications

Myocarditis using scintigraphy has been demonstrated to occur in 50–70 % of patients [52]. Autopsy and biopsy studies in patients with acute Kawasaki disease also report myocarditis as a common finding [53]. Myocarditis is often detected by auscultation of a gallop rhythm; rarely patients develop signs or symptoms of congestive heart failure. Myocardial function rapidly improves after treatment with high-dose immunoglobulin therapy, suggesting that improvement of myocardial function may be associated with resolution of the systemic inflammation. In most patients, myocardial dysfunction, which resolves promptly with immunoglobulin treatment, has no long-term sequelae. The severity of the myocarditis does not appear to be related to the presence or absence of coronary artery aneurysms [54].

Pericarditis is often observed in Kawasaki disease, with a small pericardial effusion detected by echocardiography in almost 30 % of patients within the second week of illness [4]. Inflammation of the endocardium involves the pericardium, which may lead to a pericardial effusion. Rarely, the pericardial effusion requires an emergency pericardiocentesis due to cardiac tamponade, but usually it resolves during the acute phase without specific interventions.

Mitral regurgitation may result from transient papillary muscle ischemia, myocardial infarction, or valvulitis. The prevalence of mitral regurgitation is about 1 % in patients with acute or subacute Kawasaki disease [55]. Mitral regurgitation is usually mild and may resolve, but rarely can lead to congestive heart failure. Aortic regurgitation also occurs due to valvulitis in the acute or subacute phase [56].

Pathology

The vasculitis of Kawasaki disease has been studied. In the acute stage, there is immune activation of the endothelium, with increased proinflammatory cytokines leading to panvasculitis predominantly of small- to medium-sized arteries. Aneurysms can develop in any artery

including coronary, celiac, mesenteric, femoral, iliac, renal, subclavian, axillary, and brachial arteries [57].

Treatments

First-Line Treatment

The main goals of pharmacological therapy in Kawasaki disease are suppression of the underlying inflammatory response and inhibition of platelet aggregation to prevent coronary thrombosis. In the United States, the United Kingdom, Europe, and Japan, standard therapy in Kawasaki disease consists of intravenous immunoglobulin (IVIG) at 2 g/kg given in a single infusion over 10–12 h together with oral acetylsalicylic acid at 80–100 mg/kg daily in four divided doses. At least two-thirds of the patients will be afebrile by 24 h after the IVIG infusion ends, and approximately 85 % of the patients will be afebrile by 36 h. IVIG treatment should be initiated as soon after diagnosis as possible. Although IVIG infusion within 10 days of the onset of illness has been shown to reduce the risk of coronary artery abnormalities, IVIG should still be given in patients diagnosed after 10 days of illness. Rare exceptions to this would include the patient who is now afebrile, without signs or symptoms of inflammation (and without current clinical manifestations of Kawasaki disease), who has no laboratory evidence of inflammation (normal CRP and ESR), and who has a normal echocardiogram. The mechanism of action of IVIG in Kawasaki disease remains unknown. Possible mechanisms of IVIG include decreasing cytokine production, neutralization of antigens, blockade of the Fc receptors, and suppression of activated monocytes and macrophages [58]. The adverse effects of IVIG include fever, chills, aseptic meningitis, renal insufficiency (usually reversible), anaphylaxis, and hypotension [59]. Like other blood products, IVIG undergoes tests for HIV blood-borne pathogens, but transmission of a currently unknown pathogen (i.e., currently not tested for) is theoretically possible. Live vaccines should be deferred for 11 months after receipt of high-dose IVIG.

High-dose acetylsalicylic acid (80–100 mg/kg daily) is used together with IVIG, due to the anti-inflammatory effect. In Japan, lower salicylate doses are utilized (30–50 mg/kg daily). Generally, the acetylsalicylic acid can be reduced to a low-dose regimen of 3–5 mg/kg daily (given as a once-daily oral dose), once the child is afebrile for at least 48 h after IVIG treatment. Low-dose acetylsalicylic acid acts as an inhibitor of platelet function (antithrombotic effect), which should be continued for 6–8 weeks if no coronary artery abnormalities are present (patients with coronary artery abnormalities should be on prolonged acetylsalicylic acid). The risks of acetylsalicylic acid include elevation of transaminases, transient hearing loss, and, rarely, Reye syndrome. Although Reye syndrome is rarely experienced in the current era, the association with acetylsalicylic acid has been reported in Kawasaki disease patients [60]. Therefore, acetylsalicylic acid should be withheld if patients have any symptoms of influenza or varicella virus infection. Cardiologists often substitute other antiplatelet agents temporarily in this situation. Immunizing patients and family members with influenza vaccine is an important way to decrease the risk of patients contracting influenza. Patients with Kawasaki disease should receive only the injectable (killed) influenza vaccine (live, attenuated influenza vaccine is contraindicated in patients taking acetylsalicylic acid).

Second- and Third-Line Treatment

Approximately 10–15 % of patients may have persistent or recurrent fever $\geq$36 h after the initial IVIG administration. Persistent fever generally represents ongoing inflammation. These patients, as initial IVIG nonresponders, are at risk of developing coronary artery abnormalities. There are no randomized studies indicating the best second-line therapy for IVIG nonresponders. Many experts use a second dose of 2 g/kg IVIG [61]. Other experts use steroids, infliximab, or rarely cyclosporine. A small subset of patients (2 % or 3 %) will remain febrile despite second-line therapy. There are no guidelines for the

management of these children who have ongoing inflammation and a high risk of coronary involvement. Referral to a center with expertise in Kawasaki disease management is recommended for children who do not respond to a first dose of IVIG.

Corticosteroid therapy has been used as second- or third-line therapy for patients with ongoing fever and inflammation after IVIG, but steroid use has been controversial. An early Japanese study, published in 1979, suggested that corticosteroids were associated with increased risk of coronary aneurysms and may be potentially harmful to patients with Kawasaki disease [62]. After this report, the use of corticosteroids in Kawasaki disease decreased dramatically. However, this study was based on a small number of patients and was not stratified according to risk factors for the development of aneurysms; thus, these data are difficult to interpret. Since this report, several studies have reported more positive experiences with steroids. A Japanese retrospective study revealed that steroid pulse therapy was beneficial in the prevention of coronary artery abnormalities [63]. Pulsed steroid therapy is usually initiated using intravenous methylprednisolone 30 mg/kg over 2 h once daily for 1–3 days. The risks associated with steroid therapy include leukocytosis, hyperglycemia, and rarely hypertension. Intravenous heparin or low molecular weight heparin may be given along with methylprednisolone, especially in patients with coronary artery abnormalities because steroids may increase thrombogenicity. A meta-analysis involving 862 Kawasaki disease patients demonstrated significant reduction in the incidence of coronary artery aneurysms in the patients receiving corticosteroids [64]. However, a US randomized trial reported that IVIG plus steroid pulse therapy had equal efficacy, but found no significant difference in the prevalence of coronary artery abnormalities, adverse events, and illness days spent in hospital compared with standard IVIG therapy [65]. As a result of conflicting studies, steroids (pulse steroids or oral steroids with taper) continue to be controversial in Kawasaki disease but are used by many experts as second- or third-line therapy [66].

A recent, prospective, multicenter, randomized, open-label, blinded-endpoints trial (*RAISE study*) investigated the use of steroids plus IVIG versus IVIG + acetylsalicylic acid in 125 patients with Kawasaki disease at increased risk for coronary artery aneurysms [67]. In this study, patients at high risk for severe Kawasaki disease (as defined by a risk score) [66] were randomized to one of two treatment arms: IVIG (2 g/kg given over 24 h and acetylsalicylic acid 30 mg/kg per day) versus IVIG (2 g/kg given over 24 h) plus prednisolone (2 mg/kg per day given until the CRP <5 mg/dL; once the CRP was <5 mg/dL, the predinsolone was tapered over the next 15 days, then stopped). The incidence of coronary artery abnormalities was significantly lower in the IVIG plus prednisolone group than in IVIG plus acetylsalicylic acid group. This study has not been repeated in the US population to date. Additionally, the standard therapy in Japan (used in one of the study arms) is different from that used in the United States. Specifically, the dose of acetylsalicylic acid used in Japan (30 mg/kg/day) is lower than the 80–100 mg/kg/day dose used in the United States as "high-dose" therapy for the first few days after diagnosis. Second, IVIG is infused over 24 h in Japan, as opposed to 10–12 h in the United States. Whether either of these factors or whether the same results would be seen in a more genetically diverse population is unknown. However, this study is an interesting addition and will likely prompt further research in this area. Other therapies that are reported in the literature for refractory Kawasaki disease include infliximab [68], abciximab [69], cyclosporine [70], cyclophosphamide [71], methotrexate [72], and plasma exchange [73]. Infliximab is a humanized mouse monoclonal antibody to tumor necrosis factor-α. Tumor necrosis factor-α is a pro-inflammatory cytokine and plays a pivotal role in rheumatoid arthritis and other vasculitides. Tumor necrosis factor-α levels are elevated in patients with acute Kawasaki disease, and the highest serum levels were observed in patients with coronary artery abnormalities [74]. Recently, the experience of infliximab use in IVIG nonresponders in an

open-label study has been published [68]. However, there are no large studies addressing the clinical efficacy of infliximab therapy. Although several reports have described potential benefits of other therapies in Kawasaki disease, no large studies on the efficacy of these agents exist.

Follow-Up Management

Prevention of Coronary Artery Thrombosis

Once a coronary artery aneurysm has been identified, it is critical to prevent thrombosis and occlusion in the aneurysm. There are no prospective or controlled data in children with coronary artery aneurysms; thus, recommendations are derived from the experience in adults with coronary disease. The prevention regimens, including antiplatelet therapy and/or anticoagulant therapy, depend on the severity of coronary involvements.

Antiplatelet Therapy

Platelet activation persists throughout the convalescent phase in Kawasaki disease. After the acute phase, there is a hypercoagulable state when marked elevation of the platelet count occurs, predisposing to coronary artery thrombosis. Therefore, antiplatelet therapy plays a pivotal role in the management of patients with or without coronary artery abnormalities. Agents used in antiplatelet therapy include acetylsalicylic acid, dipyridamole, or clopidogrel. Low-dose acetylsalicylic acid therapy at 3–5 mg/kg per day as a single dose is recommended and utilized for patients without coronary artery aneurysm or with mild coronary ectasia. In patients with more severe coronary abnormalities, dipyridamole or clopidogrel may be given in addition to acetylsalicylic acid therapy because the combination therapy may suppress platelet activation by different mechanisms.

Anticoagulant Therapy

Patients with moderate to large coronary aneurysms may have a greater risk of thrombosis compared to those with small aneurysm or transient dilation. Furthermore, patients with giant or multiple aneurysms have the highest risk of thrombosis. For these patients, anticoagulant therapy is usually used together with antiplatelet therapy, which is warfarin plus acetylsalicylic acid. The warfarin therapy should be maintained at therapeutic levels with international normalized ratio of 2.0–2.5 in children.

Thrombolytic Therapy

Myocardial infarction may occur despite aggressive anticoagulant therapy, especially in patients with giant aneurysms. When serial echocardiograms show a coronary artery thrombosis, intravenous or direct intracoronary infusion (by catheterization) of thrombolytic therapy may be indicated to restore patency of the coronary artery. Tissue plasminogen activator, streptokinase, and urokinase with systemic heparin infusion have been reported used in case series [75–77]. Thrombolytic therapy is most effective within 6 h of onset of symptoms. Generally, administration of thrombolytic agents is recommended soon after the thrombosis occurs, to try to reduce mortality in patients with myocardial ischemia. Although the ideal thrombolytic regimen and technique of catheter intervention have not been established in the pediatric population, immediate thrombolytic therapy is suggested in patients with evidence of ischemic events.

Catheter and Surgical Interventions

Use of percutaneous transluminal coronary angioplasty (PTCA) has been reported in children with stenotic lesion of coronary arteries [78]. Unfortunately, it is often difficult to reestablish the patency of the coronary arteries due to marked calcifications in stenotic lesions. Therefore, PTCA is particularly useful in Kawasaki disease patients without severe calcification and

within a relatively short time period after the onset of the illness. Percutaneous coronary rotational ablation is another strategy for patients with severe calcified coronary stenosis [78].

Long-term outcomes after coronary artery bypass grafting (CABG) in childhood are still unknown. CABG is sometimes recommended for patients with long-segment stenosis, ostial stenosis, multiple stenoses, severe occlusion of the left main coronary artery or the left anterior descending coronary artery, severe occlusion of greater than one major coronary artery, collateral coronary arteries in jeopardy, recurrent myocardial infarction, or severe left ventricular dysfunction.

Long-Term Follow-Up

The outcomes resulting from coronary aneurysms vary from complete resolution of the aneurysm to fatal myocardial infarction. The long-term prognosis for patients with coronary abnormalities depends on the size of the coronary aneurysm or other cardiovascular involvement. Recently the American Heart Association Guidelines devised a stratification system to categorize patients by their risk level as follows [33].

American Heart Association Guideline Risk Level I and II

Risk Level I is characterized by no coronary artery changes on echocardiography, and Risk Level II includes those patients with transient coronary artery ectasia or dilatation resolving by 8 weeks after disease onset. In both groups, antiplatelet therapy such as acetylsalicylic acid is recommended only through 6–8 weeks after disease onset, and no activity restrictions are recommended. Periodic reassessment, counseling regarding cardiovascular risk factors, and adherence to a heart-healthy diet and lifestyle are recommended. For Risk Level I, periodic reassessment is recommended for every 5 years, whereas follow-up is recommended every 3–5 years for patients that are classified as Risk Level II.

Risk Level III

This group includes patients with isolated small to medium (3–6 mm, z-score 3–7) coronary artery aneurysms. Low-dose aspirin is recommended to be continued at least until the aneurysms regress. Echocardiographic and electrocardiographic evaluations are recommended annually. Counseling regarding cardiovascular risk factors and adherence to a heart-healthy diet and lifestyle are recommended. Although physical activity does not need to be limited, a cardiac stress test should be performed every 2 years. If abnormalities are noted on the stress test, angiographic evaluation is recommended.

Risk Level IV and V

This group includes the patients with at least one large coronary artery aneurysm (>6 mm), including giant aneurysms and the patients with multiple or complex aneurysms without obstruction. All of these patients require long-term antiplatelet therapy. Warfarin therapy is also required when patients have giant aneurysms. Echocardiographic and electrocardiographic evaluations are recommended every 6 months. In addition, cardiac catheterization should be performed between 6 and 12 months after the acute illness. A cardiac stress test is recommended to help delineate the degree of physical activity that should be allowed. Collision and high-impact or contact sports should be avoided due to risk of bleeding with anticoagulant therapy. The Risk Level V group includes patients with coronary artery obstruction evidenced by angiography. Recommendations are similar to those of Risk Level IV, but these patients often also require beta-adrenergic blocking agents. Like all other patients with a history of Kawasaki disease, counseling regarding other cardiovascular risk factors and adherence to a heart-healthy diet and lifestyle (with modified physical activity if indicated) is recommended.

Future Studies

Approximately 50–70 % of coronary aneurysms will regress within the first year or 2 years after diagnosis [79]. The likelihood of coronary aneurysm regression over time appears to be related to the aneurysm size. Other factors influencing aneurysm resolution include age at presentation, proximal versus distal location, and morphology of the aneurysm [79]. As aneurysms regress, fibrous intimal thickening and endothelial dysfunction may occur in patients with Kawasaki disease [80]. Some follow-up studies have shown prolonged endothelial dysfunction even in children without any evidence of coronary abnormalities [81]. Definitive long-term follow-up studies on children with Kawasaki disease are ongoing.

Pericardial Diseases

131

Cécile Tissot

Abstract

The pericardium is a thin fibrous membrane that separates the heart from the remaining mediastinal structures. Disease of the pericardium presenting as acute pericarditis, pericardial effusion, and cardiac tamponade can be life-threatening in some cases. The subsequent development of chronic or recurrent pericarditis is a feared complication, although less frequent in the pediatric population. Post-pericardiotomy syndrome is a medical syndrome referring to an inflammatory phenomenon that occurs a few weeks after surgical incision of the pericardium. Structural abnormalities including congenitally absent pericardium and pericardial cysts are usually asymptomatic.

The etiology of pericardial disease is often difficult to determine and remains idiopathic in a large number of cases. The accurate diagnosis of pericardial diseases is a well-recognized clinical challenge that often requires the integration of imaging and invasive hemodynamic measurements. Recent advances in multimodality noninvasive cardiac imaging with cardiac computed tomography (CT) and magnetic resonance imaging (MRI) have aid in determining the etiology of pericardial pathology.

This chapter described those different pathologies of the pericardium, the clinical manifestations, diagnosis, and treatment.

Acute pericarditis • Congenital • Constrictive pericarditis • Jugular venous pressure • Pericardial effusion • Pericardium • Pulsus paradoxus • Tamponade

Introduction

Pericardial diseases are defined as abnormalities of the visceral or parietal pericardium that may or may not have an impact on cardiac function. Pericardial diseases are divided into diseases affecting the pericardial layers, including acute, chronic, or recurring pericarditis and constrictive pericarditis, and those affecting the pericardial sac, including pericardial effusion and tamponade. In children, diseases of the pericardium consist mostly of infectious and inflammatory processes. Rarely, neoplastic lesions as well as congenital structural defects may be the cause. Pericardial diseases may present with chest pain, pericardial friction rub, fever, and acute hemodynamic compromise or can be asymptomatic, depending on their etiology.

Anatomy and Physiology

The pericardium consists of a sac surrounding the heart. It is made of a thin inner visceral layer made up of mesothelial cells, called the *serous (visceral) pericardium or epicardium*, and a thick outer layer made up of collagen and elastic fibers, called the *fibrous (parietal) pericardium*. Those two layers are separated by a virtual space containing a small amount of physiological fluid which serves as lubricant [1]. The pericardial space normally contains <30 ml of fluid in the adult and considerably less in infants and children. The pericardial fluid is produced by the visceral pericardium and is an ultrafiltrate of plasma. The pericardial fluid normally drains through the right lymphatic duct via the right pleural space and through the thoracic duct via the parietal pericardium [2].

The pericardium envelops the heart and great vessels and reflects around the great vessels forming the pericardial recesses and sinuses. The pericardium is anchored to the diaphragm by the pericardiophrenic ligament and to the sternum by the sternopericardial ligament, providing support for the heart within the thoracic cage. It is thought that the presence of the parietal pericardium helps maintain a functionally optimal cardiac shape.

Although an intact pericardium is not critical to the cardiovascular function, it assumes some minor functions including:

- Limitation of intrathoracic cardiac motion and acute cardiac dilatation
- Preservation of diastolic and systolic interactions between the right and left ventricles
- Lubricant effect that minimizes friction between cardiac chambers and surrounding structures
- Lymphatic and immunological functions, helping prevent spread of infection from contiguous structures, especially the lungs

The normal pericardium limits cardiac distension, thereby coupling the ventricles and enhancing their interactions [3, 4]. Pressure or volume overload of one ventricle influences the compliance and filling of the contralateral ventricle via interventricular septal diastolic interactions called interventricular coupling. By influencing the effects of diastolic pressure and dimensions between the ventricles, the pericardium helps to balance the right and left ventricular output.

The normal intrapericardial pressure is subatmospheric and several millimeters of mercury (mmHg) less than the right atrial (RA) pressure. As the right ventricle (RV) fills, this passively increases pericardial pressure, which restricts further ventricular filling due to limited extensibility of the pericardium near end diastole. The intrapericardial pressure varies with the pleural pressure: the inspiratory decrease in pleural pressure slightly reduces the pericardial, right atrial (RA), right ventricular (RV), pulmonary capillary wedge (PCW), and systemic arterial pressures. Under physiologic conditions, respiratory variations influence cardiac filling and hemodynamics, but their effects on the right and left heart are different, secondary to the differences in the anatomic relationship of

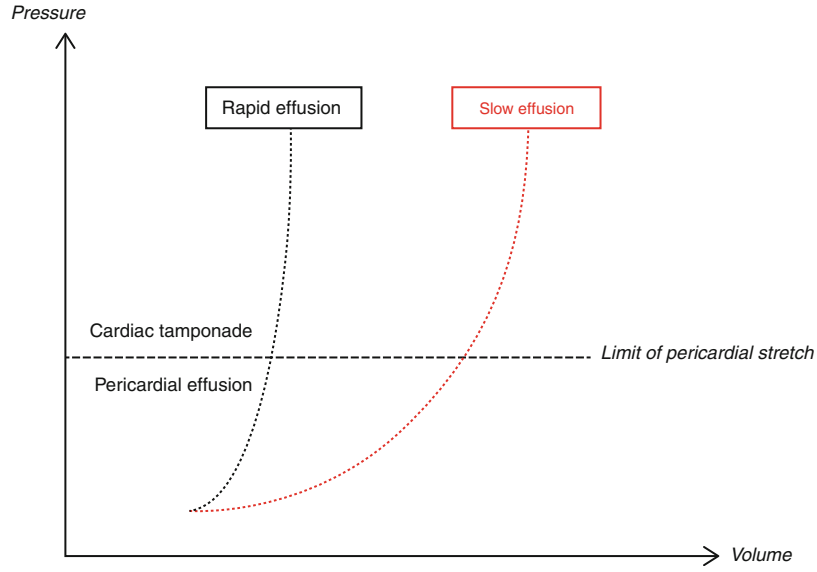

Fig. 131.1 Pericardial pressure-volume curve showing effect on pressure of rapid and slow increase of pericardial volume over time, as seen in acute and chronic pericardial effusion

the venous return to the intrapleural space [5]. The systemic venous system is extrapleural as opposed to the pulmonary venous return which is intrapleural. As a consequence, a decrease in intrathoracic pressure during inspiration has a different effect on the systemic and pulmonary venous return. During inspiration, the systemic venous return is increased by about 50 %, which increases right heart filling and output. Since the pulmonary venous return is intrathoracic, the pleural pressure changes are evenly distributed to the left heart chambers and pulmonary veins with minimal change in left heart filling and output throughout the respiratory cycle [6].

Abnormal pericardial fluid production is usually secondary to injury (postoperative pericardial effusion) or inflammation (acute pericarditis, postpericardiotomy syndrome). Transudative fluid results from obstruction of fluid drainage, while exudative fluid is secondary to inflammatory, infectious, malignant, or autoimmune processes. The normal pericardium has a small capacitance volume (about 150 ml) limited by the relative noncompliance of the parietal pericardial layer. When reserve capacitance has been reached, further increases in intrapericardial volume result in a steep increment of intrapericardial pressure. The hemodynamic repercussion of pericardial fluid accumulation is highly dependent upon the rate of accumulation in the pericardial sac. Rapid accumulation of pericardial fluid causes a sudden increase in intrapericardial pressure and hemodynamic compromise. Slow accumulation of pericardial fluid can be asymptomatic even when large fluid volumes are present (Fig. 131.1) [7].

Due to the pericardial sac's small reserved volume, an increase in pericardial volume that occurs in pathological states can exert a significant hemodynamic hindrance on ventricular compliance. Cardiac tamponade is a consequence of markedly diminished diastolic filling that occurs when the atrial and ventricular distending pressures are insufficient to overcome the increased intrapericardial pressure. During tamponade, inspiration increases inflow to the right ventricle, causing an abrupt expansion of the right ventricle during diastole at the expense of the left ventricle (Fig. 131.2) [8]. Conversely during expiration, left ventricular expansion causes right ventricular and atrial diastolic collapse. This reciprocating behavior of the ventricles during respiration is responsible for a *paradoxical pulse*, defined as an exaggeration (>10 mmHg) of the normal inspiratory decrease in systolic blood pressure [9].

Inflammation of the pericardium can manifest as a fibrinous reaction with an exudative effusion leading to thickening, fibrosis, and obliteration of the space between the two pericardial layers.

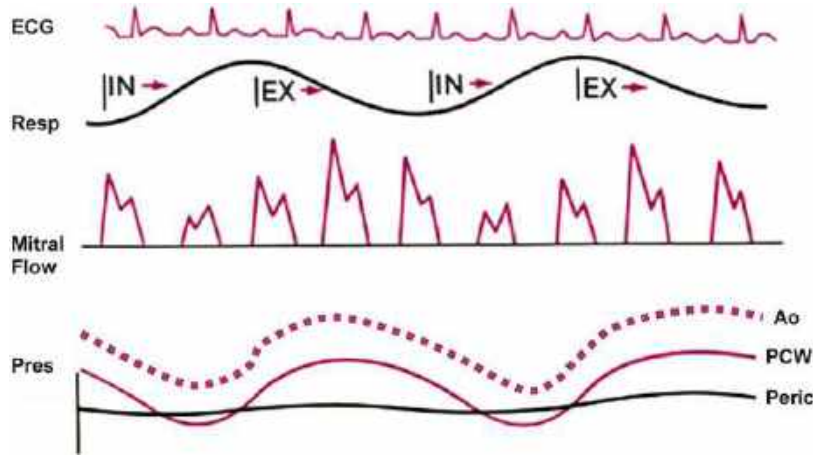

Fig. 131.2 Mechanism of pulsus paradoxus with exaggeration of inspiratory decrease in blood pressure, as seen in pericardial effusion and tamponade. *Abbreviations: ECG* electrocardiogram, *Resp* respiration, *IN* inspiration, *EX* expiration, *Pres* pressure, *Ao* aortic pressure, *PCW* pulmonary capillary wedge pressure, *Peric* intrapericardial pressure

As a result, adhesions can occur between the pericardium and myocardium leading to decreased pericardial compliance and constrictive pericarditis. This results in diminished ventricular distensibility with inability to maintain adequate preload and biventricular diastolic dysfunction. As opposed to a pericardial effusion, early ventricular filling is not altered in constrictive pericarditis. However, as the ventricles fill, they meet the resistance of the stiff pericardium, and filling pressure rises rapidly to an elevated plateau. This late diastolic phenomenon is due to a change in the volume-elasticity curve, a small increase in volume resulting in a considerable increase in end-diastolic pressure. In this situation, atrial filling pressures are elevated, reflecting both ventricular noncompliance and atrial constraint from the thick pericardium. Because of the isolated encasement of the pericardium and not the systemic veins or lungs, there is dissociation between intrathoracic and intracardiac pressures with marked respiratory variation in right and left heart filling pattern [10, 11].

Through analysis of the atrial waveforms, it is possible to understand the dynamic effect of intrapericardial and intrathoracic pressures and respiratory variations during the cardiac cycle [12]. The atrial pressure waveforms are constituted by two major positive deflections, the A and V waves, and two negative waves, the x and y descents (Fig. 131.3):

- The *A wave* (atrial contraction) follows the P wave of the electrocardiogram and is generated by *A*trial contraction.
- The *C wave* (atrioventricular valve closure) corresponds to ventricular *C*ontraction causing the atrioventricular valve to bulge toward the atrium.
- The *x descent* (atrial diastole) corresponds to atrial relaxation and rapid atrial filling and is influenced by pericardial compliance.
- The *V wave* (ventricular contraction) reflects venous return when the atrioventricular valve is closed resulting in atrial filling and increased atrial pressure during ventricular systole and is influenced by atrioventricular valve competence.
- The diastolic *y descent* (atrial emptying) represents opening of the atrioventricular valve and rapid filling of the ventricle and is influenced by the resistance to atrial emptying (atrioventricular valve opening, ventricular and pericardial compliance).

Acute Pericarditis

Etiology and Epidemiology

Acute pericarditis is the most common pericardial disease. Most cases are idiopathic (75–80 %) and presumed to be due to viral infection, particularly Enterovirus and Coxsackievirus B (Table 131.1) [13], although identifying the cause may be challenging. It may occur

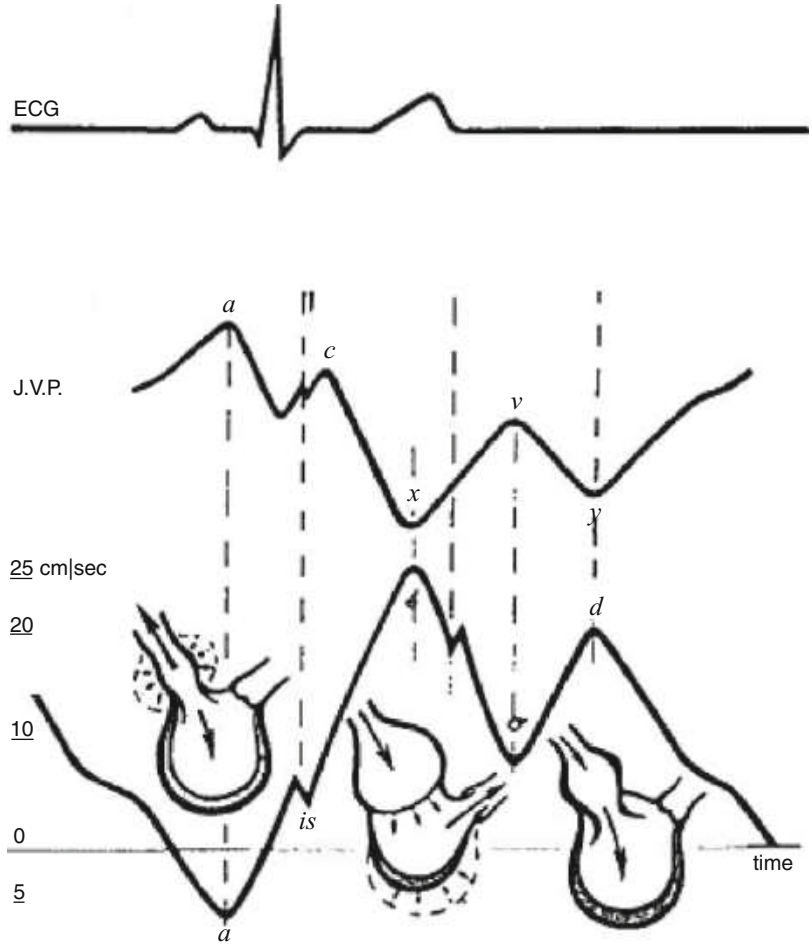

Fig. 131.3 Mechanics of jugular venous pressure and atrial wave form: - The "A" wave corresponds to atrial contraction. - The "C" wave corresponds to ventricular contraction and atrioventricular valve closure. - The "x" descent corresponds to atrial relaxation and rapid atrial filling. - The "V" wave corresponds to passive atrial filling during ventricular contraction. - The "y" descent corresponds to the rapid emptying of the atrium into the ventricle following the opening of the atrioventricular valve. *Abbreviations: ECG* electrocardiogram, *JVP* jugular venous pressure (Adapted from Kalmanson [12])

secondary to collagen vascular or rheumatic diseases, drug therapy, and cardiac surgery, as a manifestation of rheumatic fever or in association with chronic renal failure and dialysis. Effusive-constrictive pericarditis is usually secondary to infections creating a thick exudate, such as pyogenic bacteria or tuberculosis. Purulent pericarditis is a medical and surgical emergency and requires prompt antibiotic treatment and pericardial drainage to prevent adhesions and constriction. It is a life-threatening illness with mortality between 25 % and 75 % and may be primary or secondary to dissemination from another site of infection (pneumonia, septic arthritis, meningitis, osteomyelitis). Tuberculous pericarditis occurs as a result of direct spread of mycobacterium tuberculosis from mediastinal lymph nodes or secondary to hematogenous dissemination and may occur in the absence of pulmonary infiltrates. It is more common in underdeveloped countries and is fatal in 90 % of cases without antibiotic therapy. The incidence is increasing particularly in Africa, as a result of the human immunodeficiency virus (HIV) epidemic [14].

Chronic pericarditis refers to a pericarditis lasting more than 3 months and is generally secondary to inflammatory diseases or congestive heart disease. *Recurrent pericarditis* refers to either an intermittent or an incessant form of pericarditis in which recurrence occurs as soon as the therapy is discontinued and may be seen in rheumatic disease of childhood (lupus erythematosus, juvenile rheumatoid arthritis) and in post-pericardiotomy syndrome.

Table 131.1 Infectious causes of pericarditis

Causes of pericarditis	
Idiopathic	
Viral	Coxsackievirus A and B
	Adenovirus
	Cytomegalovirus
	Epstein-Barr virus

	Candidosis
	Aspergillosis
	Blastomycosis
	Echinococcosis
	Amebiasis
Parasites	Entamoeba hystolitica
	Echinococcus spp
Miscellaneous	Mycoplasma
	Chlamydia
	Rickettsiae
	Spirochetes

Signs and Symptoms

The predominant symptom is chest pain, usually retrosternal or precordial, and is present in as many as 80 % of children. The pain usually is described as sharp or stabbing, is made worse with inspiration, coughing, or movement and patients are more comfortable in the upright position. Pain may be of sudden or gradual onset and may radiate to the back, neck, or left shoulder. Associated signs and symptoms include low-grade intermittent fever, dyspnea, tachypnea, cough, and dysphagia. Acute abdominal pain is not uncommon in children. The most common and important physical finding is a pericardial friction rub, best heard at the lower left sternal border or apex when the patient is sitting forward, and may be transient. Tachycardia, out of proportion to the degree of fever, may indicate pericarditis and/or myocarditis. With bacterial pericarditis, the patient is febrile and appears toxic. In the setting of viral or autoimmune pericarditis, fever and evidence of toxicity are generally milder.

Diagnostic Workup

- Laboratory

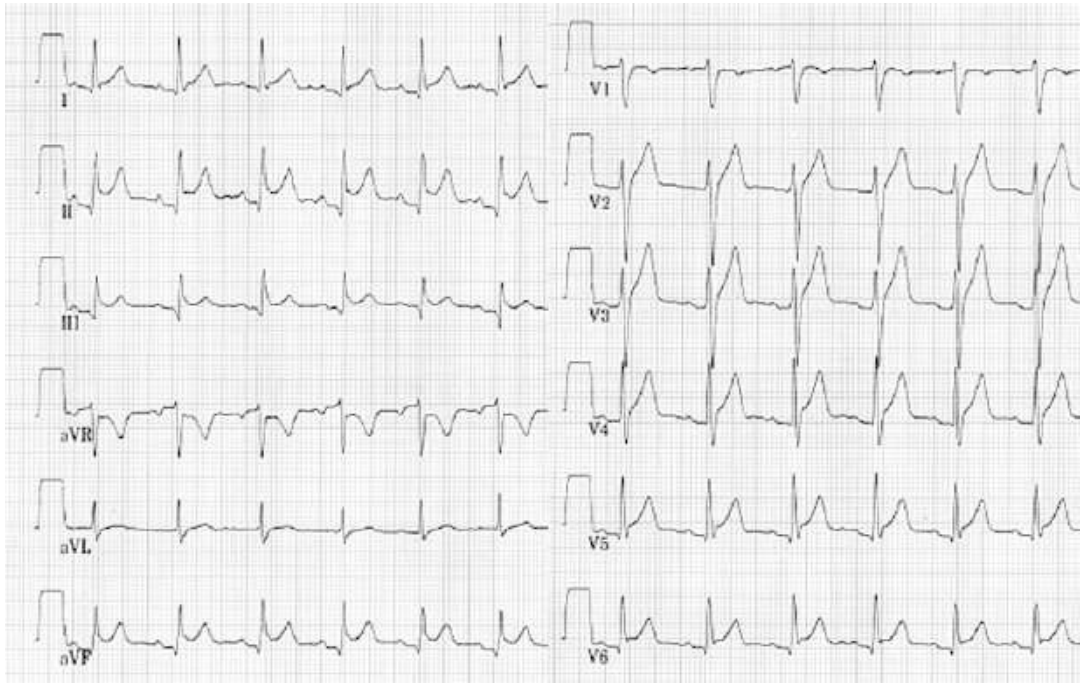
Inflammatory markers are usually elevated (C-reactive protein, ESR). Cardiac troponin I rise has been described as detectable in acute pericarditis in about 30 % of patients, reflecting injury of the underlying myocardium, and is often associated with ST-segment elevation and the presence of a pericardial effusion [15].

- Chest X-Ray

Without pericardial effusion, the chest X-ray is unremarkable except in the case of calcifications, and absence of cardiomegaly does not preclude the diagnosis of pericarditis.

- Electrocardiogram

The ECG can be diagnostic in acute pericarditis. It evolves in four stages. The first stage is characterized by ST-segment elevation and concave upward ST segments, noted in all leads except V_1 (Picture 131.1). In the second stage, normal ST segments with T- wave flattening are noted. Third stage is characterized by T wave inversion without Q wave formation with normalization of the ECG in the fourth stage (Table 131.2). Another important ECG finding is PR-segment depression.



Picture 131.1 Acute pericarditis stage 1: electrocardiogram with diffuse ST-segment elevation and PR depression except in aVR, where there is ST-segment depression and PR elevation

Table 131.2 Electrocardiographic changes in acute pericarditis

Time	ST segment	T wave	PR segment
Stage 1: hours	Diffuse elevation	Upright	Leads aVR, V1: elevation
			All others lead: depression
Stage 2	Resolution	Flattening	Resolution
Stage 3: days	Resolution	Inversion	Resolution
Stage 4: weeks	Resolution	Normalization	Resolution

- Echocardiography

The echocardiogram is often normal, unless acute pericarditis is associated with a pericardial effusion. While the finding of a pericardial effusion supports the diagnosis of acute pericarditis, its absence does not exclude it. In pericarditis, the pericardium may have a normal appearance.

- Cardiac computed tomography (CT) scan and magnetic resonance imaging (MRI)

The normal thickness of the pericardium as measured by CT scanning is less than 2 and 4 mm by MRI. The limitation of CT scan is the difficulty in differentiating fluid from thickened pericardium.

Medical Management

If an infectious cause of pericarditis is identified, appropriate antimicrobial therapy should be started. Prior to identification of the etiologic agent, broad-spectrum antibiotic coverage should be directed toward the treatment of Staphylococcus aureus and Haemophilus influenzae, and penicillinase-resistant penicillin in combination with a third-generation cephalosporin is a good association. Nevertheless, antibiotic therapy alone is not sufficient to adequately treat bacterial pericarditis as antibiotic penetration is not sufficient and will require pericardial fluid drainage.

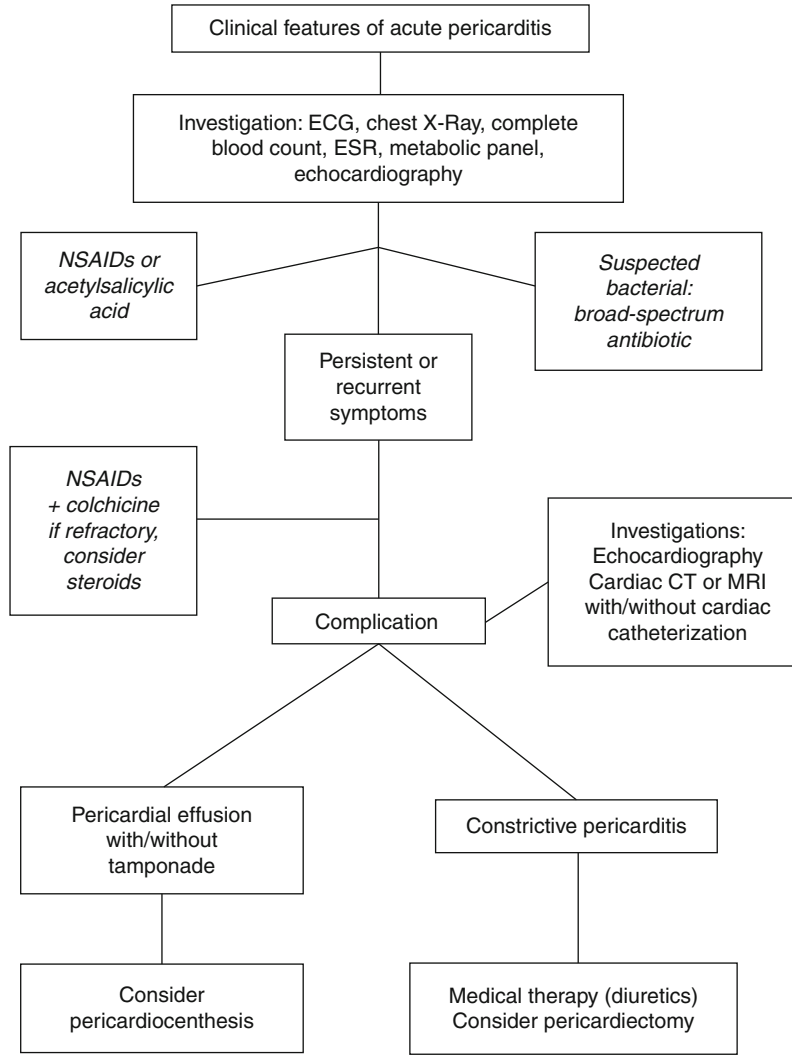


Fig. 131.4 Proposed algorithm for management of acute pericarditis. *Abbreviations: ECG* electrocardiogram, *ESR* sedimentation rate, *NSAIDs* nonsteroidal anti-inflammatory drugs, *CT* computed tomography, *MRI* magnetic resonance imaging

Treatment of viral pericarditis is predominantly symptomatic. Nonsteroidal anti-inflammatory drugs or acetylsalicylic acid is the mainstay of initial treatment and are usually used to decrease the inflammatory reaction. Acetylsalicylic acid (80–100 mg/kg/day) during 7–10 days, tapered down over 3–4 weeks, is usually the first-line treatment. Steroids therapy is rarely indicated and should be considered only when nonsteroidal agents have failed (Fig. 131.4). In adults, colchicine has been used as an initial therapy along with nonsteroidal drugs or alone and has been found to be effective in the immediate management and in the prevention of recurrences [16]. In tuberculous pericarditis, because of the high prevalence of drug-resistant organisms, initial therapy should consist of isoniazid, pyrazinamide, rifampin, and streptomycin for at least 9 months. The development of constrictive pericarditis in as many as 35 % of patients results from diffuse inflammation with subsequent pericardial thickening. It is uncertain whether adjunctive corticosteroids for 1–2 months are effective in reducing mortality or pericardial constriction in tuberculous pericarditis.

Surgical Management

As many as 50 % of patients will require pericardial fluid drainage, accomplished by pericardiocentesis or by placement of a pericardial catheter. In some patients with bacterial pericarditis, the pericardial fluid is so viscous that open drainage via a pericardial window or pericardiectomy is required. Intrapericardial administration of streptokinase has been reported to facilitate successful drainage of pericardial fluid [17].

Pericardial Effusion and Tamponade

Etiology and Epidemiology

Pericardial effusions can be associated with pericarditis or be secondary to cardiac surgery (Table 131.1) [18]. Common causes of pericardial effusions in children include prior cardiac surgery, bacterial pericarditis, malignancy, and connective tissue disorders. In a significant number of children, however, despite extensive investigation, it is not possible to identify a clear etiology. A viral cause is often considered, though rarely confirmed [19]. In developing countries, tuberculosis is responsible for approximately 70 % of cases of large pericardial effusions and most cases of constrictive pericarditis. However, in industrialized countries, tuberculosis accounts for only 4 % of cases of pericardial effusion and an even smaller proportion of constrictive pericarditis [20].

Postoperative pericardial effusions can occur in isolation or be secondary to postpericardiotomy syndrome. *Post-pericardiotomy syndrome* occurs following cardiac surgery in which the pericardium has been opened and is similar to that occurring after myocardial infarction (Dressler syndrome). The incidence approaches 30 %, although children younger than 2 years old appear to be less commonly affected. An immunologic mechanism has been postulated, with the demonstration of specific antisarcolemmal and antifibrillatory antibodies supporting this theory [21]. A viral pathogenesis has also been postulated due to seasonal variation in the incidence with a significant rise in antibody titer to several viral agents [22]. In the postoperative period, even small amount of loculated pericardial fluid, particularly when localized along the free wall of the right atrium or ventricle, can have significant hemodynamic repercussion [23]. In post-cardiac transplant patients, delayed-onset pericardial effusion (after 30 days post-transplantation) may represent acute or chronic rejection, and any effusion should be evaluated with careful attention to the immune status of the transplant recipient and promptly treated for rejection.

In acute rheumatic fever, cardiovascular involvement is characterized by pancarditis with inflammation of the endocardium, myocardium, and pericardium. Pericardial involvement is seen in 5–10 % of patients with acute rheumatic fever, almost always in association with valvulitis or myocardial dysfunction. During the acute phase of Kawasaki disease, one third of patients are found to have pericardial effusion. In children with connective tissue disorders, pericarditis occurs in approximately 10 % of patients with juvenile rheumatoid arthritis and in up to 25–50 % of those with systemic lupus erythematosus.

Hemopericardium should be suspected in any patient who complains of severe chest pain following traumatic injury. *Chylopericardium* is a pericardial effusion consisting of chyle and may be primary (idiopathic) or secondary to injury of the thoracic duct and associated with chylothorax (post-surgery).

Signs and Symptoms
