The fact that one of the main outcomes in clinical trials of TBI patients is measured at 6 months introduces a potential source of bias, as loss to follow-up is a common problem in this population. A 1998 survey of TBI trials found an average loss to follow-up of 19% at 6 months. Loss to follow-up reduces the study size, rendering effect estimates to less precise, and may introduce bias. Loss to follow-up appears to be particularly common in TBI trials, possibly because they mostly involve young males from disadvantaged social groups who are geographically highly mobile. At the moment there is no disability outcome measured at hospital discharge that can predict long-term disability. Such a measure could be potentially useful when dealing with loss to follow-up, for informing interim analysis, and could also be useful in clinical practice when communicating with patients and their families.

37.2 Prognosis

37.2.1 Definition

Prognosis, (from the Greek *pro* meaning before and *gnosis* meaning knowledge) is defined as "the result of looking forward". In the context of clinical epidemiology, prognosis can be defined as "the probable course and outcome of a health condition over time" or as "the future risk of adverse outcomes among people with existing disease".

Importance of Prognosis in Clinical Practice

Clinical practice involves three main activities: identifying disease (diagnosis); treating disease (therapy); and predicting disease course and outcome (prognosis). Although these three activities are interrelated, distinctions between them are made in clinical research. Prognosis-related research is considered to be the one most neglected.
Prognosis was historically one of the most important activities of medical practice. Up until the late 19th century, 10% of the content of medical textbooks was dedicated to prognosis; however, by 1970 this had decreased to almost zero. Predicting the future was traditionally the task of both priests and doctors, but with the advent of effective therapies the dominance of the clinical encounter shifted to diagnosis and therapy. Nonetheless, prognosis research has recently begun to attract increasing interest.[25]
Among the reasons for this resurgence, Christakis proposed:

- Interest in human terminal care and the decision of withdrawing or not life support from critical patients.
- Avoidance of futile treatment for reasons of justice or costs.
- Availability of new technologies (e.g., genetic testing and biomarkers).
- Increasing emphasis on patient autonomy.
- Increasing prevalence of chronic diseases.

37.2.2 Prognostic Models

Definition

Outcome prediction studies come under a variety of names: prognostic models; prediction models; risk scores; prognostic indices; clinical prediction rules; clinical prediction guides; and clinical decision rules. According to some authors, the term "clinical decision rules" applies only to those models that also provide a diagnostic or therapeutic recommendation. Throughout this chapter I will use the term "prognostic model" will be used and it can be defined as the "mathematical combination of two or more patient or disease characteristics to predict outcome".

Performance of Prognostic Models

The performance of prognostic models refers to how "accurate" a given model's predictions are in relation to observed data. According to Rothman, "accuracy in estimation implies that the parameter that is the object of measurement is estimated with little error". In the particular context of prognostic models, accuracy has two main components: calibration and discrimination.
Calibration refers to the agreement between predicted and observed probabilities. If, for example, according to the model, TBI patients with certain characteristics have a probability of mortality of 30%, it would be expected that 30 out of 100 patients with such characteristics would die if the model were perfectly calibrated. Calibration can be mea-

sured in different ways: graphically by plotting observed against predicted outcomes or with a statistical test such as the Hosmer-Lemeshow test. This test compares the observed number of people with events within risk groupings (e.g., deciles of risk) with the number predicted by the model. A small p value implies lack of fit.

Discrimination, on the other hand, is a measure of how well a given model separates those who develop the outcome from those who do not. It is generally measured with the area under the receiver operator curve (ROC) or the C statistic. A ROC is constructed by plotting pairs of true positive rate (sensitivity) and false positive rate (1-specificity) for several cut-off values of probability of the outcome. The area under the ROC can be interpreted as the probability that a randomly selected person with the outcome will have a higher predicted probability than a randomly selected person without the outcome. For example, if a model has an area under the ROC (or C statistic) of 0.7, this means that the model will estimate a higher probability of the outcome for subjects with the outcome 70 out of 100 times if we choose a random pair of subjects with and without the outcome.

The relative importance of calibration and discrimination will depend on the intended application of the prognostic model. For example, calibration of the model will be more relevant for counselling an individual patient, while discrimination could be more important for triage in a setting with limited resources.

In addition to the measures of discrimination and calibration, we might be interested in performance measures for specific thresholds when a clinically relevant cut-off is already established. The accuracy rate (or correct classification rate) is calculated as (true positive + true negative)/total and the complement that is the error rate (misclassification rate) that is defined as (false positive + false negative)/total. The problem with these measures is that equal weight is given to positive and negative results, whereas false negatives are generally more important than false positives. Furthermore, the accuracy rate will be high, by definition, for a frequent or infrequent outcome. For example, if the average mortality for a condition is 7%, the accuracy rate would be 93% if the model classifies all the patients as survivors.

More recently, new measures such as the net reclassification improvement (NRI) have been proposed. The NRI has four components: the proportion of individuals with events who move up or down a category and the proportion of individuals without events who move up or down a category. The NRI is obtained by combining the four components, but they should also be reported separately.

Finally there are also overall performance measures such as the R^2, which is the amount of explained variation in the outcome explained by the model, and the Brier score which is a measure of the difference between actual outcomes and prediction. These measures do not distinguish among the different performance components (calibration and discrimination), so they are not very useful.

Inaccuracy of Clinical Prediction

Given the lack of interest in prognosis, medical training in this area is weak. So it is not surprising that doctors feel poorly prepared and that they often disagree or are inaccurate in their predictions. Numerous studies have shown that physicians make errors when formulating a prognosis. In many of these studies the term accuracy is used in the more general epidemiological sense (measured with little error), and they do not necessarily use the standard specific measures of accuracy described above for evaluating prognostic models.

In a systematic review comparing physicians' clinical predictions of survival in terminally ill cancer patients with actual survival, the authors found eight studies (involving 1563

subjects) and reported that the median clinical prediction of survival was 42 days and the actual median survival was 29; overall, there was poor agreement (weighted kappa 0.36) between clinical prediction and actual survival.
In a cohort study involving 16 Dutch nursing homes and 515 terminally ill non cancer patients, the authors compared physicians' predictions with actual survival. The physicians were asked to predict death in the following periods: 1 week (0 to 7 days); 8 to 21 days; and between 22 and 42 days. The positive predictive value of physicians' predictions was high for those patients expected to die within 1 week (92%), but it much lower for patients who were expected to die within 8 to 21 days (16%) or within 22 to 42 days (13%).

37.3 Prognosis in Traumatic Brain Injury

37.3.1 Potential Role of Prognosis in TBI

Potential Role of Prognostic Models

Prognostic information could be potentially useful for decision making. Taking into account that most TBI cases occur in low and middle income countries, accurate prognostic information could be of paramount importance. The human brain is hard put to collect and summarize quantitative data for making predictions and even more so in emergency situations such as the treatment of TBI patients. Because common problems arising in emergency situations, e.g., stress, fatigue, poor communication, and interruption of thinking, are all exacerbated by the need to take rapid decisions, prognostic models could play a useful role in the management of TBI patients.
In the context of TBI, clinical prediction models instead of clinical decision models would be more appropriate because of the lack of evidence of effective interventions according to baseline risk. Nonetheless, clinical prediction models still have the potential to influence TBI management. As mentioned before, Murray et al. demonstrated that the introduction of computer-based outcome prediction altered TBI patient management. The potential impact of accurate prognostic information could be particularly important in low and middle income countries where resources are limited.
Furthermore, in such a critical setting, accurate and consistent prognostic information provided by a prognostic model may also be helpful for counselling patients and relatives. It has been shown that physicians change their own predictions when they need to communicate them to patients or relatives. Therefore, the use of prognostic models will not only result in more accurate predictions but will also increase the consistency when communicating with patients and their families.

Potential Role of Explanatory Prognosis Studies

The identification of prognostic variables in causal pathways could inform the design of RCTs of potential interventions. This is particularly important in the context of TBI research where evidence for effective interventions is lacking. There are two main pathophysiological mechanisms to be interfered after TBI. The first is related to the inflammatory response. Numerous trials have investigated inflammatory response (neuroprotection studies), but no evidence of a clinical effect has been found to date. The only trial large enough to detect a plausible clinical effect, the CRASH (Corticosteroid Randomisation After Significant Head Injury) trial, reported an increase in mortality. The second potential pathway of intervention is related to intracranial bleeding. Although there is some evidence that intracranial bleeding is associated with worse prognosis, its

relationship is not well characterized. Explanatory prognosis studies could shed light on this association, which would be useful to inform the design of future trials.

37.3.2 What is Already Known About Prognosis in TBI

Individual Prognostic Factors

The Brain Trauma Foundation conducted a systematic review of individual early indicators of prognosis in severe TBI. The authors evaluated each study in the systematic review according to criteria intended to establish study strength. These criteria included:

- Twenty-five or more patients in the series with complete follow-up.
- Outcomes measured – Glasgow Outcome Scale or Mortality – at 6 months or more.
- Data gathered prospectively, although retrospective examination from a database created for an ongoing cohort of patients could be used.
- Glasgow Coma Scale score measured within 24 hours.
- Appropriate statistics (e.g., multivariate analysis) used to include adjustment for prognostic variables.

According to these criteria, the evidence of prognosis was:

- Class I: Those papers containing all of the above characteristics.
- Class II: Those papers containing four of the five characteristics, including prospectively collected data.
- Class III: Those papers containing three or fewer of the above characteristics.

They also constructed 2 X 2 tables and evaluated the positive predictive value for mortality for each potential predictor.

The evidence reported for each of the most important predictors is described below.

Glasgow Coma Scale: Class I evidence of an increasing probability of poor outcome with a decreasing GCS in a continuous, stepwise manner. Since its introduction in 1974, the GCS has consistently shown a correlation with outcome: the lower the score, the worse the prognosis. Yet some controversies remain. For example, the type of relationship with outcome (linear or non linear) and the influence of timing of GCS measurement on its validity. It has been suggested that with more intensive pre-hospital management, which includes sedation and intubation, a valid GCS score is more difficult to obtain. Despite these concerns, the GCS score remains an important predictor in TBI. The motor component of the GCS has also been found to be associated with outcome.

Age: Class I evidence of an increasing probability of poor outcome with increasing age in a stepwise manner. It is well established that older age predicts poor outcome after TBI, which could be related to an increased risk of intracranial hematoma and a decreased capacity for repair of the brain with age. In addition, as in any other condition, it is possible that the worse prognosis associated with age is related to concomitant comorbidities. A meta-analysis evaluating the relationship between age and poor outcome in TBI patients reported that this relationship was better expressed as a linear and quadratic term and that the best fitting threshold was 40 years.

Blood pressure: A systolic blood pressure <90 mmHg was found to have a positive predictive value of 67% for poor outcome. Hypotension, defined as a systolic blood pressure <90 mmHg, is associated with a poor prognosis. Early hypotension appears to exacerbate the development of intracranial hypertension. A single episode of hypotension has been associated with a doubling in mortality.

Pupillary light reflex: Class I evidence of a positive predictive value of at least 70% for poor outcome was reported for bilaterally absent pupillary light reflex. Abnormalities of the pupillary light reflex are an indirect measure of herniation and brainstem injury.

Dilation and fixation of one pupil indicates herniation, while bilaterally dilated and fixed pupils reflect brainstem injury. It has been estimated that one fixed pupil is associated with a mortality of 54%, whereas patients with bilateral fixed pupils have twice the mortality (90%). Direct oculomotor trauma should be excluded when considering the prognostic information of pupil abnormalities.

CT Scan characteristics: Class I and Class II evidence of a positive predictive value of at least 70% for poor outcome was reported for abnormalities on the first CT scan, Traumatic Coma Data Bank (TCDB) CT classification, compressed or absent basal cisterns, and traumatic subarachnoid hemorrhage. Different CT classifications have been proposed as predictors of unfavourable outcome in TBI. The TCDB (or Marshall) classification (Table 37.2) is the most widely used and has been shown to be associated with increased mortality in the majority of studies but not in all.

The following individual CT characteristics have been shown to be associated with higher mortality: midline shift >5 mm, compression and obliteration of the basal cisterns.

Intracranial bleeding is divided into extracerebral (epidural, subdural and subarachnoid) and intracerebral or parenchymal. All types of intracranial bleeding are associated with a worse prognosis. Although some studies have shown an association between the size of intracranial bleeding and prognosis, the empirical evidence is limited, most studies having small sample sizes and restricted populations. The further subdivision between evacuated and non-evacuated hematomas proposed in the TCDB classification is criticized by some authors because, so they argue, it could be influenced by differences in patient management between centres. Recently, it has been proposed that combining individual CT predictors is preferable to using the TCDB classification for prognostic purposes.

Other predictors not included in the Brain Trauma Foundation Review are genes and biomarkers.

Genes. The presence of the apolipoprotein E4 (APOE4) allele has been associated with poor outcome after TBI. A recent systematic review identified 14 cohort studies involving 2527 subjects. Only seven studies (1868 subjects) presented dichotomous data on the GOS and could be included in the meta-analysis. The APOE4 allele was significantly associated with a poor outcome after TBI (relative risk [RR] = 1.36, 95% CI 1.04-1.78) However, the risk of bias was high in the majority of the studies, with only two having assessed outcome blinded to genotype and a follow-up larger than 80%.

Biomarkers. The protein S100B is a marker for brain damage and has been proposed as a marker for poor outcome after TBI. A review of 18 studies evaluating this association reported that patients with high levels of S100B may have a higher risk of disability. However, this systematic review had many limitations as it did not evaluate the risk of bias of the studies included nor did it address the probability of reporting bias.

Injury	Description
Diffuse injury I (no visible pathology)	No visible intracranial pathology seen on CT scan
Diffuse injury II	Cisterns are present with midline shift 0-5 mm and/or lesions; densities present; no high or mixed densities lesion >25 cc; may include bone fragments and foreign bodies
Diffuse injury III (swelling)	Cisterns compressed or absent with midline shift 0-5 mm; no high or mixed densities lesion >25 cc
Diffuse injury IV (shift)	Midline shift >5 mm; no high or mixed lesion >25 cc
Evacuated mass lesion	Any lesion surgically evacuated
Non-evacuated mass lesion	High or mixed lesion >25 cc not surgically evacuated

Table 37.2 **Marshal CT classification.**

the population to moderate and severe TBI. They found 31 studies and their conclusions were very similar to the those reported in this chapter. Most prognostic models included GCS, age and pupil reactivity, they were developed from small sample sizes, and they were rarely externally validated or presented in a practical way.

37.4 Prognostic Models

Since the publication of a prognostic model in TBI patients by Jennet et al. 30 years ago, many other prognostic models have been devised. Nevertheless, no model is universally accepted or widely used and a comprehensive review of all models is still lacking. A recent systematic review found that although studies on prognostic models for TBI are numerous, their quality is relatively poor. In addition, they are rarely validated on external populations or presented to physicians in a user-friendly way. Furthermore, few are developed using populations from low and middle income countries where most trauma events occur. It is noteworthy that only 2% of the models included patients from low-income countries, although 90% of trauma events occur in these countries. Although biologically prognostic factors should be the same worldwide, it is reasonable to consider that the baseline risk and the strength of the association could differ depending on the medical care received. This difference could affect the accuracy of the prognostic models in different settings.

GCS, age and pupil reactivity were the most common variables analyzed as predictors, whereas GOS and mortality were the most common outcomes investigated. Multiple logistic regression was the multivariable analysis most frequently used.

Several limitations in the quality of the models were found. The majority did not include a thorough discussion of the rationale for including predictor variables. Only a minority had a loss to follow-up of less than 10%. Potentially this is an important limitation as the loss to follow-up could be related to prognosis and could lead to bias. Furthermore, only four models handled the missing data by using statistical imputation. In the multivariable analysis, automatic procedures (stepwise) were quite common in logistic regression. There is no agreement on the appropriateness of this strategy. This is reflected by the conflicting recommendations for quality assessment in prognostic studies; while the use of stepwise was considered as good quality in one study, in another it was considered as a flaw. One of the limitations was that most studies did not explicitly consider the clinical criteria to enter the variables in the model beyond the automatic procedures. Interactions were hardly ever explored, although this is strongly recommended in multivariable analysis [2].2 Another common weakness was the lack of power of the models. Most were derived from small samples though it is well established that large samples are required for reliable selection of predictors. Only one third included at least 10 events per variable. It has been proposed that this is the minimum ratio of events to variables large enough to allow an adequate precision of the estimates.

It is also important to report how well the model works and to report performance measures. Remarkably, not all the studies reported a measure of discrimination and only a few reported a measure of calibration. Even when a discrimination measure was reported, less than half presented confidence intervals to provide readers with an estimation of its precision.

For a model to be generalizable to other populations, it is important to conduct an external validation. Only seven models (three reports) developed and validated a model, but in only two of them was the validation performed on patients from a different centre.

Finally, to be useful, the method to estimate prognosis should be clearly reported and, to be clinically practical, it should be user-friendly. Only half of the models clearly explained how to obtain the prognostic score, and only one tenth were reported in such a way that could be easily applicable in a clinical setting. None of the models evaluated the clinical credibility of the different presentations.

Two models developed by Hukkelhoven et al., one for mortality and the other for unfavourable outcome, were those which met most of the methodological and clinical criteria. A thorough discussion of the predictors was included, the missing data were handled appropriately, the assumptions of the model were tested, an external validation in two different populations was performed, and the discrimination and calibration measures were presented. The sample size was 2269 patients and 1542 patients for the validation. Furthermore, a simple score chart was developed to estimate the outcome probability. The predictors included in the final model were age, GCS motor score, pupil reactivity, hypoxia, hypotension, CT scan abnormalities, and the presence of traumatic subarachnoid hemorrhage. The discrimination of the model was >0.8 for both outcomes, however, the calibration was poor. The limitations were that the models included only patients from developed countries and were restricted to moderate and severe TBI cases.

37.5 CRASH Prognostic Models

Using variables that are available at the bedside, the CRASH investigators have developed prognostic models for predicting two clinically relevant outcomes in TBI patients. The models have good discrimination and good fit using internal validation. The models for high-income country (HIC) patients with moderate or severe TBI also showed acceptable discrimination when externally validated.

The basic model includes the variables: age; GCS; pupil reactivity; and major extracranial injury. The CT model includes the same variables as the basic model plus the CT scan findings: petechial hemorrhage, obliteration of the third ventricle, midline shift, subarachnoid hemorrhage, and non evacuated hematoma. After finding evidence for interaction between some of the predictors and the outcome, different models for HIC and low- and middle-income countries (LMIC) were developed. All the models are posted on the internet (Figure 37.1).

For selecting the variables those for which there was strong evidence of an association with the outcomes in both regions were selected, so that a common core of variables could be selected. The rationale for this strategy was that a common model for the different regions and outcomes would be simpler to use. In these models, the variable “hours since injury” was left out, because there was strong evidence of an association in the LMIC but not in the HIC.

On the other hand, for the variable “presence of major extracranial injury” there was strong evidence of an association with 6-month unfavourable outcome in

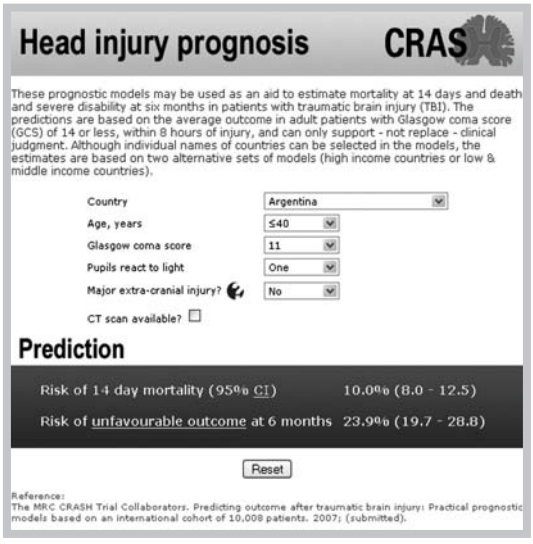

Figure 37.1. Screen shot of the CRASH model.

the two regions with both models, but there was weaker evidence for an association with mortality in the LMIC. In the basic model the odds ratio (OR) was 1.15 (95% CI 0.99-1.34) and the strength of this association weakened in the CT model (OR 1.08, 95% CI 0.91-1.28).Similarly, there was strong evidence for an association with the presence of petechial hemorrhages on the CT scan in the LMIC but it was weaker in the HIC, so this variable was kept in all the models.

37.6 Individual Predictors

37.6.1 Demographic and Clinical Predictors

Age

Increasing age was associated with worse outcomes, but this association was most apparent after 40 years of age. A similar threshold has been reported elsewhere. In their systematic review, Hukkelhoven et al. found the best fitting threshold for age was 39 years; however, they reported that the best way to analyse age was a linear and a quadratic term. However, it does not seem biologically plausible that the increased risk associated with age only starts after 40 years of age. However, it is unlikely that a different way of analysing this variable would have changed the main conclusions of the study. Whatever way is chosen to describe this variable, there is consistent evidence that a positive association exists between age and poor outcome. Plausible explanations for this relationship include extracranial comorbidities, changes in brain plasticity, or differences in clinical management associated with increasing age. Further research is needed to explore these mechanisms.

Glasgow Coma Scale

Total GCS score showed a clear inverse linear relationship with mortality. The finding that mortality was lower in patients with a GCS score of 3 than in those with a GCS of 4 may be due to GCS scores of sedated patients being reported as GCS 3. Previous studies have suggested that total GCS could have become less useful as a predictor in an era of early sedation and pre-hospital intubation. In this study, however, GCS still has an acceptable discriminative ability, particularly in the LMIC. When GCS was analyzed as a categorical variable (mild, moderate and severe), although it showed an acceptable discrimination, it was lower than the discrimination of GCS as a continuous variable.
In terms of discrimination, total GCS was superior to each of the individual components (motor, eye and verbal). Among the different GCS components, the motor item was the most discriminative. In a recent review of the predictive ability of GCS in TBI patients, the authors concluded that the motor component score has the same discriminative ability as the total GCS score. According to the findings of this study, however, total GCS is superior to the motor component in terms of discrimination.

Pupil Reactivity

In agreement with previous studies, the absence of pupil reactivity was a strong predictor of poor outcome. The effect estimate (odds ratio) for mortality was among the highest of all predictors. When measured with the Z score, however, it was only the third strongest predictor after age and GCS. This finding could be explained by random error, as the standard errors were larger due to the relatively low frequency of pupil abnormalities (6% with one pupil unreactive and 8% with both pupils unreactive).

Major Extracranial Injury

Patients with a major extracranial injury showed an increased risk of poor outcome. Other studies have shown an independent effect of extracranial injury. For example, Signorini et al. found that extracranial injuries as measured with the Injury Severity Score (ISS) were an independent predictor of mortality. Other studies have failed to report such an association. Nevertheless, it is well accepted that other variables which could be a consequence of presenting extracranial injuries, such as hypotension, are associated with poor outcome in TBI patients.

Hours Since Injury

Only patients from the LMIC who were randomised more than 1 hour after the injury had a higher risk of poor outcome than those randomised in the first hour. Although there is clinical consensus that TBI patients should receive rapid treatment after the injury, there is no empirical evidence demonstrating an association between time since injury and poor outcome. Furthermore, the CRASH trial cohort has limited information to evaluate this association, as only patients who were hospitalized within 8 hours of injury were included.

Cause of Injury

Cause of injury was not found to be an independent predictor of poor outcome. In a previous meta-analysis of 11 studies, the authors found that the cause "fall" was associated with increased mortality, but it did not remain as an independent predictor after adjustment for age. The only category found to be an independent predictor was "other", which was associated with a decreased risk in mortality when compared to the cause "road traffic accident" in the LMIC. Unfortunately, the "other" category includes a wide range of diverse causes, so it was not possible to disentangle the possible explanation for this finding.

Gender

There was no strong evidence for an association between gender and poor outcome. Although some studies have claimed a better outcome in female patients, a recent systematic review concluded that there is no evidence for a gender-related difference in outcome.

CT Scan Predictors

The majority of previous publications have used the CT Marshall classification to evaluate the predictive ability of CT findings; however, it has recently been shown analysis of an individual's CT predictors to be a better strategy. All abnormal CT findings, except for evacuated hematoma, were associated with poor outcome.

The CT category "obliteration of third ventricle or basal cisterns" was most strongly associated with poor outcome. This result is in keeping with the recent

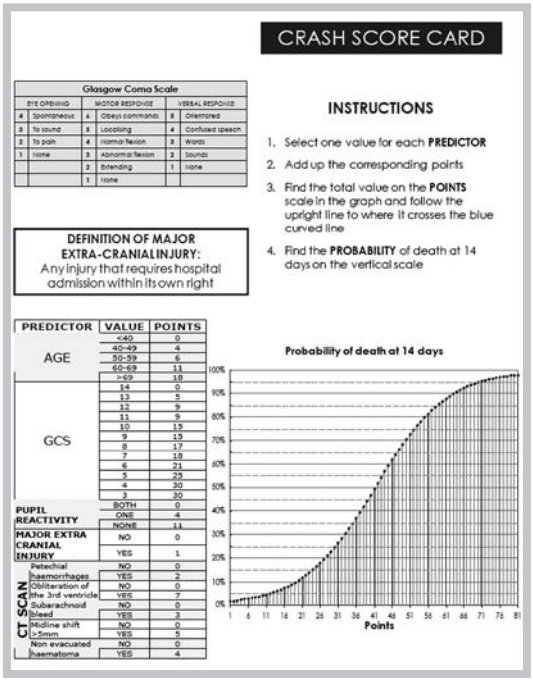

Figure 37.2. The CRASH score card.

findings that absence of basal cisterns is the strongest predictor of 6-month mortality. As previously reported, traumatic subarachnoid hemorrhage was found to be an independent predictor. The finding that a non-evacuated hematoma was associated with an increased risk of poor outcome is consistent with studies showing an increased risk of poor outcome with different types of intracranial hematoma. Unfortunately, the CRASH trial did not present enough data to explore this association in more detail (Figure 37.2).

37.6.2 Differences Between Patients From LMIC and HIC

Early Mortality

Patients from LMIC had a worse early outcome than those from HIC. Regional differences in TBI outcome between Europe and North America have been reported previously, but the difference in mortality between LMIC and HIC has not been explored.

The adjusted odds ratio for mortality at 14 days for LMIC patients versus HIC patients was 1.94 (95% CI 1.64-2.30). No conclusions about the causes for this difference can be drawn from the data presented in the CRASH trial. However, some findings could raise hypotheses to be tested in future studies. For example, LMIC patients arrived at the hospital later than HIC patients and a larger proportion had data on current GCS, a possible indicator that a smaller proportion of LMIC patients was intubated or sedated on hospital admission. These two findings indicate that treatment for LMIC patients is delayed longer. Furthermore, a lower proportion of LMIC patients underwent a CT scan, indicating that CT was not performed in some patients with potentially treatable lesions.

Unfavourable Outcome at Six Months

Another interesting finding was that although 14-day mortality was higher in patients from LMIC, there was no evidence for a difference in unfavourable outcome at 6 months. This could be because patients from HIC who did not die early had a higher frequency of disability or because disability at 6 months was measured with the GOS, the interpretation of which could vary between different settings.

Differences in the Strength of Association of Predictors

Another important finding was the difference observed in the strength of association between several important predictors and outcome. A recent study is the first study to report such differences according to whether patients are from HIC or LMIC.

Although GCS was a strong predictor of poor outcome in both regions, the authors have found that it had a higher discriminative ability in LMIC patients than in HIC patients. This might be due to differences in quality of care or because the low GCS scores reported for HIC patients reflected a greater use of sedation rather than TBI severity. In LMIC patients the GCS (measured as a continuous variable) had a C statistic similar to both the basic and the CT model, whereas the difference between the C statistic of the models and the GCS was larger in HIC patients.

The other variable that showed a different strength of associations according to the region was age. Increasing age was associated with a worse prognosis in HIC patients than in LMIC patients. This was because of the lower risks at younger ages in HIC, while HIC and LMIC patients have similar risks at older ages.

Some abnormal CT findings were stronger predictors in HIC compared to LMIC. This could be due to better technology and therefore more accurate CT diagnosis in HIC.

37.7 Comparison With Previous Studies

The systematic review reported above identified over 100 prognostic models for TBI patients, but methodological quality was considered adequate in only a few. Two of the more methodologically robust models showed similar findings to the CRASH models with good discrimination but worse calibration. They, too, included GCS, age, pupil reactivity and CT scan results as predictors but they did not include the presence of major extracranial injury, and none of them included patients from LMIC.

Subsequent to the publication of the CRASH prognostic models, the investigators from the IMPACT study, the database in which the CRASH prognostic models were validated, developed a series of prognostic models for TBI patients. The IMPACT dataset included 8509 patients with moderate and severe TBI from 11 studies conducted between 1984 and 1997 in HIC. They developed three types of models to predict mortality at 6 months, and unfavourable outcome at 6 months, as defined by the GCS. The three models developed were:

- A core model that included age, motor score component from GCS, and pupillary reactivity.
- An extended model that included the core model variables plus secondary insults (hypoxia and hypotension) and CT characteristics (Marshall CT classification, subarachnoid hemorrhage and epidural hematoma).
- A laboratory model that included the variables from the core and extended models, plus glucose and hemoglobin.

The core model was developed using the whole dataset (8509 patients), while the other two models used smaller samples as they were forced to restrict the sample to studies with the relevant variables.

The extended model was derived from 6999 patients and the laboratory model from 3554 patients. Because of missing values for some of the variables in the different studies, they used the method of chained equations to impute the missing data. A total of 5%, 13% and 8% of the values were imputed on the core model, the extended model and the laboratory model, respectively. For the internal validation, the area under the ROC was calculated with a cross-validation procedure, where each study was omitted in turn. The discriminatory ability of the models for predicting unfavourable outcome at 6 months in the internal validation ranged from 0.66 to 0.87, with the highest discrimination (0.87) reported for the extended model to predict mortality when evaluated in one of the observational studies.

The core and extended models were externally validated in 6681 patients with moderate or severe TBI from the CRASH trial. The area under the ROC for unfavourable outcome was 0.78 and 0.80 for the core and the extended model, respectively. The calibration was poor for all the models when assessed with the Hosmer-Lemeshow test ($p < 0.001$) and graphically. When they restricted their validation to patients from HIC, the discrimination did not change but the graphical display of the calibration for the extended model to predict 6-month mortality improved. The authors presented a simple score with an accompanying figure and also made the models available as a web-based calculator.

The models developed by the IMPACT study share some aspects with those derived from the CRASH trial. The variables included in the IMPACT core model and my included age, pupil reactivity and the GCS (although IMPACT models included the motor component, while CRASH trial included total GCS). Both CT models included subarachnoid hemorrhage as a predictor. A direct comparison of the strength of the association was not possible as the IMPACT study reported proportional odds logistical regression and

the effect measures are not comparable with the one derived from CRASH. Importantly for both studies, internal and external validation was performed. Finally, both studies attempted to make the models easily available to doctors worldwide with a web-based calculator and in a simple paper-based format. However, they presented some differences.

The models developed with data obtained from CRASH trial, were derived from patients from HIC and LMIC, while the IMPACT models were derived only from patients from HIC. Another difference is that the CRASH models were derived from a more recent period (1999-2004) than the IMPACT models (1984-1997). Also, the CRASH dataset had very few missing variables, while imputation methods were necessary to handle the extent of missing data for the IMPACT models. On the other hand, some of the IMPACT models included more variables which have also been shown to be strong predictors of poor outcome (i.e., hypotension, hypoxia, hemoglobin and glycemia). Finally, a common feature of the external validation for both studies was that the discrimination was acceptable, but the calibration was poor when assessed with the Hosmer-Lemeshow test.

37.8 Strengths and Weaknesses of This Study

Among the CRASH prognostic models strengths are the use of a well-described inception cohort of patients, prospective and standardised collection of data on prognostic factors, few missing data, very low loss to follow-up, and the use of a validated outcome measure at a fixed time following the injury. All of these factors provide reassurance about the internal validity of the models. The large sample size in relation to the number of prognostic variables examined is another particular strength.

With regard to its external validity, there are few prognostic models developed from LMIC patients. The models developed with CRASH dataset are the first with a large sample size and adequate methodology and included the complete spectrum of TBI patients ranging from mild to severe. The external validation confirmed the discriminatory ability of the models in patients from HIC and graphically showed good calibration for the CT model. Unlike most published prognostic models, my models. Finally, the data required to make predictions with the model are easily available to clinicians, and a web-based risk calculator was developed.

There are some limitations: the data from which the models were developed originate from a clinical trial and this could therefore limit its external validity. For example, the patients were recruited within 8 hours of injury and the accuracy of the models for patients evaluated beyond this time window cannot be estimated. Nevertheless, the CRASH trial was a pragmatic trial that did not require any additional tests and therefore included a sample of 'real-world' patients. Furthermore, not including other predictors such as hypotension and hypoxia. However, although these variables have been reported to be independent predictors, it has also been shown that they do not add much to the performance of prognostic models after most important predictors (age, GCS and pupil reactivity) are already entered into the model.

Another limitation was that the models validation came from HIC.

Furthermore, the variables "major extracranial injury" and "petechial hemorrhages" were excluded because they were not available in the IMPACT sample. However, neither of these variables were among the strongest predictors. The external validation showed good discriminatory ability, albeit somewhat lower than in the original data.

37.9 Implications

37.9.1 Implications for Patients in LMIC

Most of the burden of TBI is on LMIC countries where case fatality is high and resources are limited. Several predictors differed in their strength of association with outcome according to a country's income level, suggesting that it may be inappropriate to extrapolate from models based on HIC populations to poorer settings. Prognostic models developed with CRASH trial dataset, showed good discrimination and good calibration in this setting.
However, GCS used as a continuous variable demonstrated an acceptable ability to discriminate poor outcome in TBI patients from LMIC. When the discrimination was evaluated with categorical GCS, as is used in clinical practice (i.e., mild, moderate and severe), its discrimination was lower.
In terms of calibration, the models showed better agreement than total GCS between predicted probability and observed outcomes when analysed graphically, particularly for those patients with intermediate risk.

37.9.2 Implications for Patients in HIC

Basic and CT models showed good discrimination, and the latter showed the highest discrimination of all the models developed. The calibration of the models was good when evaluated with the Hosmer-Lemeshow test. Most importantly, the models kept an acceptable discriminative ability when externally evaluated, although the calibration, in particular for the basic model, was poorer.
Both models substantially increased the discriminatory ability of GCS. The CT model in particular showed very good calibration in the external validation in this setting.

37.9.3 Other Implications

These prognostic models have important implications in clinical decisions and can also inform research purposes, for instance, in the design and analysis of clinical trials, through prognostic stratification, or they can be used in clinical audits by allowing adjustment for case-mix.

37.10 Future Research

The differences between the prognostic models for LMIC and HIC patients are important. Although most of the burden of trauma occurs in LMIC, most research takes place in HIC. Very few prognostic models for TBI have been developed in LMIC. More research is therefore needed in the LMIC to obtain reliable data from these settings. An improved understanding of the differences between these regions might also clarify the mechanisms of predictors that are not immediately obvious when analysing a homogeneous population.
The models were developed and validated through a rigorous methodological process to ensure their internal validity. However, for prognostic models to be used, they need to be user friendly. Research into the different ways of presenting the models to physicians is needed to ensure that they are of practical use in the clinical setting.

As the CRASH models were developed using data from a clinical trial, further prospective validation in independent cohorts is needed to strengthen the generalizability of the models. The future challenge is to evaluate their impact on patient outcomes.

38.1 Introduction

Trauma-induced spinal cord injury (SCI) and the deficits in sensory and motor function associated with it constitute one of the most devastating of critical illnesses. The ensuing disability and impairment deeply undermine self-esteem and productivity, placing an enormous socioeconomic burden on the individual, the family and the community as a whole. The estimated incidence of traumatic SCI resulting in quadriplegia is 30-40 cases or 100,000 inhabitants per year, with 6000 new cases annually in Brazil, one new case per day in the State of Parana alone, and one person every week in the city of Curitiba. It predominantly affects young males (80%); the average age of patients in most published studies is around 25 years. The cervical spine is the most vulnerable segment, accounting for 50% of cases. The other 50% refer to the thoracic (29%), lumbar (15%) and sacral (4%) segments. The most frequent causes are motor vehicle accidents (approx. 60%), falls, including diving in shallow water (20%), urban violence (15%), sports (4%), and work-related accidents (1%). Only 5% of spinal injuries occur in children. In children less than 9 years of age, 67% of spinal injuries involve the upper cervical spine (occiput-C2). Unlike head trauma in adults, the mortality rate is higher in children, and the leading cause of death is related to injuries other than the spinal lesions. Early identification of traumatic SCI at the accident site is essential for optimizing the recovery of these patients. The identification of patients at risk is the first step in the pre-hospital care of SCI. Risk groups are:

- All victims of serious accidents.
- Trauma patients with loss of consciousness.
- Trauma patients with minor complaints about the spine (lower back or neck pain or muscle contracture) or the spinal cord (partial loss of sensation or numbness, weakness, paralysis).
- Signs suggestive of SCI: abdominal breathing, priapism.

Some 20% of all patients with SCI have a second serious spinal injury at another level not always accompanied by the primary SCI. Such patients often have other concurrent injuries either directly associated with SCI, including arterial dissection (carotid and/or spinal artery), or not related to thoracic trauma and/or abdominal pain.

Although the nature of SCI, its causes and consequences have been known since antiquity, and despite considerable advances in its treatment, the main obstacle that has remained since Hippocratic times is that the damaged neurons do not heal. Hence, the focus of therapy is injury prevention and rehabilitation.

In 1927 Cushing published a series of cases of cervical spinal trauma seen in soldiers during the First World War, reporting 80% mortality in the first 4 weeks, mainly due to respiratory tract infections or decubitus sores. These figures have changed considerably

since then. In a series published by this author of 230 patients treated for cervical subaxial fractures (C3-C8) over a 5-year period (1996 to 2000), the survival rate was 94%. That many survive with severe neurological sequelae argues for the creation of specialized rehabilitation centres, as has been done in some areas of the country.

The main advances in recent years have derived from a better understanding of the pathophysiological mechanisms underlying the genesis of SCI. Two types of injury are involved in determining neurological injury of the spinal cord: primary and secondary injury. Primary injury (passive) results from the kinetic forces to the spinal cord during the accident, causing loss of normal nerve impulse transmission and acute paralysis. The primary injury is composed of morphological, metabolic and electrolyte alterations. Morphological changes include: petechiae, hemorrhages, axonal swelling, rupture of the myelin sheath, ischemic endothelial injury, and hemorrhagic necrosis. The metabolic changes are mainly characterized by altered glucose utilization, with an increase in glucose consumption in the first hour after injury, anaerobic glycolysis due to the decreasing oxygen content in the tissues, the subsequent reduction in ATPase activity of the enzyme, and interference with the cell's energy production. This cascade of events leads to abnormalities in calcium, sodium and potassium electrolyte levels due to the abnormal flow of electrolytes into the cells and the release of metabolites and lysozymes.

Secondary injury, mediated by active cellular and molecular processes, occurs over the hours and days after the accident. It involves the activation of an inflammatory cascade, where post-traumatic ischemia leads to changes in calcium metabolism, formation of edema and free radicals, release of excitatory amino acids and endogenous opioids. This mechanism results in oxidation, lipolysis and cell death, and represents the main therapeutic window in spinal trauma.

38.2 Terminology

38.2.1 Standards for Neurological and Functional Classification of SCI

In response to disparate SCI classification schemes which hindered the interpretation of results and comparison across patient series and different types of treatment, the American Spinal Injury Association (ASIA) called together an interdisciplinary commission (in-

Point	Description	Explanation
A	Complete	No sensory or motor function preserved, including absence of anesthesia and anal contractions and anesthesia in segments S4-S5
B	Sensory incomplete	Sensory but not motor function is preserved below the neurological level and includes the sacral segments S4-S5 (light touch, pin prick at S4-5 or deep anal pressure) and no motor function is preserved more than 3 levels below the motor level on either side of the body.
C	Motor incomplete	Motor function is preserved below the neurological level and more than half of key muscle functions below the single neurological level of injury have a muscle grade <3 (grades 0-2)
D	Motor incomplete	Motor function is preserved below the neurological level and at least half of key muscle functions below the neurological level of injury have a muscle grade ≥3
E	Normal	If sensation and motor function as tested with the International Standards for Neurological Classification are graded as normal in all segments, and the patient had prior deficits

Table 38.1. ASIA (American Spinal Injury Association) Impairment Scale (modified from Frankel).

cluding experts from neurosurgery, orthopedics, physical rehabilitation medicine, physiotherapy and epidemiology) to unify the standards for SCI evaluation and to allow accurate communication between different health services. In 1992 the committee published its own classification system: the International Standards for Neurological and Functional Classification of SCI (ISNCSCI 3rd revised edition).
Through a systematic examination of specific dermatomes and myotomes, as described below, one can determine the segment affected by SCI. This test allows the definition of several indicators of neurological damage, for example: Neurological Level, Sensory and Motor Speed (right and left sides), Sensitivity Index (pain and sensitivity to light touch), Motor Index, and Zone of Partial Preservation.
The protocol developed by ASIA also introduced the ASIA Impairment Scale (AIS) (which replaces the modified Frankel classification) and the recommended Measure of Functional Independence (FIM), a new approach to assess the impact of SCI on activities of daily living and functions and to assess a patient's capacity and progress in rehabilitation (Table 38.1).

38.2.2 Sensitivity Examination

This exam involves testing the sensitivity of specific points (key points) in 28 dermatomes on the left and right sides of the body. In each of these key sensory points pain sensitivity (using a pin prick) and sensitivity to light touch (light touch with cotton) are examined. The perception of pain and sensitivity to light touch at each of the key points is scored on a scale of 0 to 2:

- 0: Absent.
- 1: Altered (or partial perception altered, including hyperesthesia).
- 2: Normal.
- NT: Not testable.

When one examines the perception of pain, the patient's inability to distinguish between blunt sensation (pin head) and the tip should be scored as 0 (absent). Table 38.2 shows the location of the key sensory points.

Point	Description
C2	Occipital protuberance
C3	Supraclavicular fossa
C4	Upper border of the acromion – clavicular joint
C5	Lateral border of the antecubital fossa
C6	Thumb
C7	Middle finger
C8	Little finger
T1	Medial (ulnar) from the anticubital fossa
T2	Apex of the axilla
T3	Third intercostal space (IC)*
T4	Fourth IC space (nipples)*
T5	Fifth IC space (between T4 and T6)*
T6	Sixth IC space (at the level of the xiphoid process)*
T7	Seventh IC space (half way between T6 and T8)*
T8	Eighth IC space (half way betweenT6 and T10)*
T9	Ninth IC space (half way between T8 and T10)*
T10	Tenth IC space (navel)*
T11	Eleventh IC space (half way between T10 and T12)*
T12	Midpoint of the inguinal ligament*
L1	Half the distance between T12 and L2
L2	Middle third of anterior thigh
L3	Internal femoral condoyle
L4	Internal malleolus
L5	Dorsum of the foot at the level of the third metatarsophalangeal joint
S1	Outer edge of the calcaneus
S2	Midline of the popliteal fossa
S3	Ischial tuberosity
S4-S5	Perianal area (evaluated as a single level)

Table 38.2. Key sensory points.
* Indicates that the point is in the middle clavicular line

Assessment of postural sensation and perception of pressure or pain is considered optional for in-depth evaluation of SCI. If examined, it is recommended to classify them using the same sensitivity scale (absent, altered, normal). When examining an extremity, the index finger and the first toe on each side of the body should be tested.
Besides these key sensory points, during the digital rectal exam, you should try to assess the deep anal pressure, which will be used along with the perianal sensitivity score (S4-S5) for determining whether the injury is complete or incomplete.

38.2.3 Motor Examination

This exam tests 10 specific muscles (key muscles) on both sides of the body graded on a 6-point scale (Table 38.3). Table 38.4 lists the key muscles to be examined.
In addition to the examination of these muscles, the external anal sphincter should be examined for contraction around the finger of the examiner and the voluntary anal contraction classified as present or not (yes or no on the form). The latter information is used exclusively to determine if the injury is complete or incomplete.
As an option, other muscles should be examined to assess motor function in SCI; however, the results are not used to determine the motor index, motor level, or complete injury. It is suggested that the following muscles be examined: diaphragm, deltoid, and crural biceps. Muscle strength is scored as absent, weak or normal.

Point	Description	
0	Without contraction (total paralysis)	
1	Visible or palpable muscle contraction without movement	
2	Active movement without gravity	
3	Active movement against gravity	
4	Active movement against gravity	• 4- light resistance • 4 moderate resistance • 4+ high resistance
5	Normal active movement against gravity and sufficient resistance to be considered normal if inhibiting factors (i.e., pain, disuse) are not present	
NT	Not testable	

Table 38.3. The 6-point scale.

38.2.4 Sensitivity Index and Sensitivity Level

The sensory scores (0, 1 or 2) noted on the grid generate four values: pin prick right and left sides and light touch right and left sides, with a maximum score of 56 for each side. Adding the pin prick and light touch scores for both sides of the body yields the total pin prick and light touch score (maximum 112 each). The sensory index is a numerical way to document altered sensory function, allowing for comparison and analysis of the patient's evolution over the following days.
The sensory level on each side of the body is defined as the most caudal dermatome where the sensory score is normal (score=2) for both pin prick and light touch. The zone of partial preservation (ZPP) is defined as the region on each side of the body where sensory function (not absent) is present but not normal (score=1).

	Muscle
C5	Elbow flexors (biceps)
C6	Wrist extensors (extensor carpi radialis brevis and longus)
C7	Elbow extensors (triceps)
C8	Finger flexors (distal phalanx of middle finger)
T1	Finger abductor (little finger)
L2	Hip flexors (ileopsoas)
L3	Knee extensors (quadriceps)
L4	Ankle dorsiflexors (tibialis anterior)
L5	Long toe extensors (extensor hallucis longus)
S1	Ankle plantar flexors (triceps surae)

Table 38.4. Muscles to be examined.

38.2.5 Motor Index and Motor Level

The test grades motor function of the right and left sides of the body. The total scores are obtained by summing the scores of the different muscle groups (0-5) on each side of the body. The motor index provides a means to document motor function numerically.
Determination of the motor level differs from that used to define the sensory level. This is due to the fact that most muscles are innervated by a single peripheral nerve formed by nerve roots from more than one nerve segment (usually two segments). So the selection of a muscle or a muscle group, or a key muscle in this case, to represent a single spinal segment is a simplification, which is the idea that subsidies in any muscle, the innervation by one segment and the absence of innervation by another segment will result in a weakened muscle. Briefly, a muscle with function graded 3 at least is considered to have intact innervation from the proximal segments. To determine the motor level, the proximal key muscle should have a grade of 4 or 5, since this muscle has two intact segments that innervate it. For example, if there is no response of the key muscles of C7 and C6 has a grade of 3, then the motor level of the body that was examined is C6, and C5 for the muscle to do so, will have a grade of at least 4.
The examiner will determine if the muscle with a grade 4 is completely innervated. This is necessary because in some patients several factors could inhibit maximum effort during the clinical examination at certain stages after injury. Examples include pain, patient position, hypertonicity and disuse. A grade 4 should not be considered normal if the examiner finds that none of these factors inhibiting pain is present and the patient is doing his utmost and still has only grade 4.
In conclusion, the motor level (the lowest motor segment with normal function, which can differ for the two sides of the body) is defined as the lowest key muscle that has at least grade 3, if the muscles in the segment above this level are classified as normal (grade 4 or 5).

Type of Injury

Complete Injury

There is no preservation of motor or sensory function below the neurological level of injury, including lack of voluntary anal contraction and sensation of the anal and perianal region. The ASIA classification emphasizes the importance of examining perineal sensation and anal contraction in the diagnosis of complete injury, because they are the most sacral fibres in relation to the internal somatotopic organization of the tracts and the most protected from injury. About 3% of patients with complete injury at initial examination will recover some function within 24 hours. The persistence of complete injury over 24 hours indicates that the probability of recovery of distal function is practically nil.

Incomplete Injury

Any residual sensory or motor function below the injury must be included in the concept of distal protection:

- Preservation of sensation (including sense of position) or movement in the lower limbs (including isolated voluntary finger flexion(s) of the foot).
- “Sacral preservation” preserved perianal sensitivity (sensitivity in the union of perianal skin and mucosa, as well as deep anal sensitivity) and counter-voluntary external anal sphincter on digital examination.
- For the characterization of incomplete injury, the contraction is voluntary and not an anal reflex. An injury should not be considered incomplete if there are preservation, isolation, and sacral reflexes (e.g., bulbocavernous). Priapism is a sign often associated with complete injuries.

Types of incomplete injury are:

- Brown-Séquard syndrome (ipsilateral proprioceptive and motor and sensory loss of contralateral pain and temperature).
- Central cord syndrome (occurs almost exclusively in the cervical region, with preservation of sacral sensitivity and greater weakness in the lower than the upper region).
- Previous marrow syndrome (produces a loss of motor function and sensitivity to pain and temperature, while preserving proprioception).

The term "**spinal shock**" has been used to characterize two different situations which occur simultaneously in SCI:

- Hypotension (shock) is observed in patients with SCI (arterial blood pressure is usually around 80 mmHg), which is caused by multiple factors:
- Loss of muscle tone due to paralysis of skeletal muscles below the level of injury resulting in venous plethora and therefore relative hypovolemia.
- Interruption of the sympathetic with: loss of vascular tone (vasoconstriction) below the level of injury; parasympathomimetic neurotransmitter inhibition without bradycardia.
- Blood loss, injuries associated with true hypovolemia.
- Transient loss of all spinal reflexes below the level of injury accompanied by paralysis lasting a variable period of time (approximately 2 weeks to several months); its resolution is manifested by spasticity below the level the lesion.

38.3 Initial Treatment

Patients with SCI are admitted to the intensive care unit (ICU) for two reasons: hemodynamic or respiratory instability due to trauma associated with spinal cord injuries or severe injury. One should take into account that the therapeutic options in traumatic SCI are based on the potential for reversal of pathophysiological changes that occur after trauma and that determine the irreversibility of the injury or its aggravation. These changes include: ischemia, hypoxia and lipid peroxidation, and will dictate the most important initial care.

38.4 Spine Immobilization

The spine should be immobilized before removing the patient from the accident site and maintained during transport to prevent active or passive movement of the spinal column. Patients with traumatic spinal cord injury admitted to the ICU, especially if unconscious, must remain immobilized and retained on the transport stretcher with containment systems, such as sandbags and supports or hard paste (Philadelphia type), until fixation and fracture stabilization.

38.4.1 Cervical Traction

Cervical traction serves to reduce displacement fractures, restore spine alignment, and immobilize it to prevent subsequent damage. The three most commonly used devices for this purpose are: the pin type (blunt pins requiring skin incision and pre-drilling of the skull), Gardner-Wells pins (more practical and often used), and fixing rings (mainly used with a halo vest).

For placement of the pins of Gardner-Wells tongs, the patient is positioned on a stretcher to facilitate access to the cranial region, the temporal region of the head is shaved, an antiseptic (PVP-iodine) is applied to the skin, and a local anesthetic infiltrated (lidocaine with epinephrine or xylocaine with epinephrine 1:200,000). The insertion point is located in the temporal crest, immediately above the insertion of the temporalis muscle, 3-4 cm above the pinna. The head is pulled into a neutral position in line with the spinal column. An insertion point 2 cm posterior will achieve flexion (facet block) and a point 2 cm above will achieve extension. The skin may or may not be incised at the site; however, it is useful to mark the spot where the insertion is performed in order to place the device in symmetrical traction. Both pins should be pushed simultaneously to the limit while feeling bone resistance. The pins should be checked 24 hours later and retightened to prevent them from loosening. If the intention is to maintain traction and there is no need to correct subluxation, traction should be applied initially with weights of 2.5 kg to higher segments (up to C4) and 5 kg for the lower segment at a maximum of 10% body weight in adults. To reduce blocked facets, the rule is:

$$\text{Weight (kg)} = 1.5 \times \text{Number of the affected segment}$$

You can increase the weight (2 kg each time) every 15 minutes, with radiographic control (X-ray in profile), up to 25% of body weight. Relaxation of spinal muscles can be achieved with diazepam 50-10 mg IV, taking care not to sedate or cause respiratory failure. Once achieved, the reduction is maintained at a weight of 2.5 to 5 kg.
The patient should be kept under daily radiographic control or repeated after each move or transport.
The main steps to be taken are:

- Check for neurological deterioration after reduction due to extrusion of disc herniation with spinal cord compression (if neurological worsening is observed, magnetic resonance imaging scan should be obtained).
- Do not hold in traction fractures involving the occipito-C1 segment or hanged fractures (hangman or traumatic spondylolisthesis of the axis).
- Do not pull the pin in children <3 years of age.
- Avoid penetration of the skull: set too low (in the temporal squama) in osteoporotic bone or excessive pressure.

38.5 Maintenance of Blood Pressure

Blood pressure should be monitored closely and mild hypertension induced to ensure adequate spinal cord blood flow in the first hours after trauma. Fluid replacement is a crucial point in initial therapy and the infusion of an appropriate combination of crystalloids and colloids will depend on the presence of associated lesions and urine output. One must be careful, however, to avoid overhydration, which can lead to overloading of the right heart chambers and pulmonary edema.
Because there is traumatic sympathectomy, and the predominant tone of the parasympathetic autonomic nervous system, as an adjunct in the treatment of refractory hypotension, dopamine (2-5 μg/kg/min) is recommended provided there are no other contraindications, mainly due to injuries to other organs. Phenylephrine should be avoided because it has a positive inotropic action and because of the possible effect of increased vagal tone, leading to intense bradycardia. Atropine (0.5 mg) can be used to aid in the treatment of bradycardia.

The use of pneumatic or medical antishock trousers (MAST) can be useful to stabilize the lumbar spine and compensate for the loss of vascular tone in the lower limbs, preventing venous retention.

38.6 Maintenance of Oxygenation

In SCI patients, paralysis of the intercostal muscles (neck injury) and even the diaphragm (lesions above C4) will determine situations of inadequate ventilation.
Hypoxia in the injured spinal cord regions will contribute to worsen the pathophysiological cascade known to occur after trauma; therefore, it is extremely important to maintain adequate oxygenation by closely monitoring changes in blood gases, if possible with appropriate probes and registers. Arterial blood gases should be obtained at regular intervals. Clinical signs of agitation, restlessness and disorientation signal insufficient oxygen and should be observed closely.
To maintain adequate oxygen supply (fraction of inspired oxygen [FiO_2] and ventilation), one can resort to:

- A nasal breathing tube
- Intubation. If intubation is indicated in the presence of cervical SCI, it must be done without moving the spinal column (without producing extension) by means of blind nasotracheal or flexible fiberscope intubation. Tracheotomy may sometimes be necessary.

Although a multicenter, randomized, double-blind trial (NASCAR II) compared three groups (methylprednisolone (n=162), naloxone (n=154) and placebo (n=171); however, some design flaws can be observed and are grounds for criticism:

- There were no pre-established anatomical limits.
- Patient selection did not require a minimum motor impairment for inclusion.
- Patients were randomized to treatment within 12 hours yet the study concluded that 8 hours was the “cut-off time”.
- Medical treatment (monitoring, blood pressure, respiratory care, deep venous thrombosis prophylaxis, nutritional support and early rehabilitation) was not taken into consideration among the different centres.
- Surgical treatment was not specified in terms of protocol treatments for the same types of injury.
- It was not reported whether the modest clinical improvement observed affected the measure of independence function.
- There were potential statistical errors of interpretation: it was not clear which statistical methods were used and why when comparing the groups, there was simplification of subgroups, incomplete presentation of odds ratios and post hoc analysis; ultimately, findings were graded as evidence class.

The prognosis worsens if treatment is started 8 hours after injury.
Duration of the maintenance infusion initiated within 3 hours of trauma must be maintained for 8 hours. If started between 3 and 8 hours after injury, there may be a greater benefit with infusion at the same dosage for 47 hours, with a slightly higher risk of infection and pneumonia (NASCIS III).

38.6.1 Monsialoganglioside GM1

There is growing evidence that substances like monsialoganglioside GM1 (SYGEN®) may affect neuronal survival by exerting an action like that of neurotrophic factors. As ob-

served in vitro and in vivo, its mechanism of action rests is similar to that of neurotrophic factors, with a direct anti-apoptotic action on tyrosine kinase receptors (TrK), preventing DNA fragmentation. In a study published by Geisler in the United States, involving about 800 patients, the use of GM1 was compared versus placebo. The results were favourable, with improved sensory and motor function observed in the GM1 treated group.
Dosage:

- Initial dose: 300 mg as loading dose (IM or IV).
- Maintenance dose: 100 mg/day for 30 days (IM or IV).

The drug should not be administered concomitantly with methylprednisolone because its effect does not appear to show synergism of action but competitiveness instead.

38.6.2 Other drugs

Tirilazad (a drug with action similar to methylprednisolone but without most of the side effects), naloxone, calcium channel blockers, antioxidants and free radical blockers, neurotrophic factors, are among the drugs being investigated for the pharmacological treatment of SCI; however, no evidence of their effectiveness has been forthcoming.

38.7 General Care of SCI Patients

38.7.1 Nasogastric Tubes

Nasogastric tubes are especially useful for suction, to prevent vomiting and aspiration, and to decompress the abdomen if distended, which can interfere with breathing. Ileus is common in the acute stage and may last several days. Unless there are contraindications, nutrition should be initiated early.

38.7.2 Bladder Catheterization

In the acute stage, exacerbated by the degree of hypotension, there is a significant reduction in the captive volume of urine produced, up to complete anuria, which can last from 3 to 12 hours. In the acute phase, the bladder is unable to empty by reflex (so-called areflexic bladder). This occurs even in cervical lesions, and can progress to spastic bladder. Placement of a urinary catheter (Folley catheter) is useful at this stage, especially for tight control of urine output, which will serve to guide fluid restoration and prevent bladder distension due to urinary retention.
Placement of an indwelling catheter, however, to keep the bladder sphincter open, predisposes in the long term to atrophy with a higher probability of urinary incontinence. As it is necessary to keep the bladder in a regime of low pressure, preventing vesicoureteral reflux and hydronephrosis, limiting the likelihood of infection and preventing incontinence, intermittent bladder catheterization should be instituted as soon as the patient's general condition is stabilized (usually within 24 hours), then replacing the indwelling catheter.

38.7.3 Thermal Regulation

Vasomotor paralysis produces a state of poikilothermia (loss of temperature control). One must be careful to avoid situations of hypothermia in cold weather, keeping the pa-

tient warm with blankets or thermal quilts, as well as situations of hyperthermia, which can be particularly harmful in acute SCI. Spraying water on the skin of the limbs and trunk or applying cold compresses are useful and practical measures to promote heat exchange on hot days.

38.7.4 Skin Care

Prevention of decubitus sores should be initiated starting from the time of admission of the SCI patient to the ICU. Care should be taken to avoid prolonged periods on long on hard surfaces (transport boards, X-ray or CT table), the bed kept dry with sheets stretched at all times, and the skin kept hydrated. Whenever possible, the patient should be mobilized, even as a block, at least every 2 hours. In patients with major instabilities, guards with special air or water mattresses or supports with gel or water bags at the points of greatest pressure should be placed (ankles, heels and sacral region, elbows and shoulder blades). The recognition of areas of hyperemia or catastrophic skin changes should initiate more aggressive therapeutic measures, including massage with moisturizing oils and creams, while preventing direct contact between body areas and hard surfaces.

38.8 Laboratory Evaluations

38.8.1 Radiological Evaluation

The proper treatment of spine fractures relies on accurate radiological examination. Several techniques available, including: plain radiographs of the spine, dynamic studies in flexion/extension, computed tomography (CT), myelography and CT myelography, and magnetic resonance imaging (MRI). Each o has its advantages and their combined use will allow visualization and assessment of bone structures, ligaments, the compromising stability, spinal cord, and soft tissues.
It is generally agreed that bone structures are more visible on plain radiographs and that CT and MRI allow better visualization of the spinal cord and soft tissues.

X-ray

The Advanced Trauma Life Support (ATLS) instruction manual recommends that a profile radiograph of the cervical spine be obtained in all patients with multiple trauma. Additional views such as anteroposterior (AP) and transoral may be necessary, especially in patients with neck pain or muscle spasm revealed by palpation of the vertebral tissues, those with a supraclavicular injury, or those with high-speed, high-impact injuries, such as ejection from a moving vehicle.
X-ray of the thoracic and lumbar spine should be obtained in all trauma patients who: 1) have been thrown out of a moving vehicle or fallen from height >3 m; 2) complain of chest or lumbar pain; 3) are unconscious; 4) are unable to refer back or chest pain or have altered mental status examination that prevents a correct evaluation of the back; 5) present with injury sustained from an unknown mechanism of trauma, or other lesions that suggest SCI.
The correct interpretation of cervical spine X-rays depends on adequate visualization of the cervicothoracic junction. For the radiograph to be declared as satisfactory, there is no need to see at least the upper plateau of T1. Failing that, this view should be repeat-

ed with a lateral view of the caudal traction arms. If you still cannot view the cervicothoracic junction, radiographs should be obtained in the swimmer position (incidence of Fletcher). If it is not displayed, and the patient is neurologically intact, the patient remains in a collar and seeks a planar tomography (single) (polytomogram) in a non-emergency or if there is a neurologic deficit, a CT scan of the spine at levels not seen properly should be performed. In this case, reconstruction or three-dimensional sagittal reconstruction can be useful for assessing the alignment.

The cervical spine radiograph is evaluated in a sequence of steps:

- **Evaluation of alignment**. Observe four lines superimposed over the radiograph and define their outline. The first line (marginally above), the smoother, less curved than the others, the convexity above, is formed by a line joining the front edge of the vertebral body. Two similar lines tangential to the posterior edge of the body and the base of the spinous processes (and subsequent marginal spinolaminar lines). These two lines enclose the spinal canal. The last line is traced following the union of the tips of the spinous processes.
- **Evaluation of the odontoid process**. Measure the distance between the posterior arch of C1 and the odontoid process. In children this distance can be up to 5 mm, while the adult it should not exceed 2 mm.
- **Swelling or bruising of the soft parts**. The space between the front edge of the upper cervical vertebrae and the pharyngeal air column has at most two thirds the thickness of the body of the second cervical vertebra. Below the C3-C4 level the prevertebral soft tissue should not exceed the anteroposterior diameter of the vertebral body. Sometimes the observation of these changes, even in the absence of obvious fracture or dislocation, serves as an indicator for a more thorough investigation with CT or MRI.
- **Intervertebral spaces and vertebral bodies**. Intervertebral distances may be altered in cervical degenerative disc disease, usually, with accompanying osteophytes. The evaluation of the regularity of the contour of the vertebral bodies may show fractures with displacement of fragments. A characteristic feature is the displacement of a small fragment of the plateau above the lower vertebra, which is accompanied by a sagittal fracture of the body and displacement of fragments into the canal, known as the tear drop fracture.
- **Interspinous distances**. Abnormal opening or spacing of a pair of spinous processes reveals a ligament rupture. AP projection should be obtained to analyze the interspinous distance. If it is 1.5 times greater than that of both adjacent levels, this indicates posterior ligament rupture. AP projection will display alignment of the spinous processes in the midline, which is altered with lateralization of one, when there is unilateral blockade of the facets.
- **Dynamic imaging studies**. It is possible to observe situations of pure ligamentous injury with trauma, involving posterior ligament complex rupture without fracture. Flexion-extension can help detect these lesions, aiming to find hidden instability. If head bending is limited due to muscle spasm of the spine, a hard paste (Philadelphia) should be applied and the radiographs in flexion/extension repeated within a week or two. It is recommended that this study be performed by a radiologist or under the supervision of a neurosurgeon. The patient must be conscious and cooperative (to avoid dynamic study in traumatic brain injury patients, or under the influence of drugs or alcohol). You should not notice any dislocation >3.5 mm in the previous X-rays, in which case the instability is already defined. Patients must be neurologically intact. If there is neurologic deficit, other type of imaging study, for example, MRI, should be done. The patient should be placed in a chair and instructed to flex the neck slowly and stop when he beings to feel pain. X-ray series are ob-

tained at intervals of 5-10 degree increments in flexion or extension, and if normal, the patient should be encouraged to go ahead. This is repeated until a diagnosis of instability is made, or the patient cannot flex due to pain or limited mobility. The study of flexion/extension may show mild subluxation in all cervical spaces but always with displacement

38.8.2 Computed Tomography

Computed tomography (CT) has proven extremely useful in assessing spinal trauma. The level to be studied can be determined by the abnormalities found on the radiograph or the simple level of neurological deficit, identified clinically, if the chest X-rays are normal or inconclusive. This happens most often with thoracolumbar than with neck fractures. CT allows perfect delineation of the vertebral bodies and determining the integrity of the spinal canal. It should be made thin sections (1.5 to 3 mm), the levels of suspicion, and sagittal or three-dimensional reconstruction techniques can be useful for assessing alignment of the vertebral bodies. CT is not a screening test for spinal trauma. Determination of an inadequate level to be examined, by either inappropriate radiographs or incorrect clinical assessment, can cause injuries to go unnoticed. Although highly accurate in demonstrating blocking facets and retropulsion of fragments into the canal, sometimes subluxations cannot be revealed.

38.8.3 Magnetic Resonance Imaging

Until the introduction of MRI, no radiological method was able to directly visualize the traumatized spinal cord. MRI can show precisely ligament injuries and damage to the spinal canal by bone fragments, herniated disc, epidural hematoma or subluxation. However, it is the direct visualization of the spinal cord, al-

Figure 38.1. Plain radiograph showing cervical spine fracture and dislocation of C5-C6 with bilateral locking of facets.

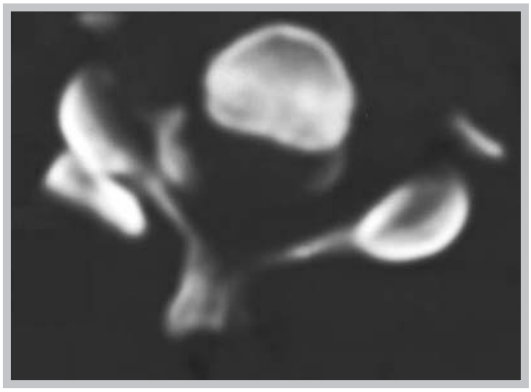

Figure 38.3. Axial tomography of the spinal column showing unilateral facet lock on the left.

lowing the diagnosis of spinal cord transection, contusion, edema, or ischemia hematomyelia that makes MRI superior to all other methods. MRI should be performed in situations of incomplete injury, alignment with normal or no apparent bone lesion, to exclude cord compression by soft tissue such as disc herniation or hematoma. It is also indicated in situations of deterioration, with worsening of the deficit or new deficit, or when the fracture level differs from the level of the deficit observed.

The disadvantages of MRI are that it is not always possible to perform in acutely traumatized patients, it is unavailable in many emergency rooms, and it is not impossible to perform in patients under respiratory or cardiovascular support. Access to manoeuvre the patient can be extremely difficult and MRI takes longer to perform than CT. MRI in a patient wearing a cervical collar is not always possible or will produce images of poorer quality. Patients in traction and wearing metal devices are also ineligible for MRI.

Figures 38.1-38.6 show some examples of laboratory findings.

38.9 Surgical Treatment

The aim of surgical treatment of spine fractures is to decompress the spinal cord and protect it, restore stability, and promote neurological recovery. In many cases, however, stability can be achieved with the use of external orthoses (vests, halo traction, etc.).

Some types of fractures are inherently unstable and require surgery with internal fixation. In such circumstances, opinions differ about what should be done (anterior, posterior, type of instrumentation) and when it should be done (immediate surgery, early or late).

The only universally accepted indication for immediate surgery is progressive neurological deterioration in a patient with spinal canal stenosis due to bone fragments, disc, or hematoma, or an irreducible dislocation. Also, spinal cord compression in a patient with incomplete neurological injury is allowed in some centres as a criterion for immediate decompression.

Figure 38.6. **MRI of the cervical spine (T2). Postoperative C5 corpectomy. Note the signal change in the vertebral bodies corresponding to the implant material (screws and plate) and the signal change in the spinal injury showing hemorrhagic contusion and perilesional edema.**

There are several published studies showing increased morbidity and neurological deterioration after early surgery for traumatic SCI. In contrast, more recently, several authors recommended early surgical intervention, especially in the anterior cervical spine, to allow early mobilization of the patient and reduce complications. In fact, the SCI patient is susceptible to various systemic and neurological complications despite treatment, including pneumonia, decubitus ulcer, thrombophlebitis and pulmonary embolism. It seems obvious that keeping the patient immobilized in bed will not help to avoid this type of complication. Wilberger in 1991 showed a significant reduction (by half) of such complications with early surgery without increasing neurological morbidity. One can also argue that decompression of the spinal cord in the acute phase, by reducing the degree of ischemia, can reduce the effect of the secondary pathophysiological cascade that occurs after trauma. In a recent study, a reanalysis of NASCAR II, there was no statistically significant benefit from early or late surgery in relation to the degree of recovery. There was a trend toward better recovery in patients operated on in the first 25 hours or after 100 hours as compared to the intermediate surgery group.

Currently, it is accepted that if surgery is needed for the treatment of a broken column, assuming that the patient is clinically stable, there is no significant increase in risk associated with early intervention and reduction of downtime can be considerably conducive to patient recovery.

38.10 Functional Independence Measure (FIM)

To fully describe the impact of SCI on the individual and to monitor and evaluate the progress associated with treatment, assessment of activities of daily living is performed. The Functional Independence Measure (FIM) is a tool to assess the degree of function; it is widely used in the United States and is gaining acceptance internationally.

FIM focuses on six areas of functioning: self-care, sphincter control, mobility, locomotion, communication and psychosocial interaction. For each area two or more activities/elements are evaluated for a total of 18 items. For example, self-care is composed of six activities: eating, grooming, bathing, dressing the upper body, dressing the lower body, and personal hygiene (Figure 38.7).

Each of the 18 items is evaluated in terms of independence of function on a 7-point scale (Table 38.5).

- 7: Complete Independence. Fully independent.

- 6: Modified Independence. Requiring the use of a device but no physical help.
- 5: Supervision. Requiring only standby assistance or verbal prompting or help with set-up.
- 4: Minimal Assistance. Requiring incidental hands-on help only (subject performs >75% of the task.
- 3: Moderate Assistance. Subject still performs 50-75% of the task.
- 2: Maximal Assistance. Subject provides less than half of the effort (25 to 50%).
- 1: Total Assistance. Subject contributes <25% of the effort or is unable to do the task.

Thus, the total FIM score (the sum of all activities) estimates the degree of disability in terms of safety, dependency on others and devices needed. The profile of scores by area are specific aspects of daily life that are most affected by SCI.

When assessing SCI patients with the FIM, it should be taken into account that the tool was originally developed for evaluating the disabled in general and that it covers broad areas of activities affected by disability. Although we have explored the reliability and validity of the FIM, its validity as an instrument to accurately measure the degree of function across the population with SCI has yet to be demonstrated empirically. For example, it is unclear whether the self-care items are sufficiently sensitive to assess changes in function observed during the rehabilitation of quadriplegics. In addition, we found the items investigating areas of communication and social life less reliable than other areas of evaluation.

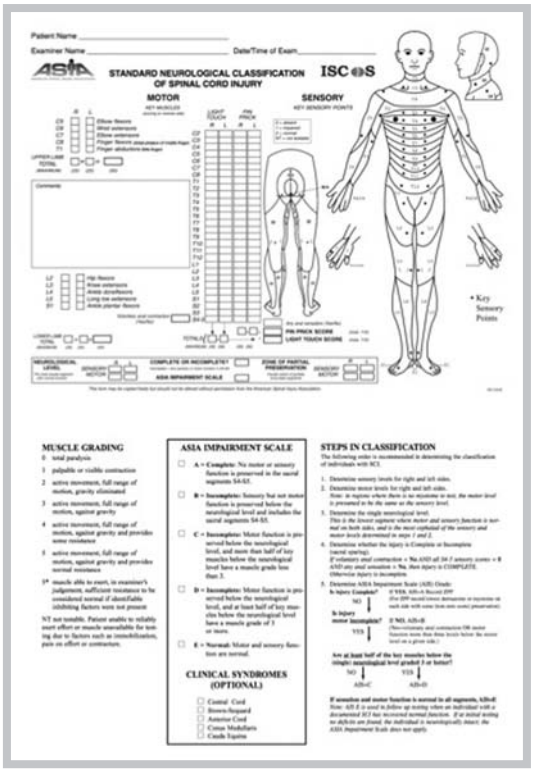

Figure 38.7. FIM form.

Despite these difficulties, we recommend the use of FIM as it is relatively easy to use, reflects major functional aspects in SCI, and the parameters for its use were carefully constructed.

Points	Item	Assistance
7	Total independence (timely, safely)	Not needed
6	Modified independence (extra time, devices)	
	Modified dependence	Needed
5	Supervision (coaxing, cuing, prompting)	
4	Minimal assistance (performs 75% or more of task)	
3	Moderate assistance (performs 50-74% of task)	
	Complete dependence	
2	Maximal assistance (performs 25-49% of task)	
1	Total assistance (performs <25% of task)

39.1 Introduction

In this chapter, we lay the scientific foundation for managing acute spinal cord injury by discussing the definitions of primary and secondary spinal cord injury (SCI). Understanding these concepts is important to implementing effective strategies aimed at reducing long-term neurological deficits. Afterwards, we review the important distinction between spinal and neurogenic shock and outline management strategies for patients suffering from diminished autonomic function. We describe the various spinal cord syndromes that will help clinicians correlate neurological findings to specific areas of pathology in the spinal cord. Lastly, we will cover specific patient management practices and clinical concepts essential to the care of patients during the acute stages of SCI and for optimizing neurological outcome.

39.2 Pathophysiology of Spinal Cord Injury

Acute SCI can be considered in terms of the primary injury, usually as a result of trauma or assault, and the biological mechanisms subsequent to this event, termed secondary injury. It is of critical importance to be aware of these secondary mechanisms because most of the intensive care and surgical strategies performed immediately after the injury aim to limit this damage in the attempt to improve the chances of functional neurological recovery.

Primary SCI refers to the damage inflicted on the neural elements as a result of an acute traumatic event. This can take the form of shear forces disrupting white mater tracts or hemodynamic compromise from blood vessel disruption. This damage occurs at the time of the injury and is, to date, irreversible. Secondary SCI is a se-

Primary mechanisms of injury	• Initial injury to the spinal cord; occurs at the time of trauma • Severing of axons • Cellular death
Secondary mechanisms of injury	A complex cascade of events that invariably follows primary injury: • Hypotension and hypoxia often cause or exacerbate these events • Ischemia • Vasospasm • Delayed axonal loss and apoptosis (programmed cell death) • Ion-mediated cell damage • Excitotoxicity • Neuroinflammation • Mitochondrial dysfunction • Oxidative cell damage

Table 39.1. **Primary and secondary mechanisms of spinal cord injury.**

quence of hemodynamic and biochemical events that occur in response to the initial injury. While a detailed review of these mechanisms is beyond the scope of this chapter, we will highlight a few of the essential mechanisms to offer an introductory understanding. Secondary injury can take the form of systemic hypotension or hypoxia resulting in focal ischemia around the area of injury. Another form of secondary injury occurs at the cellular level and can take the form of ion-mediated cellular damage, excitotoxicity, apoptosis, oxidative cell damage, mitochondrial dysfunction, neuroinflamation or vasospasm. Each of these secondary mechanisms can theoretically be mitigated with various medical or surgical strategies. Such strategies will be outlined in the second and third part of this chapter. A summary of primary and secondary mechanisms of SCI are summarized in Table 39.1.

In managing a patient with a SCI the treating team must adhere to Advanced Trauma Life-support (ATLS) Guidelines. The neurological examination should be done following stabilization of the airway, breathing, circulation and management of any other immediately life-threatening situation. Following this, a neurological examination should be carried out with the following two concepts in mind: spinal shock and neurogenic shock.

39.2.1 Spinal Shock

Spinal shock refers to depressed spinal reflexes caudal to the injury site following SCI. This is an important concept to understand as the initial neurological examination may not be an accurate reflection of disrupted neuronal circuits, including those that control motor and sensory pathways. Normally, these reflex pathways receive continuous input from the brain. When this tonic input is disrupted, the normal reflex pattern is disrupted and can vary from areflexic through to hyperreflexic depending on the time since the original injury.

Ditunno recently proposed a four-phase model to explain the clinical observations that occur caudal to the site of injury [1]. Briefly, these phases are as follows: Phase 1 (from the time of the injury to approximately 24 hours later) is characterized by hypo- or areflexia, which ensues from disrupted descending modulation. Phase 2 (between 24 and 72 hours following injury) is characterized by gradual return of the reflex. This is thought to result from neurotransmitter receptor up-regulation or denervation supersensitivity. Phase 3 (1-4 weeks following injury) is clinically characterized by hyperreflexia, which is the result of axon-supported synapse growth. Phase 4 (1-12 months after injury) is also characterized by hyperreflexia and results from cell-body-supported axon growth. The important point to gain from this discussion is that descending modulation can be suspended in the phase immediately following SCI. Clinically, this translates into the potential for a misleading representation of deficits if spinal reflexes are absent following injury. It is therefore recommended that patients not only be examined on presentation to the treating physician but also at the 72-hour mark following injury.

39.2.2 Neurogenic Shock

Neurogenic shock is a potentially life-threatening condition and must be managed as such. Without a clear understanding of this condition, inappropriate management of a trauma patient, who often suffers concomitant hemodynamic instability, could be fatal. Neurogenic shock is defined as a disruption of the sympathetic nervous system with preserved parasympathetic activity. This typically occurs in patients suffering a severe SCI at the level of T6 or higher. A comprehensive, open-access review was recently published in 2008 [2] and the reader is referred to this for a detailed understanding. The sa-

lient clinical aspects are reviewed here. Disruption of the sympathetic division of the autonomic nervous system has three effects on the cardiovascular system: coronary blood flow, cardiac contractility and heart rate [3]. With preserved parasympathetic activity this translates clinically into bradycardia (and possibly other cardiac arrhythmias) in a setting of profound hypotension [4]. A prudent clinician must look for these characteristics in combination, as many trauma patients are hypotensive as a result of blood loss or intravascular hypovolemia but will mount an appropriate tachycardia response.

The treatment of neurogenic shock is therefore quite difficult. While it is theoretically possible to distinguish between hypovolemic and neurogenic shock, this is not so clinically. In fact, acute trauma patients sustaining a high cervical SCI may suffer from both conditions. It has therefore been recommended by the Consortium for Spinal Cord Medicine to rule out other causes of shock before assuming a diagnosis of neurogenic shock [5]. The practical treatment of these patients rests on initially restoring intravascular volume and if symptoms of neurogenic shock persist, vasopressors (such as dopamine) should be used. The goal of treatment in the first week after sustaining a SCI is to maintain a mean arterial blood pressure of 85 mmHg [6,7].

39.2.3 Spinal Cord Syndromes

A detailed and consistent neurological exam is essential to the management of the patient with acute SCI. We recommend the use of the American Spinal Injury Association and International Spinal Cord Injury Society (ASIA-ISCoS) scale for characterizing the severity of injury [8]. In brief, an ASIA A grade refers to a complete injury with no sensory or motor function present from the level of injury to the sacrum. An ASIA B grade is assigned to a patient with some preserved sensation but no motor function from the level of injury to the sacrum. ASIA C and D grades are differentiated by the absence or presence of grade 3 power (full motion against gravity), respectively. ASIA E is reserved for acute SCI patients who are neurologically intact. A form illustrating how the neurological examination is recorded according to the ASIA-ISCoS standards can be obtained for free from the ASIA website (http://www.asia-spinalinjury.org).

Neurological examination of the patient should be performed immediately following the injury and ideally within 72 hours, especially if spinal shock is suspected. One should be aware of the terminology used to describe deficits and different SCI syndromes. Paresis refers to weakness or partial paralysis. For example, hemiparesis describes weakness on one side of the body. In contrast, both paralysis and the suffix plegia refer to no movement. For example, hemiplegia refers to no movement on one side of the body. Keeping these terms in mind, we turn our attention to spinal cord syndromes that occur when a select region of the spinal cord is damaged, resulting in a predictable pattern of neurological deficit. These syndromes are outlined in Table 39.1 and expanded on in the paragraphs that follow.

Transverse spinal cord lesions disrupt all motor and sensory pathways at and below the level of the lesion. There is a sensory level that corresponds to the level of the lesion. Common causes of this syndrome include trauma or more rarely spinal cord tumours.

Hemi-section of the spinal cord, commonly referred to as the Brown-Sequard syndrome, is characterized by damage to one half of the spinal cord and all motor and sensory pathways at that level and neurological deficits at and below that level. This results in ipsilateral upper-motor neuron weakness and ipsilateral loss of vibration and position sense at and below the level of lesion. There is contralateral loss of pain and temperature sensation below the level of the lesion. There may also be ipsilateral loss of pain and temperature at the level of the lesion for one or two spinal segments if the lesion has damaged

posterior horn cells before the fibres have crossed to the other side. Common causes of this type of injury include penetrating trauma or a tumour compressing only one side of the spinal cord.

Central cord syndrome is commonly caused by a traumatic spinal cord contusion, post-traumatic syringomyelia or a medullary spinal tumour. This lesion tends to affect pathways that are in the immediate vicinity of the central portion of the spinal cord and the symptoms differ depending on the size of the lesion. Small lesions affect the spinothalamic fibres that cross in the ventral commissure and cause bilateral regions of suspended sensory loss to pain and temperature. If the lesion is larger, anterior horn cells, corticospinal tracts and posterior columns may be affected. Loss of these pathways respectively results in lower-motor neuron deficits at the level of the lesion, upper-motor neuron signs below the level of the lesion, and loss of vibration and position sense below the level of the lesion. In addition to suspended pain and temperature loss with small lesions, larger lesions can result in complete loss of pain and temperature below the level of the lesion if the anterolateral pathways are compressed from a medial aspect. Given the spinal cord laminations, sacral sparring is observed.

Posterior cord syndrome involves bilateral loss of vibration and position sense below the level of the lesion as a result of disruption of the posterior columns. If the lesion is large enough, one may observe upper-motor neuron signs below the level of the lesion indicating involvement of the lateral corticospinal tracts. Common causes include trauma or a posterior located tumour. In addition, vitamin B12 deficiency or tertiary syphilis can cause isolated involvement of the posterior columns.

Anterior cord syndrome results in loss of pain and temperature sensation below the level of the lesion (spinothalamic pathways), lower-motor neuron signs at the level of the lesion (anterior horn cell damage) and upper-motor neuron signs below the level of the lesion (lateral corticospinal tracts). In addition, urinary incontinence is common because of the ventral location of the descending pathways controlling sphincter function. Common causes of this syndrome include trauma and anterior spinal artery infarct.

39.3 Acute Management of the Patient With Spinal Cord Injury

The ATLS guidelines emphasize the need to establish and stabilize airway, breathing and circulation in trauma patients. These important steps in resuscitation precede neurological examination or imaging of the neuraxis. Spinal precautions should be implemented throughout resuscitation, with special care to avoid manipulation of the cervical spine during intubation. Major life-threatening thoracic, abdominal or extremity injuries may be masked by SCI. Continuous cycling through primary and secondary trauma surveys should minimize the risk of missing such injuries or changes in neurological function.

39.3.1 Hemodynamic Support and Oxygenation

Serial neurological examination is paramount to detecting any deterioration in function quickly and preventing permanent deficit. Accurate neurological examination may not be possible in a patient who is sedated or under general anesthetic. Furthermore, the pharmacological agents administered may produce hypotension and small vessel vasoconstriction, which can induce further ischemic damage to the injured spinal cord. The period of induction during administration of a general anesthetic may be a period of rel-

ative hypoperfusion secondary to hypotension. Under these circumstances, all members of the health care team must be vigilant in maintaining the hemodynamic parameters outlined in the next paragraph.

As stated in the first part of this chapter, a mean arterial blood pressure of 85 mmHg should be maintained during the first week following SCI [6,7]. Vale et al. employed arterial lines and Swan-Ganz central catheters to monitor patient hemodynamics. Volume resuscitation with crystalloid and blood products were initially used to maintain a mean arterial blood pressure of 85 mmHg. If required, a dopamine (2.5-5 μg/kg/min) infusion was started to meet this target. Mean arterial pressure was further supplemented with levophed (0.01-0.2 μg/kg/min) when needed. When administering vasopressors to the patient with SCI, it is important to avoid agents that would produce vasoconstriction of the small vessels supplying the spinal cord. Aggressive management of mean arterial pressure and oxygenation are one the most important aspects of acute care in the patient with SCI. Similarly, intraoperative blood loss should be closely monitored. Vale et al. administered blood products to keep hematocrit >32%. We often administer blood products early, as opposed to waiting for hemoglobin/hematocrit to reach critical levels [7].

39.3.2 Neuroprotection

Inducing regional or systemic hypothermia for acute SCI aims to minimize secondary injury by lowering enzymatic activity and energy requirements of the injured spinal cord. Many of the studies examining the impact of hypothermia on acute SCI reported the experience in small groups of patients with heterogeneous clinical characteristics. The results were further confounded by the administration of multiple neuroprotective measures simultaneously. Kwon et al. [9] reviewed the relevant literature in 2008 and concluded that there is no compelling evidence that hypothermia (systemic or regional) improves neurological outcome in acute SCI. Furthermore, systemic hypothermia carries an increased risk of bacteremia/infection, coagulopathy, raised intracranial pressure and cardiac arrhythmia. While a randomized control trial to examine the utility of hypothermia in SCI is under development, we do not recommend inducing hypothermia for neuroprotection in acute SCI.

The administration of pharmacological agents to mitigate the effects of primary and secondary mechanisms of acute SCI remains controversial. Methylprednisolone, GM-1 ganglioside, thyrotropin-releasing hormone, nimodipine and gacyclidine have been tested in prospective randomized control trials of acute SCI in humans [10,11]. Only methylprednisolone and GM-1 ganglioside have shown modest benefits in neurological outcome [10]. For the purposes of this text, we will focus on the protocol for administering methylprednisolone in acute SCI.

The National Acute Spinal Cord Injury study (NASCIS I) randomized SCI patients into two cohorts; a 100 mg loading dose of methylprednisolone followed by 25 mg every 6 hours for 10 days in one group, and a 1000 mg loading dose of methylprednisolone followed by 250 mg every 6 hours for 10 days in a second group [12]. There were no differences in neurological outcome between the two groups at 1 year after injury [12]. NASCIS II investigated a 30 mg/kg bolus of methylprednisolone over 1 hour followed by 5.4 mg/kg/h over the following 23 hours and included a placebo group and naloxone administration group [13]. The results from the overall group showed no significant differences in neurological outcome at 6 months, though subgroup analysis demonstrated improved motor and sensory outcomes in the patients receiving methyprednisolone within 8 hours of injury [13]. NASCIS III examined outcomes in acute SCI patients receiv-

ing 30 mg/kg bolus of methypredniosolone followed by 5.4 mg/kg/h for either 23 hours or 47 hours [14]. Patients could be randomized into a third group receiving tirilazad mesylate [14]. The patients treated with methylprednisolone for 48 hours had better neurological outcomes in comparison to the other treatment groups if therapy was initiated within 3-8 hours of injury [14]. The 48-hour regimen was associated with an increased risk of sepsis and pneumonia [14]. Bracken reviewed five studies (including NASCIS I, II and III) investigating methyprednisolone in acute SCI and concluded that high-dose therapy was safe and modestly effective in improving neurological outcome [15].

There is still considerable debate as to whether or not high-dose methylprednisolone should be administered in the context of acute SCI. This has led to variability in the decision to administer methylprednisolone and specific protocols [16]. The senior author of this chapter has published his protocol for administering methylprednisolone following acute SCI based on the timing of administration [10]. Patients with acute non-penetrating SCI should receive methyprednisolone as per the NASCIS II protocol if started less than 3 hours after injury. If started between 3 and 8 hours after injury, then the NASCIS III 48-hour protocol should be applied. If therapy cannot be administered within 8 hours of injury, or there is a penetrating SCI, then methylprednisolone should not be administered for neuroprotection. The decision to administer methyprednisolone must account for medical comorbidities. For example, the risks of administration may outweigh the benefits in a patient with diabetes mellitus and a complete thoracic SCI injury. Blood glucose levels must be carefully monitored during the course of methylprednisolone therapy, and hyperglycemia aggressively managed with an insulin infusion.

39.3.3 Surgical Management of Acute Spinal Cord Injury

Prior to discussing the surgical management of SCI, it is necessary to outline appropriate imaging used to identify the extent and type of bony and soft tissue injuries. Selecting the anatomic spinal area to be imaged depends on the neurological examination. A quadraplegic patient requires imaging of cervical spine (skull base to top of T1), while a paraplegic patient with a thoracic sensory level requires a radiograph of the entire thoracic spine. While plain radiographs may be an appropriate first step, computed tomography (CT) scan is essential for characterizing bony pathology, while magnetic resonance imaging (MRI) is used to identify soft tissue injury, including injury to the spinal cord. The clinician should be aware that a significant proportion of SCI patients have more than one anatomic level of spinal injury, which may or may not be contiguous. Appropriate imaging is essential to planning further surgical management.

Closed reduction aims to relieve compression of the spinal cord by restoring normal bony alignment. The technique involves applying traction force to the skull through rigid fixation with Gardner-Wells tongs or Halo, and reducing a cervical dislocation. Increasing weight is added over time while neurological status and radiographic monitoring of the cervical fracture dislocation are assessed between traction increments. Traction may be an appropriate first step in a conscious patient who can undergo reliable serial neurological assessment, especially in the setting of bilateral locked facets [17]. This technique does not address compression secondary to hematoma or soft tissues. It may be impossible to obtain and/or maintain bony reduction with this technique. Surgical decompression and reduction offer the advantage of addressing all compressive etiologies immediately and providing the opportunity for internal fixation. Attempts at closed reduction should not delay definitive surgical decompression, open reduction and internal fixation of the spine. Evolving evidence suggests that early decompression may enhance recovery after cervical SCI and has acceptable safety, though this remains somewhat controversial. The

guidelines for the management of acute cervical spine injuries published in 2002 include early open or closed reduction of cervical fractures as a management option for SCI [18]. However, in actual practice, there appears to be considerable heterogeneity in the timing of surgery for acute SCI [19]. This variability in surgical timing may be due, in part, to a lack of a clear definition of "early surgery" or other factors, including logistical issues such as delays in medical transfers and the availability of key imaging or surgical resources.

Recent systematic reviews of the literature suggest that there is a biological basis for surgical decompression of the spinal cord within 24 hours of injury [10,19-21]. Preliminary results from the Surgical Treatment of Acute Spinal Cord Injuries Trial (STASCIS) indicate that decompression within 24 hours of injury may actually improve outcome in patients with isolated SCI [22]. Early decompression (within 24 hours) should be considered as part of the therapeutic management of any patient with SCI, particularly those with cervical SCI. Very early decompression (within 12 hours) should be considered for a patient with an incomplete cervical SCI (with the possible exception of the central cord syndrome). An international survey [23] indicates that the majority of spine surgeons prefer to decompress the acutely injured spinal cord within 24 hours. The majority of spine surgeons prefer to decompress the cervical spine for patients with complete or incomplete cervical spinal cord injury within 24 hours.

39.3.4 Pressure Ulcers

Preventing pressure ulcers is a life-long concern in SCI patients. The risk of developing a pressure ulcer is stable over the first 10 years after injury, with a reported prevalence of 11.5% within the first year of injury and 14.3% within 10 years of injury [24]. Preventing pressure ulcer following acute SCI may initially be overshadowed by issues of transportation, resuscitation, decompression and stabilization.

A recent systematic review of the literature identified a number of possible risk factors for the development of pressure ulcer in the acute SCI period (defined as prior to admission to a rehabilitation facility) [25]. Mobility level, activity level, lung disease, decreased mental status and nutritional status were identified as risk factors for the development of pressure ulcer, though the evidence was considered insufficient based on conflicting evidence between studies included in the review [25]. Low blood pressure was considered a possible risk factor with moderate evidence, as were transport time to hospital and time on a spine board [25]. Length of stay in hospital, tracheostomy and vertebral osteomyelitis were reported as possible risk factors with insufficient evidence[25]. Based on these results, both patient factors and medical management factors seem to play a role in the development of pressure ulcer.

There are no recognized guidelines for pressure ulcer prophylaxis in the acute phase of SCI. We would recommend removing the patient from the spine board upon arrival to hospital and optimizing oxygenation, hemodynamics and nutrition. These measures are supported by other authors [26]. A high level of clinical suspicion and vigilance, with frequent inspection of anatomical pressure points are required to provide adequate protection and early detection of pressure ulcer.

Results of a recent multicenter, international, prospective cohort study (STASCIS) indicate that not only is early surgery safe and feasible but results in better neurological outcomes at 6-months follow up relative to SCI patients who undergo surgical decompression beyond 24 hours. This trial defined early surgery as <24 hours and the mean time to surgery of the early group was 14.2 +/- 5.4 hrs. Late surgery was defined as occurring beyond 24 hours and in this study had a mean time 48.3 hr [27].

39.3.5 Venous Thromboembolism

Venous thromboembolism (VTE) is common in the SCI population. A recent review indicated that clinically symptomatic deep venous thrombosis (DVT) and pulmonary embolism (PE) occur in 12 to 64% of SCI patients not treated with thromboprophylaxis, while asymptomatic VTE may be more common [28]. The Guidelines for Management of Acute Cervical Spinal Injuries recommend prophylactic VTE treatment for patients with severe motor deficits [18]. In 2004, guidelines for the prevention of VTE recommended starting all acute SCI patients on thromboprophylaxis once primary hemostasis is evident [29]. Low-molecular-weight heparin was recommended over single therapy with unfractionated heparin, compression stockings or an inferior vena cava filter [29]. A combination of these latter modalities was recommended in instances where there was a contraindication to low-molecular-weight heparin during acute phase SCI [29]. The recommendations included in both sets of guidelines were based on strong clinical evidence in the scientific literature [18,29].

There are currently no recommendations for a particular low-molecular-weight heparin. Most guidelines are based on studies employing enoxaparin for VTE prophylaxis [18,29,30]. A retrospective study comparing the rate of VTE in SCI patients on prophylactic dalteparin or enoxaparin reported clinically symptomatic DVT or PE in 1.6% of the enoxaparin group and 9.7% in the dalteparin group [30]. The difference was not statistically significant due to insufficient power [30]. The balance of evidence favours the use of enoxaparin (40 mg subcutaneous once daily) for VTE prophylaxis in the acute SCI population.

39.3.6 Nutritional Support

The early period of acute SCI is characterized by disturbed metabolic activity and increased nitrogen excretion [26,31]. While the benefits of enteral nutrition in critically ill patients are accepted, there is little information supporting early feeding in acute SCI. A pilot, randomized control trial demonstrated no differences in septic complications between patients fed within 72 hours of SCI and those fed after 120 hours of the injury [31]. Only 17 patients were included in the analysis, making it difficult to draw any conclusions from the results. A retrospective review of 27 SCI patients started on enteral feeds a median of 2 days after injury reported no major complications in the group, though two patients had feeds interrupted due to high gastric aspirates [32]. Early enteral feeding should be considered in the acute SCI population, with consideration of their hypercatabolic state, with enough nutritional support to accommodate 1.5 times the normal basal metabolic rate.

39.4 Conclusion

Understanding the pathophysiology of SCI is essential to optimizing patient management. Maintaining a mean arterial pressure ≥85 mmHg, appropriate administration of methylprednisolone, and early surgical decompression are essential to optimizing the neurological outcome. Recognition of the common medical issues encountered by SCI patients (thromboembolism, pressure ulcer, altered nutritional requirements) and their avoidance are essential to improving overall outcome. We recommend that the reader be familiar with the following key references.

Cerebrovascular Diseases

40 Stroke Units: Organization, Past, Present and Future

Blanca Fuentes [1], **Exuperio Díez Tejedor** [1]

[1] Stroke Center and Department of Neurology. La Paz University Hospital. Autónoma University of Madrid, Spain

40.1 Objective

The creation of stroke units has been a milestone in the management of cerebrovascular diseases. Paving the way was the change from a nihilistic attitude, which precluded stroke patients from care and left them to face the natural evolution of stroke, to one of responsive action undertaken as a first level emergency. In this chapter we give a brief historical overview of the development of the stroke unit and the organizational aspects that have been shown to be essential for its effectiveness.

40.2 Historical Overview

In the 1970s the first stroke units were designed as intensive care units, with monitoring of vital functions and the use of aggressive treatments. Admitted to such units were patients with severe stroke, major neurological deficits, and poorer general status. Although the results were variable and fewer complications were reported, the stroke units did not convincingly demonstrate they could effectively reduce mortality.

Subsequently, the concept of stroke units evolved into non-intensive acute care units characterized by systematization of patient care, with trained staff, admission criteria, systematic diagnostic and therapeutic procedures, attention to acute management and early functional and social rehabilitation, and effective multidisciplinary collaboration.

Several randomized trials have demonstrated stroke unit effectiveness in terms of mortality, functional recovery and chronic institutionalization rates (Table 40.1).

Intensive Care Stroke Units		
Kennedy et al. 1970	Prospective Randomized	No differences in mortality Reduction in complications rates
Drake et al. 1973	Retrospective Non randomized	No differences in mortality Reduction in complications rates Trend toward reduction in long-stay hospitalization
Pitner and Cornelius 1976	Prospective	Not effective with respect to mortality
Norris and Hachinski 1976	Prospective Non randomized	Not effective with respect to mortality

Non-intensive Care Stroke Units		
Strand et al. 1985, 1986	Prospective Randomized	Decrease in length of stay Reduction in long-stay hospitalization
Indredavik et al. 1991, 1997, 1999	Prospective Randomized	Reduction in mortality Decrease in length of stay Better functional outcomes Reduction in long-stay hospitalization 5-10 years follow-up: persistent benefit in terms of mortality and functional outcome
Stroke Teams		
Wood-Dauphinee et al. 1984	Randomized vs. general wards	Non significant efficacy
Webb et al. 1995	Prospective Historical controls	Decrease in length of stay Reduction in complications rates (↓ urinary infections)
Dey et al. 2005	Prospective Randomized	Premature interruption of the study No significant differences in mortality at 6 weeks or at 12 months
Van der Walt et al. 2005	Retrospective Historical controls	Reduction in severe complications rates Decrease in length of stay Increase in percentage of patients functionally independent at discharge
Stroke Units vs. General/Neurological Wards		
Jorgensen et al. 1995	Prospective Community-based	Reduction of in-hospital, 6-month and 12-month case-fatality Decrease in length of stay Reduction in long-stay hospitalization
Ronning and Guldvog 1998	Quasi-randomized Controlled	Reduction in 10-day, 1-year and 18-month mortality
Jorgensen et al. 1999	Prospective Community-based	Reduction in relative risk of death at 5 years
Stegmayr et al. 1999	Transversal Multicenter	Reduction in mortality Increase in discharge to home Reduction in long-stay hospitalization
Glader et al. 2001	Prospective Cohorts	Reduction of daily activities dependence Lower mortality at 2 years of follow-up
Krespi et al. 2003	Retrospective Historical controls	Reduction in mortality Decrease in length of stay
Cabral et al. 2003	Prospective Randomized	Non-significant trend toward reduction in mortality
Stavem et al. 2005	Case-control	20% reduction in mortality at day 30 after adjustment for age, gender and stroke subtype
Candelise et al. 2007	Retrospective Multicenter	Reduction in mortality or dependence rates
Zhu et al. 2009	Retrospective Historical controls	Reduction in mortality Decrease in length of stay
Stroke Units vs. Stroke Teams		
Kalra et al. 2000 Evans et al. 2001	Randomized 3 groups • Stroke Unit • Stroke Team • Home	Stroke Unit group: Reduction in mortality at 3, 6 and 12 months Better functional outcomes at 3, 6 and 12 months Reduction in complications

Díez Tejedor et al. 2001 Fuentes et al. 2006	Prospective Historical controls	Better functional outcome at discharge Decrease in length of stay Reduction in complications Reduction in long-stay hospitalization Decrease in health costs Consistent long-term benefits after operation.
Cadilhac e Ibrahim 2004	Prospective Simple blind	Higher rates of adherence to key processes of stroke unit care compared with other care models
Non-monitored Stroke Units vs. Critical-care Monitored Stroke Units		
Sulter et al. 2003	Pilot study Randomized	Reduction in mortality in the monitored stroke units
Cavallini et al. 2003	Prospective Non randomized	Better functional outcome in monitored stroke unit

Table 40.1. **Selected studies comparing different stroke care models.**

Furthermore, several meta-analyses have confirmed the effectiveness of stroke units in reducing early mortality and at 1 year after stroke, with a reduced risk of death and of death or long hospitalization, as well as a non-significant trend for reduced death or dependency. It has been demonstrated that all stroke patients, regardless of age, severity or etiological subtype, benefit from stroke unit care.

Although stroke unit care is considered a care measure with evidence level grade I based on randomized trials and meta-analyses, there is currently no widespread implementation of such care, unlike what has happened to coronary care units. Various studies and surveys on stroke unit population coverage showed disparate figures, with about 10% of stroke patients admitted to a stroke unit in France or Italy and 60-70% in Scandinavian countries. This contrasts with the epidemiological, social and health impact of reduction in stroke mortality and the higher percentage of patients who are able to return home after hospital discharge, as the number of stroke units in a given country rises. In fact, stroke unit care is the only organization proved to reduce stroke-related death and it is also the only intervention that has been shown to be associated with lower rates of functional dependence on long-term follow-up. And unlike other treatments for cerebral infarction such as intravenous thrombolysis, stroke care may be applicable to most patients.

For these reasons, international health organizations such as the World Health Organization, the World Stroke Organization and the European Stroke Organization have supported recommendations to implement stroke units.

40.3 Current Concept of the Stroke Unit

Over time and following the publication of several studies, the term “stroke unit” has been used to describe different care models based on different organizational aspects such as timing of admission from the onset of symptoms (acute stroke unit, <7 days vs. non-acute stroke unit, >7 days); or the specific objectives of a stroke unit: acute care, rehabilitation, and mixed when acute care and rehabilitation are combined.

At present there is some variability in the departments where a stroke unit can be set up (neurology, geriatrics, internal medicine, and rehabilitation). Stroke units attached to neurology and internal medicine wards seem to focus more on the specific acute care of stroke, whilst those operating within geriatrics or rehabilitation departments

are more oriented to physical rehabilitation. Within and across countries experience in stroke management may reside in different hospital departments (general medicine, geriatrics), mainly due to the provisions of local health policy and the availability or development of medical specialties; however, it is generally recommended that a stroke unit be attached to a neurology department. A stroke unit may consist of a multidisciplinary structure coordinated by a neurologist specialized in cerebrovascular diseases, specially trained medical personnel, and dedicated beds for stroke patients.

This heterogeneity of concepts and designs has generated confusion as well as the difficulty of comparing studies. It is therefore essential to distinguish the stroke unit from other systems of stroke care. A stroke unit may be defined as a geographic area where acute stroke patients arriving from emergency services, outpatient clinics or from other hospitals are admitted and from which, once stabilized, they can be transferred to the neurology and rehabilitation wards of the hospital, home or another hospital. Thus, acute stroke unit care includes critical non-intensive measures during the acute stroke phase. Following stabilization, the patient is then transferred to a neurology ward for general neurological diagnostic and therapeutic evaluation before being discharged home or transferred to a rehabilitation ward or a geriatric unit. As this concept of acute

Infrastructure	Personnel	Services	Other
Minimum			
Dedicated beds for stroke patients	Multidisciplinary Team Stroke-expert neurologist Trained nurses Rehabilitation physician and physiotherapists Speech and occupational therapists	Non-invasive monitoring: • EKG • Oxygen saturation • Blood pressure Body temperature Neuroimaging 24/7 (at least CT) Extracranial doppler sonography	Written protocols for stroke diagnosis, management and prevention Early mobilization and rehabilitation Continuous medical education in stroke management Professional education programs for health personnel Education programs for patients, relatives and caregivers
Recommended			
Stroke outpatient clinic		Transcranial doppler sonography Extracranial dupplex sonography Availability of echocardiographic studies: TTE, TEE Neuroimaging: MRI Vascular neuroimaging: angio-CT, magnetic resonance angiography, transfemoral cerebral angiography	Stroke pathways Stroke database

Table 40.2. **Minimum and recommended requirements for a stroke unit according to current international recommendations.**

CT = computed tomography
EKG = electrocardiogram
MRI = magnetic resonance imaging
TEE = transesophageal echocardiography
TTE = transthoracic echocardiography

stroke unit care is the one most widely accepted today as a paradigm for the stroke unit, this is the model to which we will refer in the rest of this chapter.
The medical specialty considered as embodying "stroke expertise" varies from country to country, depending on health policy and the various systems of medical specialization; nonetheless, the stroke care delivered by medical specialists in neurology has been shown to be superior over other specialties. Therefore, it is now recommended that a stroke unit be attached to a neurology department. Without any prejudice to its multidisciplinary nature, stroke care should be coordinated by a neurologist expert in stroke management and provided by specially trained staff. The activity of the stroke unit must be operative around the clock, with the physical presence of a neurologist on call. It is important to state admission criteria and to develop explicit diagnostic and treatment protocols, as well as coordinated work programs with other specialties such as cardiology, neuroradiology, neurosurgery, vascular surgery, rehabilitation and geriatrics. It is also recommended that the stroke unit be equipped with facilities for non-invasive multi-parameter monitoring (EKG, oximetry, blood pressure and temperature) and with an ultrasound laboratory for studying cerebral circulation (at least transcranial Doppler and continuous Doppler for cervical arteries) (Table 40.2).
Numbering among the factors associated with stroke unit benefits is the reduction in hospital-related complications and a greater adherence to care protocols for general care, diagnostic procedures and documentation.

40.4 Evolution and Development of Stroke Units

Although the effectiveness of the stroke unit is amply demonstrated, further organizational measures have been proposed to increase their benefits: non-invasive continuous monitoring and implementation of clinical pathways.

40.4.1 Stroke Unit With a Non-invasive Continuous Monitoring Facility

Early rehabilitation has long been considered as the most important component of stroke unit care and a determinant of its effectiveness. But since Indredavik noted the influence of general care, particularly in relation to blood pressure control and early treatment of hyperthermia, the importance of maintaining homeostasis has become increasingly evident, as it has also been associated with short-term outcome and fewer complications. These beneficial effects were shown in a stroke unit where assessment of vital signs was performed four times daily and non-invasively. Several recent studies have underscored the importance of continuous monitoring of these parameters; and their involvement in the prognosis of patients demonstrated lower mortality at 3 months and 1 year and a better prognosis at discharge. This benefit was probably due to prompt detection of complications (cardiac events, fever, hypertension, hypotension and hypoxia) in the monitored patients, and therefore the ability to act quickly on them. At present, the provision of continuous monitoring is essential for a new stroke unit.

40.4.2 Clinical Stroke Pathways

Several approaches to the implementation of clinical pathways in stroke care, mainly in rehabilitation, have been described, but the impact such pathways can have on the

acute phase of stroke remains to be elucidated. What has been pointed out is an increase in diagnostic procedure performance and a reduced risk of urinary tract infections or rate of hospital readmission. However, we still lack enough scientific evidence about its benefits in stroke outcomes, as indicated by two Cochrane reviews, because of methodological limitations (non-randomized design of most studies). Only one study with historical controls has analyzed the impact of the introduction of a clinical pathway in an acute stroke unit, showing higher quality in the diagnostic process and reduction in urinary tract infection rates as an in-hospital complication. In addition, clinical pathways specifying the different daily diagnostic and therapeutic measures that should be applied to stroke patients would ensure continued quality of care. On the other hand, such pathways could avoid reducing the provision of services on weekends and holidays, as several studies have shown, concluding that patients admitted to a stroke unit on a weekend or during holiday periods had higher mortality and worse functional recovery. This fact has been attributed to the reduction of clinical staff, with a lower intensity of multidisciplinary treatment and delays in the rehabilitation process. It is therefore necessary to ensure continued care in the stroke unit that includes not only an appropriate ratio of nurses but also the proper implementation of diagnostic, physiotherapeutic and rehabilitation processes on weekends and holidays.

40.5 Future: Stroke Networks and Stroke Centers

Unquestionably, the creation of stroke units has been a milestone in stroke care, yet we must recognize that they cannot act in isolation. There is an increasing need for the coordination of stroke care networks to ensure the best care for the entire population, as it would be impossible to establish high-level stroke units operating diagnostic and therapeutic services in all hospitals. Therefore, many scientific societies and governments are developing stroke care plans for the coordinated organization of available resources to create networks of care for stroke patients. The objectives of these systems go beyond the medical care of acute stroke patients to include aspects of population health education in primary and secondary prevention, develop stroke warning systems for the rapid response of emergency services, specialized stroke treatments, rehabilitation and advocacy for the quality of life of these patients.
Thus, from an organizational point of view, we can consider three levels of stroke care.

40.5.1 Stroke Centers

In addition to having a stroke unit, they also ensure the provision of complex diagnostic or therapeutic procedures for selected patients. The minimum facilities for these centers include:

- Infrastructure:
  - Stroke Unit.
  - Intensive Care Unit.
  - Emergency Department.
  - Stroke Database.
- Personnel:
  - Neurologist physically present in the hospital every day and 7 days a week.
  - Interventional neuroradiologist 24/7.
  - Stroke Medical Coordinator.
  - Stroke-trained neurologists.

- Stroke-trained nurses.
- Rehabilitation physician and physiotherapists.
- Stroke-expert neurosurgeons.
- Vascular surgeons with experience in carotid surgery.
- Diagnostic radiologists expert in stroke diagnosis.
- Intensivists.
- Social workers.

- Diagnostic procedures:
  - Extracranial and transcranial doppler sonography.
  - Extracranial and transcranial duplex sonography.
  - Brain diagnostic imaging: CT and MRI.
  - Vascular neuroimaging: angio-CT, magnetic resonance angiography, transfemoral cerebral angiography.
  - Functional neuroimaging.
  - Echocardiography.
- Invasive treatments:
  - Revasculazation procedures: carotid surgery, angioplasty and stenting.

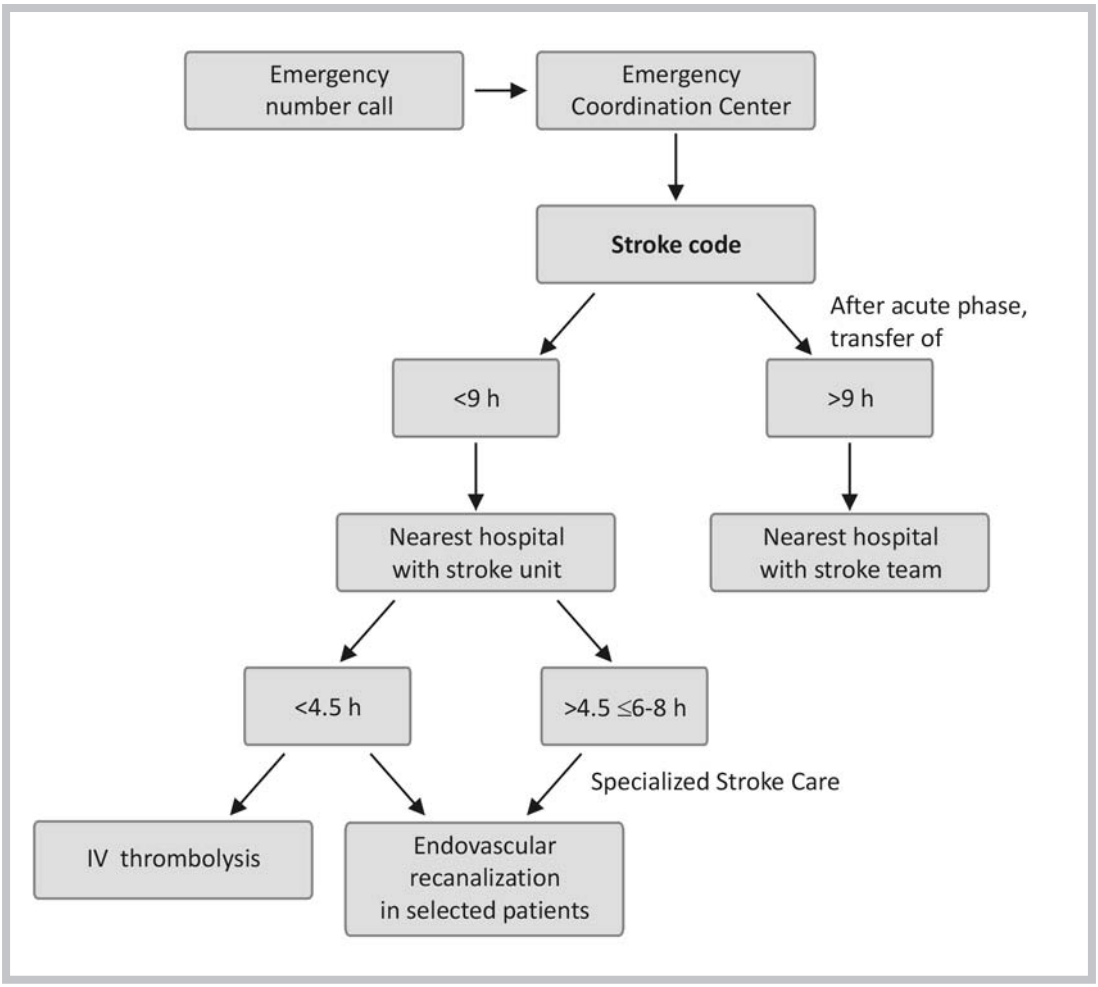

Figure 40.1. **Stroke Code of The Madrid Stroke Network. Activation and distribution of stroke patients by the emergency coordination center.**

- Endovascular procedures: aneurysm and intracranial vascular malformations, intraarterial reperfusion and recanalization.
- Neurosurgical procedures: hemicraniectomy, surgical evacuation of brain hemorrhage, external drainage for hydrocephalus, surgical excition of aneurysms and intracranial vascular malformations.
- Cardiovascular surgery.

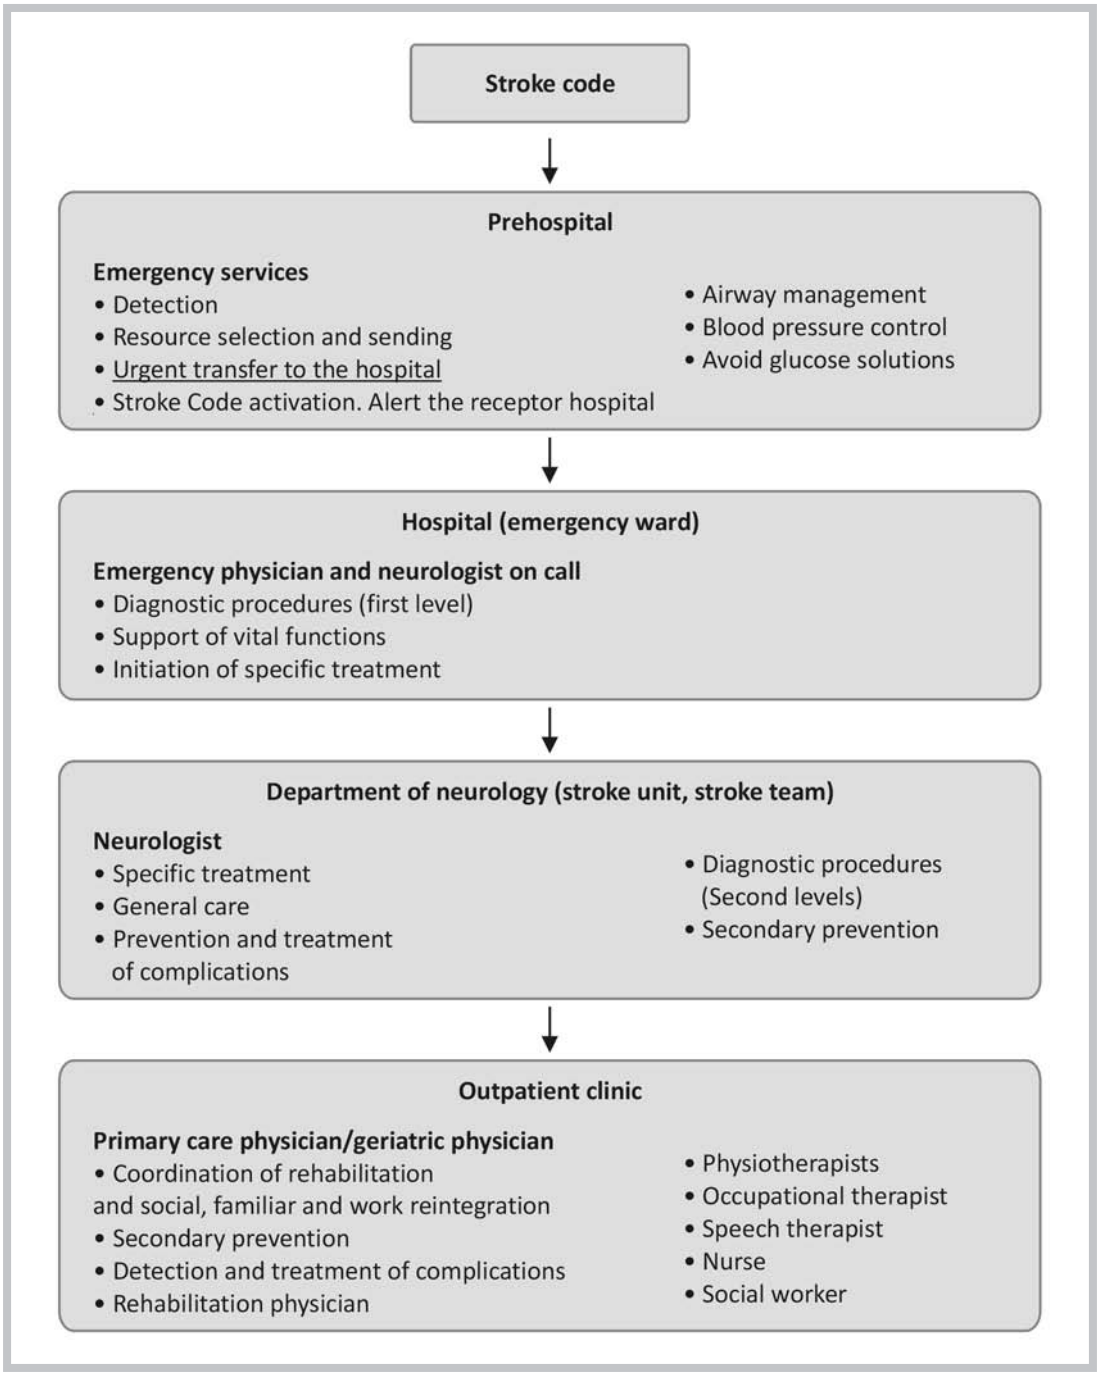

Figure 40.2. **Integration of extra-and intra-hospital stroke code in a stroke care network. Priorities and tasks.**

- Programs:
  - Established networks with extra- and intra-hospital stroke codes (Figures 40.1 and 40.2).
  - Multidisciplinary work plans with participation of different specialists involved in stroke management: vascular surgeons, neurosurgeons, cardiologists, rehabilitation physicians, neuroradiologists.
  - Diagnostic and therapeutic protocols.
  - Education and research programs.

40.5.2 Stroke Unit Hospitals

They are provided by a stroke unit with all the diagnostic and therapeutic procedures needed for acute stroke care, with a neurologist physically present in the hospital every day and 7 days a week. Recommended organizational elements are:

- Infrastructure:
  - Stroke Unit.
  - Intensive Care Unit.
  - Emergency Department.
  - Stroke Database.
- Personnel:
  - Stroke Medical Coordinator.
  - Neurologist physically present in the hospital every day and 7 days a week.
  - Stroke-trained nurses.
  - Physiotherapists.
- Diagnostic procedures:
  - Brain CT scan 24/7.
  - Emergency laboratory 24/7.
  - Extracranial and transcranial sonography.
  - Non-invasive multiparametric monitoring.
- Programs:
  - Established networks with extra- and intra-hospital stroke codes.
  - Multidisciplinary work plans with participation of different specialists involved in stroke management: vascular surgeons, neurosurgeons, cardiologists, rehabilitation physicians, neuroradiologists.
  - Diagnostic and therapeutic protocols.

40.5.3 Stroke Team Hospitals

In those hospitals where a stroke unit is not possible, mainly because of the scarce number of acute stroke patients admitted, stroke care is provided by stroke teams, defined as multidisciplinary teams specialized in stroke management. As they are not large enough, these hospitals do not generally have a neurologist physically present 24/7 nor the facilities for specific treatments like intravenous thrombolysis during the acute stroke phase. When necessary, patients are transferred to a hospital with a stroke unit or to a stroke center in order to complete the treatment. To ensure fluidity of patient referral systems and to allow early administration of drugs within a narrow therapeutic window, it is essential to develop inter-hospital coordination systems included in the stroke networks. These hospitals will have:

- Infrastructure:
  - Emergency Department.

- Personnel:
  - Stroke Team directed by a stroke-expert neurologist.
  - Physiotherapists.
- Diagnostic procedures:
  - Brain CT scan 24/7.
- Programs:
  - Stroke care protocols.
  - Inter-hospital referral protocols.

Finally, we wish to underscore the need to regularly assess the performance of patient care in the stroke unit to verify that the benefit is maintained over time. For this task indicators are being developed in relation to diagnostic and therapeutic procedures applied, including evaluation of time to treatment.

41 Regional Stroke Systems of Care and the Role of Telemedicine in Supporting Acute Stroke Care: Case Study of the US system

Lee H. Schwamm [1], Soojin Park [2]

[1] Vice Chairman, Department of Neurology, Director, TeleStroke & Acute Stroke Services, Massachusetts General Hospital. Associate Professor of Neurology, Harvard Medical School, Department of Neurology- MGH, Boston MA, USA

[2] Assistant Professor of Neurology, Hospital of the University of Pennsylvania, Anesthesiology and Critical Care, Hospital of the University of Pennsylvania, Director of Neurocritical Care Monitoring and Informatics, University of Pennsylvania, USA

41.1 Introduction

Stroke affects 15 million people worldwide each year, leaving 5 million disabled, and 5 million dead [1]. Intravenous thrombolytic therapy (tissue plasminogen activator, t-PA) has been shown to reduce disability after ischemic stroke, if administered within a 3 hour time window [2] and this has been replicated safely in community practice registries in the US and Europe [3,4]. More recently it has been shown to be beneficial in selected patients in a 3-4.5 hour time window [5,6]. While it has redefined acute ischemic stroke care, it has been demonstrated again and again that there are barriers that limit the optimal availability of this therapy. Such barriers are multifold and range from ineffective candidate identification to loss of opportunities for drug administration (summarized in Table 41.1).

The delivery of intravenous t-PA encompasses more than simply the reconstitution and administration of a drug for a well-defined indication. Whether a patient gets t-PA and how rapidly is influenced not only by where the patient is when symptoms occur, but also by where the patient is brought to medical attention. Whereas coronary artery ischemia is heralded by characteristic chest pain and other associated "positive" symptoms, ischemic stroke is marked by the sudden loss of function, often with the inability to recognize the situation or obtain help. Patients experiencing acute ischemic stroke symp-

Community education	Pre-hospital period	Emergency Department
• Stroke symptom recognition • Availability of t-PA and awareness of the limited time window	• Negative or loss of symptoms associated with brain infarction • Isolation at time of symptom onset • Knowledge to activate Emergency Medical Services • First contact to a primary care site or non-stroke center • Stroke recognition by call-takers • Lack of an established Emergency Medical Services/Ambulance Triage System	• Workflow processes within emergency departments (emergent imaging, laboratory evaluations) • Lack of bedside neurology or stroke expertise within time window

Table 41.1. Barriers to intravenous t-PA administration [7,8].

toms are dependent upon their companions and passersby for recognition and activation of Emergency Medical Services.

The indication for t-PA is moderate to severe ischemic stroke patients identified and treated within 4.5 hours of onset, with a thoughtfully considered exclusion of several relative and absolute contraindications. Thrombolytic administration in a well-selected group carries with it a 6% risk of symptomatic brain hemorrhage; this risk is presumably higher in poorly selected candidates. In the hyperacute setting, the risk of drug administration despite relative contraindications must be weighed against the risk of disability after an untreated moderate to severe ischemic stroke. This medical decision-making process often occurs in the context of a medicolegal environment which, at least in the US, has found in favor of plaintiffs most often in the setting of failure to provide IV t-PA rather than in the setting of symptomatic hemorrhage after tPA [9].

Access to needed stroke expertise (ideally, but not necessarily, at the bedside) is integral to the timely and appropriate administration of t-PA. Ultimately, whether a patient in that moment has access to such expertise is determined largely by geography, economic circumstance, and the existence of an established and functional stroke system of care delivery. It can have profound impacts on outcomes (Figure 41.1). The universal availability of stroke neurologists in the US is limited by a shortage of trained specialists and varying desirability of practice environments.

To ensure equitable access to acute stroke care within a region, pre-hospital and hospital organizations must work together to pre-specify a communication and transfer plan for any patient arriving at any given location. Hospitals with available stroke physicians and specialized resources for endovascular therapy should accept responsibility for collaborating with other facilities within their region to promote access to advanced acute stroke care [10].

In most regions, such informal relationships exist, in the form of consults via plain old telephone service (POTS). Over a simple telephone connection, advice is given "blind-

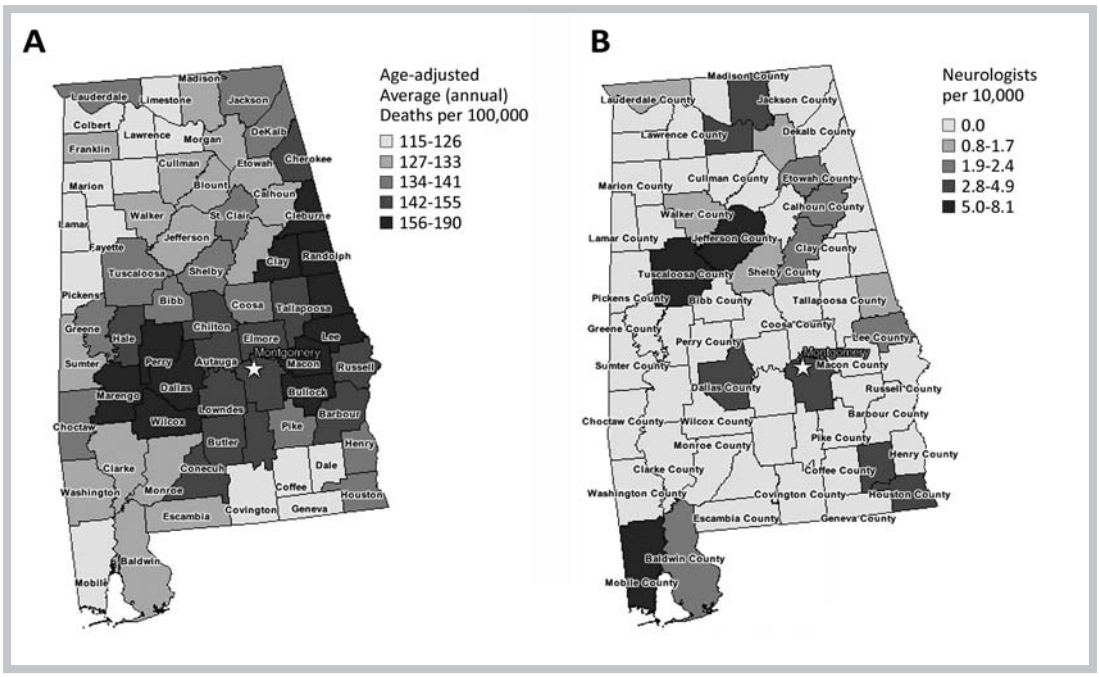

Figure 41.1. **Stroke death rates in relation to availability of neurologists in Alabama. From CDC Heart Disease and Stroke Maps. A. Stroke death rates, total population aged 35+, 1991-1998. B. Neurologists.**

ly" without the ability to evaluate a patient's neurologic exam or CT scan, interview multiple family members, and based on the description of a local physician with variable stroke experience. While there are advantages to a telephone stroke system because of its relative safety [11] and wide availability, a direct comparison study suggested that telemedicine is associated with reduced mortality after stroke and required less correction of initial impressions [12]. In cases where the available information does not foster confidence, a transfer might be initiated without administration of t-PA with the hope that the patient can be evaluated in person at the receiving hospital. In such cases, eligible patients may miss the time window for administration while in transit.

Stroke outcomes in a region can be improved by developing a system of care around an infrastructure that addresses the needs of the stroke patient through all phases of their care. This involves the entire time-treatment spectrum from prevention to rehabilitation. The components of an ideal stroke system have been defined elsewhere[10] and are summarized in Table 41.2.

- Primordial and primary prevention
- Community education
- Notification and response of emergency medical services
- Acute stroke treatment
- Subacute stroke treatment and secondary prevention
- Rehabilitation
- Continuous quality improvement activities within each domain and across the system itself

Table 41.3. **Examples of some successful telestroke programs employing different models of care delivery pre- and post-thrombolysis decision-making.**

Telemedicine can be a tool within a stroke system that offers safe and effective universal access to acute stroke care [11,13,14] (Table 41.3.). In addition to telemedicine-supervised t-PA administration for neurologically underserved areas, it can allow the retention of appropriate patients while referring high-risk and interventional cases to a comprehensive stroke center. When transferred patients are first consulted via telemedicine, the receiving doctors (and patients) are at a distinct advantage of having already been introduced and may pick up the course in mid-treatment rather than initiating new assessments upon arrival at the comprehensive stroke center. Telestroke can increase use of tPA at spoke sites and decrease time to tPA administration [14,15].

In addition to clinical care, there are educational benefits of an established relationship and audiovisual connection between hospital organizations within a stroke system. Continuing medical education around stroke care can easily be accomplished on a scheduled basis. Ongoing site training and quality assurance meetings can also be accomplished via audiovisual connection, overcoming geographic and time barriers.

41.2 Conclusions

Achieving excellence in ischemic stroke care across a geographic region begins with the collaboration of key stakeholders and institutions to develop the necessary infrastruc-

ture for a system of care delivery. The entire spectrum of a stroke patient's care, from prevention to rehabilitation, can be positively affected by the establishment of stroke systems. Telemedicine is a tool for a stroke system that can enhance the equitable distribution of stroke education and access to urgent neurologic expertise.

42 Acute Ischemic Stroke: General Approach

Daniel Agustín Godoy [1]

[1] Neurointensive Care Unit, Sanatorio Pasteur, Catamarca, Argentina. Intensive Care Unit, San Juan Bautista Hospital, Catamarca, Argentina

42.1 Introduction

Ischemic stroke includes several entities that have in common the disruption of cerebral blood flow resulting in transient or permanent dysfunction of one or more regions of the cerebral or cerebellar parenchyma. Ischemic stroke has multiple etiologies and its pathophysiology varies accordingly. It is a very heterogeneous disease; therefore, knowledge of its triggering mechanisms will aid in interpreting the manifestations of stroke correctly and to properly plan therapy and secondary prevention.

Disorders of cerebral circulation are the third leading cause of death in the developed countries and the leading cause of long-term disability. While there are little official data, the incidence of stroke in Argentina is estimated to be between 110 and 285 cases per 100,000 individuals, with more than 500,000 people living with the sequelae of stroke.

Much of the permanent and irreversible brain damage occurs in the early hours after the event: this explains why ischemic stroke is a “true medical emergency” requiring high levels of suspicion, skill, determination and timely response by medical staff. The term “brain attack” was created to draw a parallel with heart attack, thus reaffirming the severity of the event and the urgency with which these patients should be treated. Recent U.S. surveys reveal that most people are unable to recognize stroke symptoms when they occur. Educational programs targeting the population are needed, since only through prompt recognition of symptoms can effective treatments be initiated.

42.2 Pathophysiology of Ischemic Stroke

42.2.1 Brain Metabolism

The brain weighs about 1200 to 1500 grams, accounts for only 2% of body weight, but receives 15% of total cardiac output and utilizes 20% of the oxygen and 25% of the glucose consumed by the body. The high energy requirement of the brain, without available oxygen or glucose reservoirs, makes the availability of energy substrates critical in ensuring the normal functioning of brain tissue.

Normally, the brain’s energy demand is met almost exclusively by the metabolic oxidation of glucose. The oxygen consumption of an adult human brain is around 170 mmol/g/min, whereas glucose consumption is near to 30 mmol per minute per gram of tissue, with a oxygen/glucose consumption ratio of 6:1.

Cerebral blood flow (CBF) is normally 50 to 60 ml per 100 grams of tissue per minute. The brain extracts 33% and 10% of the total available oxygen and glucose, respectively. 60% of the energy produced is used to maintain transmembrane ion gradients, and the

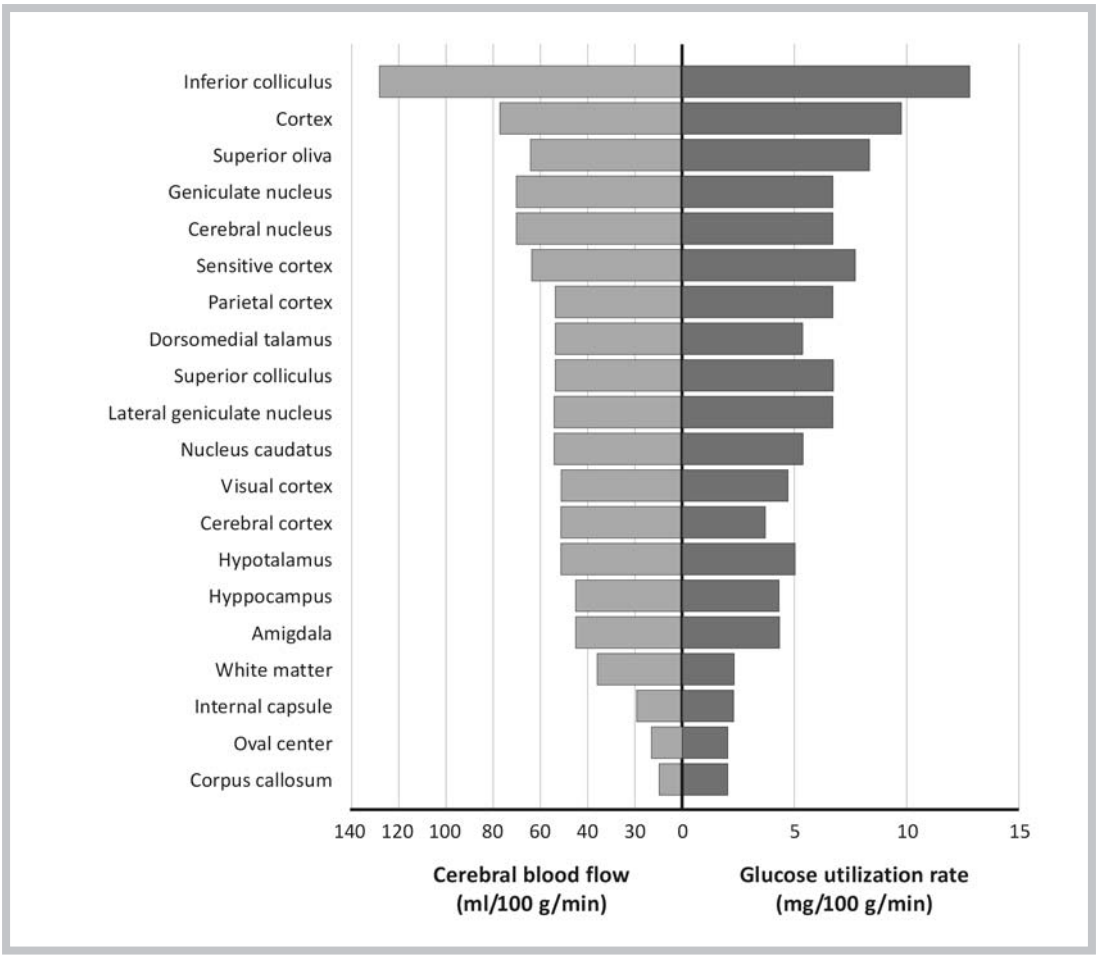

Figure 42.1. **Differences in cerebral blood flow and glucose utilization rate according to anatomic region.**

remaining 40% is used for synthesis, release and reuptake of neurotransmitters and the replacement of cell structures. Both oxygen and glucose consumption, as well as CBF, vary according to the different needs and functions of each anatomic region (Figure 42.1). The gray matter requires a greater availability of energy substrates than the white matter due to the presence of cell bodies and high synaptic activity.

42.2.2 Determinants of Cerebral Blood Flow and Cerebral Autoregulation

The major determinants of CBF are:

- Cerebral perfusion pressure (CPP).
- Vessel diameter expressed as cerebral vascular resistance (CVR).
- Blood viscosity.

$$CFF = CPP/CVR$$

CPP is defined as the difference between mean arterial pressure (pressure at the beginning of the circuit [MAP]) and cerebral venous pressure (pressure at the end of the cir-

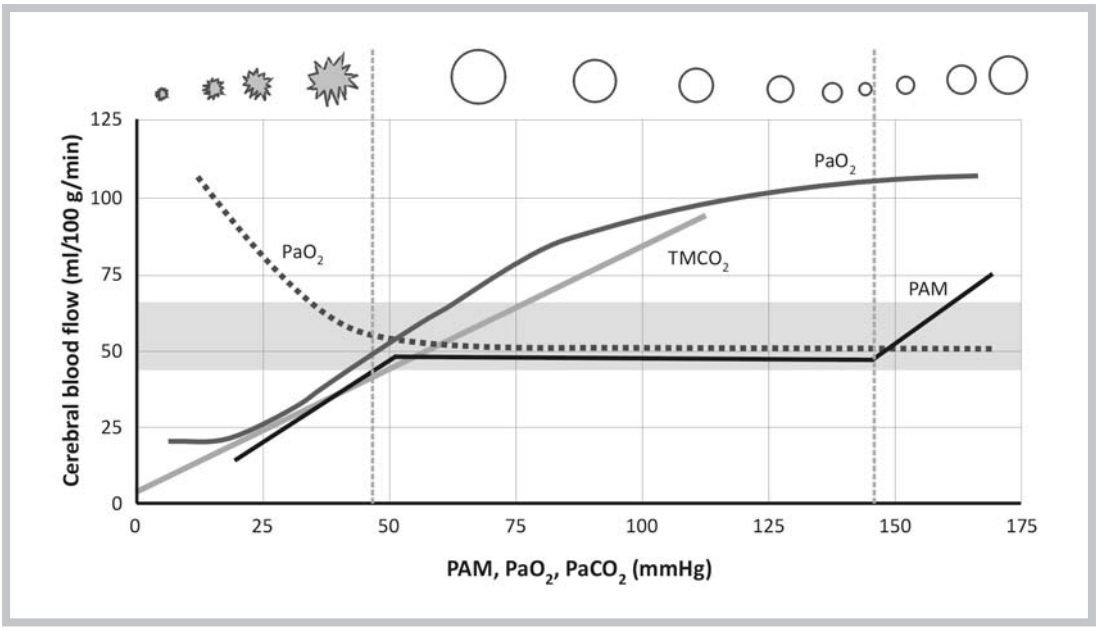

Figure 42.2. **Cerebral autoregulation.**

cuit [CVP]). However, from a practical point of view, the latter is very difficult to measure and is fairly accurately reflected by intracranial pressure (ICP), thus:

$$CPP = MAP - ICP$$

Cerebral vascular resistance is determined by the ability of the cerebral blood vessels to contract or expand in different situations or in response to stimuli. This property of the cerebral vasculature, which allows it to maintain CBF constant despite variation in CPP, is called cerebral autoregulation (Figure 42.2).

Normally, CBF is maintained relatively constant between 50 and 150 mmHg of mean arterial pressure. Outside these limits, CBF passively follows arterial pressure, which means that the vasculature will collapse at MAP <50 mmHg, with a consequent decrease in CBF. At the other extreme, MAP >150 mmHg overloads vasoconstrictive capacity, leading to vasodilation with a consequent increase in CBF.

Cerebral oxygen consumption is another determinant of CBF. As metabolic demands rise, CBF increases directly and proportionally to meet them.

42.3 The Ischemic Penumbra Area

42.3.1 Definition

After an acute ischemic attack, at least two areas in the brain parenchyma can be observed: a central one, the “core”, with established and irreparable structural damage, and therefore necrotic, and a larger peripheral around the core with the potential to recover lost functions, known as the “penumbra”. The penumbra is a region of brain tissue with functional damage at risk of being affected irreversibly but still potentially viable, so that the damage may be reversed with appropriate therapeutic measures.

42.3.2 Concentric Four-compartment Ischemia Model

Hypoperfused brain parenchyma, depending on the magnitude and duration of ischemia, can be compartmentalized into (Figure 42.3): a center or core (4) which represents the irreversibly damaged or infarcted tissue. Surrounding the core with variable extension it is the penumbra area (3) at serious risk of definitive stroke. Between the unaffected area (1) and the ischemic penumbra there is a zone of "benign oligemia" (2) which usually survives the attack, even without early reperfusion, depending primarily on the "time" factor.

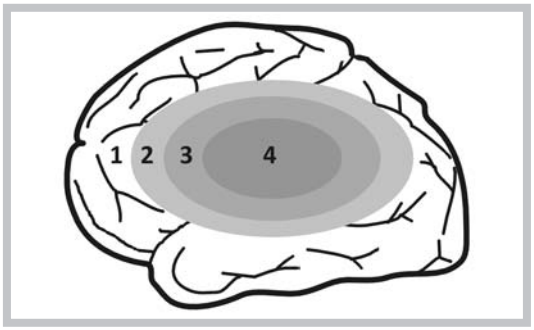

Figure 42.3. **Four-compartment brain ischemia model.**
1 = unaffected area
2 = benign oligemia
3 = penumbra area
4 = ischemic core

42.3.3 Relationship Between Cerebral Blood Flow and Penumbra Area

By definition, the penumbra is an ischemic region with decreased CBF. Experimental and clinical studies have demonstrated two critical thresholds during focal cerebral ischemia. When CBF drops below 20 ml/100 g/min, the neurons lose their spontaneous or induced ability to conduct electrical impulses: this is the "threshold of electrical failure" characterized by alterations on the electroencephalogram (EEG) and in evoked potentials. Typical EEG findings in this phase are the slow pathologic activity (theta and delta waves), with the concomitant disappearance of physiological alpha and beta rhythms.
When CBF reaches 10 ml/100 g/min, the cells are unable to maintain transmembrane ion gradients: this is the "threshold of ionic failure", which produces ionic collapse, causing a massive influx of calcium into the cell, triggering cascades of different nature and complexity that interact with a single purpose – neuronal death.

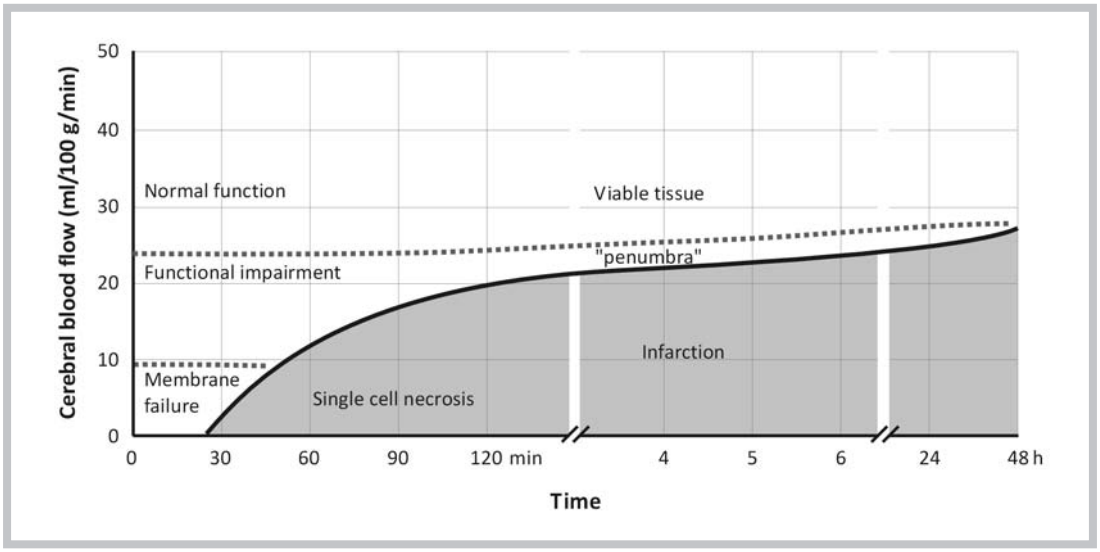

Figure 42.4. **Schematic relationship between CBF and ischemia/infarction. CBF below the threshold and with the "time" since the event causes cell death and infarction.**

Hence, it is very important to keep in mind that the value of CBF determining the "point of no return" depends on the time elapsed since the beginning of ischemic insult.
Although the penumbra develops consequent to an ischemic event, positron emission tomography (PET) and magnetic resonance imaging (MRI) studies have shown that during the acute phase the CBF may be decreased, normal or increased, depending on the immediate reperfusion of the ischemic but not the necrotic tissue. And although reperfusion occurs relatively quickly, it is not always beneficial nor does it guarantee functional recovery of the affected area.
From a metabolic point of view, the penumbra is characterized by increased cerebral oxygen extraction and a decreased rate of oxygen utilization. In this way, areas with a metabolic rate <1.7 ml/100 g/min almost invariably progress towards infarction, whereas those areas which maintain an oxygen utilization rate >2.5 ml/100 g/min remain unchanged. Intermediate values are associated with an indistinct evolution towards necrosis or full recovery.

42.3.4 The Concept of Therapeutic Window

"Time is brain" is the American sentence created to raise public awareness, and to awaken health providers involved in the chain of care of these patients, to the fact that every hour of ischemia and tissue injury that elapses increases the degree and the extent of irreversible neuronal damage. An average of 6 hours is considered as the period during which threatened or at risk cells can be kept viable by restoring blood flow or initiating therapeutic measures to prevent the spread of the penumbra towards infarction. This period is called "therapeutic window".

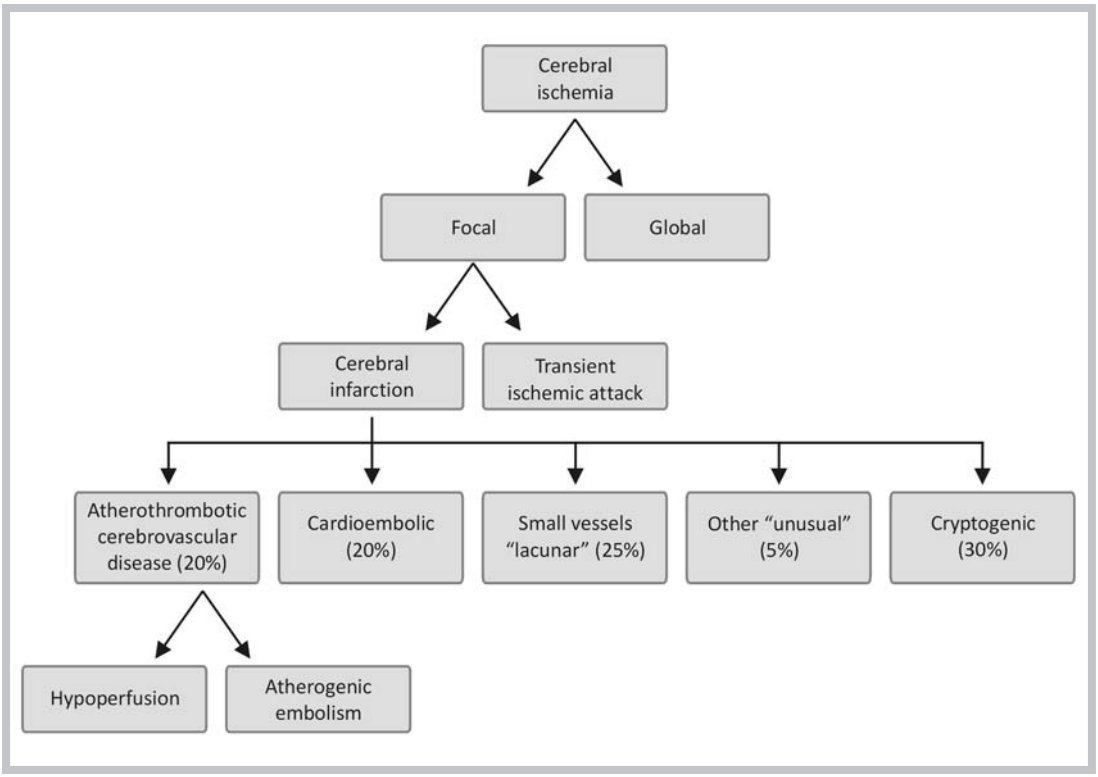

Figure 42.5. **Classification of ischemic stroke according to the triggering mechanism.**

42.3.5 Classification and Diagnostic Criteria of Ischemic Stroke

Grouped under the term "cerebral ischemia" are those entities that share qualitative or quantitative abnormalities in blood supply to the brain. Two main groups are distinguished: a) focal when ischemia affects only one region of the brain parenchyma, and b) global when ischemia affects the whole brain. Focal cerebral ischemia is further subdivided into: a) transient ischemic attack (TIA); and b) stroke.

42.4 Transient Ischemic Attack (TIA)

In light of current knowledge, primarily supported by advances in neuroimaging techniques, TIA is defined as a "brief episode of neurologic dysfunction caused by cerebral or retinal ischemia with signs and/or symptoms lasting no more than 60 minutes and without evidence of infarction on neuroimaging." Recent guidelines suggest eliminating the time factor from the definition. There is a trend towards considering TIA as a benign entity: nothing could be more wrong. It is a serious entity which carries the risk of death or severe disability, and it should never be underestimated. Nonetheless, TIA provides a unique opportunity to start early treatment and prevent progression to stroke. It is estimated that after a first episode of TIA, 10 to 20% of patients will have an infarction in the next 90 days (half in the subsequent 24-48 hours), so that: t**he development of signs and/or symptoms of cerebral ischemia is a medical emergency.**

The causes of TIA are the same as those for stroke (atrial fibrillation, carotid disease, etc.). They will be discussed in detail below, along with measures to prevent future attacks. The diagnosis of TIA, because problematic, requires high index of suspicion and common sense. The clinical history is important; but as it is sometimes impossible to collect data from a patient with altered speech or consciousness during the event, the neurologic examination may identify or clarify the existing deficits.

The clinical features of a TIA depend on the origin and the vascular territory affected. Often, carotid TIAs present with unilateral ocular symptoms such as transient monocular blindness or "amaurosis fugax"or sensory-motor deficits contralateral to the lesion, whereas vertebrobasilar TIAs are generally less localized and last shorter. Isolated unilateral sensory or motor deficits affecting at least two body regions (face, arm or leg) can guide us towards the diagnosis of lacunar TIA.

Since metabolic disorders (e.g., hypoglycemia, hyponatremia, severe hypoxemia, etc.) can obscure the clinical features, laboratory measurements should include: complete blood count (CBC), glycemia, uremia, creatinine, coagulation studies, C-reactive protein and blood gases according to the situation. In addition, routine studies should include chest radiograph, electrocardiogram (ECG), Holter monitoring if occasionally necessary to detect paroxysmal arrhythmias and an echocardiogram is mandatory to determine not only cardiac function but also the possibility of cardioembolic sources detection. In this context, and where feasible, a transesophageal echocardiography is preferable, as because it is more sensitive and specific, especially when checking the aortic arch, the mitral valve or the presence of a patent foramen ovale. It is essential to obtain computed tomography (CT) or MRI studies for diagnosis, as they will rule out or confirm other causes of neurologic dysfunction such as: brain tumor, subdural hematoma, bleeding, or others. Also important is examination and study of the carotid arteries with either Doppler ultrasound or MR angiography, which have a sensitivity of 83 and 86%, respectively, to detect stenosis >70%. Digital angiography is used only to confirm the findings and for selecting the surgical technique and tactics to employ.

42.4.1 Risk Assessment

TIA must be properly evaluated not only to define the most appropriate treatment but also to refer the patient to the most appropriate facility and to prevent recurrence and/or occurrence of stroke or cerebral infarction. Rating scales such as the California or ABCD score have been developed and independently validated. A recently modified version of these scores, called ABCD2, has shown better predictive power of stroke within 7 days of the event. The scale is composed of clinical variables (Table 42.1): the risk is considered high when the score is >4 points.

These scores do not incorporate the findings of neuroimaging which by themselves have a high predictive value. For instance, the presence of new infarction increases from 2 to 15 times the possibility of a short-term stroke, whereas blood vessel occlusion demonstrated by MR angiography raises that possibility fourfold.

Variable		Score
Age >60 years		1
Arterial pressure >140/90 mmHg		1
Symptoms: speech disturbance	Without focal weakness	1
	With focal weakness	2
Duration of symptoms	10 to 59 minutes	1
	>60 minutes	2
Diabetes		1

Table 42.1. ABCD2 score.

42.4.2 Treatment

Antiplatelet Drugs

Aspirin reduces the relative risk (average 22%) of cerebrovascular accidents and long-term cardiovascular events after a first episode of stroke or TIA. Aspirin also prevents recurrence and improves functional outcomes. The optimal dose has not been determined; however, while the beneficial effect of the drug is indifferent for doses from 75 to 1300 mg a day, low doses between 200 and 325 mg are preferred due to the lower probability of side effects.

In patients allergic to aspirin or in whom TIA recurs under treatment with the drug, some authors suggest the use of clopidogrel 75 mg daily. A recent study suggested that combining clopidogrel with aspirin or vice versa doesn't enhance the benefit in relation to aspirin or clopidogrel alone in reducing the rate of cerebral and myocardial infarction or cardiovascular death. The ESPS II European study showed that the association of dipyridamole and aspirin slightly improves aspirin's effectiveness.

Anticoagulants

While the use of anticoagulants has not been tested in TIA, the wide experience gained in ischemic stroke suggests that in patients with atrial fibrillation, anticoagulation therapy reduces the risk of recurrence. In patients without atrial fibrillation, the use of anticoagulants afford no greater benefit than with aspirin. A meta-analysis of 21 placebo-controlled trials of several anticoagulants in patients with cerebrovascular ischemic stroke failed to show benefits.

Statins

Recent studies support the use of statins based on their pharmacological effects independent of inhibition of HMG-CoA reductase and thus their effects on cholesterol or atheromatous plaque. They can reduce endothelin levels, prevent the degradation of

oxidized LDL by nitric oxide synthase, with an indirect vasodilator effect; they can inhibit cell proliferation and have other properties such as anti-inflammatory action, inhibition of thrombogenesis, and platelet aggregation and atherosclerotic plaque stabilization.
Several recent, properly designed large-scale studies with long follow-ups have demonstrated that statin use (specifically pravastatin, lovastatin and simvastatin) significantly reduces morbidity and mortality due to vascular events, including strokes and TIAs.

Carotid Endarterectomy

This topic will be discussed in more detail in another chapter. TIA secondary to carotid stenosis >70% clearly benefits from this therapeutic modality.

Control and Prevention of Risk Factors

All measures to reduce or eliminate the risk factors for brain or cardiovascular diseases are also effective in preventing the recurrence of TIA or its evolution towards stroke. Statins reduce the relative risk by 29%, even in the absence of dyslipidemia, while antihypertensive drugs lower the relative risk by 25-30%.
In diabetic patients the strict control of glycemia is a priority. Weight control, exercise, smoking cessation and moderate alcohol consumption are other voluntary preventive measures that should not be overlooked.

42.5 Atherosclerotic Carotid Disease

Carotid stenosis is an entity that clearly predisposes to TIA or stroke. An estimated 20% of ischemic cerebrovascular accidents are caused by atherosclerotic plaques in the initial portion of the internal carotid artery. Involved in its pathogenesis are many factors: mechanical forces that damage the endothelium, triggering reflexes and the release of inflammatory mediators, expression of adhesion molecules, and secretion of growth and chemotactic factors that induce the proliferation of smooth muscle cells and macrophages in the vessel wall. Other mechanisms included are: synthesis of a connective tissue matrix incorporating cholesterol, platelets, fibrin and lipoproteins, thus forming atherosclerotic plaques.
The clinical picture and Its signs and symptoms are similar to those described for TIA.
Assessment must be completed with high-resolution Doppler ultrasound, MR angiography, transcranial Doppler with the study of cerebral vasoreactivity and detection of emboli.

42.5.1 Therapeutic Approach

The therapeutic approach to patients with carotid atherosclerosis should be directed towards achieving the following goals:

- Stabilize and halt the progression of atherosclerotic plaque by modifying or removing the above risk factors, together with the use of statins, angiotensin-converting enzyme inhibitors and aspirin.
- Eliminate or reduce the stenosis by carotid endarterectomy or angioplasty with stent implantation.

Endarterectomy in Symptomatic Carotid Stenosis

The use of this technique for symptomatic stenosis ≥70% is strongly supported by three studies: NASCET, the American Veterans cooperative study, and the European ECST.

The NASCET showed that, after 2 years, the rate of ischemic stroke ipsilateral to the affected carotid territory was 26% in the medically treated group versus 9% in the surgical group: this amounts to a relative risk reduction of 65% and an absolute reduction of 17%. For patients with stenosis <50%, the three trials unanimously agreed on the lack of efficacy of surgery.
In moderate stenosis (50-69%), surgery does not provide a significant benefit according to the ECST. For this same group, the NASCET showed that the rate of fatal and nonfatal ischemic accidents was 22.2% in the group under medical treatment versus 15.7% in individuals undergoing endarterectomy, with an absolute risk reduction of 6.5%.
Factors associated with better outcomes were: gender (being male), age >75 years, more severe stenosis, stroke with hemispheric symptoms in the last 3 months, intracranial stenosis, the absence of microvascular ischemia (leukoaraiosis or small hypodense images in the periventricular white matter), and presence of collateral vessels.

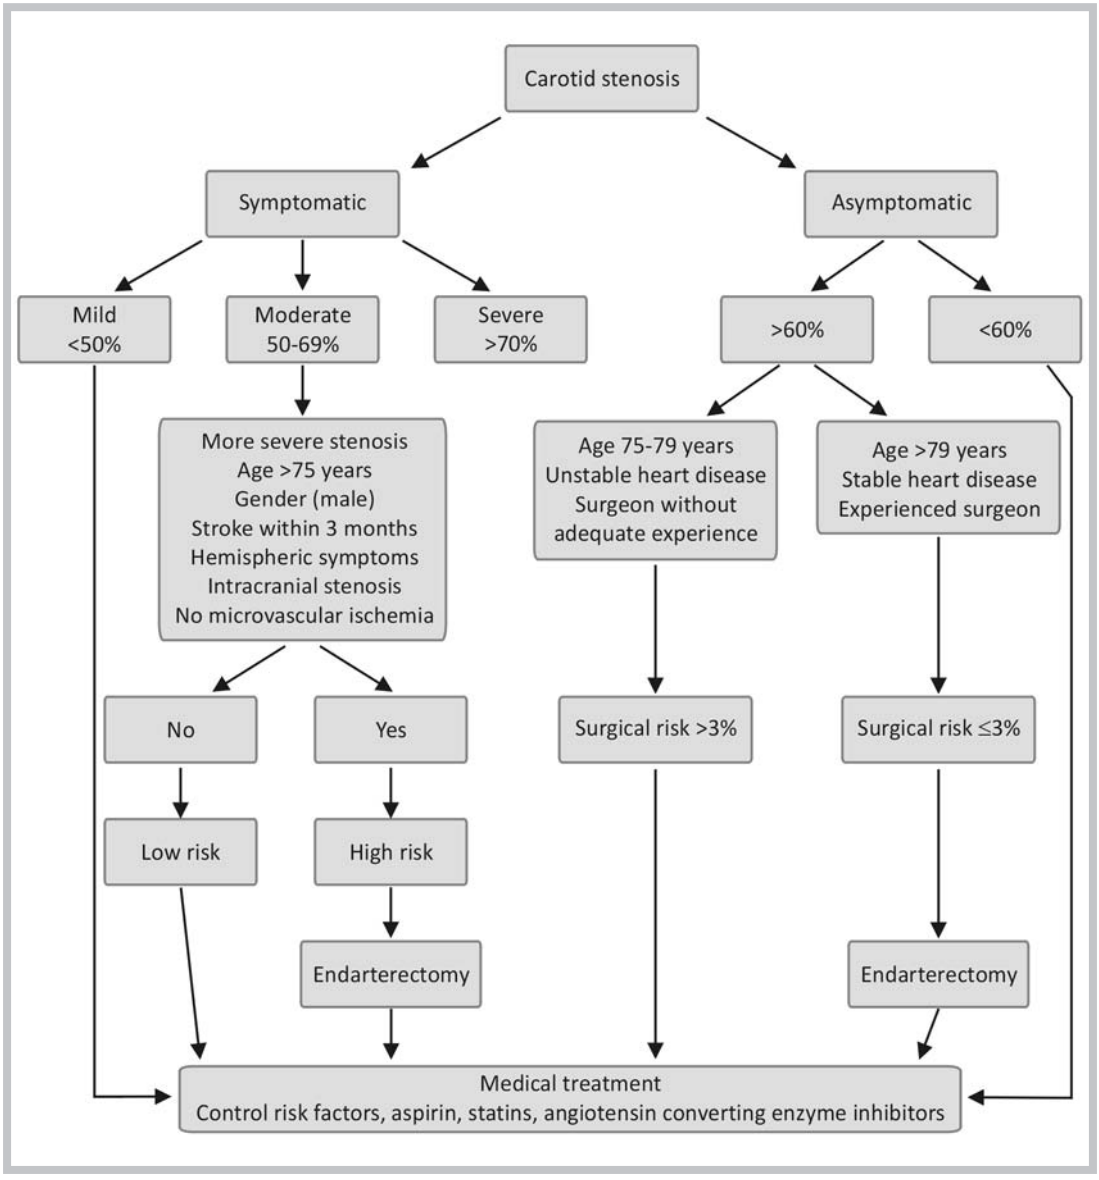

Figure 42.6. **Systematic management of patients with carotid stenosis.**

An additional aspect to consider in global assessment is the presence of ulcerated or complicated plaques, a finding that often aids in the selection of intervention.
When outlining the strategy to follow, the presence of co-morbidities and surgeon's experience should not be omitted.

Role of Endarterectomy in Asymptomatic Carotid Stenosis

Patients with significant carotid lesions (>60%) and no symptoms were evaluated in a multicentre US-Canadian study (ACAS) involving 1661 subjects followed for a 5-year period. The rate of cerebral ischemic event and/or death was 5.1% among the operated patients and 11% for the medical treatment group (absolute risk reduction of 6%).
The key to success in this group of patients resided in the excellent results obtained by the surgical teams involved. Surgery-related morbidity and mortality was about 1.4%. Based on these data, if the perioperative complication rate exceeds 3%, the potential benefits of surgery are nullified.

Endarterectomy Versus Endovascular Treatment

The effectiveness of endarterectomy has been widely demonstrated in large-scale studies throughout the world but the studies lack validation in those individuals considered at high surgical risk. In such patients, endovascular treatment is an attractive alternative. As endovascular techniques and prosthetic material were being developed, as well as neuroprotection measures, postoperative care studies (characterized by a heterogeneity of the patients enrolled as well as the techniques used) comparing both treatment modalities were performed. Some studies viewed surgical endarterectomy as the gold standard, while others found that endovascular treatment had the same or better results than surgery. An evidence-based medicine analysis by the Cochrane group of five trials involving a total of 1269 patients concluded that to date there is no reason to change current recommendations to perform endarterectomy. Moreover, the use of endovascular techniques should be limited to clinical trials to date.

42.6 Cerebral Infarction

When cerebral circulation is suddenly interrupted and causes tissue necrosis, we speak of cerebral infarction. Several subtypes are distinguished; therefore, the following aspects should be considered in the evaluation of stroke patients:
According to the underlying pathophysiological mechanisms, different entities are recognized:

- **Atherothrombotic infarction.** Large (>1.5 cm in diameter) usually compromising the cortical, subcortical, carotid or vertebrobasilar territory. Diagnosis requires the presence of risk factors and previous generalized vascular compromise (peripheral arterial disease, ischemic heart disease, previous TIA, etc.) or vascular compromise demonstrated on further imaging studies such as Doppler, angiography, etc. Cardioembolic source should be excluded.
- **Cardioembolic infarction.** Usually cortical, moderate to large in size, with acute onset. Maximum neurological deficit from the beginning. TIA in several territories supports the diagnosis. Embolic sources (echocardiogram) and lack of atherothrombosis in large arteries must be demonstrated.
- **Lacunar or small vessel infarction.** Deep brain injury or small injury in the brainstem (<1.5 cm in diameter). Arterial hypertension and diabetes support the diagnosis. Microatheromatosis and lipohyalinosis are characteristics in anatomopathology.

- **Infarction of undetermined etiology or "cryptogenic".** Features similar to atherothrombotic, two or more etiologies can coexist. Diagnosis is made by exclusion after checking the most common causes of infarction.
- **Infarction of unusual cause.** Variable size, without predilection for any vascular territory. It usually develops in individuals without classcrisk factors for cerebrovascular disease. It may be the beginning of a disease or occur during its course, e.g., vasculitis associated with connective tissue diseases (systemic lupus erythematosus, etc.), infections (endocarditis, pneumococcal meningitis, etc.), cancer, etc. Other causes: traumatic arterial dissection, complicated migraine, etc.

According to evolutionary profile:

- **Formed or established infarction.** When clinical manifestations occur from the beginning without worsening or improvement. An infarction can be considered established in a carotid territory if the neurological deficit remains changed after 24 hours, while the time period is extended to 72 hours for infarctions involving the vertebrobasilar territory.
- **Progressive or evolving infarction.** Worsening of the initial clinical features with either deepening of the deficit or the occurrence of new symptoms or both.
- **Infarction with trend toward improvement.** Follows a regressive course;usually recovery rate is near to 80% within 3 weeks.

According to the compromised vascular territory, we propose the draft of the classification of stroke in the community of Oxfordshire:

- Total Anterior Circulation Infarction (TACI). The following criteria must be met:
  - Cortical dysfunction or dysfunction of higher brain functions such as aphasia, acalculia or visuospatial impairment.
  - Motor and/or sensory disorders in at least two of the following areas: face, upper limbs, lower limbs.
  - Homonymous hemianopsia.
- Partial Anterior Circulation Infarction (PACI). When some of the following criteria are present:
  - Cortical dysfunction or dysfunction of higher brain functions.
  - Two TACI criteria.
  - Motor and/or sensory deficit narrower than the LACI (e.g., deficit in only one limb).
- Lacunar Infarction (LACI). This subtype doesn't affect higher brain functions or cause hemianopsia. One or more of the following signs or symptoms may be present:
  - Pure motor syndrome affecting at least two of the three body parts (face, arm, and leg).
  - Pure sensory syndrome affecting two of the three body parts.
  - Sensory-motor syndrome compromising two of the three body parts.
  - Ipsilateral ataxic hemiparesis.
  - Clumsy hand.
  - Focal and acute abnormal movements.
- Posterior Circulation Infarction (POCI). Diagnosed when one of the following events is present:
  - Ipsilateral involvement of cranial nerves with contralateral motor and/or sensory deficit.
  - Bilateral motor and/or sensory deficit.
  - Oculomotor pathology.
  - Cerebellar dysfunction.
  - Isolated homonymous hemianopia.

42.6.1 Role of Neuroimaging in Ischemic Stroke

Imaging is essential in the initial evaluation of stroke victims. It is virtually impossible to differentiate ischemia from bleeding based purely on clinical medicine. CT without contrast material is the initial method of choice for diagnosis of a patient with acute neurological deficit, since it is available in most emergency units, can be performed quickly, and is the best method for identifying acute hemorrhage. It can also be performed in critically ill patients and patients under multiple monitoring devices or mechanical ventilation. Diagnosis of ischemic stroke is more difficult in the first 12 hours. Characteristics of the infarction in CT scan are a decrease in attenuation of parenchyma or hypodensity of about 10 to 30 HU, however, it may not be visible for until 24 hours after stroke onset. Only 5% of cerebral infarctions remain isodense during their evolution.

It is essential to investigate for the "early signs of infarction" visible in the first 6 hours in 85% of patients with ischemia of the middle cerebral artery. These signs can appear isolated or coexist with others. They are:

- Spontaneously hyperdense sylvian artery (Figure 42.8).
- Blurring of the boundaries of the lenticular nucleus (Figure 42.9).

Figure 42.7. Structured sylvian infarction.

Figure 42.8. Sign: hyperdensity of the middle cerebral or sylvian artery.

Figure 42.9. Blurring of the boundaries of the lenticular nucleus.

Figure 42.10. Effacement of the insular ribbon.

- Insular effacement (Figure 42.10).

Cerebral edema manifested by effacement of sulci, ventricular distortion, deviation of the midline, and blurring of the boundary between the gray and white matter (Figure 42.11).

Valuable when present, these signs are not often seen in the initial study and their absence does not necessarily rule out ischemic infarction. They allow for the selection of patients eligible for thrombolytic therapy.

Magnetic resonance imaging is very useful in the evaluation of acute stroke. T1 and T2 sequences identify acute ischemia in an earlier stage compared with CT. The development of new techniques such as diffusion (diffusion-weighted imaging) and perfusion seem to be more sensitive and specific in the early hours.

The evaluation of images obtained by the diffusion imaging technique helps the clinician to identify 98% of infarctions in the early hours and is very effective in differentiating new ischemic strokes from existing ones. The combination of both techniques (diffusion and perfusion) may provide prognostic information to differentiate ischemic brain tissue from tissue with irreversible damage.

The comparative disadvantages of MRI versus CT are that MRI takes longer to perform, is not always available in all hospitals, is susceptible to patient motion artifacts, and is contraindicated in patients with pacemakers, intracranial surgical clips and very obese patients.

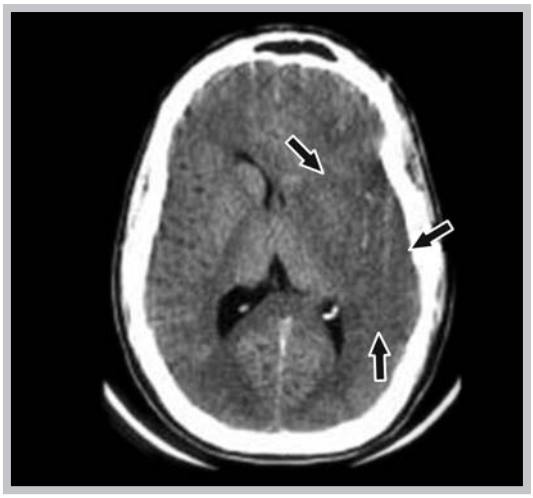

Figure 42.11. Early signs of cerebral edema (effacement of cortical sulci, ventricular distortion, absence of differentiation between the gray and white matter, midline deviation).

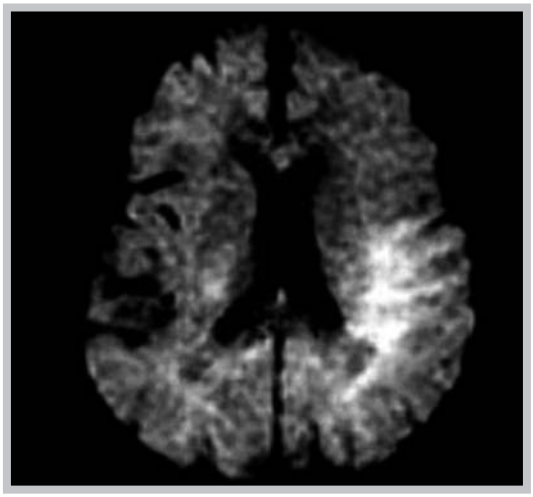

Figure 42.12. MR scan obtained with diffusion-weighted imaging.

42.6.2 Clinical Assessment Scales

Assessment scales are useful tools to reliably and objectively quantify the severity of stroke, its evolution, the final result, and when evaluating the benefit of a therapeutic measure.

Neurological scales allow us to detect deterioration or improvement in basic neurological functions; they must be applied systematically on admission and at set intervals at follow-up. The best one for the evaluation of patients in stupor or coma is the Glasgow Coma Scale (GCS), which was initially designed for assessing traumatic brain injury (TBI) and not for stroke. Among the neurological scales specific for stroke, the most widespread in Latin America is the scale devised by the US National Institutes of Health (NIH Stroke Scale). Other neurological assessment scales for stroke are the Scandinavian or Canadian neurological scales (www.strokeassociation.org).

42.6.3 Acute Phase Treatment

The best therapeutic results are unquestionably obtained with early recognition and diagnosis of the situation. The "nihilistic" concept must be set aside to make way for a strategy to shorten times, as aptly summarized with the concept "Time is brain." Furthermore, efforts should focus on educating the general population and health professionals in the early identification of stroke symptoms to minimize the time of arrival at a specialized centre where these patients can be treated.
Cerebral resuscitation, together with clinical assessment and initial treatment, should begin without delay, as the final results largely depend on the speed with which this true medical emergency is approached.

42.6.4 Prehospital Phase

Depending on infrastructure facilities and human resources available, the initial steps should be directed to the diagnosis of the situation. Clinical examination is essential, because the patient is often unable to communicate, minimizes symptoms or reports them as simple and unspecific malaise. In the United States, abbreviated neurological assessment scales, such as the Cincinnati or Los Angeles scales, have been developed for use by paramedics assisting patients in the prehospital phase. Paramedics with basic training have demonstrated a sensitivity of about 62% in the detection of stroke, which increases to 90% on average when they have received trained in using a rating scale.
In Argentina, as in many other Latin American countries, prehospital emergency services have a doctor on board, providing a unique opportunity to achieve the established objectives.
The next step – perhaps the most important – is to establish the "time zero or time of onset of symptoms." If the patient is "awake" with symptoms of stroke, time zero is when the patient was seen "normal" for the last time.
During transfer, support is the same as in any medical emergency. The ABC rules are followed, i.e. ensuring airway patency and ventilation, monitoring cardiovascular and neurological status, as well as checking blood glucose levels if possible.
Stroke patients may have an altered state of consciousness and reduced cough and deglutition reflexes: the risk of aspiration and airway obstruction due to relaxation of the laryngopharyngeal muscles makes them particularly predisposed to the development of such secondary insults such as hypoxemia or hypercapnia.
Oxygen should be administered when arterial oxygen saturation monitoring is not available or when <92%.

42.6.5 Evaluation in the Emergency Room

Upon arrival at the hospital, monitoring of vital signs and ABC measures will continue. In the meantime, preferably two venous accesses will be placed, samples taken for blood tests, and chest radiograph and an electrocardiogram should be obtained. The latter can identify acute myocardial infarction or arrhythmias predisposing to stroke, such as atrial fibrillation. Beginning infusion of isotonic fluids (normal saline); and if present, hypoglycemia will be quickly treated, oxygen administration will continue and the stroke team recluted. Neurological status is will be assessed with a scale such as NIH Stroke scale. A CT scan will be obtained after clinical stabilization. Every effort should be made to ensure that all the above measures, including analysis of the images, take no longer than

45 minutes. The management of arterial hypertension, controversial and debated, is considered in detail below. Here, we mention only the formal contraindication to the use of vasodilators such as sublingual nifedipine as an abrupt drop in pressure levels may increase the extent of infarction. If CT detects no bleeding, ischemic stroke is diagnosed, and if the patient is in the window period, i.e., within 3 hours since the onset of symptoms, thrombolytic therapy should be considered.

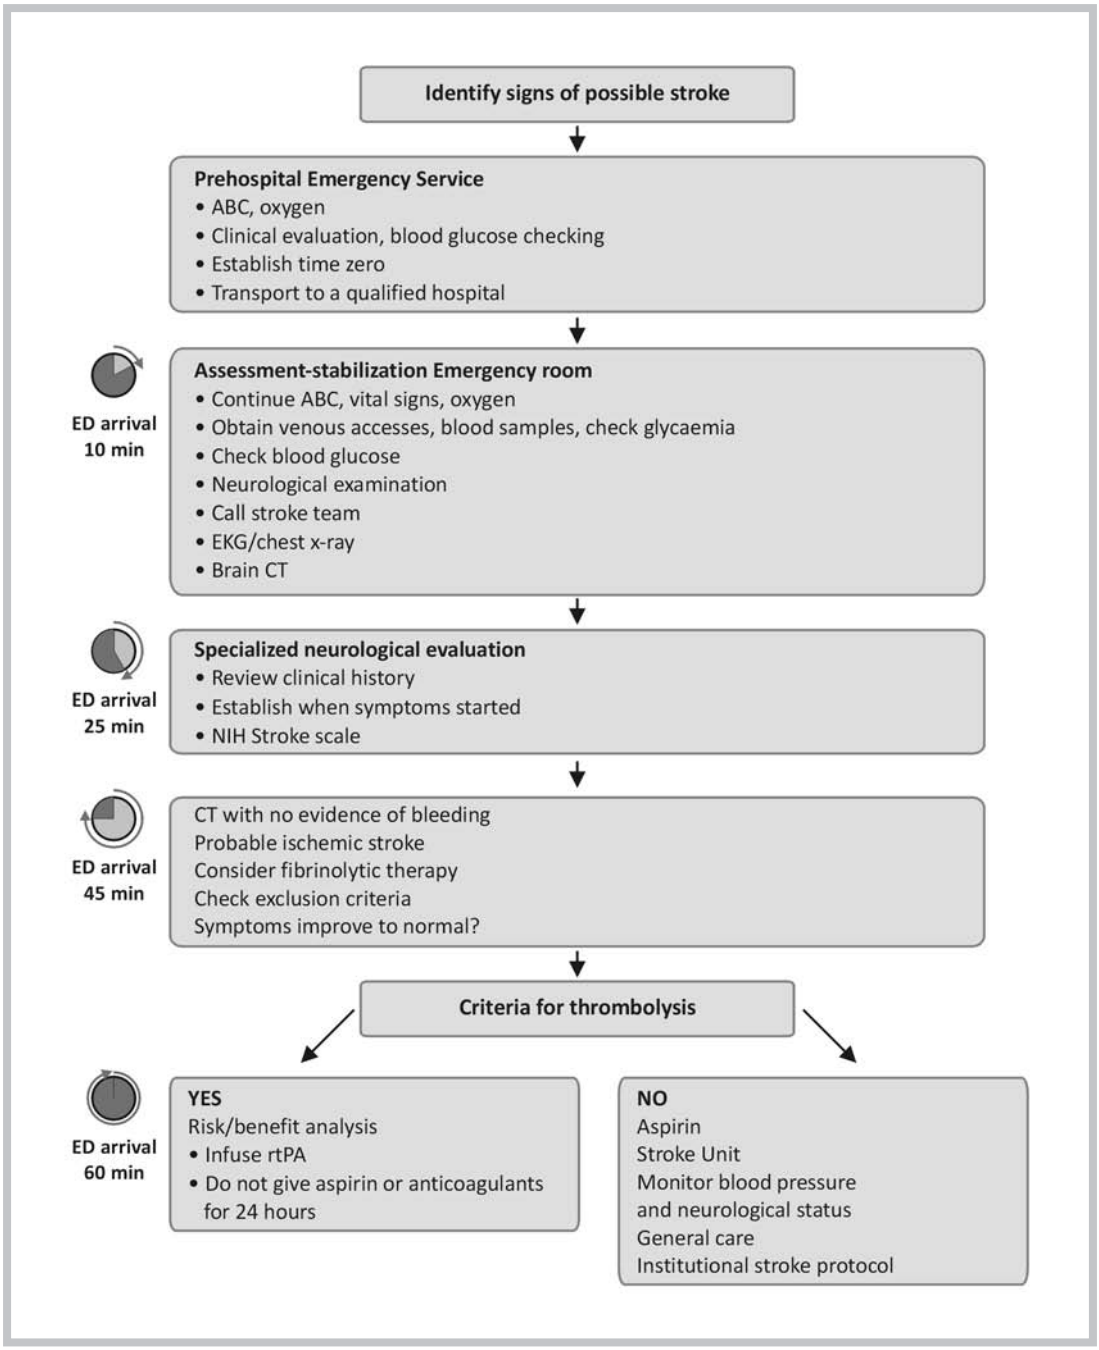

Figure 42.13. **Algorithm for the management of patients with suspected stroke.**
rtPA = recombinant tissue plasminogen activator

42.6.6 Stroke Units or Neurointensive Care Unit

Stroke units were first developed in North America in the 1960s in the wake of the success of coronary care units. Basically, a stroke unit is a section of a hospital where stroke patients are treated by a multidisciplinary team with a special expertise in stroke, including physicians, nurses, physiotherapists, occupational therapists, speech therapists and social workers.

Recent studies show an 18% relative decrease in mortality, a 3% absolute reduction in mortality and in the need for home care. Additional benefits were obtained with a 6% increase in the number of surviving patients able to perform activities of daily living.

Minimum requirements	Additional tests (performed according to physician's opinion)
• 24-hour availability of CT • Multidisciplinary team composed of internists/ intensivists, trained nurses, physiotherapists, speech therapists, rehabilitation experts, occupational therapists • Guidelines and protocols • Echocardiography, neck vessel Doppler • ECG, Holter monitoring • Biochemical laboratory tests (coagulation test) • ECG monitoring, blood pressure, blood oxygen saturation, temperature and blood glucose levels	• MRI/MR angiography • Diffusion-perfusion MRI • CT angiography • Digital subtraction angiography • Transesophageal echocardiogram • Transcranial Doppler • Diagnostic and interventional neuroradiological consultation • Neurosurgical consultation

Table 42.2. Essential requirements for the management of stroke patients.

- CT
- ECG/chest x-ray
- Blood chemistry: blood count, platelet count, international normalized ratio (INR), kaolin partial thromboplastin time (KPTT), prothrombin time and concentration, serum electrolytes, glucose, C-reactive protein (CRP), erythrocyte sedimentation rate, cardiac enzymes, blood gases, urea, creatinine, liver profile, complete urine
- Pulse oximetry
- Lumbar puncture in selected cases
- Carotid and transcranial Doppler
- ECG
- Transthoracic and transesophageal echocardiography
- Electroencephalogram
- MR angiography
- Cerebral angiography

Table 42.3. Supplementary examinations in an acute stroke emergency.

- Postictal paralysis (Todd's paralysis)
- Migraine
- Tumours
- Abscess, herpes encephalitis, meningococcal meningitis, other infections
- Chronic subdural hematoma
- Metabolic disorders (hyponatremia, hypoglycemia, hyper-hypocalcemia, etc.)
- Cerebral venous thrombosis
- Demyelinating diseases (multiple sclerosis, etc.)
- Hysteria, conversion disorder crisis

Table 42.4. Situations that can be mistaken for ischemic stroke and should be ruled out.

42.6.7 Management in the Critical Care Unit

General Treatment

The basic support measures are determined by the adequate support of vital functions, monitoring of neurological status, cardiorespiratory function, and early detection and correction of all situations that could potentially exacerbate or perpetuate the initial damage.

Airway management is essential as these patients constitute a high-risk population. Airway obstruction, aspiration of gastric contents, pulmonary edema and its consequences (hypoxemia and/or hypercapnia) are deleterious situations in the context of brain injury. These alterations are the end product of a number of disorders including: decreased level of consciousness, loss of cough and/or swallowing reflex, laryngopharyngeal muscle relaxation, etc. If a patient is able to maintain an "adequate ventilatory drive", the administration of supplemental oxygen via nasal tube, masks, continuous positive airway pressure (CPAP) or pressure support are recommended. Normoxemia (PaO_2 >90 mmHg, arterial oxygen saturation >95%) and normocapnia ($PaCO_2$ = 35-40 mmHg) are the objectives to be achieved. Based on clinical judgement, the decision whether to initiate endotracheal intubation should be made as quickly as possible, since delayed implementation exacerbates pre-existing injuries and increases morbidity and mortality as a result of secondary damage caused by hypoxemia, hypercapnia or aspiration of gastric contents.

With regard to mechanical ventilation indication, we adopt an aggressive policy and we indicate in the following situations:

- GCS ≤8 points.
- Neurological deterioration.
- Intracranial hypertension.
- Respiratory failure.
- Abnormal ventilatory patterns.
- Inability to achieve normocapnia and normoxemia, in spite of supplemental oxygen, bronchodilators, intensive kinesiotherapy, etc.

Another cornerstone of treatment is the achievement of cardiocirculatory stability. Arterial hypotension should be avoided at all costs because it is one of the secondary factors causing increased progression of injury. Since most of these patients are hypovolemic, volume expansion with isotonic fluids becomes a priority.

Controversy surrounds the type of solutions to infuse and the colloids versus crystalloids debate continues. Nevertheless, we recommend the use of isotonic solutions (saline 0.9% or slightly hypertonic 3.5%), with the goal of obtaining central venous pressures of about 10 to 12 cm of water. Under no circumstances (except in hypoglycemia) should hypotonic solutions such as dextrose or Ringer's lactate be prescribed as they induce and/or worsen cerebral edema, promote the synthesis of neurotoxic agents such as glutamate, cause local tissue acidosis: when combined, all these factors increase intracranial pressure.

The association of brain and cardiovascular disease is very common because they share the same risk factors, so the presence of arrhythmias is not surprising.

EKG in the acute phase may show ST segment changes, or T wave, which simulate an acute myocardial infarction, including an increase in cardiac enzymes. Arrhythmias are rarely life-threatening. Atrial fibrillation with high ventricular response or ventricular arrhythmias require immediate and aggressive treatment. Not to be forgotten in the search of etiology, the detection and correction of electrolyte disturbances, mainly of magnesium and potassium. Heart failure, acute myocardial infarction or sudden death can complicate the clinical course.

Achieving a physiological balance between organ systems becomes a priority when resuscitating the brain. Maintenance of homeostasis of the interior milieu, particularly with regard to metabolism and the compartmental distribution of water and sodium, is of vital importance. Inevitably, disturbances in sodium and water balance alter the osmolarity: such changes, in turn, result in profound changes in all cells of the CNS. In hyperosmolar states, water leakage from the cell interior occurs, resulting in dehydration of the cell itself. Conversely, in hyposmolar states there is a net gain of water with consequent cellular edema. The incidence of hyponatremia in neurocritical patients is about 10%, but more important is that it contributes to increased mortality according to the associated disease: the reported increases range from 7 to 60%.

Hypernatremia, less frequent (1%), is an epiphenomenon reflecting the severity of brain insult. The etiologies of both disorders are multifactorial and have been discussed elsewhere in this book; however, it's important remember here the ordered and systematic search for causes, because therapies can be diametrically opposed.

Elevated blood glucose levels, a product of metabolic alterations, response to stress, etc., are common in critical illnesses, including those of neurological origin. Current evidence demonstrates that hyperglycemia has deleterious effects in several acute brain diseases, including ischemic stroke, contributing to worsening of outcome in both diabetic and non-diabetic patients.

Hyperglycemia exerts its harmful effects through multiple mechanisms, including impaired blood-brain barrier permeability, production of oxygen free radicals, local tissue acidosis, stimulation of inflammation and the release of excitatory amino acids, etc.

Tight control of blood glucose, at least in theory, is associated with multiple benefits, including elimination of osmotic diuresis, maintenance of neutrophil and macrophage function, decreased production of oxygen free radicals, stimulation of nitric oxide production, etc.

Furthermore, insulin has both anti-inflammatory and neuroprotective effects, allowing us to hypothesize benefits while adopting aggressive treatments of elevated blood glucose levels in the acute phase of stroke.

However, studies investigating this issue in neurocritical patients have not yet been designed or carried out. We don't even know the glycemic cohort suitable for initiating treatment. American and European guidelines only recommend starting treatment at greatly increased levels, i.e., >180 mg/dl or >300 mg/dl, respectively. Both are too high if we consider the available evidence, i.e., that lower levels of about 153 mg/dl are associated with poor outcome at 3 months, and that values >140 mg/dl reduce the efficacy of thrombolytic therapy.

In our unit, we monitor blood glucose levels at frequent intervals, i.e., initially every 2 hours, correcting values >150 mg/dl with regular intravenous insulin. We will later (in another chapter of this book) analyze this aspect in greater detail.

Hyperthermia should be treated urgently and aggressively, as it has noticeable deleterious effects on neurons and the blood-brain barrier by triggering inflammation, stimulating the production of oxygen free radicals, increasing the levels of excitatory amino acids, increasing the cerebral metabolic demand of oxygen: taken together, all these variables contribute to the establishment of the initial damage and the extension of the ischemic area. Moreover, the presence of fever exerts negative effects on the subsequent evolution of these patients, but it is unclear which methodology should be used for its correction. As a general rule, we will take all necessary measures, either pharmacological (paracetamol, ibuprofen) or physical (cold baths, thermal blankets), in order to maintain a core body temperature <37.5°C.

Furthermore, swallowing and digestive disorders should not be underestimated in this patient population. Intestinal paralysis (ileus) and gastroparesis are common. Num-

bering among the pathophysiologic mechanisms involved are an altered reflex action caused by brain damage, the interaction of inflammatory mediators such as cytokines or commonly used drugs such as morphine, fentanyl, phenytoin, norepinephrine, etc. Moreover, a typical practice in intensive care units throughout the world is the prophylaxis of gastric ulcers or stress-related hemorrhagic gastritis with the use of proton pump inhibitors, like omeprazole, or H2 receptor antagonists, like ranitidine: but both raise intestinal pH, thus favouring the growth of bacteria, mainly Gram-negative bacilli.

In addition, if we consider that the lower esophageal sphincter (whose main function is to prevent the reflux of gastric contents) does not work properly, it comes as no surprise that the risk of continuous pulmonary microaspiration is very high: this explains one of the most important reasons for the genesis or development of pneumonia associated with mechanical ventilation.

Therefore, we add to the therapeutic regimen gastrokinetics like metoclopramide or cinitapride, along with simple measures as maintaining the patients in a semi-recumbent position. The hypercatabolic state and swallowing disorders in these patients require that they be fed early, i.e., within the first 24 hours, preferably via the enteral route using nasojejunal tube.

These seemingly obvious measures should not be overlooked. Their importance is sometimes underestimated, or worse, not taken into due account: the care of the eyes, skin and mucous membranes, and, above all, the gingival mucosa and oral cavity, which must undergo periodic washing with chlorhexidine or other similarly effective mouthwashes. Patient position should be regularly changed to prevent the development of pressure ulcers, and deep vein thrombosis prophylaxis instituted with elastic bandages, pneumatic sequential compression sleeves or the use of low-molecular-weight heparins.

Finally, some words with regard to the management of arterial hypertension, 80% of ischemic stroke patients in the acute phase have blood pressure values above the threshold considered normal by the current definition (>140 mmHg systolic and/or >90 mmHg diastolic). It is also true that in most cases the blood pressure will spontaneously decrease with time.

The debate over whether or not to treat arterial hypertension continues. TSome supporting treatment are based on the fact that very high blood pressure values may cause direct endothelial damage or would exacerbate or trigger cerebral edema, increase the likelihood of hemorrhagic transformation of infarction, especially in patients undergoing revascularization by drug therapy with tissue plasminogen activator, and cause direct endothelial damage.

Those claiming otherwise argue that a loss of cerebral autoregulation occurs in the acute phase of ischemic stroke, so that CBF becomes “pressure dependent”: lowering blood pressure would therefore decrease CBF, thus exacerbating the already compromised situation of the penumbra area. Recent clinical studies have indicated that the extent of decline in arterial pressure in the first 24 hours post-stroke is independently associated with neurological deterioration, increased infarct size and poor outcome 3 months after the event.

There are certain situations accompanying stroke where arterial hypertension should be inevitably and immediately treated:

- Aortic dissection.
- Acute myocardial infarction.
- Acute pulmonary edema.
- Hypertensive encephalopathy.
- Hypertensive nephropathy with malignant course.

Table 42.5 lists the current American and European recommendations for the management of arterial hypertension in the acute phase of ischemic stroke.

Arterial pressure (mmHg)	ASA	EUSI
SAP ≤220 or DAP ≤120	Do not treat	Do not treat
SAP >220 or 140 <DAP <120	• Labetalol • Nicardipine	• Labetalol • Nicardipine • Urapidil • Captopril • Clonidine • Hydralazine
DAP >140	Sodium nitroprusside	Sodium nitroprusside- nitroglycerin

Table 42.5. **Management of blood pressure in the acute phase of ischemic stroke. Current guidelines suggested by the American Stroke Association (ASA) and the European Stroke Initiative (EUSI).**
DAP = diastolic arterial pressure
SAP = systolic arterial pressure

Patients selected for thrombolysis have had a greater risk of hemorrhagic complications, so that the target to obtain in arterial pressure values are lower than those mentioned above, i.e., about 185/105 mmHg.

42.6.8 Specific Therapy

Thrombolytic Agents

Fortunately, the last decade was marked by a noticeable change of attitude toward the treatment of ischemic stroke. Like a phoenix rising from the shadows dominated by nihilism, active intervention lit up the dark horizon.

As we said previously, neurons begin to die almost immediately when deprived of oxygen for even a few minutes. Around this area of irreversible brain damage so called "core'', there is a hypoperfusion area which receives blood flow and sufficient oxygen to maintain cell viability. Time is fundamental to preserve the "stunned brain". This area so called "penumbra'' is threatened but potentially salvageable with prompt and appropriate therapy.

The recombinant tissue plasminogen activator (rtPA) when administered intravenously has proved effective in restoring blood flow to ischemic myocardium. By analogy, the principle of recanalization of obstructed vessel with thrombolytic agents was applied to ischemic stroke.

In 1995, the American National Institute of Neurological Disorders and Stroke (NINDS) published the results of a randomized, placebo-controlled study in which rtPA was administered to ischemic stroke patients within 3 hours from the onset of symptoms. The study involved 625 patients and showed no significant differences in terms of mortality: however, at 3-month follow-up there was an 11% absolute increase in the number of patients who had completely recovered or with minimal consequences. The dose used was 0.9 mg/kg body weight at a maximum dose not exceeding 90 mg; 10% of the total dose was administered as a bolus, the remaining as continuous infusion for 1 hour. CT without evidence of bleeding was an indispensable requirement, and inclusion and exclusion criteria for the study were properly specified. To date, they are used in the protocols of thrombolysis in almost all centres around the world, including ours (Table 42.6) with minor modifications mainly concerning neuroimaging.

Two European studies (ECASS I-II) did not replicate the results of the NINDS; however, the ECASS I used a higher dose of rtPA (1.1 mg/kg), and both trials tested a more wide therapeutic window lasting up to 6 hours. Another difference in the methodology of

these studies in reference to the NINDS was that the presence of major signs of early infarction was a reason in CT scan for excluding patients.

A first meta-analysis of the three cited studies (NINDS, ECASS I-II) showed a 45% reduction in the probability of unfavourable results if we use the dose and therapeutic window recommended by the NINDS.

Recently, the results of six studies (total of 2775 patients) on the time of beginning of rtPA infusion were released. In brief, the shorter the time interval between the onset of stroke and thrombolysis, the greater probability of better results, strengthening the concept of "Time lost, brain lost."

Always keep in mind that after rtPA infusion, "antiplatelet agents or anticoagulants should not be administered in the following 24 hours." During the infusion period, frequently and obsessively monitoring of arterial pressures levels should be guaranteed and, as noted above, do not allow pressures to rise higher than 180/105 mmHg of systolic and diastolic respectively.

If there is neurological deterioration, the presence of brain hemorrhage should always be suspected, the infusion of rtPA should be immediately stopped, coagulation parameters checked, a CT scan urgently obtained, a neurosurgeon alerted, and hemotherapy with cryoprecipitates, fresh plasma, and platelets ordered..

Based on the results of ECASS-III, it has recently been recommended to widen the therapeutic window for fibrinolytic infusion to 4.5 hours from symptom onset. This trial, designed and carried out in Europe, compared versus placebo the efficacy of rtPA infusion versus placebo at doses used in the NINDS study in the period of 3 to 4.5 hours from the onset of symptoms.

Inclusion criteria for fibrinolysis in ischemic stroke	• Age >18 years • Clinical diagnosis of stroke with NIH Stroke scale score >4 and <25 • Onset of symptoms within 4.5 hours • CT without evidence of hemorrhage

Exclusion criteria for fibrinolysis in ischemic stroke	• Medical history
	  · Stroke or head trauma in the previous 3 months
	  · History of intracranial hemorrhage may increase the risk of bleeding
	  · Surgery or major trauma in the previous 2 weeks
	  · Gastrointestinal bleeding or hematuria in the previous 3 weeks
	  · Arterial punctures in the previous week
	  · Pregnancy or breastfeeding
	• Clinical findings
	  · Rapidly improving neurological symptoms
	  · Seizures at admission
	  · Clinical picture with suspected subarachnoid hemorrhage despite negative CT
	  · SBP >185 mmHg or DBP >110 mmHg despite treatment
	  · Acute myocardial infarction
	  · Pericarditis
	• Diagnostic imaging
	  · CT evidence of hemorrhage
	  · CT hypodensity or effacement of the sulci in more than one third (33%) in the territory of the middle cerebral artery
	• Laboratory
	  · Glycemia >400 mg/dl or <50 mg/dl
	  · Platelet count <100,000/mm^3
	  · Patients taking anticoagulants with increased INR
	  · Patients receiving heparin for 48 h with prolonged KPTT

Table 42.6. **Criteria for the use of rtPA in ischemic stroke patients in the neurointensive care units at the Pasteur Sanatorium, Catamarca, Argentina.**

In this study, were excluded patients older than 80 years, those who were treated with oral anticoagulants, or with severe stroke as defined by a NIH Stroke scale score >25 or individuals with a prior history of diabetes and stroke. Moreover, the inclusion and exclusion criteria were similar to the NINDS. The symptomatic hemorrhage rate varied according to the definition used, but was consistent with previous trials, being higher in the group treated with fibrinolytics. The mortality of the groups was similar, but the patients treated with rtPA had a better functional outcome (52.4 vs. 45.2%, OR 1.34, 95% CI 1.02-1.76; RR 1.16; p 0.04) after 90 days from the event.

Intra-arterial thrombolysis is a promising option, as evidenced by a series of cases which must be validated in the future. In theory, this technique would offer some advantages compared to intravenous therapy, including more effective recanalization rates, widening of the therapeutic window (all by direct infusion into the thrombus), as well as the possibility of reducing the adverse effects of the drug, etc. Prourokinase and rtPA are agents used in the trials. Disadvantages include the need for a specialized neuroradiologist and team available 24 hours 7 days a week. To date, its use is restricted to clinical research.

Antiplatelet Agents. Anticoagulation

Aspirin. It's the only drug tested on a large scale for the treatment of ischemic stroke in acute phase. Two studies, international (IST) and Chinese (CAST) trials, have concluded that aspirin started within 48 hours from stroke reduces the immediate risk of recurrence or death in hospital, as well as the risk of death or functional dependence 6 months later. The daily doses were 160 and 300 mg for the CAST and IST, respectively. In addition, the two studies showed a good safety profile for the drug. It should not be administered within 24 hours after thrombolysis.

Anticoagulation. Different heparins and regimens have been used and all have failed to show any positive effect in the acute stage of stroke; therefore, it is not recommended for routine use. However, there are situations where it may be beneficial:

- Presence of cardioembolic stroke at high risk of recurrence; for example: atrial fibrillation, artificial heart valves, acute myocardial infarction with mural or intracavitary thrombi, left atrial thrombosis.
- C and S protein deficiency.
- Antiphospholipid syndrome.
- Carotid and/or vertebral dissection.
- Cerebral venous thrombosis.
- Intra-extracranial symptomatic stenosis: before surgery.
- In crescendo TIA or stroke-in-progression.

Statins. The last decade was characterized by experimental and clinical studies which demonstrated in different ways the benefits of treatment with inhibitors of hydroxymethyl-glutaryl CoA reductase, independently of their effects on serum cholesterol levels, since, paradoxically, hypercholesterolemia is not a validated risk factor for ischemic stroke. Moreover, hypocholesterolemia is considered a predisposing factor for the development of spontaneous intracerebral hemorrhage, and not ischemic stroke. Statins have potential benefits, including:

- Protection of the vascular endothelium.
- Increased nitric oxide synthesis.
- Anti-inflammatory.
- Immunomodulation.
- Stimulation and regulation of progenitor cells.
- Neuro- and synaptoplastic effect.
- Stabilization of atherosclerotic plaques.

- Increase of cerebral blood flow.

From a clinical point of view, statins:

- Decrease the incidence of brain and cardiovascular events.
- Improve the functional outcome after ischemic stroke.
- Reduce mortality.
- Withdrawal of therapy has a rebound effect on the cerebral and coronary vasculature, with devastating effects.

It is our current practice to use of simvastatin or atorvastatin 40 mg daily for 1 week and then continue with 20 mg/day for the first 3 months after an ischemic cerebrovascular event.

43 Ischemic Penumbra: Role of Neuroimaging in Treatment Decision

Alvaro Cervera [1], Geoffrey A. Donnan [2]

[1] Comprehensive Stroke Center, Hospital Clínic, IDIBAPS, Barcelona, Spain
[2] Director, Florey Neuroscience Institutes, Melbourne Brain Centre, Heidelberg, Victoria, Australia

43.1 Introduction

Thrombolysis with alteplase is the only medication approved for acute ischemic stroke. Alteplase has shown to be effective if given within 3 hours after symptoms onset. However, due to the narrow time window, less than 5% of patients with this condition receive this drug. To be able to treat a greater number of patients it would be crucial to extend this time window.

There are different approaches aimed at increasing the traditional 3 hour time window. There are studies analyzing the efficacy of alteplase in eligible patients who present with acute ischemic stroke in either the 3-4.5 hours (in the third European Cooperative Acute Stroke Study; ECASS III), or the 3-6 hours (in the third International Stroke Trial; IST-3) time windows. The recently published positive result of ECASS III has extended the time window to 4.5 hours, although there might be some delay in establishing this in standard clinical practice. The second approach is to select patients that are more likely to respond to the thrombolytic treatment. The main target for this selection is based on the ischemic penumbra concept.

This chapter aims at describing what ischemic penumbra is, how we can assess penumbra in clinical practice, what evidence we have for using penumbra as a tool for treatment decision, and what the future of penumbra in stroke treatment is.

43.2 Definition of Ischemic Penumbra

After the occlusion of a major cerebral vessel the brain tissue of the corresponding vascular territory suffers from focal ischemia. This will lead to ischemic injury, which magnitude and localization will depend on the extent, severity, and duration of the perfusion deficit. Experimental studies employing middle cerebral artery occlusion have established that local cerebral blood flow (CBF) values below 0.10-0.12 ml/g/min lasting 2 hours or longer are associated with consistent infarction, whereas higher flows avert irreversible injury.

While the blood vessel is still occluded, there will be different zones in the ischemic region if the CBF values are taken into account (Figure 43.1). In the ischemic core, due to the low CBF values, injury is irreversible. This area is surrounded by brain tissue that is functionally affected but still viable if adequately reperfused: the ischemic penum-

bra. However, not all the hypoperfused tissue surrounding the ischemic core can be called ischemic penumbra. There is an area in the periphery of the ischemic penumbra where there are low CBF values, the fate of which will not depend on recanalization. This area that will not be recruited into the ischemic core is called "area of benign oligaemia".

Therefore, ischemic penumbra is the potentially salvageable cerebral ischemic tissue that is present around the ischemic core. This concept arose by clinical observations of fluctuating neurological deficits that suggested different perfusion thresholds for loss of neuronal function and cell death. After the description of these thresholds in experimental models of ischemia, penumbra was defined as the portion of the ischemic zone with reduced cerebral blood flow, absent electrical activity, but preserved ion homeostasis and transmembrane electrical potentials. However, in clinical practice it is more relevant to define ischemic penumbra as the portion of the ischemic tissue that is still potentially viable.

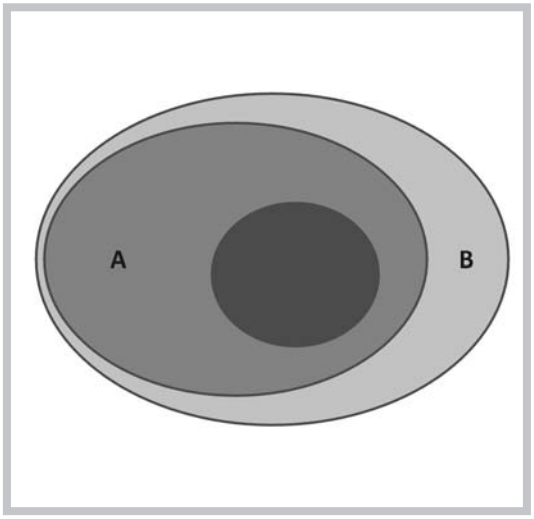

Figure 43.1. **Schematic representation of the ischemic tissue after a major vessel occlusion. In black there is represented the ischemic core, irreversibly damaged. The ischemic penumbra is represented by the "A" area. This is the tissue that can be salvaged after the use of thrombolytic therapy. Surrounding the ischemic penumbra, there is the benign oligaemia area ("B" area), which will survive regardless there is reperfusion or not.**

Penumbral tissue is an abnormal tissue with physiological and biochemical characteristics of cellular dysfunction but not cellular death, caused by hypoperfusion. This tissue has to be in the same vascular territory as the infarct core. The main relevance of this tissue is that it can either survive or progress to necrosis, and its salvage is associated with better clinical outcome. Thus, ischemic penumbra can be defined as the ischemic tissue which function is impaired and it is at risk of infarction. The clinical relevance is, therefore, that this tissue can potentially be salvaged if there is reperfusion. If reperfusion is not achieved this tissue at risk will be recruited into the infarct core.

The tissue surrounding the infarct core remains viable, but severely compromised because of metabolic, hemodynamic, and neurochemical alterations characteristic of the ischemic environment. In this region, endogenous protective mechanisms (i.e., local expression of survival factors) and residual collateral blood flow are only able to delay the otherwise inevitable cell death process leading to infarct growth. In normal brain an increase in local glucose metabolism is closely coupled to a reactive increase in local CBF to match the metabolic demands. The dissociation between metabolism and flow is pronounced in focal cerebral ischemia. Maintenance or focal increases in glucose utilization have been observed in brain regions adjacent to the ischemic core. Therefore, the uncoupling of metabolism and flow is an important pathogenetic mechanism that affects the critical energy balance in the penumbra.

Lastly, the ischemic penumbra is a dynamic tissue structure of limited viability surrounding a focus of dense cerebral ischemia. The flow thresholds for electrical and membrane failure are not constant but increase in a time-dependent manner. Therefore, with time increases the viability of the penumbra will decrease and more tissue will be recruited in the core.

43.3 Neuroimaging Tools to Assess Ischemic Penumbra

Just a conventional cranial computed tomography (CT) is enough to select stroke patients to receive alteplase in the 3 hour time window (or 4.5 hours if we take into account the results of ECASS III). However, many authors defend the use of more sophisticated technology to improve the selection of patients and the avoidance of hemorrhagic complications, but there is not enough evidence to recommend further neuroimaging assessment in the approved time window.

While conventional CT can detect hemorrhage and the ischemic core, the new neuroimaging tools are able to characterize the ischemic penumbra by assessing brain perfusion and metabolism. This information can help us to extend the therapeutic window, to exclude patients that do not require thrombolysis because they do not have penumbra, to detect patients who more probably will be harmed by treatment or are unlikely to respond (for example in the malignant pattern in which a very large diffusion weighted image on MR is matched by a similarly sized perfusion image), or to select patients that have not responded to intravenous alteplase to rescue intra-arterial thrombolysis.

There are many neuroimaging tools that have shown efficacy in penumbra assessment. However, there is lack of consensus on the appropriated method to measure penumbra.

43.3.1 Positron Emission Tomography

Positron emission tomography (PET) is a nuclear medicine imaging technique which produces a three-dimensional image of functional processes. It is based on the detection of pairs of gamma rays emitted by a positron-emitting radionuclide (tracer), which is introduced into the body on a biologically active molecule. Multitracer PET using the ligands $H_2{}^{15}O$ and $^{15}O_2$ has been used to quantitatively measure cerebral blood flow (CBF), cerebral metabolism of oxygen ($CMRO_2$) and cerebral oxygen extraction fraction (OEF). The quantitative measurement of CBF, $CMRO_2$, OEF and cerebral blood volume (CBV) allows the assessment of perfusion and energy metabolism. Thus, in ischemic stroke is possible to detect the four tissue subtypes: core, penumbra, oligaemia and unaffected tissue, as well as the thresholds that reliably and efficiently separate them.

^{11}C-flumazenil is a PET radioligand that binds to the benzodiazepine site on the neuronal [gamma]-aminobutyric acid receptor and has been applied with $^{15}O_2$ tracers in acute stroke patients. This ligand it is able to distinguish ischemic core from penumbral tissue early after acute stroke. ^{11}C-flumazenil binding below 3.4-times the mean of contralateral white matter predicts irreversible tissue damage, and a CBF of 14.1 ml/100 g per minute is the penumbral threshold.

Another marker, ^{18}F-fluoromisonidazole, provides a direct image of the penumbra, but not of the ischemic core. Studies with ^{18}F-fluoromisonidazole have shown that penumbra may last for long periods in some patients, and that penumbral salvage is time-independent, with at least 50% tissue survival even beyond 12 h.

PET is considered the gold standard to study ischemic penumbra, because it provides quantitative mapping of many physiological parameters. However, its utilization is not practical in clinical studies, because of it complexity, cost, and its limited availability.

43.3.2 Magnetic Resonance Imaging

The ischemic penumbra can be evaluated with magnetic resonance imaging (MRI), using diffusion-weighted (DWI) and perfusion-weighted (PWI) sequences. Currently, DWI

and PWI MRI studies are the most widely used clinical imaging modalities to detect the presence of penumbra.

DWI measures alterations in the diffusion of water molecules. The degree of free diffusion of water molecules can be quantified with the apparent diffusion coefficient (ADC). The changes detected with DWI are due to metabolic failure leading to disruption of ion homeostasis and cytotoxic edema. The DWI image visualizes acute ischemic lesions within minutes, and identifies acute infarcts within 6 hours after onset with high sensitivity and specificity. The hyperintense lesions represent the irreversible damaged brain tissue, so the altered region detected with DWI is a reasonable representation of the infarct core.

PWI detects the signal loss of flow that occurs during the dynamic tracking with the use of gadolinium, an intravenous paramagnetic contrast agent. With this technique it is possible to delineate ischemic areas as an abnormal perfusion area, which is commonly defined by time domain parameters on dynamic contrast-enhanced imaging, including mean transit time (MTT), time to peak (TTP), or T_{max}. MTT is the time between arterial inflow and venous outflow. TTP represents the time from the beginning of gadolinium injection to the maximum enhancement within an intracerebral region of interest. T_{max} is the time to peak of the residue function, indicating bolus delay between the site of selection of the arterial input function and the tissue. Therefore, T_{max} represents bolus arrival time, without the confounding effects of bolus administration.

The mismatch between a PWI lesion and a DWI lesion is the MRI signature of the ischemic penumbra. The PWI-DWI mismatch region is defined as the difference in volume of tissue between the smaller diffusion lesion and the larger perfusion lesion. The mismatch provides an estimation of the extent of penumbra and can be used to monitor infarct growth over time. Ischemic penumbra is defined when there is at least a 20% discrepancy between the two volumes. It is observed in over 50% of middle cerebral artery territory stroke patients when studied up to 6 hours after the symptoms onset of stroke, and it may persist up to 24 hours. In the absence of reperfusion the DWI lesion typically expands into the PWI volume. This expansion is not only dependent on time, as it might be influenced by blood glucose concentrations, temperature, hematocrit, systemic hypoxia, and age.

However, using MRI in the acute stroke setting has some disadvantages. The time taken to acquire the data is longer than in conventional CT. Moreover, the procedure is not applicable in some patients because of claustrophobia or the presence of pacemakers or metal objects. There is also a small risk of nephrogenic systemic fibrosis in patients with severe renal impairment who receive gadolinium, but the use of contrast agents could be avoided in the future by the use of new techniques such as arterial spin labelling. Another limiting factor is the need for automated, online image analysis.

Although it has shown to be a good tool to assess acute ischemic stroke patients, there are some uncertainties regarding MRI to assess penumbral tissue. In animal models of ischemia and some clinical studies, it is possible to observe a very early reversibility of the DWI lesions. Therefore, the acute DWI lesion may not only represent tissue destined for infarct, but also severely ischemic tissue that may still be saved from necrosis. Even severely reduced ADC values, very early after stroke, are reversible in some patients. Also, DWI lesions can reappear after an initial disappearance following treatment. This is probably due to inflammatory tissue injury, delayed mitochondrial dysfunction, and apoptosis. Moreover, there can be false negatives of DWI in patients with ischemia in the posterior circulation.

On the other hand, PWI can detect areas of hypoperfusion that are not really penumbral tissue, but benign oligaemia. Thus, PWI techniques may overestimate the amount of tissue that is critically hypoperfused. This is important in penumbra assessment, as these

areas of benign oligaemia will survive regardless of reperfusion. It is possible to reduce the volume of benign oligaemia, and therefore to improve the precision of PWI for estimating the volume of penumbral tissue in acute stroke patients and improve the accuracy of early prediction of final infarct volume, by using a threshold to exclude areas with minimal delay in contrast arrival times. The use of a strict T_{max} threshold (>4 or >6 seconds) might reduce the percentage of patients considered to have a mismatch, but identifying mismatch patients who are more likely to have salvageable tissue. TTP maps are easiest to generate and to interpret visually. However, MTT or TTP can be increased even in areas without hypoperfusion if the perfusion pressure is reduced, as happens in autoregulation.

There are alternative methods to improve the definition of mismatch, such as a larger mismatch ratio than the typically selected 1.2. The original concept of PWI-DWI mismatch introduced an arbitrary ratio of 20%, but there is no evidence to support it. This volume ratio is very conservative and the increases are more modest because of the cubed root relation of radius with volume.

Despite these uncertainties, MRI remains the most practical tool for identifying tissue at risk of infarction in the early phase of acute ischemic stroke. Moreover, there are new MRI techniques than can help to avoid the uncertainties in infarct core and penumbra assessment. Arterial spin labelling, a non-invasive perfusion MRI technique, uses electromagnetically labelled arterial blood water to measure CBF. A quantitative estimate of the OEF can be obtained using MRI with the results in good agreement with values reported in the PET literature. By combining MRI-measured OEF and CBF via quantitative perfusion studies it might be possible to obtain a measure of the $CMRO_2$ using MRI in acute stroke patients.

43.3.3 CT Perfusion

Conventional cranial CT is the most important imaging technique for acute stroke because of its easy availability and accessibility. It is helpful to discard intracranial hemorrhage and to detect the appearance and extent of early infarct signs. However, it gives little information about the presence and extension of ischemic penumbra. Although hypodensity on CT within the first 6 h may represent irreversibly infarcted tissue, tissue at further risk of damage cannot be clearly distinguished with conventional CT.

However, the combination of CT perfusion and CT angiography allows the evaluation of ischemic penumbra. The baseline CT perfusion should have 3 components: unenhanced CT, vertex-to-arch CT angiography (CTA), and dynamic first-pass CT perfusion.

CT perfusion involves the dynamic acquisition of sequential CT slices during the administration of contrast material and an analysis of time-concentration curves for each pixel. Brain tissue flow can be described by several parameters including CBF, CBV, and MTT. CBV is the total volume of flowing blood in a given volume in the brain, with units of millilitres of blood per 100 g of brain tissue. CBF is the volume of blood moving through a given volume of brain per unit time, with units of millilitres of blood per 100 grams of brain tissue per minute. MTT is the average transit time of blood through a given brain region, measured in seconds. In CT perfusion, the ischemic core is defined as the CBV lesion volume, i.e. the equivalent to the DWI lesion in MRI. The mismatch between the MTT or CBF lesion and the CBV lesion represents the ischemic penumbra.

Ischemic penumbra is defined by a CBF below 34% of the non affected hemisphere, with a CBV above 2.5 ml/100 g, and a MTT of be more than 145% of the contralateral side. The infarcted tissue is defined by a CBV below 2.5 ml/100 g.

The general principles underlying the computation of perfusion parameters such as CBV, CBF, and MTT are the same for both MR imaging and CT. The most important advantage of CT perfusion is the linear relationship between contrast concentration and attenuation in CT, which facilitates quantitative measurement of CBF and CBV. The main disadvantage of CT perfusion is the relative limited coverage, as most machines are only able to cover 4 brain slices, so the volumetric assessment of the core and penumbra might be incomplete. Nevertheless, newer CT equipment is able to cover the whole brain with a single bolus injection, similar to PWI-MRI.
The advantages of this technique are their wider availability, as it can be performed in any centre that has spiral CT. Also, the assessment is quicker than with MRI, and there are no concerns about claustrophobia, pacemakers, or metallic objects. Studies can immediately follow plain CT and be completed within about 5 minutes. However, the risk of contrast-induced nephropathy is more important than with MRI.

43.4 Clinical Relevance of Ischemic Penumbra: Using Penumbra as a Proof-of-concept

The aims of thrombolytic therapy are the recanalization of the occluded artery and salvage of the ischemic penumbra. Imaging penumbra might allow selection of patients for thrombolysis beyond 3 hours. Two phase II trials of thrombolysis with alteplase – the DEFUSE and the EPITHET trials – incorporated penumbral imaging and are worthy of further discussion.
The Diffusion and Perfusion Imaging Evaluation for Understanding Stroke Evolution (DEFUSE) trial was a prospective, open label, non randomized, multicenter trial aimed at confirming eligibility for intravenous thrombolysis with alteplase within 3 to 6 hours after onset. It included 74 patients, who received open-label alteplase and were analyzed using MRI and MRA within 3-6 hours of stroke onset and at 24 hours. The main hypothesis was that prespecified MRI profiles could be used to identify patients who have a robust clinical response to reperfusion when treated with alteplase 3-6 hours after stroke onset. The presence of mismatch was assessed if the PWI lesion was more than 20% larger than the DWI lesion. This study showed that it is safe to use MRI to define mismatch, and that thrombolytic treatment is effective in patients with mismatch. However, patients were not selected on the basis of MRI findings. In DEFUSE, early reperfusion in patients with a mismatch was associated with favourable outcome. These results were better after the exclusion of patients with malignant mismatch (i.e., a baseline DWI ≥100 ml, and/or PWI ≥100 ml with a T_{max} ≥8 seconds). This positive effect of alteplase was not observed in patients without mismatch.
The Echoplanar Imaging Thrombolytic Evaluation Trial (EPITHET) was a phase II trial aimed at analyzing the effect of intravenous alteplase on ischemic lesion growth, reperfusion, and clinical outcome in patients with ischemic penumbra 3 to 6 hours after stroke onset. It was a randomized, double-blinded, placebo-controlled, multinational trial. Patients were treated with either alteplase or placebo, and were imaged with MRI before treatment and repeated at day 3-5. Mismatch was defined as a PWI/DWI volume >1.2 ml, and PWI-DWI volume ≥10 ml, and hypoperfusion volumes were defined using a T_{max} delay of 2 seconds or more. MRI was not used to select patients, but to determine the effect of alteplase on lesion growth, reperfusion, and clinical outcomes. The primary endpoint was a greater attenuation of infarct growth in patients with an imaging mismatch who received alteplase than in those who received placebo. The study enrolled 101 patients, 52 allocated to alteplase and 49 allocated to placebo. The prevalence of

mismatch was 86%, and arterial occlusion on MRA was seen in 62% of patients. The geometric mean growth of the ischemic lesion was about two-thirds in the alteplase group compared to the placebo group, although this difference was non significant. The incidence of reperfusion was significantly higher in patients with mismatch who received alteplase. Recanalization was associated with lower infarct growth and good neurological outcome in patients with mismatch. Although EPITHET was not powered to test differences in clinical outcomes, there was a better functional recovery at 3 months in the treatment group. The primary outcome measure of this study was negative, but other measures supported the hypothesis of attenuated infarct growth with alteplase beyond 3 hours.

Both studies provide strong biological support for the relation between infarct growth, reperfusion, and clinical outcome in the 3-6 hours time window after onset of stroke. However, these trials had some limitations. The analysis of the imaging data might have led to an underestimation of the true mismatch volumes, and neither study was powered to test the mismatch hypothesis.

There are other studies testing demosteplase, another thrombolytic agent which has some theoretical advantages over alteplase. In the DIAS trial there was a dose-response effect on reperfusion rates seen on PWI with greatest benefits with either 90 μg/kg or 125 μg/kg desmoteplase in the 3-9 hour time window. These results were replicated in the US Dose Escalation of Desmoteplase for Acute Ischemic Stroke (DEDAS) trial. With this encouraging data, the phase III DIAS-2 study, the largest penumbral selection trial with 186 patients, was undertaken. The primary outcome measure was clinical recovery at 3 moths. Good outcome was similar in the placebo and in the 90 μg/kg desmoteplase groups. However, patients who received 125 μg/kg desmoteplase had lower recovery and higher mortality. Most deaths in the latter group were non-neurological and occurred late in the trial, and were more likely due to chance.

There are other trials in acute ischemic stroke that have used the principle of penumbral selection (GAIN MRI substudy, Citicoline study, Normobaric oxygen study, COOL AID hypothermia). These are phase II trials that have tested the hypothesis that improving reperfusion or recanalization is safe, feasible, and might provide infarct growth attenuation on imaging. For example, in the GAIN trial, patients treated with gavestinel showed attenuation on infarct growth on DWI.

43.5 Future Analysis of Ischemic Penumbra

The DEFUSE and EPITHET studies have provided biological support for the therapeutic responsiveness of patients with mismatch. However, there is still no evidence that these patients would have better clinical outcomes when given alteplase. Therefore, new studies are needed to provide proof that mismatch tissue is a viable therapeutic target in human beings. Using larger sample sizes, such as combining the DEFUSE and EPITHET databases, could provide further indirect evidence.

The evidence given in the EPITHET study has encourage the investigators to plan a phase III trial (the EXTEND trial) which will randomize patients with mismatch detected by MRI to receive alteplase or placebo in the 4.5-9 hour time window.

Also, an ongoing trial, Magnetic Resonance and Recanalization of Stroke Clots Using Embolectomy (MR RESCUE) is assessing the benefits of reperfusion interventions, comparing patients with and without penumbral mismatch.

Other stroke groups are conducting observational studies assessing penumbra with CT perfusion to select patients. A conventional CT is used before starting treatment with al-

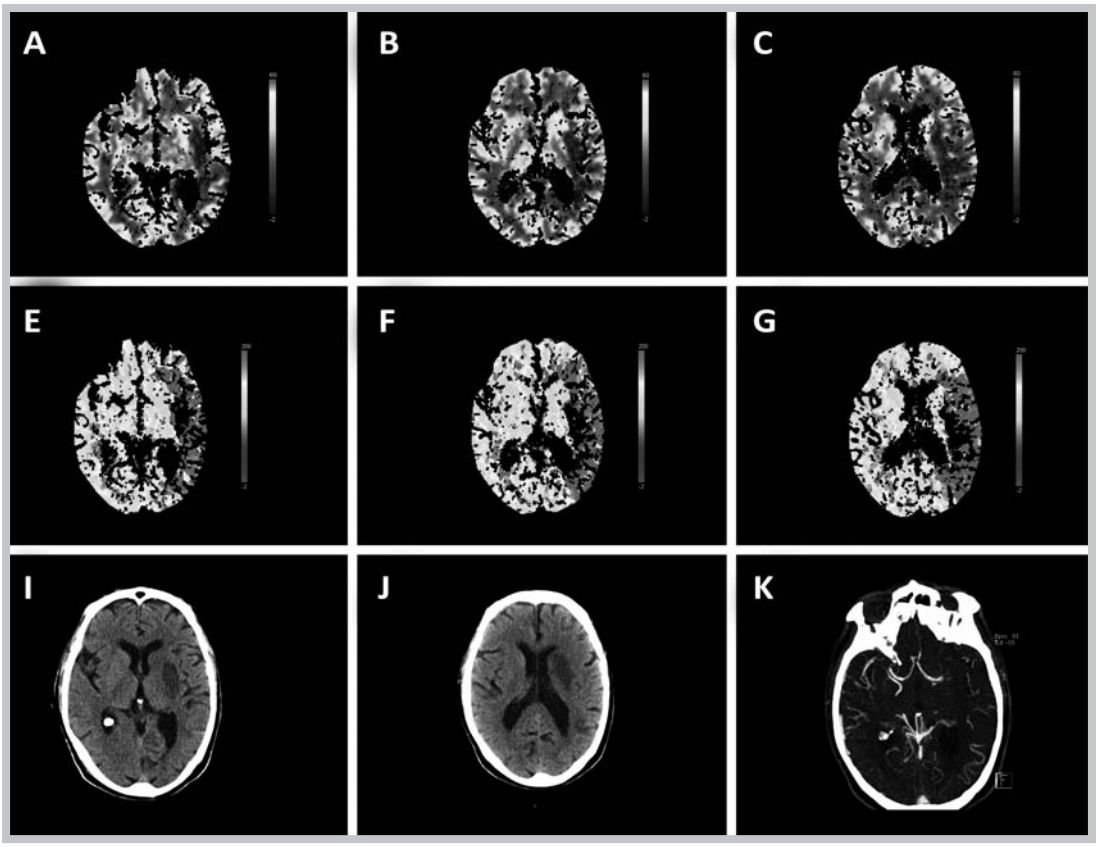

Figure 43.2. **Perfusion CT in acute stroke performed after intravenous treatment with alteplase. A-D: The CBV maps showed a moderate area of volume alteration in the deep territory of the left middle cerebral artery (MCA). E-H: The TTP maps disclosed a larger area of hypoperfusion that includes most of the left MCA territory. K-L: Angio-CT detects and occlusion of the left MCA in the M1 segment. This patient received rescue treatment with intra-arterial alteplase, and the conventional CT performed 3 days after stroke onset showed a moderate infarction in the deep territory of the MCA, closely resembling the initial CBV lesion. Thus, this case illustrates how neuroimaging assesses ischemic penumbra, and how thrombolytic treatment can limit lesion growth.**

teplase, and after treatment a CT perfusion is performed to detect patients with a large mismatch or a persistent arterial occlusion. After that, selected patients receive rescue intra-arterial thrombolysis.

To conclude, we have robust data which suggests that it is possible to extend the therapeutic window of thrombolysis using the mismatch (i.e. the ischemic penumbra) as a proof of concept. However, more evidence is needed to use it in routine clinical practice. This information will become available in the next years, once the ongoing phase III trials are published.

44.1 Introduction

In order to optimize outcomes, the management of the acute stroke patient must be an organized, concerted effort. The focus of treatment in the acute setting is to stabilize the patient and restore blood flow to the brain. There are multiple steps which must be addressed before successful treatment can begin in a timely fashion. This chapter will briefly discuss the pathophysiology and goals of treatment and will highlight the critical steps necessary in rapid evaluation and management of the acute stroke patient.

44.2 Pathophysiology

Ischemic stroke causes death of brain tissue due to interruption of blood flow to a region of the brain, most commonly due to occlusion of a cerebral or cervical artery. Thus, the primary goal of therapy is to open the artery and re-establish blood flow as quickly as possible. The ischemic "core" is the area of brain destined to die. The core is surrounded by an area at risk of death, the ischemic "penumbra". In the penumbra, there is blood flow within the thresholds necessary to preserve function; however, this flow is tenuous [1]. The penumbra remains salvageable if blood flow is re-established in a timely fashion. However, as time passes, the ischemic core expands to include the penumbra and decreases the amount of viable tissue. It has been estimated that every minute that passes without treatment, a patient loses about 2 million neurons [2].

44.3 Pre-hospital Care

The care of the acute ischemic stroke patient begins with recognition of signs and symptoms of stroke by the patient and/or family members. Since future therapies are likely to have similar time constraints, increasing the number of patients eligible for AIS (acute ischemic stroke) treatment is paramount. The use of emergency medical services (EMS) transport can significantly decrease the time to emergency evaluation and treatment [3-6]. EMS use is strongly associated with decreased time to initial physician examination, initial computed tomography (CT) imaging, and neurological evaluation [6-9]. In addition, family members are most often responsible for initiating calls to EMS for AIS [10] thus increasing stroke symptom awareness in this group may increase the number of patients who arrive at the emergency department within the treatment window. It is also worthwhile for EMS to consider transporting a witness with the patient or at least a cell phone number of someone who can verify the history. Based on this information, a plan

for acute stroke treatment must include coordination of pre-hospital care. It is also necessary to consider whether EMS should bypass hospitals which do not have resources to treat stroke in favor of the closest facility that can initiate acute stroke treatment [11]. The American Heart Association and the American Stroke Association have described the "Stroke Chain of Survival" which links the actions by patients, family, and healthcare providers to maximize outcomes [12]:

- Rapid recognition and reaction to stroke warning signs.
- Rapid EMS dispatch.
- Rapid EMS system transport and hospital pre-notification.
- Rapid diagnosis and treatment in the hospital.

44.4 Emergency Evaluation and Diagnosis of Acute Ischemic Stroke

While this section is organized by different components of the initial evaluation, in reality these assessments should happen concurrently and as rapidly as possible.

44.4.1 History

Once the diagnosis of stroke is suspected, time of onset of symptoms should be established. If the patient wakes from sleep or is "found" with symptoms, then **time of onset is the last time the patient was observed to be normal**. Determination of symptom onset time is critical for establishing eligibility for acute therapies. Often, inaccurate times are initially provided at the scene but with further probing and additional information from witnesses, time of onset becomes more accurate. Useful questioning walks the patient or witness through their routine for that particular day in order to accurately establish the time the patient developed symptoms or when EMS was activated [13]. Atherosclerotic risk factors and other co-morbidities should be assessed as well as medications.

44.4.2 Physical Examination

The physical exam can provide important clues to stroke etiology and possible contraindications for thrombolysis, especially in an aphasic patient, e.g.:

- **Head and neck**: Signs of trauma, carotid bruits, jugular venous distension.
- **Cardiac**: Rate and rhythm, murmurs.
- **Skin**: Recent surgical scars or hematoma, trauma, livedo reticularis or other findings which might suggest recent procedures, hepatic dysfunction, or coagulopathy.

Stabilization of the patient is a priority. Airway, breathing and circulation (ABCs) should all be supported. Intubation may be necessary if the patient cannot protect his/her airway. In this case, your neurologic assessments become limited. While you are preparing to intubate the patient, take a moment to be sure simple measures such as positioning or suctioning do not improve the situation.

44.4.3 Neurological Examination

Initial stroke severity is an important predictor of outcome. The NIH Stroke Scale (NIHSS) provides a rapid, reliable, and reproducible assessment of stroke severity and can be followed over time to monitor for recovery or neurologic worsening [14,15]. It can be obtained electronically at http://www.ninds.nih.gov/doctors/NIH_Stroke_Scale.pdf (Table 44.1).

	Stroke Scale Items		Score
1a	Level of consciousness (0-3) 0 = Alert; keenly responsive 1 = Not alert; but arousable by minor stimulation to obey, answer, or respond 2 = Not alert; requires repeated stimulation to attend, or is obtunded and requires strong or painful stimulation to make movements (not stereotyped) 3 = Responds only with reflex motor or autonomic effects or totally unresponsive, flaccid, and areflexic		___
1b	LOC questions (0-2) 0 = Answers both questions correctly 1 = Answers one question correctly 2 = Answers neither question correctly		___
1c	LOC commands (0-2) 0 = Performs both tasks correctly 1 = Performs one task correctly 2 = Performs neither task correctly		___
2	Best gaze (0-2) 0 = Normal. 1 = Partial gaze palsy; gaze is abnormal in one or both eyes, but forced deviation or total gaze paresis is not present 2 = Forced deviation, or total gaze paresis not overcome by the oculocephalic maneuver		___
3	Visual (0-3) 0 = No visual loss 1 = Partial hemianopia 2 = Complete hemianopia 3 = Bilateral hemianopia (blind including cortical blindness)		___
4	Facial palsy (0-3) 0 = Normal symmetrical movements 1 = Minor paralysis (flattened nasolabial fold, asymmetry on smiling) 2 = Partial paralysis (total or near-total paralysis of lower face) 3 = Complete paralysis of one or both sides (absence of facial movement in the upper and lower face)		___
5 & 6	Motor arm and leg 0 = No drift; limb holds 90 (or 45) degrees for full 10 seconds. 1 = Drift; limb holds 90 (or 45) degrees, but drifts down before full 10 seconds; does not hit bed or other support. 2 = Some effort against gravity; limb cannot get to or maintain (if cued) 90 (or 45) degrees, drifts down to bed, but has some effort against gravity. 3 = No effort against gravity; limb falls 4 = No movement UN = Amputation or joint fusion, explain: _____	5a Motor left arm (0-4 or UN) 5b Motor right arm (0-4 or UN) 6a Motor left leg (0-4 or UN) 6b Motor right leg (0-4 or UN)	___ ___ ___ ___
7	Limb ataxia (0-2 or UN) 0 = Absent 1 = Present in one limb 2 = Present in two limbs UN = Amputation or joint fusion, explain: _____		___
8	Sensory (0-2) 0 = Normal; no sensory loss 1 = Mild-to-moderate sensory loss; patient feels pinprick is less sharp or is dull on the affected side; or there is a loss of superficial pain with pinprick, but patient is aware of being touched 2 = Severe to total sensory loss; patient is not aware of being touched in the face, arm, and leg		___

9	Best language (0-3) 0 = No aphasia; normal 1 = Mild-to-moderate aphasia; some obvious loss of fluency or facility of comprehension, without significant limitation on ideas expressed or form of expression. Reduction of speech and/or comprehension, however, makes conversation about provided materials difficult or impossible. For example, in conversation about provided materials, examiner can identify picture or naming card content from patient's response 2 = Severe aphasia; all communication is through fragmentary expression; great need for inference, questioning, and guessing by the listener. Range of information that can be exchanged is limited; listener carries burden of communication. Examiner cannot identify materials provided from patient response 3 = Mute, global aphasia; no usable speech or auditory comprehension	___
10	Dysarthria (0-2 or UN) 0 = Normal. 1 = Mild-to-moderate dysarthria; patient slurs at least some words and, at worst, can be understood with some difficulty 2 = Severe dysarthria; patient's speech is so slurred as to be unintelligible in the absence of or out of proportion to any dysphasia, or is mute/anarthric UN = Intubated or other physical barrier, explain:_____	___
11	Extinction and inattention (formerly Neglect) (0-2) 0 = No abnormality 1 = Visual, tactile, auditory, spatial, or personal inattention or extinction to bilateral simultaneous stimulation in one of the sensory modalities 2 = Profound hemi-inattention or extinction to more than one modality; does not recognize own hand or orients to only one side of space	___
	Total score

Diagnostic Tests

There are some diagnostic studies that should be performed routinely on all patients in whom ischemic stroke is suspected. These tests can help to identify other conditions which may influence treatment options.

- **Non-contrast head CT or MRI**: Excludes intracranial hemorrhage.
- **Laboratory evaluation**: Blood glucose, electrolytes, complete blood cell count with platelet count, prothrombin time, activated partial thromboplastin time, international normalized ratio, and renal function.
- **Cardiovascular studies**: Cardiac enzymes, 12-lead ECG, cardiac monitoring.

Additional tests may be performed as indicated by the patient's history, exam, or comorbidities:

- Liver function studies.
- Toxicology.
- Pregnancy test.
- Chest X-ray.
- Lumbar puncture (recall, if the patient has an emergent LP, thrombolysis would no longer be considered a treatment option).

The NIH has published recommended time frame goals in which each important aspect of evaluation should occur (Figure 44.1) [16].

Each institution will have its own strengths and weaknesses. When reviewing these goal time frames, it is important to take a critical view of treatment paradigms and find ways to improve our systems. When goals have been met, it then becomes important to sustain these efforts with regular assessments. Equally as important is ensuring protocol

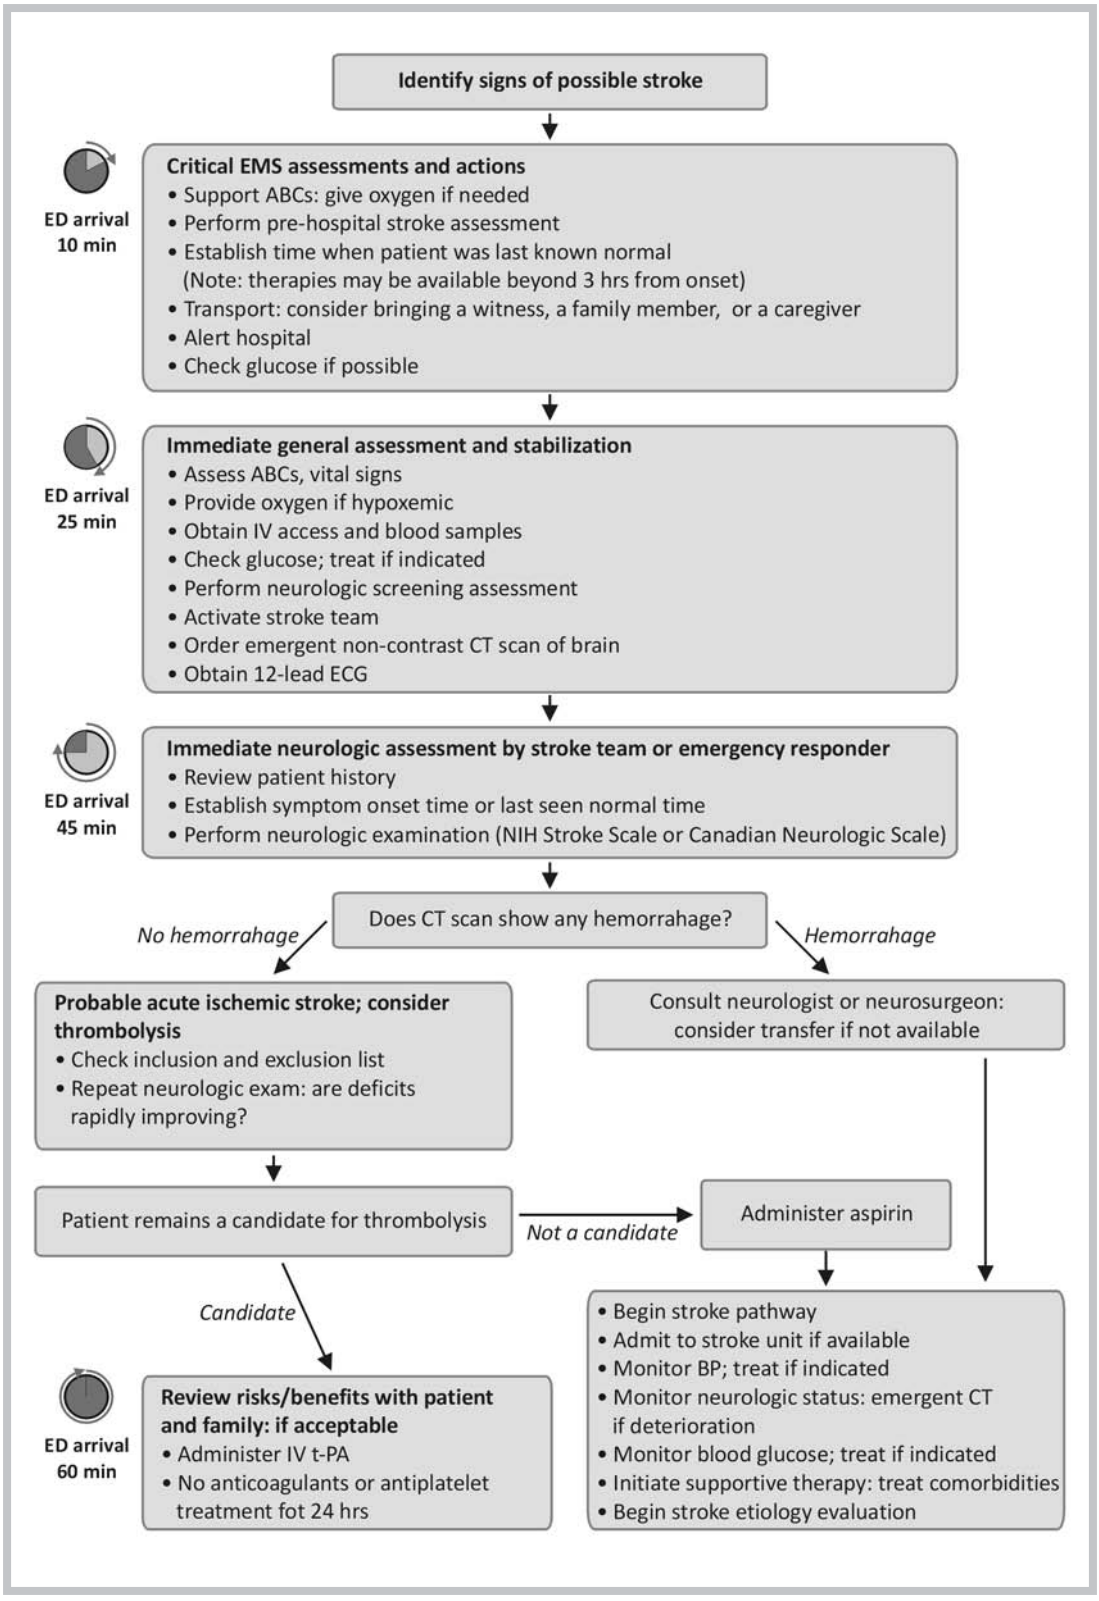

Figure 44.1. **Goals for the management of patients with suspected stroke. Adapted from [12].**

compliance since protocol adherence has been demonstrated to lower the risk of hemorrhagic complications [17]:

- A physician should evaluate a stroke patient within 10 minutes of arrival at the ED doors.
- A physician with expertise in the management of stroke should be available or notified within 15 minutes of patient arrival. Depending on the protocol established, this may be accomplished by activating a stroke team.
- A CT scan of the head should begin within 25 minutes of arrival. The CT interpretation should be obtained within 45 minutes of arrival. This gives adequate time to perform the scan, process the images, and interpret the results.
- For ischemic stroke, treatment should be initiated within 60 minutes.
- The time from patient arrival at the ED to placement in a monitored bed should not exceed 3 hours.

44.5 General Medical Care

44.5.1 ABCs

As mentioned previously, the acute stroke patient must be managed as any other acutely ill patient with attention to stabilization of airway, breathing and circulation (ABCs). All patients must have continuous cardiac and oxygenation monitoring. Pneumonia is a common complication of stroke and steps to reduce the risk of aspiration should be taken. In general, most patients receive supplemental oxygen via nasal cannula with a goal pulse oximetry ≥92% [12].

44.5.2 Hyperglycemia

Hyperglycemia in the acute setting of stroke has been associated with worsened outcome [18] and we tend to be aggressive with treatment. The ideal range for glucose levels in the acute setting of stroke has yet to be determined. Thus, at this time, the goal should be to maintain glucose in a normal range.

44.5.3 Hyperthermia

Fever in the acute setting of stroke has been associated with an increase in mortality [19] and worsened outcome [20]. It has been estimated that for an increase of 1 °C, the risk of poor outcome doubles [19]. Thus, sources of fever should be treated and antipyretic treatments should be employed to lower the temperature of febrile patients to the normal range. Hypothermia as a treatment for stroke appears promising and is currently under investigation.

44.5.4 Hypertension

Management of hypertension in the acute setting of stroke remains controversial. There is evidence to suggest that lowering BP rapidly from very high values may be detrimental by reducing penumbral blood flow, which may increase infarct volume and result in worse outcome [21,22]. However, theoretical reasons for lowering blood pressure in-

clude decreasing the risk of developing edema, hemorrhagic transformation, and neurologic deterioration [11].

Treatment of hypertension in the acute setting of stroke differs depending on whether the patient is a thrombolytic candidate:

- Patient is **not** a thrombolytic candidate: Current recommendations are to withhold antihypertensive agents unless BP >220/120 mmHg [11].
- Patient **is** a thrombolytic candidate: BP should **not** be >185/110 mmHg at the time of and during treatment with IV rt-PA in order to decrease the likelihood of hemorrhagic transformation. Medications listed in the most recent treatment guidelines to control BP include [11]:
  - Labetalol 10-20 mg, may repeat x 1; or
  - Nicardipine infusion starting at 5 mg/hr and titration of 2.5mg/hr at 5-15 minute intervals to a maximum of 15 mg/hr; or
  - Nitropaste 1-2 inches.
- If blood pressure cannot be maintained within the specified range with the above treatments, then rt-PA should not be administered.

When antihypertensive treatment is indicated, the patient should be under close monitoring. Some patients may have a hemodynamic component to their stroke mechanism and lowering BP too aggressively could cause neurologic deterioration.

There is a U-shaped relationship between mortality and admission blood pressure [23]. While definitive evidence for optimal blood pressure parameters during the acute setting of stroke is lacking, current practice is to avoid excessively high or low blood pressure, especially when associated with neurologic deterioration. A reasonable goal would be to reduce blood pressure by 15-25% over the first 24 hours [11].

After the first 24 hrs, it is reasonable to initiate oral antihypertensive agents for gentle blood pressure control. It is preferable to know the status of the blood vessels before being too aggressive with blood pressure management. For example, if a patient has carotid stenosis, one might consider starting with a low dose of a short acting agent to avoid dropping the blood pressure too quickly for a prolonged amount of time.

44.6 Treatment Considerations

It is generally accepted that the more rapidly flow is re-established to the ischemic tissue, the more complete recovery will be. Thus, the goal of treatment is restoration of blood flow to the ischemic area. If flow cannot be re-established through the affected vessel, then the goal of treatment is to maximize collateral flow and minimize the risk of developing secondary complications (e.g. cerebral edema, infection, deep venous thrombosis). Currently, the most effective proven way to re-establish blood flow within the first three hours of stroke is IV rt-PA. With the recent publication of ECASS-III*:* Thrombolysis with Alteplase 3 to 4.5 Hours after Acute Ischemic Stroke [29], guidelines in Canada and Europe have been amended to recommend the use of IV rt-PA up to 4.5 hours in patients with acute ischemic stroke who meet the treatment criteria. However, as of now, guidelines in the US have not yet changed and the use of IV rt-PA after 3 hours remains an off-label use of the drug. Unfortunately, many patients will not present within the time frame to receive this medication. For this reason, aggressive supportive care after the stroke remains equally as important in maximizing outcome.

When a patient presents within the first 3 hours after symptom onset, he/she must be considered for thrombolysis. Once the initial assessment and diagnostic studies have been completed, the emergency responder should discuss the possibility of thrombol-

ysis with the patient and family, if able. This gives the family and patient some time to process the emergent situation and the treatment possibilities **before** a definitive decision has been made.

If you know you have significant delays with any particular step in the treatment pathway, start fixing it now. If it takes an hour for your laboratory to report an INR, start identifying the problem and the appropriate people to help fix it. If you cannot get a head CT within the recommended time frame (25 minutes), start figuring out ways to decrease your time; the problem could be transport or it could be that stroke patients don't have the appropriate priority in the radiology system. It is critically important to involve administration in helping you to minimize the time to treatment. Even if the patient is not eligible for IV rt-PA, rapid assessment and management is the best treatment for all patients.

IV rt-PA remains the only FDA approved treatment in the US for acute ischemic stroke within the 3 hour window. There have been 6 large multicenter, randomized, placebo-controlled trials (RCT) to test the benefit of rt-PA for AIS [24-28,29]. The studies differ slightly in terms of time to treatment, dose of medication, exclusion criteria, and definition of symptomatic ICH. However, the primary and secondary outcomes evaluated were similar, as were safety data, allowing interpretation as individual studies as well as facilitating evaluation via pooled analysis. In a pooled analysis [30], all 2775 patients who had been randomly allocated to rt-PA or placebo were included. In this analysis, the odds of a favorable outcome at 3 months increased as the time to treatment with rt-PA decreased ($p = 0.005$). These findings strongly confirm that rapid treatment with rt-PA is associated with better outcomes at 3 months. Outside the 3-hour window, the benefit of rt-PA is small in an unselected group. As such, the sample size necessary to demonstrate a positive effect in this time window is quite large. Recently, a large, randomized trial of the use of IV rt-PA in the 3-4.5 hr window was published and demonstrated the efficacy of IV rt-PA in acute ischemic stroke [29]. ECASS III confirms the findings reported in the pooled analysis which suggested that the benefit of IV rt-PA extended beyond the 3 hour window. However, because the treatment effect decreases with time, a larger number of patients must be treated to demonstrate this beneficial effect. The number needed to treat (NNT) to prevent 1 additional patient from death or disability is 11 for all rt-PA doses and times [31]. When only patients treated with 0.9 mg/kg in under 3 hours are considered, the NNT ranges from 3-7 [2,31]. Despite this data, IV rt-PA remains underutilized. With the recent findings in ECASS III, it is necessary to underscore the importance of rapid assessment and treatment. Expanding the treatment window to 4.5 hrs means that more patients will be eligible for treatment, NOT that we have more time to treat those patients who present within the 3 hr window. The likelihood of a good outcome is closely linked with time to treatment and so the goal door-to-needle time remains ≤60 minutes.

A re-analysis of the NINDS rt-PA trial found that while increasing age, stroke severity, a history of diabetes, and pre-existing disability were all associated with a decreased likelihood of having a favorable clinical outcome at 3 months, there was no evidence that any of these variables modified the rt-PA treatment effect to a significant degree [32]. In fact, among patients who qualify for therapy according to the NINDS study inclusion and exclusion criteria, no sub-group can be identified based on demographic, historical, or physical exam variables that benefits less or more from IV rt-PA when administered within 3 hours of symptom onset [33]. What is clear, however, is that the risk of hemorrhage increases when the NINDS protocol is not followed [17].

In order to reduce the risk of complications with rt-PA, there should be a clear treatment protocol. It is helpful to review the inclusion and exclusion criteria with the patient/family as well as with another treating physician or nurse to make sure that all the important

	Yes	No
Inclusion criteria: A NO answer to any of the criteria below excludes the patient from thrombolysis		
• Age 18 or older		
• Time last seen normal well established to be less than 180 minutes before treatment would begin		
• Clinical diagnosis of ischemic stroke causing a potentially disabling neurological deficit defined as: impairment of language, gait, motor function, cognition, gaze, and/or vision; or neglect		
• CT scan rules out hemorrhage		
Absolute contraindications: A YES answer to criteria below excludes the patient from thrombolysis		
• Intracranial hemorrhage on pretreatment neuroimaging		
• Patient has a clinical presentation that suggests subarachnoid hemorrhage, even if the initial CT scan is normal		
• Recent (within 3 months) intracranial or intraspinal surgery, serious head trauma, or previous stroke		
• History of intracranial hemorrhage		
• Uncontrolled hypertension at time of treatment (e.g. >185 mmHg systolic or >110 mmHg diastolic) on repeated measurements.		
• Intracranial neoplasm, arteriovenous malformation, or aneurysm		
• Known bleeding diathesis* including but not limited to: ▪ Current use of oral anticoagulants (e.g., warfarin sodium) or an International Normalized Ratio (INR) >1.7 or a prothrombin time (PT) >15 seconds ▪ Administration of heparin within 48 hours preceding the onset of stroke and have an elevated activated partial thromboplastin time (aPTT) at presentation ▪ Platelet count <100,000/mm^3		
• Active internal bleeding		
Relative contraindications: A YES answer to criteria below warrants a careful consideration of the risks and benefits of thrombolytic therapy. In some cases, it may be reasonable to proceed with thrombolysis, despite a relative contraindication		
• Patient has: ▪ Only minor stroke symptoms ▪ Major symptoms which are rapidly improving by the time treatment would begin		
• Patient has had major surgery in the previous 14 days		
• Patient is lactating or known or suspected to be pregnant		
• Patient has history of GI or urinary tract hemorrhage in previous 21 days		
• Patient has had arterial puncture at a non-compressible site or a lumbar puncture or any spinal epidural injection in the previous 7 days		
• Patient has a history of MI in the previous 3 months		
• Patient has clinical presentation consistent with post MI pericarditis		
• Active bleeding or acute trauma (fracture) on exam		
• Abnormal glucose level (<50 mg/dl)		
• Patient had a seizure at onset of stroke and lacks clinical evidence of ischemic stroke		
• CT shows evidence of new hypodensity greater than 1/3 of MCA territory		
• Patient is menstruating or has dysfunctional uterine bleeding		

Table 44.2. **Checklist for administration of thrombolytic therapy for acute ischemic stroke.**
* In patients without recent use of oral anticoagulants or heparin, treatment with rt-PA can be initiated before availability of coagulation study results but should be discontinued if the INR is >1.7 or the partial thromboplastin time is elevated by local laboratory standards.

details of the medical history have been captured and verified. Things are (hopefully) happening very quickly in the ED and it's easy to get distracted. Adherence to protocol will ensure every patient gets treated quickly and safely. A sample check-list of exclusion criteria is included in Table 44.2, adapted from the alteplase package insert.

44.6.1 Treatment With IV rt-PA

Note: only rt-PA has been approved for treatment of acute ischemic stroke. Other drugs that are used for acute myocardial infarction may not be used for stroke. These include reteplase, tenecteplase, and streptokinase. Make sure to double check the name of the drug since some hospitals do not carry rt-PA [13].

The serious adverse effects of rt-PA are mainly hemorrhagic complications. For this reason, absolute contraindications to the use of IV rt-PA include:

- Evidence of ICH on pretreatment evaluation.
- Suspicion of subarachnoid hemorrhage on pretreatment evaluation.
- Recent (within 3 months) intracranial or intraspinal surgery, serious head trauma, AIS in the past 3 months.
- History of intracranial hemorrhage.
- Active internal bleeding, intracranial neoplasm, arteriovenous malformation, or aneurysm.

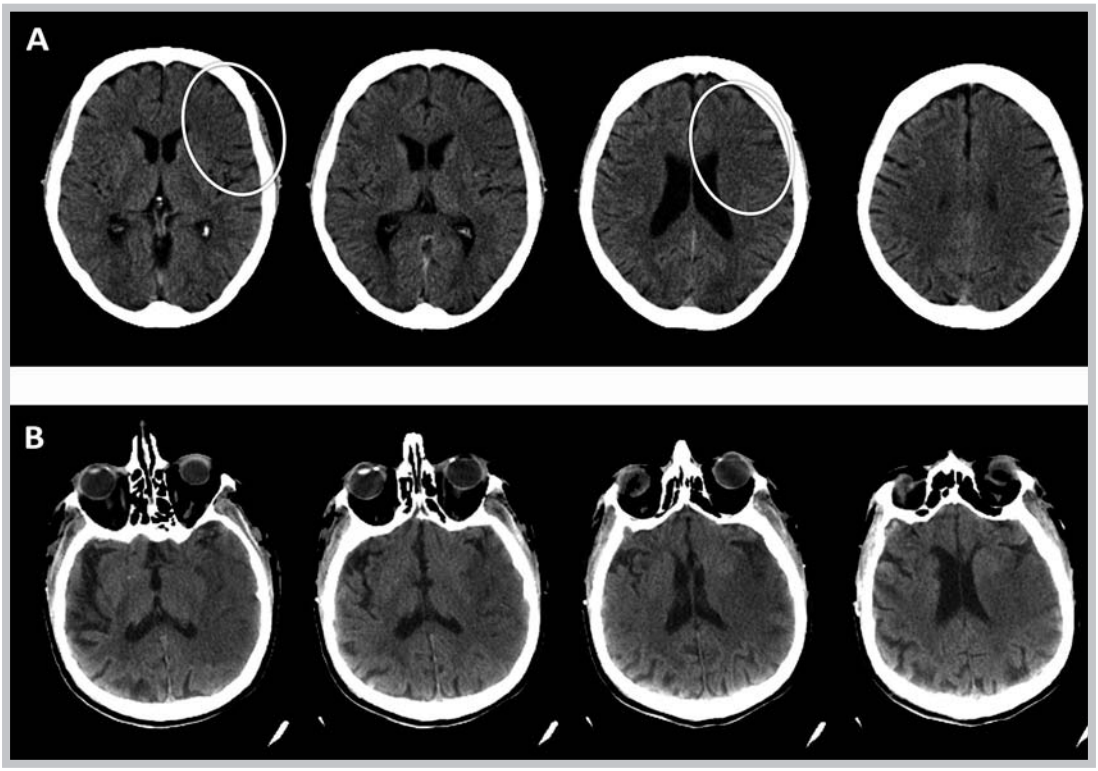

Figure 44.2. **CT findings in acute ischemic stroke. (A). Early ischemic changes which do not exclude the use of thrombolysis: circles demonstrate loss of the gray-white junction and mild sulcal effacement. Neither of these signs on CT precludes the use of thrombolysis. (B). Ischemic changes which do exclude the patient from thrombolysis: this figure demonstrates a clear hypodensity that is well-demarcated and is >1/3 of the left MCA distribution. This extent of change is typically not seen within 3 hours of symptom onset.**

- Known bleeding diathesis including current use of oral anticoagulants with an INR >1.7 or PT >15 seconds, administration of heparin within 48 hours preceding onset of stroke and an elevated aPTT at presentation, platelet count <100,000/mm^3.

Relative contraindications include:

- Uncontrolled hypertension at time of treatment (e.g., >185 mmHg systolic or >110 mmHg diastolic).
- Seizure at the onset of stroke.
- CT shows evidence of new hypodensity greater than 1/3 of MCA territory (Figure 44.2).

Points to keep mind:

- All invasive procedures that are necessary should be performed prior to administration of rt-PA (e.g. Foley, NGT, intubation, IVs, etc.) to minimize the risk of bleeding complications. However, treatment should not be delayed for these procedures unless they are required to stabilize the patient. It is ideal to have 2 large bore IVs in place for rt-PA treated patients.
- The use of aspirin or clopidogrel does not exclude the patient from thrombolysis.
- Early ischemic changes on CT do not exclude the patient from thrombolysis (Figure 44.2).

At times, it can be difficult to differentiate between acute stroke and conditions which mimic stroke, e.g. Todd's paralysis, complicated migraine, conversion disorder, etc. Recent data on misdiagnosis of stroke suggest that when patients with these conditions are treated with thrombolytics, hemorrhagic complication is not frequent [11,34].

Patients with seizure as presentation of stroke were not included in rt-PA trials. Thus, seizure at presentation should be considered only as a relative contraindication.

There is no lower or upper limit on NIHSS that qualifies (or disqualifies) a patient for treatment with thrombolysis. Rather, the treatment decision should be based upon whether the patient has a debilitating deficit which warrants treatment. For example, an NIHSS of 2 for a homonymous hemianopsia in a 50 year-old truck driver is a disabling deficit and warrants treatment despite the low score. Similarly, a high NIHSS also should not exclude the patient from thrombolysis. While we know that stroke severity is associated with increasing rate of ICH [35], this group of patients, overall, still stands to benefit from thrombolysis.

Procedure [13]:

- Dose:
  - Infuse 0.9 mg/kg (maximum dose 90 mg).
  - 10% of the dose given as IV bolus over 1 minute.
  - Remaining 90% infused over 60 minutes.
  - In order to help avoid dosing errors, utilize tools that automatically calculate dose when weight is known instead of relying on manual calculation; verify dose and weight with nurse or other emergency responder; some treating clinicians opt to "waste" the rt-PA that will not be used in order to avoid a possible overdose if the infusion pump does not work as expected.
- Post-rt-PA orders:
  - Admit the patient to an intensive care or stroke unit for monitoring.
  - Perform neurological assessments every 15 minutes during the infusion and every 30 minutes thereafter for the next 6 hours, then hourly until 24 hours after treatment.
  - Monitor blood pressure every 15 minutes for the first 2 hours and subsequently every 30 minutes for the next 6 hours, then hourly until 24 hours after treatment.
  - If necessary invasive monitoring is not able to be placed prior to rt-PA administration, delay placement of nasogastric tubes, indwelling bladder catheters, or

intra-arterial pressure catheters until 30-60 minutes after the rt-PA infusion has been completed.

- Patients should NOT receive aspirin, Aggrenox, clopidogrel, ticlopidine, warfarin, heparin or any other antithrombotic or anticoagulant for 24 hrs after receiving rt-PA.
- If the patient develops severe headache, acute hypertension, nausea, or vomiting, discontinue the infusion (if rt-PA is being administered) and obtain emergency CT scan.
- Obtain a follow-up CT scan or MRI at 24 h before starting anticoagulants or antiplatelet agents.

44.6.2 Anticoagulants and Antiplatelet Agents

Acute Anticoagulation

Data from recent trials do not support the routine use of urgent anticoagulation as treatment for acute stroke. Urgent anticoagulation with unfractionated heparin or low molecular weight heparins has been associated with an increased risk of bleeding complications, symptomatic hemorrhagic transformation of the ischemic stroke, and has not been shown to improve outcomes. Currently, the use of anticoagulation should be restricted to special cases such as cerebral venous thrombosis and possibly extracranial arterial dissection.

Acute Antiplatelet Agents

If a patient is not eligible for IV rt-PA, then aspirin 325 mg should be administered [11]. Aspirin should not be considered instead of IV rt-PA if the patient meets thrombolytic criteria. Aspirin is the only oral antiplatelet agent that has been studied in the acute setting of stroke. The International Stroke Trial [36] and the Chinese Acute Stroke Trial [37] demonstrate a small, but significant reduction in death and disability when aspirin is administered within 48 hrs of stroke. Other oral and IV antiplatelet agents have not been definitively studied in the acute setting of stroke and cannot be recommended instead of or in addition to aspirin in the acute setting for routine care.

While clopidogrel has been proven safe and effective in acute coronary syndromes, this has not been prospectively tested in the setting of acute ischemic stroke. Plavix is currently being evaluated within 12 hours of TIA or minor stroke in the Platelet-Oriented Inhibition in New TIA and minor ischemic stroke (POINT) Trial [38]. A phase III trial studying the glycoprotein IIb/IIIa receptor inhibitor, abciximab, within 5 hrs of symptom onset was halted due to safety concerns [39]. Thus, at this time no other antiplatelet agent can be recommended in the acute setting of stroke.

44.6.3 Complications of Thrombolysis

Hemorrhage

The risk of symptomatic intracranial hemorrhage (ICH) is increased with the use of IV rt-PA and ranges between 1.7 to 6.4% depending upon how symptomatic ICH is defined [24,40-42]. In a multicenter retrospective and prospective investigation of individual data from 1205 patients treated in routine clinical practice with rt-PA within 3 hours of symptom onset, patients who developed ICH often had diabetes mellitus, atrial fibrillation, or other cardiac disease. Higher levels of serum glucose, lower platelet counts, increasing age, and stroke severity were associated with increasing rate of ICH [35]. While

these factors may be associated with ICH, their presence or absence does not necessarily reflect which patients may or may not benefit from treatment with rt-PA. Thus, these factors should not be used to guide treatment, but rather for individualized counseling of patients and their families as well as to provide insight into the pathophysiology of rt-PA related ICH for future studies.

rt-PA related ICH [13]:

- Stop rt-PA infusion if still running.
- Goal fibrinogen level >100 mg/dl with cryoprecipitate.
- Type and cross.
- Check fibrinogen level immediately and every 6 hours.
- Give 10-20 units of cryoprecipitate before level returns (1 unit raises fibrinogen by 5-10 mg/dl. Assume there is no fibrinogen and adjust dose when level is back).
- Repeat cryoprecipitate if needed.
- May use fresh frozen plasma (FFP) in case of no cryoprecipitate (1 unit of cryoprecipitate is made from 1 bag of FFP).
- May give platelet concentrate if low.

Angioedema

In one report, angioedema occurred in 5.1% of patients treated with IV rt-PA and was associated with the use of angiotensin-converting enzyme inhibitors and signs on initial CT of ischemia in the insular and frontal cortex [41]. Most of the cases were mild, but severe reactions do occur and can progress rapidly, necessitating close observation of patients who receive thrombolytics, both for neurologic changes and angioedema.

44.6.4 Intra-arterial Thrombolysis and Endovascular Therapy

With the publication of ECASS III, it is clear that the benefit of IV rt-PA extends beyond 3 hrs in an unselected population. Thus, whereas previously, patients presenting outside the 3 hr window might have been considered primarily as candidates for IAT, these patients are now candidates for IV thrombolysis, which, in many facilities can be initiated much sooner than IAT. Given the time involved in preparing for IAT, whenever possible, all eligible patients should receive IV rt-PA and IAT should not be considered instead of IV rt-PA in eligible patients. This ensures that thrombolytic therapy has been initiated as quickly as possible, even while still considering additional therapeutic options. There is a small amount of data which demonstrate that full dose rt-PA may be just as safe as a lower dose [41,43]. This combined treatment approach should take place at experienced centers and **ideally within the framework of a randomized, controlled trial**.

A majority of the patients who present with an NIHSS ≥10 will have a large vessel occlusion [44,45]. IV rt-PA is still the best treatment option for these patients who are eligible, however the recanalization rates of IV rt-PA alone warrant consideration of additional 'rescue' therapy in carefully selected patients.

New mechanical retrieval devices for embolectomy are promising in achieving recanalization. However, they have not been demonstrated in a randomized controlled fashion, to improve outcomes. Based on the available literature, consider IAT in the following situations where large vessel occlusion is suspected.

≤6 hrs after symptom onset:

- In patients with an NIHSS ≥10 or with a disabling deficit in whom a large vessel occlusion has been identified on TCD, CTA, MRA regardless of whether or not IV rt-PA has

been administered. Keep in mind, all patients who are eligible for IV rt-PA should receive it while considering IAT.

- In patients who are not eligible for IV rt-PA, endovascular therapy is a reasonable consideration (e.g. recent surgery, INR >1.7), with or without IA thrombolytics, though in these patients, IA thrombolytic should not be considered a "safer" alternative to IV rt-PA.

As with IV rt-PA, the "window" for treatment with IAT is difficult to define and is certainly different in select patient populations. Assigning the same arbitrary time restrictions to IAT is counter-intuitive to our clinical reasoning and ignores the clinical experience we have gained over the last decade since PROACT as well as the technological advances in neuroimaging. We have made significant progress in achieving recanalization with endovascular techniques and demonstrating "tissue at risk" vs. irreversibly damaged tissue with new imaging modalities. However, we have still not demonstrated the best way to interpret this information, nor the best way to apply this information to clinical decision making. Again, these treatments ideally should occur within the framework of a randomized, controlled trial. That said, it would also be reasonable to consider IAT in patients 6-8 hrs after symptom onset in the scenarios listed below. With rare exception, these cases have more advanced imaging than the routine head CT prior to proceeding with treatment.

6-8 hrs of symptom onset:

- Basilar artery occlusion: the natural history of this disease carries such a poor prognosis that our own treatment window extends to 24 hrs.
- Patients with large artery occlusion in whom advanced neuroimaging demonstrates a significant amount of "salvageable" tissue and only limited or no irreversible damage.

44.6.5 Acute Medical Complications

Patients with acute ischemic stroke are at an increased risk of developing medical complications. These include:

- Infections: aspiration pneumonia, urinary tract infection. It is important to maintain aggressive pulmonary toilet and to screen all patients for dysphagia. In addition, all invasive monitoring should be discontinued as soon as is deemed safe from a medical standpoint.
- DVT: unless there is a contraindication (e.g. IV rt-PA within the last 24 hrs) all ischemic stroke patients should be started on DVT prophylaxis as soon as possible. Typically, a dose of enoxaparin 40 mg SC [46] is started as soon as possible. The dose should be adjusted for decreased renal function.
- Sundowning, confusion, agitation: patients with stroke tend to be older and can become disoriented in an unfamiliar setting. Frequently these patients try to get out of bed and are at risk of falling; they pull out feeding tubes and IVs. Supportive measures such as allowing the family to stay with the patient, familiar objects or pictures can be very helpful in keeping the patients calm. In general, try to avoid the use of sedating medications. However, if absolutely necessary, low doses of antipsychotic agents can be helpful. Keep in mind that older patients with AIS may be sensitive to the side effects and it may be prudent to administer an initial dose lower than one would use in the outpatient setting, e.g. haldol PO or IV 0.5-1 mg; risperdone 1 mg PO, quetiapine 25 mg PO. There is data to suggest that newer antipsychotic agents increase mortality in patients with dementia with prolonged treatment [47], so these medications should be used with caution.

44.6.6 Acute Neurological Complications

With neurologic worsening, the same principles apply in terms of stabilizing the airway and circulation. Early neurologic deterioration in the first few days tends to be related to a neurologic reason compared with deterioration in the subacute setting which is usually due to systemic reasons [48].

Stroke Enlargement

Stroke enlargement can occur when there is clot progression, an arterial stenosis which worsens or progresses to occlusion, or when there is re-occlusion after recanalization [13,48]. Ideally, one prefers to treat the acute vascular abnormality **before** the neurologic deterioration occurs rather than treating after the fact. The key is emergent neurovascular imaging to detect larger artery stenosis/occlusion by TCD, CT angiography (CTA), or MR angiography (MRA). Patients with mild deficits who have abnormal vascular imaging tend to be at risk of deterioration. The finding of a small diffusion weighted lesion on MRI and relatively minor neurological deficit in the setting of large artery occlusion indicates a high risk of progression. In such patients, one might consider early intervention such as IV thrombolysis despite the low NIHSS score, intra-arterial therapy, carotid endarterectomy, or carotid stenting.

Drop in Perfusion Pressure

Simple things such as dehydration, a drop in blood pressure, and body positioning can affect neurologic status. All patients should receive IV fluids with normal saline (avoid hypotonic or saline with D5). In addition, if tolerated, the ideal position is to have the head of bed flat. This horizontal position has been shown to improve cerebral perfusion pressure [49] and in some cases has been associated with neurologic improvement [50].

Recurrent Stroke

Recurrent stroke due to an embolic event can occur in the same region or can be in a different location. TCD can be useful to detect microemboli.

Cerebral Edema and Mass Effect

Patients with large proximal occlusion (terminal ICA, MCA) are at high risk of neurologic deterioration due to a large area of injured tissue developing edema and subsequent mass effect. In younger patients, this process can be rapid, developing with the first 12-24 hrs, and is heralded by increasing lethargy followed by focal signs of herniation. Recent randomized controlled trials demonstrate that urgent hemicraniectomy is not only life-saving but is also associated with improved outcome [51-53]. Of note, the patients in these trials were younger, <60 years, and so were likely better able to recover from the trauma of surgery and stroke severity and were taken for early surgical treatment. Younger patients with this type of “malignant” syndrome should be considered for early surgical treatment.

Hemorrhagic Transformation

Symptomatic hemorrhagic transformation (HT) occurs more frequently in patients who receive IV thrombolysis, ranging from 2-6.4% depending upon how ‘symptomatic’ is defined. The risk factors associated with HT are discussed elsewhere.

Seizure

Seizure is more common in cortical ischemic stroke. The reported frequency of seizures during the first days of stroke ranges from 2% to 23% [54,55] but is probably on the lower end of the range. Seizures are more likely to occur within 24 hours of stroke and are usually partial, with or without secondary generalization. Status epilepticus is uncommon [13]. Seizure prophylaxis is not recommended, however treatment of acute seizures with continued therapy to prevent further seizures is recommended.

44.6.7 Evaluation of Stroke Etiology

Once the acute treatment phase is complete, the goal of the diagnostic evaluation is to determine stroke etiology in order to guide secondary prevention treatment. The "routine" stroke evaluation consists of laboratory studies, a limited cardiac evaluation and neurovascular imaging. Most patients should undergo the following studies:

- Laboratory evaluation: Chemistry, CBC, PT/PTT, fasting lipids, hemoglobin A1C.
- Cardiac studies: 12-lead ECG, transthoracic or transesophageal echocardiogram with a bubble study; if a bubble study demonstrates a right-to-left shunt, in the appropriate patient, it would be reasonable to consider an evaluation for DVT (paradoxical embolus).
- Neurovascular imaging: MRI is desirable. CT is a great screening tool for the emergency setting, but MRI provides a wealth of information that can help with determining stroke etiology. Vascular screening in the form of TCD, MRA, CTA or carotid ultrasound. If screening studies are abnormal, it may be necessary to proceed to conventional cerebral angiogram. In patients in whom the etiology is unclear, it is preferable to include the great vessels as well as the extracranial carotids and intracranial vasculature.

When patients are younger or have few or no vascular risk factors, additional evaluation should be tailored to the individual patient and can include:

- Laboratory evaluation for hypercoagulable state.
- Laboratory evaluation for systemic vasculitis.
- Lumbar puncture for CNS vasculitis (primary or secondary); don't forget infectious causes of CNS vasculitis (syphilis, VZV, HSV, etc.).
- Diagnostic cerebral angiogram.

44.7 Additional Considerations

Once the acute plan of care for treatment has been completed and the neurologic status is stable, it is important to begin treatments that will improve the patient's chances for improved outcome and avoid the medical complications of stroke. These plans should include:

- Rapid mobilization of the patient with occupational, physical and speech therapy as soon as possible to assist with a long-term plan for rehabilitation and a safe nutritional plan (i.e. can the patient tolerate an oral diet or will he require placement of a feeding tube).
- Education of the patient and family of stroke risk factors, prevention, and the importance of activating emergency services should this happen again; counseling about the patients residual deficits and what to expect in the next few days to weeks.
- Secondary stroke prevention treatment targeted toward the patient's risk factors.

44.8 Conclusions

In summary, acute ischemic stroke is a neurologic emergency which requires a rapid, multidisciplinary approach in order to achieve the best possible outcomes. Acute stroke treatment begins with the recognition of stroke and activation of emergency medical services. Once the patient is in the emergency department, stabilization of the patient and restoration of blood flow are priorities. All patients should be considered for thrombolysis. If the patient meets inclusion criteria, IV rt-PA should be administered as quickly as possible with a goal door-to-needle time ≤60 minutes. Intra-arterial therapies (IAT) are an option when large vessel occlusion is suspected but should not be considered instead of IV rt-PA in otherwise eligible patients. IAT should take place at experienced centers. When patients are not eligible for thrombolysis, aspirin should be administered. The importance of aggressive medical management to avoid the complications of stroke cannot be over-emphasized. Diagnostic evaluation for stroke etiology can help tailor secondary prevention treatment to the individual patient's risk factors.

45 Acute Management of Ischemic Vertebrobasilar Stroke

Raymond T.F. Cheung [1]

[1] Division of Neurology, Department of Medicine, and Research Centre of Heart, Brain, Hormone and Healthy Aging, University of Hong Kong, and Acute Stroke Services, Hong Kong West Cluster, Hong Kong

45.1 Introduction

Updated guidelines on the immediate or early management of ischemic stroke and transient ischemic attacks (TIAs) are available. These guidelines do not specifically address the management of ischemic vertebrobasilar stroke. In the beginning of this chapter, the clinical scenario of acute basilar artery occlusion is illustrated by a case. This chapter will briefly outline the vascular anatomy, pathophysiology, presentation, imaging findings, and prognosis of ischemic vertebrobasilar stroke. Early recanalization is the treatment goal. The emphasis is on the recent advances in intravenous (IV) and intra-arterial (IA) thrombolysis, angioplasty and stenting, and mechanical thrombectomy.

The vertebrobasilar arterial system constitutes the posterior circulation. Ischemic vertebrobasilar stroke accounts for about 20% of ischemic stroke. Compared to strokes in the anterior circulation, ischemic vertebrobasilar stroke is generally more severe and has higher fatality rates of up to 90%. Prior to the catastrophic presentation of severe ischemic vertebrobasilar stroke, most patients have experienced milder symptoms for days to weeks. Recent advances in chemical thrombolysis and mechanical thrombectomy provide some hope for better outcomes. These have also aroused interest in management protocols aimed at early detection and/or staged escalation therapy for ischemic vertebrobasilar stroke.

45.2 Case Report

A 69-year-old woman is known to have diabetes mellitus, a past history of carcinoma of vulva treated with chemotherapy and radiotherapy in 2006, and a more remote history of modified radical mastectomy for carcinoma of the right breast. There was no history of any prior neurologic symptoms. She presented with sudden collapse at 18:30. Assessment at the emergency room showed a raised blood pressure of 202/96 mmHg and a low Glasgow Coma Scale (GCS) score of 4. Her right pupil was dilated with sluggish response to light. She was intubated at the emergency room. Urgent computed tomography (CT) of the head revealed normal findings at 18:58. Urgent magnetic resonance imaging (MRI) and angiography (MRA) of the brain revealed acute basilar artery occlusion with no restriction defect on diffusion-weighted imaging (DWI) at 20:13 (Figure 45.1).

Neurological examination at 21:30 showed absent Doll's eye sign, spastic tetraplegia with no active limb power and bilateral upgoing plantar responses. Her National Institutes of Health Stroke Scale (NIHSS) score was 40. Urgent cerebral digital subtraction angiography (DSA) confirmed the presence of acute basilar artery occlusion (Fig-

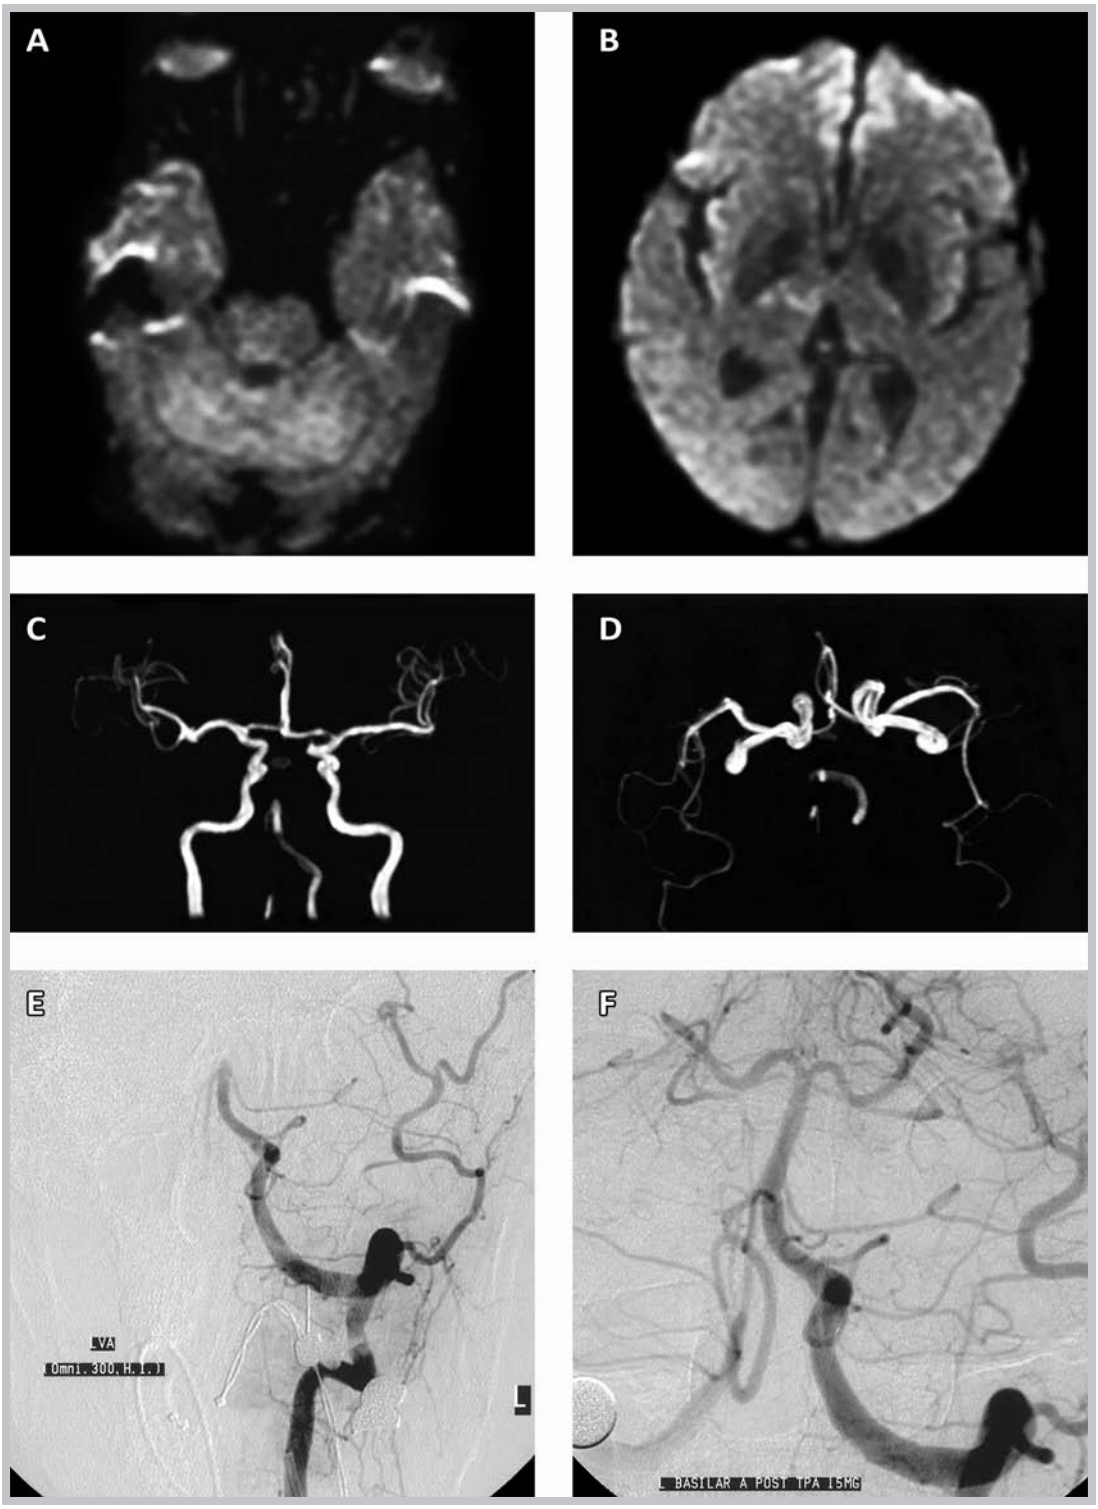

Figure 45.1. **Urgent MRI revealed no restriction defect on DWI (A, B) but urgent MRA revealed acute basilar artery occlusion (C, D). Urgent DSA confirmed the presence of acute basilar artery occlusion with no visualisation of the right vertebral artery, the PICA on both sides, the AICA on both sides and the basilar perforators. The basilar artery was recanalized using mechanical thrombectomy plus IA rtPA (F).**

ure 45.1). In addition, the right vertebral artery, the posterior inferior cerebellar artery (PICA) on both sides, the anterior inferior cerebellar artery (AICA) on both sides, and the basilar perforators were not visualized on DSA. Mechanical thrombectomy was attempted using a 3-mm alligator retrieval device, and IA infusion of 15 mg of recombinant tissue plasminogen activator (rtPA) was commenced at 23:00 (about 4.5 hours after onset).

The basilar artery was successfully recanalized about 8 hours after onset (at around 02:30 on the next day) (Figure 45.1).

Unfortunately, she developed severe shock from lower gastrointestinal bleeding, hematuria and sepsis, and inotropic agents at high doses were required to maintain her blood pressure. The bleedings were due to post-irradiation colitis and cystitis. Repeat CT of the head 2 days later revealed an extensive pontine infarction with multiple bilateral infarctions in the cerebellum, occipital lobes and thalami (Figure 45.2).

Repeat MRA of the brain and neck showed that all major extra- and intracranial arteries were patent. She remained in a locked-in state. Despite maximal supportive care, she developed recurrent episodes of septic shock, lower gastrointestinal bleeding, and hematuria. Finally, she died of irreversible shock about 4 months after her ischemic vertebrobasilar stroke.

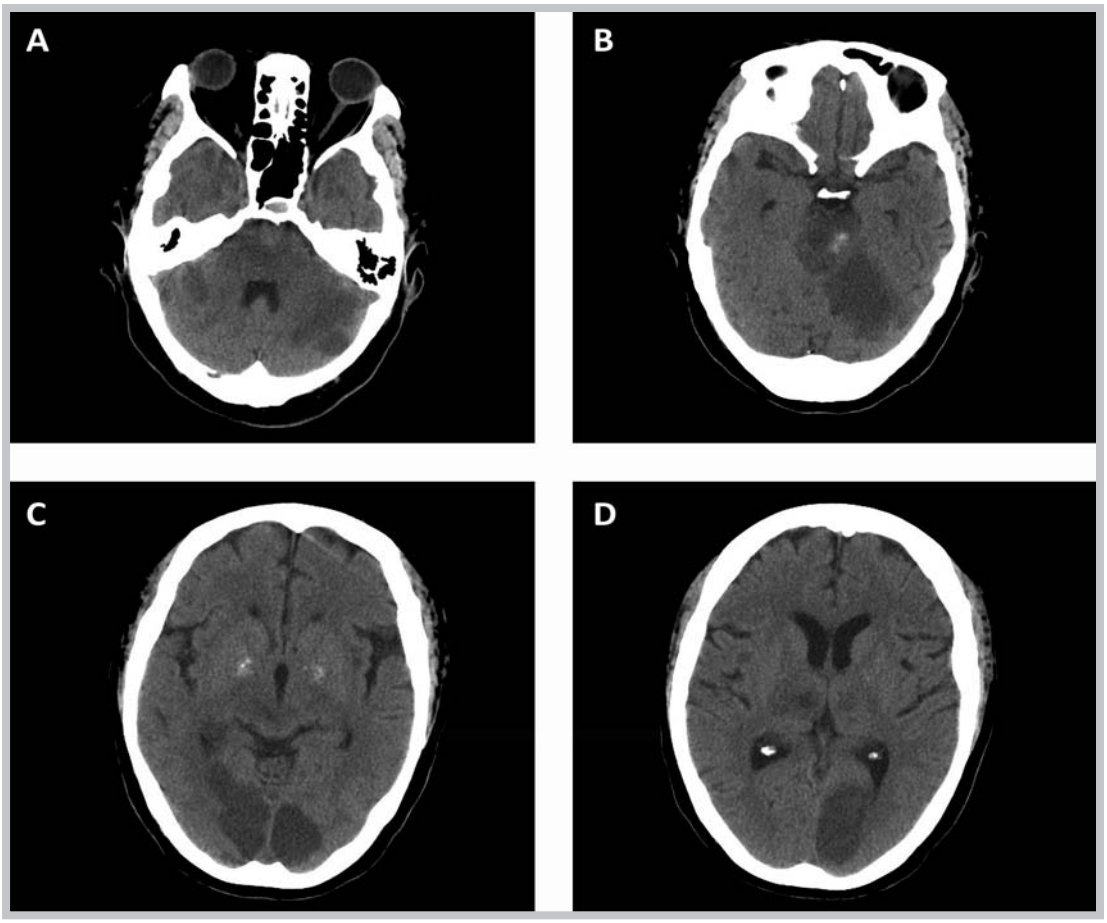

Figure 45.2. **Repeat CT of the head 2 days after presentation revealed an extensive pontine infarction (A, B) with multiple bilateral infarctions in the cerebellum (A, B), occipital lobes (C, D) and thalami (D). A hyperdense area over the left side of the pons (B) might represent hemorrhagic transformation.**

45.3 Vascular Anatomy

The vertebral artery, a branch of the subclavian artery, passes through the transverse foramina from C5 or C6 to C2 and arches around C1 to enter the foramen magnum. Its PICA supplies blood to the posterior and inferior part of the cerebellum, the inferior vermis and the lateral part of the medulla. At the pontomedullary junction, the left and right vertebral arteries combine to form the basilar artery. The AICA, superior cerebellar artery (SCA) and three groups of penetrating pontine arteries are branches of the basilar artery before its termination into two posterior cerebral arteries (PCAs) at the upper pons. The AICA supplies the anterior and inferior part of the cerebellum and mid-pons. The SCA lies close to the PCA and supplies the superior part of the cerebellum and the upper pons. The three groups of penetrating arteries supply the pons. The PCA supplies the medial and inferolateral parts of the temporal lobe and the medial and lateral parts of the occipital lobe. The thalamogeniculate and thalamoperforating branches of the PCA supply the lateral part of the thalamus, the lentiform nucleus and the midbrain. Following acute basilar artery occlusion, it is not surprising to find multiple and bilateral infarctions over the pons, cerebellar hemispheres and occipital lobes.

45.4 Pathophysiology

Similar to ischemic strokes in the anterior circulation, atherothrombosis, cardioembolism, artery-to-artery embolism and small vessel disease are the major mechanisms of ischemic vertebrobasilar stroke. Atherosclerotic steno-occlusive disease of the vertebral artery is commonly encountered at either its origin extracranially or its distal part intracranially. Common sites of atherosclerotic steno-occlusive disease of the basilar artery are seen around the AICA and the basilar artery tip. Cardiogenic and artery-to-artery emboli to the posterior circulation are less common than the anterior circulation; emboli typically lodge in the distal part of the vertebral artery or the basilar artery or at a site proximal to a pre-existing stenosis. Rare causes of ischemic vertebrobasilar stroke include fibromuscular dysplasia, temporal arteritis, migraine, dissection, and dolichoectasia. Apart from diabetes mellitus, no cause of acute basilar artery occlusion was identified in the index case.

Neurons place a high metabolic demand on energy in the form of adenosine triphosphate (ATP) to maintain their transmembrane ionic gradients, electrical activities, synaptic transmission, macromolecular synthesis, efficient intracellular transport, and cytoskeletal integrity. ATP is derived from the oxidative metabolism of glucose under normal circumstances; anaerobic glycolysis generates only one-sixteenth the amount of ATP from oxidative metabolism and also leads to lactic acidosis. During focal ischemia, reduction in cerebral blood flow is severe at the centre (ischemic core) and milder in the surrounding peripheral zone (ischemic penumbra). Rapid reversal of ischemia (reperfusion) within a treatment time window is an effective treatment of ischemic stroke.

45.5 Presentation

The clinical presentation of ischemic vertebrobasilar stroke is highly variable, ranging from TIAs or minor stroke to rapidly progressive brainstem dysfunction or coma at onset. Important determining factors are the etiology, location of occlusion, and severity

of ischemia. Typical symptoms include headache, dizziness, vertigo, diplopia, confusion, coma, dysarthria, unilateral or bilateral weakness, unilateral or bilateral numbness, and/or homonymous visual field loss or total blindness. Neurological examination may reveal pupillary abnormalities, abnormal ocular movements, ataxia, facial palsy, hemiplegia or quadriplegia, bilateral extensor plantar responses, homonymous hemianopia or total cortical blindness, and/or depressed GCS score. The index case presented with severe symptoms due to acute basilar artery occlusion. Despite immediate diagnosis and early recanalization, she fell into a locked-in syndrome or state. This dreadful consequence is due to severe destruction of the basis pontis. In the majority of patients, preceding warning symptoms of vertebrobasilar ischemia occur over an interval of 2 days to several weeks, but these were absent in the index case.

45.6 Diagnostic Imaging

The index case illustrates the usefulness of neuroimaging in confirming the diagnosis of ischemic vertebrobasilar stroke. Urgent brain CT effectively excludes intracerebral hemorrhage, subarachnoid hemorrhage and many mimics of stroke. MRI with DWI is very useful in detecting early or hyperacute infarction in the vertebrobasilar territory, and CT angiography, MRA or DSA is required to confirm acute vertebrobasilar occlusion.

45.7 Prognosis of Acute Basilar Artery Occlusion

Acute basilar artery occlusion carries a high mortality rate of 80 to 90% when untreated or upon treatment failure. The most critical factors for natural prognosis are the degree of ischemia and the site of occlusion. Incomplete occlusion with good collateral supply is associated with better outcome. A proximal occlusion is worse than a distal occlusion. A high NIHSS score >20, quadriplegia or coma at presentation predicts a poor outcome. In contrast, a better prognosis is associated with a low NIHSS score at baseline, shorter length of occlusion, younger age, embolic occlusion, and absence of brainstem infarction. Thus, the index case was expected to have a high mortality from the beginning. Timely and successful recanalization could have improved her prognosis. Unfortunately, the potential benefits of early recanalization were nullified by the severe shock plus the use of vasoconstrictive inotropic agents at high doses. There is no evidence that anticoagulation and other supportive treatments would improve the outcome. The spontaneous recanalization rate within a clinically meaningful time window is estimated to be 20% or less.

45.8 Development

Depending on the etiology and severity of ischemic vertebrobasilar stroke, the natural prognosis of ischemic vertebrobasilar stroke is highly variable, and some patients may respond better to a specific treatment than others. Numerous case series are available in the literature, but there are no randomized controlled trials to identify a superior treatment strategy. The general consensus on treatment targets of acute severe vertebrobasilar occlusion is rapid recanalization by IV thrombolysis, IA thrombolysis, angiographic stenting, and/or mechanical thrombectomy. A prospective, observational, mul-

ticentre, international registry of consecutive patients presenting with a symptomatic and radiologically confirmed BA occlusion was set up in November 2002: the Basilar Artery International Cooperation Study (BASICS) registry. With a target number of 500 patients, the BASICS registry will address the relationship between functional outcome and clinical presentation, duration of symptoms, early changes on brain CT, location of occlusion, type of treatment, recanalization, as well as stroke etiology. It will also document the most common complications of three treatment options, i.e., antithrombotic treatment alone, IV thrombolysis, and IA therapy. Furthermore, the registry will report on some outcome parameters at 1-year follow-up. As of December 2006, the data of 400 patients from 12 countries were collected; 61% of patients had a NIHSS score ≥20, 55% were treated with IA therapy, 29% were treated with antithrombotics alone, 6% were treated with IV thrombolysis, and 10% received no acute treatment. The overall mortality was 45%, and 29% had a good outcome.

45.8.1 Intravenous Thrombolysis

IV thrombolysis using rtPA is the standard treatment of ischemic stroke presenting within 3 hours and up to 4.5 hours of onset. The dose is 0.9 mg/kg body weight (maximum 90 mg), with 10% given as a bolus followed by a 60-min infusion. All exclusion criteria should be absent. The blood pressure should be kept <185/100 mmHg prior to and during the first 24 hours of thrombolysis. The increased risk of symptomatic hemorrhagic transformation is associated with a history of diabetes, elevated blood glucose, severe stroke, advanced age, longer delay of treatment, use of aspirin, history of congestive heart failure, and protocol violations. Randomized controlled trials of IV thrombolysis using rtPA did not specifically include or exclude patients with ischemic vertebrobasilar stroke. In a recent systematic analysis comparing IV and IA thrombolysis as therapy for acute basilar artery occlusion, Lindsberg and Mattle reported that 76 of 420 (18%) patients were given IV thrombolysis. The recanalization rate was 53%, the survival rate was 50%, and 22% had good outcomes. Most centres allow for a treatment time window of 6 to 12 hours in patients with severe neurological deficits due to acute basilar artery occlusion and up to several days in patients with a progressive stroke of lesser severity. Studies are ongoing to evaluate the benefits of IV thrombolysis within 24 hours of ischemic vertebrobasilar stroke, as well as the potential of newer IV thrombolytic agents.

45.8.2 Intra-arterial Thrombolysis

The intra-arterial approach has been advocated because the thrombolytic agent can be locally delivered to the thrombus at a high concentration. Multiple case series support the notion that IA thrombolysis achieves a better recanalization rate in large artery thrombosis. Nevertheless, data on the clinical efficacy of IA thrombolysis are lacking from randomized trials. The only randomized study on IA thrombolysis for acute stroke is the Prolyse in Acute Cerebral Thromboembolism (PROACT) II study which included acute stroke due to proximal middle cerebral artery occlusion within 6 hours of onset. Successful recanalization was associated with good outcomes and survival. IA thrombolysis can be achieved using rtPA or prourokinase (Prolyse®). Clinical use of the latter has not been approved by regulatory agencies. IA thrombolysis has become a standard treatment for acute large artery thrombosis in many comprehensive stroke centres. The treatment time window of IA thrombolysis is 6 hours. Compelling but unproven reasons for IA thrombolysis include severe neurological deficits, presentation between 3 and 6 hours after onset, recent history of major surgical procedures, and occlusion of major

extra- or intracranial arteries. Lindsberg and Mattle compared IV and IA thrombolysis as therapy for acute basilar artery occlusion and reported that 344 of 420 (82%) patients were given IA thrombolysis. The recanalization rate was 65%, the survival rate was 45%, and 24% had good outcomes. A higher mortality rate despite a better recanalization rate after IA thrombolysis can be due to the selection of more severe patients and/or a greater delay in IA thrombolysis when compared to IV thrombolysis. Macleod and colleagues randomized 16 patients with confirmed vertebrobasilar occlusion within 24 hours of onset to either IA urokinase or conservative management; good outcomes were seen in 4 of 8 (50%) patients in the IA arm and in 1 of 8 (13%) patients in the control arm. Unfortunately, the trial was prematurely terminated because of slow recruitment and withdrawal of the sponsor.

45.8.3 Transluminal Angioplasty and Stenting

Re-occlusion may occur after successful thrombolysis, especially at the site of atherosclerotic stenosis. When symptoms are due to residual atherosclerotic stenosis and/or re-occlusion at an atherosclerotic plaque, transluminal angioplasty with or without stenting may be considered. Gomez and colleagues reported their experience in 12 patients with symptomatic basilar artery stenosis. The mean stenosis was reduced from 84 to 44%; at 6 weeks, 8 patients had good outcomes, 2 had arterial dissection and 2 had thromboembolism. In a retrospective study, Imai and colleagues reported their experience on primary transluminal angioplasty and stenting in 28 patients with occlusive lesion of the intracranial vertebrobasilar artery within 7 days of onset. Of 16 patients with total occlusion, 81% had a baseline NIHSS score >20, 81% had technical success, and 19% had a good outcome. Of 12 patients with high-grade stenosis, 8% had a baseline NIHSS >20, 92% had technical success, and 75% had a good outcome. In the Carotid And Vertebral Artery Transluminal Angioplasty Study (CAVATAS), an international multicentre trial, 16 patients with symptomatic vertebral artery stenosis were randomized to receive endovascular angioplasty and stenting or best medical treatment alone. Endovascular intervention was successful in all 8 patients, but 2 had TIAs during the procedure. During a mean follow-up of 4.7 years, there was no recurrence in vertebral artery stroke in either group. Nevertheless, 3 patients in each group died of myocardial infarction or anterior circulation stroke, and 1 endovascular patient had a non-fatal anterior circulation stroke.

45.8.4 Endovascular Mechanical Thrombectomy

The Mechanical Embolus Removal in Cerebral Embolism (MERCI) trial evaluated a device which can mechanically remove an occlusive thrombus from an intracranial artery within 8 hours of onset of stroke. A recanalization rate of 48% was reported in 141 patients. In a pooled analysis of the MERCI and Multi-MERCI trials, recanalization was achieved in 21 of 27 (78%) patients with acute vertebral artery occlusion. Good outcomes were seen in 41%, and the mortality rate was 44%. Good outcomes were associated with successful recanalization. In the Multi-MERCI trial, patients with persistent large artery occlusion despite IV thrombolysis were recruited.

Another mechanical device, named the Penumbra System, was evaluated in a prospective, single-arm study within 8 hours of onset of stroke due to intracranial artery occlusion. Altogether, 21 arteries of 20 patients were successfully recanalized, the mortality rate was 45%, and good outcomes were seen in 45% of patients. The U.S. Food and Drug Administration has approved the clinical use of both the MERCI Device and the Penumbra System.

45.8.5 Combined Therapy

Combined Local Fibrinolysis and Intravenous Abciximab in Acute Vertebrobasilar Stroke Treatment (FAST) is a multicentre study designed to evaluate the potential benefit of combining IA rtPA at half dose and IV Abciximab (bolus followed by 12-hour infusion) in 47 patients with acute vertebrobasilar occlusion. Percutaneous transluminal angioplasty and stenting was performed in case of severe residual stenosis. Eligible patients had preserved brainstem reflexes. Recanalization was achieved in 72%, a good outcome was seen in 34%, and the mortality rate was 38%. The FAST cohort has demonstrated the feasibility of the combination therapy to improve recanalization and clinical outcome within a mean treatment time window of 6 hours from onset.

45.8.6 Staged Escalation Therapy

Pfefferkorn and colleagues proposed their staged escalation therapy in acute basilar artery occlusion. All eligible patients with acute basilar artery occlusion were given standard IV thrombolysis within 6 hours of onset in a community hospital. Upon transfer to a comprehensive stroke centre, brain CT and CT angiography were repeated. When there was persistent basilar artery occlusion, endovascular mechanical thrombectomy was performed to achieve recanalization. This approach is similar to that of the Multi-MERCI trial. Of 16 patients, 15 achieved recanalization, 7 required mechanical thrombectomy, 4 were dead at 3 months, and 7 had a good outcome.

45.8.7 Subsequent Management

Management in a stroke centre or an acute stroke unit is highly desirable. In addition to supportive care and rehabilitation, secondary prevention should be achieved by effective control of vascular risk factors, use of a statin, use of antiplatelet agents in atherothrombotic strokes, and use of anticoagulation in cardioembolic strokes. Intracranial large artery stenosis, including basilar artery stenosis, carries a higher risk of recurrent stroke. Warfarin treatment cannot be recommended because of its association with a higher rate of myocardial infarction, sudden death and hemorrhage. Instead, transluminal angioplasty with or without stenting may be considered.

45.9 **Key Concepts**

Ischemic vertebrobasilar strokes are less common but generally more severe than anterior circulation strokes. Angiographically documented acute vertebrobasilar occlusion is a clinical catastrophe with a mortality rate approaching 90% despite standard medical therapy including anticoagulation. Prompt detection and early recanalization may alter the outcome. Recanalization can be achieved by IV or IA thrombolysis and/or mechanical thrombectomy. An effective protocol to identify acute vertebrobasilar occlusion is crucial. Combination therapy and staged escalation therapy are feasible. As new and newer modalities of therapy become available, randomized studies are required to prove the effectiveness of these treatment options. In addition, studies on outcome predictors and appropriate selection of newer therapeutic modalities are needed.

46.1 Introduction

Population studies highlight that stroke is the third leading cause of death and the leading cause of disability in developed countries. Incidence and prevalence of this condition increase exponentially with age. Young patient have different characteristics from the adults and therefore deserve an independent analysis. From the public health point of view, stroke in young patients carries a great challenge not only for individuals but for society as a whole. The disability acquiered early in life means a significant loss of years of productivity of the patient, resulting in a significant economic burden for the entire population.

In this chapter we review the epidemiology, more frequent etiologies and prognosis of ischemic stroke in young patients. Cerebral venous pathology and bleeding, as well as therapeutic alternatives in patients with stroke are treated in their respective chapters.

46.2 Epidemiology

46.2.1 Incidence

The Northern Manhattan Stroke Study (NOMASS) is a prospective population study designed to determine incidence, risk factors and prognosis of stroke in a multiethnic urban population.The inclusion criteria for this study included: 1) individuals over 20 years of age; 2) diagnosis of first stroke; and 3) at least 3 months of residence in the area of northern Manhattan. Patients with transient ischemic attacks were not included. The main racial group in this cohort is African-American of Caribbean origin. In a period of 4 years, 924 cases of stroke were detected. Of these, 74 were individuals between 20 and 44 years of age with an estimated age-specific annual incidence of stroke of 23 per 100,000 inhabitants. In patients older than 45 years, 80% of cases were cerebral ischemia, 15% parenchymal hemorrhages, and only 5% SAH. In the subgroup of individuals with cerebral ischemia, the distribution by stroke subtype in young patients and adults is shown in Figure 46.1. The results indicate that the mechanisms of ischemic stroke vary with age. Cardioembolic stroke is observed more frequently in adults; in comparison, younger patients have a higher rate of cryptogenic stroke. This suggests that the causes of ischemia in young patients are more heterogeneous and that the evaluation of this group should differ significantly from that of adult patients with typical cardiovascular risk factors.

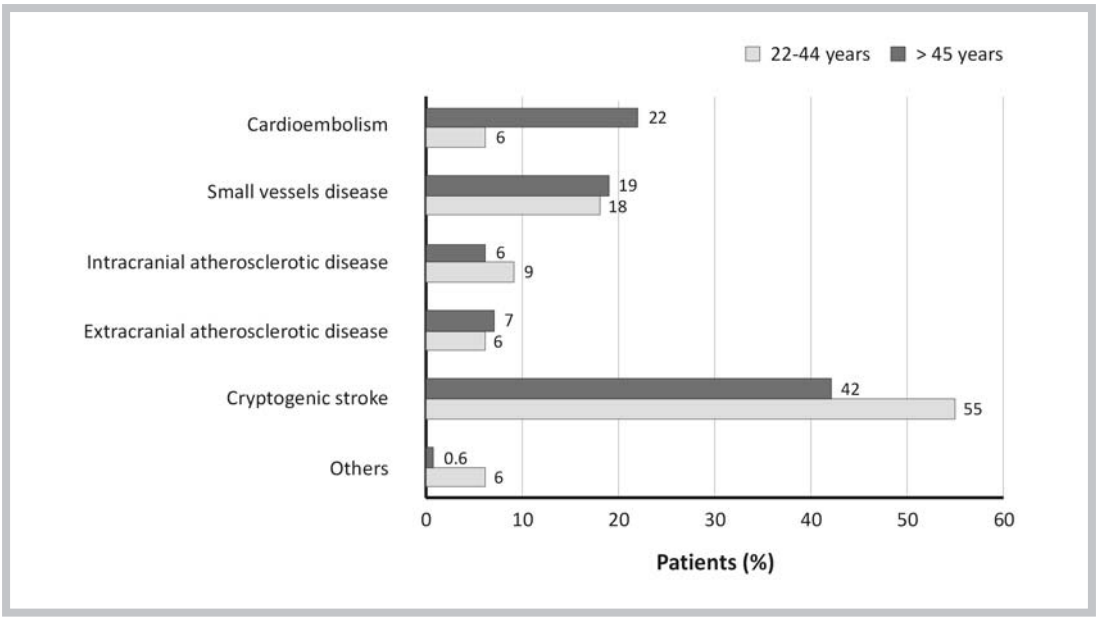

Figure 46.1. **Subtype mechanism of ischemia in patients between 20 and 44 (white bar) and more than 45 years (black bar) of age at first stroke in the Northern Manhattan Stroke Study [Jacobs, 2002].**

The NOMASS study, like other epidemiological studies, shows that the incidence, prevalence and consequences of stroke differ across different racial or ethnical groups. In younger patients, the relative risk of stroke in Hispanic or African-Americans is about 2.5 times higher than in white Caucasians. Even more significant are the racial differences observed in the Greater Cincinnati/Northern Kentucky Stroke Study which involved 3136 patients with first stroke. The sample analyzed a biracial metropolitan population

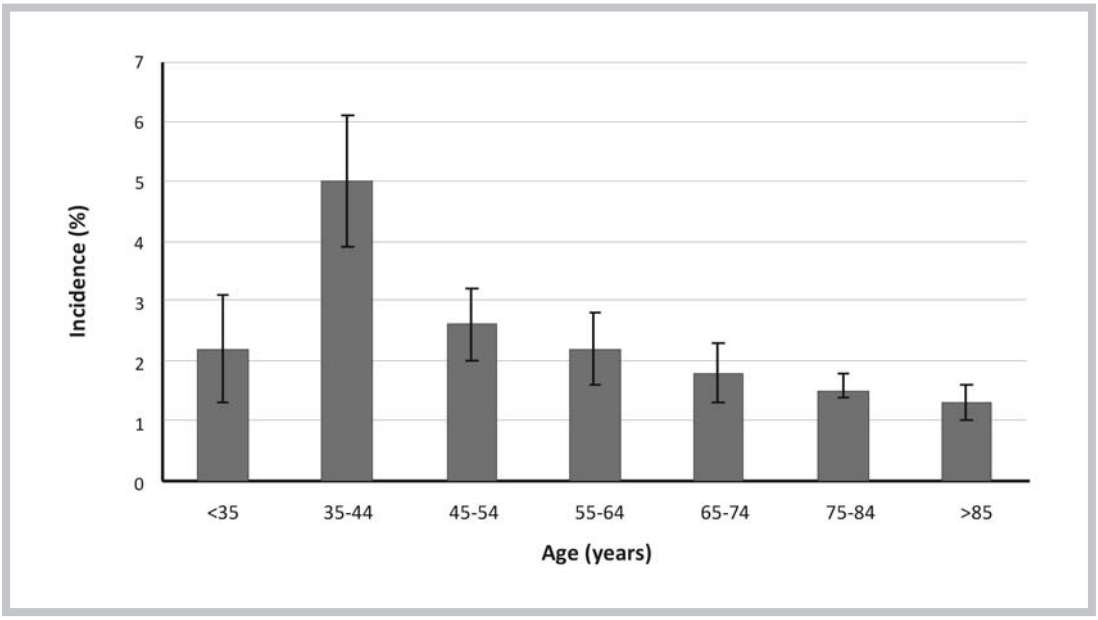

Figure 46.2. **Relative incidence of first stroke by age in African-Americans as compared to whites in the Northern Manhattan Stroke Study [Jacobs, 2002].**

composed mostly of white Caucasians (~70%) and African-Americans (29%). Compared to Caucasians, the relative risk of first stroke in African-Americans was 2.2 for those under 35 years of age, 5.0 for those aged 35-44 years, and 2.6 for those aged 45-54 years. These racial differences were attenuated at older ages (Figure 46.2).

Although the causes of these differences have not been determined, epidemiological studies suggest differences in vascular risk factors. Population studies show an increased prevalence and suboptimal control of cardiovascular risk factors (hypertension, diabetes, and obesity) in populations with low socioeconomic status and a higher prevalence of smoking in middle-high socioeconomic levels.

46.2.2 Prevalence

In 2005, the "Behavioral Risk Factor Surveillance System" (BRFSS) survey was performed in the United States. The study used randomly generated telephone numbers for questioning the civilian outpatient population over 18 years of age. Subjects had to answer the question "Have you ever been told by a doctor or other health professional that you had a stroke?". Of a total of around 356,000 individuals, approximately 2.6% responded affirmatively. On the basis of the data obtained from this survey, it has been estimated that the prevalence of cerebrovascular disease is 0.8% in individuals aged 18-44 years, 2.7% for those between 45 and 64 years, and 8.1% in those over 65 years.

Many strokes are asymptomatic or unrecognized. This suggests that the prevalence of this disease is in the general population underestimated. The NOMASS study illustrates this concept. In this trial, 892 subjects aged 55 years and older who were never diagnosed with stroke were assessed by magnetic resonance imaging (MRI) of the brain. The overall prevalence of subclinical brain infarction was 17.7%. Due to the design of this study, no data are available for patients younger than 55 years. However, the prevalence of subclinical ischemic stroke in relatively young individuals (55-65 years) was 9.5%; this rate is higher than that expected on the basis of the information obtained in the BRFSS survey. Similar to what was observed with incidence, the prevalence of ischemic stroke in relatively young African-Americans (55-65 years) was significantly higher (28.9%) than that observed in Caucasians (4.1%). These results confirm that the prevalence of stroke in the general population, even in relatively young patients, is greater than estimated.

46.2.3 Risk Factors

Cerebral ischemia in adult patients is close linked to traditional cardiovascular risk factors like hypertension, hypercholesterolemia, diabetes, obesity, and smoking. The presence, severity and suboptimal control of these co-morbidities increase the risk of small-vessel atherosclerotic disease, large-vessel occlusive disease, cardiomyopathy, valvulopathy, and cardiac conduction disorders. A worrying observation is the exponential increase observed in the last two decades in the prevalence of vascular risk factors related to eating habits, sedentary lifestyle, obesity and diabetes. Population studies conducted in the United States indicate that these conditions affect mostly African-Americans and Hispanics.

Cardiovascular risk factors are the pathophysiological basis for the vast majority of strokes in adults. In young patients suffering from cerebral ischemia, the prevalence of cardiovascular risk factors is significantly higher than in the general youth population. As in adult patients, the severity of these risk factors is directly related to the risk of developing cerebral ischemia. For example, data obtained in the Stroke Prevention in Young Women Study show that the risk of stroke in young women between 15 and 49 years of

age increases with the number of cigarettes smoked per day (odds ratio [OR] = 2.2 for 1 to 10 cigarettes/day, 2.5 for 11 to 20 cigarettes/day, 4.3 for 21 to 39 cigarettes/day, and 9.1 for 40 or more cigarettes/day).

46.3 Stroke Etiology in Young People

Stroke in adult patients is, in most cases, the result of endothelial injury caused by sustained exposure to vascular risk factors. As a corollary of this phenomenon, the vast majority of studies carried out to delineate the causes, evaluation, management and prognosis of cerebral ischemia have been conducted in groups of adult patients. However, as noted above, stroke in young patients differs significantly from that of adults. With a sample of 428 subjects, the Baltimore-Washington Cooperative Young Stroke Study is perhaps the largest epidemiological study carried out in 15 to 44 year-old patients with first stroke. The biracial population analyzed included approximately 60% of African Americans and 36% of Caucasians. In this study, about 50% of patients had at least one probable cause of stroke, 20% had at least one possible cause of stroke, and 30% had no probable or possible causes of stroke. The frequency distribution by cause of stroke seen in the first subgroup is summarized in Figure 46.3. Drug abuse, contraceptive use, thrombophilia and non-atherosclerotic arterial disease (including vasculitis and vascular dissection) are relatively uncommon causes of stroke in adult patients. However, in this study, these conditions were the etiologic factor for approximately 50% of cases of cerebral ischemia.

Like other epidemiological estimates, vascular risk factors and causes of stroke vary with race or ethnic group studied. In a retrospective study including 264 young patients of Chinese origin aged between 15 and 45 years of age, the stroke subtype more frequently observed was the cryptogenic type (Figure 46.4). The most prevalent risk factors were hyperlipidemia (53%), smoking (50%), hypertension (46%) and family history of stroke (29%). Within the subgroup with stroke due to other causes, the most common etiol-

Atherosclerotic arterial disease

ogies were arterial dissection (39%), antiphospholipid syndrome (17%), and Moyamoya disease (15%). Observed subtypes of stroke in epidemiological studies that include younger patients belonging to certain races or ethnic groups are summarized in Table 46.1.

Table 46.2 summarizes the conditions associated with the development of cerebral ischemia in young patients. The following sections discuss the most relevant pathologies.

46.4 Arterial Dissection

The annual incidence of brain supplying arterial dissection in the general population is 2.6 to 2.9 per 100,000 inhabitants. It is highly probable that the actual incidence is higher than that reported because most of the cases are asymptomatic or present with pain often considered "benign" and not investigated properly. About 70% of cases occur in patients between 35 and 50 years of age. It is estimated that between 10% and 25% of cerebral ischemia in patients under age 45 years are due to this disease, making arterial dissection of the second cause of stroke in young patients.

Traditionally, arterial dissections are divided into traumatic and spontaneous. This subdivision has been questioned because it is considered that a significant number of "spontaneous" dissections are the result of mechanical stress or trauma caused by sudden movements, hyperextension or high-speed acceleration of the neck: 80-90% of cervical-cranial dissections occur in the extracranial portions of the vessel, particularly in its mobile sector. The most vulnerable areas are the portion overlying the carotid bulb and the extracranial segments of the vertebral arteries (segement V3). Intracranial dissections are much less frequent: the affected vessels, in order of decreasing frequency, are the internal carotid artery, the middle cerebral artery, and the V4 segement of the vertebral arteries.

Arterial dissection originates from a tear in the intima which is separated from the rest of the vessel wall and forms a double lumen with an intramural hematoma (Figure 46.5). In other cases, the hematoma originates in the tunica media and subsequently extends into the intima (subintimal dissection), allowing the passage of clots into the bloodstream. The hematoma may also expand into the adventitia (subadventitial dissection), weakening the vessel wall and allowing the development of pseudoaneurysms or dissecting aneurysms. The intracranial vessels are particularly vulnerable to this compli-

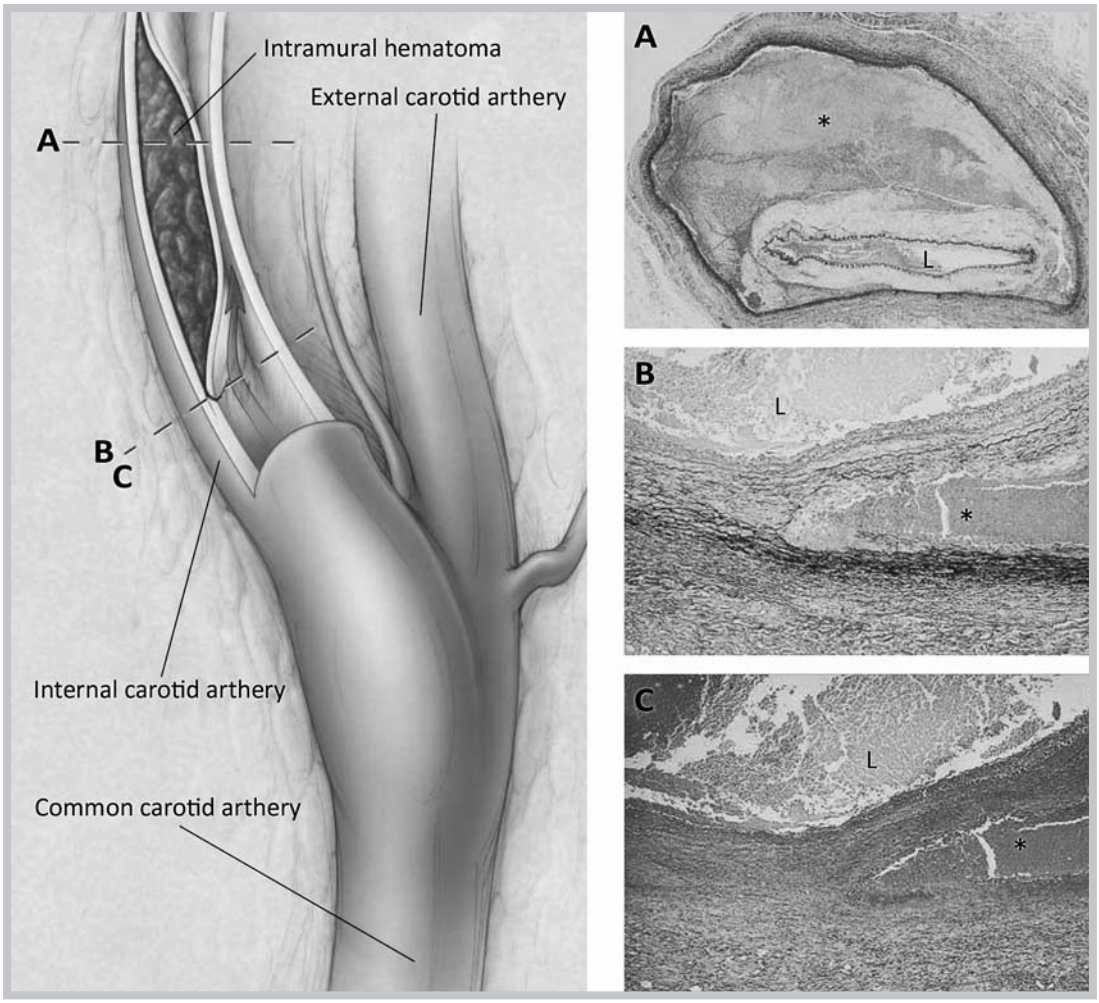

Figure 46.5. **Pathological findings in a 37-year-old patient with carotid artery dissection. The micrograph of the extracranial portion of the right internal carotid artery (panels A, B and C) shows a dissection between the outer layer and the tunica media causing stenosis of the arterial lumen (L). Intramural hemorrhage (asterisk) extends almost completely around the artery (panel A) (van Gieson stain, 4x). At higher magnification, the internal carotid artery shows fragmentation of the elastic lamina (panel b) (van Gieson stain, 25x) with accumulation of a pale substance in the tunica media shown by the blue staining of mucopolysaccharides (panel C) (Alcian Blue, x25). These changes are consistent with the diagnosis of cystic necrosis of the tunica media [Schievink, 2001].**

cation because of the absence of external elastic lamina and the thin adventitia. Once formed, the hematoma expands longitudinally in a proximal and distal way. Compression on the true lumen decreases blood flow, with the consequent risk of cerebral hypoperfusion. While subintimal dissections are associated with ischemic stroke, subadventitial dissections are associated with subarachnoid hemorrhage (SAH). Imaging studies obtained by nuclear magnetic resonance suggests that the pathophysiological mechanism that causes ischemia is, in most cases, thromboembolism.

It has been postulated that arterial dissection is a result of structural instability of the vessel wall. About 15-20% of patients with this disease have fibromuscular dysplasia, and 1-5% have hereditary connective tissue diseases such as type IV Ehlers-Danlos syndrome, Marfan syndrome, autosomal dominant polycystic kidney disease, osteogenesis

imperfecta type 1, pseudoxanthoma elasticum, and α1 antitrypsin deficiency. In addition, arterial dissection has been linked to other arterial diseases such as cystic necrosis of the lamina media and Moyamoya disease. Other risk factors are migraine, recent infection, pregnancy, hyperhomocysteinemia, smoking, hypertension, and use of oral contraceptives.

The clinical presentation is variable but is most often accompanied by ipsilateral or widespread neck pain, facial pain or headache which may precede the occurrence of stroke for days or weeks. Subintimal dissections usually cause transient ischemic attack or stroke; the clinical presentation depends on the infarcted area but most patients present with amaurosis fugax, hemiparesis, or hemiparesthesia. Vascular distension is frequently observed in subadventitial dissections and can cause ispilateral Horner syndrome, pulsatile tinnitus or tinnitus, or cranial neuropathy (most often involving cranial nerves IX-XII). Vertebral dissections usually present with pain located in the neck, occipital region, or trapezius muscle; the pain can also radiate down the arm simulating a radicular neuralgia. The neurological deficits include diplopia, dysarthria, ataxia, and dizziness. The most common presentation is Wallenberg syndrome, which is caused by ischemia in the posterior inferior cerebellar artery territory. Intracranial dissections may present with SAH or ischemia. The latter is rarely transient and evolves into infarction more often than in extracranial dissections.

The diagnosis of arterial dissection has historically been based on radiographic findings obtained from digital cerebral angiography. In the classic form, dissection of the internal carotid artery shows a reduction in vessel calibre, sometimes with total occlusion, with its tapered distal end resulting in a typical “flame” image, followed by a long narrow column of contrast agent which may extend to the skull base (Figure 46.6).

Other typical angiographic findings are arterial dilation in the proximal or distal to the dissection, double lumen, intramural or intraluminal clot formation, and dissecting aneurysm. intraluminal clots and dissecting aneurysm. Magnetic resonance imaging (MRI) and nuclear magnetic resonance angiography (MRA) are non-invasive methods that allow simultaneous evaluation of the major cervico-cerebral vessels and brain parenchyma. MRA reveals the presence of vascular stenosis or occlusion. The T1-fat-saturated sequence shows an expansion of the vascular wall and the presence of intramural hemato-

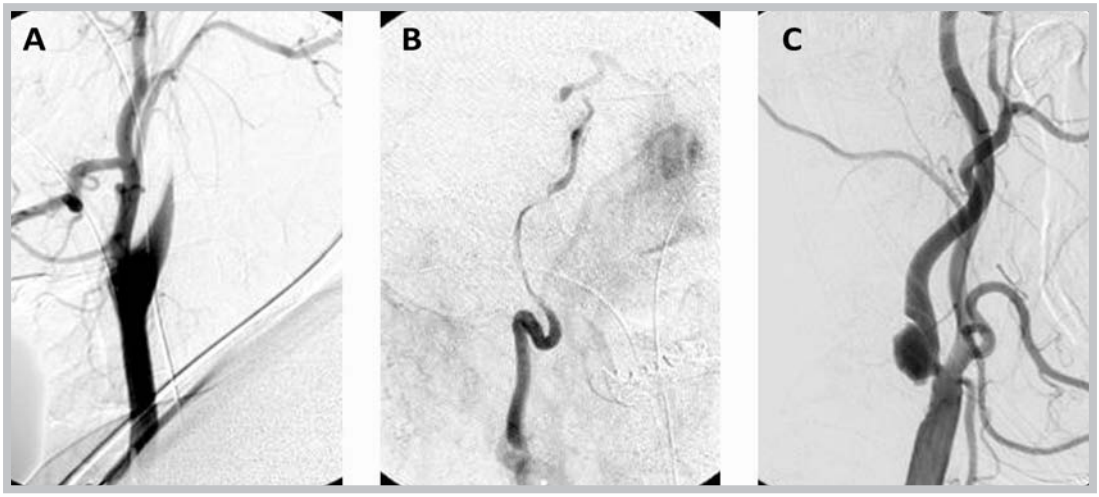

Figure 46.6. **Conventional catheter angiography showing carotid dissection with reduction of the calibre of the internal carotid artery with its distal end forming a “scarf” (A), followed by a long, thin column of contrast material forming the “string sign” (B). A pseudoaneurysm caused by subadventitial dissection (C).**

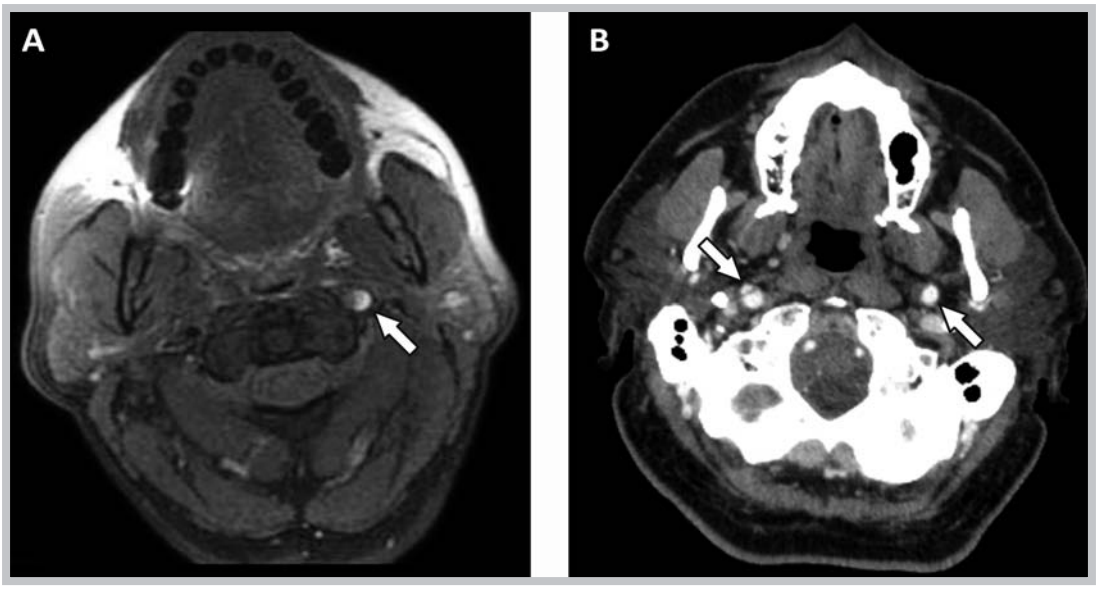

Figure 46.7. **MRI T1 sequence scan with fat saturation showing dissection of the left internal carotid artery with a hyperintense lesion in the wall corresponding to an intramural hematoma (arrow, panel A). CT image showing a double lumen right internal carotid artery (arrow with solid line, panel B) and the normal left internal carotid artery (arrow with dotted line).**

ma, the latter visualized as a hyperintense lesion with a half-moon shape (Figure 46.7). The intensity of the hematoma on T1- and T2-weighted sequences depends on the age of the dissection. In addition, diffusion-weighted imaging, T2-weighted and fluid-attenuated inversion-recovery (FLAIR) sequences can identify parenchymal ischemic lesions. In comparison, vertebral artery dissections most commonly affect the poserioinferior cerebellar artery territory. The sensitivity and specificity of MRI to detect dissection of the extracranial portion of the internal carotid artery is 95% and 99%, respectively, whereas in the portion of the extracranial vertebral artery, the sensitivity and specificity of MRI are 60% and 98%, respectively. Computed tomography angiography (CTA) is a non-invasive method that allows the identification of double lumen (Figure 46.7).

Because it is faster than MRI, CTA has become the radiographic test of choice for evaluating unstable patients. Recent studies suggest that CTA is superior to MRA for detecting vertebral artery dissections, and both techniques are similar for studying the carotid artery. However, MRI allows more detailed assessment of brain parenchyma, thus providing the physician with information of prognostic value. Finally, Doppler ultrasound of the carotid and transcranial Doppler ultrasound are useful in evaluating patients with suspected arterial dissection. The decrease or absence of blood flow in the affected vessel, distal retrograde flow and bidirectional flow in the carotid artery are indirect signs of high degree stenosis or obstruction in the appropriate clinical context and are sugges-

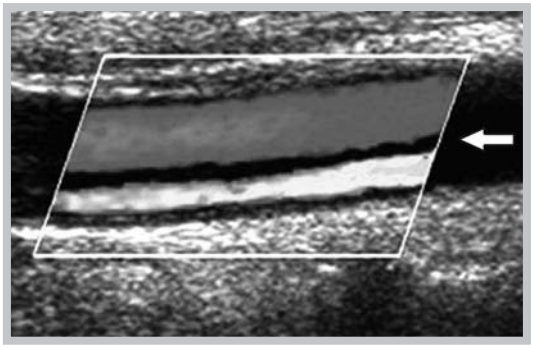

Figure 46.8. **Doppler ultrasound image of the carotid artery in a patient with arterial dissection. The image shows a double lumen, a high flow rate (lower) and a low flow rate (higher), separated by an "intimal flap" (white arrow).**

tive of a diagnosis of dissection. With color Doppler ultrasound the intimal flap and double lumen can be observed (Figure 46.8); usually the flow velocity in the false lumen is lower than that in the true lumen; alternatively, the flow in both compartments may have opposite directions.

The treatment of ischemic stroke associated with arterial dissection is controversial. Currently, there are no randomized trials comparing the efficacy of antiplatelet agents and anticoagulants in the management of this disease. The treatment of intracranial and extracranial dissection differs according to the authors. On the basis of the pathophysiological mechanism of ischemia in patients with extracranial dissections, the use of intravenous heparin is usually recommended, followed by oral anticoagulants for 3-6 months, with the aim of achieving an international normalized ratio (INR) between 2 and 3. More controversial is the use of anticoagulants in patients with intracranial dissection because of the risk (probably low) of SAH in patients with subadventitial dissection. The use of anticoagulants is related to the theoretical risk of intramural hematoma expansion, but the low number of reports describing this complication suggests that it is unusual.

If the use of anticoagulants is contraindicated, we suggest the use of antiplatelet agents that can be continued indefinitely. The use of thrombolytic agents in patients presenting within 3 hours of symptom onset has been described. Most of these reports include a small number of patients. Based on the mechanism underlying the ischemia, it is likely that this treatment is effective in patients who present in the hyperacute state. However, no prospective studies investigating the efficacy and adverse effects of thrombolytics in the treatment of dissection pressure are available. Finally, a few studies describe the use of angioplasty and stenting as alternatives in the management of patients with intra-or extracranial dissections. Manipulation of the dissected vessel may cause blood clots to shed, with the risk of causing further ischemia. Therefore, this treatment is reserved for cases refractory to medical treatment with anticoagulants.

The risk of recurrence of this disease is low. In a retrospective study involving 459 individuals with carotid dissection, the risk of recurrent ischemia at 31 months was 0.9%; half of the cases occurred in the subacute period and the other half was due to recurrent dissection.

46.5 Thrombophilia

It has been estimated that about 5-10% of cases of cerebral ischemia in the general population are caused by thrombophilia; this percentage is even higher in younger patients. Maintenance of homeostasis depends on the combined action of procoagulant and anticoagulant mechanisms, and the deficiency of inhibitory factors as well as the elevated levels of certain mediators of the coagulation system increase the risk of thrombosis. There are numerous inherited and acquired hypercoagulable states, those most frequently encountered in clinical practice are summarized in Table 46.3.

Hereditary	• Resistance to activated protein C due to mutation of factor V Leiden • 20210 mutation, prothrombin gene • Protein C deficiency • Protein S deficiency • Antithrombin III • Polymorphism in the gene for the enzyme methylenetetrahydrofolate reductase
Acquired	• Antiphospholipid syndrome • Thrombotic thrombocytopenic purpura • Myeloproliferative syndromes

Table 46.3. **Hypercoagulable states inherited and acquired more frequently encountered in clinical practice.**

Syndrome	Control group asymptomatic (%)	Patients with deep vein thrombosis (%)	Patients with a family history of venous thrombosis (%)	Patients with ischemic stroke	
				%	OR (95% CI)
PC deficiency	0.14-0.5	3.2	4.9	1.4	0.7 (0.2-3.1)
PS deficiency	0.1	2.2	5.1	0.9	0.9 (0.1-6.7)
ATIII deficiency	0.02-0.2	1.1	4.2	5.2	1.3 (0.5-3.3)
FVL	3-6	19	46	4.6	2.1 (0.6-6.8)
MGP	1-2	6.3	18	3.7	1.9 (0.5-6.2)

Table 46.4. **Prevalence of hereditary hypercoagulablility syndromes in Caucasians.**

ATIII = antithrombin III
CI = confidence interval
FVL = factor V Leiden
MGP = 20210A mutation of the prothrombin gene
OR = odds ratio
PS = protein S

Patients with inherited thrombophilias typically present with venous thrombosis; arterial thrombosis, however, is observed less frequently. Thus, the pathophysiological mechanisms of cerebral ischemia more common in patients with thrombophilia are venous sinus thrombosis and paradoxical embolism of thrombus originating in the veins of the legs or pelvis. The prevalence of inherited hypercoagulable states in Caucasians is low, and the role of these as causative agents of ischemia is controversial (Table 46.4).

A meta-analysis including a total of almost 18,000 cases and 58,000 controls was used to study the role of Factor V Leiden (FVL), the mutation 20210 of the prothrombin gene (PGM), and polymorphism in the gene for the enzyme methylenetetrahydrofolate reductase (MTHFR) in the development of cerebral ischemia. The risk of stroke was 1.33 (95% confidence interval [CI], 1.12 to 1.58) in patients with FVL, 1.24 (95% CI, 1.08 to 1.42) in patients with MTHFR, and 1.44 (95% CI, 1.11 to 1.86) in patients with PGM.

In a meta-analysis including approximately 54,000 subjects studied the association between inherited thrombophilias and arterial ischemia (including myocardial infarction, ischemic stroke and peripheral vascular disease). The risk of arterial ischemia in patients under 55 years with FVL was 1.37 (95% CI, 0.96 to 1.97), 1.66 (CI 95%, 1,13-2, 46) in patients with MTHFR and 1.41 (95% CI, 1.13 to 1.76) in patients with PGM.

Antiphospholipid antibodies are circulating IgG, IgM or IgA antibodies that recognize anionic and neutral membrane phospholipids. From a clinical point of view, the most rele-

Clinical examination	• Arterial thrombosis (cerebral, ocular, peripheral, myocardium, pulmonary, mesenteric) • Venous thrombosis (lower limbs, pelvis, venous sinus, hepatic (Budd-Chiari syndrome), pulmonary) • Intracardiac thrombosis • Repeated spontaneous abortions • Livedo reticularis • Cardiac disorders (valvular disease, verrucous endocarditis, Libman Sacks endocarditis, myxomatous degeneration of the mitral valve) • Pulmonary hypertension • Chorea
Laboratory tests	• False-positive VDRL • Thrombocytopenia • Hemolytic anemia • Elevated antinuclear antibody • Prolonged partial thromboplastin time • Hypocomplementemia (reduced c4)

Table 46.5. **Clinical and laboratory features associated with antiphospholipid syndrome.**

vant are the lupus anticoagulant, anticardiolipin antibodies and β2-glycoprotein antibodies. The phosphatidylserine antibody is seen less frequently and has been less studied. Antiphospholipid antibodies are mostly acquired, although they can sometimes be inherited. Antiphospholipid syndrome (APS) is characterized by the presence of antiphospholipid antibodies in the context of arterial or venous thrombosis. The prevalence of APS in the general population is estimated to be between 1.0% and 6.5% and its presence is suspected in individuals with history of repeated spontaneous abortions, connective tissue diseases (such as lupus), the presence of livedo reticularis on clinical examination, and ischemia of unknown origin in young patients. In laboratory studies, APS is suggested by a prolonged partial thromboplastin time, a false positive venereal disease research laboratory (VDRL) test, and a moderate thrombocytopenia. Other findings that suggest the presence of this condition are summarized in Table 46.5.

APS produces a hypercoagulable state and is observed in approximately 10% of patients with cerebral ischemia. This percentage is even higher in younger patients. The IgG isotype was statistically associated with the occurrence of stroke, and IgM isotype is considered an acute phase reactant whose level increases after certain infections. The role of IgM and IgA in ischemic stroke has not been clarified yet.

The management of venous or arterial thrombosis in patients with hypercoagulablity states is controversial. The presence of deep vein thrombosis (DVT) in the legs, and probably in the pelvis, in individuals with ischemic stroke and inherited thrombophilia, should prompt the assessment for cardiac variants causing right-to-left shunt and paradoxical embolism. If there is no alternative mechanism of ischemia, the use of heparin followed by warfarin sodium is recommended in order to achieve an INR between 2 and 3.

In the WARSS APASS trial (Antiphospholipid Antibodies and Stroke Study - Warfarin Aspirin Recurrent Stroke Study), the effectiveness of warfarin compared to aspirin in preventing the recurrence of cerebral ischemia in individuals with antiphospholipid antibodies was compared. This study included a total of 1770 individuals, 720 had antiphospholipid antibodies and 1050 were controls. The risk of recurrent stroke at 2 years was similar in both groups. Moreover, the frequency of recurrent cerebral ischemia in the individuals with antiphospholipid antibodies was similar. On the basis of these results, there is no evidence to justify the use of oral anticoagulants in patients with first ischemic stroke and antiphospholipid antibodies; in such patients the use of antiplatelet agents is reasonable. Differently, in patient with cerebral ischemia and APS we recommend the use of heparin followed by warfarin sodium in order to achieve an INR between 2 and 3. Due to the autoimmune mechanism underlying the APS, the possible role of iatrogenic immunosuppression with steroids or immunosuppressive drugs such as azathioprine, cyclophosphamide, cyclosporine, intravenous gamma globulin, and plasmapheresis has been suggested. The benefits and potential adverse effects associated with the use of these agents in preventing recurrent ischemic stroke have not been evaluated in clinical trials; therefore, these treatments are considered experimental and reserved for patients refractory to antithrombotic therapy.

46.6 Sickle Cell Anemia

Sickle cell anemia (SCA) is an autosomal recessive genetic disorder caused by a mutation in codon 6 of the β-globin gene. This mutation causes the substitution of a residue of valine for glutamic acid which induces a change in the spatial structure of the hemoglobin molecule (HbS). Two of the most serious complications of this disease are ischemic

stroke (75% of cases) and cerebral hemorrhage (25% of cases). The most frequently affected population is children and young adults. Under low oxygen tension, deoxygenated HbS forms insoluble polymers that precipitate in the microvessels. The endothelial injury that occurs in this condition generates a non-inflammatory arteriopathy affecting the large vessels of the circle of Willis, causing stenosis and ischemia. In areas of severe stenosis, a phenomenon of neovascularization may occur that generates small collateral vessels (moyamoya), which are fragile and increase the risk of cerebral hemorrhage. Other pathophysiological mechanisms of ischemia that can occur in this disease include hypercoagulability, related to an increased production of thrombin, platelet activation, and high levels of inflammatory mediators, and cardioembolic stroke. The latter, however, is rarely observed.

In the early 1990s, Adams showed that the average flow velocity in the middle cerebral artery of patients with SCA as measured by transcranial Doppler ultrasound (TCD) is directly correlated with the risk of stroke. This observation was the starting point for the Stroke Prevention Trial in Sickle Cell Anemia I (STOP I) study. This trial compared medical treatment with regular transfusion in the prevention of cerebral ischemia in patients with SCA. Approximately 2000 individuals with SCA (age range, 2-16 years) were studied by TCD and those with flow velocity in middle cerebral artery >200 cm/sec were randomized to receive medical treatment or periodic transfusions to reduce the level HbS <30%. The annual risk of stroke was 10% in the control group and 0.5-1% in those treated with regular transfusions. Moreover, in the latter group a significant decrease in flow velocity in the middle cerebral artery was observed. This trial was followed by the STOP II trial which investigated whether it was safe to stop periodic transfusion in patients who had normalization of flow velocity in the middle cerebral artery. This study was aborted early after seeing a rapid reversal of the hemodynamic benefit achieved and the occurrence of two cases of cerebral ischemia after regular transfusions were discontinued.

The management of young adult patients with SCA and stroke include the use of antiplatelet agents and the control of classical cardiovascular risk factors associated with the occurrence of cerebral ischemia. The use of regular transfusions can be considered in order to reduce the HbS <30-50%. However, it should be noted that most of the patients analyzed in STOP I and II studies were children and it is unclear whether the results can be extrapolated to adults. In addition, chronic transfusion is associated with complications and carries the risk of causing iron overload which requires the use of oral chelators.

46.7 Patent Foramen Ovale

Based on autopsy studies, it was estimated that the prevalence of patent foramen ovale (PFO) in the general population is 26%. Its pathological value is controversial. The PFO, as well as atrial septal defects, allows communication between venous and arterial blood and increases the risk of paradoxical embolism. Right-to-left shunt may be revealed or increased by manoeuvres or activities that increase intrathoracic pressure, the flow direction also can be reversed in certain pathological conditions.

In a clinical trial in patients <55 years of age, the prevalence of PFO was 40% in those with ischemic stroke and 10% in the control group (P <0.001). Within the group of patients with ischemia, the prevalence of PFO in individuals with known cause of stroke was half of those without an identifiable cause of stroke (20% versus 40%, P <0.10). This study, like others, shows an association between PFO and the presence of ischemia, particularly in individuals with cryptogenic stroke. In addition, several studies show that the

association of this disease with ischemic stroke increases with the size of PFO. On the basis of observations it has been suggested that, besides allowing paradoxical embolism, PFO may be a direct causal agent of cerebral ischemia.

There are several techniques that allow the diagnosis of PFO. Among the echocardiographic techniques, transthoracic echocardiography (TTE) is the most widely used method. Trans-oesophageal echocardiography (TEE) is more invasive, but its sensitivity is higher and it is considered the reference method. Atrial septal defect is a discontinuity in the interventricular septum, whereas PFO has a valve-like structure. In addition, the PFO does not always manifest at rest, requiring in such cases the use of techniques that can provoke it, as the Valsalva manoeuvre. In transcranial Doppler, micro-bubbles are used as a contrast method; they are injected intravenously while the peripheral middle cerebral artery is interrogated. The presence of microbubbles in the arterial system in a "shower" or "curtain" pattern is consistent with a right-to-left shunt. Depending on the clinical context, it can suggest the presence of PFO or arteriovenous fistula. In comparison with TEE, transcranial Doppler has a sensitivity in the detection of PFO of 68-89% and a specificity of 92-100%.

The management of ischemic stroke of unknown cause in patients with PFO alone (without atrial septal aneurysm) has generated controversy. There is no evidence in the literature to suggest that warfarin is superior to antiplatelet agents in preventing recurrent stroke. As an alternative to medical treatment, surgical or percutaneous closure of PFO has been suggested. In a recent prospective study, however, PFO closure in patients with cryptogenic stroke or TIA did not offer a greater benefit compared to medical therapy alone for the prevention of recurrent ischemic events. At present, medical treatment with antiplatelet agents for patients with cryptogenic stroke and PFO is recommended. Treatment with warfarin is reserved for individuals at high risk of recurrence, as those with hypercoagulable states or DVT. Percutaneous closure of PFO is recommended only for recurrent stroke cases unresponsive to medical treatment.

46.8 Retinococleocerebral Artery (Susac's Syndrome)

Susac's syndrome (SS) is characterized clinically by the triad of encephalopathy, fluctuating sensorineural hypoacusia and sudden visual loss. The pathophysiological mechanism is a microangiopathy that affects the vessels of the brain, retina and cochlea producing microinfarcts. The cause of this disease is unknown, although there is evidence suggesting a mechanism of autoimmunity whose target organ is the endothelial cell. Histopathology shows the presence of a predominantly lymphocytic perivascular infiltrate, microinfarcts, adventitial thickening, and endothelial proliferation (Figure 46.9).

Magnetic resonance imaging of the brain shows the presence of microinfarcts with a typical "snowball" appearance located, more often, in the corpus callosum and the supratentorial white matter (Figure 46.9).

The diagnosis of SS is mainly clinical and radiological. Encephalopathy and the motor or sensory deficits have been observed in 80% of cases, vision loss and hearing loss have a frequency of 46% and 52%, respectively. The typical triad is much less common, occurring only in 20% of individuals. In the peripheral blood there is usually an elevation of serum markers of inflammation such as erythrocyte sedimentation rate and C-reactive protein, and the cerebrospinal fluid shows elevated protein and lymphocytic pleocytosis. The ophthalmologic exam is characterized by occlusion of branches of the central retinal artery, and the audiogram shows hearing loss with a predilection for mid and low frequencies.

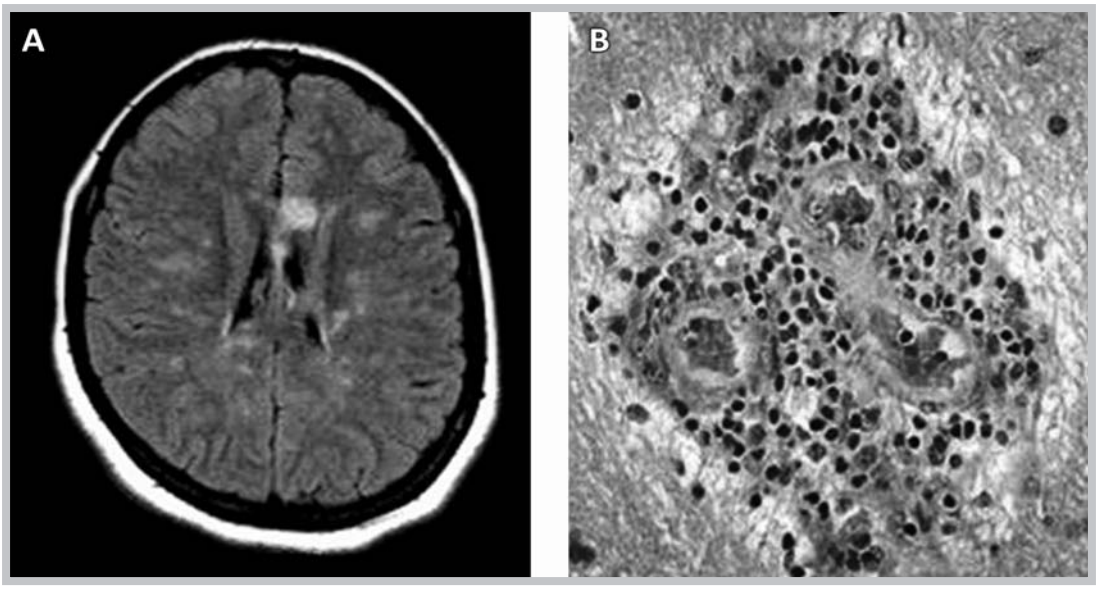

Figure 46.9. **A Magnetic resonance imaging (fluid attenuated inversion recovery [FLAIR] sequence) axial section of a patient with Susac's syndrome showing an ischemic lesion in the form of a "snowball" in the ischemic knee of the corpus callosum. Note the smaller ischemic lesions affecting mainly the white matter. B. Brain biopsy preparation showing adventitial thickening, endothelial proliferation and a predominantly periarteriolar lymphocytic infiltrate (staining: hematoxylin and eosin, 400x) [Fox, 2006].**

Treatment of SS is controversial and is based largely on studies with a small number of patients and the postulated mechanism of autoimmunity. Intravenous steroids are often used in the acute state. In refractory cases, plasmapheresis or intravenous gamma globulin administration are suggested. The use of other immunosuppressive drugs like azathioprine and cyclophosphamide has been reported in the literature, with variable results. Antiplatelet and anticoagulant agents are usually ineffective for treating this condition.

Susac's syndrome has a self-limiting course lasting from a few months to 5 years. Early diagnosis and rapid initiation of immunosuppressive therapy have a direct impact on the prognosis of these patients.

46.9 Cerebral Autosomal Dominant Arteriopathy With Subcortical Infarcts and Leukoencephalopathy (CADASIL)

CADASIL is an autosomal dominant systemic arteriopathy caused by a mutation ni the Notch3 gene. This gene is located on chromosome 19p 13.2-13.1 and encodes a membrane receptor involved in signal transduction mechanisms and neural development of Drosophila. In humans, its role is unknown, but it has been postulated that it's important for maintaining the structural stability of vascular smooth muscle cells. In patients with CADASIL, the membrane receptor Notch3 accumulates in the plasma membrane of these cells in the intracranial and extracranial vessels; electron microscopy shows intraneuronal granular osmiophilic deposits. Clinically, CADASIL is associated with migraine (usually with aura) that develops in 40-70% of cases in the third or fourth decade of life. The most severe complication of this entity is recurrent ischemic stroke which occurs in

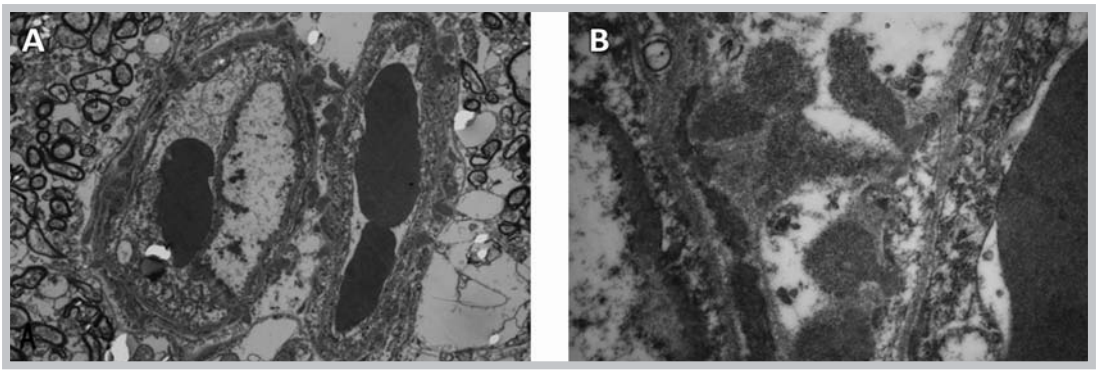

Figure 46.10. **Electron microscopy of skin biopsy preparation from a patient with CADASIL showing arteriolar ultrastructure. Panel A: granular osmeophilic deposits are seen in smooth muscle cells. At higher magnification, these granular osmeophilic deposits are irregularly shaped, 0.2 to 1 mm in size and consist of fine granules [Arima, 2003].**

80-85% of patients 30-50 years of age. Other typical clinical manifestations are psychiatric disorders and subcortical dementia.

Magnetic resonance imaging of brain shows ischemic lesions in the periventricular white matter and around the basal ganglia, with particular focus on the anterior pole of the temporal lobe and external capsule. These changes are not specific to CADASIL and may be absent in initial stages of the disease. The diagnosis of CADASIL is based on the identification of the Notch3 gene mutation. Electron microscopy of skin biopsy shows the presence of granular osmiophilic deposits adjacent to the basement membrane of smooth muscle cells of the arteriolar wall (Figure 46.10). These findings have a sensitivity of 45% and a specificity of 100% in the diagnosis of CADASIL; the immunological staining using anti-Notch3 monoclonal antibody increases the sensitivity of skin biopsy to 100%. Finally, this disease can also be diagnosed by identifying the mutation in the Notch3 gene in a sample of peripheral blood. This method, however, is expensive and laborious.

In the absence of specific treatment for this disease, efforts should focus on identifying and correcting cardiovascular risk factors. Death usually occurs 20 years after the onset of symptoms.

46.10 Fabry Disease

Fabry disease (FD) is a genetic disorder caused by deficiency of-galactosidase α (α-gal). This enzyme is a lysosomal hydrolase involved in the metabolism of glycosphingolipids. Its deficiency causes the intralisosomal accumulation of sphingolipids with α-galactosyl residues, particularly globotriaosylceramide (Gb3). The gene coding for the α-gal is located on the X chromosome and more than 400 mutations have been described. These are de novo mutation; therefore, the lack of family history of FD does not exclude the diagnosis of this condition. The age of onset is variable and depends on the residual enzyme activity. The most frequent manifestations of FD are listed in Table 46.6. Historically, it was considered that FD affected men and women were asymptomatic carriers. However, there are numerous reports indicating that, due to non-random tissue-specific X chromosome inactivation, women may have atypical presentations.

Ischemic stroke is one of the most severe complications of this disease. A study on 721 young adult patients 18-55 years of age with cryptogenic stroke (289 women and 432

men) showed the presence of mutations in the α-gal compatible with FD in 2.4% of women and 4.9% of men. Based on this information, it has been estimated that the FD is responsible for 1.2% of cryptogenic ischemic stroke in young adults. Cerebral ischemia in individuals with FD usually occurs in the posterior circulation. Its pathophysiology has not yet been fully elucidated. In addition to cardioembolic mechanism, patients with FD have vascular disease in the small and large cerebral vessels. It has been postulated that the accumulation of Gb3 in endothelial cells and muscle present in the vascular wall produces progressive stenosis of the small cerebral vessels and great vessels. However, the accumulation of Gb3 causing the weakening of vessel wall and dolichoectasia slowing the blood flow and increasing the risk of thromboembolism. Other proposed mechanisms include accelerated atherosclerotic disease and a possible prothrombotic state.

The diagnosis of FD is based on the determination of the enzymatic activity of α-gal in leukocytes or plasma. However, this technique allows the identification of heterozygotes. In women, in particular, gene sequencing may be necessary.

Dermatologic	• Angiokeratoma • Hypohidrosis or anhidrosis
Renal	• Proteinuria • Lipiduria • Tubular dysfunction (polyuria and isosthenuria) • Progressive kidney failure • Azotemia
Ocular	• Corneal opacities • Vascular lesions of the conjunctiva or retina • Lens opacities
Gastrointestinal	• Recurrent diarrhoea, vomiting or constipation • Postprandial bloating or abdominal pain • Weight loss
Cardiac	• Left ventricular hypertrophy • Syntolic and diastolic dysfunction • Valve disease (mitral regurgitation/insufficiency) • Arrhythmias • Coronary artery stenosis
Nervous system	• Cerebrovascular disease • Acroparesthesias • Hearing loss and tinnitus
Psychiatric	• Depression

Table 46.6. **Manifestations of Fabry disease.**

The treatment of FD is based on the identification and correction of modifiable vascular risk factors. It has been demonstrated that intravenous infusion of α-gal (1 mg/kg 2 times per week) in patients with FD significantly decreases the amount of Gb3 deposited in endothelial cells, and slowed the progression of kidney disease, a reversal of hypertrophic heart disease, resulting in slowed progression of kidney disease, reversal of hypertrophic heart disease, and improvement in autonomic activity and neuropathic pain. Due to the small number of patients studied, it is unclear whether enzyme replacement can reduce the recurrence of cerebral ischemia. In light of the benefits observed in this study, intravenous infusion with early α-gal treatment is recommended for patients with FD. In heterozygous individuals with ischemic stroke the use of antiplatelet agents or anticoagulants (depending on the case) and the correction of vascular risk factors are recommended. Intravenous infusion of α-gal should be considered in refractory cases.

46.11 MELAS Syndrome

The MELAS syndrome (mitochondrial encephalopathy, lactic acidosis and stroke-like episodes) is a progressive neurodegenerative disease caused by mitochondrial dysfunction. Almost 80% of patients with this condition have a mutation in mitochondrial DNA in the

position of tRNA-Leu 3243. However, other mutations in mitochondrial or nuclear DNA can cause the same syndrome.

Table 46.7 summarizes the most frequent manifestations of this disease. Each mitochondrion has a variable number of copies of mutated mitochondrial DNA and the content of dysfunctional mitochondria varies from one cell to another. This variability (heteroplasmy) makes the amount of mutated mitochondrial DNA differ from one tissue to another and makes the presentation of MELAS syndrome heterogeneous. The most susceptible tissues are those with a high metabolic rate. In the nervous system, mitochondrial dysfunction and consequent energy deficit present with stroke-like episodes. Clinically the patient presents with neurological deficits that correlate with parenchymal brain lesions. On magnetic resonance imaging, these are typically hyperintense hyperintense on diffusion-weighed image sequences and apparent diffusion coefficient, suggesting the presence of vasogenic edema. These lesions are not located in a defined vascular area, have a predilection for the posterior regions of the brain and may progressively extend to other areas. Their origin has not yet been established. It has been postulated that mitochondrial failure of intracerebral small vessels causes vascular dysfunction affecting the perfusion of the brain parenchyma (the "mitochondrial angiopathy" theory). Alternatively, it has been suggested that mitochondrial DNA mutation causes intracellular energy failure resulting in tissue hypoxia or anoxia (the "cytopathic" theory).

Treatment of patients with MELAS is based on improving the production of ATP and the transfer of electrons. To this end, substrates, such as coenzyme Q10, are frequently utilized. Coenzyme Q10 is usually used alone or in combination with creatine and lipoic acid. Idebenone is a synthetic analogue of coenzyme Q10 and has the advantage of having a better permeability for the central nervous system. Currently, there are no studies that demonstrate any benefit of these or other substrates of the respiratory chain in patients with MELAS. Dichloracetate indirectly activates the pyruvate dehydrogenase complex increasing the consumption of lactic acid. This enzyme converts the endogenous inhibitor of pyruvate dehydrogenase. Dichloroacetate causes an increase in the activity of pyruvate dehydrogenase, which increases the consumption of lactate and decreases the lactic acidosis observed in these patients. However, this drug is neurotoxic and has not been shown to be beneficial in the treatment of patients with MELAS. More recently it has been reported that L-arginine reduces the symptoms associated with stroke-like episodes, normalizes the levels of lactate and pyruvate, and reduces the recurrence of subsequent episodes. Finally, it has been suggested the use of carnitine in order to improve the β-oxidation of fatty acids and cellular energy homeostasis. Due to the low fre-

Constitutional	• Exercise intolerance • Short stature
Renal	• Nephropathy
Ocular	• Optic nerve atrophy • Pigmentary retinopathy • Ophthalmoplegia
Auditory	• Hearing loss
Gastrointestinal	• Gastrointestinal dysmotility • Vomiting
Cardiac	• Dilated cardiomyopathy • Left ventricular hypertrophy • Arrhythmias
Central nervous system	• Epilepsy • Stroke-like episodes • Encephalopathy/ dementia • Headache (usually migraine) • Elevated protein and lactate levels in the CSF
Peripheral nervous system	• Myopathy • Peripheral neuropathy
Endocrine system	• Diabetes mellitus

Table 46.7. Manifestations of MELAS.

quency of MELAS, the benefit of these and other drugs has not been demonstrated in randomized trials.
MELAS patients often have a progressive cognitive impairment and neurological systems. The latter is related to the occurrence of stroke-like events and recurrent seizures.

46.12 Evaluation in Young Patients With Stroke

In the absence of an established causal mechanism of cerebral ischemia, the assessment of young patients with stroke should include alternative pathologies, some of which are rarely found in elderly patients. Several of these entities have therapeutic peculiarities that can considerably change the prognosis and natural history. For illustrative purposes, Table 46.8 provides a guide for the evaluation of young individuals. It should be emphasized that the evaluation of these cases can be complex, extensive and expensive. Diagnosis and individualized plans for each patient are in the hands of the treating specialist who, according to personal experience, will select diagnostic studies at a reasonable cost.

Initial assessment	• Non-invasive
	  · CT/MRI
	  · CTA/MRA (or Duplex)
	  · Transthoracic
	  · Holter monitoring
	  · Lipid profile
	  · Basic evaluation of hypercoagulable state: red blood cell and platelet count, clotting studies (PT and aPTT), lupus anticoagulant factor, screening for sickle cell anemia, thalassemia
	  · Homocysteine
	  · Toxicology screening (cocaine, alcohol, etc.)
	  · Basic rheumatologic assessment
	  · VDRL
	• Invasive
	  · Cerebral angiography
	  · Transesophageal echocardiogram

Advanced assessment	• Advanced rheumatologic assessment • Advanced hypercoagulability studies • Lactic acid • Serology of genetic diseases (alpha-gal activity, sequencing of Notch-3 and alpha-gal genes) • Skin biopsy • Brain biopsy

Table 46.8. Suggested stroke assessment in young patients. Note: This table simply summarizes the most frequent complementary studies in the etiological diagnosis of stroke in young people. The goal is to simply provide a guide, not an exhaustive reference for the reader. The order of the studies should be individualized depending on the past medical history, family history, and physical exam findings.
CT = computed tomography
CTA = computed tomographic angiography
MRA = magnetic resonance angiography
MRI = magnetic resonance imaging

46.13 Prognosis

The mortality within 30 days of young stroke patients varies between 10% and 34% depending on ethnicity. Nevertheless, these data should be analyzed carefully since the size of the samples is usually small. In the NOMASS trial, for example, among the 924 stroke cases identified, only 74 occurred in patients under 44 years of age; in this study, mortality within 30 days of patients between 20 and 44 years was 17% versus 16% observed in patients older than 45 years. In the group of young patients, the highest mortality was observed in individuals with parenchymal hemorrhage (36%), followed by SAH (12%), and ischemic stroke (6%).
Studies based on administrative data show a lower mortality at discharge in young patients with stroke. For example,

in a study of over 26,000 stroke patients in Canada, the mortality rate was 5.6% in patients under 50 years of age, 6.2% in those aged 51-65 years, 12.7% in those aged 66-80 years, and 24.2 % in those older than 80 years. These data confirm that age is one of the two most important prognostic factors in patients with ischemic stroke (after stroke severity).

As in adults, the prognosis in young patients depends, at least in part, on the degree of complexity of the disease and the experience of the medical team. A recent study com-

Table 46.9. **Characteristics of patients younger than 55 years with stroke treated in Eastern and Western Europe. Modified from [Bhalla, 2008].**

pared the mortality and disability (measured by the Barthel Index) at 3 months in patients younger than 55 years with stroke treated in Eastern Europe and Western Europe. A total of 201 cases were detected, which were uniformly distributed in the two study groups. The study results are shown in Table 46.9. In patients treated in Western Europe, where health care services are superior, the prognosis was significantly better than in those treated in Eastern Europe. These results confirm that, as in adult patients, the level of expertise of the medical centre, the intensity of treatment and quality of service provided in the acute post-stroke period all have a direct impact on the prognosis of young patients suffering from this condition.

46.14 Conclusions

The pathophysiological mechanism of stroke in adult patients is closely related to atherosclerotic arterial disease and cardiac conduction disorders. In younger patients, however, about 50% do not have these risk factors, suggesting the existence of alternative pathophysiological mechanisms. Identifying the cause of ischemia is the first step in developing therapeutic plan that will improve the prognosis of individuals with this devastating condition. Additional population studies are needed to precisely delineate the etiology, assessment, management and prognosis of adult patients with cerebral ischemia of different origins.

47 Extracranial Atherosclerotic Carotid Artery Disease

Luciano Sposato [1], **Franciso Klein** [1]

[1] Neurology Department, Vascular Research Institute,INECO Foundation, Buenos Aires, Argentina

This chapter is organized in five sections. The first presents epidemiological, anatomical and pathophysiological concepts, clinical manifestations and a diagnostic approach. The second, third and fourth sections discuss carotid endarterectomy (CEA), carotid angioplasty (CA) and medical treatment, respectively. The fifth and final section analyzes the treatment strategies for the frequent presentation of concomitant coronary and carotid disease.
The approach to carotid artery disease is presented from a practical point of view, addressing problems of clinical relevance and a review of the available scientific literature.

47.1 Introduction

The relevance of the carotid arteries and their relationship with brain circulation was documented in 438 BCE by the Greeks [1]. More than 1500 years later, in 1951, Fisher described a case series of patients with carotid artery disease who experienced a transient ischemic attack (TIA). He mused that "it is conceivable that vascular surgery will some day find a way to bypass the occluded segment of an artery during the period of ominous transient symptoms." [2]. The first randomized studies to assess the utility of CEA were carried out between 1969 and 1970 [3]. Since then, a growing body of scientific evidence endorses both medical treatment and surgical procedures for the reduction of cerebrovascular risks.
According to international series, between 10 and 15% of ischemic strokes occur in a setting of carotid disease [4,5]. An analysis of 10 studies including 5043 patients (personal communication) on the subtype distribution of ischemic stroke in Argentinean hospitals revealed that 11% of cases were attributable to carotid artery disease according to the Trial of ORG 10172 in Acute Stroke Treatment (TOAST) criteria classification [6]. Of an estimated incidence of 100,000 ischemic strokes per year in Argentina, 11,000 could be due to carotid disease. The epidemiologically significant is that carotid artery disease is a preventable cause of ischemic stroke [7] and that the recurrence rate of ischemic stroke is 26% within 3 months after TIA [4,8].

47.1.1 Basic Anatomy of the Internal Carotid Artery

The internal carotid artery (ICA) can be divided in seven segments (Figure 47.1) [9].
It has its origin in the common carotid artery (CCA) at the level of the C3-C4 or C4-C5 vertebrae. The first segment is the cervical segment (C1), comprising the carotid bulb and the ascending portion. The carotid sinus or bulb is the widest portion (7.5 mm) and the one most frequently affected by atherosclerosis. The ascending portion measures 4.7 mm in diameter on average. The C2 or petrous segment starts where the ICA

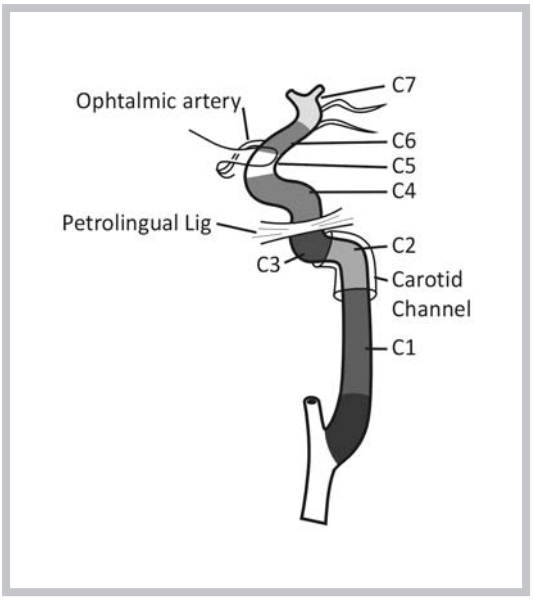

Figure 47.1. Internal carotid artery.

enters the carotid canal in the petrous or temporal bone. It consists of two subsegments: the ascendant and the horizontal. The C3 or lacerum extends from the foramen lacerum to the petrolingual ligament. The C4 or cavernous segment begins at the petrolingual ligament, courses across the cavernous sinus and consists of three subsegments: posterior-ascendant, horizontal and anterior-ascendant. The union of the second subsegment with the first and third form the posterior and anterior genu, respectively. The C5 or clinoid is a short, wedge-shaped segment that begins at the proximal dural ring and ends at the distal dural ring. The C6 or ophthalmic segment originates after the distal dural ring, extending distally to the origin of the posterior communicating artery, and giving rise to the ophthalmic artery.

The final portion is the C7 or communicating segment, which ends where the ICA divides into its two terminal branches, the middle cerebral artery (MCA) and the anterior cerebral artery (ACA). As its name indicates, it gives rise to the posterior communicating artery (PoCA).

47.1.2 Pathophysiology of Carotid Artery Atherothrombosis

Stenosis severity seems to be the most important risk factor for ischemic stroke [10]. This notwithstanding, the relevance of the structural conformation of atheromatous plaque has recently been emphasized [11], which is why it seems more adequate to use the term “carotid artery disease” instead of “carotid stenosis”.

The vascular endothelium is responsible for maintaining the patency of the arterial wall through the balanced release of pro-atherogenic (thromboxane, angiotensin II, endothelin, thrombin, etc.) and anti-atherogenic substances (prostacyclins, nitric oxide, serotonin, histamine, etc.) Vascular risk factors, hemodynamic effects and some specific humoral products may cause endothelial dysfunction, a systemic and potentially reversible process. This dysfunction triggers the formation of carotid atheromatous plaque, which begins with cholesterol internalization and the incorporation of inflammatory cells into the vascular wall [12]. Local rheological factors and shear stress produced by the blood flow on certain regions of the arterial tree such as the carotid sinus favor these pathological phenomena.

Unless there is early intervention to reduce risk factors, the atheromatous plaque becomes increasingly vulnerable: reduced thickness of the fibrous capsule [13], ulceration, intraplaque hemorrhage due to vasa vasorum rupture, large necrotic lipidic core (>40%) [16,17] or in situ thrombosis [18].

Histologically, the vulnerable plaque shows an intense inflammatory-macrophagic infiltrate [19]. An increase in neovascularization of the plaque through the vasa vasorum has recently been described [20]. Each of these factors is associated with a higher risk of arterio-arterial embolic phenomena. Nevertheless, not all vulnerable plaques can generate embolisms. In fact, they can also be found in the carotid arteries of asymptomat-

ic patients [14]. The “vulnerable patient” theory, which draws on the concept of thrombophilia or a transient pro-thrombotic state induced by various triggering mechanisms [21], has been advanced to explain this phenomenon. It has been observed that such patients exhibit elevated levels of C-reactive protein (CRP), leukocytosis, metalloproteinases, proteolytic enzymes and other biological markers [22-24]. These markers are intrinsically related to oxidative stress and inflammatory processes, and might be the mediators in the transformation of non-vulnerable plaques into vulnerable ones.

47.1.3 Ischemic Stroke Etiopathogeny in Patients with Carotid Artery Disease

Ischemic stroke in patients with carotid artery disease can be explained in terms of processes related to the arterial stenosis itself or to unrelated mechanisms such as cardioembolism, small vessel disease or, less frequently, hypercoagulability states. Among the 1021 strokes that occurred in 2885 NASCET patients, 11% were due to cardioembolism, 21% to small vessel disease, and 68% to carotid disease.

When analyzing exclusively the strokes that occurred in asymptomatic patients with stenosis >70% in the ICA territory (contralateral to the treated ICA), 45% were attributable to cardioembolism or small vessel disease [25], which is consistent with the multiple mechanism phenomenon proposed by Caplan [26].

With regard to the mechanisms directly related to carotid artery disease, we must consider hemodynamic phenomena causing severe hypoperfusion (<20% of brain blood flow compared to the contralateral hemisphere) [27], local thrombosis on a vulnerable plaque with subsequent distal embolism [18,28] or microthrombi formation on the surface of macro- and microscopically undamaged endothelial plaques (endothelial dysfunction without structural damage) [29,30]. Infrequently, emboli originating in the heart and impacting on a pre-existent carotid stenosis can be found.

47.1.4 Risk Factors

In general, risk factors for atheromatous plaque formation are the same as those that lead to atherosclerosis of other vessels, such as the intracranial, coronary, inferior limb arteries, etc.: arterial hypertension, dyslipidemia, smoking, diabetes, sedentary lifestyle, obesity, infectious disease and metabolic syndrome among others. Perhaps the most in-

	Asymptomatic carotid artery disease [n=113]	Ischemic stroke or TIA [n=175]	p
Age, years (mean ±SD)	67.3±8.2	67.6 ± 13.0	1.00
Male gender (%)	74.3	64.6	0.08
Arterial hypertension (%)	86.7	83.4	0.45
Diabetes mellitus (%)	32.7	22.9	0.06
Dyslipidemia (%)	75.2	54.3	<0.01
Smoking (%)	58.4	42.3	0.01
Myocardial infarction (%)	35.4	17.1	<0.01

Table 47.1. **Risk factor load in patients with asymptomatic carotid artery disease and in patients with ischemic stroke of non-carotid origin [Data from Stroke Center. Neuroscience Institute, Favaloro Foundation, 01/01/06 to 12/31/08].**

teresting fact is that the cardiovascular risk factor load is higher in patients with carotid artery disease (even asymptomatic) than in those who suffered an ischemic stroke of non-carotid origin. This finding is shown in Table 47.1 which compares the risk factor load of patients with asymptomatic carotid disease to those who suffered an ischemic stroke of non-carotid origin.
Dyslipidemia and smoking seem to be risk factors differentially associated with carotid disease. These data further support the hypothesis that an accumulation of risk factors might be necessary for the formation of atheromatous plaque which may later become vulnerable but not sufficiently so to cause an ischemic stroke.

47.1.5 Clinical Manifestations of Ischemic Stroke due to Carotid Artery Disease

More severe neurological syndromes usually arise in ischemic strokes caused by carotid artery disease than in those doe to such other mechanisms as small vessel disease. Greater severity is related to the large size of infarcts. They have been classically defined as being >15 mm, although this threshold has recently been questioned [31]. Localization is usually cortico-subcortical, with a predominance of the MCA territory. This explains why, aside from the classical motor and/or sensory deficit signs, a patient with an ischemic stroke of carotid origin may present cortical signs such as aphasia, neglect, anosognosia, sensory extinction or visuospatial disturbances.
A distinctive clinical finding is retinal compromise presenting as transient monocular blindness (amaurosis fugax), ipsilateral to carotid disease. Less frequently, irreversible monocular blindness may arise. It usually manifests within a few seconds (described like a curtain coming down or sideways), rapidly affecting vision with possible total visual loss. It may last from a few seconds to minutes (usually <10 minutes). It may also start as a progressive darkening of vision in the affected eye. These transient phenomena are caused by hypoperfusion of the ophthalmic artery or microembolisms from the ICA to the central retinal artery with posterior recanalization mediated by the endogenous fibrinolytic system [32].
Clinical manifestations such as dizziness, vertigo or syncope are not attributable to carotid artery disease [33].

47.1.6 Diagnosis of Carotid Artery Disease

Patients with a history of ischemic stroke should be screened for the presence or absence of both extra- and intracranial carotid disease. In the general population without a history of stroke or TIA, the indication for carotid artery disease evaluation is questionable. According to the U.S. Preventive Services Task Force (USPSTF), the potential benefit derived from the identification and later surgical resolution of a carotid artery stenosis >70% in asymptomatic patients does not outweigh the risk of postoperative brain digital subtraction angiography (DS-A) and the surgery itself. In conclusion, the USPSTF recommends not screening the general population for carotid disease (Level D evidence) [34].
Over the past years, considerable progress in the visualization and identification of the vulnerable plaque components has been achieved with ultrasound techniques such as intravascular Doppler ultrasound (IVUS) and other imaging methods, including magnetic resonance angiography (MRA) and multislice angiotomography. These procedures have become daily practice in specialized national and international medical centres (Figure 47.2).

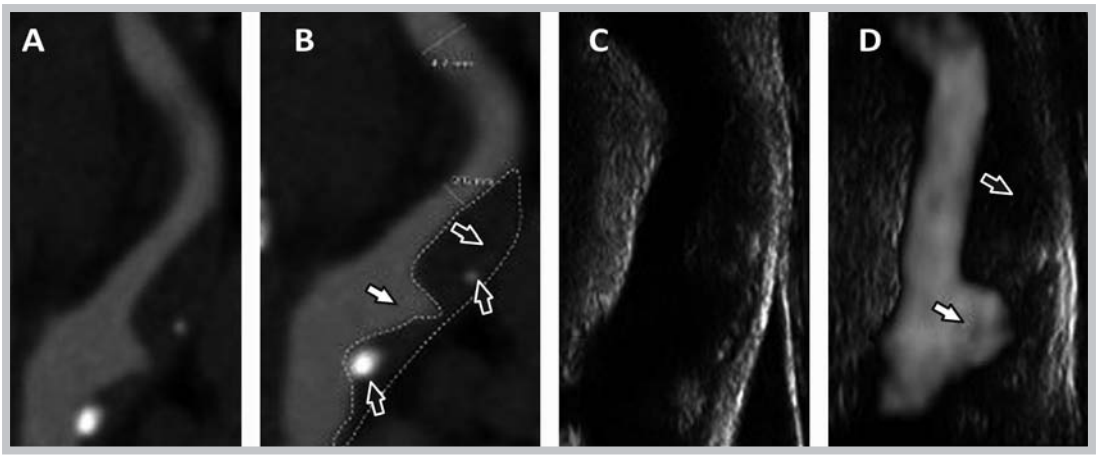

Figure 47.2. **Doppler ultrasound with power doppler and angiotomography of the internal carotid artery. (A, B). CT-A of the ICA showing a bulbar stenosis by a plaque with fibrolipidic component (pointed arrows), scarce calcium component (black arrows) and a large ulcer (white arrows). (C, D). Doppler and power doppler ultrasound scans of the same artery.**

Nevertheless, their real clinical and epidemiological value needs to be confirmed by large prospective studies before they can be formally recommended, given the fact that they still lack a defined role in the algorithm for the evaluation of patients with carotid artery disease (Level B evidence, class IIa) [35]. For the time being, of all the arterial abnormalities that can be documented by diagnostic tests, only the degree of stenosis is consistently significant in multivariate models, yielding the highest predictive value for ipsilateral ischemic stroke [36].

Several strategies or diagnostic algorithms for the evaluation of patients with carotid artery disease have been proposed. The method used for determining stenosis degree is not a minor detail. Many of the discrepancies in the results of randomized studies on the surgical approach to carotid artery disease can be explained by differences in the measurements [37,38].

Carotid artery color Doppler ultrasound (CDUS), because of its relatively low cost and wider availability, is the most widely used technique in clinical practice [39]. Nevertheless, it is highly operator dependent. Another of this method's drawbacks is the impossibility to evaluate proximal CCA and distal ICA, which limits the detection of tandem stenosis [40]. Moreover, by not assessing intracranial circulation, the possibility of detecting aneurysms is lost, these being findings that might radically change the choice of treatment [40]. It should be noted that intracranial circulation could be assessed by transcranial Doppler (TCD). But because the sound beam is hampered by osseous interposition, TCD requires additional training, which results in a lower rate of use. Finally, the quality of the printed images is usually not sufficient for evaluation by a professional who was not present during the test, which is why the attending clinician frequently has to trust the report blindly. These remarks aside, there is a growing tendency to plan surgical treatment based on CDUS scans performed by two different operators or on imaging findings from CDUS and another non-invasive method instead of DS-A. Although excellent correlations between CDUS and DS-A have been reported, they were never perfect, an essential criterion for the choice of surgical strategy [41]. Several studies confirm that surgical choice cannot be made based upon information obtained exclusively from CDUS [42,43].

MRA with time of flight (TOF) requires no use of paramagnetic contrast material. Still, dynamically administered contrast material to visualize the whole arterial tree, from its

beginning in the aortic arch to its terminal branches, has substantially improved image quality. This method is known as contrast-enhanced MRA (CEMRA). Like non-contrast MRA, it overestimates stenosis degree in severe pre-occlusive obstructions. Apart from this, it requires longer acquisition periods (albeit shorter than TOF MRA), which may result in a reduction of image quality if the patient moves. Some authors suggest that it is the most accurate non-invasive diagnostic method, having an excellent anatomic correlation and allowing an adequate evaluation of intracranial circulation [40,44].

Cerebral angio-tomography (CT-A) affords the possibility of obtaining images of the whole arterial tree much quicker than with CEMRA, thus avoiding movement artifacts. It requires the administration of iodinated contrast material by a pump operated by trained personnel, exposing the patient to high doses of radiation. This technique allows more exact visualization of the anatomical features of the arteries, as well as plaque components. Based on our experience, the diagnostic yield seems to be higher when evaluating the images dynamically from the CT console monitor than when analyzing the slides in a negatoscope or through a selection of digitalized images. Image reconstruction, which may entail some hours, is a disadvantage but it allows visualization of the intracranial circulation with remarkable clarity and detail.

DS-A is considered the gold standard for the assessment of extra- and intracranial cerebral arteries. It requires an intra-arterial catheter for the injection of iodinated contrast material and involves a considerable radiation burden. Between 1% (incapacitating and/or fatal) and 4% (mild) of ischemic strokes may arise as complications [45]. Other complications such as catheter insertion site hematoma may occur. Another disadvantage is that, because it can only identify plaque ulceration, it provides no information on plaque morphology. There are several methods for measuring the degree of stenosis. The two most widely used are those described in the NASCET and ECST (European Carotid Surgery Trial) studies (Figure 47.3) [46,47]. The more widely used is NASCET's [48], although both are reliable and correlate well with one another. The following formula must be applied to convert measurements: ECST = 40 + (0.6 x NASCET).

In conclusion, CDUS is an adequate method for carotid artery disease screening in patients with a history of ischemic stroke or TIA. It is preferable over other methods because of its wider availability and lower cost. When the potential presence of intracranial disease may result in therapy modification, appropriate non-invasive tests will be necessary (MRA or CT-A). Both NASCET and ECST used DS-A to confirm the degree of stenosis [46,47]. Extrapolation of the two trials' conclusions to patients evaluated with non-invasive tests such as MRA, Doppler or CT-A may be risky, hastening wrong decisions. Nonetheless, the American Heart Association/American Stroke Association (AHA/ASA) suggests that when consistent results are obtained from two non-invasive methods (CDUS, MRA, CT-A), DS-A is not necessary. This imaging study may be reserved for those cases in which non-invasive methods do not correlate. (Level B evidence, class IIa) [35].

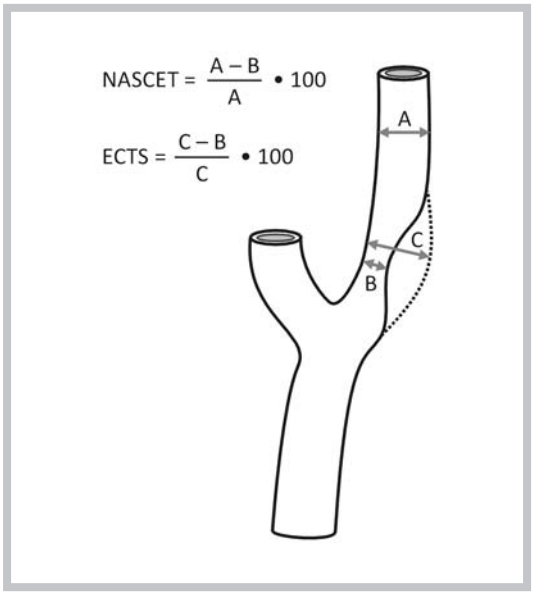

Figure 47.3. **Measurement of extracranial carotid stenosis according to NASCET and ECST.**

The AHA/ASA guidelines for the evaluation of extracranial ICA stenosis degree and selection of candidates for CEA are: a) CDUS should not be used as the only diagnostic method when considering endarterectomy (Level A evidence, class III); b) the method of choice for measuring stenosis degree is DS-A (Level A evidence, class I); c) two non-invasive methods may be used (CDUS, MRA, CT-A) for the assessment of stenosis degree, although less accurate than DS-A, which may increase the chance of indicating an erroneous treatment (Level B evidence, class IIa); d) subocclusive lesions are more accurately detected by DS-A, closely followed by CT-A (Level B evidence, class IIa) [49].

47.2 Carotid Endarterectomy

Just 7 months after Fisher envisaged the first carotid surgery [2], Raúl Carrea performed the first operation on a patient with carotid artery obstruction, removing the atherosclerotic plaque and anastomosing the external carotid artery (ECA) to the ICA[50,51]. The first CEA with the presently used technique (except for slight modifications) was performed by Michal DeBakey in 1953, but the case report was not published until 1975 [52]. The patient had a 19-year follow-up and died from an acute myocardial infarction. In 1954, Eascott performed carotid artery repair by partial resection of a previously thrombotic ICA and CCA and posterior direct anastomosis [53]. With time, the number of endarterectomies gradually increased until the 1980s, when studies began to warn about the increased rates of postoperative stroke and death [54-56]. In the early 1990s, following publication of the NASCET and ECST, enthusiasm for CEA was rekindled, opening a new chapter in primary and secondary stroke prevention [46,47,57].

47.2.1 Endarterectomy

There are two surgical techniques: the classical approach and the eversion technique (Figure 47.4). The first consists of longitudinal resection of the ICA to remove the atheromatous plaque [58]. The second involves transversal resection of the ICA origin around its entire circumference, followed by eversion of the adventitia and tunica media. With this procedure, the ICA atheroma is removed, followed by endarterectomy of the CCA with the classical technique; finally, the ICA bulb is re-anastomosed at the bifurcation [59].

The advantages and disadvantages of both techniques are summarized in Table 47.2. A systematic revision of randomized studies comparing classical endarterectomy to eversion technique endarterectomy (2590 surgeries) showed no significant difference in perioperative stroke, death or local complications [60].

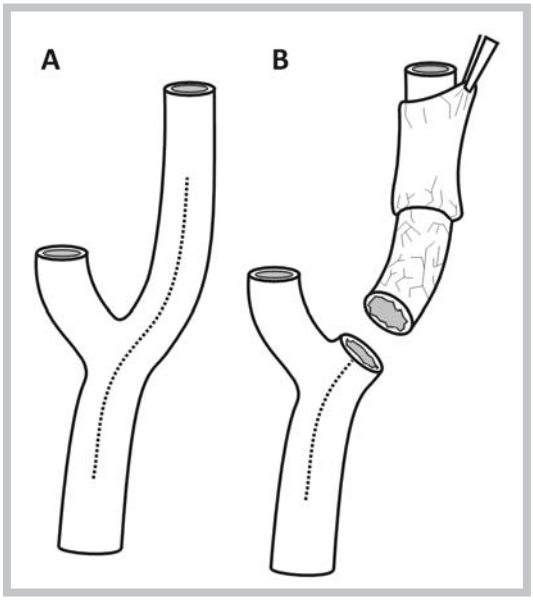

Figure 47.4. **Classic endarterectomy and eversion endarterectomy. (A). Classic endarterectomy with longitudinal resection along the ICA and CCA. (B). Eversion endarterectomy.**

Classic endarterectomy	Eversion endarterectomy
Advantages	
Shunting from the beginning of surgery	Lower re-stenosis rate
Distal atheroma resolution possible	No need for patching
Continuous view of distal intimal segment	Redundant segment resection possible (prevents kinking)
	Shorter surgical time
Disadvantages	
Longer surgical time	Inability to place shunt until plaque is removed
Predisposition to long-term kinking (due to elongation of the ICA during surgery)	Distal intimal segment might not be visualized
	Risk of failure to detect intimal flaps
	Technical difficulties with plaques with distal extension

Table 47.2. **Advantages and disadvantages of classic endarterectomy and eversion endarterectomy.**

47.2.2 Patch Use

One of the risks or potential complications of CEA is re-stenosis. Long-term re-stenosis is usually due to inadequate control of risk factors. On the other hand, re-stenosis during the first year is generally caused by neointimal hyperplasia [61]. Various different patch types have been used to prevent neointimal hyperplasia. Although patches may be associated with infection or hematoma (in case of rupture), their use has reduced the rats of severe complications.

A systematic review of 10 randomized studies comprising 2157 procedures in 1967 patients compared the result of endarterectomy performed with autologous (venous) or synthetic patches vs. primary closure surgeries (without patch) [62]. Patch use was associated with a reduction in the risk of ipsilateral stroke at 30 days (OR 0.31, 95% CI 0.2-0.6; p <0.001). Long-term follow-up also evidenced a lower re-stenosis rate (OR 0.24, 95% CI 0.2-0.3; p <0.00001) and lower risk of stroke or death (OR 0.59, 95% CI 0.4-0.8; p <0.0001).

47.2.3 Intraoperative Shunting

During the surgical procedure, while the atheromatous plaque is being removed, it is necessary to stop ICA circulation. This may be done with or without shunting. With the first option, hemispheric blood flow is maintains by placing a shunt between the CCA and the ICA distal to the clamping site. Without shunting, brain blood flow from the clamped ICA is maintained by collateral circulation from the circle of Willis or through extracranial circulation from the ECA. A study using continuous monitoring of brain blood flow and electroencephalography (EEG) during CEA showed that without the use of shunting, the hemispheric blood flow in some patients was close to zero [63]. This resembles the effect of cardiorespiratory arrest on the brain. Use of intraoperative shunting allows the surgeon more time and might work as a brain protection system to reduce the risk of ischemic stroke due to hypoperfusion. Nevertheless, most post-CEA ischemic strokes are produced by embolism of particulate matter detaching from the arterial walls and not by hypoperfusion. In fact, placing a shunt might favor embolism from the CCA as well as dissection. Two randomized studies assessing the potential benefit of shunting involved 590 patients and showed a non-significant trend toward a reduction in the risk of stroke

or perioperative death [64,65]. Due to the lack of conclusive results, no recommendations on the use of shunt during CEA can be made yet.

47.2.4 Local or General Anesthesia

CEA can be performed with either local or general anesthesia. Local anesthesia has several theoretical advantages. First, shunting might not be necessary because the patient is awake and therefore available for constant evaluation throughout the surgery. This would allow the use of intraoperative shunting only when there is evidence of focal neurological deficits. For the same reasons, continuous brain blood flow monitoring or EEG would not be necessary. Nevertheless, it should be noted that not all patients tolerate the procedure, many requiring conversion to general anesthesia.
Despite the theoretical advantages of local anesthesia, the randomized General versus Locoregional Anesthesia in Carotid Surgery (GALA) study that compared local anesthesia vs. general anesthesia in CEA showed no differences in the risk of stroke, acute myocardial infarction or death at 30 days [66]. A systematic review of 4335 surgeries including the 3526 cases in the GALA study revealed no difference in the risk of stroke or death related to the type of anesthesia used [67]. Based on these results, the choice of anesthetic modality should be at the discretion of the surgical team.

47.2.5 Postoperative Complications

As with any surgical procedure, local, neurological or systemic complications may arise after CEA. Reported complication rates differ across studies [68]. This derives mainly from methodological issues. A relatively reliable approach is to analyze studies under two criteria: a) those on patients with symptomatic carotid disease vs. asymptomatic carotid disease; and b) those in the context of randomized studies vs. observational studies (Table 47.3) [69-74].

Study (no. of subjects)	Stroke	Death	AMI	Stroke or death	Stroke, AMI or death	Hematoma	Local infection	Cranial nerves
Randomized studies in asymptomatic patients								
ACAS (814) [69]	1.2	0.1	0.4	1.5	1.7	ND	ND	ND
ACST (1405) [70]	2.5	1.1	1.0	2.8	3.6	ND	ND	ND
Total (2219)	2.0	0.8	0.8	2.3	2.9	ND	ND	ND
Randomized studies in symptomatic patients								
NASCET (1415) [71]	5.4	1.1	1.0	6.5	7.3	7.1	2.0	8.6
ECST (1729) [72]	6.7	1.0	0.5	7.1	7.3	3.1	0.2	6.4
Total (3144)	6.1	1.0	0.7	6.8	7.3	4.9	1.0	7.4
Observational studies in asymptomatic patients								
NYCAS (6655) [73] (1377) [74]	2.5 [24]	ND	ND	3.0 [73]	ND	4.7 [74]	0.7 [74]	5.3 [74]
Observational studies in asymptomatic patients								
NYCAS (2653) [73] (611) [74]	5.3 [73]	ND	ND	6.4 [73]	ND	6.3 [74]	0.9 [74]	7.7 [74]

AMI = acute myocardial infarction
ND = no data

47.2.6 Hyperperfusion Syndrome and Revascularization Hemorrhage

Hyperperfusion syndrome (HPS) after carotid endarterectomy or carotid angioplasty is generally reported to be between 0 and 3%. It may present clinically as a diffuse or facial, periorbital or fronto-temporal headache, vomiting, confusion, seizures or focal motor deficits. Hemodynamically, it is defined as an increase >100% in revascularized hemisphere blood flow compared to preoperative values [79]. Endothelial dysfunction mediated by free radicals and the subsequent disruption of cerebral autoregulation are thought to be the central phenomena of the pathophysiological cascade.

The principal risk factors are postoperative hypertension, diminished cerebrovascular reserve, prolonged hyperperfusion (↑cerebral blood flow >100%) after the procedure, contralateral ICA occlusion, scant collateral circulation and severe stenosis of the operated ICA, among others [80]. Thus, the best means of prevention is with strict control of postoperative arterial pressure. Neuroimaging showing diffuse, unilateral cerebral edema is a characteristic feature, although edema can also be observed in the contralateral hemisphere (Figure 47.5).

Less frequently, HPS can be complicated by intracranial hemorrhage (ICH). In a survey including a total of 122,856 endarterectomies and 13,047 angioplasties performed in the United States in 2005, the frequency of ICH was 0.016 and 0.15%, respectively [81], indicating this complication was ten times more frequent in angioplasties than in endarterectomies. In this study, angioplasty was an independent predictor for ICH (OR 5.9, 95% CI 3.1-11.1; p <0.001).

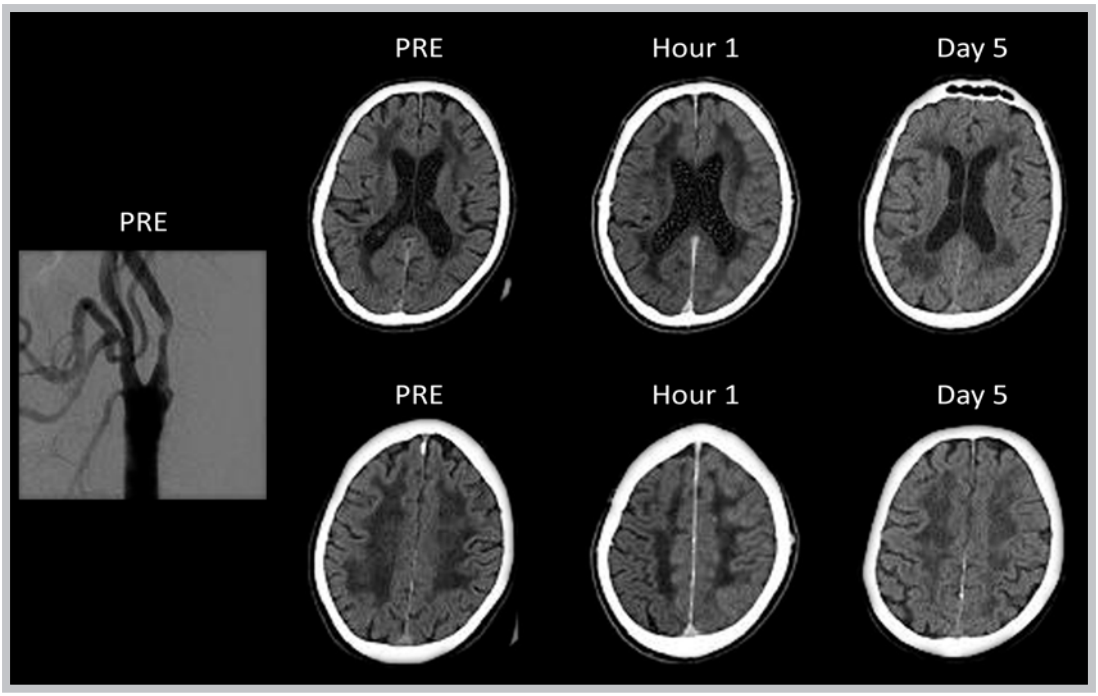

Figure 47.5. **Digital subtraction angiography and non-contrast enhanced computed tomography of a patient with hyperperfusion syndrome after left carotid artery stenting. Digital angiography and the brain computed tomographies of a 65-year-old patient before (PRE), 1 hour, and 5 days after angioplasty with stenting of the left ICA. Note the stenosis in the left carotid. Evident left hemispheric edema on tomographies obtained 1 hour and 5 days after angioplasty.**

47.2.7 Procedural Risk Stratification

The risk of complications secondary to CEA depends on a number of variables. As noted in Table 47.3, complications are more frequent in procedures for symptomatic stenosis than for asymptomatic stenosis. This observation is consistent with a review of 59 studies that revealed a higher risk for symptomatic patients (OR 1.62, 95% CI 1.45 - 1.81; P <0.00001) [82]. Table 47.4 summarizes the main variables influencing the risk of post-CEA complications [83,84].

Based on independent risk predictors, two models for CEA-associated risk stratification have been developed [85,86]. The Halm model seems to be more appropriate for predicting neurological, medical and surgical complications (Table 47.5) [74,86]. The risk score is obtained by adding a point for each of the following factors: a) active coronary disease (grade IV angina or unstable angina); b) stroke (non TIA) related to surgery; and c) ≥50% contralateral ICA stenosis. One point is to be subtracted if local anesthesia is given. The maximum score is 3 and the minimum -1. The model is used to predict the com-

Variable	HR	95% CI	p
Ipsilateral postoperative stroke in stenosis ≥70%, symptomatic [77]			
Female gender	0.79	0.64-0.97	0.03
Age 65 to 74 years	1.23	1.00-1.51	0.001
Age ≥75 years	1.70	1.28-2.56	0.001
Diabetes	1.31	1.05-1.65	0.02
Ulcerated or irregular plaque	1.35	1.11-1.64	0.003
Cerebral TIA vs. retinal TIA	1.88	1.38-2.55	<0.0001
Stroke vs. retinal TIA	2.33	1.74-3.13	<0.0001
Contralateral ICA occlusion	1.30	098-1.88	0.16
Previous stroke or TIA	1.20	0.99-1.46	0.07
Stroke or postoperative death in stenosis 50 to 69%, symptomatic [77]			
Female gender	1.50	1.14-1.97	0.004
Age 65 to 74 years	0.99	0.76-1.32	0.78
Age ≥75 years	0.83	0.49-1.41	0.78
Diabetes	1.45	1.05-2.02	0.03
Ulcerated or irregular plaque	1.37	1.03-1.83	0.03
Cerebral TIA vs. retinal TIA	2.62	1.68-4.09	<0.0001
Stroke vs. retinal TIA	1.91	1.22-3.01	<0.0001
Contralateral ICA occlusion	2.21	1.33-3.67	0.002
Previous stroke or TIA	1.59	1.21-2.09	0.001
Postoperative death in symptomatic and asymptomatic patients [76]			
Age ≥75 years	1.36	1.07-1.68	0.02
Age ≥80 years	1.80	1.26-2.45	<0.001
Postoperative stroke or death in symptomatic and asymptomatic patients [76]			
Female gender	1.31	1.17-1.47	<0.001

Table 47.4. **Variables affecting risk of complications at 30 days post CEA.**
CI = confidence interval
HR = hazard ratio

Halm score	Stroke or death	Cardiac	Medical, non cardiac	Minor neurological	Surgical wound
-1	0.7	2.1	1.4	4.3	3.3
0	1.7	3.0	2.4	6.4	5.3
1	5.9	6.1	4.9	8.7	8.3
≥2	13.0	8.8	7.8	12.8	9.8

Table 47.5. **Halm score for predicting post-CEA complications. All values are expressed as percentage.**

plications until postoperative day 30: a) stroke or death; b) cardiologic complications (ventricular tachycardia, unstable angina, acute myocardial infarction, congestive heart failure); c) non-cardiologic medical complications (assisted mechanical ventilation, postoperative pneumonia, sepsis, kidney failure, pulmonary thromboembolism, deep vein thrombosis or gastrointestinal hemorrhage); d) minor neurological complications (TIA, seizures, cranial nerve damage); e) surgical wound complications (hematoma or infection).

A neurologist is usually consulted to aid in deciding whether a patients with carotid artery disease should undergo endarterectomy. Complication rate and risk stratification is useful in the decision-making process for predicting the likelihood of postoperative complications but not whether a patient should undergo surgery or not. Instead, a decision for or against surgery should be based on two fundamental criteria: a) individual recurrence risk stratification when given the best medical treatment; and b) the applicability of randomized study results to the patient based on such diverse criteria as stenosis degree, age, gender, etc. (see below) [87].

47.2.8 Indications for CEA in Symptomatic Patients

The results of NASCET were published In 1991. This study sought to demonstrate the unequivocal benefit of surgical treatment in reducing stroke recurrence in symptomatic patients [46]. Seven years later, the final results of ECST (the European counterpart) were published with very similar results [47]. That same year, an analysis of the long-term NASCET results was published [88]. The Veterans Affairs Trial 309 (VA309) had to be interrupted when the NASCET results and a preliminary ECST analysis were published in 1991 [88]. To sustain these results, all the studies required compliance to a surgical complications rate <6%.

The three large, randomized studies proved the utility of CEA in symptomatic patients with stenosis >70%. To understand the implications of these conclusions and their applicability to clinical practice, the concept of “symptomatic carotid disease” needs to be clarified, given that not all symptoms should be considered related to the ICA. Both NASCET and ECST defined symptomatic carotid disease as a history of ischemic stroke or TIA in a carotid territory appearing up to 6 months previous to randomization. Although not exactly the same, the definition relevant for clinical practice should be “any ischemic stroke or TIA with clinical manifestations attributable to a carotid territory in the 6 months prior to the first visit”. The temporal parameter, as we will see, is not a minor detail. Although no evidence exists on this subject, we believe that carotid disease in patients with silent ischemic lesions on neuroimaging should not be considered “symptomatic” unless it can be proved (by MRI diffusion-weighted images or by comparison with previous studies) that these lesions have been present for less than 6 months.

47.2.9 Individual Risk Stratification Under Medical Treatment

There are several instruments to predict the risk under medical treatment. The most sophisticated is the Carotid Stenosis Prediction Tool available online (http://www.stroke.ox.ac.uk). This tool was developed by Rothwell and Oxford University collaborators, based on the analysis of ECST data, and later validated with NASCET's. This system classifies patients in quintiles. Those in the three lower quintiles would not benefit from CEA at year 5 (RAR_{5a} [risk-adjusted ratio] 0-2%), those in the fourth quintile would have a moderate benefit (RAR_{5a} 10.8%, 95% CI 1.0-20.6), and those in the highest quintile would have the maximum benefit (RAR_{5a} 32.0%, 95% CI 21.9-42.1). Alternatives to this model are the tables for risk stratification by color available on the same website.

47.2.10 Applicability or External Validity of Randomized Trials

Once the patient's individual risk is assessed, the next question is whether they might benefit from CEA. To answer this question, it is necessary to know if the patient meets the qualifying criteria that emerged from an analysis of the randomized studies. Specifically, we must determine whether age, gender, stenosis degree and other variables in our patient match the characteristics of those subgroups that benefited from CEA in NASCET and ECST.

As stated above, the degree of stenosis remains the most relevant piece of information when deciding on the surgical strategy in patients with carotid artery disease [36]. Nevertheless, it is not the only criterion. Several other variables may significantly interact with stenosis degree, modifying the potential impact of surgery on the reduction of risk for ischemic stroke recurrence [37]. Table 47.6 shows the number needed to treat with CEA to prevent a stroke or postoperative death over the next 5 years after surgery (NNT_{5a}) and the absolute risk reduction for the same outcome for the same follow-up period (RAR_{5a}), stratified by stenosis degree and the interaction with other variables [84].

The data from Table 47.6 should be analyzed cautiously. Except for subocclusive lesions, CEA reduces the risk of stroke or death in all patients with stenosis >70%. Besides the degree of stenosis, to define a lesion as subocclusive it should meet the following angiographic criteria: a) poststenotic ICA collapse; b) faster filling of the ECA than the ICA; and c) preferential filling of intracranial circulation through the collateral circulation [7]. These are usually associated with stenosis >99%. A benefit from CEA could not be proved for this specific group in the combined analysis of NASCET; ECST and VA309 (RAR_{5a} -0.1, 95% CI -10.3-10.2) [37]. Despite this seeming lack of benefit, some patients with subocclusive lesions might benefit from this intervention. Those with recurrent TIA despite optimal medical treatment might be among them. In the ECST, in fact, CEA was associated with a significant TIA RAR_{5a} in patients with subocclusive lesions. (RAR_{5a} 15%, NNT_{5a} 7; p <0.007) [92]. As shown in Table 47.6, patients with stenosis <50% do not benefit from CEA. The group with carotid artery stenosis between 50 and 69% requires further analysis. In such patients the presence of other variables may tilt the balance toward or against surgery. In this subgroup analysis, CEA was not found to be effective in women, diabetics or patients with contralateral ICA occlusion. Nor was it beneficial for those whose qualifying symptom was a retinal event or TIA [84].

These data informed the AHS/ASA recommendations: a) CEA is recommended in patients with ischemic stroke or TIA in the last 6 months and ipsilateral carotid stenosis between 70 and 99%, as long as the surgeon's documented perioperative morbimortality rate is <6% (Level A evidence, class I); b) endarterectomy is recommended in patients with ischemic stroke or TIA in the last 6 months and carotid stenosis between 50 and

69%, depending on patient-specific factors such as age, sex, co-morbidities and severity of initial symptoms (Level A evidence, class I); c) CEA is not recommended when carotid artery stenosis is <50% (Level A evidence, class III) [93].

47.2.11 Age and CEA

The relationship between the age of a patient with symptomatic carotid disease and the potential benefit of endarterectomy deserves specific mention. On the one hand, postoperative mortality is higher in patients between 75 years (OR 1.36, 95% CI 1.07-1.68; p=0.02) and 80 years of age (OR 1.80, 95% CI 1.26 - 2.45; p <0.001) [83]. A similar though not significant trend has been observed for the risk of stroke and postoperative death in both age groups. Nonetheless, as shown in Table 47.6, the benefit of endarterectomy increases with age. These data might seem contradictory. The higher benefit of surgery in patients aged 75 years and older is explained by the fact that, in the long run, the recurrence rate for medical treatment overweighs the risk of perioperative stroke or death. Based on this, there are no reasons to contraindicate CEA in patients aged older than 75 years with a life expectancy >5 years.

Despite this consideration, some guidelines (see section on angioplasty) recommend carotid angioplasty in patients >80 years. An interesting meta-analysis reports the following risk factors for patients >80 years who underwent carotid angioplasty and CEA, respectively: acute myocardial infarction 0.93 vs. 2.20% (p=0.083), mortality 1.98 vs. 1.11% (p=0.253), and 7.04 vs. 1.91% (p <0.01), According to the authors, the only significant difference was evidenced in stroke frequency in patients who underwent carotid angioplasty [94]. This notwithstanding, reanalyzing the study data, the OR of CEA for different outcomes shows a lower risk of stroke and death but a higher risk of acute myocardial infarction with CEA. In summary, CEA seems to be associated with a lower risk for stroke and death but a somewhat higher frequency of acute myocardial infarction in the elderly.

47.2.12 Relevance of Time Elapsed Between Symptom Presentation and Surgery

The time between symptoms onset and surgery influences the expected benefit, which will be higher the earlier the procedure is performed. An inverse relation between time to surgery and intervention benefit documented in randomized studies since the 1990s can be explained by several mechanisms.

On the one hand, the recurrence risk is highest during the first days after the first neurological event and then decreases with time, possibly due to the effect of medical treatment on atheromatous plaque stabilization [14,95]. On the other, it is reasonable to presume that time might also favor the development of collateral circulation. Finally, and after some weeks, by balancing the potential beneficial effect of CEA with the recurrence risk, the result is neutral, counterbalancing the usefulness of surgical intervention. As shown in Table 47.6, the most beneficial period for CEA is the first 14 days. In patients with symptomatic carotid stenosis >70%, the favorable effect of CEA is lost if deferred beyond 90 days, while in those with symptomatic stenosis 50 to 69%, it is lost after the first 14 days, making it not reasonable to indicate surgery beyond these time windows.

The meaning of “the first 14 days” warrants careful analysis. First, this period corresponds to the time between randomization and surgery in studies such as NASCET and ECST. This time window should not be considered as a synonym for a “period between

initial symptoms and surgery". In both NASCET and ECST, the patients were randomized by symptoms occurring up to 6 months earlier. This means that the period between the occurrence of symptoms and randomization (up to 6 months) should be added to the randomization-surgery time the studies reported. Hence, we could assume that the real time window in which CEA was beneficial in the randomized studies was more than 14 days.

Second, the fact that CEA might be more effective during the first 14 days does not necessarily imply that all patients should undergo surgery during that period. Paradigmatic cases that escape the standard of immediate surgery are **crescendo TIA** and **stroke in evolution**. Crescendo TIA can be defined in several ways but such events usually fit into one of the following categories: a) 2 or more episodes in the last 24 hours [96]; b) 3 or more episodes in the last 3 days [73]; and c) 3 or more episodes in the last 7 days [97,98].

Nevertheless, a systematic review revealed that urgent CEA in crescendo TIA or stroke in evolution was associated with a higher risk of stroke and perioperative death than delayed surgery (OR 4.6, 95% CI 3.4-6.3; p=0.001) [101]. The absolute risk for stroke or postoperative death attributable to urgent CEA was 20.2 (95% CI 12.0-28.4) for stroke in evolution and 11.4 (95% CI 6.1-16.7) for crescendo TIA (95% CI 6.1-16.7). Emergency surgery in patients with minor stroke or TIA with stable neurological syndromes was not associated with a higher perioperative risk (OR 1.2, 95% CI 0.9-1.7, p=0.17).

47.2.13 Indications for CEA in Asymptomatic Patients

The annual risk for ipsilateral stroke in patients with carotid stenosis >50% varies between 2 and 3% [102], increasing to 16.6% (95% CI 1-32) [103] during for a 15-year follow-up period. Acute myocardial infarction and nonvascular-related death risk also seem to be higher: 24% (95% CI 14-34) [103]. Age and presence of diabetes increase the risk [103].

Analyzing the results of large randomized studies on CEA in asymptomatic patients is much less complex than studies on symptomatic patients. The most relevant are the Asymptomatic Carotid Atherosclerosis Study (ACAS) [104] and the Asymptomatic Carotid Surgery Trial (ACST) [70]. The Veterans Affairs Cooperative Study (VACS) recruited only a male population [105]. The design of CASANOVA (Carotid Artery Stenosis with Asymptomatic Narrowing: Operation Vs. Aspirin) was criticized for its low number of patients and for excluding those with >90% carotid artery stenosis [106]. Finally, MACE (Mayo Clinic Asymptomatic Carotid Endarterectomy), comparing aspirin vs. CEA, had to be suspended for safety reasons when an excess of deaths due to acute myocardial infarction was detected in the randomized endarterectomy arm [107].

ACAS enrolled asymptomatic patients with carotid stenosis between 60 and 99% [104]. ACST enrolled patients with no history of stroke or TIA in the previous 6 months and with stenosis ≥60% [70]. Both studies showed a reduction in stroke risk in CEA patients. Although both ACAS and ACST formed the basis for the analysis of the utility of CEA in asymptomatic patients, they are not identical. The most controversial discrepancy was that in the ACAS, the participating surgeons had to demonstrate results with a perioperative morbimortality rate <3%, whereas in the ECST, NASCET and ACST the surgeons were required to report a complication rate <6% Moreover, some of the surgeons who were originally selected were later excluded from the study due to the adverse outcomes in their first patients [108].

Noteworthy is that the ACAS reported a strikingly low rate of surgical complications. Table 47.7 compares stroke and postoperative death rates in this study with those of ACST

(1.5 vs. 2.8%; p=0.07) and those of an observational study involving 6655 asymptomatic patients in New York (1.5 vs. 3.0%; p=0.02) [73]. As shown in the table, the postoperative mortality rate in the ACAS was 8 times lower than that of the two other studies. A meta-analysis of outcome after CEA not performed in randomized trials also showed a complications rate 8 times lower than that reported for ACAS [109]. The low complications rate observed in the latter might limit the reproducibility of its conclusions in clinical practice, particularly when considering the lack of information from many centres about their surgical complications rates.

In the ACST, the most questionable fact is that patients were randomized and underwent surgery with a non-centrally audited carotid artery CDUS [110]. This might have resulted in increased underreporting of subocclusive lesions, as well as mistakes in estimating the degree of stenosis [111].

Unlike symptomatic carotid studies, both the ACAS and ACST concluded that increasing degrees of stenosis are not related to a higher benefit from endarterectomy. This merits careful interpretation. Based on these data, the only variable related to stenosis degree that should be considered in the surgical indication is whether it is higher or lower than 60%.

As with symptomatic carotid disease, other variables can tilt the decision for or against surgical intervention. Gender seems to be a determinant with a higher impact on CEA outcome in asymptomatic patients. A meta-analysis of the ACAS and ACST results evidenced a reduction in the risk of perioperative stroke and death at 2.3 years in men (OR 0.49, 95% CI 0.36-0.66) but not in women (OR 0.86, 95% CI 0.63-1.45) [112]. Hence, CEA would not be advisable in asymptomatic women.

Carotid atheromatous plaque progression can occur in approximately 9% of patients within 6 to 9 months. It is defined as moving from a lower to a higher category on a scale that stratifies the degree of stenosis according to 6 levels: 0 to 29%, 30 to 49%, 50 to 69%, 70 to 89%, 90 to 99%, and 100%. It is not only associated with a higher risk of ipsilateral stroke (HR 2.0, 95% CI 1.0-4.1; p=0.04) [113-115] but also with a higher risk of acute myocardial infarction (HR 2.4, 95% CI 1.1-5.4; p=0.04) and cardiovascular death (HR 1.8, 95% CI 1.0-3.0; p=0.04) [113]. Although the postulated association is clear, there is still no evidence to recommend endarterectomy solely on the criterion of carotid plaque progression, although it might be an element to be considered in the decision process.

With regard to age, according to the ACST, the difference in the risk of stroke in the carotid territory between those who underwent surgery and those who did not was 7.8% (95% CI 4.3-11.3, p <0.0001) in patients <65 years and 7.5% (95% CI 4.7-10.3; p <0.0001) in patients 65 to 74 years of age [70]. Due to the low number of patients involved, determining whether endarterectomy might have been of benefit for patients >77 years was impossible. The way in which these data were presented should be carefully considered, given that the RAR_{5a} for the combined outcome of stroke of any cause and perioperative death were not reported.

Another risk marker in asymptomatic patients is the presence of microemboli detected by carotid artery ultrasound or TCD imaging. In a recent study, the annual event rate in

Endpoints	ACAS			ACST		
	NNT_{5a}	RAR_{5a}	p	NNT_{5a}	RAR_{5a}	p
Stroke	17	5.9	0.004	19	5.4	0.0001
Disabling stroke or death	37	2.7	0.26	40	2.5	0.004

Table 47.7. **NNT_{5a} and RAR_{5a} of CEA to prevent different endpoints in asymptomatic patients.**

asymptomatic patients with carotid stenosis between 60 and 99% and microemboli was 4.6%, while the rate was 2.4% (p=0.032) [116] for those without microemboli. The value of microemboli detection in clinical practice is yet to be determined.

In conclusion, CEA in asymptomatic patients should be reserved for a select subgroup. So far, this group has been defined as men <75 years of age, with stenosis >60%, as long as the surgical team's documented morbidity and mortality rate is <3%. It is highly likely that more evidence supporting non-surgical medical treatment over surgery will emerge very soon. In that eventuality, CEA might not be the first option for a great majority of asymptomatic patients and the most important approach will be to optimize medical treatment and interventions to reduce the risk of coronary disease, which remains the leading cause of mortality in this population.

47.3 Carotid Angioplasty

Although CEA is the most commonly performed procedure to reduce stroke risk in patients with symptomatic and asymptomatic carotid stenosis, the advent of percutaneous techniques has lead to the development of carotid angioplasty (CA) and CA with stent (SCA) techniques. The first CA procedure was described by Mathias in 1977 [117,118].

Among the potential advantages of CA and SCA are their less invasive nature is emphasized (they can be performed under local anesthesia and sedation), shorter hospital stay, and lower probability of complications associated with concomitant coronary disease. Unlike CEA, which is limited to the cervical carotid, endovascular procedures can be performed on much more cephalic lesions, and even in the intracranial carotid. A subgroup of patients who might benefit from CA and SCA are those with "tough or hostile necks", presenting a higher risk of complications with CEA. Patients with a history of radiotherapy or cervical surgery or tracheostomy are included in this group [119,120].

Notwithstanding its advantages, percutaneous procedures also carry the risk that mobilization and eventual displacement of the atherosclerotic plaque might result in a higher incidence of neurological events [121].

For CA and SCA, some other considerations should be taken into account:

- CEA benefits in symptomatic patients have been demonstrated, and the rate of complications is low when performed by experienced surgeons. Therefore, results, complications and hospital stay in percutaneous techniques should be compared to those of CEA.
- Morbidity and mortality associated with the use of intravascular devices remains to be clearly defined.
- Acute intraoperative carotid occlusion, unlike acute occlusion in other territories, might not be surgically corrected in an emergency procedure.
- Re-stenosis after a percutaneous procedure might be very hard or even impossible to repair surgically.

47.3.1 Angioplasty

Percutaneous angioplasty has been extensively used in the treatment of peripheral and coronary vascular diseases, whereas it has been much more cautiously applied to carotid disease due to the risk of dissection and embolic stroke. Moreover, because the main etiology in stroke of carotid origin is predominantly embolic, the increase in carotid diameter with CA has a less attractive biological approach than removal of the embolic source. Initial studies reported a rate of major or minor stroke of 1.4% and 2.7% respec-

tively, while other series demonstrated embolic complications in up to 12% of cases. In some series, re-stenosis occurred in up to 15% of patients and dissection in up to 5% (complications that were significantly reduced with the increasing use of stents).
CA is performed in a conscious patient, allowing for real-time intraoperative neurological monitoring. Nevertheless, unlike CEA in which intolerance to clamping can be treated with shunt placement, options are limited when ischemia of embolic origin occurs during CA or SCA, which is why all efforts have been directed to minimizing the risk of intraoperative embolism. On the other hand, ischemia time during CA or SCA is <1 minute is attractive compared to the much longer arterial clamping time in CEA. Since the advent of modern stents, CA is rarely performed without them.

47.3.2 Stents

The first balloon-expandable stents were replaced very favorably by self-expandable-stents. The first cobalt-chrome alloy stents (Wallstent®) were later replaced by current stents made of nitinol, a nickel-titanium alloy with a thermal memory and greater adaptability to the vessel wall. According to stent design configuration of cell opening, stents are classified as **open-cell** (more navigable and adaptable to vascular tortuosities), **closed-cell** (with a higher radial tension, better plaque containment and probably less emboligenous potential), and **hybrid stents** (a central closed cell with open cells at the edges).

47.3.3 Protection Systems

Filters, proximal occlusion balloons and distal occlusion balloons are used to minimize embolism risk. Distal protection filters are wires that pierce the lesion and have a bag-shaped receptacle with 80 to 140 micron perforations at its ends designed to capture the detached particles. Easy to use, they are the most widely employed system [125]. Its main disadvantage is the need to pierce the lesion without the system in function, which is why they are not readily used in critical lesions, with visible thrombi or in patients with recurrent symptoms.
Proximal occlusion balloons block blood flow through the vessel by balloon-mediated occlusion of the ECA and CCA under the obstruction [126]. In the system created by Parodi, the guide catheter has an auxiliary port from which an inverted flow from the internal carotid to the femoral vein is created. In both cases, the lesion is pierced and the stent is advanced with no active flow through the carotid, removing as much residual material as possible before finishing the procedure [127]. These systems are useful in critical lesions, with visible thrombi or with recurrent symptoms. Its disadvantages are its wider diameter and longer learning curve.
Lesion piercing by the guide (with consequent embolic risk) is necessary when using distal occlusion balloons as well. A balloon distal to the stenosis is then inflated to force flow to detour into the ECA while the plaque is treated. Although simpler in use, its use is becoming increasingly restricted [128].

47.3.4 Comparative Studies

A systematic review of 10 randomized controlled studies published as of March 2007, which compared CEA versus SCA in 3178 symptomatic and symptomatic patients, reported [129]: a) primary outcome for a new stroke or death at 30 days favored CEA according

to a fixed-effect model, but the result was not statistically significant in a randomized-effect model (which is less likely to underestimate confidence intervals); b) there were no significant differences between CEA and endovascular treatment in stroke risk or death on long-term follow-up; c) data interpretation was difficult due to the wide confidence intervals, significant heterogeneity in the studies, some of which were preliminarily interrupted. The reviewers concluded that there was insufficient evidence to recommend a change in recommending CEA as the treatment of choice for carotid artery disease.

The Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS) enrolled 504 patients with carotid or vertebral artery stenosis. There were no significant differences in the incidence of mortality or severely disabling stroke (10% for each group) or any type of stroke (6% for each stroke) between the procedures [130] at 30 days or after a 3-year follow-up period. No differences were found in the risk of procedure-related stroke or death between angioplasty and endarterectomy. Nevertheless, the conclusions were limited by the heterogeneity of the study population (stents were used in only 25% of patients). Recent follow-up studies have shown that the rate of re-stenosis in patients with CA is three times that of the CEA group, although the risk of ipsilateral stroke is low [131,132].

The SPACE (stent-protected angioplasty versus carotid endarterectomy) study was a European study involving 1183 patients and designed to demonstrate the non-inferiority of SCA compared to CEA for severe symptomatic carotid stenosis treatment. Patients with a high risk, non-controlled hypertension or re-stenosis were excluded [133]. At day 30, combined ipsilateral stroke or death outcome were equal in both groups (6.8 vs. 6.3%), although it did not statistically prove the non-inferiority of SCA vs. CEA. In a post hoc analysis, old age in the SCA group (but not in CEA) was associated with a higher risk of ipsilateral stroke or death [134]. There were no significant differences during the 2-year follow-up for the combined risk of perioperative ischemic stroke and death [135]. The criticisms raised against SPACE were that the use of embolism protective devices was optional and that they were used in only a 27% of cases, although there were no differences in the results at 30 days (when the perioperative factor was assessed).

The Endarterectomy Versus Angioplasty in Patients with Symptomatic Severe Carotid Stenosis study (EVA-3S) conducted in France also evaluated the hypothesis that SCA was not inferior to CEA in patients with severe symptomatic carotid stenosis [136]. This study excluded high-risk patients with unstable angina, unstable diabetes or non-controlled hypertension, as well as patients with a history of revascularization procedures. Incidence of any stroke or death at 30 days was higher with SCA than with CEA (9.6 vs. 3.9% with a relative risk (RR) of 2.5). The study was prematurely discontinued due to excess mortality in the SCA branch. The 4-year follow-up results also showed a higher incidence of negative combined outcome for SCA vs. CEA (11.1 vs. 6.2%) [137]. The difference was mainly due to the high number of perioperative strokes, while during later follow-up there were no significant differences. The main criticism raised against this trial was the lack of experience of many of the operators, the use of different classes of stents and protective devices. The use of the latter was also optional.

Unlike previous studies, SAPPHIRE evaluated non-inferiority of SCA vs. CEA in patients with symptomatic (>50%) and asymptomatic carotid stenosis (>80%) considered to have a high surgical risk [138,139]. Over 70% of patients were symptomatic. All patients received a stent with an embolic protection device. Results at 1 year showed that SCA was not inferior to CEA and a reduction in the combined endpoint for stroke, acute myocardial infarction, and death in the SCA vs. the CEA-treated group. Non-inferiority of SCA vs. CEA could not be proved beyond 1 year, and there were no significant differences in the secondary endpoint (primary endpoint plus ipsilateral stroke or death between the first

and third year). Despite difficulty in interpreting these analysis, the conclusion that SCA might not be inferior to CEA in patients with high risk should probably be considered valid for this study group (Table 47.8) [140].

47.3.5 Recommendations

The ICCS-SPREAD Joint Committee, a collaborative initiative by Italian scientific societies for the treatment of vascular disease, issued recommendations for the organization of multidisciplinary teams involved the decision-making in the treatment of patients with carotid stenosis, as well as the knowledge and training requirements for an operator to be certified for performing a revascularization procedure, emphasizing that guidelines should be adjusted to evidence emerging from ongoing studies [141].
Table 47.8 lists the "high-risk" conditions for CEA according to the ICCS-SPREAD Joint Committee and SAPPHIRE [138,141]. In patients with such characteristics treated by team with certified qualifications, SCA might be prioritized over CEA.
Nevertheless, Roghwell and Roffi, in two recent independent comments, called for a reconsideration of the lack of evidence for SCA results in patients eligible for CEA. Therefore, CEA should be still considered the first choice when attempting carotid revascularization [142,143].

47.4 Medical Treatment

The growing body of data on the importance of medical treatment as a primary and secondary prevention strategy will be examined in this section. We shall also discuss the use of antithrombotics before, during and after CEA.

47.4.1 Current Status of Medical Treatment

Medical (non surgical) treatment of vascular disease is the basis on which prevention measures are built. It includes: a) risk factor assessment; b) cessation of harmful habits and unhealthy lifestyle (smoking, excessive alcohol intake, recreational drug use, sedentarism); c) diet (risk-profile specific) and weight loss; d) use of antiplatelet therapy; e) antihypertensives; and f) statins [144]. An important feature of medical treatment for carotid artery disease is that, exceptions aside, it helps prevent general vascular risk. Not only does it prevent stroke but also acute myocardial infarction, heart failure and peripheral vascular disease. Moreover, unlike endarterectomy or angioplasty (which are aimed to prevent mainly hemodynamic and arterio-arterial mechanisms), medical treatment reduces the risk of stroke across the entire spectrum of stroke subtypes and, apart from preventing carotid artery events, it also reduces small vessel and cardioembolic strokes.
Over the past years an intriguing question has arisen: Can the best medical treatment replace CEA and CA in patients with carotid disease? We have already pointed out that no randomized study endorses SCA as the best **prevention strategy** [142,143]. Therefore, this treatment is just an option for well selected cases in which the patient does not meet the criteria for CEA. Based on this observation, throughout the rest of this section we will examine the relationship between medical treatment and CEA in symptomatic and asymptomatic patients.
Based on the results of studies such as NASCET and ECST, it seems unlikely that current best medical treatment could be better than CEA in symptomatic patients. Therefore, the current role for best medical treatment in patients with symptomatic carotid disease is to enhance the demonstrated benefit of CEA.
For asymptomatic carotid disease, the picture is different. If we consider the marginal benefit of CEA in asymptomatic patients, best medical treatment–as developed so far--might probably be better than surgical intervention [145].

47.4.2 Current Best Medical Treatment vs. CEA in Symptomatic Patients

Randomized studies assessing CEA benefits in symptomatic patients started in 1983 [105] and were completed by July, 2003 [70]. These studies proved that surgery plus best medical treatment initiated at randomization time and maintained during the follow-up period is superior to best medical treatment alone. Nonetheless, in the last 25 years medical treatment has evolved spectacularly with development of new drugs and the discovery of new properties for old ones. This has led to recent questioning of the current applicability of conclusions from studies such as the ACAS and ACST.
A recent systematic review set a turning point in the history of CEA vs. best medical treatment in asymptomatic patients with carotid stenosis >50% [146]. The relevance of this article, with its exceptional analysis of evolution and impact of best medical treatment on stroke rates in patients with asymptomatic carotid disease over the last 25 years justifies a detailed discussion of its results and most interesting findings.
The most significant finding was evidence for a progressive reduction in the rate of cerebrovascular events in patients under best medical treatment included in hospital observational studies between 1985 and 2007: ipsilateral stroke -1.4% ($p < 0.0012$) and any-territory stroke -2.5% ($p < 0.00012$). According to the author's analysis, when comparing the effect of best medical treatment to that of CEA performed in randomized studies in the following years, surgical intervention stopped being better than best medical treatment by the 1980s for ipsilateral stroke, by 1990 for any territory stroke, and by 2001 for

stroke or TIA in any territory. This occurred despite an increase in the prevalence of arterial hypertension (↑5%) and average patient age (↑5.5%), although there was a significant reduction in smokers (↓15%), men (↓8%), coronary disease (↓37%) and peripheral vascular disease (↓11%). The main conclusion is that since 2001, best medical treatment is at least as effective as CEA combined with best medical treatment 10 to 20 years ago. If we also consider that best medical treatment is 3 to 8 times less expensive (another conclusion of this study) for stroke prevention, the balance certainly shifts toward the use of the first option.

At least two observations on Abbott's work can be made. Based on his study, we know that for symptomatic patients with carotid stenosis >50%, current best medical treatment is at least as good as CEA plus best medical treatment 10 to 20 years ago. However, to determine best therapeutic option for 2010 we should compare current (2010) best medical treatment with CEA plus best medical treatment 10 to 20 years ago. A randomized trial for this purpose would require a very large number of patients due to effectiveness parity between both therapeutic interventions. Therefore, the cost would be hard to justify, even more so when considering applicability obstacles or external validity. One way to shed light on this matter would be to create large multicentre registries. In Abbott's study, since the analysis was performed on data from socioeconomically developed countries (the Netherlands, Canada, the United States and Australia), it might be risky to extrapolate this study's conclusions to other countries [147]. What we can certainly suggest is that the introduction of health policies aimed to optimize vascular prevention programs may have an enormous impact. Meanwhile, CEA will remain an option for a small, selected patient subgroup.

Whatever the conclusion regarding this question, patients with symptomatic or asymptomatic carotid artery disease should be treated with the currently available best medical treatment. Further information on this subject can be obtained from the AHA/ASA secondary prevention guidelines [93].

47.4.3 Antithrombotic Therapy Before, During and After CEA

Platelet adhesion and aggregation increase during CEA, especially during clamping and unclamping of the ICA [148]. This phenomenon may be boosted by a reduction in the antiaggregant effect of aspirin during surgery [149]. As a result, thrombosis at the surgical site can be postoperatively detected in 2.7% of cases [150]. Aside from local thrombosis, 5% of CEA patients develop an increased degree of microembolization detected by ultrasound in the first 2 hours after surgery [150] and 30-60% of these patients will suffer an ischemic stroke in the subsequent hours [150,151].

47.4.4 Antithrombotics During CEA

The combined use of aspirin (330 mg/day) and dipiridamol (75 mg/day) has significantly reduced platelet accumulation at the endarterectomy site [153]. These data are consistent with the positive effect shown by aspirin, when administered in 75 mg/day doses before surgery, on the reduction of severe stroke in the first month as compared against placebo [154]. The ACE (Aspirin and Carotid Endarterectomy) Trial showed that lower doses of aspirin (81 mg/day and 325 mg/day) administered before and after CEA were associated with a reduced risk for stroke, acute myocardial infarction and death at 3 months (6.2 vs. 8.4%; p=0.03) compared to higher doses (650 mg/day and 1300 mg/day) [155]. Combination therapy with aspirin (150 mg/day) and clopidogrel (75 mg/day) administered 5 days prior to CEA also reduced the number of microemboli detected dur-

ing the first 3 postoperative hours (OR 0.10, 95% CI 0.01-0.79) compared to aspirin alone (150 mg/day) without an increase in bleeding complications [156]. With regard to the specific use of clopidogrel, although small studies have shown it has a relative safe profile when administered before surgery [157], the company that markets the drug recommends its discontinuation 5 to 7 days before any elective surgery [158].

A patient with a crescendo TIA or a progressive stroke due to carotid artery disease is relatively often encountered in clinical practice. Although the utility of i.v. sodium heparin (with or without a previous bolus) and low-molecular-weight heparin have been investigated, with none of these have proved useful in the reduction of neurological damage due to stroke or the prevention of early recurrence [159]. Based on these data and the higher risk of cerebral and non-cerebral bleeding, the AHA/ASA advises against its use after TIA or acute ischemic stroke [159].

In summary, aspirin use (75-100 mg/day) before CEA seems safe and necessary to reduce the risk of microembolization and postoperative stroke (recommendation grade IA from the American College of Chest Physicians) [160]. Until strong evidence supporting the benefits and safety of clopidogrel emerge, its use is not recommended in the perioperative period; nevertheless, there is no evidence to support deferred surgery in patients previously receiving this drug. Finally, patients should not be treated with anticoagulation while awaiting CEA.

47.4.5 Antithrombotics During CEA

Different therapeutic attempts to reduce the risk of embolization during CEA have been tried, especially before clamping and unclamping. Although some studies have shown a reduction in the microembolic load and risk of perioperative stroke with Dextran administration in patients undergoing CEA, its use has not been widely accepted due to the risk of heart failure and other complications [161,162].

The American College of Chest Physicians' recommendation for intraoperative antithrombotic management is the use of i.v. non-fractionated sodium heparin [160]. Close control with intraoperative coagulation tests is also advisable.

Controversies surround whether intraoperative i.v. anticoagulation should be reversed with Protamin after the procedure. Protamin is usually associated with hemodynamic alterations and does not necessarily reduce the risk of postoperative bleeding [160,163]. On the other hand, anticoagulation reversion with Protamin may be associated with a higher risk of local thrombosis [164].

In conclusion, anticoagulation with i.v. non-fractionated heparin should be started before ICA clamping and there is not enough evidence to advice for or against anticoagulation reversion with Protamin.

47.4.6 Antithrombotics After CEA

A recent meta-analysis evidenced that platelet antiaggregants reduce stroke risk (OR 0.58, 95% CI 0.34 - 0.98; P=0.04) after CEA but do not seem to have a significant effect on mortality (OR 0.77, 95% CI 0.48 - 1.24) or perioperative bleeding (1.71, 95% CI 0.73 - 4.03) [165]. The antithrombotic of choice should be selected according to each patient's risk profile. The American College of Chest Physicians recommends aspirin use (81-100 mg) indefinitely. Given that up to 30% of patients with large vessel disease may also present a cardioembolic source, we recommend their systematic investigation with transoesophageal echocardiography (TOEE), since in such cases, and after CEA, the an-

tithrombotic treatment of choice would then be oral anticoagulation instead of platelet antiaggregation [166].

47.4.7 Antithrombotics Before, During and After CA

The rationale for antithrombotic use in patients undergoing CA is to prevent thrombi formation during the immediate postoperative period and to reduce early (first 30 days) or late re-stenosis risk. Intimal damage due to mechanical trauma during SCA causes the release of collagens and other endothelial proteins which stimulates platelet aggregation and adhesion. Subsequent endothelial repair involves intense cellular infiltration of the parietal thrombus, with smooth muscle cell proliferation and migration. The exacerbation of this process is referred to as "neointimal hyperplasia" and is the main cause of re-stenosis during the first 30 days [167]. Late re-stenosis usually refers to atherosclerotic phenomena related to inadequate control of vascular risk factors [168].

47.4.8 Antithrombotics Before CA

Asymptomatic microemboli detected on carotid artery CDUS have become progressively relevant as predictors of stroke and TIA [169] and are more frequent in symptomatic than asymptomatic carotid disease [170]. The Clopidogrel and Aspirin for Reduction of Emboli in Symptomatic Carotid Stenosis Trial (CARESS) is a randomized study that compared aspirin-clopidogrel therapy (300 mg loading dose plus maintenance with 75 mg/day for 7 days) vs. aspirin alone (75 mg/day) in 107 patients with carotid stenosis >50%, that had been recently (last 3 months) symptomatic [171]. The number of asymptomatic microemboli were lower in the dual therapy group (reduced RR of 39.8%, 95% CI 13.8-58.0; p <0.005). The recurrent stroke frequency was 0.0% in the dual therapy group vs. 7.1% in the only-aspirin group (P=0.44). major bleeding Neither group experienced. We did not discuss CARESS results in the section on CEA and antithrombotics because it has already been mentioned that clopidogrel use in the days prior to surgery is not recommended. However, combination therapy with clopidogrel and aspirin might indeed be an interesting option in a small and properly selected group of patients with symptomatic carotid stenosis >70% awaiting angioplasty.

47.4.9 Antithrombotics During CA

Routinely, after a diagnostic angiography confirming previous findings and before introducing a guide wire through the stenotic site, 5000 to 7500 units of non-fractionated sodium heparin are administered through the intra-arterial catheter [172], then and throughout the procedure, heparinized saline is infused [172]. Some centres use abciximab during the procedure.

47.4.10 Antithrombotics After CA

Based on experience with coronary angioplasty, all randomized CA studies have used a combination of aspirin and clopidogrel in variable doses and timing. Randomized studies and angioplasty registries have shown the utility of this therapeutic approach [173,174]. Table 47.9 summarizes dual therapy schemes after CA as used in the principal randomized studies. Currently, patients undergoing CA should receive a combination of aspirin and clopidogrel for at least 30 days.

Study	Post-stenting dosis	Duration
ARCHeR [175]	Aspirin* 325 mg/day + clopidogrel** 75 mg/day or ticlopidine** 500 mg/day	*12 M **14 D
BEACH [176]	Aspirin* 325 mg/day + clopidogrel** 75 mg/day or ticlopidine** 500 mg/day	*12 M **30 D
CAVATAS [130]	Aspirin* 150 mg/day + Non-fractionated Heparin for just 24 hours	*>12 M
EVA-3S [137]	Aspirin 100 to 300 mg/day + clopidogrel 75 mg or ticlopidine 500 mg/day	30 D
SPACE [134]	Aspirin 100 mg/day + clopidogrel 75 mg/day	30 D
SAPPHIRE [138]	Aspirin 81 to 325 mg/day + clopidogrel 75 mg/day	14 - 28 D

47.5 Carotid Artery Disease and Coronary Disease

47.5.1 Epidemiology

Given that atherosclerosis predominates in older patients, gradual population aging has led to a proportional increase in the number of patients with coronary disease, carotid disease or both [177]. The prevalence of carotid artery disease in patients undergoing surgical myocardial revascularization (SMR) varies according to different series. In five studies reporting carotid artery CDUS results of patients undergoing SMR, the prevalence of carotid stenosis >80% was 6.0% (CI 95% 5.4-6.6) [178-183].
In a cohort of 176 patients who underwent CEA at the University Hospital of the Favaloro Foundation in Buenos Aires between 2006 and 2008, 54.5% (95% CI 47.2-61.7) had a history of coronary disease defined as stable chronic angina, unstable angina, or a previous SMR, coronary angioplasty or acute myocardial infarction. These data are consistent with those published by other authors [183,184].
Carotid artery disease and coronary disease are predisposing factors for complications in patients undergoing SMR [185] and CEA [186], respectively. Some 17% of patients with untreated coronary disease suffer a myocardial infarction during the perioperative CEA period [186]. The risk of ischemic stroke after SMR with on-pump or off-pump surgery is 3.8 and 1.9%, respectively [187].

47.5.2 Screening for Carotid Artery Disease in Patients Undergoing SMR

Screening for carotid artery disease in patients undergoing SMR can be done selectively or non-selectively. The predictive factors for carotid artery disease are: age [188-190]; carotid bruit [190-192]; previous stroke or TIA [190-192]; CEA history [191]; peripheral vascular disease [190,191]; and history of smoking, arterial hypertension and diabetes [189,190]. The American College of Cardiology and the American Heart Association management guidelines for patients undergoing SMR recommend screening for carotid disease in patients >65 years, with left main coronary artery trunk disease, peripheral vascular disease, smokers, with a history of stroke or TIA or with a carotid bruit (Level C evidence) [193].

47.5.3 Screening for Carotid Disease in Patients Undergoing CEA

According to studies using SPECT or graded exercise testing, 25% of patients undergoing CEA are asymptomatic coronary disease carriers [194,195]. However, when assessment is performed with coronary angiography, this proportion can be 84% [196]. Based on this evidence, the AHA/ASA guidelines recommend searching for coronary artery disease in patients with a history of stroke or TIA of carotid origin, emphasizing that randomized studies are needed to confirm this suggestion [197]. To date, there are no specific strategies for coronary disease screening before CEA in patients with asymptomatic carotid disease.

Finally, we will present some questions for which we have no definitive answers: a) Is it hazardous to perform a stress test on a patient with severe carotid disease? b) Is it relevant if the patient has bilateral carotid artery disease? c) Given that CEA must be performed as soon as possible in symptomatic patients, is it advisable to delay the surgical schedule to disclose coronary disease? d) If the patient has concomitant coronary disease, which would be the adequate approach?

47.5.4 Therapeutic Approach to Patients With Concomitant Carotid and Coronary Disease

The three most serious complications associated with SMR and CEA are stroke, acute myocardial infarction and death. Owing to the lack of definite scientific evidence, the best therapeutic strategy for patients with concomitant carotid and coronary disease has the subject of ongoing debate.

Before analyzing the evidence, it is necessary to identify two possible scenarios: a) the patient scheduled for SMR, diagnosed with carotid stenosis ≥50% during preoperative evaluation; and b) the patient scheduled for CEA for symptomatic carotid disease, who is preoperatively diagnosed with coronary artery disease.

With regard to the first scenario, a recent systematic review that compared SMR plus best medical treatment versus SMR plus best medical treatment plus CEA found no study that could be selected for analysis [198]. Despite the lack of evidence, it is interesting to mention a study involving 3942 patients undergoing cardiovascular surgery [199]: 6% (239) had carotid disease ≥50%; the stroke frequency was higher in this group than in those without carotid disease ≥50% (7.5 vs. 1.5%; P <0.001) The most striking feature of this study is that, of the 18 ischemic strokes in patients with carotid disease ≥50%, only 4 (20%) occurred in the territory ipsilateral to the affected carotid. The rest happened in other or multiple territories. This finding underscores that strokes in patients undergoing SMR are more often in those with carotid artery disease, although the mechanism is not directly related to the surgery. In fact, the most frequent stroke mechanism in these patients is particulate embolism from the thoracic aorta at the moment of clamping and unclamping, as well as from extracorporeal circulation [200]. This study contributes to the controversy on whether or not to treat carotid artery disease in patients who are scheduled for SMR.

In the second scenario (a patient undergoing CEA for symptomatic carotid disease, diagnosed with coronary artery disease), various different strategies can be considered: a) CEA followed by SMR; b) SMR and posterior CEA; c) synchronous CEA and SMR (on-pump); d) synchronous CEA and MRS (off- pump); and e) CA followed by SMR. We present the available evidence for each option in Table 47.10 [201-203].

	CA then SMR		Synchronous CEA and SMR *		Synchronous CEA and SMR **		CEA then SMR		SMR then CEA	
	Risk % (95% CI)	N	Risk % (95% CI)	N	Risk % (95% CI)	N	Risk % (95% CI)	N	Risk % (95% CI)	N
Ipsilateral stroke	-	760								
Any stroke	4.2 (2.4-6.1)	760

48 Intensive Care Management in Space-Occupying Middle Cerebral Artery Stroke

Jennifer Diedler [1], **Marek Sykora** [1], **Werner Hacke** [1]

[1] Department of Neurology, University of Heidelberg, Germany

48.1 Definition, Risk Factors and Clinical Signs

Space occupying middle cerebral artery (MCA) infarction – also termed malignat MCA infarction – develops in around 1 to 10% of patients with supratentorial infarcts. Up to 80% mortality has been reported in older series [1]. In patients with malignant MCA infarction severe brain edema develops due to a vicious circle starting from unsuccessful or too late recanalization, followed by large brain ischemia and cytotoxic edema, leading to impaired substrate supply in the areas adjacent to the infarct, promoting further ischemia and brain swelling. Recently, a novel phenomenon, spreading depolarization, has been recognized to cause secondary brain injury including edema formation in malignant ischemic stroke [2]. In the course of these events, intracranial pressure raises and may lead to lethal brain herniation.

The early identification of patients at risk for developing a malignant course in large MCA infarction is of great importance for therapeutical decision making. Several clinical and radiological parameters have been suggested to predict the development of life thretatening brain edema. They however, lack sufficient predictive power to reliably guide potential surgical therapy [3]. So far, solely the size of ischemic lesion seems to be a reasonable sensitive and specific parameter to predict the development of a malignant course [4]. Patients at risk for malignant brain edema usually present with a severe stroke syndrome with hemiplegia, hemisensory symptoms, frequently ipsilateral gaze devation, followed by impaired consciousness. Patients with carotid artery or proximal MCA occlusion in whom respective large MCA and/or anterior cerebral artery (ACA) territory infarction is suspected should be monitored closely. An alarming sign for development of malignant brain edema with an increase in intracranial pressure is a gradual decrease in consciousness. Respiratory insufficiency and pupillary enlargement are “late” signs and indicate brainstem dysfunction due to mass effects and require immediate attention. Severe brain edema usually develops around day 2 to 5 after the ictus.

- Risk factors for development of a malignat course:
  - Severe neurological deficit on admission
  - Impaired consciousness on admission (LOC > 0)
  - Large infarct on CT or MRI (>145 cm^3), including the basal ganglia
  - Proximal MCA occlusion, ICA occlusion
  - Tandem ICA and MCA occlusion
  - Unsuccessful recanalization
  - Young patients
- Clinical red flag: decrease in consciousness!

48.2 Conservative Management

Approximately 5% of all ischemic stroke patients undergo mechanical ventilation, mainly due to impaired consciousness and/or diminished protective airway reflexes. Further

indications for mechanical ventilation include tachypnoe >25-30/min, bradypnoe <4-6/min, paO_2 <60 mmHG, paCO2 >55-60 mmHg or $Sa0_2$ <85-90% despite 100% oxygen mask therapy. Ventilation, preferably with pressure control mode, should be initiated with tidal volumina of 6-10 ml/kg and respiratory frequency of 12-15/min. PEEP levels of 5-8 mbar are considered safe. Higher PEEP levels should be delivered under close MAP, ICP and CPP monitoring due to the concerns that increased intrathoracic pressure by PEEP may critically lower MAP and CPP. I:E ratio seems not to have effects on ICP or CPP. Ventilation and oxygenation goals include $paC0_2$ 35-45 mmHg, paO_2 > 80 mmHg and SaO_2 >95%. Accurate blood pressure (BP) management in ischemic stroke is essential. Current guidelines advice not to lower BP until 220 mmHg systolic and/or 120 diastolic blood pressure is reached [5]. However, in severe brain edema with significantly increased ICP and impaired autoregulation, lower thresholds may be applied, dependent on the actual state of autoregulation, ICP a CPP levels. Common intravenous BP lowering agents include urapidil, propranolol, labetalol, enalapril and clonidine. Caution should be applied in vasodilatators as nitroglycerin and dihydralazine or calcium-channel blockers nifedipine and nimodipine as these agents may potentially increase the ICP by vasodilation. However, no study exists confirming these assumed effects in human stroke. Following the acute phase, usual enteral antihypertensive therapy including combinations of angiotensin receptor blockers, angiotensine-converting enzyme inhibitors, beta-blockers, calcium antagonists and diuretics should be initiated.

Best medical treatment for increased intracranial pressure (ICP) in malignant stroke does not differ from standard ICP management as performed in patients suffering from other causes of cytotoxic brain edema. In contrast to vasogenic edema, steroids are not recommended. When brain edema has progressed to the point that the patients need to be intubated and mechanically ventilated, placement of an ICP probe is advisable in order to monitor patients. Therapeutic targets are to maintain ICP below 20 mmHg and CPP around 60-70 mmHg. However, there is no clear evidence to support these thresholds. First steps to combat increased ICP include proper analgosedation, using standard medications such as continuous intravenous benzodiazepines or propofol in combination with opiates. Ketamine may also be used as long as arterial CO_2 and mean arterial pressure are controlled. Mild hyperventilation with an arterial CO_2 target around 30-35 mmHg may be applied but the possibility of unwanted side effects of vasoconstriction have to be taken into account, in particular in the yet uninjured areas. Long-term hyperventilation leads to compensatory mechanisms which counteract the effect of vasoconstricion and may trigger a rebound effect. Therefore, mild hyperventilation is only an option for short interventions. Elevation of the head to 30° may be considered but the effect on CPP has to be monitored.

Standard drugs include osmotherapeutics such as mannitol or glycerosteril. Long term application has been associated with a rebound phenomenon triggered by the osmotic substrates crossing to the brain parenchyma due to a damaged blood brain barrier. Hypertonic saline may be applied as well. Other options include tromethamine which via reduction of cerebral acidosis leads to vasoconstricsion or barbiturates as last tier therapy, leading to a decrease in cerebral metabolism and blood flow. Above mentioned measures frequently are used to bridge the time until the patient will be operated.

48.3 Decompressive Surgery

Decompressive hemicraniectomy represents the treatment of choice in malignant MCA infarction. Evidence for the benefical effect of decompressive surgery in patients be-

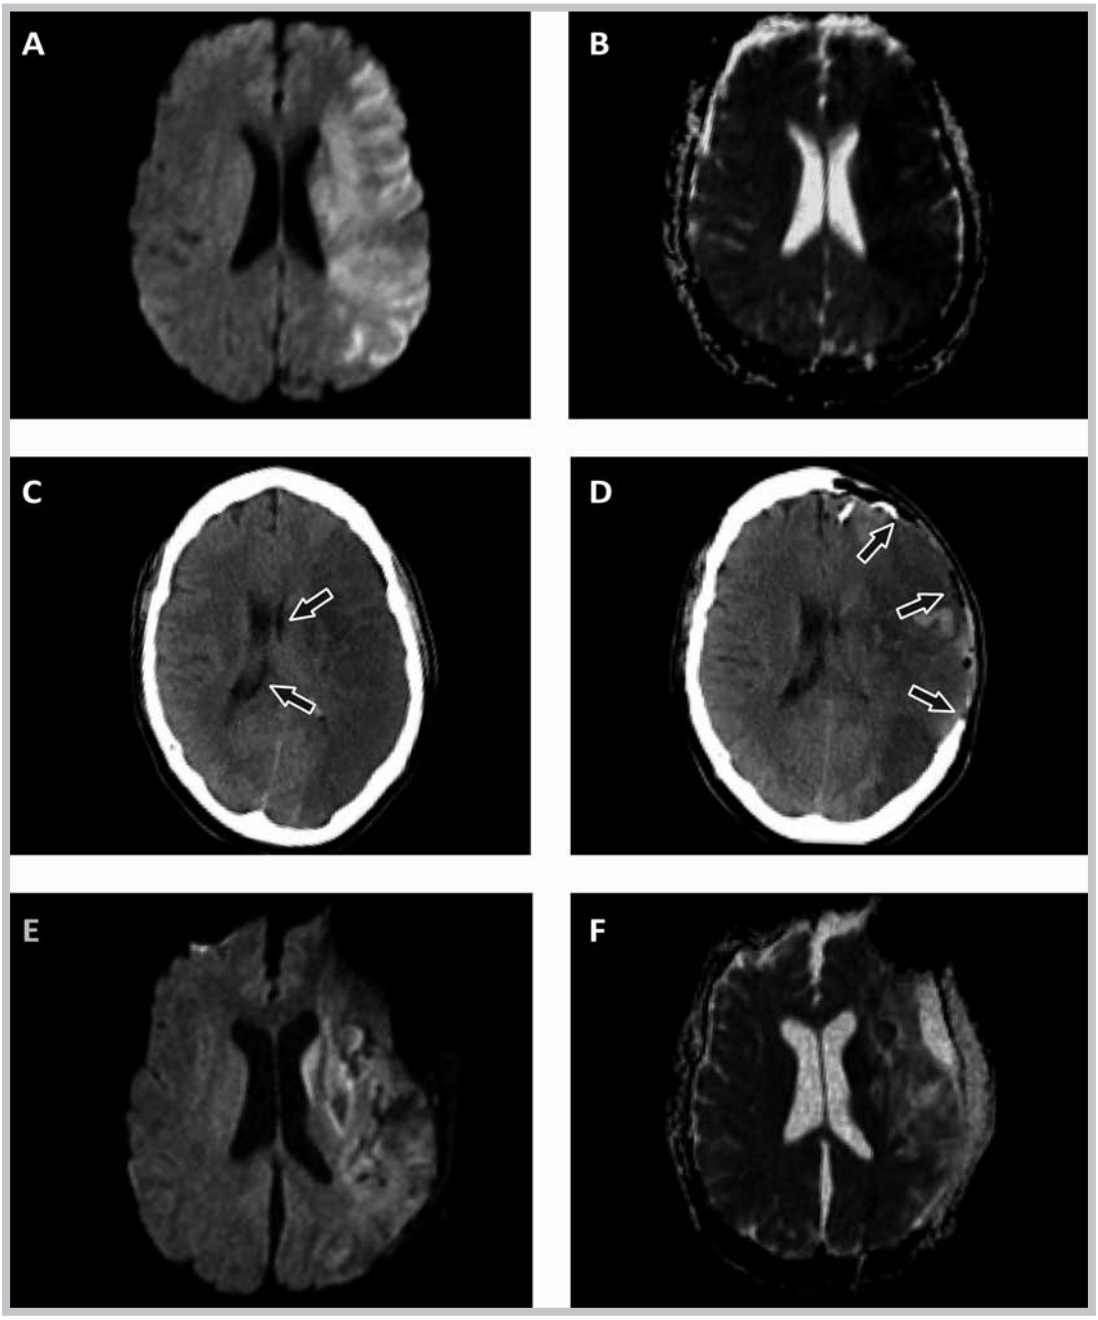

Figure 48.1. **Diffusion-weighted MRI (A) and corresponding ADC map (B) of a 53-year-old patient with aphasia and right-sided hemiparesis (NIHSS 19) show signs of cytotoxic edema indicating acute left-sided MCA infarction on admission. MRI-based thrombolysis was performed with 80 mg rt-PA 1 hour after symptom onset. (C) The follow-up CT scan at 24 hours shows signs of raised ICP with midline shift, compression of the lateral ventricles, and impending subfalcial herniation (arrows). Hemicraniectomy was performed 30 hours after symptom onset. (D) Postoperative CT scan: the vector of brain extension is reverted to the newly created compensatory space to relieve the pressure on midline structures. Follow-up diffusion weighted MRI scan (E) and ADC map (F) 16 days after hemicraniectomy show signal normalization and reduction of mass effect of the MCA infarction. The patient was transferred to a rehabilitation clinic 21 days after the infarction. At that time he was awake, had nonfluent aphasia, and brachio-facial hemiparesis on the right side (NIHSS 13). [Courtesy of M. Blatow, Department of Neuro-Radiology, University of Heidelberg].**

tween 18 to 60 years in malignant MCA stroke has been provided by three randomized trials including 93 patients (52 surgery with 48 hours, 41 conservative treatment) [6]. The primary outcome measure in these trials was the modified Rankin scale (mRS) at one year. The distribution of the mRS at one year differed significantly between the conservative and the operative group: 75% of patients in the surgery group had a mRS ≤4 compared to 24% in the conservative group. 43% of patients attained a mRS ≤3 in the surgery group versus 21% in the conservative arm. Mortality at one year was significantly different between groups: 78% of patients who underwent surgery versus 29% in the conservative group survived ($p<0.0001$). The number needed to treat (NNT) was 2 for survival with mRS ≤4, 4 for survival with mRS ≤3, and 2 for survival irrespective of functional outcome. However, despite a level 1A evidence recommendation in European guidelines, the potential neurological deficits should be discussed with the patient and/or the family and one should always consider the individual opinion of a patient facing survival with a severe neurological deficit.

Based on these persuading results, the DESTINY II study had been undertaken, assessing the benefits of decompressive surery in patients older than 60 years. The study has not been published yet, however, the preliminary results clearly suggest that also elderly patients may benefit from decompressive surgery.

Above mentioned studies have performed surgery within the first 48 hours after ictus. While several studies had suggested that early hemicraniectomy may be preferable, in a larger case series of 138 patients, age however has been the only factor relevant for outcome, while time to surgery had no effect [7]. Still, it seems advisable to identify patients at risk for maligant stroke as early as possible in order to minimize the risk of further brain injury. If a malignant course seems predictable and a consent regarding surgery is gained, the operation should be performed rapidly since waiting for further clinical deterioration carries no benefit.

48.4 Hypothermia

Due to the evidence from randomized trials for the benefit of decompressive surgery, application of mild (>33°C) or moderate hypothermia (29-33°C) for malignant brain edema following ischemic stroke has so far been abandoned. This is in line with the result of one study comparing decompressive surgery and hypothermia, concluding that hemicraniectomy was associated with lower mortality rates and complications than hypothermia [8]. The combination of hemicraniectomy with hypothermia is recently under investigation (DEPTH-SOS).

In contrast, the neuroprotective effects of mild hypothermia in the early phase after stroke have not been properly explored. Data from patients following cardiac arrest seem promising [9]. It is unknown and subject of current studies if early application of hypothermia may impede the development of malignant brain edema. At the moment, the use in awake stroke patients is being assessed.

49 Acute Management of Cerebral Venous Thrombosis

José M Ferro [1], Patrícia Canhão [1]

[1] Department of Neurosciences, Serviço de Neurologia, Hospital de Santa Maria, University of Lisboa, Lisboa, Portugal

49.1 Introduction

Thrombosis of the dural sinus and cerebral veins is less common and has a more varied clinical presentation than other types of stroke. CVT is also more difficult to diagnose, as magnetic resonance imaging (MR) and venography are needed to confirm the diagnosis. Furthermore, CVT can be a manifestation of several systemic diseases, a complication of other central nervous system (CNS) disorders, of pregnancy or of the use of drugs with thrombogenic proprieties.

The most frequent symptoms of CVT are headaches, seizures, motor, sensory or language deficits, and altered consciousness. Acute seizures are more frequent in patients with supratentorial parenchymal lesions, sagittal or cortical vein thrombosis and motor or sensory defects.

Symptoms and signs can be grouped in four major syndromes:

- Isolated intracranial hypertension: headache with or without vomiting, papilledema and visual symptoms.
- Focal syndrome: focal deficits, seizures or both.
- Encephalopathy: multifocal signs, mental status changes, stupor or coma.
- Cavernous sinus: diplopia, ocular pain, cheimosis, proptosis, oculomotor palsies

The clinical presentation is influenced by:

- Site and number of occluded sinuses and veins:
  - Cerebral cortical vein thrombosis without dural sinus involvement can cause focal seizures, motor or sensory deficits with or without headache.
  - In occlusion of the sagittal sinus, motor deficits, bilateral deficits and seizures are frequent.
  - Patients with isolated thrombosis of the lateral sinus often present with isolated intracranial hypertension or isolated headache; aphasia is frequent if the left transverse sinus is involved.
  - If the deep cerebral venous system is occluded, the clinical picture is usually more severe, with coma, mental symptoms and bilateral motor deficits.
- Presence of parenchymal lesions:
  - Patients with parenchymal lesions are more likely to be comatose or to have motor deficits or aphasia and seizures.
- Age of the patient:
  - Decreased vigilance and mental symptoms are more common in elderly patients.
  - Headaches and isolated intracranial hypertension are more frequent in younger patients.
- Gender: headaches are more common in women.
- Interval from onset to presentation:
  - Patients with a chronic or subacute course are more likely to present with isolated intracranial hypertension and to show papilledema.

Concerning prognosis, several recent prospective series and systematic reviews consistently established the current vital and functional prognosis of patients with acute CVT, showing a 15% overall death or dependency rate. The predictors of poor long-term prognosis derived from the ISCVT cohort were:

- Age >37 years.
- Male gender.
- Glasgow Coma Scale (GCS) score on admission <9.
- Mental status disorder.
- Deep cerebral venous system thrombosis.
- Hemorrhage on CT/MR.
- CNS infection.
- Malignancy.

This predictive model was validated in two other cohorts.

The acute case-fatality is low (4%). Predictors of mortality at 30 days are depressed consciousness, mental status disorder, thrombosis of the deep cerebral venous system, right hemispherical hemorrhage and posterior fossa lesions. The main cause of death is transtentorial herniation secondary to a large hemorrhagic lesion. Other causes include herniation due to multiple lesions or to diffuse brain edema, status epilepticus, medical complications and pulmonary embolism.

Recanalisation occurs in 40-90% of patients, mostly within the first 4 months, but is not related to outcome. Long-term complications of CVT include seizures, headaches, vision loss, dural arteriovenous fistulae and recurrent venous thrombosis of the brain, extremities or pelvis. Recurrent CVT is rare (2-7%) and also difficult to document, particularly if a previous follow-up MR/MRV is not available. In the Rochester Mayo Clinic series, the likelihood of recurrent venous thrombosis was the same after CVT and lower extremity deep venous thrombosis. Recurrence of CVT was not influenced by warfarin therapy. In children, age at CVT onset (>2 years), persistent venous occlusion, the G20210A mutation and non-administration of anticoagulation predict recurrent CVT or systemic venous thrombosis.

49.2 Confirmation of Diagnosis by Neuroimaging

Confirmation of diagnosis of CVT by neuroimaging implies the visualization of an occluded sinus or vein and of the thrombus. MR combined with MR venography (MRV) is the most sensitive examination technique for the diagnosis CVT. However, even using MR plus MRV, there are some diagnostic difficulties particularly concerning the diagnosis of cortical vein thrombosis, which has a low interobserver reliability. Gradient echo (GRE) T_2* weighted sequences with thrombus susceptibility effect (SE) should always be performed if the working diagnosis of CVT is raised. T2* SE images show the thrombus, including an isolated cortical vein thrombosis, as a hypointense area. Multidetector CT venography (CTV) can be used as an alternative to MRV, with an excellent sensitivity and specificity for the diagnosis of CVT.

49.3 Etiological Investigation

The most frequent causes or associated conditions with CVT are listed in Table 49.1. The relative weight of these causes varies accordingly to world regions. In countries with low

Gross National Income, infection, anemia and puerperium-related CVT are more common.

More than half of patients have more than one cause for their CVT, while in about 15% no cause can be found despite extensive investigation. Some rules of thumb are suggested during the etiological workup:

- Systematic prothrombotic screening must always be performed, even when an "obvious" cause is already detected.
- Prothrombotic screening includes: protein S, C, anti-thrombin III, factor V Leiden and prothrombin G20210A mutations, homocysteine, lupus anticoagulant, anticardiolipin and anti-phospholipid antibodies.
- In middle aged and elderly patients a comprehensive search for a malignancy should be performed.
- When no underlying cause can be found, a high anticardiolipin antibody titre, a vasculitis or a malignancy can be found in a repeated evaluation 3 to 6 months after the acute phase of CVT.

Series	ISCVT	Pakistan and Middle East
Nr. of patients	624	109
Genetic thrombophilia	22%	12%
Antiphospholipid antibodies	6%	1%
Hyperhomocysteinemia	5%	9%
Malignancy	7%	4%
Anemia	9%	NA
Pregnancy*	6%	NA
Puerperium*	14%	31%
All infections	12%	18%
ENT, face and neck infections	8%	12%
Oral contraceptives*	54%	12%

Table 49.1. Common (>5%) causes of cerebrovenous thrombosis [Ferro, 2004; Khealani, 2008].

* among women
ENT = ear, nose and throat
ISCVT = International Study on Cerebral Vein and Dural Sinus Thrombosis
NA = not available

49.4 Treatment in the Acute Phase

Management of acute CVT includes:

- Treatment of the underlying condition.
- Antithrombotic treatment.
- Symptomatic treatment.
- Prevention and treatment of complications.

Antithrombotic and symptomatic treatment are discussed in the following paragraphs.

49.4.1 Antithrombotic Treatment

Anticoagulation

Currently, there is broad consensus on the use of either IV heparin or SC low-molecular-weight heparin (LMWH) in acute CVT to prevent thrombus propagation and pulmonary embolism and to increase the chances of recanalisation. The use of heparin in acute CVT is supported by three clinical trials and a meta-analysis of two of these trials which showed a relative risk of 0.46 (95% CI 0.16-1.31) of death or dependency after anticoagulant therapy as compared to placebo. Several observational series showed that heparin is safe and can be used in acute CVT patients with intracranial hemorrhagic lesions. Limited data suggest that anticoagulant therapy is also safe in children with CVT.

Procedure	• Catheterization of the sigmoid, transverse and superior sagittal sinuses via the femoral venous or jugular approach • Chemical thrombolysis: ▪ Urokinase, suggested dosage: bolus 100,000 to 600,000 IU, followed by infusion of 100,000 IU/h during 24 hours or longer if needed or ▪ rtPA Bolus: 1-5 mg followed by infusion: 1-2 mg/h during 24 hours or longer if needed • Mechanical thrombolysis by disruption (guiding catheter), removal (balloon catheter) or suction (rheolytic catheter) may be performed according to local experience and preferences
Contraindications	• Documented bleeding disorder • Thrombocytopenia (<100,000/l) • Severe liver or renal dysfunction interfering with coagulation • Acute pancreatitis • Oesophageal varices • Uncontrolled severe hypertension (diastolic >120 mmHg) • Recent bleeding diathesis (<3 months) • Recent (<24 h) surgery
Main side effects	• Risk of bleeding, including puncture site* • Hemorrhage from tissue or organ* • Pain due to dural sinus manipulation • Hypofibrinogenemia • Nausea and vomiting

Table 49.2. **Local thrombolysis with urokinase or rtPA (treatment may be modified according to local procedures).**
* In case of serious bleeding, thrombolytic administration should be discontinued and administration of coagulation factors may be required

Endovascular Thrombolysis

Endovascular thrombolysis, with or without mechanical thrombus disruption, is used in some centres as an alternative to heparin in severe cases or in patients who fail to improve on anticoagulation. Direct thrombolysis aims to dissolve the venous clot by delivering a thrombolytic substance (urokinase or rtPA) within the occluded sinus through an intravenous catheter. In some cases, mechanical endovascular disruption of the thrombus may also be used. No randomized trials of endovascular treatment for sinus thrombosis have been done. In a systematic review, new symptomatic intracranial hemorrhages were reported in 5% of patients and a poor outcome in 13% of those treated with thrombolytics (mortality 9%, dependency 4%). Intracranial hemorrhage after thrombolysis was reported in 17% of cases, and was associated with clinical worsening in 5%. However, the possibility of publication bias must be kept in mind. In a recent Dutch series of 20 patients treated with IV local thrombolysis, 12 recovered to independent living and 6 died. Local thrombolysis was not useful in patients with large infarcts and impending herniation. A randomized trial to compare endovascular treatment vs. heparin in acute CVT was recently launched. Before such a trial is completed, endovascular treatment cannot be routinely recommended and should be reserved for critical cases which fail to improve on anticoagulation and do not have an indication for decompressive surgery.

49.4.2 Symptomatic Treatment

Treatment of Intracranial Hypertension

In patients with severe headache and papilledema, intracranial hypertension can be reduced and symptoms relieved through a therapeutic lumbar puncture. Despite the lack

In all cases	• Anticoagulation in therapeutic dosages with IV heparin or SC LMWH, except in patients with systemic contraindications for anticoagulation • Headache relief with paracetamol or tramadol • Treatment of underlying and associated systemic or CNS conditions
In cases presenting with isolated headache or intracranial hypertension syndrome	All the above plus: • Headache relief if needed with acetazolamide or therapeutic lumbar puncture
Cases with seizures	• Start valproate
Cases with symptomatic large hemispheric ischemic or hemorrhagic lesions with mass effect	• Osmotherapy with mannitol • Consider hemicraniectomy, if impending transtentorial herniation
Cases with encephalopathy or comatose, with diffuse brain edema or bilateral ischemic or hemorrhagic lesions	• Osmotherapy with mannitol • Consider hemicraniectomy, if impending transtentorial herniation due to one unilateral lesion • Intensive care unit admission with sedation, hyperventilation to a target $PaCO_2$ of 30 to 35 mmHg, and ICP monitoring • Consider local endovascular thrombolysis with urokinase or rtPA

Table 49.3. **Treatment of CVT according to clinical presentation and neuroimaging findings.**

of randomised trials, acetazolamide is also used in some centres to relieve symptoms (headache, vision loss) of increased intracranial hypertension.

General recommendations to control acutely increased intracranial pressure (ICP) include elevating the head of the bed, osmotic diuretics such as mannitol, intensive care unit admission with sedation, hyperventilation to a target arterial carbon dioxide tension ($PaCO_2$) of 30 to 35 mmHg, and ICP monitoring. Corticosteroids are not indicated, unless they are needed to treat the underlying condition.

Hemicraniectomy may be life-saving in patients with parenchymal lesions producing impending herniation. The surgical procedure should include the removal of a large cranial bone flap over the whole area of the parenchymal lesion, opening of the dura and insertion of a dural patch. Cranioplasty is performed after at least 6 weeks with the stored bone flap or acrylate.

A recently published retrospective registry and systematic review of published cases indicates that decompressive surgery (hematoma evacuation or hemicraniectomy) is life saving in acute CVT patients with large hemispherical or posterior fossa lesions and impeding herniation, even in patients with severe neurological condition, such as coma or fixed pupils. Complications of hemicraniectomy include intracranial bleeding, infection, hydrocephalus and depressed skull bone defect.

A lumboperitoneal shunt (at the L2-3 or L3-4 level) is indicated in patients with persistent symptoms of increased intracranial hypertension and/or vision loss who do not improve with repeated lumbar punctures. Complications of this procedure include shunt block or other malfunctioning, infection, cerebrospinal fluid (CSF) leakage with intracranial hypotension and radiculopathy.

Treatment and Prevention of Seizures

Acute seizures and supratentorial lesions are the risk factors for subsequent early seizures. Patients with both risk factors should be prescribed antiepileptic drugs. Prophylactic antiepileptics can also be considered in patients with one of these risk factors and should be avoided in patients with neither of the two. Concerning the choice of the antiepileptic, phenytoin, carbamazepine or valproate are possible first-line options. Val-

proate is preferred because it causes less interference with oral anticoagulants and can be used intravenously. If phenytoin, carbamazepine or valproate is not tolerated, lamotrigine, topiramate or leviracetam can be used as alternatives.
Patients with status epilepticus should be treated according to guidelines for this epileptic condition: 3-stage approach with immediate administration of diazepam or lorazepam IV, followed by phenytoin or phosphenytoin IV and by barbiturate coma if the epileptic activity does not stop.
As described above, CVT has a wide spectrum of clinical and symptomatic presentations. Management in the acute phase should be tailored to the severity, clinical syndrome and neuroimaging findings of the individual patient (Table 49.3).

49.5 Education and Medication Upon Discharge

To reduce the risk of recurrent thrombotic events, namely, deep venous thrombosis of the limbs, treatment with oral anticoagulants, aiming at an international normalized ratio (INR) between 2 and 3, is given for a variable period depending on the patient's inherent thrombotic risk. Anticoagulants can be prescribed for only 3 months if CVT was related to a transient risk factor (e.g., pregnancy, infection). In patients with idiopathic CVT or CVT associated with "mild" thrombophilia, the period of anticoagulation must be extended for 6 to 12 months. In patients with "severe" thrombophilia (e.g., two or more prothrombotic abnormalities; antiphospholipid syndrome), anticoagulants should be given for life.
Patients with persistent symptoms of increased intracranial hypertension and/or vision loss can be treated with repeated lumbar punctures or a lumboperitoneal shunt.
Antiepileptics are recommended for patients with seizures in the acute phase and for those who experience a seizure after the acute phase. Antiepileptics can also be considered for patients without seizures but with either supratentorial hemorrhagic lesions or motor deficits.
Oral contraception and hormonal replacement therapy should be stopped. Emergency contraception is also contraindicated. Women of reproductive age should not become pregnant while on oral anticoagulants because of the teratogenic effects of these drugs. CVT and pregnancy or puerperium-related CVT are not a contraindication for future pregnancy. Although pregnancy and the puerperium are risk factors for CVT, the risk of complications during a subsequent pregnancy among women who have a history of CVT is low.

49.6 Key Concepts

Consider the possibility of CVT in patients with unexplained severe headaches of recent onset, new seizures or encephalopathy.
Use MR with T2* sequences and veno-MR to confirm the diagnosis of CVT.
Always perform thrombophilic screening, even when CVT is associated with a transient risk factor.
Anticoagulation is indicated in all cases, even if there are intracranial hemorrhages, except if there are systemic contraindications.
Endovascular thrombolysis should be reserved for critical cases which fail to improve on anticoagulation and do not have an indication for decompressive surgery.
Hemicraniectomy may be life-saving in patients with large venous infarcts or intracerebral hemorrhages causing eminent herniation.

50.1 Introduction

Intracerebral hemorrhage (ICH) occurs in 1 or 2 out of 10 patients with cerebrovascular disease (CVD), being more frequent in adults with hypertension. ICH is the less studied type of CVD and generally the most stigmatized by nihilism and fatalism; for that reason it is considered by some authors as "the great forgotten one", in spite of its high (50%) mortality observed in the acute phase and the incapacitating sequelae at 6 months in 20 to 30% of survivors.

Cranial computed tomography (CT) is still the best basic tool to guide ICH diagnosis, its etiology, therapeutic approach and prognosis. Current and future topics in the management of ICH include a rigorous versus standard control of blood pressure, pharmacologic and non-pharmacologic neuroprotection, the handling of peri-hematoma edema and the use of hemostatic therapies. The role of surgery in ICH is uncertain; however, clot fibrinolysis and minimal invasion drainage system are promising approaches.

50.2 Definition

ICH, also known as intraparenchymal brain hemorrhage, spontaneous intracerebral hemorrhage or nontraumatic intracerebral hemorrhage, refers to a hematic collection within the parenchymal tissue ensuing from the irruption of blood, the etiology, location and volume of which depend largely on patient age and other risk factors [1].

ICH occurs most often as a sudden nonconvulsive neurological deficit, with increasing severity after the onset. CT findings of ICH can appear as a hyperdense parenchymal area of variable dimension, with a supra- or infratentorial location, with or without mass effect over the cerebral structures, midline deviation with or without irruption into the ventricular system. Primary or spontaneous ICH occurs in the absence of trauma or pre-existing cerebrovascular malformations (CVM); in adults and the elderly almost 85% is due to hypertension or amyloid angiopathy.

50.3 Epidemiology

The frequency of ICH has been reported in 5 to 19% of all CVD types, predominantly in adult males [2]. In the United States, the highest incidence is among Blacks (50/100.000 habitants), Asians, and Hispanics as compared to Whites (incidence of 25/100,000 habitants) [2-5].

In Latin America, owing to the lack of ICH data from hospital registries, its frequency is estimated to be 19 to 50% [6-9]. Lavados et al., in their study in Chile, reported an incidence of 27.6/100,000 habitants, with an increase related to age; in people <35 years of age it was reported in 4.3/100,000 habitants, it increases up to 84.4/100.000 in patients aged 55 to 64 years, and reaches 204.2/100,000 in those >75 years [10].
Notwithstanding the lack of data, the frequency of ICH is projected to double by the year 2050, due to shifts in racial demography and the aging population [11-13].

50.4 Risk Factors

Hypertension, the leading risk factor for ICH, is reported in over 60% of cases, mainly when untreated or treatment is irregular, associated with smoking, and occurs before 55 years of age [1,12]. Alcoholism is associated with ICH by altered coagulation mechanisms and blood vessel integrity resulting from chronic alcohol consumption or acute intense intake [1,12]. Smoking has been associated more frequently with subarachnoid hemorrhage; nevertheless, it has also been associated with ICH [14].
The role of hypocholesterolemia as an independent risk factor for ICH is controversial, being apparently relevant only in hypertense subjects with factor XIII-alpha coagulation system mutation [15]. Congophilic angiopathy is associated with ICH due to β-amyloid protein deposition in the walls of the cortical-leptomeningeal vessels [1,12], usually occurring in persons over 55 years of age without hypertension, predominates in lobar topography, is highly recurrent, and can be multiple when ICH is present. Apolipoprotein-E seems to play a key role in the pathogenesis of amyloid angiopathy and the genotype in its recurrence (Figure 50.1).
Other risk factors for ICH such as caffeine consumption and illicit drugs use, obesity and antiplatelet therapy are areas of recent analysis. Anticoagulants usually are associated with large hemorrhages and high mortality.

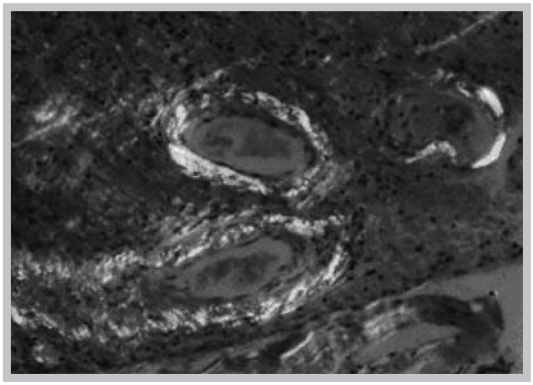

Figure 50.1. **Congophilic deposits characteristic of amyloid angiopathy.**

50.5 Clinical Diagnosis

Clinical manifestations of ICH depend on the location of the hematoma, its initial volume and growth, aperture to the ventricular system, as well as mass effect and midline deviation. Patients with ICH usually present with severe neurological impairment after the onset and can worsen in the first hours. Headache, altered consciousness, motor or sensory deficit and seizures are frequent in supratentorial ICH, whereas headache, dizziness, vomits, ataxia, ophthalmoparesis and deterioration of consciousness with or without motor signs are proper to infratentorial ICH. Because its clinical presentation can also occur in ischemic CVD, neuroimaging studies are essential to differentiate between these possibilities.

50.6 Neuroimaging Diagnosis

50.6.1 Computed Tomography

Simple phase CT easily distinguishes ICH from cerebral infarct (Figure 50.2). It practically detects 100% of hematomas, except when <1 cm, located in the posterior fossa or in those patients with severe anemia (hematocrit <20) [16].
Contrast-enhanced CT is not necessary in acute stage ICH and its indication should be reserved for specific cases depending on hematoma location, the presence of edema and other features suggestive of vasculitis, rupture of CVM or intra-tumor bleeding [1,16].
Besides its utility in determining hematoma size and location, CT also allows the follow-up of complications, including cerebral herniation, midline displacement, cistern and brainstem compression, opening to the ventricular system, hydrocephalus, rebleeding, peri-hematoma and delayed edema.

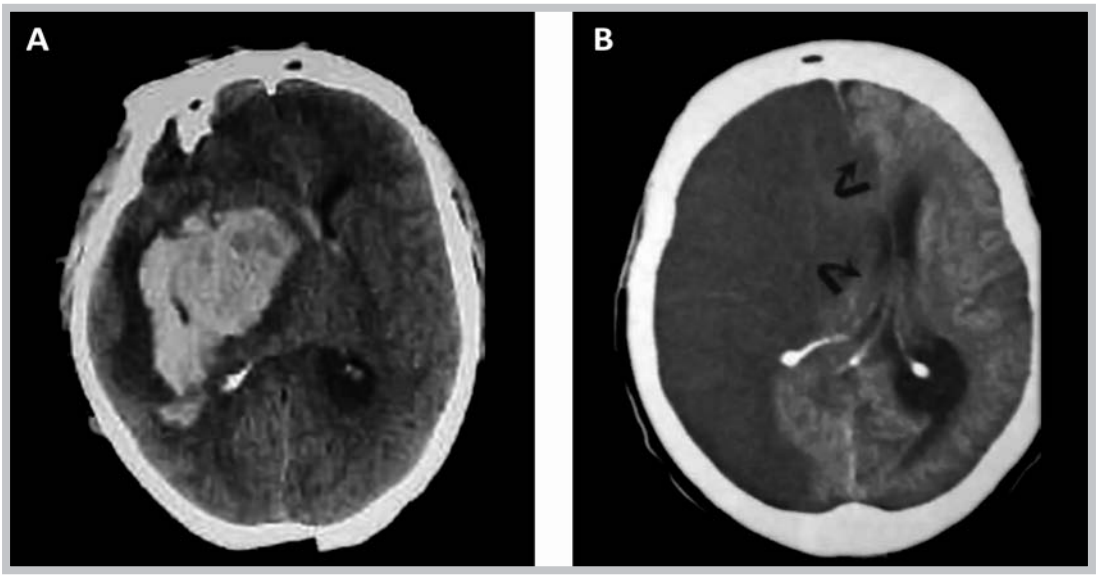

Figure 50.2. **(A) CT scan with massive right ganglia hemorrhage. (B) Right hemispheric infarct. Both images show pronounced mass effect and midline displacement.**

Location

Topography considers the epicentre as the site where the hematoma originates. For a more precise location, we must clarify whether the ICH is supra- or infratentorial. In supratentorial ICH, a lobar hematoma (frontal, temporal, parietal, occipital); basal ganglia (putamen, caudate nucleus, thalamus, striato-insular) or intraventricular location must be specified. Infratentorial ICH is localized in the brainstem (midbrain, pons, medulla) or the cerebellum (Figure 50.3).

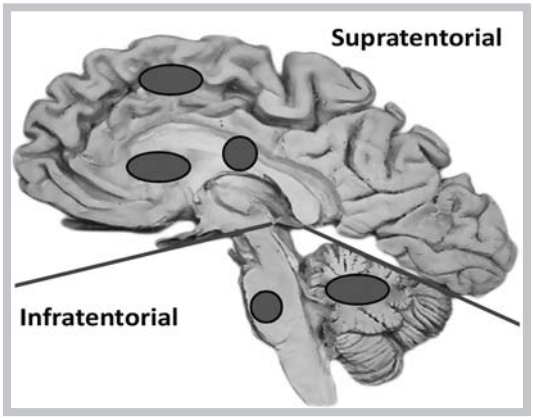

Figure 50.3. **Supra- and infratentorial locations of intracerebral hemorrhage.**

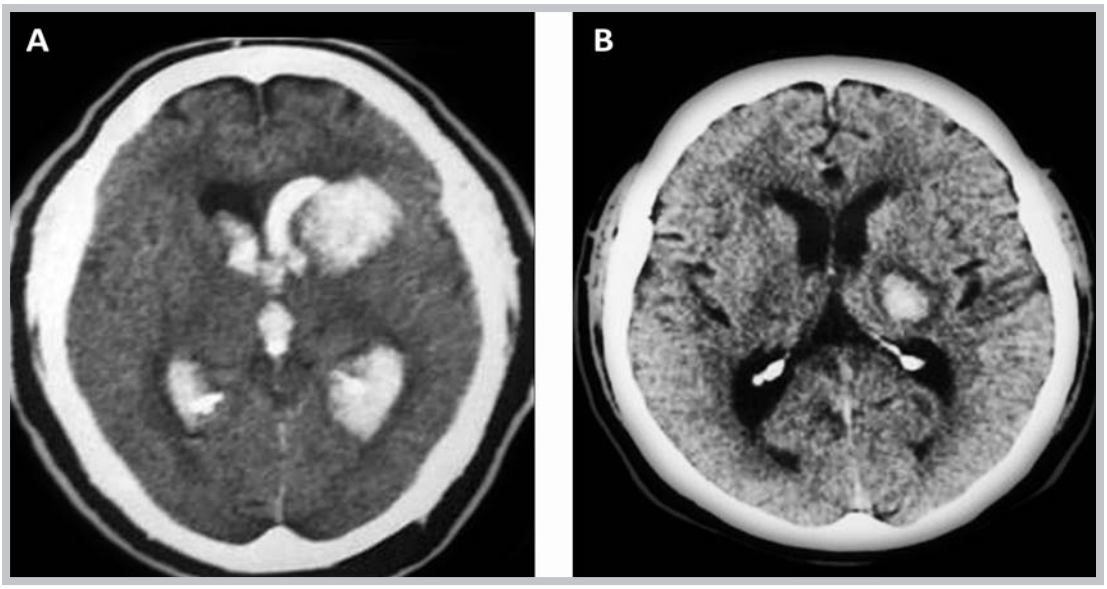

Figure 50.4. (A) Intracerebral hemorrhage with and (B) without ventricular aperture.

Ventricular Opening

Irruption of blood into the ventricular system has been associated with poor prognosis, which is why it is important to establish its presence or absence, to identify the ventricles involved, and determine its volume if possible [17] (Figure 50.4).

Intraventricular hemorrhage volume can be measured with the use of sophisticated CT scan software; however, because of its infrequent use, it is recommended to calculate the Graeb´s index [17]. Mild=1-4; moderate=5-8; severe=9-12 (Table 50.1).

	Score
Lateral ventricles (each ventricle apart)	
Blood traces in the ventricle	1
Blood fills less than half of the ventricle	2
Blood fills more than half of the ventricle	3
Lateral ventricle is full and expanded	4
Third and fourth ventricle (each ventricle apart)	
Blood is present in the ventricle	1
Ventricle is full and expanded	2

Table 50.1. Graeb's index to calculate intraventricular hemorrhage extent.

Volume

Hematoma volume is an important predictor of mortality, making its measurement necessary. As in intraventricular hemorrhage, the use of CT software allows the quantification of hematoma volume; however, since institutions may lack CT scan tools, a knowledge of alternative methods to calculate hematoma volume is needed. The most useful and common method is the ABC/2 formula (considering ICH as an ellipsoid or a football) [18,19]. The major diameter of hemorrhage (A) is multiplied by its perpendicular major diameter (B), times the number of sections (in cm) in which the hemorrhage appears on the CT scan (C), and the final product is divided by two. To calculate the value of C, the CT

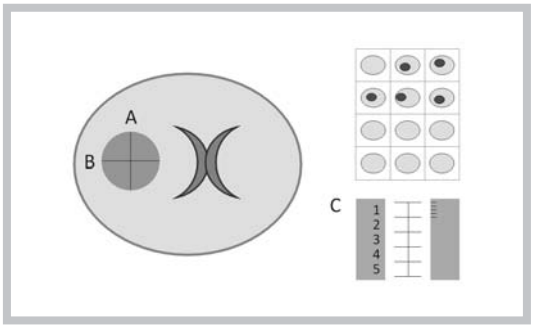

Figure 50.5. Calculation of hematoma volume with the ABC/2 formula.

slice showing the largest hematoma is taken as a reference (100%) and the smallest as 25%, because the size of the hematoma will appear different on the sequence of CT scans; if a subsequent section of the reference slice shows a hematoma half its size, the value is corrected by giving this section 0.5 cm (Figure 50.5).

Density and Shape

A recent analysis of the treatment of ICH with activated Factor VII proposed that a strong predictor for hematoma expansion is irregularity in the shapes and edges of the hemorrhage, as well as heterogeneity in its density [20]. This issue will be discussed later.

Other Tomographic Characteristics of ICH

Imaging findings vary depending on the evolution of the hemorrhage over time. In the hyperacute stage (first 4 hours), the extravasated blood has not yet formed a clot, producing an irregular hyperdense collection within the cerebral parenchyma. The presence of a blood-fluid level suggests an ICH in a very early phase, hemorrhage within a pre-existing cavity, or a hemorrhage due to coagulopathy or fibrinolytic therapy. In the acute phase (5 to 72 hours), a pre-existing hematoma becomes dense due to clot formation [21].

50.6.2 Computed Angiotomography (CTA)

CTA is an alternative non-invasive tool to angiography and magnetic resonance angiography (MRA), with the disadvantage that it requires contrast material and prolonged processing time. Nevertheless, a recent finding during the procedure (within the first 3 hours of ICH) termed “spot sign”, has been proposed as a strong predictor of hematoma expansion. The sign consists of a small “spot” or “point” inside the hematoma and suggests active bleeding from Charcot microaneurysms or from vessels with vascular damage [22].

50.6.3 Angiography

Angiography should be reserved for patients without a clear cause of ICH, especially in young normotensive patients, subjects with hemorrhage opened to the subarachnoid space, in those with prominent vessel structure as evidenced by CT or MR, when a vasculitis is suspected or in cases of sympathomimetic drug use [16,23,24]. Angiography is also recommended in patients with primary intraventricular hemorrhage and in those with perisylvian sulcal or fronto-orbital hemorrhage to dismiss the presence of aneurysms [16,23].

50.6.4 Magnetic Resonance and Magnetic Resonance Angiography (MRI, MRA)

These imaging studies are recommended in aged patients with absolute or relative contraindications to angiography due to blood dyscrasias, anticoagulant use, absent femoral pulse, severe atherosclerosis, as well as contraindication of the use of contrast material in patients with renal failure or multiple myeloma [16,23].
MR provides more information than CT about the hematoma borders, peri-hematoma edema and mass effect over other structures. It also helps to evaluate the dam-

age associated with the hematoma and to define its possible mechanism, for example: arteriovenous malformation (heterogeneous image with empty signals and calcifications), intratumoral bleeding or cavernous angioma [16,23-27]. The disadvantages of MR include long procedural time, contraindication in persons with metal prosthesis, pacemaker wearers, or in those under mechanical respiration or multimonitoring.

MR with gradient-echo (also T2*) has proved an important tool in the study of quiet focal damage that corresponds histopathologically to hemosiderin deposits, termed micro-hemorrhages or microbleeds. Lobar microbleeds have been related to amyloid angiopathy, whereas ganglionar microbleeds have been associated with hypertension [28].

50.6.5 Histopathologic Study

In all patients with hematoma evacuation or autopsy, it is mandatory to confirm the etiologic diagnosis. The sample must include the wall of hematoma and blood vessels. Congo red tissue staining is necessary in elderly subjects to confirm amyloid ICH [29].

50.7 Etiology of Intracerebral Hemorrhage

Hypertension is the main cause of ICH, explaining 60-80% of cases. Hypertension places arterioles (100 to 300 microns in diameter) under constant mechanical stress, leading to hyperplasia of smooth muscle cells which results in atherosclerosis [1,12] (Figure 50.6).

Over time, the muscle cells die and are replaced by collagen tissue (lipohyalinosis), leading to ectasia and occlusion (principal substrate of infarcts) and the formation of Charcot-Bouchard microaneurysms (considered today as the origin of ICH) (Figure 50.7) [1,12].

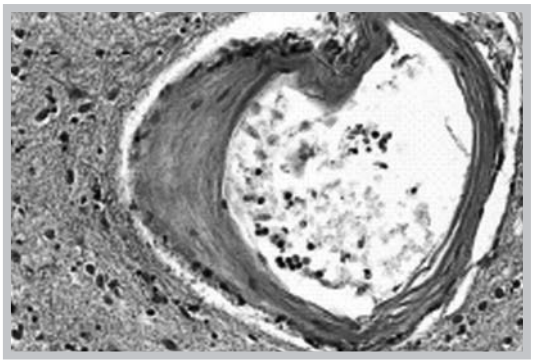

Figure 50.6. **Arteriole in which the muscle wall has been replaced by collagen.**

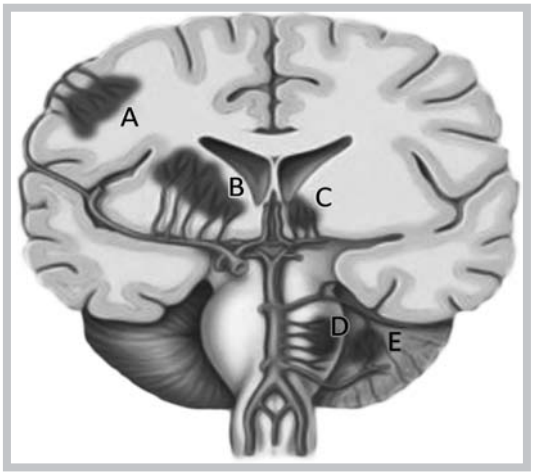

Figure 50.8. **Location of hypertensive ICH hemorrhage. Reproduced with permission of Qureshi [12].**

A = lobar
B = basal ganglia
C = thalamus
D = protuberance
E = cerebellum

The most common sites for arteriolar damage are the bifurcation of penetrating vessels such as the lenticulostriatal, the thalamic perforating arteries, and the brainstem penetrating arterioles. Previous changes match the common topography of ICH in the basal ganglia (35-45%), cerebral lobes (20-25%), thalamus (10-15%), cerebellum (5-10%) and pons (5%) (Figure 50.8).

Other ICH-associated conditions are CVM rupture, hematological dyscrasias, anticoagulants or antiplatelet use, intratumoral bleeding, cerebral venous thrombosis, alcohol intake, legal or illegal use of sympathomimetic drugs, primary or secondary vasculitis of the central nervous system (CNS) and endocarditis [1,12]. When the cause cannot be defined due to inconsistent or insufficient findings, ICH is considered as undetermined. When all diagnostic procedures are negative, the etiology is considered cryptogenic or idiopathic. Uncommon causes of ICH are listed in Table 50.2 [1,12].

In a daily practice, ICH location, patient age plus other associated conditions may suggest a possible etiology. For example, lobar ICH in a young patient is strongly suggestive of a CVM rupture; whereas lobar ICH in a non-hypertensive aged subject leads to consider amyloid angiopathy [1,12,30,31].

In a fronto-orbital ICH, it is mandatory to discard aneurysmal rupture, mainly in the presence of interhemispheric or basal subarachnoid hemorrhage. A hematoma with important perilesional edema will orientate toward discarding brain tumor as a cause of ICH. Basal ganglia hemorrhage in a young pregnant woman with pre-eclampsia is highly suggestive of a hypertensive cause or puerperal vasculopathy; in such patients a lobar ICH location must orientate toward considering cerebral venous thrombosis (Table 50.3).

50.8 Pathophysiology of ICH

ICH is a dynamic and complex process of simultaneous or consecutively interrelated events which can be grouped into the following phases:

a. Hematoma formation. This occurs whitin the first 60 minutes. Irruption of blood into the brain destroys the parenchymal tissue, alters intracerebral homeostasis, triggers an increase in local pressure with mass effect, leading to displacement of vectors and distortion of intracranial structures. In addition, the hemorrhage by itself is the source of three other deleterious events: cellular death by necrosis and apoptosis, inflammation and vasogenic edema [32-42].

b. Hematoma expansion. In 38% of patients, hematoma continues to grow after the initial event in the first 3 hours, which is associated with neurological deterioration and poor prognosis. In two thirds of such cases, hemorrhage expansion is already evident in the first hour (Figure 50.9) [43].

Hematoma expansion occurs in the absence of coagulopathies. Although the mechanisms by which this occurs are not yet fully understood, it seems to be due to continuous bleeding from the initial site of the ICH or by small "satellite" hemorrhages in the periphery of the clot [44,45].

Other risk factors or conditions contributing to hematoma growth are issues of meticulous analyses, both in clinical and molecular scenarios, and they represent an opportunity area for therapeutic interventions. Alcohol abuse, hyperglycemia, reduced prothrombin activity, hypofibrinogenemia and liver diseases have all been associated with this phenomenon [43,46]. The "spot sign" as evidenced by CTA, early hematoma density and shape are predictors of hematoma expansion that require further studies to confirm its precise value [20,28].

c. Edema. It appears after 24 hours around the hematoma and reaches its major expression at the fourth day, before slowly decreasing [32,33,35-37,39-42,45]. Severe edema develops mainly in the white matter, is primarily vasogenic, and results from increased blood-brain barrier permeability due to its destruction or dysfunction and the action of

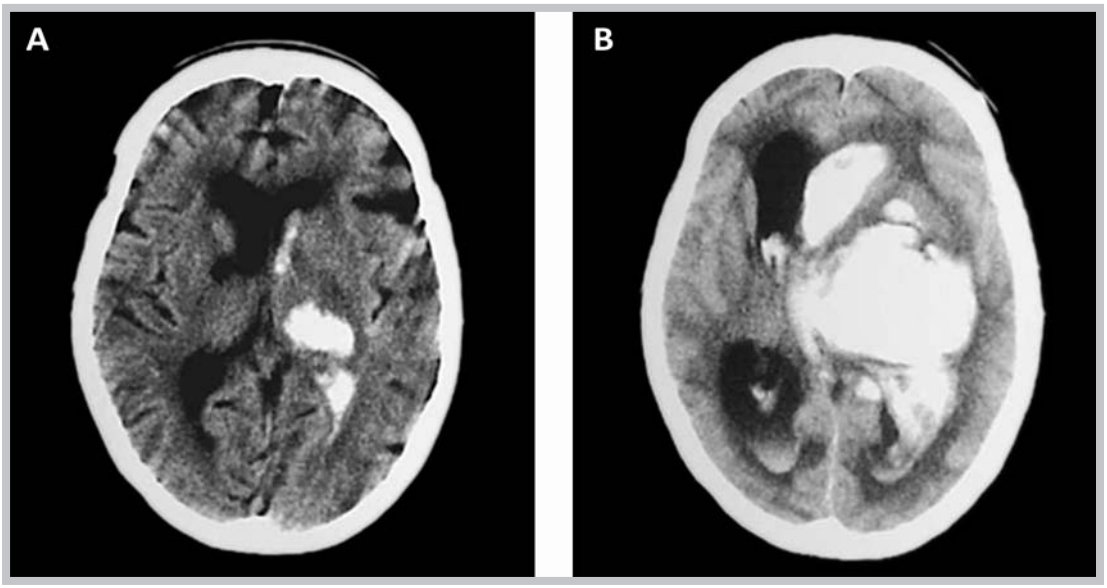

Figure 50.9. Hematoma expansion observed in the first hours.

neurotoxic substances like thrombin or metalloproteinases released from the extracellular matrix.

For many years, "peri-hematoma'' edema was considered as an "ischemic penumbra'' area, similar to that present in cerebral infarcts; nevertheless, SPECT (single-photon

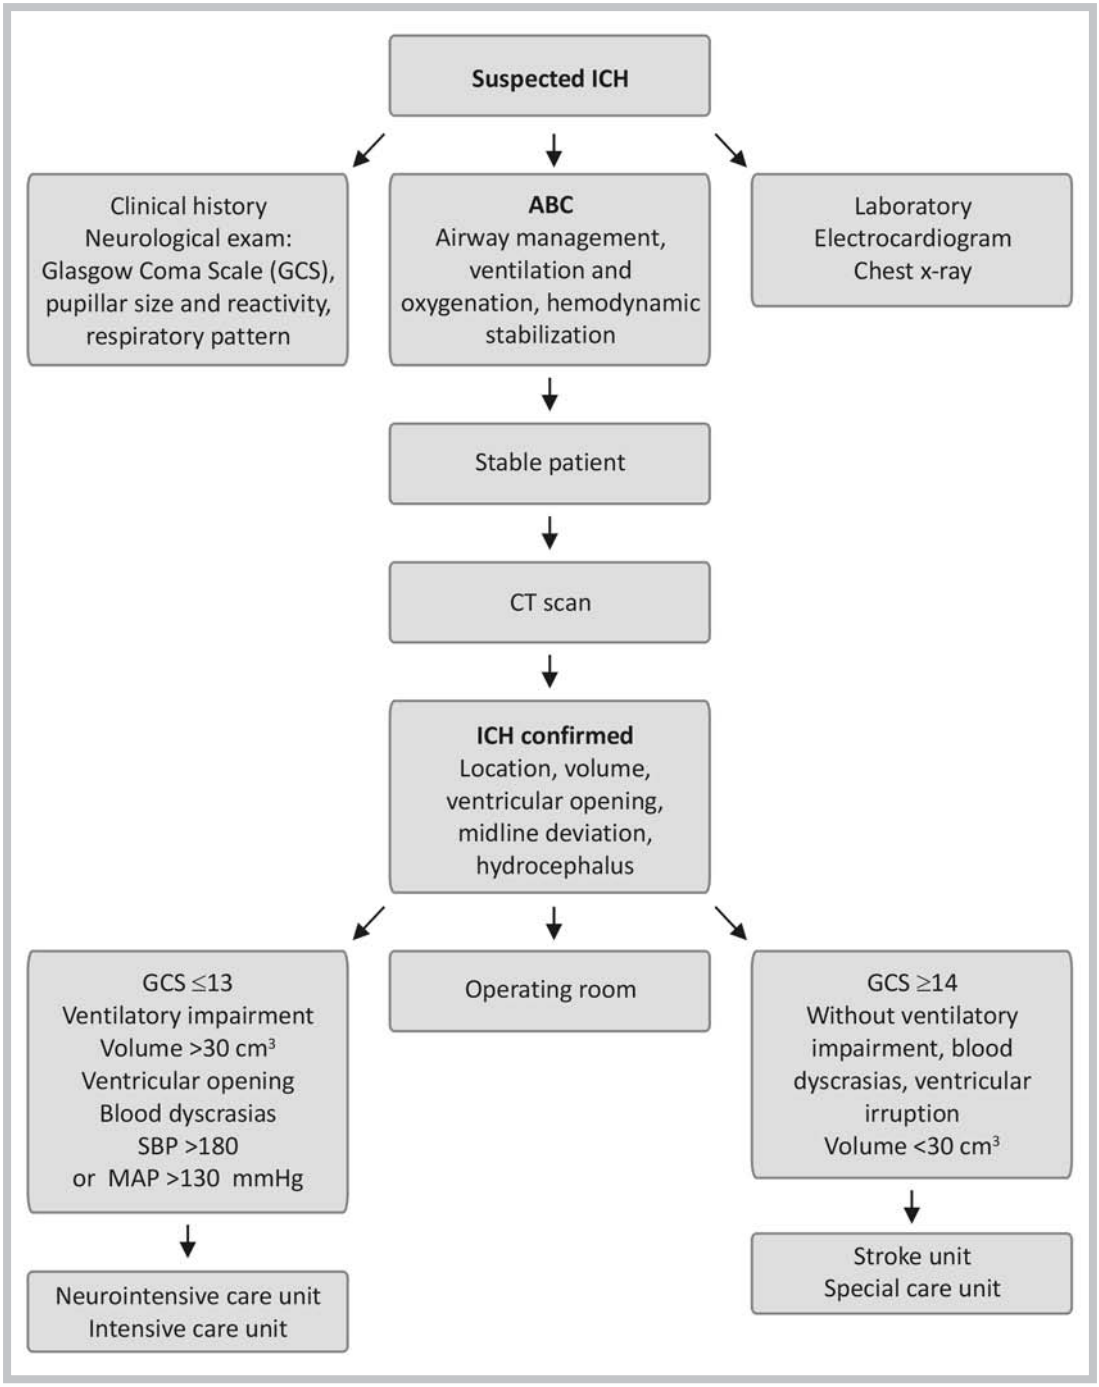

Figure 50.10. **Initial management of intracerebral hemorrhage.**
SBP= systolic blood pressure
MAP= mean arterial pressure

emission computed tomography), PET (positron emission tomography), diffusion-perfusion MRI techniques and microdialysis have all reliably concluded that this zone corresponds to a regional reduction in brain blood flow resulting from the concomitant decrease in metabolic demand or the presence of mitochondrial dysfunction [35,36,41,47].

50.9 Medical Treatment of ICH

The treatment for all types of ICH is medical, possibly surgical, and will preferably be carried out in a neurointensive care unit [48]. For surgical approaches, patient age and co-morbidities are important issues, as are the neurological status at emergency room arrival, hematoma location and volume, displacement of midline structures, ventricular irruption, hydrocephalus, etiology and patient or family end-of-life preferences [1,12,23]. In spite of these variables, some of which easily measurable, ICH treatment remains uncertain [49,50].

50.9.1 Initial Treatment of ICH

The objective is to reduce intracranial pressure and to avoid neurological and systemic complications [23,27]. Management begins with general measures (ABC approach), airway control for optimal ventilation and oxygenation for hemodynamic stabilization. A brief neurological examination must include assessment with the Glasgow Coma Scale (GCS) or the National Institutes of Health Stroke Scale (NIHSS), as well as the evaluation of pupillar form, size and reactivity, together with the respiratory pattern. The decision whether to institute endotracheal intubation is based on clinical judgment, since its delay aggravates the pre-existing neurological damage and increases morbidity and mortality as a result of the secondary insult from hypoxemia, hypercapnia or aspiration pneumonia [11,39,43,44,51-59].

Hypotension needs to be immediately corrected with iso- or hypertonic fluids, colloids and amines such as phenylephrine, dopamine or norepinephrine to maintain adequate cerebral perfusion pressure. The following laboratory parameters must be obtained: hemogram, glycemia, urea, serum creatinine, electrolytes, coagulogram (including platelet count, prothrombin time, partial thromboplastin time and INR), serum cardiac enzymes, arterial gasometry and toxicological profile (in cases of suspected drug abuse). The electrocardiogram and chest x-ray are useful to evaluate cardiovascular function in patients with or without a history of arterial hypertension in the preoperative work-up, and also to detect early non-neurological complications (arrhythmias, pneumonia) [23]. Under no condition should an unstable patient be transferred for complementary studies.

Once obtained, cranial CT findings must be analyzed jointly by the neurosurgery team to decide the initial management according to the flowchart shown in Figure 50.10.

50.9.2 Medical Treatment of ICH in Critical Care Units

General Measures

The general measures of care for ICH patients are similar to those for other acute cerebral insults [23,51,58]. It is recommended to establish a central venous route, high calibre peripheral pathways and an arterial line. The advantages of this approach are that it allows for the precise monitoring of volemia and average arterial tension for easy se-

rial extraction of blood samples without the need for extra procedures on the patient; it also helps when volume expanders are required, colloids, mannitol, plasma or total blood without interfering with the simultaneous administration of sedatives, analgesics, antihypertensives or other drugs.

With regard to the use of intravenous solutions, isotonic sodium chloride 0.9% (physiological solution) or slightly hypertonic solution (3.5%) is recommended, depending on various different factors, including natremia, cerebral salt-wasting syndrome, inappropriate antidiuretic hormone secretion syndrome, endocranial hypertension, volemia, mass effect on CT (midline deviation, cistern effacement), etc. Under no circumstances (except in hypoglycemia) should hypotonic solutions such as dextrose or Ringer´s lactate be given because they worsen the cerebral edema, promote the synthesis of neurotoxic neurotransmitters such as glutamate, produce local tissue acidosis (a powerful stimulator of cerebral vasodilatation), and increase cerebral blood volume with elevation of intracranial pressure [23,51,58]. The "6 N" or "six normalities'' serves as a mnemonic rule (Figure 50.11).

Fever must be aggressively treated because of its deleterious effects on neurons and the blood-brain barrier: stimulation of the production of free radicals and elevation of excitatory amino acid levels. Fever also increases the cerebral metabolic demands of oxygen, with repercussions on intracranial pressure, in addition to decreasing the seizures threshold [60].

Hyperthermia has been associated with poor prognosis [61]. Studies by Godoy et al. have demonstrated a close relationship between the systemic inflammatory response syndrome (SRIS) as a predictor of worse prognosis and mortality in ICH, with fever being a component of the syndrome [62]. The authors recommend its management by physical means, thermal blankets, and the administration of acetaminophen in doses of up to 2 g daily when rectal temperature exceeds 37.5°C. This practice is in line with recent results of a multicenter study on acetaminophen in stroke [63].

Assisted mechanical ventilation is indicated in patients with one or more of the following criteria: GCS ≤8; neurological deterioration (defined as worsening of 2 or more GCS points); endocranial hypertension; respiratory insufficiency; abnormal ventilatory pattern; inability to obtain normoxemia and normocapnea, in spite of additional airway support; and immediate postoperative measures.

If a tracheotomy is created, independently of the time at which it is indicated, it should be done by the percutaneous route. On the other hand, due to the hypercatabolic state

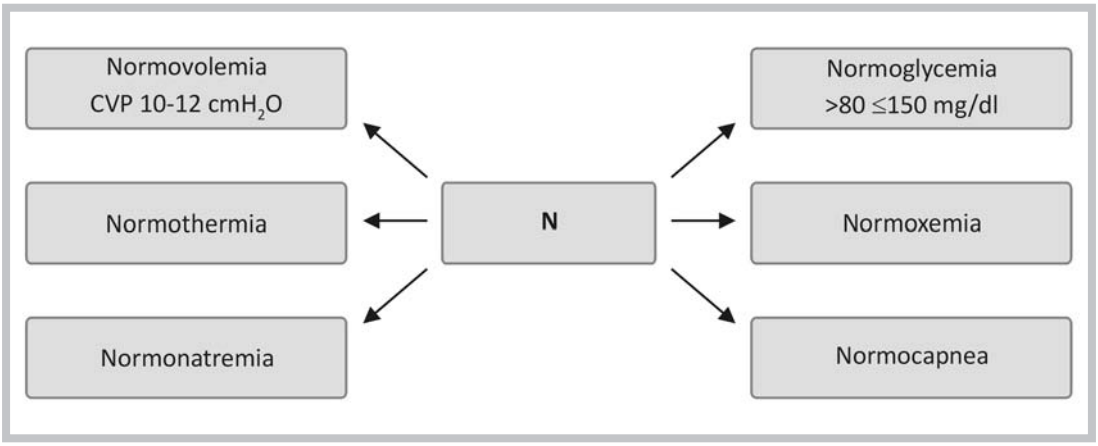

Figure 50.11. **The "6 N", the mnemonic rule to keep in mind when taking care of ICH patients.**
CVP= central venous pressure

and to the difficulty in swallowing in these patients, feeding must be initiated early, within the first 48 hours and preferably by the enteral route with a nasojejunal tube. Gastrokinetics (e.g., methoclopramide or cinitapride) are recommended for concomitant gastroparesis caused by the primary brain damage, the release of cytokines and other mediators, as well as the routine use of opioids or phenytoin, [23,51,58].

Additionally, and despite recent controversies, the head should be maintained 30 degrees from the horizontal plane in a "neutral" position, i.e., without anteroposterior or lateral flexion-extension, to improve the volume-pressure ratio of the cranial cavity, venous drainage, and the redistribution of cerebrospinal fluid; this measure also reduces the probability of mycroaspiration and mechanical ventilation-induced pneumonia.

Other equally important measures [58] include the use of artificial eye drops and frequent eyewashes, frequent oral hygiene with clorhexidine or other similarly effective mouthwashes. To prevent the development of pressure ulcers, the patient's position should be regularly changed - an air or water mattress is not a substitute for this basic care practice. Stress ulcer prophylaxis can be achieved with H_2 blockers, proton pump inhibitors or contact antacids such as sucralfate. Deep venous thrombosis prophylaxis can be achieved by using elastic bandages or pneumatic sleeves with sequential compression. In patients at high risk for thrombembolism such as those with obesity, prolonged immobilization, or hip fracture among others, subcutaneous heparin administration or low-molecular-weight heparinoids are recommended after first 24 hours of ICH.

Specific Measures

Normoglycemia

The strict control of glycemia levels is associated with multiple benefits, including the prevention of osmotic diuresis, maintenance of neutrophil and macrophage function, reduced free radicals production, increased nitric oxidase production and improved erythropoiesis [44,54,55,58]. Nevertheless, studies suggesting an aggressive control of hyperglycemia have not been conducted in ICH. Godoy and his group recommend strict glycemia monitoring and treatment with current insulin therapy if glycemia >150 mg/dl levels [64-66].

Anticonvulsants

Seizure frequency in ICH varies from 5 to 28% depending on the diagnosis method, being the highest when continuous electroencephalography is conducted [23,43,46,52]. Although anticonvulsive prophylaxis in ICH is controversial, the use of anticonvulsants is recommended in the following conditions: seizures as the presenting symptom of ICH, history of epilepsy or seizures with or without anticonvulsants use, lobar ICH with cortical extension and during the postoperative period [54-59,66-69]. Anticonvulsants are indicated in the first month and should be increased later. If seizures recur, the condition must be treated as an epileptic form.

Hemostatic Therapy

Recombinant activated factor VII (rFVIIa or NovoSeven®) is a powerful hemostatic activator used in the treatment of hemophilia [43]. rFVIIa acts primarily in endothelial damaged sites, promoting complexes formation with exposed tissue factors [43,46]. These properties were initially promising for ICH patients, especially in the expansion phase of hematoma in the first hours of evolution [46,66,69-71]. Nevertheless, the high expectations generated by a rFVIIa phase II study were not supported by the results of a recent phase III study [71,72]. Although the expansion of hematoma was reduced in the patient group treated with rFVIIa, no functional benefit was observed at 90 days. On the other hand, the high frequency of venous and arterial thromboembolic adverse events ob-

served in the rFVIIa arm, in both the phase II and III studies, are an important issue for its present recommendation [71,72].

Management of Coagulopathies

Patients anticoagulated with coumarin or warfarin have a 5 to 10 times higher risk of a life-threatening ICH, making the reversion of their effects urgent, with both intravenous vitamin K at a daily dose 2 mg; fresh frozen plasma of up to 15 ml/kg body weight (4 or 5 units), or the concentrated infusion of coagulation factors II, VII, IX and X [11,54,58,66,67,71]. Management should never be delayed while waiting for coagulation tests, the combined use of all available therapeutic tools being frequent in daily practice.

Heparin is inactivated by its antagonist, the sulfate of protamine at 1 mg for every 100 units of heparin. Patients with thrombocytopenia or platelet dysfunction can be treated with platelet concentrate infusion or with a unique dose of 0.3 μg/kg of desmopresine acetate.

Blood Pressure Management

Few aspects in the acute phase of ICH management have generated as much controversy as the handling of blood pressure. Some authors consider that high values are associated with hematoma expansion, greater peri-hematoma edema, and an increased risk of recurrence. Others have argued that its decrease is associated with ischemia due to reduced brain perfusion [11,73,74]. Although the American Heart Association (AHA) guidelines suggest the blood pressure values for which treatment must be initiated, their recommendations lack evidence (level V, degree C), since they were reviewed in patients with ischemic stroke and did not undergo substantial modifications [23,51].

Recent works propose a systolic blood pressure <160 mmHg which, besides being safe, reduces the probability of rebleeding [73-75]. Based on class IV evidence, the 2005 European Stroke Initiative (EUSI) recommends the following [58]: the blood pressure reduction as a routine is not recommended; in chronic hypertensive patients, blood pressure must be treated when systolic and diastolic values exceed 180/105 mmHg, respectively, with a mean arterial pressure (MAP) of 125 mmHg as a target; in non-hypertensive patients, blood pressure values >160/95 mmHg must be treated with the objective to reach to reach a blood pressure of 150/90 mmHg or a MAP of 110 mmHg. Reductions >20% of basal values must be avoided.

Both guidelines agree on early and aggressive treatment of blood pressure when one or more of the following conditions exist: acute pulmonary edema; aorta dissection; acute myocardial infarction; hypertensive encephalopathy; and acute renal failure [51,58].

With regard to antihypertensive drugs use, the literature recommends labetalol as a first-line election, followed by esmolol or nicardipine. The use of nitroprusside sodium and nitroglycerin must be avoided since they have a remarkable vasodilator effect on the cerebral vasculature [51,58]. Clonidine, a low-cost drug accessible and available in almost all intensive care units, is safe in spite of a weak evidence of use [54]; a load drug administration must be avoided, since it can stimulate peripheral receptors with a rebound effect. Clodinine is a presynaptic alpha-agonist that, in addition to its antihypertensive effects, also contributes to mitigate the sympathetic hyperactivity observed in these patients, besides having the advantage of an antiemetic, analgesic, and mild sedative effects. The conventional dose is 0.2 to 0.5 μg/kg/min.

The ATACH (Antihypertensive Treatment of Cerebral Acute Hemorrhage) study of safety and feasibility demonstrated that nicardipine by the intravenous route is viable in the strict control blood pressure [75]. However, we must await the results from the larger scale study (ATACH-2) to confirm these findings and to know its impact on mortality and disability in the short, medium and long term.

CSF = cerebrospinal fluid
CT = computed tomography
HSS= hypertonic saline solution
ICP= intracranial pressure
MAP = mean arterial pressure

A similar pilot study, titled INTERACT (Cerebral Intensive Blood Pressure Reduction in Acute Hemorrhage Trial), showed the safety in the intensive management of systolic blood pressure values when they are reduced up to 140 mmHg [76]. The clinical impact is now analyzed under the scope of another study (INTERACT-2). The medical treatment of ICH in the neurointensive care unit is summarized in Figure 50.12.

Independently of surgical hematoma drainage or not, sequential intracranial hypertension management is indicated (Figure 50.13). It begins with general measures (sedation, analgesia, hyperthermia and seizures control while avoiding hypoxemia, and hypercapnia). If intracranial hypertension persists, ventricular drainage up to 20 ml/h is recommended, in addition to the use of 7.5% hypertonic saline solution as osmotherapy, together with mild hyperventilation, maintaining CO_2 levels between 30 and 35 mmHg. The use of muscle relaxants is not mandatory unless strictly needed. A new CT can be obtained at any time as deemed necessary by the neurosurgery staff. All these therapeutic approaches are considered “first level measures” and a poor response is associated with poor prognosis [23,52,54,56,77].

50.10 Surgical Treatment of ICH

The surgical treatment of the ICH is highly controversial, especially for supratentorial hematomas [34,49,77]. The hypothetical benefits of surgical drainage are that it decreases the hematoma mass effect, avoiding the release of neurotoxic products and preventing prolonged tissue-blot interaction, besides improving regional blood flow and peri-hematoma brain metabolism [78]. Nevertheless, these theoretical advantages must be weighed against the inevitable damage of normal parenchyma to access the hemorrhage [40,79-81]. Most neurosurgeons agree on the need to drain lobar or cerebellar hematomas in patients with clinical deterioration. What remains uncertain is the appropriate surgical approach to a ganglionic ICH [40,79,80].

The AHA guidelines [23,51] recommend surgical treatment in the following conditions: cerebellar hematomas >3 cm in diameter in patients who clinically deteriorate, have hydrocephalus, secondary brainstem or fourth ventricle compression (evidence C); secondary CVM hematomas; medium to larger volume lobar hematomas in young patients with neurological worsening.

The lack of studies with suitable methodology had lead mainly to low-evidence studies, some of which date from the pre-CT era or were derived from a few patients series [82-85]. Recent studies such as the STICH (International Surgical Trial in Intracerebral Hemorrhage) could not satisfy this question [50]. In this multicentre, international study, 1033 patients with supratentorial ICH within the first 72 hours were recruited and randomized to medical versus surgical treatment. Based on the uncertainty or doubt principle with respect to the utility of surgery, all those patients in which neurosurgeons were convinced of the benefits of surgery were operated and not included in the study. The average time from ICH onset to surgery was 30 hours. The results showed no difference in mortality or incapacity at 3 months, which is why the results of this study do not change the present practice [50].

A small subgroup of STICH patients with a better evolution was, however, identified: those with a GCS score between 9 and 12, with more superficial hematomas located to ≤1 cm of the brain cortex. An ongoing collaborative study in lobar ICH (STICH-2) is now comparing medical versus surgical treatment.

50.10.1 Ventricular Extension of ICH

Ventricular extension of ICH occurs in about 40% of patients, mainly when located deep in the thalamus, caudate, putamen or cerebellum [43,44,56,86-91]. Intraventricular hemorrhage carries a poor prognosis, nevertheless, it is the volume and not just its presence that determines the predictive value, being invariably fatal when >20 ml [67,86,88-92]. Its deleterious effects are associated with the development of hydrocephalus, intracranial hypertension, and ischemia of the cortical structures [86,87,91,93]. External ventricular drainage is a therapeutic option; however, its beneficial role remains uncertain.

The permeability of ventriculostomy is difficult to maintain due to frequent obstruction by clots, which is why different studies have used fibrinolytics like urokinase, streptokinase and rtPA [86,88]. Various studies in small series have shown good results related to a minor use of permanent peritoneal derivations and a reduction in mortality with acceptable functional prognosis; nevertheless, despite the high risk of complications such as infections or hemorrhages, prospective multicentre trials, have validated the effectiveness of this approach.

50.10.2 Hydrocephalus

Hydrocephalus develops due to the external compression of the ventricular system by the mass effect of hematomas, mainly those located in the thalamus or putamen which deviate the midline and compress the foramen of Monro, and also by small hemorrhages near of ventricular system as occur in the cerebellar vermis. The second mechanism is by clots obstructing the normal circulation of cerebrospinal fluid [93,94].

Independently of its cause, hydrocephalus leads to intracranial hypertension, cerebral ischemia and neurological deterioration. In addition, it is an independent predictive factor of mortality and inauspicious evolution, mainly when associated with supratentorial hemorrhages. Hydrocephalus is frequently treated with ventriculostomy; nevertheless, the benefit of this therapeutic modality has not been established. New alternative approaches utilizing minimally invasive procedures such as simple drainage by stereotaxia and thrombolysis with hematoma aspiration are technically promising but lack sufficient evidence for their generalized use.

Surgical treatment of secondary ICH due to rupture of arteriovenous malformations (AVMs), cavernous or venous angiomas is not usually urgent. A relatively low mortality in the acute phase of ICH due to AVMs (8.9-19.2%), associated with the reduced risk of immediate recurrence (3-17% for the first year and 2-6% thereafter), as well as the ab-

* Scales designed in addition for predicting good functional outcome

** Other variables also were proved

sence of vasospasm, makes time a non-critical condition for their treatment [95]. Mortality associated with ICH due to cavernous angiomas is similar that from AVMs; nevertheless, the risk of recurrence of bleeding is less (0.25-0.7% per year for non-familiar supratentorial cavernous angiomas and up to 6.5% per year for familiar cases) with a risk of recurrence of bleeding of 1.3% depending on the number of lesions per year [96]. The better prognosis relies on closer follow-up, waiting for clot reabsorption, with control studies (MRI) and careful planning of an eventual surgery in candidate cases.

50.11 Mortality and Prognosis in ICH

Acute mortality in ICH varies from 20 to 70%, being many factors its determinants [1,9-11]. A wide range of clinical, molecular and tomographic markers have been identified as predictors of mortality. The GCS score and the volume of the hematoma are variables with the highest weight and consistency in different cohorts. Recently, and by coincidence with this so called "forgotten pathology", there has been renewed interest in the proposal of several systems for predicting mortality in-hospital and at 30, 90 and 180 days after ICH. Table 50.4 shows the prognostic scales for 30-day mortality [91,92,97-99].

Some of these scales also were developed for predicting a good evolution and none of them have been validated in cohorts independently. The scale proposed by Hemphill [92] is one of the most accepted at the moment, since is simple to apply and is reproducible and highly predictive (Table 50.5). The scale has been validated and modified by others in different scenarios, including the proposals by the authors of this chapter [97-99].

The predictive good prognosis at 3 months after ICH is similar to the findings at in-hospital or at 30 days evolution. A recent scale, denominated the FUNC score (Functional Prediction of Outcome in Patients with Primary Intracerebral Hemorrhage) demonstrated that at 3 months, poor or good prognosis is associated with age, GCS at emergency room arrival, hemorrhage location and volume, in addition to previous cognitive deterioration (a good prognosis was based on a GCS >4) [100].

50.12 Conclusion

ICH is the most catastrophic of all forms of CVD. It still is "the great forgotten one" in spite of recent interesting studies. It

seems to be more frequent in Latin America than in other countries, calling for the need to design incidence studies that could confirm it. Risk factors, clinical presentation and radiological findings are uniform in all scenarios. The best medical and surgical management remains uncertain. There is an urgent need for the initiation, termination and validation of all local or multicentre studies that could confirm or reject currently proposed therapeutic options such as neuroprotection, hemostatics use, blood pressure control, and the best surgical instrumentation with consequent safe and effective access.

51.1 Introduction

Non-traumatic subarachnoid hemorrhage (SAH) is a neurological emergency caused by the extravasation of blood into the space normally occupied by cerebrospinal fluid. Its most common cause is the non-traumatic rupture of intracranial saccular aneurysms, accounting for over 80% of cases. The remaining 20% are due to pre-truncal or perimesencephalic hemorrhage (10% of cases) or remote etiologies such as rupture of cavernous malformations, spinal arteriovenous malformations or mycotic aneurysms among others (Table 51.1).

The annual global incidence of SAH has been estimated at 6-7 cases per 100,000 inhabitants, and the risk is 1.6 times higher in women. SAH is implicated in <10% of strokes after 45 years of age and in about 50% of those occurring before age 35 years. The fatality rate is 51%, and at least 46% of survivors have long-term cognitive deficits which significantly impact their quality of life. The prognosis is strongly related to the state of consciousness on admission, the patient's age and the amount of bleeding evidenced on the initial brain scan. These variables have been used to develop different scales to enable rapid stratification of patients. Those most commonly used in clinical practice are the Fisher (Table 51.2), the World Federation of Neurosurgeons (World Federation of Neurological Surgeons, Table 51.3), and Hunt and Hess (Table 51.4). The last, in particular, has important prognostic value.

Inflammatory injury of the cerebral arteries	• Mycotic aneurysms • Behçet's disease • Primary CNS angiitis • Churg-Strauss vasculitis • Wegener's granulomatosis
Non-inflammatory injury of the cerebral arteries	• Arterial dissection • Cerebral arteriovenous malformation • Fusiform aneurysms • Dural arteriovenous fistula • Cerebral cavernous angioma • Cerebral amyloid angiopathy • Moyamoya disease • Reversible cerebral vasoconstriction syndrome • Cerebral amyloid angiopathy
Spinal vascular lesions	• Saccular spinal aneurysm • Spinal arteriovenous malformation • Spinal cavernous angioma
Hematological	• Sickle-cell disease • Coagulopathy
Tumours	• Pituitary apoplexy • Malignant glioma • Acoustic nerve tumour • Angiolipoma • Schwannoma • Cervical meningioma • Spinal cord hemagioblastoma • Meningeal carcinomatosis • Cauda equina melanoma
Drugs	• Cocaine • Antithrombotics
Hereditary causes	• Polycystic kidney disease • Ehlers-Danlos type IV • Pseudoxanthoma elasticum • Fibromuscular dysplasia • Neurofibromatosis

Table 51.1. Uncommon causes of non-traumatic SAH.

Grade	Volume of blood on admission head CT
I	No detectable blood
II	Diffuse subarachnoid blood without localized vertical clots <1 mm wide
III	Localized clots in the subarachnoid space or with a vertical blood layer ≥1 mm
IV	Bleeding with extension into the intraventricular or intraparenchymal compartments

Table 51.2. Fisher's scale.

Grade	Glasgow Coma Scale	Clinical picture
I	15	Without motor deficit
II	13-14	Without motor deficit
III	13-14	With motor deficit
IV	7-12	With or without motor deficit
V	3-6	With or without motor deficit

Table 51.3. World Federation of Neurosurgeons Scale.

Grade	Clinical picture	Prognosis
I	Asymptomatic, mild headache or nucal rigidity	75-90% with good outcome 5-15% mortality and/or vegetative state
II	Moderate to severe headache, nucal rigidity, cranial nerve paresis	
III	Obtunded, confusion, mild motor deficit	55-75% with good outcome 15-30% mortality and/or vegetative state
IV	Stupor, moderate to severe hemiparesis early decerebrate posture or neurovegetative imbalances	30-50% with good outcome 35-45% mortality and/or vegetative state
V	Coma, decerebrate posture	5-15% with good outcome 75-90% mortality and/or vegetative state

Table 51.4. Hunt and Hess scale.

Low clinical suspicion	• Limited evaluation of patients presenting with acute severe headache • Ignoring that headache associated with SAH can improve spontaneously • Not knowing that the SAH can present with atypical characteristics • Ignoring that hypertension and ECG changes can accompany SAH
Limitations of computed tomography	• Patient with SAH presenting late in its course • Anemia • Low-volume bleeding • Technical limitations (suboptimal images, thick cuts at the skull base)
Limitations of the lumbar puncture	• Not performing a lumbar puncture in patients with suboptimal, normal or non-diagnostic head CT • Not recognizing xanthochromia in the CSF • Ignoring that the sensitivity of spectrophotometry of CSF is superior to direct observation with the naked eye • Lumbar puncture performed very early in the course (<12 h) or very late (>2 weeks) • Failure to recognize the difference between the results of a traumatic tap and bleeding from a real SAH

Table 51.5. Frequent causes of misdiagnosis of SAH.

51.2 Diagnosis

Retrospective studies have suggested that approximately 1-4% of patients presenting to the emergency room with headache have SAH. The initial hemorrhage can be fatal or cause severe neurological sequelae, and early treatment of the aneurysm reduces not only short-term complications but also improves medium- and long-term prognosis. This makes the early diagnosis of SAH a key factor, which is based on the triad of clinical symptoms, lumbar puncture and the use of complementary diagnostic imaging studies. A study by Vermeulen and Schull in Toronto, Canada, reported that 5.4% of patients presenting to the emergency room with SAH are misdiagnosed; this rate rises to around 20% for patients with low-grade bleeding. Therefore, high clinical suspicion is essential to avoid diagnostic errors that might delay the implementation of appropriate treatment plans (Table 51.5).

51.2.1 Clinical

Typically, SAH presents with severe diffuse headache of acute onset which reaches its peak in seconds. Patients describe the headache as “the worst in their life.” However, it is the acute onset and not the severity that characterizes the headache of SAH. In some cases, the headache completely ceases within minutes or hours and is called “sentinel headache”. It has been shown that many patients with sentinel headache can develop SAH within the 3 weeks following the episode. Other symptoms frequently found in these patients, such as nausea, vomiting and photophobia, are nonspecific and of limited diagnostic value. Two thirds of patients with SAH present with impairment of consciousness, and half of these are already in a coma. Meningismus, which is often observed, is secondary to meningeal irritation caused by blood in the subarachnoid space. This takes place between 3 and 12 hours after the bleeding but it may be absent in deeply comatose patients or in those with mild SAH. Fundoscopic examination is of paramount importance: 1 in 7 patients develop intraocular hemorrhage, which is more common in those presenting with impaired consciousness. The pathophysiological mechanism of these hemorrhages involves a sustained increase in intracranial pressure that blocks the drainage of the central retinal vein in its course through the optic nerve sheath, causing preretinal flame hemorrhages (subhyaloid hemorrhage) located near the optical disc. When there is a sudden increase in intracranial pressure, intraocular bleeding can be more severe and extend to the vitreous humour, causing the so-called Terson syndrome.

Frequently seen are focal neurologic deficits which can have a localizing value of the bleeding site (Table 51.6).

These occur when the aneurysm compresses a cranial nerve or when the bleeding extends into the brain parenchyma. Alternatively, aneurysm rupture can lead to severe va-

Neurological deficit	Localization of the aneurysm
Partial or complete paresis of the oculomotor nerve	Posterior communicating artery
Paraparesis or abulia	Anterior communicating artery
Hemiparesis and aphasia	Middle cerebral artery
Paresis of the VI nerve	Limited localizing value
Ataxia and nystagmus	Posterior fossa

Table 51.6. **Localization of the aneurysm based on the clinical picture.**

soconstriction, and eventually, localized ischemia. This explains why the clinical manifestations of SAH are sometimes indistinguishable from those of an ischemic stroke or intraparenchymal hemorrhage.
In the acute phase of SAH systemic findings such as severe hypertension, hypoxemia, or electrocardiographic changes including depression or ST segment elevation, T wave flattening, presence of Q wave, QT prolongation and bundle-branch block can be observed. In addition, about 3% of cases can evolve into a cardiac arrest.

51.2.2 Lumbar Puncture

About 3% of patients presenting within 12 hours of the onset of symptoms of SAH have normal imaging studies. Since lumbar puncture demonstrates the presence of blood in the cerebrospinal fluid, it is important to have a high degree of clinical suspicion and have a lumbar puncture performed in all patients presenting with acute onset headache suggestive of SAH with a normal computed tomography (CT) of the head. Typically, lumbar puncture in patients with SAH has a high cerebrospinal fluid opening pressure with a xanthochromic appearance and abundant red blood cells. Xanthochromia occurs when the hemoglobin from red blood cells extravasated into the subarachnoid space is metabolized to bilirubin. The latter has a spectrophotometric maximum wavelength absorption at 450-460 nm, allowing its quantification with high sensitivity. This method, in turn, allows to differentiate the presence of bilirubin from other pigments derived from the blood such as oxyhemoglobin or iodinated antiseptics used to disinfect the skin.
In patients with significant bleeding, the cerebrospinal fluid may have a bloody aspect. In such cases, the cerebrospinal fluid should be centrifuged, and a yellowish supernatant will confirm the presence of xanthochromia. In doubtful cases, the presence of bilirubin can be demonstrated spectrophotometrically in the laboratory. Since the enzymatic metabolism of hemoglobin to bilirubin can only occur in vivo, the cerebrospinal fluid should be stored protected from light and ultraviolet radiation which can degrade bilirubin and give false negative results.
Because the metabolism of hemoglobin to bilirubin requires 6 to 12 hours, it is advisable to perform a lumbar puncture 6 or, if possible, 12 hours after the onset of SAH symptoms. The cerebrospinal fluid obtained before 6 hours usually shows a high count of red blood cells without xanthochromia, as observed in traumatic lumbar punctures.
In clinical practice, a widespread technique to differentiate traumatic puncture from SAH is the comparison of the number of red blood cells present in the cerebrospinal fluid obtained at the beginning and end of the lumbar puncture; however, this observation can be unreliable.

51.2.3 Ancillary Radiographic Tests

Computed Tomography

Brain CT without contrast material is one of the most useful studies for investigating SAH and the first to be ordered when the diagnosis is suspected. Subarachnoid

Figure 51.1. Non-contrast enhanced head CT obtained in a patient with SAH.

bleeding appears on the CT scan as a hyperdensity localized to the subarachnoid space, more commonly in the basal cisterns and the Sylvian fissure (Figure 51.1). The sensitivity of this technique depends on several factors:

- **Technique**. The scan plane should be parallel to the hard palate. It should be noted that the sensitivity of CT depends directly on the amount of blood extravasated into the subarachnoid space. If there are only small amounts of bleeding, the sensitivity of CT can be increased by cutting thin slices (3 mm) from the base of the skull.
- **Time since the onset of symptoms**. In the first 12 hours, CT can reveal extravasation of blood into the subarachnoid space in approximately 100% of cases; however, this percentage decreases to 93% between 12 to 24 hours. Over the following days, the blood circulation and elimination from the subarachnoid spaces causes the sensitivity of CT to decrease markedly. It is estimated that the sensitivity of a CT scan performed on the seventh day post-bleeding is only 50%.
- **Hematocrit**. The blood density appearing on CT depends directly on its hemoglobin concentration. Blood hemoglobin <10 mg/dl may be isodense on CT.
- **Scanner resolution**. The sensitivity of third-generation CT scanners to diagnose SAH is around 92-98%. It has been suggested that fifth-generation equipment has superior sensitivity which would approach 100%.

In some uncommon cases, blood doesn't extravasate into the subarachnoid space but into the brain parenchyma, ventricular system or subdural space instead, causing intracerebral, intraventricular or subdural hemorrhages, respectively. A CT scan can also show false positive results as in cases of diffuse cerebral edema where congestion of the cerebral vessels occurs and appears on the scan as hyperdensity of the basal cisterns. This radiographic finding, called pseudo-subarachnoid hemorrhage, must be considered in the appropriate clinical context.

Magnetic Resonance Imaging

Brain magnetic resonance imaging (MRI) is an important ancillary study in the evaluation of patients with SAH. In MRI, unruptured aneurysms are hypointense on T_1 and T_2-weighted images and FLAIR (fluid attenuated inversion recovery) (Figure 51.2).

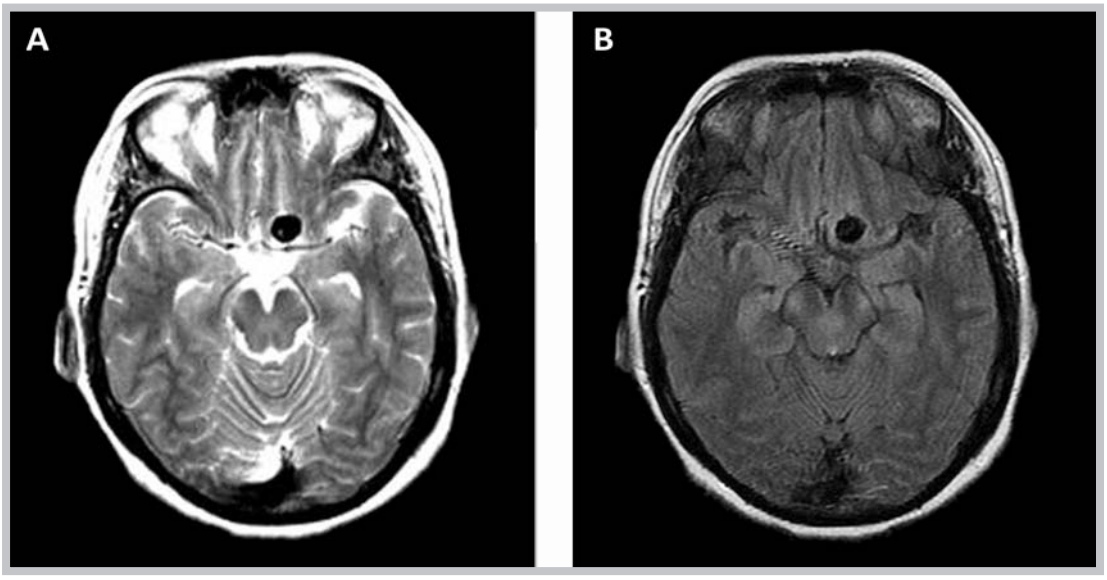

Figure 51.2. **MRI obtained in a patient with an unruptured left internal carotid artery aneurysm. Axial T_2-weighted-image (A) and FLAIR image (B).**

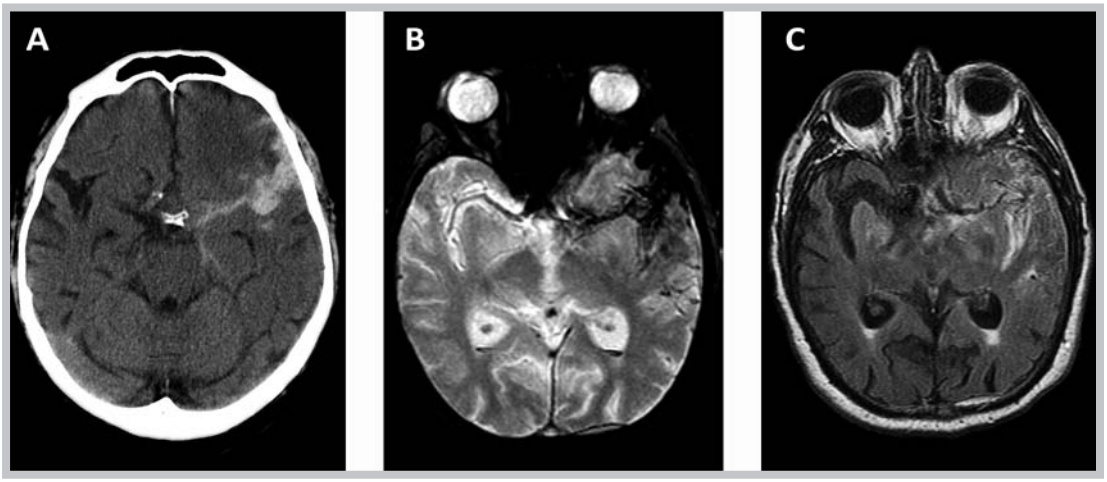

Figure 51.3. **CT images (A) and MRI – GRE sequence (B) and FLAIR sequence (C) – obtained in a patient on day 4 after the rupture of a left middle cerebral artery aneurysm.**

It has been suggested that in the first 5 days, the sequences of proton density and FLAIR are as sensitive as CT for diagnosing the presence of blood in the subarachnoid space. In addition, FLAIR and GRE (gradient echo) sequences can demonstrate the presence of blood after day 4 with a sensitivity of 100% and 85%, respectively (Figure 51.3), a period in which the sensitivity of CT decreases significantly. The undisputed superiority of MRI over CT is that the former can locate not only the aneurysm responsible for SAH but also rule out other etiologies that make up the differential diagnosis, such as tumours or cerebral venous thrombosis which often go completely unnoticed on a CT scan.
MRI requires patients to remain motionless for a considerable amount of time. This limits its use in patients with an altered level of consciousness. In addition, MRI is contraindicated in patients with pacemakers or other implanted metallic devices which are incompatible with magnetic radiation.

Ancillary Angiographic Studies

Ancillary angiographic studies such as magnetic resonance angiography (MRA) and three-dimensional computed angiotomography (CTA) are non-invasive diagnostic mo-

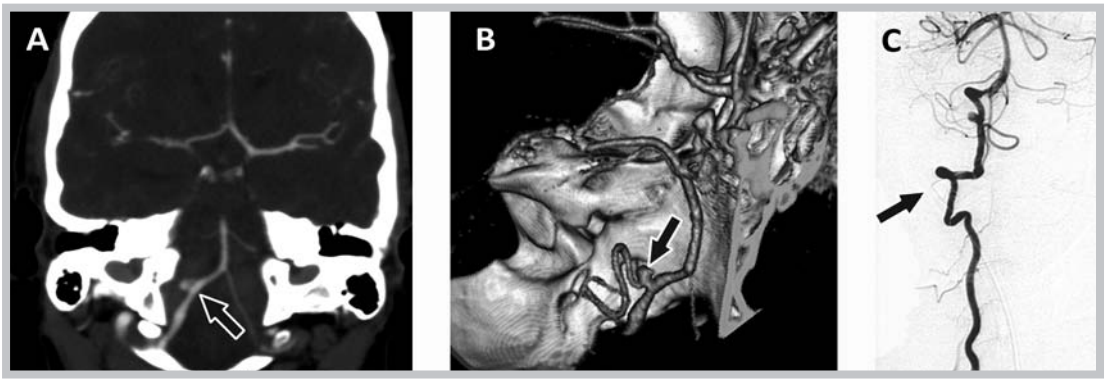

Figure 51.4. **Images obtained in a patient with an aneurysm at the branching of the right postero-inferior cerebellar artery (PICA). A coronal reconstruction obtained by CTA (A), its digital 3D reconstruction (B), and the image obtained by DSA after the injection of contrast material in the right vertebral artery (C). The arrow indicates the location of the aneurysm.**

dalities that allow the identification of the vessel in which the aneurysm originates, the study of its anatomical configuration, and its anatomic relationship with other brain structures. These considerations are of vital importance when choosing the treatment modality (see below).

Three-dimensional computed angiotomography. 3D CTA has considerably evolved recently. To visualize the intracranial vessels, a volume <100 ml of iodine contrast material is injected at a rate of about 4 ml/sec, and the area between the first cervical vertebra and the vertex is scanned. A 3D reconstruction of the intracranial vascular tree is created from the source images. The sensitivity of CTA varies with the size of the aneurysm. Compared to digital subtraction angiography (DSA), considered the gold standard for the detection of cerebral aneurysms, CTA has an average sensitivity of 95% (Figure 51.4). Correct evaluation with CTA will include not only a careful review of the vascular reconstruction but also the source images (Figure 51.5).

Magnetic resonance angiography. The three basic techniques used by MRA for the study of the cerebral vascular tree are the time of flight, phase contrast magnetic resonance angiography, and gadolinium infusion. They allow the visualization of the intracranial vasculature by acquiring two-dimensional or three-dimensional flow-sensitive imaging with background suppression. Three-dimensional images have better resolution and are therefore superior to two-dimensional images. Like CTA, MRA sensitivity

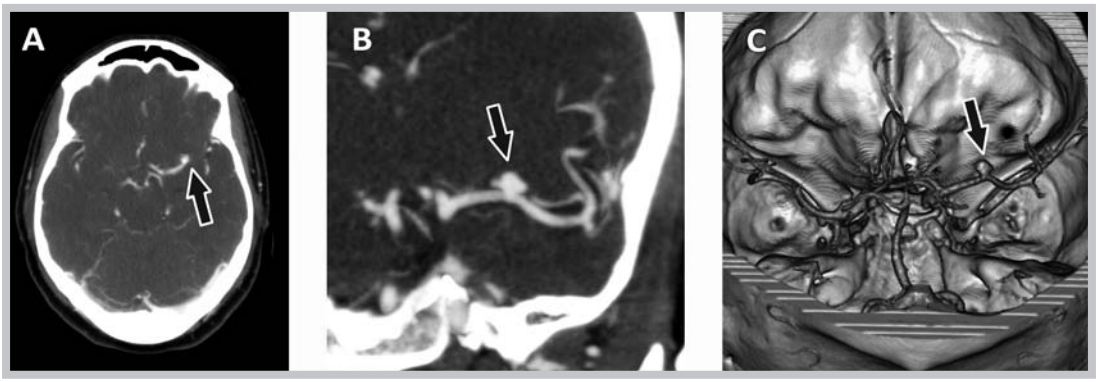

Figure 51.5. **CTA images in a patient with an aneurysm of the left middle cerebral artery. Axial cut from the CTA source images (A), a coronal cut (B), and the digital 3D reconstruction (C). The arrow indicates the location of the aneurysm.**

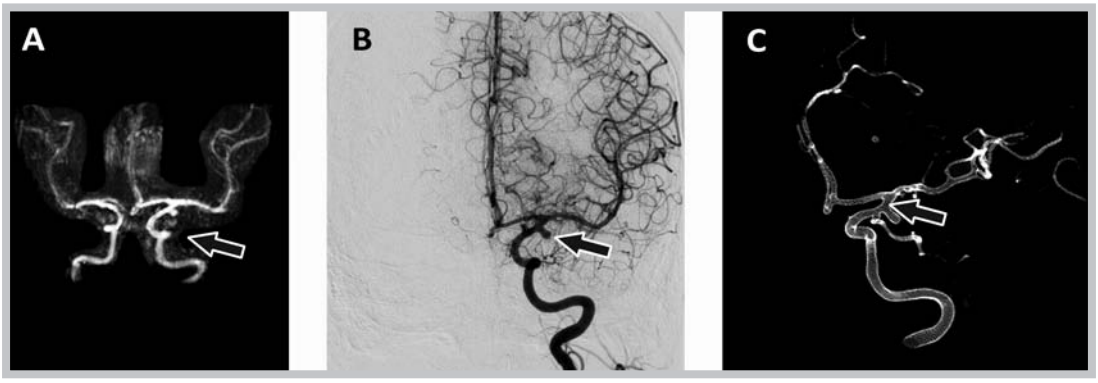

Figure 51.6. **Images obtained in a patient with a left internal carotid artery aneurysm. MRA antero-posterior view after 3D reconstruction (A), DSA after the injection of contrast material in the left internal carotid artery (B), and DSA digital reconstruction (C). The arrow indicates the location of the aneurysm.**

depends on the size of the aneurysm. Compared to digital subtraction angiography, the average sensitivity of MRA is about 90-95% (Figure 51.6). MRA has the advantage of not exposing the patient to the potentially adverse effects of radiation and intravenous iodine contrast. However, the procedure requires the patient to remain motionless for a considerable amount of time, which limits its use in patients with psychomotor agitation. As in CTA, the interpretation of MRA should include a careful review of the vascular reconstruction and source images.

Digital subtraction intra-arterial angiography. DSA is considered the gold standard for detecting aneurysms. It should ideally be done within 24 hours of bleeding and should include the four large vessels (both internal carotid arteries and both vertebral arteries). As a general rule, when multiple aneurysms are observed, the largest, more irregular one is generally considered e the one responsible for the SAH as long as it matches the location suggested by the intracranial bleeding pattern. One of the main advantages of DSA is that, depending on the anatomical features, the same procedure can be used for endovascular treatment (see below). However, the technique is not devoid of potential complications. Its limitations include the use of radiation and contrast material, the risk of transient or permanent ischemic neurological complications, and re-rupture of the aneurysm, which are estimated at around 2% altogether.

Whatever the method chosen to investigate the source of SAH, it should carefully evaluate all cerebral vascular beds, given that up to 15% of patients will have multiple an-

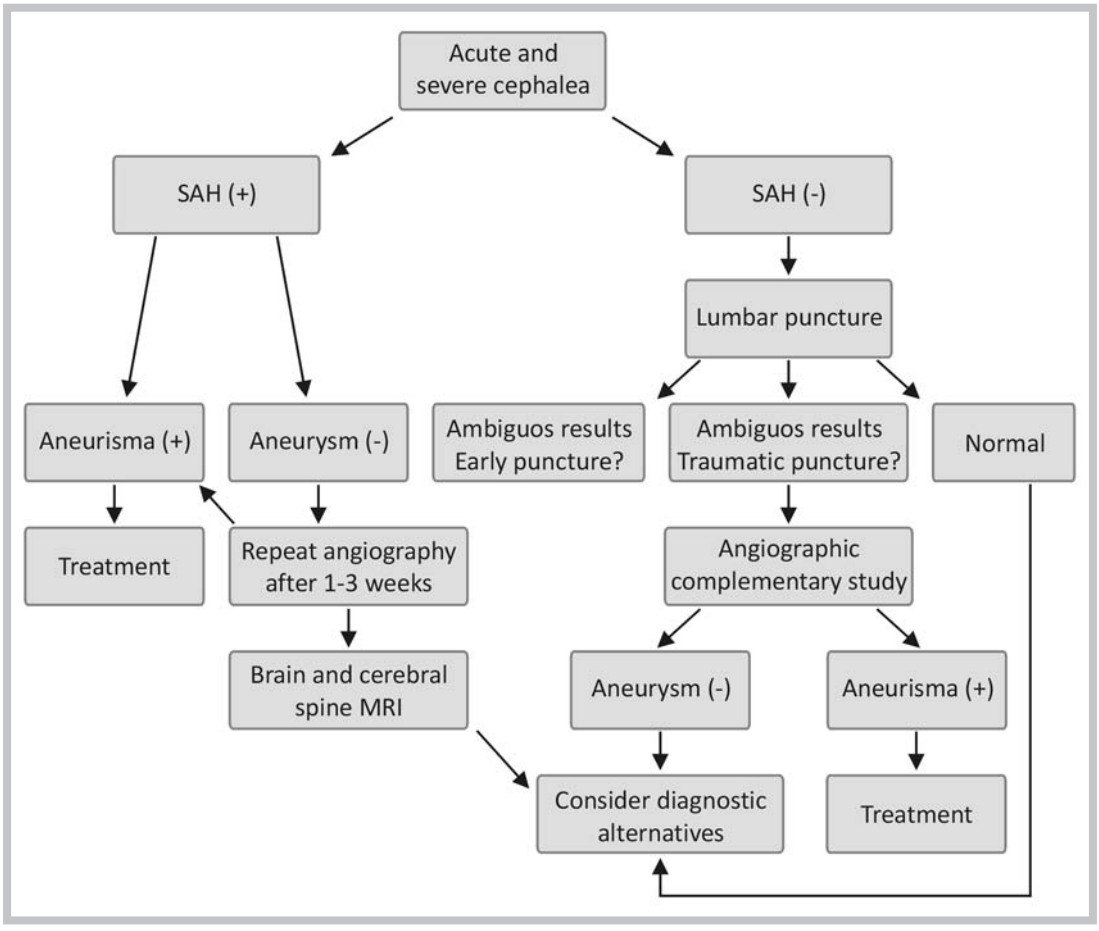

Figure 51.7. Suggested algorithm for the diagnosis of SAH.

eurysms. In those cases where angiographic studies fail to identify the source of the subarachnoid bleeding, we recommend repeating the study in 1 to 2 weeks. If in this instance an aneurysm is not found, an MRI study of the brain and cervical spinal cord should be obtained to investigate the possibility of vascular malformations of the brain, brainstem or spinal cord which may be partially thrombosed and hidden in the angiographic studies. The suggested diagnostic algorithm is shown in Figure 51.7.
Finally, it is important to note that a large percentage of the population over age 50 has small aneurysms (<5 mm) that are found incidentally and do not necessarily require treatment. Therefore, additional angiographic studies must be interpreted within the appropriate clinical context and reserved for the evaluation of patients in which SAH has been diagnosed.

51.3 Treatment and Management

In the approach to management of aneurysmal subarachnoid hemorrhage (SAH), consideration should be given to the clinical grade and initial presentation in each case. Resuscitative measures, airway, breathing and circulation, should be followed emergently with greater attention to unstable patients with worse neurological grades. Typically, all patients with aneurysmal SAH, irrespective of its grade, are admitted to our specialized ICU (Neurocritical Care Unit) where a combination of frequent neurological evaluation in addition to ICU monitoring protocols are instituted. It should be emphasized that patients with a low-grade SAH on presentation may rapidly deteriorate, making frequent neurological evaluation of paramount importance. Once the clinical suspicion of SAH is confirmed by CT or lumbar puncture, initial medical management should follow while diagnostic measures are being carried out. This helps to identify and treat potential medical factors that may contribute to neurological deterioration.
Airway. Low-grade SAH may manifest from a mild depressed mental state to a comatose state and in this setting there is a high risk of respiratory compromise due to poor or absent protective airway reflexes. Other factors that may compromise respiratory function include neurogenic pulmonary edema (discussed below) and trauma after falls due to sudden loss of consciousness or seizures. There should be a low threshold to intubation and initiation of mechanical ventilation in this setting. Attention should be paid to hypercapnia as this may worsen a frequent finding of raised intracranial pressure in this group of patients. Following intubation, anesthetic agents that decrease cerebral metabolism and also assist in blood pressure control such as propofol are reasonable. Other options include midazolam and fentanyl.
Blood pressure control. Most patients with aneurysmal SAH will present with elevated blood pressure due to pain, anxiety and sympathetic activation. A systolic pressure >160 has been associated with rebleeding or re-rupture, with an estimated mortality >50% in this sub-population. Several antihypertensives are available in the ICU setting, however, it is important to recognize the effects of each agent on cerebral autoregulation, predictable dose-response pattern, and safety profile. Continuous infusion of an antihypertensive such as nicardipine, a calcium channel antagonist, is our drug of choice in the initial acute setting, which is titrated to a set blood pressure range. The low end goal is to maintain adequate cerebral perfusion without increasing (high end goal) the risk of re-rupture or worsening intracranial pressure (ICP). Other options include labetalol and esmolol infusions. In cases where the blood pressure are relatively low (140-160 mmHg), intermittent intravenous labetalol and occasionally hydralazine (if there are no concerns of marked ICP elevations) are reasonable options. The use of nitroprusside is usually

avoided in neurological emergencies due to its potential of worsening raised ICP and its toxicity with prolonged infusion, which is sometimes necessary in these clinical settings.

Bed rest. Historically, bed rest in a quiet surrounding has been prescribed in patients with aneurysmal SAH under the assumption that any form of excitement would increase the risk of rebleeding due to surges in blood pressure. In addition to the management of pain and anxiety, it constitutes part of our treatment protocol.

Pain and anxiety. Acute SAH presents as a sudden severe headache and has been described as "the worst headache in my life". Therefore, it seems reasonable that the accompanied surge in catecholamines results in an increase in sympathetic activity with an antecedent rise in blood pressure. In non-intubated patients we have found low-dose opioids (e.g., morphine) to be helpful in this regard. We specifically avoid non-steroidal anti-inflammatory drugs (NSAIDs) due to the increased risk of bleeding from their antiplatelet effect.

Antifibrinolytic therapy. Studies of antifibrinolytic agents, such as epsilon aminocaproic and tranexamic acid, in aneurysmal SAH demonstrated a reduction in rebleeding; however, an increased incidence of thromboembolic events offset any benefit. In the majority of studies, antifibrinolytic agents were used for at least 96 hours. In a Swedish study comparing the use of tranexamic acid initiated within a mean of 4.9 hours from symptom onset, until the aneurysm was secured, and given for <72 hours, the incidence of rebleeding was lower in the treatment group. There was no difference in thromboembolic events or delayed cerebral ischemia in this study. We have occasionally used short-term antifibrinolytic agents in highly selected patients for a short duration if a delay in securing the aneurysm is anticipated as may occur in medically unstable patients or in the long-distance transfer of SAH patients. These agents are then held 6-8 hours prior to securing the ruptured aneurysm. However, our preference is to achieve aneurysm occlusion within 24 hours of symptom onset, obviating the need for antifibrinolytic agents in most cases. It seems that this approach accomplishes the goal of preventing rebleeding and obviates the need for antifibrinolytic agents and their potential complications.

Seizure treatment and prophylaxis. The frequency of seizures after SAH is reported to be 6-20%, with about half of episodes occurring during the perioperative period. Risk factors associated with seizures in retrospective series include middle cerebral artery aneurysm, intraparenchymal or subdural hematoma, cerebral infarcts, thickness of the SAH clot, and hypertension. Often, seizures manifest with rhythmic motor movements and are associated with altered state of consciousness. Persistent loss of consciousness is worrying and should be aggressively evaluated for non-convulsive status epilepticus or raised ICP. We have frequently encountered patients with persistent alterations of consciousness who were reported to have had recurring "seizure-like" events after SAH that were non-epileptic on the electroencephalogram (EEG) and persisted despite adequate anticonvulsant medication. It appears that some of these events may be manifestations of cerebral posturing due to a sudden sustained rise in ICP, known as plateau waves. However, since seizures have been associated with intracranial injury, it is important that they be aggressively treated especially in cases of status epilepticus. The initial management involves the use of benzodiazepine (e.g., lorazepam and diazepam) and an anticonvulsant such as phenytoin or valproic acid. The use of new intravenous agents such as levetiracetam and lacosamide remain adjunct options. When there is no improvement in the level of consciousness or seizures persist, continuous EEG monitoring is a helpful tool for differentiating epileptiform from non-epileptiform events but it should not deter continuing management of status epilepticus. The presence of status epilepticus typically warrants long-term anticonvulsant treatment with outpatient follow up.

In seizure prophylaxis, there have been very few reports suggesting its benefit especially in the long term. There is some concern about worse cognitive outcome at 3 months with phenytoin reported in a few series. The major argument for seizure prophylaxis is that it decreases the risk of rebleeding from an unsecured aneurysm due to a seizure event. This theoretical benefit should be weighed along with the potential long-term effects by selecting patients with the above mentioned risk factors for seizures. When seizure prophylaxis has been instituted, limiting it to a duration of 7-14 day appears reasonable. We have occasionally continued prophylaxis for a longer period in patients with epileptiform discharges on EEG but without seizures and temporal hematoma associated with an middle cerebral artery aneurysm.

Nimodipine. Nimodipine has been demonstrated to improve functional outcome after aneurysmal SAH. It is typically given at doses of 60 mg every 4 h. It can cause hypotension and headache; the hypotensive effects are beneficial in the initial stages when blood pressure control is important. Subsequently, as one nears the vasospasm period when hypotension needs to be avoided, its use becomes challenging. Its benefit appears to be related to cerebral neuroprotection since its effect on vasospasm is minimal. This is further discussed in the section "Vasospasm" below.

Fever. See below.

51.3.1 Surgical and Endovascular Management

Patients with aneurysmal SAH are at an increased risk of re-rupture of the patent aneurysm (3-4% in first 24 h and 1-2% daily for 30 days) with a mortality rate >55%. The definitive approach to preventing further clinical deterioration from re-rupture involves securing the aneurysm via endovascular coiling or surgical clipping. Several studies have suggested that an increased time to securing a ruptured aneurysm increases the risk of rebleeding. However, in the International Cooperative Study on the Timing of Aneurysm Surgery, the overall outcome was not significant. Our approach is to secure the aneurysm as soon as possible with either surgical or endovascular techniques. In our opinion, this allows for easier management of vasospasm, a known and common complication of aneurysmal SAH.

The advent of endovascular treatment of intracerebral aneurysms with detachable coils has complemented and in some situations replaced surgical clipping in securing a ruptured aneurysm. The decision on which method of securing the aneurysm depends on several factors such as patient age, clinical grade, location (anterior vs. posterior circulation), aneurysm size and morphology, presence of other vascular injuries (e.g., intracerebral or subdural hematoma), procedural efficacy and facility-specific characteristics (availability of technical and infrastructure support).

Endovascular Management

This treatment technique involves deploying platinum coils through microcatheters into an aneurysm with the goal of achieving complete obliteration and prevent future rebleeding. This relatively minor invasive approach to treatment has made coiling a more attractive technique in securing aneurysms. The effectiveness of the procedure in the treatment of ruptured aneurysm can be measured by the procedural efficacy (rebleed rate and angiographic recurrence rate of a treated aneurysm). Comparison with surgical clipping in the International Subarachnoid Aneurysm Trial (ISAT) found a relative risk reduction of death or dependency by 23.9% at 1 year in the endovascular group. However, the rebleed rate at 1 year in the endovascular group was 2.9% vs. 0.9% in the surgical clipping group. The long-term outcome in this study, (mean follow-up, 9 years), suggest-

ed a non-significant increase in rebleed rate in the endovascular group. Murayama et al., in a series with a follow-up of over 11 years, reported that 55% of aneurysms treated with endovascular coiling could be completely occluded. The factors affecting incomplete occlusion and recurrence were aneurysm size and shape. It is important to note that aneurysm size and shape were also identified as predictors of rebleeding.

An anticipatory approach to the care of patients prior to an endovascular procedure is critical. Attention should be paid to adequate airway and ventilation management, blood pressure control, avoiding anesthetic agents (e.g., ketamine) and hypercapnia that may increase intracranial pressure. If an ICP monitor is already in place, close monitoring of ICP changes and especially the ICP waveform as a predictor of intracranial compliance and peri-procedural complication is informative. In the absence of an ICP monitor, sudden blood pressure spikes or evidence of procedural aneurysmal rupture may present an emergent need for placement of an ICP monitor with external CSF diversion. Other medical measures in treating raised ICP with hyperosmolar agents (mannitol, hypertonic saline), sedative anesthetic (benzodiazepine, barbiturates) may be considered in refractory elevated ICP. In some cases, the need for stent placement in an attempt at vascular reconstruction while securing an aneurysm may arise. In this circumstance, the subsequent need for antiplatelet therapy makes this an important determining factor in the timing of invasive procedures such as placement of external ventricular drains (EVD). Also of interest is the development of intra-arterial thromboembolism during endovascular coiling. Several case series have reported treatment of this complication with a glycoprotein IIb-IIIa antagonist such as abciximab with relative good outcomes. The frequency of aneurysmal rebleed and primary intracerebral hemorrhage in these series has been low, though hemorrhagic conversion of a cerebral ischemic lesion has been described. These patients should be monitored closely for neurological deterioration.

The selection of patients for endovascular coiling is therefore important so as to optimize benefit and reduce the above mentioned risk following treatment. In the ISAT study, the mean age was 52 years with older patients (>70 years) preferably undergoing endovascular coiling due to the higher surgical risk. For the same reason, we typically will consider endovascular treatment for patients older than 50 years, especially in

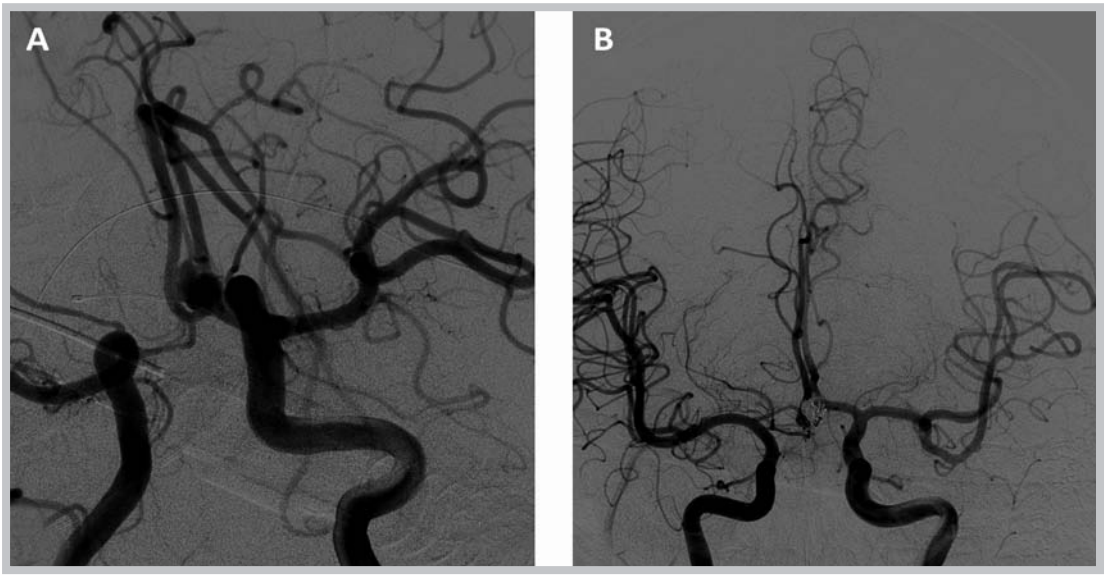

Figure 51.8. Cerebral DSA showing an aneurysm of the anterior communicating artery (A). Cerebral DSA immediately after endovascular occlusion of the aneurysm with platinum coils (B).

a setting of multiple medical conditions that preclude surgical clipping. Other features that are optimal for endovascular coiling include: aneurysms in the cavernous segment of the internal carotid artery aneurysm, internal carotid artery and posterior circulation (e.g., basilar tip), aneurysm neck diameter <5 mm, and a neck diameter to largest aneurysm dimension ratio <0.5.

In recent years, following the publication of the ISAT study, endovascular treatment of intracranial aneurysms has gained wider acceptance. Techniques and materials have improved significantly, so that wide-necked aneurysms which were once impossible to embolise can today be occluded with the help of balloons or stents (balloon-assisted coiling, stent-assisted coiling). However, the largest concern is the fact that on subsequent follow-up angiography some of the endovascular-treated aneurysms have grown due to initial incomplete filling of the aneurysm sac or have compacted coils in the dome of the aneurysm as a result of the water hammer effect generated by pulsatile blood flow allowing the neck to eventually grow and increase the risk of a re-rupture. This means that a significant proportion of these aneurysms require retreatment by adding more coils (with the risk associated with this new procedure). A slightly increased risk of re-rupture of coiled aneurysms when compared with surgically clipped ones has also been reported.

Surgical Management

Cerebrospinal fluid diversion and aneurysmal clipping are the main surgical treatments of intracranial aneurysms. The use of CSF diversion techniques is important at different stages in the treatment of aneurysmal SAH. At initial presentation, poor-grade SAH may be secondary to acute hydrocephalus requiring emergent ventriculostomy. Other CSF diversion techniques are typically reserved for late complications of SAH (discussed below). Though surgical clipping is a more invasive procedure, it accomplishes complete obliteration of the aneurysm in 91.8% of cases.

Ventriculostomy. This procedure involves the placement of a soft catheter into the ventricle to allow ICP measurement and CSF drainage. This can be done at the bedside or in the operating room during surgical clipping of the aneurysm. The benefit of an external ventricular drain stems from the experience that not all poor-grade SAH are immediately catastrophic due to complete cerebral circulatory arrest. Some 20-30% of patients with aneurysmal SAH have acute hydrocephalus and may manifest as poor-grade SAH. We emergently place an EVD in all our poor-grade patients to measure and relieve the intracranial pressure via cautious CSF drainage. This improves the clinical grade of some patients and thus decreases mortality. Acute deterioration from a good grade SAH may also result from acute hydrocephalus and is clinically suggested by worsening mental status, upgaze palsy, slow pupillary response, bilateral 6th cranial nerve palsy and bilateral lower extremity spasticity. Hence, the indications for an EVD in aneurysmal SAH are hydrocephalus, intraventricular hemorrhage, and poor-grade SAH. A theoretical advantage has been suggested in placing an EVD in patients with large amounts of SAH. Clearing of the bloody CSF may decrease the severity of vasospasm, but this remains to be proven clinically. When we use this approach, it is not done at the expense of increasing the risk of infection due to prolonged EVD use. Opponents to this theory suggest that the CSF drained is primarily from the ventricles where it is produced, thereby discouraging drainage of subarachnoid blood in the cisterns via their natural pathways.

As with every procedure in the intensive care unit, EVD insertion carries risks – aneurysmal rebleeding, infection (ventriculitis), and intracerebral hemorrhage. Theoretically, the concern about aneurysmal rebleeding is due to relieving the tamponade effect of elevated ICP on the transmural wall pressure of the aneurysm. Our practice has been to set a high pressure CSF drainage level (e.g., 20-25 mmHg) to avoid this complication in

patients with unsecured aneurysms while preserving cerebral perfusion pressure. Placing an EVD under strict sterile technique, maintaining a closed system, and timely decision on removing the EVD are important factors that help in minimizing infection. Other preventive measures include the use of antibiotic-coated catheters or antibiotic prophylaxis (e.g., cefazolin 1 g/8 h or clindamycin in patients with penicillin allergy) which are continued for the duration of the EVD. This, however, is a controversial issue: it decreases the rate of ventriculostomy-associated infections but increases the incidence of methicillin-resistant Staphylococcus aureus (MRSA) and Gram-negative infections. However, we have found daily CSF surveillance for glucose, protein, cell count, gram stain and culture to be helpful. A low glucose level with or without CSF positive cultures is highly suspicious of CSF bacterial infection. Prompt removal of the EVD and broad-spectrum antibiotics are our initial aggressive approach. Intracerebral hemorrhage complicating EVD insertion is commonly seen in the setting of an underlying coagulopathy, rupture of a bridging vein or cortical vessel and multiple passes or attempts to drain the ventricles. In non-emergent circumstances, we aim to correct the underlying coagulopathy or thrombocytopenia (INR <1.4 and platelet >100,000/µl) prior to inserting an EVD. In the case of an emergency EVD, we have found transfusing with fresh frozen plasma and/or platelets, as required before, during and after the procedure, to be helpful in reducing these complications. Factor VII could also be an option in these settings, but the cost limits its availability in some centres.

Surgical clipping. This surgical procedure accomplishes a higher rate of aneurysm obliteration as compared to endovascular repair and hence less need for re-exploration of the aneurysm. In the ISAT study, surgical clipping demonstrated a lower rebleed rate compared to aneurysm coiling. Also, the study showed that the need for retreatment of the aneurysm persisted in the long term after coiling as opposed to surgical clipping. It appears that surgical clipping was more beneficial in younger patients and larger lumen aneurysms. Among these features, other patient or aneurysm characteristics that favour surgical clipping include middle cerebral artery aneurysm, very small or large to giant aneurysms, wide neck aneurysm, associated intracerebral hemorrhage or parenchymal hematoma, and failed endovascular coiling. Despite the apparent advantage in securing a ruptured aneurysm, not all patients are eligible for surgical treatment. Relative exclusion criteria include poor clinical grade or complicated medical history, severe diffuse brain swelling that limits retraction during surgery, posterior circulation aneurysms due to their technically difficult access.

Another advantage of surgical clipping is the ability to create an internal CSF diversion by fenestration of the lamina terminalis during the surgical procedure. Some case series have suggested a decrease in the incidence of chronic hydrocephalus requiring a CSF shunt after this procedure. Uncommonly, decompressive craniectomy may be offered in the setting of severe diffuse cerebra edema, especially when there is associated intracerebral hemorrhage.

Post-operative care is geared towards:

- Detection of intracranial bleeding after surgery (intra-or extra-axial).
- Monitoring of specific complications of aneurysms, such as the development of diabetes insipidus after surgical clipping of anterior communicating artery aneurysms secondary to occlusion of hypothalamic perforating arteries or the detection of lower cranial nerve palsy associated with surgery for aneurysms of the posterior circulation.
- Early detection of brain, cerebellar or brainstem infarctions associated with the surgical procedure (particularly associated with the clipping of aneurysms of the middle cerebral artery, anterior cerebral, posterior inferior cerebellar and basilar artery aneurysms).

- Occurrence of seizures in the postoperative period and disturbances in the level of consciousness secondary to non-convulsive epilepsy.
- Development of cerebral edema or venous infarction associated with handling and surgical retraction.

Our practice is to control blood pressure with intravenous antihypertensives for the next 24-36 hours after the exclusion of the aneurysm. Subsequently, tight blood pressure control is relaxed as part of the preventive measures of vasospasm associated with aneurysmal SAH. Intubated patients are left on mechanical ventilation with short-acting sedatives for 24 hours; the ventilator is turned off for intermittent neurological evaluation.

51.3.2 Medical Management After Initial Aneurysm Treatment

Once a ruptured aneurysm is secured, the focus on medical management holds significant importance. The incidence of medical complications of aneurysmal SAH (23%) equals the rebleeding and vasospasm rates (23% and 22%, respectively). Our approach in this setting is guided by the principles of anticipating and preventing delayed cerebral ischemia due to vasospasm, with the management of medical complications peculiar to specific aneurysms (e.g., diabetes insipidus in anterior communicating artery aneurysm) and distinguishing neurological deterioration as a primary event or as a secondary manifestation (e.g., encephalopathy due to fever, hyponatremia, hypo- or hyperglycemia).

Fluid management. An important aspect of aneurysmal SAH management involves close attention to intravascular volume status. Following invasive procedures, especially with endovascular coiling, significant diuresis has been observed due to injection of contrast dye, with the concern that vasospasm may be worsened in the dehydrated state. Thus, close attention to periprocedural fluid balance is helpful in maintaining and responding to changes in intravascular volume. Ideally, strict intake-output monitoring should be instituted at admission. We have also found daily weight measurement to be helpful especially in some settings, as this also accounts for insensible losses over time. The goal is to maintain a slightly positive balance (500 ml) and if a central venous line is available, a central venous pressure (CVP) of 4-8 mmHg. Obviously, this approach should be adjusted in patients with cardiopulmonary dysfunction. We have found that placing a CVP monitor in this subgroup of patient is helpful, however, the timing should be such that it coincides with the period of vasospasm. Our choice of intravenous fluid is normal saline used at a standard infusion dose of 100-125 ml/h, suited to the conditions and requirements of a particular patient. This is also reasonable in patients with cerebral edema, as the main objective in these cases is to try to maintain a normal serum sodium level, while avoiding hyponatremia. We avoid the use of any hypotonic solution, except for enteral feeding usually supplemented with doses of saline (100-200 ml bolus every 4-6 h via gastric tube) or salt tablets (NaCl) by the same route.

Maintaining a “slightly wet state” has been routine practice in the management of SAH in recent years. We recognize that in patients with poor or borderline cardiorespiratory status this approach may increase the rate of complications such as pulmonary edema or difficulty in weaning off mechanical ventilation. Obviously, this policy must be tailored to this group of patients.

Electrolyte abnormalities. Electrolyte abnormalities are common in several clinical series. They may result in encephalopathy, or even cerebral edema in the case of hyponatremia. Hyponatremia is seen in 20-40% of patients and may result from the syndrome of inappropriate ADH secretion (SIADH) or cerebral salt wasting (CSW). Although

CSW and SIADH are viewed as distinct syndromes, it is our opinion that the two lie on a spectrum of sodium metabolism abnormalities in SAH. The presence of hyponatremia, increased urine sodium and hypovolemia usually suggests CSW. It appears that an increase in atrial and brain naturietic peptide after SAH may play a pathophysiological role in CSW. We have found CSW to be more common in SAH and that it heralds vasospasm; very rarely do we encounter isolated SIADH in our patient population. Some series have reported an early dilutional hyponatremia due to an observed surge in arginine vasopressin resulting in retention of free water. The hyponatremia of CSW can be treated with hypertonic saline infusions, fludrocortisone or oral salt tablets. Importantly, the associated diuresis should be replaced as it may lead to dehydration which is associated with cerebral hypoperfusion in cases of severe vasospasm. In a setting of SIADH, the challenge is to avert intravascular volume contraction. Hypomagnesemia is frequently seen, and aggressive correction has been investigated in several studies in an attempt to prevent vasospasm and delayed cerebral ischemia. The results have been conflicting. The rationale for this approach is the experimental demonstration of increased intracellular calcium associated with neurotoxicity ischemia and cell death; magnesium, a natural calcium antagonist, is thought to inhibit these cellular mechanisms. In a recent serie, a decrease in vasospasm was observed but no significant benefit with aggressive supplementation. Our approach continues to be to normalize the levels to the upper limit of the normal reference range (>2.0 mg/dl).

Hypernatremia occurs in such settings as: iatrogenic effect of hypertonic saline solution for managing intracranial hypertension and diabetes insipidus associated with severe diffuse brain damage (usually in the context of a very poor-grade SAH) or immediately after treatment of an anterior communicating artery aneurysm with compromise of the perforating vessels that supply the hypothalamus. Judicious use of hypotonic solutions, strict monitoring of serum sodium values, and potential use of desmopressin (DDAVP) needs to be evaluated in each case. In cases of diabetes insipidus, because severe dehydration can happen in some patients, it needs to be recognized immediately and treated aggressively with appropriate fluid replacement.

Fever. In most circumstances, the definition of fever as a temperature >38.5°C is reasonable but should not lead to complacency in aggressive management of low-grade fever which may manifest as encephalopathy or progressive neurological worsening. Evaluating for infectious and non-infectious causes allows for thorough assessment and appropriate intervention. Non-infectious causes to be considered include vasospasm, atelectasis, venous thromboembolism and transfusion-related reactions. The importance of prompt identification and treatment stems from the impact of fever on acute brain injury which includes altered mental status (encephalopathy), increased oxygen consumption causing an increased metabolic strain on injured neuronal and glial tissue, ischemic injury and worsening of cerebral edema leading to increased intracranial pressure. We have employed common physical (e.g., cooling blankets and Bair hugger cooling system) means and pharmacological agents (acetaminophen) with a goal temperature of <37.5°C. Of concern is the role of shivering in patients at risk of elevated intracranial pressure. Low doses of fentanyl have been helpful in our patient population. In cases were sedation is employed, propofol has been a helpful option. Rarely if ever should muscle relaxant be considered due to the increased incidence of critical illness neuropathy and myopathy.

In recent years the use of more sophisticated cooling methods such as intravascular catheters and contact cooling systems has increased and has proved to be a more effective and easy way to maintain temperature within the desired range and also allow optimization of gradual warming in cases where hypothermia is applied. In summary, strict temperature control and manipulation within the normal or desired range is one of the

current key interventions (and not so hard to achieve) that could prevent or ameliorate ischemic damage and progression of cerebral edema.

The diagnosis of fever of central origin is one of exclusion and can be established only when all other causes have been excluded. It is relatively common, usually overdiagnosed, and the danger is to by-pass treatable causes of fever. It is generally associated with severe brain damage or hypothalamic lesions.

Infections. Apart from being an important cause of fever, infections are a potential cause of increased length of ICU stay, morbidity and mortality in SAH. Common infections seen in SAH patients include pneumonia, urinary tract infections, bloodstream infections, meningitis and ventriculitis (see above). It appears that infections in SAH patients are more common in those with a central venous catheter, under mechanical ventilation or with a ventricular drain for intraventricular hemorrhage. It is believed that the heightened inflammatory response that follows infections also worsens the inflammatory component of cerebral vasospasm after aneurysmal SAH. Except for patients with EVD where we employ CSF surveillance, we do not conduct routine surveillance for other infections, relying more on the clinical picture of fever, increased sputum production or discoloration in ventilated patients, elevated white blood cell count and infiltrates on chest X-ray. Initial broad-spectrum antibiotic therapy is reasonable when subsequently narrowed to microbiological sensitivity results.

Anemia. It seems that there is a direct effect of SAH on red blood cell production, possibly related to increased cytokine production. Other possible factors include frequent phlebotomies, complications of invasive procedures and hemodilution from intravenous fluid infusions. The definition of anemia requiring transfusion has varied in different series and is controversial due to reports of poor outcome in SAH patients receiving transfusion and an increased risk of vasospasm. The reason for a poor outcome is unclear, though it is possible that patients who received blood transfusion were severely ill patients. Another consideration is the depleted nitric oxide (NO) content of packed red blood cells (PRBC). Nitric oxide is a potent vasodilator and may have a significant role in reversing vasospasm hence PRBC transfusion may decrease circulating NO concentration, with decreased end-organ perfusion by the microcirculation. Also, older PRBCs have proinflammatory properties and so may exacerbate the inflammatory component of vasospasm.

Despite these proposed drawbacks of blood transfusion in SAH patients, reports from recent studies suggest that low brain tissue oxygen and cellular energy dysfunction (lactate/pyruvate ratio >40) has been correlated with hemoglobin (Hb) <9 g/dl; however, the effects on functional outcome are unknown. Transfusion of PRBC in patients with Hb <7 g/dl has been our practice. In the 7-10 g/dl population, our decisions are driven by factors such as cardiac disease with evidence of dysfunction or impending failure, need for volume expansion with an added effect of increasing tissue oxygen delivery and the presence of vasospasm or risk of cerebral ischemia.

Hyperglycemia. The adverse effect of hyperglycemia on neuronal function in the clinical setting of acute brain injury is known, as has been observed in acute ischemic stroke, traumatic brain injury and in several series of aneurysmal SAH. In one series, blood glucose >200 mg/dl was a significant predictor of poor functional outcome in acute ischemic stroke and SAH. Other smaller series have shown hyperglycemia to be associated with an increased risk of symptomatic vasospasm and rebleeding in SAH patients. What constitutes an acceptable range for blood glucose has been the subject of debate based on studies on intensive insulin therapy due to concerns of severe hypoglycemia. The relationship between hyperglycemia and poor functional outcome appears to be independent of a history of diabetes mellitus in brain-injured patients in some series. In acute ischemic stroke studies, a worse functional outcome was observed in hyperglyce-

mic non-diabetic patients compared to diabetic patients. Also, in series involving SAH populations, the correlation of hyperglycemia and poor functional outcome was independent of factors that predicted hyperglycemia, such as diabetes mellitus. Hyperglycemia in these circumstances may be one part of a general stress response to the primary brain injury. The effects of the stress response leading to an increased sympathetic nervous system response as well as increases in stress hormones such as corticosteroids, glucagon and somatotropin may play an additional role in stress-induced hyperglycemia. However, despite the benefit of tight glycemic control, a common complication, hypoglycemia is likely to lead to significant neuronal dysfunction and may result in seizures and ischemia. This is based on observations using microdialysis techniques demonstrating critical decreases in cerebral glucose, an elevated lactate/pyruvate ratio, and cerebral glycerol (a marker of tissue damage or cellular distress) levels with normalization of hyperglycemia to a target of 140 mg/dl. Clinical studies have also identified hypoglycemia <60 mg/dl as an independent predictor of mortality at discharge. So far, all these point to a possible and significant detrimental effect of aggressive and tight glucose control in a subpopulation of patients with acute brain injury who may actually tolerate and benefit from a higher serum glucose level as compared to non-brain injured patients. Our approach is to institute aggressive treatment of blood glucose >180 mg/dl, starting at a low titration regimen. Where needed, conversion to a longer-acting insulin regimen is considered once clinical stability has improved and before discharge from the ICU.

Deep venous thrombosis. In the presence of focal weakness due to neurological injury, the incidence of deep venous thrombosis (DVT) appears to be higher in neurocritically ill patients. The use of prophylactic antithrombotic agents is complicated by the relatively increased risk of intracranial hemorrhage. Clearly, all antithrombotics should be avoided in the setting of acute SAH until the aneurysm is secured. This also applies to postsurgical patients for the first 24 hours, after which the decision to reinstate antithrombotic agents should be entertained. Heparin given at a dose of 5000 units twice a day has been our initial approach for the first few days, which is then advanced to an 8-hourly regimen as stability in hemorrhage is demonstrated. In addition, weekly venous duplex surveillance of the lower extremities is part of our routine practice. In our opinion, this offers an opportunity for aggressive treatment of progressive distal or proximal DVT. If proximal DVT is documented in the lower extremities and the patient has a contraindication to systemic anticoagulation (such as very recent bleeding, presence of intracerebral or extra-axial hemorrhage, presence of a fresh ventriculostomy, severe hypertension induced as part of vasospasm treatment), we proceed to the placement of a retrievable inferior vena cava filter with the idea that it will probably be safe to start anticoagulation later on and eventually remove the filter. In patients with distal DVTs of the lower extremities (below the popliteal vein), the treatment possibilities include systemic anticoagulation, inferior vena cava filter placement or venous duplex follow-up every 3 or 4 days (without treatment) to exclude the spread to more proximal veins. If this occurs, it should be treated like any proximal DVT.

Pulmonary complications. This represents a common complication in up to 80% of SAH patients and correlates with an increased ICU length of stay and poor functional outcome (impact on functional outcome varies in different series depending on whether neurological outcome was a main measure or not). Frequently encountered pulmonary complications include pneumonia, pulmonary edema, pneumothorax, transfusion-induced acute lung injury and pulmonary embolism. Pneumonia is observed more in aspiration due to poor airway control due to encephalopathy, ventilated patients or lung seeding from bacteremia. Pulmonary edema is commonly a result of fluid overload. Occasionally, one may come across patients who develop tachypnoea, hypoxia and bilateral pulmonary infiltrates, which raise the suspicion of neurogenic pulmonary edema. This

usually follows an acute neurological insult such as SAH, head injury, intracerebral hemorrhage, and seizures with or without status epilepticus. There may be pulmonary shunting, however, the electrocardiogram, echocardiogram and central venous pressures may be normal. Two possible theories have been linked to this phenomenon. One states that there is a sudden increase in sympathetic tone following an acute neurologic insult inducing pulmonary vasoconstriction due to massive catecholamine release with subsequent alteration of the Starling forces in the lungs with a resultant shift of fluid into the pulmonary alveoli. The second theory suggests an increase in inflammatory mediators that damage the endothelium, leading to abnormal capillary permeability. Fluid overload may also lead to pulmonary edema, which commonly occurs in patients with poor cardiac function and or overzealous fluid resuscitation during treatment for vasospasm. Management in both circumstances requires close attention to maintaining adequate ventilation with invasive or non-invasive methods depending on the severity of the respiratory insufficiency, avoiding manoeuvres that decrease cerebral perfusion pressures such as high positive end-expiratory pressures. Administration of intravenous fluids or several doses of volume expanders (e.g., albumin) for a few hours with cautious diuresis using low doses of diuretics have been helpful in our experience. It is important to note that dehydration worsens ischemia due to vasospasm so that in this setting maintaining an adequate intravascular volume is highly important. Hence, small doses of diuretics (e.g., furosemide 10 mg intravenously) given ever so often, while carefully monitoring the input-output balance has been our approach. The use of central venous pressure monitoring is helpful in directing diagnosis and treatment in these dicey situations.

The frequency of pulmonary embolism in neurologically ill patients is relatively low (0.3%) but can be devastating, nonetheless.

The treatment of pulmonary embolism often becomes a complex decision, particularly in the presence of a fresh external ventricular drainage, very recent bleeding, intracerebral or extra-axial hemorrhage or patients with vasospasm and severe induced hypertension, since the risks of bleeding in the context of systemic anticoagulation are quite high. Our practice in such circumstances has been to place an inferior vena cava filter until it is safe to start anticoagulation. In some cases, we have started continuous intravenous anticoagulation with heparin at low doses in order to obtain an activated partial thromboplastin time (aPTT) 1½ times above the patient's baseline aPTT (we don't use a bolus dose of heparin) for the following 36-48 hours. If the patient is neurologically stable, we repeat a head CT without contrast material to monitor the presence of asymptomatic intracranial bleeding. If there is not new bleeding, we then slowly increase the heparin dose to achieve the ideal aPTT in the following 24-36 hours. A new head CT is performed to rule out bleeding and if the patient remains stable, we start a low-dose oral anticoagulant, trying not to exceed the ideal prothrombin time for that patient. Of course, if the patient develops a new bleeding, heparin is stopped immediately, and emergent reversal with protamine is considered.

Cardiac complications. The effect of acute intracranial insults on cardiac function appear to be multifactorial, with instability of the autonomic function a proposed mechanism. Several reports in the epilepsy literature have described cardiac arrhythmia following discharge from epileptic foci in the brain. The same has been observed in acute ischemic and hemorrhagic strokes and commonly reported to involve the insula and parieto-temporal cortex. Similar observations have been made with a vast array of electrocardiographic abnormalities observed in up to 92% of SAH patients. These include ST segment alterations (15-67%), T wave changes (12-92%), prominent U waves (4-52%), QT prolongation (11-66%), conduction abnormalities (7.5%), sinus bradycardia (16%) and sinus tachycardia (8.5%). Life-threatening arrhythmias are less common and are mostly supraventricular tachyarrhythmias associated with older age, prior history of an ar-

rhythmia, hyperglycemia, brainstem herniation and myocardial infarction. Management of arrhythmias should follow typical measures with caution in the setting of cerebral edema and vasospasm to avoid hypotensive events that would compromise cerebral perfusion or lead to delayed cerebral ischemia (DCI). Following acute aneurysmal SAH, there has been reports of a marked elevation of endogenous catecholamines from the cardiac sympathetic nerves leading to a syndrome described as neurogenic stunned myocardium. The clinical syndrome is characterized by tachycardia, elevated troponin I, transient lactic acidosis, diffuse T-wave inversions, prolonged QT interval, reversible left ventricular wall abnormalities, pulmonary edema and cardiogenic shock. This neurogenic stunned myocardium is associated with a wide spectrum of reversible left ventricular wall motion abnormalities and includes a subset of patients with a typical pattern of apical akinesia and concomitant sparing of basal segments called "tako-tsubo cardiomyopathy". It is important to emphasize that most of these stress-related scenarios are eventually reversibly. Poor clinical grade, advanced age, prior use of cocaine and amphetamines have been described as risk factors for neurogenic stunned myocardium. We have consistently observed tachycardia and elevated troponin levels with this syndrome. Though elevated cardiac enzymes is a common finding in SAH, occurring in 68% of patients in one series, it appears that these findings, along with abnormalities on electrocardiography and echocardiography, were associated with delayed cerebral ischemia, poor outcome and death at 6 months. The interplay between acute brain injury and secondary cardiac injury such as neurogenic stunned myocardium becomes complicated in attempts at decreasing the effects of vasospasm after SAH. In cases where there is a need to augment intravascular volume and cerebral perfusion, we have typically leaned towards preserving brain function while closely monitoring cardiac functions with serial cardiac enzymes, electrocardiogram and echocardiograms. We have also found measuring central venous pressures and non-invasive cardiac index monitoring a reasonable and reliable substitute to placing pulmonary artery catheters. It is our routine practice to obtain a baseline transthoracic echocardiogram within 48 hours of admission to assess the patient's cardiac anatomy and function, as probably a third or more of patients with SAH may need adjustment of the hemodynamic status at some point in their course. Early knowledge of situations such as low baseline ejection fraction, severe left ventricular hypertrophy or hypertrophic stenosis of the outflow tract of the left ventricle is essential when selecting the drugs to be used for manipulation of the hemodynamics in these patients.

Hydrocephalus and the need for long-term CSF shunt. The management of acute hydrocephalus has been discussed earlier. This section addresses the 18-26% of patients who will ultimately require permanent CSF shunting due to subacute or chronic hydrocephalus (3-7 days and >1 week, respectively). Predicting these patients may sometimes be difficult, with some series suggesting advanced age, ventriculomegaly, intraventricular hemorrhage, poor clinical grade and female sex as possible associated factors. It seems reasonable to assume that the development of hydrocephalus after SAH is related to the presence of blood. Studies on animal models of hydrocephalus show an increase in intracranial pressure following the injection of blood into the subarachnoid space as opposed to saline. However, chronic hydrocephalus has also been associated with decreased CSF outflow from the fourth ventricle and/or compromised resorption of CSF through the arachnoid villi from fibrin deposition in these structures, since instillation of heparinised blood only results in a transient rise in intracranial pressure. However, the subsequent development of chronic hydrocephalus may be a result of an interplay between these two processes. SAH from posterior circulation aneurysms is associated with a higher incidence of hydrocephalus than anterior circulation aneurysmal rupture, possibly due to fibrin deposition in the fourth ventricular outflow and it may be the primary factor in chronic hydrocephalus. The diagnosis of chronic hydrocephalus

is based on clinical and radiological grounds. Clinical features include worsening mental status, which may be slow and progressive, bilateral sixth cranial nerve palsy and upgaze restriction. The presence of progressive ventriculomegaly on imaging studies supports the diagnosis. If an EVD was inserted during admission, a diagnosis of hydrocephalus is also possible during the weaning process of the EVD. This is evidenced by monitoring the CSF volume and ICP as the "pop-off" pressure is increased, rising CSF drainage volume output and ICP, with each increase in pop-off predicting a need for internalization of CSF drainage. Another tool is measuring the bicaudate index – a ratio of the width of the frontal horns at the level of caudate nuclei and the diameter of the brain at the same level. Reference ranges vary by age but are usually between 0.16-0.21

When we consider that the patient can begin weaning off the ventriculostomy, we do it gradually by increasing the opening pressure at a rate of about 5 mmHg per day (for example, if the ventriculostomy was opened at 10 mmHg, now we increase it to 15 mmHg and 24 hours later to 20 mmHg, etc.). During this dynamic process, we carefully watch for the presence of:

- Signs of neurological impairment (usually manifesting as impaired consciousness, sometimes subtle upward vertical gaze impairment and/or increased extensor tone of the lower limbs).
- Headache as a new manifestation or a significant increase in its intensity.
- Increased intracranial pressure.
- Ventricular enlargement on head CT as measured by the bicaudate index (a ratio of the width of the frontal horns of the lateral ventricles at the level of the caudate and the diameter of the brain at the same level). The ranges vary according to age.

If none of the above occurs, then we close the ventriculostomy and observe the patient; a new head CT is performed 24-48 hours later, and then we decide whether the ventriculostomy can be discontinued. Some other schools have a more aggressive policy for ventriculostomy weaning, placing many more permanent CSF shunts (a ventriculoperitoneal shunt in general). We prefer a slower weaning that allows us to drastically reduce the need for permanent CSF diversion, with a consequent decrease in long-term complications associated with this procedure. Long-term follow-up head CT is important because some patients may develop hydrocephalus with a delay of several weeks or possibly months. Some studies have proposed intraoperative fenestration of the lamina terminalis as a preventive measure, although other studies have shown no difference in the rate of development of chronic hydrocephalus.

51.3.3 Vasospasm

Following aneurysmal SAH, cerebral vasospasm remains a significant cause of mortality and morbidity in 50% of cases. Cerebral vasospasm refers to the narrowing of arterial blood vessels, leading to a decrease in brain perfusion, and has been linked to delayed cerebral ischemia (DCI). In this circumstance, vasospasm is termed symptomatic vasospasm. Cerebral vasospasm in general occurs in 30-70% of cases of SAH, afflicting the younger population (<35 years of age) more frequently, hence causing a greater impact on lost productive years. The relatively lower prevalence of cerebral vasospasm in the elderly has been attributed to stiffening of the vascular wall by atherosclerosis. The onset of vasospasm is typically 3-5 days after aneurysm rupture and peaks at about 7-10 days and subsequently resolves over a period of 2-3 weeks.

Vasospasm can be classified on clinical grounds based on the presence or absence of clinical neurological deficits: symptomatic or asymptomatic vasospasm; by sonography (transcranial Doppler) based on mean flow velocity in the cerebral vessels; radiological-

ly based on the presence of stenosis across a specific cerebral vessel. The presence of symptomatic vasospasm or DCI correlates with a poor outcome; therefore, preventive measures and therapeutic manoeuvres in this circumstance become important.

Our understanding of the pathophysiology of cerebral vasospasm in aneurysmal SAH is incomplete; however, the presence of oxyhemoglobin within the subarachnoid space and cisterns appears to instigate smooth muscle spasm and impaired autoregulation. This is supported by the relationship of clot thickness to the development of vasospasm and it may be that cisternal blood depletes vasodilatory or activates vasoconstrictor mediators. Also, pathological sections of arterial walls in cerebral vasospasm show an infiltration of the arterial wall by inflammatory cells which may perpetuate smooth muscle vasospasm and vessel wall stiffening. The significance of these pathophysiological mechanisms has been recently called into question as not all patients with vasospasm are symptomatic, i.e., DCI. In fact reversing vasospasm has not resulted in a reduction in DCI, as suggested in the CONSCIOUS study, raising the hypothesis that vasospasm may be an epiphenomenon or play a limited role in the ultimate development of DCI. Several other mechanisms that lead to DCI have been proposed, such as microcirculatory dysfunction, microthromboembolism, imbalance of endogenous vasodilators (nitric oxide) and vasoconstrictors (endothelin-1), and cortical spreading depression. Though several questions remain about the role of vasospasm in DCI, it constitutes an important aspect of SAH since there is a strong correlation between vasospasm and DCI. Hence, diagnosis, monitoring and treatment of vasospasm remain very important.

Clinical Features

In most cases, especially in the early phase, vasospasm is predominantly asymptomatic. Subsequently, headache, slow mentation, mild disorientation may be initial manifestations in these tenuous states. This should prompt detailed neurological examination focusing especially on the territory supplied by the vessel at risk, with a low threshold for calling abnormal changes. It is helpful to document a change in serial clinical examination (especially if performed by the same examiner) or to demonstrate sonographic evidence of a serial rise in mean flow velocity in the vessel in question. It cannot be overemphasized that attention to detail during the neurological examination in detecting subtle neurological changes is key to identifying DCI, as it helps direct the next diagnostic and or therapeutic intervention.

Also, it is important to remember that in most cases the installation of vasospasm is progressive as well as the decreased cerebral blood flow in the affected territory. This means that the ischemic areas commonly affected are initially the ones with higher metabolic consumption, such as the cerebral cortex; therefore, the typical initial signs of brain dysfunction associated with vasospasm may include the appearance of minimal encephalopathy, subtle disturbances in understanding and/or language expression, presence of inattention or neglect of one side of space, appearance of some apraxia, difficulty recognizing objects, the appearance of defects in the visual field or the presence of hemiparesis. Such abnormalities on the neurological examination are sometimes missed by the inexperienced observer, so it is important to perform a routine and repeated comprehensive neurological examination in patients with aneurysmal SAH at risk of developing vasospasm. In poor-grade or sedated and ventilated SAH patients, identifying subtle neurological changes by clinical examination is a challenge. In this circumstance, the use of short-acting sedatives to enable neurological examination while the sedatives are turned off becomes paramount. Some other clues in the diagnosis of vasospasm include an unexplained sustained rise in blood pressure and or ICP, if an ICP monitor is in place, the development of fever without a clear infectious source, and the appearance of hyponatremia generally secondary to a cerebral salt wasting syndrome.

Transcranial Doppler Ultrasound

This non-invasive method of measuring blood flow within a vessel by Doppler sonogram is based on the principle that the velocity of blood flow in an artery is inversely proportional to the ratio or luminal diameter of the vessel. The reflection of the ultrasound waves bouncing back from the red blood cells is used to measure the velocity during systole and diastole, from which mean flow velocity (MFV) and pulsatility index (PI) are calculated. These two parameters have been used as an index of severity of vasospasm. Cerebral vasospasm is suggested by a rising MFV and falling PI. Despite its non-invasiveness, ease of use and availability, transcranial Doppler (TCD) is plagued by significant limitations. The sensitivity of TCD is 67%, specificity 99%, with a positive predictive value of 97% and a negative predictive value of 78%. This holds for assessing the middle cerebral artery but may become highly unreliable in other vessels. In certain circumstances such as a hyperdynamic state, the absolute values of the MFV may be misleading; instead, using the Lindergaard ratio (ratio of velocity in the target intracranial vessel to the velocity in the ipsilateral extracranial carotid artery) is helpful for tracking trends. Monitoring with TCD is operator-dependent, showing wide variations according to operator experience and technique. Our approach has been to perform daily TCDs, typically by the same operator and following the trend of MFV and PI with frequent detailed neurological examination which guides our decision for further diagnostic options or treatment modification. In our opinion, TCD is a very useful daily screening tool for vasospasm in patients with aneurysmal SAH.

Radiological Studies

The significance of imaging studies in cerebral vasospasm hinges on the demonstration of vessel narrowing with or without cerebral ischemia. The role of non-contrast CT study of the head relies on the appearance of hypodensities in vascular territories suggesting cerebral ischemia. The obvious limitations of a delayed diagnosis and a low specificity and sensitivity are driving the search for more reliable CT studies. Contrast-enhanced CT angiograms demonstrate vessel narrowing up to the second order intracranial vessels suggesting vasospasm in SAH and is usually combined with CT perfusion studies. There has been a trend towards the use of perfusion CT studies to measure the mean transit time (MTT), cerebral blood volume (CBV), and cerebral blood flow (CBF) to predict cerebral ischemia. It appears that prolonged MTT may be an early predictor of DCI and angiographic vasospasm. The usefulness of these modalities is evident in patients with symptomatic vasospasm, especially in settings of nonspecific changes on the neurological exam or in the sedated and ventilated difficult to examine patient. Frequently we have encountered patients who develop high MFV, suggesting severe vasospasm with a normal or unchanged neurological exam. We typically have performed a CT perfusion study at day 7-9 from aneurysm rupture to assess for radiological evidence of cerebral ischemia.

Conventional cerebral angiography remains the gold standard for diagnosing vasospasm up to third and fourth order vessels. It has the advantage of prompt diagnosis and treatment with either balloon angioplasty or intra-arterial vasodilators. There is no consensus on the timing of the angiogram, with some authorities opting for a routine angiogram in all patients during the peak vasospasm period, with the intent to offer endovascular treatment following the diagnostic angiogram. Our experience has been that symptomatic vasospasm may be reversible with medical treatment alone, thus avoiding the added risk of the angiogram. Therefore, we reserve a diagnostic cerebral angiography for cases of unexplained neurological deterioration or for patients sedated and ventilated where it is very difficult to see changes in the neurological examination established after

aggressive medical treatment, as well as in cases where the artifacts produced by clips or coils prevent the correct interpretation of angio-tomographic images (CTA) or in patients in whom cerebral ischemic symptoms persist despite medical treatment. In these latter cases, we proceed immediately (after about 1 hour of aggressive medical treatment) to angiography to confirm the diagnosis of vasospasm and to perform mechanical or pharmacological angioplasty.

Medical Treatment

The aim of medical management of cerebral vasospasm is to decrease the risk of ischemia by improving cerebral blood flow, decreasing ICP, and decreasing metabolic oxygen demand. Historically, the triple 'H' therapy (hypertension, hypervolemia and hemodilution) has been the mainstay in the management of cerebral vasospasm although more recently the focus from triple-H therapy has shifted to the maintenance of euvolemia and induced hypertension. This represents a hyperdynamic state to increase cerebral perfusion pressure and cerebral blood flow. Despite its wide application, there is no strong evidence to support its use. It is important to note that the approach to management should be divided into prevention and treatment of vasospasm. The preventive measures include avoiding medical complications such as hyperglycemia, acidosis, electrolyte abnormalities, hypoxia, fever, and seizures as discussed earlier. Also, maintaining euvolemia may be guided by a slight positive fluid balance to accommodate for insensible losses. Two small randomized trials comparing prophylactic hypervolemia and euvolemia showed no difference in symptomatic vasospasm, cerebral blood flow or outcome. The development of CSW, which is common with cerebral vasospasm, adds a bit of a challenge to the care of these patients, as there is inappropriate diuresis and hyponatremia. Hypertonic saline infusion is commonly used but may in itself be an iatrogenic cause of diuresis. Hyponatremia and diuresis should be monitored closely and replaced, as they has been associated with the development of DCI. Prophylactic nimodipine should be started at the initial contact with the patient, as it has been shown to improve outcome by decreasing the relative risk of DCI by 18%; however, it has minimal or no effect on the incidence of vasospasm. Quite frequently, when a hyperdynamic state is needed, the hypotensive effect of nimodipine may pose a challenge. In this circumstance, splitting the dose (from 60 mg q4/h to 30 mg q2/h) may be helpful. Discontinuing the administration of nimodipine may occasionally be required in patients where higher arterial pressures have demonstrated neurological improvement. In recent studies, statins, HMG-CoA inhibitors, have had mixed reports on their effect on vasospasm and DCI. Reports have suggested that the anti-inflammatory properties and upregulation of endothelial nitric oxide synthetase plays a role in decreasing vasospasm and DCI. The results of the ongoing large randomized controlled trial (STASH) will hopefully shed more light on this.

As vasospasm progresses, the development of a neurological deficit should prompt an adjustment in treatment goals. The decreased cerebral blood flow associated with DCI has been reported to reverse with increased blood flow from volume expansion equalling non-ischemic brain on PET scans. Also, the use of vasopressors has been reported to increase cerebral blood flow in ischemic brain tissue. Despite the absence of randomized studies, it seems that initiating a hyperdynamic state in high-risk patients is reasonable, though it must be added that this comes at a price of potentially significant complications such as cardiac failure, pulmonary edema, cerebral edema, electrolyte derangements, bleeding diasthesis from the dilution of clotting factors and renal injury. We find that TCD monitoring is helpful as one trends the MFV and PI especially in patients with thick perisylvian clot. The presence of a MFV >200 cm/s and a PI <0.6 suggests sonographic vasospasm in high-risk patients, so that inducing a hyperdynamic state seems reasonable. There are several ways to accomplish the hyperdynam-

ic state and it should be tailored according to each specific patient. Aiming for a central venous pressure goal of 12-14mmHg, or in cases of baseline cardiac dysfunction, a non-invasive cardiac output/index monitoring goal of 3-4 l/min/m^2 has been helpful to guide therapy. Our fluid of choice in the absence of hyponatremia or cerebral salt wasting is 0.9% saline. We have used 250 ml of 5% albumin given 3-4 times a day in this setting as a volume expander. Reports suggest that it may be effective in the setting of cerebral salt wasting to help maintaining an adequate intravascular volume. Fludrocortisone promotes sodium and fluid retention and can be effective when given in anticipation of symptomatic vasospasm as it requires 48 hours to take effect. We have usually reserved it for high-risk symptomatic vasospasm patients and/or patients with CSW. The use of vasopressors is common; however, we restrict its use to high-risk patients with poor response to fluid therapy in the setting of symptomatic vasospasm. Studies comparing vasopressor agents are lacking and the choice of agent is tailored to the patient's underlying co-morbidities. In the presence of preserved cardiac function, phenylephrine or norepinephrine has been our first choice agent, reserving dopamine for the setting of bradycardia. If there is evidence of cardiac dysfunction, a combination of phenylephrine or norepinephrine with dobutamine or milrinone is a viable option. Vasopressors are titrated with the aim of obtaining a systolic blood pressure necessary to achieve the reversal of neurological deficits (we usually try to achieve a systolic blood pressure of around 200 mmHg or up to 220 mmHg in selected cases). If pure ionotropic agents are used, we aim for a cardiac index of above 3 l/min/m^2 that could result in the reversal of the neurological deficits. While the patient is on vasopressors, daily monitoring of electrocardiogram, cardiac enzymes, lactic acid and chest X-ray are implemented to assess for evidence of end-organ damage. In neurogenic stunned cardiomyopathy, the use of ionotropic agents such as dobutamine or milrinone might be preferred, with an intra-aortic balloon pump being a last resort. Several recent reports have suggested that cardiac output goal-directed therapy appears safe and effective in reversing neurological deficits in patients with no known cardiac dysfunction, the advantage being the prevention of complications of hypertension.

Endovascular Treatment

The modalities employed in treating vasospasm include balloon angioplasty and intra-arterial infusion of vasodilating agents. In most cases, endovascular treatment is reserved for symptomatic vasospasm recalcitrant to optimum hyperdynamic medical treatment. Balloon angioplasty involves the dilatation of focal spastic vessels by balloon inflation and it is reserved for segmental narrowing of proximal vessels due to increased complications which include arterial dissection, rupture, thrombosis and reperfusion injury causing hemorrhage and cerebral edema. Balloon angioplasty is very effective in reversing spastic vessels and improving clinical outcome; however, direct comparison with medical treatment is lacking. We have reserved it as a second line treatment option for symptomatic vasospasm due to the magnitude of its complications. Intra-arterial agents used in the treatment of symptomatic vasospasm include papaverine, verapamil, nicardipine and nimodipine. Indications for intra-arterial vasodilators are similar to balloon angioplasty, except that it is reserved for distal vessel spasm or diffuse vasospasm where balloon angioplasty is technically not feasible or associated with high risk. Intra-arterial vasodilators are effective but unfortunately of transient effect; in addition, the use of papaverine may lead to toxic effects on the brain, causing seizures, blindness, coma and direct cortical injury. Ideally, an ICP monitor is beneficial when papaverine is used since it can cause a sudden rise in ICP due to its vasodilatory effect and increase cerebral blood volume. This is more likely in the setting of a deranged autoregulatory mechanism common in SAH.

51.4 Rehabilitation

The finding of neglect, poor judgment, poor recent memory recall, and several other findings on neurological examination are often overlooked during the bedside clinical examination. Its importance hinges on the design of rehabilitation methods and programs to optimize functional recovery. This is even more pressing as SAH afflicts the relatively young people in their most productive years. The return to a full productive life is the goal. However, the spectrum of the impact of aneurysmal SAH in patients who survive this brain insult spans from no discernible neurological deficits to severe disability. It is well known that the absence of lesions on imaging studies does not equate to an absence of neurological injury. A wide range of cognitive impairments is quite frequently observed on neuropyschometric testing. Physical and occupational therapy should be initiated as early as possible, with subsequent transfer to a rehabilitation centre familiar with brain injury. This aggressive approach to rehabilitation helps to address social adjustment, emotional and cognitive dysfunction.

52 Neurocritical Care of Patients With Arteriovenous Malformations

Karel Fuentes [1], J. Javier Provencio [2]

[1] Baptist Medical Center, Miami, Florida, USA
[2] Cerebrovascular Center, Neurological Institute, Cleveland Clinic, Cleveland, OH, USA

52.1 Introduction

Arteriovenous malformations (AVM) are vascular anomalies in which there is a group of dilated and conglomerated blood vessels allowing bloodflow from the afferent artery to the efferent veins without a capillary bed in between. The direct connection between arteries and veins through multiple fistulas allows the formation of a circuit of high flow and low resistance that exposes the nidus and the draining veins to high pressure.
AVMs may affect brain parenchyma (90%), brainstem, cerebellum or spinal cord. In this chapter we will emphasize the management of AV malformation in the brain, brainstem and cerebellum.

52.2 Anatomy and Physiology

The architecture of AV malformations consists of one or more arteries that supply blood flow to the malformation, the presence of a cluster of blood vessels that are fragile due to their thin walls and small size and the veins that drain blood. AV malformations are congenital lesions usually manifest clinically in the second decade of life suggesting that changes in hemodynamic characteristics that occur over time may increase the likelihood of rupture and hemorrhage. These hemodynamic changes appear to be caused by structural abnormalities observed in the wall of cerebral arteries; arteries deficient in the middle muscular layer [1] result in lack of flexibility of the vessel wall that impairs the ability of the artery to constrict when exposed to high pressure resulting in transmission of blood flow and pressure to the nidus and the draining veins. Consequently, the veins become “arterialized” due to exposure to high pressure. The resulting fibromuscular layer thickening, and the structural lack of the elastic lamina in the veins result in decreased flexibility and increased venous resistance which is transmitted to the small fragile blood vessels that make up the nidus increasing the risk of bleeding [2]. Additionally, it has been well documented that the presence of thrombosis and stenoses in the draining veins increases the risk of bleeding likely due to development of backpressure that increases the risk of bleeding into the nidus.

52.3 Epidemiology

The prevalence of AVMs in the general population is 0.01%. The risk of hemorrhage is 2% to 4% each year [3]. The occurrence of cerebral hemorrhage is associated with a risk of death of 5-10% [3] of patients. The possibility of permanent neurological deficits can be as high as 30-50%. Most cases are sporadic but familial predisposition has been ob-

served in case reports. It is believed that the predisposition to AVMs is congenital but that the pressure and volume changes over time result in the development of the actual AVM. They may be occasionally associated with other syndromes such as Osler-Weber-Rendu or Sturge-Weber syndrome [4,5].

52.4 Clinical Presentation

Intracranial hemorrhage is the most common clinical presentation and occurs in 42-72% of symptomatic patients. The risk of bleeding does not vary with sex of the patient and the first episode usually occurs between 20 and 40 years of age. The bleeding is usually associated with the presence of aneurysms in the feeding arteries or nidus. It is estimated that these are present in at least 7% of AV malformations. Another common cause of bleeding is the obstruction of the draining veins causing increased pressure in the nidus. In the neurocritical care unit, the patient presents in one of the following ways: 1) spontaneous rupture during an endovascular procedure to occlude the AVM causing intracerebral, intraventricular, or subarachnoid hemorrhage or any combination; 2) progressive neurological deficits simulating a stroke due to compression of adjacent tissue by edema from venous hypertension or ischemia caused by the diversion of blood to the AVM; 3) focal or secondarily generalized epilepsy caused by irritation of the cerebral cortex; or 4) headache even in the absence of bleeding. Additionally, many patients are admitted to a Neurointensive care unit for close monitoring and blood pressure control after an embolization, radiation or surgical procedure.

52.5 Classification

The classification scheme by Spetzler and Martin (the Spetzler-Martin scale) provides information about the complexity of the AVM and risk of surgical excision. The classification has been validated in a prospective study [6] and takes into account three characteristics: diameter, whether the AVM is in an eloquent brain area, and the presence or absence of deep drainage (Table 52.1). The extent of the AV malformation is obtained by adding the values. Surgery is possible with grade 1, 2, 3 lesions (grade 3 lesions usually only after embolization). The incidence of minor and major neurological deficits after surgery is significant (18% and 12% respectively) for grade 5 lesions [6].

Categories	Value
Maximum diameter	
Small <3 cm	1
Medium 3-6 cm	2
Large >6 cm	3
Localization	
Non-eloquent brain	0
In or adjacent to eloquent brain	1
Venous drainage	
Only superficial	0
Deep	1

Table 52.1. **Spetzler-Martin Classification of AV malformations. Points are awarded in each category and added up. Higher scores signify higher morbidity with surgical resection.**

52.6 Evaluation

Different imaging modalities can be used in the evaluation and diagnosis of AV malformation and their complications. Computed tomography (CT) provides high sensitivity for

detecting intracranial hemorrhage. Sometimes the presence of an AVM may be suspected if one or more dilated draining veins can be seen, but in general other imaging studies are needed to accurately make the diagnosis.
Computed tomography angiography (CTA) shows the blood vessels with more detail than time of flight imaging by magnetic resonance angiography (MRA), while magnetic resonance imaging (MRI) provides better visualization of the AV malformation and its relationship to surrounding structures. However, conventional angiography is the most sensitive test to determine the details of the architecture of the malformation. Angiography provides details regarding the presence of aneurysms in the feeding arteries or the nidus and analysis of the venous drainage pattern as well as giving indirect information about venous hypertension and thrombosis.

52.7 Specific Treatment

It is important for the neurointensivist to familiarize himself with the different modalities of treatment of AVMs as well as possible complications. The combination of different treatment modalities such as microsurgery, stereotactic radiosurgery and endovascular embolization is often used to treat these lesions which adds to the complexity of the case in the intensive case unit.
Fractionated stereotactic radiosurgery directs high-dose radiation to a specific target with less toxicity to adjacent tissues and has the advantage of not being invasive, but has the disadvantage that it can only be applied to lesions less than 3 cm in diameter. The damage caused by radiation to the area of the AVM produces occlusion of blood vessels but the occlusion occurs slowly over 1 to 3 years after dosing. Some authors report rates in 81-90% of patients treated [7,8]. Some experts comment that the lesions that can be treated with radiosurgery are the same that are easily removed with surgery in non-eloquent brain. The main disadvantage of radiosurgery is that the patient remains exposed to the risk of bleeding for a period of up to 3 years.
Endovascular embolization using various compounds (glue or particles) is one of the most widely used techniques in the treatment of AVMs. These techniques have been used primarily as adjuvant therapy prior to surgery because resolution of the AV malformation is only obtained in 13% of patients [9] when embolization is not followed by another procedure. However its value as an adjuvant therapy is important because it reduces the size of the AVM making conventional surgery or stereotactic radiosurgery more effective and less dangerous.
The aim of embolization is to remove the feeding arteries thereby reducing blood flow through the nidus and consequently decreasing the size of the malformation. Commonly, multiple staged embolization procedures are needed to gradually occlude the malformation without causing sudden hemodynamic changes that may result in bleeding or other complications.

52.8 Complications and Treatment

All three procedures, radiosurgery, embolization and conventional microsurgery have the potential for complications. The main complication of stereotactic radiosurgery is radiation damage to tissues adjacent to the AVM which occurs in 6.4% of cases [10]. Other complications include damage to the cranial nerves (1%) and an increased frequency

of epilepsy (0.7%) [10]. Endovascular embolization can lead to intracranial bleeding as a result of the rapid changes in blood flow and pressure in the nidus of the AV malformation. Another feared complication that increases the chance of rupture is thrombosis of the draining veins that can occur as a result of embolic material migrating through the AV malformation to the draining veins. In addition, even successful suppression of blood flow through the malformation can cause slow flow and thrombosis of the draining veins leading to congestion and bleeding. Occlusion of the draining veins may result in venous infarction and/or hemorrhage complicating the postoperative period. Surgery has a similar complication profile as endovascular embolization with two caveats: 1) surgery has a higher infection rate, and 2) there is a greater chance of damage to adjacent tissues.

Intracerebral hemorrhage may result from hyperemia to tissue adjacent to the AVM due to redistribution of arterial blood from the now-embolized or ligated artery to adjacent arteries. Even in tissue experiencing normal flow, congestion and hemorrhages may occur. The reason for this is that tissue surrounding the malformation that has been chronically exposed to a low flow state because of a “steal” phenomenon (the low resistance AV malformation steals blood from the higher resistance normal vessels) may respond poorly to rapid correction of blood flow due to occlusion of arteries feeding the malformation and may expose tissue that is not used to “normal” perfusion to react as though it were hyperemic.

Endovascular embolization with particles or glue carries a risk of stroke due to inadvertent embolization of arteries that feed eloquent brain. Administration of a short-acting barbiturate (methohexital) followed by a neurological examination before and after can help identify whether any of the feeding arteries supply normal tissue adjacent to the malformation. Additionally, hemodynamic changes that occur during embolization of an AVM can lead to glue embolization to tissues other than brain such as lung and heart leading to pulmonary emboli or myocardial infarctions. All patients should be carefully examined after an endovascular procedure to detect the presence of new neurological deficits or systemic embolization. The diagnosis of ischemic stroke can be accomplished using magnetic resonance imaging (MRI).

The best way to avoid the above complications is to perform gradual, staged embolization of the AV malformation avoiding sudden changes in pressure and blood flow. Additionally, strict control of blood pressure during and after the procedure is thought to be vital in preventing reperfusion injury. Data regarding the management of blood pressure in patients with AV malformations are limited and no prospective studies support a specific strategy. The management proposed in this chapter is based on physiological principles of blood flow and is the strategy used in our practice. In patients who have undergone embolization or surgery, systolic pressure is maintained below 100 mmHg for the first 24 hours to prevent reperfusion injury. The liberalization of arterial pressure requirements is then done gradually over the next few days allowing the tissue to adapt to new local blood flow. Systolic pressures of less than 110 mmHg and 120 mmHg, respectively, are preferred on days 2 and 3 after the procedure.

The use of invasive blood pressure monitoring with an arterial catheter is recommended. The agents that control blood pressure without decreasing blood flow to the brain such as the balanced vasodilators and the arterial dilator nicardipine are preferred in patients in whom the AV malformation is completely occluded. In our practice a continuous infusion of nicardipine is the first option, especially when the systolic pressure must be kept below 100 mmHg. Maintaining blood flow while limiting blood pressure ensures adequate perfusion to non-AVM areas of the brain. Nitroprusside (which decreases cardiac preload and afterload) in conjunction with labetalol can be used in cases where the AV malformation is only partially occluded because the remaining abnormal blood vessels in the nidus must acclimate to the increased blood flow shunted to

them from the embolization. In these cases, decreased blood pressure and blood flow are desirable to avoid a disproportionate increase in blood flow through residual vessels of the malformation. Other agents such as angiotensin-converting enzyme and hydralazine can be administered when the blood pressure requirements have been liberalized. It is equally important to keep the patient well-hydrated with adequate analgesia to avoid sympathetic overdrive.

The management of blood pressure is just as important in patients presenting with spontaneous rupture of an AV malformation. Always assume the presence of an aneurysm until it can be ruled out angiographically. The systolic pressure should be maintained below 140 mmHg with the aim to prevent the spread of the hemorrhage and compression of adjacent structures due to increased intracranial pressure. Usually the definitive treatment of AVM is postponed until the patient is in stable condition and intracranial pressure is normalized. In patients at risk for elevated intracranial pressure (major bleeding, Glasgow Coma Scale Score (GCS) <8, and so on). Intracranial pressure monitoring is recommended and blood pressure should be adjusted to maintain cerebral perfusion pressure >60 mmHg.

Focal or secondarily generalized epilepsy as a result of AVM is a common form of presentation and its treatment does not differ from other forms of symptomatic focal epilepsy. A minority of patients present with focal neurological deficits resulting from compression of adjacent structures by an AVM. Historically, steroids have been used as an adjunct measure until definitive treatment can be instituted, but there are no studies that support their use.

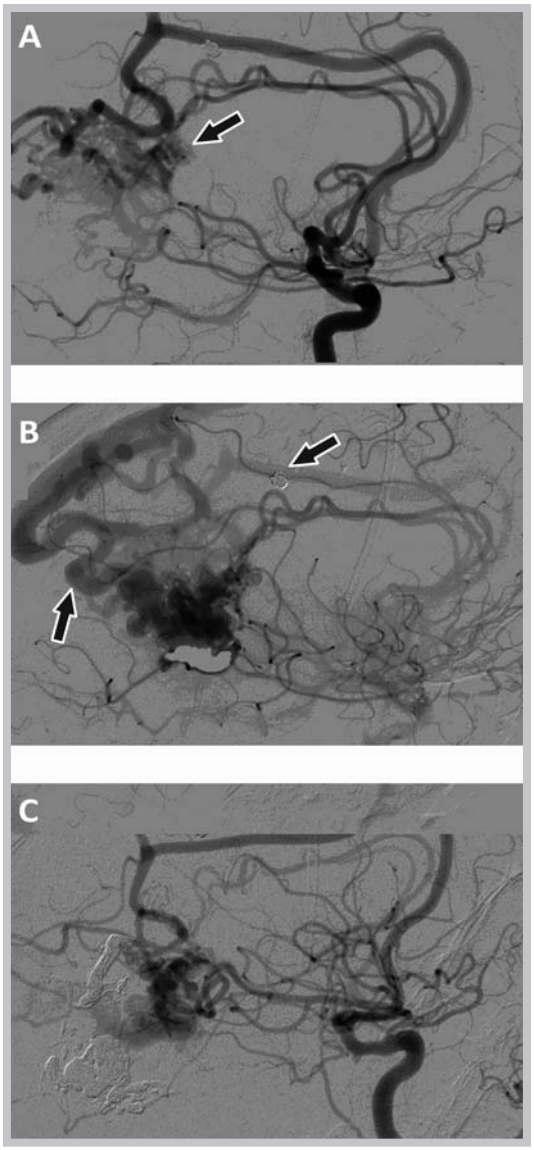

Figure 52.1. Example of MAV 1.

52.9 Conclusions and Key Points

- Intracranial hemorrhage is the most common form of presentation of AVMs.
- The presence of aneurysms in the feeding arteries or the nidus and the blockage of drainage increases the likelihood of rupture and hemorrhage.
- The Martin-Spetzler classification provides information on the risk of surgery but does not predict the risk of rupture or bleeding.

- AVMs are complex lesions and are commonly treated with a combination of embolization, microsurgery or stereotactic radiosurgery.
- Occlusion of the malformation (microsurgery or embolization) can result in bleeding due to rupture or damage to adjacent tissue reperfusion.
- The gradual embolization of the malformation and the strict control of blood pressure are the best way to avoid complications.
- Vasodilator agents such as nicardipine may be used during the early hours to control blood pressure.

53.1 Introduction

Intraventricular hemorrhage (IVH), defined as extravasation of blood into the brain ventricular system, is a condition with high morbidity and mortality. Fortunately, early diagnosis and prompt intervention due to advances in neuro-imaging and neuro-critical care has made it possible for many patients to survive and fully recover from this event.

Spontaneous intracerebral hemorrhage (ICH), which is bleeding into the brain parenchyma, has an estimated mortality of 30% as well as a high rate of morbidity among survivors [1]. Isolated IVH is quite uncommon, but IVH commonly occurs in up to 45% of all cases of ICH [1]. In patients with acute ICH, there is a strong body of evidence supporting the fact that extension into the ventricular system increases the overall mortality and is associated with poor outcomes [2-4]. The mechanism that holds IVH directly responsible for the dire neurological causata are not completely understood, but the results of recent and ongoing animal and human investigations are expanding our insight [5].

53.2 Etiology

Direct hemorrhage into the ventricles from a source or lesion that is in contact with, or part of a ventricular wall, is classified as primary IVH. Secondary IVH originates as an extension of an intraparenchymal or subarachnoid hemorrhage (SAH) into the ventricular system. About 30% of IVHs are primary and 70% are secondary. Isolated IVH is a relatively rare event, accounting only for 3% of all cases of intracranial hemorrhage [6].

Frequent causes of primary IVH include head trauma, insertion or removal of a ventricular catheter, intraventricular vascular malformations, tumors, and bleeding diathesis (Table 53.1.) Secondary IVH has some overlap but most commonly is a result of hypertensive intra-parenchymal hemorrhage into the basal ganglia and thalamus.

Primary IVH	Secondary IVH
• Germinal matrix hemorrhage in the premature newborn • Intraventricular/ periventricular vascular malformation or tumor • Coagulation or platelet disorder • Trauma • Insertion or removal of ventricular catheter • Drugs (cocaine, amphetamines) • Cerebral vein thrombosis • Idiopathic	• Hypertensive/ hemorrhagic stroke • Trauma • Vascular malformation, aneurysms, tumor • Pituitary apoplexy • Coagulation or platelet disorder • Drugs (cocaine/ amphetamines) • Vasculitis

Table 53.1. Causes of intraventricular hemorrhage.

Graeb		
Lateral ventricles	1	Trace of blood or mild bleeding
	2	Less than half of the ventricle filled with blood
	3	More than half of the ventricle filled with blood
	4	Ventricle filled with blood and expanded
3rd and 4th ventricles	1	Blood present, ventricle size normal
	2	Ventricle filled with blood and expanded
LeRoux		
1	Trace of blood	
2	Less than half of the ventricle filled with blood	
3	More than half of the ventricle filled with blood	
4	Ventricle filled with blood and expanded	
IVH score		
Lateral ventricles	1	Trace of blood or mild bleeding
	2	Less than 1/3 of the ventricle filled with blood
	3	Between 1/3 and 2/3 of the ventricle filled with blood
	4	Ventricle filled with blood and expanded
3rd and 4th ventricles	0	No blood
	1	Any blood
HCP	0	No
	1	Yes

Table 53.2 **Grading systems for IVH severity [7,8,9]. In the Graeb and LeRoux systems, each lateral ventricle is scored separately. For third and fourth ventricles, each one is scored separately, then added together. In the IVH score, each ventricle is scored separately for the mere presence of blood and each given a score 1 for the presence of hydrocephalus (HCP). Score ranges for the Graeb system is 0-12, for the LeRoux system is 0-16, and 0-23 for the IVH score. In all three systems, the higher the final score, the higher the prospect of poor outcome.**

Several grading systems have been described to classify the severity of IVH and are worth being familiar with for academic purposes [7-9] (Table 53.2).

53.3 Clinical Features and Diagnosis

The symptoms that can be directly attributed to blood within the ventricular system are indistinguishable from subarachnoid hemorrhage, with sudden onset of severe headache, nausea, vomiting, and meningismus (neck stiffness). There is typically minimal or no focal neurologic deficit, unless there is an intra-parenchymal component. With more extensive hemorrhage, consciousness progressively declines. In massive IVH, sudden loss of consciousness is the rule and generalized seizures are not uncommon [9].

The diagnosis of IVH is easily made via a non-contrasted head computer tomography (CT) scan. CT provides useful information regarding the extent of the hemorrhage and the presence or absence of hydrocephalus. It may also provide clues with regard to the etiology of IVH, based on the distribution pattern of blood within the ventricles (Figure 53.1).

Predominance of blood in the fourth ventricle with associated subarachnoid hemorrhage in the basal cisterns is typical for ruptured aneurysms of the posterior inferior

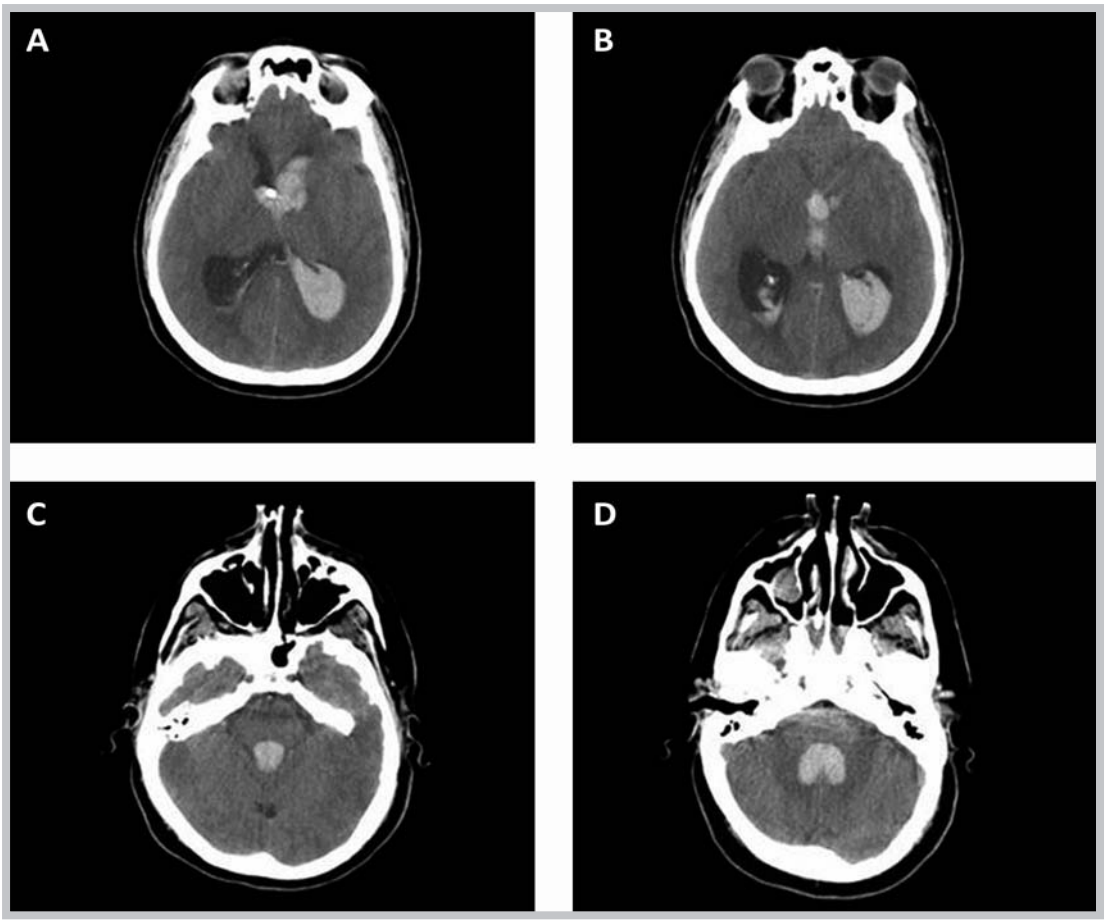

Figure 53.1. **Intraventricular hemorrhage in a 45-year-old man due to a left caudate hemorrhage extending caudally to the fourth ventricle.**

cerebellar artery. Isolated IVH in young adults should raise the suspicion for an arteriovenous malformation (AVM). IVH in association with medial thalamic or caudate intraparenchymal hemorrhage is common for patients with hypertensive ICH. In cases where

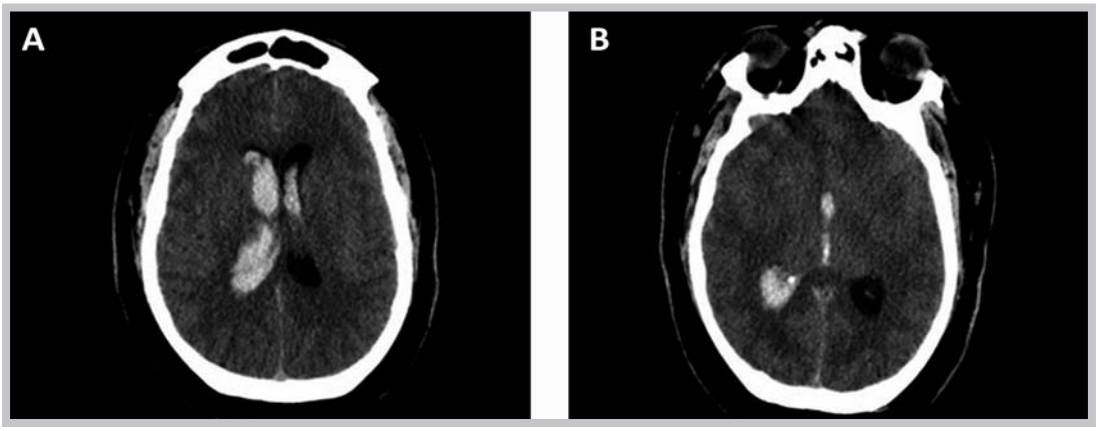

Figure 53.2. **Intraventricular hemorrhage in a 34-year-old man without evidence of a pre-existing ICH and a normal cerebral angiogram.**

the etiology cannot be delineated from CT scan alone, a gadolinium enhanced magnetic resonance imaging (MRI) and magnetic resonance angiography (MRA) of the brain is indicated to further explore and seek the etiology (Figure 53.2).
Angiography is reserved for cases with a high suspicion for AVM or aneurysms.

53.4 Pathophysiology of IVH

Acute IVH leads to acute intracranial hypertension and obstructive hydrocephalus, which then exerts pressure onto the ascending reticular activating system (ARAS) resulting in a depressed level of arousal. The presence of blood inside the ventricles may lead to obstructive hydrocephalus and subsequently to elevated intracranial pressure (ICP). Elevated ICP may significantly lower cerebral perfusion pressure (CPP) leading to cerebral ischemia, further augmenting brain injury [10].
Some studies support the theory that the blood itself causes damage to the ependymal and subependymal layers of the brain [11]. Neuropsychological data has shown that patients with IVH suffer from significant cognitive deficits even after the blood has completely disappeared, suggesting that the harmful effects of intraventricular blood may not only be due to the mere presence of blood in the ventricles, but a more complex neuro-hormonal mechanism [12]. It is likely that subarachnoid fibrosis, extensive ependymal cell loss, and subependymal glial proliferation on the walls of the ventricles is produced by blood in the cerebrospinal fluid, most likely as an inflammatory response [11,13-15].
There is very little known about the fibrinolytic system in the cerebrospinal fluid and brain tissue. Activity is localized in the vascular endothelial cells, meninges and choroid plexus, with minimal amounts of tissue-type plasminogen activator (t-PA) in the CSF of adults with no neurologic disease. In the event of ICH, increased levels of t-PA have been observed in the CSF. It is not known whether the increased levels result from an enhancement of local production or from leakage across a damaged blood-brain barrier [16,17]. Interestingly, this increase in fibrinolytic activity after an intracranial hemorrhage does not result in a rapid resolution of intraventricular blood [16-18]. Studies of serial CT scans performed on patients with IVH have seemed to suggest that the intraventricular blood gradually disappears over a period of 2 to 3 weeks after the hemorrhage [19,20]. In contrast, post-mortem studies have revealed the persistence of intraventricular blood for months after a hemorrhage [21].

53.5 Clinical Management of IVH

Treatment of IVH begins with stabilization of the patient followed by admission to an intensive care unit (ICU) where airway, neurological and hemodynamic surveillance and support are more meticulously possible. An official consensus or guideline on all aspects of IVH management - blood pressure control, indications for placing a ventricular drain, and administration of fibrinolytics – does not exist. However, lower mortality rates have been consistently observed when the treatment policy involves: 1) the use of an intraventricular drainage catheter (ventriculostomy drain) to maintain ICP within the normal range (usually less than 15-20 mmHg), and 2) Optimal management of blood pressure [5]. Management of IVH is multi-faceted and solely maintaining ICP within a normal range is insufficient to impact mortality or morbidity [22].

In our practice, all patients with IVH are admitted to the ICU for close monitoring of neurological status and hemodynamics. An intraventricular catheter is placed for emergent ICP control in patients with poor neurologic status (usually with Glasgow Coma Scale of 8 or less, signs of impending herniation) and/or radiographic evidence of ventriculomegaly secondary to the IVH. This catheter is typically kept open for continuous cerebrospinal fluid (CSF) drainage. It is crucial to correct any coagulopathies that may have contributed to the initial hemorrhage and prior to placement of this catheter. For control of elevated blood pressure, we follow the most recent American Stroke Association guidelines for management of spontaneous ICH and aneurysmal SAH: a target systolic value of 160 mmHg or less [23,24]. Anticonvulsant medications are not routinely used for isolated IVH, unless seizures were a part of the initial clinical presentation. Administration of intravenous recombinant activated factor VIIa (rFVIIa) has been shown to reduce the expansion of ICH volume when administered within 4 hours of symptom onset, but without a significant impact on survival or functional outcome [25]. There is some evidence that in patients with IVH, rFVIIa treatment may contribute to development of hydrocephalus, perhaps due to its pro-coagulant effect leading to delayed resolution of intraventricular blood [26].

A theory exists that accelerated clearance of the intraventricular clot using direct injection of thrombolytics such as recombinant tissue-type plasminogen activator (rt-PA) into the ventricles may have a positive impact on clinical outcome. The safety and efficacy of this treatment in increasing the rate of clot lysis has been demonstrated [27]. Intraventricular thrombolysis does appear to reduce mortality rate and accelerate blood clot resolution in patients with moderate to severe IVH [28,29]. Furthermore, functional outcome measures (Glasgow outcome scale, modified Rankin scale and National Institutes of Health Stroke Scale) seem to be improved in patients treated with rt-PA despite a trend toward more bleeding complications. Questions remain as to whether rt-PA is the right thrombolytic agent and what the appropriate dose is. This treatment is currently being studied in a phase III clinical (Clot Lysis: Evaluating Accelerated Resolution of Intraventricular Hemorrhage Phase III: CLEAR III). In some centers, intraventricular rt-PA is used in an “off label” fashion. We have successfully used small intraventricular doses of 1 to 2 mg rt-PA to re-establish the patency of a ventricular drain that has been obstructed by blood. For intraventricular fibrinolytic therapy, doses ranging from 2 to 4 mg of rt-PA at 12 to 24 hour intervals can be safely administered with minimal risk of bleeding complications. The injection of the fibrinolytic agent should be preceded by withdrawal of a volume of CSF equivalent to the drug volume being injected, to avoid a sudden increase in intracranial pressure. Injection is followed by a preservative free normal saline flush of 1 to 2 ml and clamping of the ventricular drain for 30 minutes to an hour. The ICP is closely monitored during this time period and if the pressures rise above 20 mmHg sustained over 5 minutes the ventricular drain is reopened, allowed to drain 5 to 10 ml and then closed again. If ICP continues to be elevated the drain is just left open and t-PA injected again in 12 to 24 hours if necessary. The decision to treat again is based on clinical status and residual intraventricular blood on follow up imaging studies

Prior to even considering fibrinolytics for the treatment of IVH the physician must be certain that the acute episode of bleeding has subsided and that any underlying condition contributing to the hemorrhage (hypertension, coagulopathy, aneurysm) has been corrected. This is critical in the management, as the administration of intraventricular fibrinolytics to a patient with vascular pathology (unsecured aneurysm) could be fatal. A repeat CT scan of the brain is performed within 12-24 hours of the onset of bleeding to assess stability of the hemorrhage.

Many practical issues concerning intraventricular fibrinolytic therapy still need to be addressed. The criteria for patient selection and the determination of an appropriate dose, timing, and protocol for administration are all the focus of CLEAR III.

53.6 Prognosis

The morbidity and mortality of patients with IVH largely depends on the extent and the volume of blood in the ventricular system [4,7,30,31]. Patients with secondary IVH fare more poorly than those with primary IVH [31,32]. If an ICH ruptures into the ventricular system, the mortality increases from 30% to 44% and if it involves all four ventricles, it can be as high as 60 to 91% [31,32]. As for the location, thalamic ICH patients with intraventricular extension seem to have the worst prognosis. Additional predictors of outcome include initial Glasgow Coma Scale and age greater than 80 years [4,31,32]. Long term consequence of IVH may involve a severe, persisting amnesic state [33].

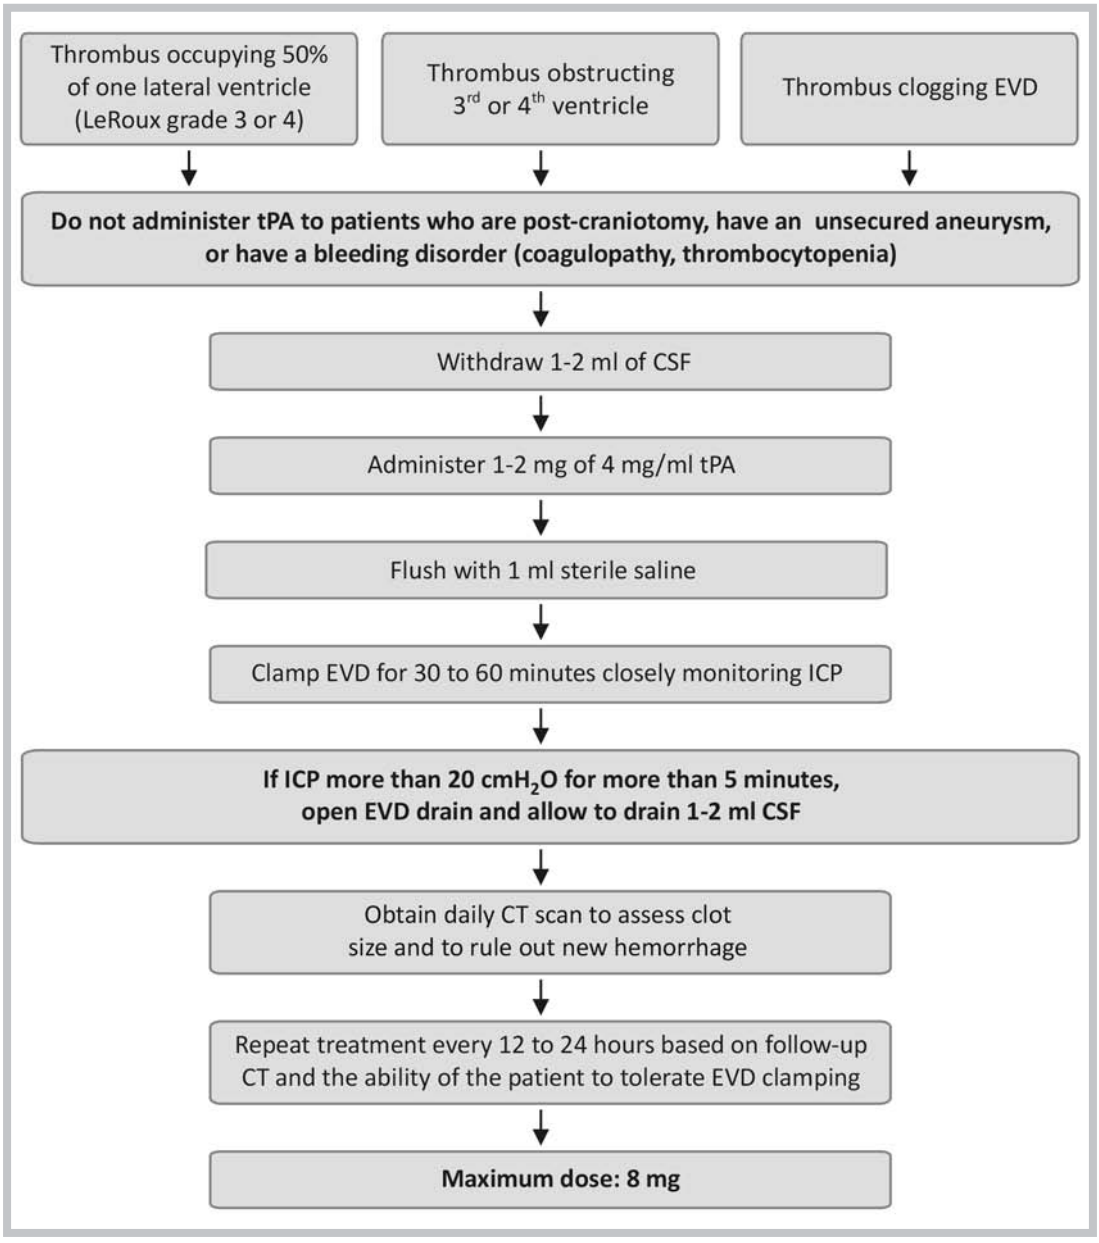

Figure 53.3. Example protocol for intraventricular thrombolysis.

53.7 Conclusions

IVH is an entity that can be associated with a large number of causes. The clinical picture depends on the severity of the hemorrhage and management consists of identifying the underlying etiology and placing an external ventricular drain to control and monitor intracranial pressure. Although reduced mortality rates have been reported with intraventricular fibrinolytic therapy, it is not clearly known if it improves neurologic outcomes.

Section 7.
Infections in NICU

54 Control and Management of Nosocomial Infections in Neurocritical Care Units

Sebastian Schulz-Stübner [1], Markus Dettenkofer [2]

[1] Deutsches Beratungszentrum für Hygiene am Universitätsklinikum Freiburg, Freiburg, Germany
[2] Institut für Umweltmedizin und Krankenhaushygiene, Universitätsklinikum Freiburg, Freiburg, Germany

54.1 Objectives

This chapter describes the impact of nosocomial (healthcare-acquired) infections (HAI), risk factors, modes of prevention and treatment and organizational concepts such as surveillance and quality management in neurocritical care units. We will focus on nosocomial infections after dealing with general recommendations for infection control practices and surveillance and the differential diagnosis of fever:

- Ventilator-associated pneumonia (VAP).
- Central line-associated bloodstream infections (CLABSI).
- Catheter-associated urinary tract infections (CAUTI).
- Infections associated with extraventricular and lumbar drains.
- Surgical site infections after craniotomy/craniectomy.
- *Clostridium difficile*-associated diarrhea (CDAD) and nosocomial diarrhea.

54.2 Background and Basic Aspects of Infection Control

Nosocomial infections put a significant additional burden on intensive care patients, care givers and public health, yet many are preventable. Specific surveillance data on HAIs in neurosurgical and neurology intensive care units (ICUs) have been published by Dettenkofer and colleagues, but oftentimes only pooled data from general ICUs are available.
Neurocritical care patients carry an increased risk for infections secondary to suppression of cell-mediated immunity in general and T-lymphocyte function in particular. This can be aggravated by transfusion requirements.
A specific additional risk factor for VAP is the higher likelihood of microaspiration secondary to the underlying neurologic dysfunction.
Therefore, a comprehensive preventive approach is needed, and the so-called standard precautions (Centers for Disease Control and Prevention [CDC], Atlanta, USA) apply to all medical settings (CDC Isolation Precautions 2007; www.cdc.gov).
The most important factor is proper **hand hygiene**. This is achieved by performing an **alcoholic hand rub** before and after each patient contact. It should be practiced by all healthcare workers (HCWs) in the neurocritical ICU, including physicians, nurses, physiotherapists, technicians and other paramedical personnel, as well as visitors with direct patient contact (http://www.who.int/patientsafety/en).
Unfortunately, compliance with this simple and highly effective technique is poor. Observational studies in ICUs report compliance rates of around 40%, which could be en-

hanced to over 65% through educational campaigns. Such awareness programs need to be repeated at least once a year to achieve a more sustained effect.

The alcoholic hand rub should be well tolerated by the HCW's skin and should contain a moisturizing agent and be devoid of colorants or perfumes. A protective skin ointment or lotion should be used at least at the beginning and at the end of the workday.

Single-use gloves should be worn each time contact with body fluids and secretions is likely and used for procedures on one patient only. After glove removal, the hands need to be disinfected with an alcoholic hand rub.

Sterile gloves are required for sterile procedures (Table 54.1). In patients with known blood-borne diseases like hepatitis B (HBV) and C virus (HCV) infection and infection with the human immunodeficiency virus (HIV), double gloving can be used for increased protection.

Vaccination of all staff members against HBV should be enforced. A written policy for the management of exposure to HIV and post-exposure prophylaxis should be in place. The logistics to provide antiviral drugs within the recommended timeframe of 2 hours after exposure need to be determined to achieve best results.

Unsterile gowns and fluid impermeable aprons are worn when contamination with body fluids is possible.

Masks and face shields will protect staff from droplets, and special masks with higher protection grades (e.g., N95 or FFP2 respirator) need to be worn if airborne precautions are necessary, as in patients with open lung tuberculosis or SARS.

All personal protective equipment should be stored close to the point of care but protected from contamination and dust.

Dispensers for alcoholic hand rub should be easily accessible at the bedside and when entering and leaving a room. Personalized bottles carried by the team members can be an alternative.

Tap water may carry high-risk micro-organisms and should be accordingly tested for *Legionella* or *Pseudomonas aeruginosa* contamination (and treated accordingly). It should

Precaution	Peripheral IV	Arterial line**	CVC	Bedside tracheostomy	Bedside ventriculostomy/ lumbar drain	Bronchoscopy/ bronchoaveolar lavage
Skin-disinfection# (e.g., chlorhexidine/ alcohol, octenidine/ alcohol)	X	X	X	X	X	NA
Sterile gloves	-	X	X	X	X	X
Sterile gown	-	-	X	X	X	(X)
Sterile drape	-	Small*	Large*	Large	Large	Small
Hair cover	-	-	X	X	X	-
Face mask	-	-	X		X	X + goggles or face shield

Table 54.1. **Precautions for invasive procedures.**

X = recommended; (X) = useful in some cases, not required; CVC = central venous catheter (includes Swan-Ganz catheters)

Contact time according to manufacturer's recommendation, e.g., 60 seconds

* Use sterile covers and sterile gel for ultrasound probes if used to guide the procedure

** For long arterial lines (e.g., PICCO® catheter), arterial sheaths for interventional radiology or intra-aortic balloon pumps or access lines for extracorporeal circulation (e.g., extracorporeal membrane oxygenation [ECMO], Novalung®) use maximal barrier precautions as with CVC insertion.

never be used for oral care, inhalation therapy or filling of humidifying devices in the breathing circuit (sterile water required).
Routine cleaning of the ICU by trained personnel is important. This should be done at least once a day and each time a visible contamination occurs. In addition, contaminated surfaces need to be disinfected with an approved surface disinfectant at the correct concentration (e.g., knobs and contact displays three times a day). All contact surfaces close to the patient need to be disinfected daily and immediately when visibly soiled.
Medical equipment and reusable products need to be cleaned and disinfected or sterilized after use according to the risk (Spaulding classification: critical, semi-critical, non-critical) and the manufacturer's recommendations by trained staff utilizing a validated process.
Surveillance of nosocomial infections according to standardized definitions (www.cdc.gov/nhsn; www.nrz-hygiene.de/surveillance/surveillance.htm) is a useful tool in quality management in the neurocritical care unit.
At least ventilator-associated pneumonia (VAP) and central line-associated bloodstream infections (CLABSI) should be monitored. Oftentimes a surveillance program will lower the rate of infectious complications simply by increasing awareness ("Hawthorne effect").
In order to prevent the development of multidrug-resistant organisms (MDRO), an antibiotic stewardship program should be established and guidelines for the empiric therapy of important infections (as outlined below) should be in place. An updated unit-specific antimicrobial resistance profile and treatment options should be available to clinicians prescribing antibiotics (e.g., pocketcard).
The differential diagnosis of fever is especially crucial in the neurocritical care unit because many patients have fever not related to an infectious cause. Examples are: intracranial bleed, stroke, drug fever (especially phenytoin-induced), blood product transfusion, adrenal insufficiency, fat emboli, cytokine-related fever, pancreatitis, acalculous cholecystitis, pneumonitis without infection, pulmonary emboli/infarction, venous thrombosis, acute myocardial infarction, dressler syndrome (pericardial injury syndrome), tumour lysis syndrome, gout, thyroid storm, malignant hyperthermia, malignant neuroleptic syndrome, serotonin syndrome, withdrawal of certain drugs (especially benzodiazepines, opioids).

54.3 Ventilator-associated Pneumonia (VAP)

Tables 54.2 and 54.3 show the data for ventilator-associated pneumonia (VAP) and central line-associated bloodstream infections (CLABSI) from the German National Surveillance System (Krankenhaus-Infektions-Surveillance-System: KISS; www.nrz-hygiene.de/surveillance/surveillance.htm).
The diagnosis of VAP in critically ill patients can be challenging because of unspecific clinical symptoms and problems with interpreting bedside chest films. Chest computed tomography (CT) can be helpful.
Ideally, a sample of lower respiratory tract secretions is obtained before empiric antibiotic treatment is started. Specimens obtained by bronchoscopy, bronchoaveolar lavage (BAL) or mini-BAL with special protected catheters might be preferable to tracheal aspirates.
Regardless of the origin, each respiratory specimen should be transported to the microbiology laboratory within 2 hours and evaluated by Gram staining and cultured for routine aerobic and facultative bacteria. Additional special stains, rapid tests, PCR tests, and special medium cultures should be performed as directed by the clinical suspicion or epidemiologic situation of the unit. Quantitative culture results can be helpful in experienced hands, and close collaboration with medical microbiology is essential.

Type of ICU	Mode of ventilation	Number		25% Quantile		Median		75% Quantile

Table 54.2. **Ventilator-associated pneumonia (VAP) surveillance data (KISS January 2005-June 2006).**

NA = no data available IR = Incidence ratio per 1000 ventilator days
UR = Utilization ratio per 100 patients

Biomarkers such as C reactive protein (CRP), procalcitonin and interleukin 1 can be helpful, as well as soluble triggering receptors expressed on myeloid cells (sTREM) from BAL fluid to facilitate the differential diagnosis of pneumonia versus atelectasis.

A parallel obtained blood culture and fluid from diagnostic and/or therapeutic punctures of pleural effusions can yield additional microbiological culture results. Three consecutive urine specimens should be examined for legionella antigen in case of clinical suspicion or known water contamination.

The repertoire of preventive measures is quite long, and available studies have often shown their effectiveness in so-called bundles only:

- Aseptic/sterile handling of respirator equipment.
- Noninvasive ventilation (NIV) when possible.
- 30-45° elevated head position.
- Regular oral care and removal of dental plaques.
- Oral decontamination with chlorhexidine.
- Oral intubation preferred (also less sinusitis).
- Adequate cuff pressure (regular monitoring).
- Subglottic suctioning (special endotracheal tube required).
- Endotracheal tube with polyurethane high-volume-low pressure cuff.
- Heat and moisture exchange (HME) filter (needs to be changed according to manufacturer's recommendations).
- Closed suctioning (no superiority to open suctioning but reduced loss of PEEP).
- Positive end-expiratory pressure (PEEP) of at least 5 cmH_2O.
- Daily interruption of sedation (cave: ICP increase).
- Stress ulcer prophylaxis with sucralfate versus H_2-blockers and proton pump inhibitors (weak effect).
- Selective decontamination of the gut (SDD; under intense debate; for high-risk patients only).

The expected pathogens vary with the onset time of VAP. Early onset VAP (<4 days ventilatory support) is characterized by infections with *Streptococcus pneumoniae*, *Haemophilus influenzae* (and *Staphylococcus aureus*). Late onset VAP (>4 days ventilatory support) is characterized by infections with *Pseudomonas aeruginosa*, extended-spectrum beta-lactamase (ESBL), methicillin-resistant *Staphylococcus aureus* (MRSA), Enterobacteriaceae, *Acinetobacter* spp., *Enterobacter* spp., and *Candida* spp.
The empiric treatment options for severe cases should therefore include:

- A third generation cephalosporin or piperacillin/tazobactam or carbapeneme.
- In combination with an aminoglycoside (single-dose regimen, blood level monitoring) or fluoroquinolone (high dose).
- Plus linezolid or vancomycin in case of risk factors for MRSA.
- Plus high-dose fluconazole in case of risk factors for *Candida albicans* or caspofungin in case of risk factors for non-albicans Candida species.

Treatment should begin immediately after clinical diagnosis and deterioration of clinical status and be narrowed according to the microbiological results as soon as possible. For guidance on specific diagnostic procedures and appropriate antimicrobial therapy, consultation with an infectious diseases specialist (this also applies to all treatment information below) is strongly advised.

54.4 Central Line-associated Bloodstream Infections (CLABSI)

While the risk of peripheral venous catheter-related bloodstream infections appears to be low, standard precautions are necessary because of the severe nature of bloodstream infection. Skin disinfection should be performed for 30 seconds with an approved disinfectant like octenidine/alcohol or chlorhexidine/alcohol (60 seconds in case of central lines). After the skin is disinfected, it should not be palpated again with unsterile gloves or bare hands. There is no maximal duration a peripheral IV line can be kept in place, but the indication should be checked critically every day. However, IV lines placed under emergency conditions in the field or emergency room should be removed as soon as possible.

Type of ICU	Number		25% Quantile		Median		75% Quantile	
	Catheter days	CA sepsis	UR	IR	UR	IR	UR	IR
All (n=374)	2,502,548	4323	50.21	0.46	69	1.23	83.45	2.24
Interdisciplinary (n=176)	1,085,418	1478	46.82	0.25	64.07	0.83	75.15	1.65
Internal Medicine (n=74)	400,657	743	44.59	0.48	55.36	1.62	68.67	2.30

Table 54.3. **Central line-associated bloodstream infections (CLABSI) surveillance data (KISS January 2005-June 2006).**

UR = Utilization ratio per 100 patients
IR = Incidence ratio per 1000 ventilator days

Arterial lines pose a slightly higher risk of catheter-related bloodstream infection and are nowadays more frequently used for hemodynamic monitoring with pulse contour devices like PICCO®, LidCO® or Flowtrac®.

Some require frequent additional blood draws and calibration (e.g., LidCO). A strictly aseptic technique should be used for all blood draws. Three-way stopcocks should be disinfected with alcohol before manipulation. The insertion of large bore arterial lines (sheaths) for access for interventional radiology procedures, intra-aortic balloon pumps or extracorporeal circulation devices (e.g., ECMO, Novalung®) require maximal barrier precautions as recommended for CVC insertion (Table 54.1).

Central venous catheters (CVCs) are frequently used for the administration of medications, volume infusion, parenteral nutrition and blood draws. Some special lines have probes for continuous central venous saturation monitoring, thus reducing the need for blood draws. Other lines are especially designed for intravascular cooling and are connected to a thermoregulation device. Special care is required not to dislodge the lines and to keep the connections clean. CVCs have the highest risk of catheter-associated bloodstream infection (Table 54.3).

Maximal barrier precautions are required for all central venous access procedures. Special carts with all necessary equipment and regular training of physicians and nurses facilitate this practice.

The indication for continuous use needs to be evaluated daily with clinical check of the insertion site, but a routine exchange of central lines is not recommended.

The best insertion site from an infection control point of view is the subclavian vein. However, for dialysis access and venous extracorporeal circulation devices, the jugular vein is preferred to prevent catheter kinking.

Peripherally inserted central catheters (PICC-lines) are sometimes used for long-term access (several weeks), as well as tunnelled CVCs or implanted port-devices (months).

If use for more than one week is anticipated, catheters coated antimicrobially may be considered.

The femoral vein seems to have the highest risk of infections and poses a special risk for colonization by faecal organisms and *Candida* spp., which should be taken into account for empiric treatment regimens of catheter-related sepsis.

If ultrasound is used to facilitate the venous puncture, the ultrasound probe should be protected with a sterile sheath and only sterile ultrasound gel should be used.

Catheter exchange over a wire can only be recommended if infection is clinically unlikely and the exchange procedure is performed for technical reasons (e.g., larger access required, leakage, etc.). However, if a catheter-related infection is suspected, the line should be removed and the tip should be cut under sterile conditions and sent to the lab for culture. Routine cultures of catheter tips are not necessary. Parallel blood cultures through the line and from peripheral veins can facilitate the diagnosis of catheter-related bloodstream infections.

If an exchange of the catheter is not feasible (e.g., implanted port, difficult access, dialysis access which cannot be replaced), antibiotic lock treatment as described by Mermel can be employed. Each catheter lumen is filled with a volume of 5 mg/ml gentamicin solution for 8 hours, which allows a rotating schedule. Treatment duration depends on how long the catheter needs to be saved. It should be continued for a week after clinical symptoms have improved.

Infusion systems should be changed every 96 hours. Those containing parenteral nutrition fluids need to be changed after 24 hours and those containing concentrated lipids (including propofol) should be changed every 12 hours. Special care to maintain aseptic conditions should be taken when drawing up propofol or other lipid formulations into syringe pumps.

Multidose vials should be avoided whenever possible. If they are used, they should be used for one patient only and always accessed with a sterile syringe and needle after careful disinfection of the rubber membrane with sterile alcohol.
Empiric treatment for catheter-related severe sepsis and septic shock should be effective against all common Gram-positive (especially coagulase-negative staphylococci) and Gram-negative organisms (especially *Pseudomonas* spp.) and, based on the individual epidemiological situation of the unit, sometimes MRSA and *Candida* spp. as well. Combination therapy includes:

- A third generation cephalosporin or piperacillin/tazobactam.
- In combination with either an aminoglyoside or fluoroquinolone and vancomycin.
- High-dose fluconazole can be added if needed.

Multiresistant organisms such as ESBL and vancomycin-resistant enterococci (VRE) require empiric coverage in outbreak situations or if the patient is already colonized or was infected with one of those organisms.

54.5 Catheter-associated Urinary Tract Infections (CAUTI)

The best preventive strategy for catheter-related urinary tract infection is to not continuously use catheters in the first place. Especially in patients with spinal cord injury, intermittent straight catheterization should be employed as soon as possible when strict fluid balance is no longer required.
If the need for long-term urinary catheterization is anticipated, a suprapubic catheter should be considered early on (e.g., patients with severe traumatic brain injury [TBI], large hemispheric stroke, subarachnoid hemorrhage [SAH] grades 4 and 5, minimal conscious or vegetative state, etc.).
Bladder irrigations or so-called bladder training should not be performed. If fluid instillation is needed for measuring bladder pressure (e.g., monitoring for abdominal compartment syndrome), a sterile transducer system should be used and a volume of 50-100 ml sterile fluid is injected. Special catheter sets with monitoring capabilities are available to reduce the need for manipulation.
When handling the Foley bag, retrograde flow must be avoided (e.g., during transport or diagnostic procedures in the radiology suite, etc.).
Empiric treatment for complicated catheter-related urinary tract infections utilizes:

- Piperacillin/tazobactam.
- Or a carbapenem.
- Or a fluoroquinolone.

and should be adjusted to culture results as soon as possible. The differential diagnosis between colonization and infection in critically ill patients can be difficult.

54.6 Infections Associated With Extraventricular (EVD) and Lumbar Drains

A special problem in the neurocritical care unit is the prevention and treatment of device-associated meningitis and/or ventriculitis. The insertion of extraventricular (EVD) and lumbar drains or monitoring bolts for intracranial pressure (ICP), microdialysis or brain tissue oxygenation may be performed as a bedside procedure in the unit under

maximal barrier precautions and aseptic conditions. Single-dose perioperative antibiotic prophylaxis can be considered, but the value of long-term antibiotic prophylaxis is highly questionable and very likely leads to the development of resistance and selection advantages for fungi.

There are several different monitoring devices and drainage systems on the market. They should all be handled in an aseptic fashion. Manipulation and disconnection should be strictly limited. Daily draws of cerebrospinal fluid (CSF) for glucose and cell count can be helpful in detecting an infectious process early but are of limited value if large amounts of blood are present (e.g., SAH).

If a nosocomial infection occurs, the most frequent organisms are:

- Coagulase-negative staphylococci (30%).
- Gram-negative rods (25%).
- Streptococci (20%).
- *Staph. aureus* (10%).

Antibiotic treatment is started with:

- High-dose vancomycin with blood level monitoring.
- In combination with a fourth generation cephalosporin (cefepime or ceftazidime) or meropenem.
- An additional combination with systemic or intrathecal gentamicin is used routinely by some centres.

Blood levels should be monitored when systemic gentamicin is given. The same empiric treatment scheme is used for ventriculoperitoneal shunt infections.

54.6.1 Surgical Site Infections After Craniotomy/Craniectomy

Surgical site infections can complicate the course of neurocritical care patients. CSF leakage and early deep tissue infection after decompressive craniectomy are among the most severe complications. The incidence of infectious complications is about 7% for delayed cranioplasties after decompressive craniectomy.

In order to detect such events early, surgical dressings should be inspected daily. Suspicious clear drainage can be checked for glucose content at the bedside to identify CSF.

Perioperative antibiotic prophylaxis should be limited to “single-shot” dosing.

Drains (e.g., subdural drains, subgaleal drains, subcutaneous drains, etc.) need to be handled with care under aseptic conditions and inspected daily.

For general aspects for prevention of surgical site infections see: http://www.who.int/patientsafety/safesurgery/en.

54.6.2 *Clostridium difficile*-associated Diarrhea (CDAD) and Nosocomial Diarrhea

Diarrhea in the ICU can be a symptom of: drug side effects, malabsorption, enteral nutrition formula, endocrinological diseases, cholestasis, inflammation, partial obstruction, infection.

All cases of diarrhea should be evaluated for *Clostridium difficile*. Outbreak situations with noro- or rotavirus are usually diagnosed by involvement of personnel and the high rate of attack. A positive toxin screen for *Clostridium difficile* is sufficient for the diagnosis in combination with the clinical picture. However, culture and typing are important for epidemiological reasons and especially in case of outbreak situations. Special infec-

tion control measures should be followed as outlined recently by the European Centre for Disease Prevention and Control (ECDC: http://ecdc.europa.eu/en).
Once positive for *Clostridium difficile*, no further testing is required and it is worthless to evaluate treatment success or to "clear" the patient. Isolation precautions may be ceased after symptoms have cleared for more than 2 days.
The primary treatment option is IV or enteral metronidazole. In severe cases (e.g., toxic megacolon), combination with enteral vancomycin should be started immediately.

55 Selective Decontamination of the Oropharynx and Gastrointestinal Tract in Neurocritical Care Unit: A Useful Tool?

Luciano Silvestri [1], Hendrick K.F. van Saene [2]

[1] Department of Emergency, Unit of Anesthesia and Intensive Care, Gorizia Hospital, Gorizia, Italy
[2] Hendrick K.F. van Saene, School of Clinical Sciences, University of Liverpool, Liverpool, UK

55.1 Introduction

Selective decontamination of the digestive tract (SDD) is an antibiotic prophylactic strategy to control serious infections of lower airways and blood, and to reduce mortality. The full protocol of SDD includes four elements: a parenteral antimicrobial to control primary endogenous infections, enteral antimicrobials to control secondary endogenous infections, hygiene and topical antimicrobials to control exogenous infections, and surveillance cultures of throat and rectum to monitor SDD prophylaxis [1,2]. The aim of this chapter is to review the philosophy of SDD, its effectiveness and safety. A section is dedicated to the impact of SDD in critically ill neurological and neurosurgical patients.

55.2 Rationale

The key to infection control in the intensive care unit (ICU) is to appreciate that the three different types of infection, primary endogenous, secondary endogenous and exogenous, are due to a limited range of potentially pathogenic microorganisms (PPMs), six "normal" and nine "abnormal", and each require a different prophylactic approach [3-6]. Table 55.1 describes the three types of ICU infections and the preventative manoeuvres. The majority of infections in ICU are primary endogenous (about 55%), i.e. caused by

Infection	PPMs	Timing	Frequency	Manoeuvre
Primary endogenous	6 "normal" 9 "abnormal"	<1 week	55%	Parenteral antimicrobials
Secondary endogenous	9 "abnormal"	>1 week	30%	Enteral antimicrobials
Exogenous	9 "abnormal"	Any time during ICU stay	15%	Hygiene combined with topical antimicrobials

Table 55.1. **Classification of infections occurring in intensive care unit. "Normal" PPMs (potentially pathogenic micro-organisms) are *Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis, Candida albicans, Staphylococcus aureus, Escherichia coli*. "Abnormal" PPMs are *Klebsiella, Proteus, Morganella, Enterobacter, Citrobacter, Serratia, Acinetobacter, Pseudomonas* species and methicillin-resistant *Staphylococcus aureus*.**

PPMs carried in the patient's digestive tract on admission to the ICU. These infections generally develop early during ICU stay (e.g., within the first week) and are caused by 6 "normal" PPMs such as *Staphylococcus aureus, Streptococcus pneumoniae, Haemophilus influenzae, Moraxella catarrhalis, Escherichia coli* and *Candida albicans*, and 9 "abnormal" PPMs such as *Klebsiella, Proteus, Morganella, Enterobacter, Citrobacter, Serratia, Acinetobacter, Pseudomonas* species and methicillin-resistant *Staphylococcus aureus*

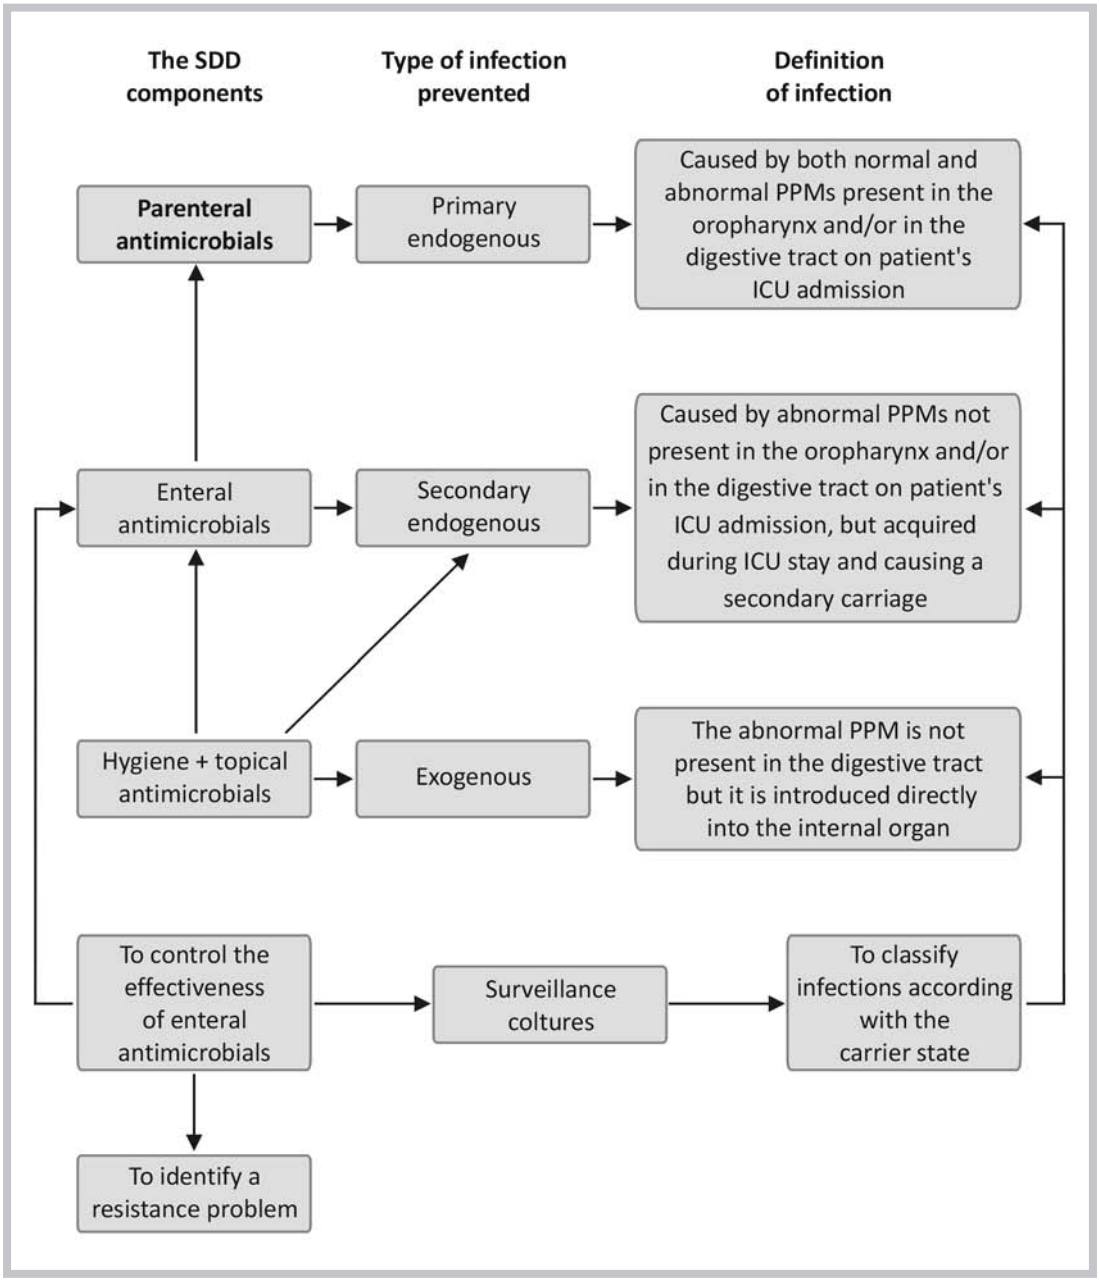

Figure 55.1. **The four components of the full protocol of SDD, and the type of infection controlled by each component.**

PPM = potentially pathogenic microorganism

ICU = intensive care unit

(MRSA). Primary endogenous infections can be controlled by the administration of parenteral antibiotics on admission to the ICU.

One third of ICU infections are secondary endogenous. They are invariably caused by 9 abnormal PPMs and develop late during ICU treatment (>1 week). These PPMs are not present in the patient's admission flora but are acquired during treatment on the ICU, followed by carriage and overgrowth, and, subsequently by colonization and infection of internal organs. Enteral administration of non-absorbable antimicrobials may control acquisition, carriage and overgrowth of these abnormal PPMs, preventing secondary endogenous infection.

Exogenous infections are caused by abnormal PPMs introduced directly into the internal organ, bypassing the carrier state. These infections may occur at any time during ICU stay. A high level of hygiene combined with topical antimicrobials is required to control exogenous infections. They occur less frequently (about 15%).

Secondary endogenous and exogenous infections are the "true" ICU-acquired infections.

55.3 The Four-component Protocol of SDD

The full SDD protocol is based on four components (Figure 55.1) [1]:

- Parenteral antimicrobials (e.g. cefotaxime 80 mg/kg/day or ceftazidime 80 mg/kg/day if the patient is suspected to carry a pseudomonal strain) for the first four days after ICU admission to control primary endogenous infections.
- Enteral administration, both oropharyngeal and intestinal, of non-absorbable antimicrobials to control secondary endogenous infections. The original protocol includes the combination of polymyxin E, tobramycin and amphoterincin B (PTA). In case of MRSA endemicity or carrier state of MRSA vancomycin can be added to classical mixture of PTA.

CI = confidence interval
NR = not reported
OR = odds ratio
RCTs = randomized controlled trials

- High levels of hygiene combined with topical antimicrobials to control exogenous infections.
- Surveillance cultures of throat and rectum taken on admission and then twice weekly (e.g. Monday and Thursday), to evaluate the efficacy of the manoeuvre and the development of resistance at an early stage.

55.4 Efficacy of SDD

SDD has been assessed in 59 randomised controlled trials (RCTs) [7], and 8 meta-analyses of only RCTs [8-15] (Table 55.2).

55.4.1 Carrier State

SDD significantly reduced oropharyngeal carriage by 87% (OR 0.13, 95% CI 0.07-0.2), and rectal carriage by 85% (OR 0.15, 95% CI 0.07-0.31) due to Gram-negative PPMs [14]. Gram-positive carriage was also reduced, but not significantly [14]. Additionally, fungal carriage was significantly reduced by 68% (OR 0.32, 95% CI 0.19-0.53) [12].

55.4.2 Lower Airway Infection

All meta-analyses showed a reduction of lower respiratory tract infection. The most robust meta-analysis by the Italian Cochrane Collaboration showed that the full protocol of SDD significantly reduced lower airway infection by 65% (OR 0.35, 95% CI 0.29-0.41) [10]. Five patients needed to be treated with SDD to prevent one episode of lower airway infection. Moreover, lower airway infection due to Gram-negatives was reduced by 89% (OR 0.11, 95% CI (0.05-0.20) and that due to Gram-positives by 48% (OR 0.52 95% CI 0.34-0.78) [14].

55.4.3 Bloodstream Infection

A recent meta-analysis including 51 randomized controlled studies comprising of 8065 patients demonstrated a significant reduction in bloodstream infections of 27% (OR 0.73, 95% CI 0.59-0.90) compared to control patients [13]. In particular, bloodstream infections due to Gram-negative PPMs were significantly reduced (OR 0.39; 95 % CI 0.24-0.63).

55.4.4 Fungal Infection

A recent meta-analysis evaluated the impact of SDD on fungal infections and demonstrated a significant reduction of fungal infections by 70% (OR 0.30, 95% CI 0.17-0.53), and a non significant reduction of fungemia due to a small sample size (OR 0.89, 95% CI 0.16-4.95) [12].

55.4.5 Mortality

Three large studies of 527 [16], 934 [17] and 6000 [18] patients have shown a mortality reduction of 30% (RR 0.70, 95% CI 0.51-0.95), 40% (OR 0.60, 95% CI 0.42-0.82), and

Table 55.3 **Summary of randomized controlled trials of SDD including patients with neurological disorders at study entry and meta-analysis of the impact of SDD on infections and mortality. Data are retrieved after reviewing 59 published randomized controlled trials of selective decontamination of the digestive tract. Patients with neurological disorders included head trauma, brain bleeding, patients with Glasgow coma scale <8, impaired consciousness, neurological disease.**

* data were found in a separate publication (Hammond JMJ, Potgieter PD, Chest 1993;104:547-51) of a subgroup of only neurological patients included in the main publication [27]. Results of meta-analysis are presented as Odds Ratios with 95% confidence interval using the random effects model. Heterogeneity was assessed by the Cochran Q statistic and the I2 measure of inconsistency. No heterogeneity was found in all comparisons with the Cochran Q statistic; I2 values of 15.6% (overall infection) and 6.5% (UTIs) were found, indicating a non significant level of heterogeneity

16% (OR 0.835, 95%CI 0.720-0.968), respectively. All meta-analyses, producing a large sample size, have shown a significant reduction in mortality. The Italian Cochrane group showed a significant mortality reduction of 22% (OR 0.78, 95% CI 0.68-0.96); twenty-one patients should be treated to save one life [10]. Similarly, the only meta-analysis with the endpoint of mortality and including randomized studies in which the full SDD protocol was used showed a mortality reduction of 29% (OR 0.71, 95% CI 0.61-0.82) [15]. This effect achieved a 42% mortality reduction in studies where SDD eradicated the carrier state (OR 0.58, 95% CI 0.45-0.77). In summary, all large randomized studies and robust meta-analyses demonstrated a significant reduction in mortality when the full SDD protocol of parenteral and enteral antimicrobials was used.

55.5 Efficacy of SDD in Patients With Neurological Disorders

Two RCTs of SDD were undertaken in subjects with neurological disorders [19,20]. Korinek et al. assessed the effect of SDD (PTA protocol including a 4% vancomycin paste) on carriage and infection in 123 neurosurgical patients: 63 received SDD and 60 placebo [19]. SDD significantly reduced Gram-negative bacilli carriage and significantly reduced the number of infected patients (29 SDD vs. 49 control, p<0.001), infection episodes (36 SDD vs. 71 control, p<0.01), bronchopneumonia (15 SDD vs. 25 control, p<0.04), urinary tract infection (12 SDD vs. 24 control, p<0.01). The authors concluded that SDD was an effective technique in reducing infectious morbidity in comatose neurosurgical patients. Gosney et al. performed a prospective, randomized, placebo-controlled, double blind study in patients with acute stroke: 103 patients received SDD and 100 received placebo [20]. There were significantly less patients with pneumonia in SDD group compared with placebo (p=0.029).

There are 22 RCTs of SDD which reported data on patients with neurological disorders at study entry (Table 55.3). Apart from the two above mentioned studies [19,20], in the other 20 RCTs [16,18,21-38], mainly in trauma patients, the number of patients with neurological disorders on admission was specified; this percentage ranged from 1.4% to 94% of the study population. In those 22 studies, including a total of 7669 patients (3782 SDD, 3887 controls), there were 851 (22.5%) and 935 (24%) patients with neurological disorders in the SDD and control groups, respectively. Remarkably, a meta-analysis of these 22 RCTs including neurological/neurosurgery patients showed that SDD signif-

Outcome	Nr. RCTs	Nr. patients		Events		OR (95% CI)	P
		SDD	C	SDD	C		
Overall infection	3	219	221	83	149	0.22 (0.10-0.48)	<0.001
LRTI	6	349	422	87	181	0.35 (0.17-0.70)	=0.0032
Mortality	6	349	422	52	68	0.82 (0.39-1.73)	ns

Table 55.4. **Meta-analysis of six randomized controlled trials of SDD including a high percentage of patients with head trauma. All RCTs including a percentage of patients with head trauma >70% of the enrolled patients were included in the analysis. Results are presented as Odds Ratios with 95% confidence interval using the random effects model. Heterogeneity was assessed by the Cochran Q statistic and the I^2 measure of inconsistency. No heterogeneity was found in all comparisons.**

C = control
CI = confidence interval
LRTI = lower respiratory tract infection
OR = Odds Ratio
RCT = randomized controlled trial
SDD = selective digestive decontamination

icantly reduced all important infectious endpoints, such as overall infection, lower airway infection, bloodstream infection, urinary tract infection, and mortality (Table 55.3). Additionally, six out of those 22 RCTs included an important percentage (>70%) of patients with head trauma on admission [19,26,30,32,33,36]. Table 55.4 shows the meta-analysis of these 6 RCTs: both overall infections and lower respiratory tract infections were significantly reduced by SDD, whilst the reduction in mortality was not significant due to the small sample size.

Therefore, these results support the use of SDD in neurocritically ill patients, including those with head trauma and severe coma, as morbidity and mortality are reduced by the prophylactic manoeuvre of SDD.

55.6 Safety of SDD

The 25 year research on SDD demonstrated that SDD does not increase the resistance problem, but rather reduces it [39]. Two of the 59 RCTs [33,40] report an increase in resistance. Interestingly, the endpoint was the number of resistant isolates rather than the number of patients with resistant isolates in these two RCTs. Three RCTs evaluated the impact of SDD on the number of patients who carried antibiotic resistant aerobic Gram-negative bacilli (AGNB) [17,18,41]. A *Klebsiella pneumoniae* producing extended spectrum beta-lactamase was endemic in a Parisian hospital [41]: carriage and infection rates were 19.6% and 9%, respectively. Once enteral antimicrobials were added to the parenteral there was significant reduction in both carriage and infection (19.6% versus 1%; 9% versus 0%). A Dutch RCT including about 1000 patients reports that carriage of AGNB resistant to imipenem, ceftazidime, ciprofloxacin, tobramycin and polymyxins occurred in 16% of patients receiving parenteral and enteral antimicrobials, compared to 26% of control patients receiving only parenteral antibiotics with a relative risk of 0.6 (95% confidence interval 0.5-0.8) [17]. The largest multi-centre RCT to date [18] includes 6000 patients, and the proportion of patients with aerobic Gram-negative bacilli in rectal swabs that were not susceptible to the marker antibiotics was lower with SDD than with standard care or selective oropharyngeal decontamination (SOD), a modified SDD protocol without the gut component. For example, carriage of multi-resistant *P. aeruginosa* was 0.4% in SDD versus 0.8% in SOD and 1.3 in the group receiving standard care ($p<0.05$).

There are four long-term studies (≥2 years) evaluating the impact of polymyxin/tobramycin on resistance amongst AGNB [42-45]. The resistance data of the long-term studies confirm the RCT findings that rates of carriage and infection due to resistant AGNB in patients receiving enteral and parenteral antimicrobials are not increased but are actually lower compared with patients receiving solely parenteral antimicrobials. Most patients who require long term treatment on ICU have overgrowth of abnormal flora, defined as 10^5 AGNB per ml of saliva and/or g of faeces. Gut overgrowth guarantees increased spontaneous mutation, leading to polyclonality and antimicrobial resistance [46]. As the parenteral antimicrobials generally fail to eradicate the abnormal carrier state in overgrowth concentrations, the enteral antimicrobials polymyxin/tobramycin aiming at converting the abnormal carrier state into normal carriage, are the essential component of SDD because they eradicate carriage and overgrowth of AGNB including resistant mutants, maintaining the usefulness of parenteral antimicrobials.

Vancomycin-resistant enterococci (VRE) and MRSA are intrinsically resistant to the parenteral and enteral antimicrobials of the SDD protocol. VRE carriage and infection were the primary endpoints of SDD RCTs in two American ICUs with endemic VRE [47,48].

Author	Study		Patients		% patients with carriage (surv) and/or infection (diagn) due to VISA and/or VRE
	Type	Period	Type	Number	
de la Cal [55]	Prospective observational	4 years	Medical/ surgical >3 days of mechanical ventilation	799	13/799 (5%) carried VRE
Cerda [56]	Prospective observational	4 years	Burns	375	No emergence of VRE or VISA in either surv or diagn
Viviani [57]	Prospective observational	2 years	Mechanical ventilation >3days	265	No emergence of VRE or VISA in either surv or diagn
Silvestri*	Prospective observational	3 years	Mechanical ventilation >4 days	193	No emergence of VRE or VISA in either surv or diagn

Table 55.5. **Long-term studies (≥2 years) of enteral vancomycin on resistance amongst *Staphylococcus aureus* and enterococci: *Staphylococcus aureus* with intermediate sensitivity to vancomycin and vancomycin-resistant enterococci.**

* L. Silvestri, personal communication
Surv = surveillance samples
Diagn = diagnostic samples
VISA = vancomycin-intermediate *Staphylococcus aureus*
VRE = vancomycin-resistant enterococci

There was no difference between test and control groups. There are seven RCTs conducted in ICUs where MRSA was endemic at the time of the trial [25,27,30,37,40,49,50], they report a trend towards higher MRSA carriage and infection rates in patients receiving SDD. The addition of enteral vancomycin to the classical SDD is required to control MRSA in ICUs with endemic MRSA [51]. Neither *Staphylococcus aureus* with intermediate sensitivity to vancomycin (VISA) nor VRE emerged in any of the six RCTs using enteral vancomycin [19,23,16,31,52,53]. Four studies using long term SDD with vancomycin (≥2 years) failed to report the emergence of VISA or VRE ([54-56], L. Silvestri, personal communication) (Table 55.5).

55.7 Conclusions

SDD has been assessed in 59 randomised controlled trials and 8 meta-analyses of only randomised controlled trials. SDD using parenteral and enteral antimicrobials consistently demonstrated a significant reduction in lower respiratory tract infection, bloodstream infection, fungal infection and mortality.

Twenty five years of clinical SDD research showed that SDD does not increase the resistance problem but rather reduces it. Two RCTs of SDD were undertaken in patients with neurological disorders, both neurosurgical patients and patients with acute stroke, and confirmed the previous results in mixed (e.g., medical/surgical) ICU population. Moreover, the majority of trauma RCTs of SDD comprised of different percentages of patients with head trauma or other neurological disorders, such as an impairment of consciousness. These studies showed a significant impact on infectious morbidity and mortality.

A meta-analysis of a subgroup of RCTs including a high percentage of neurological patients confirmed these results. For these reasons we advocate the use of SDD in critically ill neurological and neurosurgical patients.

56.1 Introduction

One of the main causes of morbidity and mortality in the industrialized countries is trauma and traumatic brain injury (TBI). In recent decades its incidence has increased constantly. Severe multiple trauma patients usually require admission to intensive care units (ICU) and most require ventilatory support.

Ventilator-associated pneumonia (VAP) is the most common nosocomial infection in the ICU, with an incidence of 10-30% [1]. In addition, VAP prolongs hospital stay and days on mechanical ventilation and contributes to an increase in mortality. Although mortality attributable to VAP in critically ill patients is still debated, the association between VAP and late mortality has been demonstrated in cohort studies, particularly in patients in whom VAP is caused by virulent pathogens such as *Pseudomonas aeruginosa* and methicillin-resistant *Staphylococcus aureus* (MRSA). In patients with VAP, there is an association between increased mortality and morbidity and inappropriate initial antibiotic treatment and delays in initiation of treatment. Early initiation and appropriate antibiotic treatment are important in the management of these patients.

In trauma patients on mechanical ventilation, VAP is a major complication, with an incidence of approximately 40 to 50%. This high incidence may be explained by the decreased level of consciousness, immunosuppression, and the need for emergency tracheal intubation. Although several recent studies have shown that VAP-related mortality in trauma patients is 8-59%, other studies found that VAP did not seem to increase mortality in severe trauma patients.

VAP in trauma patients differs from that in nontrauma patients due to characteristic risk factors and it is frequently associated with specific pathogens in the first week such as methicillin-sensitive *Staphylococcus aureus* (MSSA) and *Haemophilus influenzae*. Trauma patients have a different distribution in the incidence of VAP because, unlike nontrauma patients, the incidence of early VAP is 30-40%. According to the American Thoracic Society/Infectious Disease Society of America (ATS/IDSA) guidelines for the management of adults with hospital-acquired, ventilator-associated and healthcare-associated pneumonia, early VAP is defined as occurring within the first four days in the ICU and late VAP when it occurs after five days of admission to the ICU [2].

Brochard et al. recently showed that the beginning of VAP was associated with a higher probability of secondary brain injury, increased intracranial pressure, hypotension, fever and hypoxemia that all lead to a worse outcome [3].

The main objectives of this chapter are to review the risk factors, etiology, antibiotic treatment and prevention of VAP in trauma patients and to determine whether a different approach to such patients is needed.

56.2 Early Ventilatior-associated Pneumonia in Trauma Patients

Trauma patients can aspirate oropharyngeal secretions after brain injury, during resuscitation, and as a result of intubation. Endotracheal intubation is a major risk factor for developing VAP because it increases the risk of aspiration and weakens the bronchial clearance mechanism. The intubation procedure itself significantly increases the risk, as has been demonstrated in patients requiring reintubation [4]. Moreover, a majority of trauma patients require emergency tracheal intubation due to a decreased level of consciousness, cardiorespiratory arrest, psychomotor agitation and for air transport in some cases. Sloane et al. showed that 28% of patients who required prehospital rapid sequence intubation developed VAP and that this incidence was significantly higher than in patients intubated in the emergency department [5]. The cumulative risk of developing VAP is 3% per day of mechanical ventilation primarily within the first week of intubation.

Trauma patients often have a decreased level of consciousness that affects the swallowing reflex. Several studies have shown that the level of consciousness is also an important risk factor that increases the incidence of VAP [6,7]. Our group showed that the incidence of VAP was significantly higher among comatose patients (Glasgow Coma Score [GCS] <9) and the predominant pathogen isolated was MSSA, followed by *H. influenzae*. These data are consistent with other studies. In another study evaluating the risk factors for developing VAP within the first 48 hours of endotracheal intubation in nontrauma patients, the univariate analysis showed that high-volume aspiration of secretions, sedation, intubation for cardiorespiratory arrest or a decreased level of consciousness, emergency procedure, cardiorespiratory resuscitation, and a GSC <9 were statistically significant factors associated with VAP. But on the multivariate analysis, cardiorespiratory arrest and continuous sedation significantly increased the risk of VAP with an odds ratio (OR) of 5.13 and 4.4, respectively. Calvalcanti et al. showed in a case-control study that severe head and neck trauma, as measured by the Abbreviated Injury Scale (AIS) and Injury Severity Score (ISS), were the only independent risk factors for VAP development [8]. Moreover, they suggested that the need for supine position in patients with cervical fracture could influence this association. An interesting finding was that a GSC <8 was not associated with the development of VAP. Over 60% of patients developed early VAP and the main pathogens were MSSA and *H. influenzae*.

Due to the high incidence of early VAP caused by MSSA, several studies assessed the relationship between respiratory tract colonization and VAP. Ewig et al. performed an observational study where they analyzed the patterns of bacterial colonization in mechanically ventilated patients with severe head injury [9]. They noted that the initial colonization of the upper and lower airway was mainly by MSSA, *H. influenzae* and *Streptoccocus pneumoniae*. This colonization pattern was an independent risk predictor of subsequent colonization of the tracheobronchial tree. Although initial colonization of the tracheobronchial tree by MSSA, *H. influenzae* and *S. pneumoniae* was associated with a higher probability of early VAP, they found no independent risk factor for it. They also showed prior antibiotic use had a protective effect against these patho-

gens. Subsequently, Sirvent et al. demonstrated that tracheal colonization by MSSA, *H. influenzae* or *S. pneumoniae* within the first 24 hours of intubation was an independent risk factor for the development of early VAP in patients with TBI [10]. Bronchard et al. in a prospective observational study in TBI patients showed that nasal bacterial load of MSSA, aspiration before intubation, and use of barbiturates were independent risk factors for early VAP [3]. Recently, Agbaht et al. conducted a retrospective observational study to assess whether trauma influenced the epidemiology of VAP [11]. They found that among patients with early VAP, MSSA was the pathogen most frequently isolated in trauma patients. But in nontrauma patients *Streptococcus* spp. were the most frequent and significantly associated with early VAP. Moreover, in early VAP with prior antibiotic use, MSSA was significantly more frequent in trauma patients than in nontrauma patients. MRSA was not responsible for early episodes of VAP in trauma patients. Cases of MRSA-related VAP in trauma patients occurred in those with more than 10 days of ICU stay, when the patients had been subjected to the effect of risk factors similar to the other patients.

Other risk factors have been analyzed. Tejada et al. in a prospective cohort study found that continuous enteral feeding, craniotomy, mechanical ventilation for more than 24 hours and the use of positive end-expiratory pressure (PEEP) were independent risk factors for developing VAP in trauma patients [12]. The relationship between continuous enteral feeding and VAP has been documented in other studies. The administration of enteral nutrition with high pH via a nasogastric tube could increase gastric bacterial colonization, as well as volume, pressure and reflux. They suggested that the relationship between the use of PEEP and the development of VAP was due to the use of PEEP among patients with the acute respiratory distress syndrome (ARDS) which predisposes to the development of VAP.

56.3 Late Ventilatior-associated Pneumonia in Trauma Patients

As mentioned, in the study by Rello et al. the risk of developing VAP increased with days of intubation [7]. While cardiorespiratory arrest and continuous sedation were associated with the development of VAP in patients intubated for 48 hours, no association was found in patients intubated for more than 48 hours. In contrast, prior antibiotic use was associated with an increased risk of VAP and the main pathogen associated was *P. aeruginosa*. Ewig et al. observed that the increase in the colonization of ventilated patients during their stay in the ICU was primarily due to *P. aeruginosa* and *Acinetobacter* spp. Multivariate analysis showed that prior antibiotic use was the only risk factor for late VAP [9].

Early ventilator-associated pneumonia	Late ventilator-associated pneumonia
• Reason for intubation* • High bronchoaspiration • Emergent intubation • Cardiopulmonary resuscitation • Glasgow Coma Score <9 • Sedation	• Prior antibiotic use

Table 56.1. **Risk factors for the development of early and late ventilator-associated pneumonia.**
* Cardiopulmonary arrest or decreased level of consciousness

Agbaht et al. in a medical-surgical ICU showed that the pathogens responsible for late VAP were MSSA and nonfermentative Gram-negative bacilli (GNB) [11]. The nonfermentative GNB were significantly more frequent in late VAP than in early VAP. These pathogens were isolated from patients with risk factors such as late VAP and prior antibiotic use. They also observed that late VAP had a different distribution of pathogens in trauma patients where *Acinetobacter baumannii* was the most frequently isolated compared with nontrauma patients in whom *P. aeruginosa* was the most common pathogen isolated. MRSA was isolated from patients with more than 10 days of mechanical ventilation. This pathogen was significantly associated with the absence of trauma, late VAP, and prior antibiotic use. The main risk factors for early and late VAP in trauma patients are summarized in Table 56.1 [21].

56.4 Prevention of Ventilator-associated Pneumonia

There are several different strategies for preventing VAP. These are generally classified into nonpharmacological (Table 56.2) and pharmacological (Table 56.3) strategies. The

Strategy	Effectiveness
General measures	
Use of a formal infection-control programme	Yes
Adequate hand hygiene before and after contact with the patient)	Yes
Use of protective gloves and gowns	Undetermined
Provision of adequate nutritional support	Yes
Specific measures	
Early removal of nasogastric and endotracheal tubes	Yes
Avoidance of gastric overdistension	Yes
Oral rather than nasal intubation	Yes
Continuous subglottic suctioning	Yes
Maintenance of adequate endotracheal tube cuff pressure	Yes
Routine change of ventilator circuit	Yes
Use of noninvasive mechanical ventilation	Yes
Routine change of line-suction catheter	Not
Chest physiotherapy	Not
Humidification with heat and moisture exchangers	Undetermined
Postural changes	Undetermined

Table 56.2. **Nonpharmacological strategies for the prevention of ventilator-associated pneumonia.**

Strategy	Effectiveness
Selective digestive decontamination	Undetermined
Prior antibiotic use	Yes (intubation)
Oral hygiene with chlorhexidine	Yes
Stress ulcer prophylaxis, sucralfate vs. ranitidine	Yes
Avoid deep sedation and muscle relaxants	Yes

Table 56.3. **Pharmacologic strategies for the prevention of ventilator-associated pneumonia.**

strategies do not differ according to the type of patient since they should be applied to all patients with endotracheal intubation. Recently, the verification of compliance with a series of measures and the implementation of "care bundles" have emerged as useful integrative strategies to reduce VAP incidence.

56.4.1 Nonpharmacological Strategies for Preventing Ventilator-associated Pneumonia

Nonpharmacological strategies aim to reduce the amount of secretions that reach the lower respiratory tract and include:

- Hand washing by healthcare workers is considered the main tool for controlling and decreasing cross-transmission of nosocomial infections. Alcoholic solutions have several advantages over washing with antiseptic soap: the application requires less time for staff, their effect is more durable, and the antimicrobial spectrum is greater than that of antiseptic soap, comprising Gram-positive and Gram-negative pathogens, mycobacteria, wrap viruses and fungi. But they are not active against spore forms. Also, the supply can be adapted to any area of the room, providing greater accessibility.
- Early removal of nasogastric and endotracheal tubes. As mentioned, the cumulative risk of developing VAP is 1% per day of mechanical ventilation and early removal of the endotracheal tube is necessary. The role of nasogastric tubes is more controversial because the tubes prevent the complete closure of the lower oesophageal sphincter and could promote the conveyance of pathogens from the stomach. But it presence is essential.
- Semirecumbent patient positioning. There is unanimous agreement that patients with endotracheal intubation remain positioned at 45 degrees to reduce the ocurrence of aspiration, however, this is difficult in clinical practice.
- Continuous subglottic suctioning. Randomized studies showed a reduction in episodes of VAP. This is especially useful in patients not receiving antibiotics and during the first week of mechanical ventilation. Its effectiveness in reducing VAP by *P. aeruginosa* has not been proved.
- Maintenance of adequate of endotracheal tube cuff pressure. The recommended pressure is from 25 to 30 cmH_2O, which should be repeatedly checked daily. Pressures <20 cmH_2O allow the passage of secretions in the lower airway and pressures >30 cmH_2O could damage the tracheal mucosa.
- Routine change of the ventilator circuit. The latest studies showed no difference in the incidence of VAP with changing ventilator-circuit tubing every 48 hours, every week or if they are used throughout the patient's ICU stay, as opposed to changing every 8 or 24 hours as previously done. The tubing should be changed if there is an accumulation of secretions in it or if the tubing falls to the ground or is damaged.
- Use of humidification systems, cascade humidifier or heat and moisture exchanger. Initial studies showed that patients with heat and moisture exchangers had a lower incidence of VAP than patients with cascade humidifiers. This was because the heat and moisture exchangers had an antibacterial filter and cascade systems humidified at a temperature that did not prevent bacterial growth. But this problem has now disappeared with the new systems, so it is recommended as clinically indicated and preferably by heat and moisture exchangers.

56.4.2 Pharmacological Strategies for Preventing Ventilator-associated Pneumonia

Pharmacological strategies aim to reduce the bacterial inoculum or amount of secretions and include [13]:

- Selective digestive decontamination. This measure is not highly recommended due to the conflicting results of studies and the risk of emergence of resistant pathogens.
- Use of preventive antibiotics. As described, a decreased level of consciousness is a risk factor for the development of early VAP in trauma patients. Antibiotic administration during intubation has shown a protective effect for early VAP in a randomized and at least one observational study. In other studies, however, prolonged administration of antibiotics has been associated with an increased risk of late VAP.
- Chlorhexidine oral rinse. This practice is part of general ICU patient care. A recent meta-analysis of oral hygiene with chlorhexidine showed that it is beneficial for the prevention of VAP and this benefit is more marked in patients after cardiac surgery.
- Prophylaxis of stress ulcers with sucralfate or ranitidine. Patients on mechanical ventilation are at increased risk of gastrointestinal bleeding and therefore receive stress ulcer prophylaxis with sucralfate or ranitidine. Although the latter increases the gastric pH and may promote bacterial overgrowth, a meta-analysis found no difference in the incidence of VAP between the two treatments.
- Avoiding the use of deep sedation and muscle relaxation. As mentioned above, deep sedation is an independent risk factor for developing VAP. Current recommendations advise minimizing the use of neuromuscular relaxation and have replaced the use of sedation guidelines with fixed patterns guided by the changing state of the patient. With this approach, the daily withdrawal of sedation or a “sedation vacation” is used to assess whether the patient can start weaning. This has led to a reduction in days on mechanical ventilation and a parallel reduction in the incidence of VAP.

56.4.3 Application of “Care Bundles”

The rationale for the use of “care bundles” is that the benefit obtained from the application of a group of three to five measures intended to reduce VAP is greater than the isolated use of a single measure. The choice of a measure is supported by published evidence that i can reduce the rate of VAP. Also, it assesses the implementation of these measures and compliance with them. Our group evaluated the results of a multicenter study after the implementation of five preventive measures, including hand hygiene with alcohol solutions, shortening the duration of mechanical ventilation by adjusting sedation, chlorhexidine oral rinse, avoiding change of tubing, and ensuring correct endotracheal tube cuff pressure. This project permitted standardization of the application of preventive measures, reducing the duration of mechanical ventilation and the overall rate of VAP.

56.5 The PIRO Score

The PIRO concept derived from an attempt to classify serious infectious diseases in a way similar to TNM staging of tumours [14]. Stratification is based on the PIRO classification of sepsis episodes as a predisposing condition of the patient, the nature and extent of insult or injury, the nature and magnitude of host response, and the degree

of concomitant organ dysfunction. The concept of the VAP PIRO score was developed by our group according to this concept and adapting it to VAP for the variables that were significantly associated with mortality in a multivariate analysis of a VAP database. These parameters were selected according to previous evidence for the association with poor prognosis of VAP and good agreement with the definitions of the PIRO concept. The VAP PIRO score identifies four independent variables associated with mortality, allowing the assessment of severity in each episode. These variables are: the presence of comorbidities (chronic obstructive pulmonary disease [COPD], immunocompromised state, chronic heart failure, chronic liver disease or chronic renal failure); bacteraemia; shock; and the acute respiratory distress syndrome (ARDS) (Table 56.4). To calculate the score, each present variable is given one point. The VAP PIRO score is the sum of these four variables.

PIRO	Variables	Score
Predisposition	Co-morbidities*	1
Injury	Bacteraemia	1
Response	Systolic blood pressure <90 mmHg#	1
Organ dysfunction	ARDS **	1

Table 56.4. Variables included in the VAP PIRO score.
* Chronic obstructive pulmonary disease, immunocompromised state, chronic heart failure, chronic liver disease or chronic renal failure. One point is given for each condition present.
# Or need of vasopressor agents to maintain this blood pressure
** Acute respiratory distress syndrome

The score is simple tool for daily clinical practice that helps us to assess severity and predict mortality in patients with VAP. The score was associated with an increased risk of death in the Cox regression of high-risk patients (VAP PIRO score of 2 points; HR 2.14, 95% CI 1.19-3.86) and patients at very high risk (VAP PIRO score of 3 to 4 points; HR 4.63; 95% CI 2.68-7.99).

The main advantages of this scoring system are its simplicity, the short time needed to calculate it, and its validity for all subgroups of patients admitted to the ICU, including trauma patients, because it discriminates properly and no differences were found when comparing nontrauma patients with trauma patients, early or late VAP, and episodes with or without undetermined etiology.

56.6 Treatment

The selection of optimal antibiotic therapy should take into account the risk factors that influence the epidemiology of VAP, days of intubation, and prior antibiotic use.

In trauma patients who develop VAP within the first four days on intubation and have not received previous antibiotic treatment, the main pathogen is MSSA. Therefore, antibiotic coverage for this pathogen is required. The ATS/IDSA guidelines recommend treating early VAP with a third-generation cephalosporin (no activity against *P. aeruginosa*) fluoroquinolone or ampicillin/sulbactam. Coverage is guaranteed with any of these antibiotics. Following the survey data, Agbaht et al. reported that antibiotic treatment against MRSA is not necessary because MRSA is rare in this subset of patients [11].

Risk factors for developing late VAP are similar to nontrauma patients, which mainly include days on mechanical ventilation and prior antibiotic use. Although the proportions of pathogens in late VAP differ between trauma patients and nontrauma patients, this does not affect the antibiotic treatment since it must cover the same pathogens. Moreover, these factors should take into account each ICU epidemiology and patients' comorbidities. Therefore the general guidelines need to be adapted to local sensitivity patterns and specific characteristics of the patient's co-morbidities. Following these rules, The

Tarragona Strategy was developed for the treatment of VAP (Table 56.5) which includes ten statements based on four key points [15]: 1) immediate start of antibiotic treatment; 2) broad-spectrum antibiotic coverage followed by de-escalation based on the results of microbiology; 3) administration of antibiotics in high doses and individualized doses depending on the pharmacodynamic properties of antibiotics; and 4) choice of antibiotic penetration based on lung function of the minimum inhibitory concentration (MIC) in vitro or plasma levels. The initial use of combination therapy to treat *P. aeruginosa* significantly reduces the possibility of incorrect antibiotic treatment, which is associated with a higher risk of death [16]. However, the administration of an effective single antibiotic or combination therapy provides similar results, suggesting that switching to monotherapy is feasible and safe once the pathogen sensitivity has been determined. In patients with suspected VAP caused by MRSA, linezolid appears to be the best option. Finally, it must be borne in mind that trauma patients on mechanical ventilation and with a high creatinine clearance have an increased volume of distribution requiring higher doses of antibiotic therapy to achieve normal appropriate MIC.

1. Antibiotic therapy should be started immediately.
2. Antibiotic choice can be targeted, and in some cases based on direct staining.
3. The prescription should be modified in light of microbiologic findings.
4. Prolonging antibiotic treatment does not prevent recurrences.
5. Patients with chronic obstructive pulmonary disease or 1 week on intubation should receive combination therapy because of the risk of ventilator-associated pneumonia caused by *Pseudomonas aeruginosa*.
6. Methicillin-resistant *Staphylococcus aureus* is not expected in the absence of antibiotic exposure, whereas methicillin-sensitive *S. aureus* should be strongly suspected in comatose patients.
7. Therapy against yeast is not required, even when colonization with *Candida* spp. is present.
8. Vancomycin administration for Gram-positive pneumonia is associated with a very poor outcome.
9. The choice of a specific agent should avoid any regimen to which a patient was previously exposed.
10. Guidelines should be regularly updated and adapted to local patterns.

Table 56.5. **Tarragona strategy for therapy of ventilator-associated pneumonia.**

56.7 Conclusion

Trauma patients have a higher incidence of early VAP risk factors than nontrauma patients and MSSA is the main etiology. In this scenario, the antibiotic coverage of this pathogen is required. In trauma patients who develop late VAP, risk factors such as days on mechanical ventilation and prior antibiotic use increase the risk of developing VAP secondary to *P. aeruginosa, A. baumanni* and MSSA. In such patients the susceptibility patterns of each unit need to be taken into account. The VAP PIRO score is a useful and simple tool to assess severity and predict mortality. The implementation of "care bundles" is a step forward in the prevention of VAP.

57 The Diagnosis and Management of Central Nervous System Infections in the Neurocritical Care Unit

Wendy C. Ziai [1], **John J. Lewin III** [1]

[1] Division of Neurosciences Critical Care, Departments of Neurology and Anesthesiology-Critical Care Medicine, The Johns Hopkins Medical Institutions, Baltimore, USA

57.1 Introduction

Central nervous system (CNS) infections requiring admission to a neurocritical care unit include meningitis, encephalitis, brain and spinal epidural abscess, subdural empyema, and ventriculitis. These conditions are also complications of patients with neurologic injury and contribute significantly to morbidity and mortality. Nosocomial CNS infections may complicate neurosurgical interventions (craniotomy or ventriculostomy placement), craniocerebral trauma, and invasive neuromonitoring devices. CNS infections have acute and chronic neurologic sequelae, including seizures, hydrocephalus, focal neurologic deficits, sensorineural hearing loss, cognitive deficits, and personality change [1]. Reducing morbidity and mortality is critically dependent on rapid diagnosis and on timely initiation of appropriate antimicrobial therapy. The challenges to these goals include logistical limitations to providing immediate antibiotic therapy, pharmacokinetic barriers to achieving effective concentrations of antimicrobials at the site of infection, and changing trends in microbial resistance. Understanding the role of inflammation and the immune response in CNS infections has contributed to development of new diagnostic strategies using markers of inflammation, direct installation of antibiotics into the CNS and to the study of agents with focused immunomodulatory activity. In the Neurointensive care unit, attention should be focused on maintaining adequate cerebral blood flow, avoiding secondary complications of CNS infections, and treating the whole patient with a systems approach in order to reduce the significant non-neurologic morbidity and mortality that accompanies these diseases.

57.2 Anatomy and Inflammation of the Central Nervous System

In contrast to invertebrates in whom the brain relies on “professional” macrophages and maintains robust regenerative capacity, the vertebrate brain largely excludes hematogenous cells (lymphocytes, antibodies, neutrophils) [2]. Instead, pathogen infiltration and clearance of toxic cell debris is performed by resident “amateur” macrophages: the microglia, astrocytes, and ependymal cells which are activated to express a wide range of pattern recognition receptors (PRRs) for bacterial cell wall glycoproteins and express anti-microbial peptides.

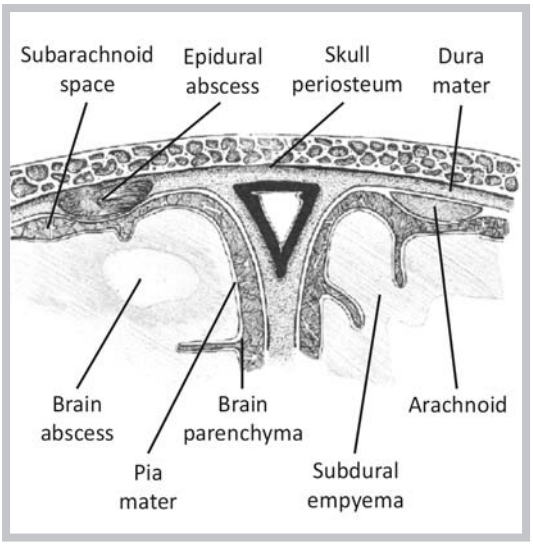

Figure 57.1. **Coronal view illustrating meningeal layers and common sites of central nervous system infections [3].**

Bacteria enter the CNS between the pia and arachnoid membranes (the subarachnoid space), a multistep process requiring evasion of host defenses (Figure 57.1). Bacteria responsible for meningitis attach to the nasopharyngeal epithelium, and are nearly all capable of secreting IgA proteases which prevent their destruction and allow them to cross the epithelium and invade the intravascular space [4,5]. Interactions between the bacterial capsular polysaccharide coat and complement regulatory proteins protect pathogenic bacteria from the complement system, increasing their ability to cross the blood-brain barrier (BBB) and enter the cerebrospinal fluid (CSF) [6].

The BBB is a highly specialized structural and biochemical barrier that regulates the entry of molecules into the brain and maintains ionic homeostasis [7,8]. The BBB is composed of nonfenestrated capillaries whose endothelial cells form continuous tight junctions that seal the paracellular cleft between adjacent endothelial membranes and prevent passive diffusion from the intravascular space to the brain parenchyma [7]. Within the CNS, a relatively low concentration of immunoglobulin and weak complement-mediated host defenses enable bacterial replication.

57.3 Pathogenesis of Bacterial CNS Infections

Clinical complications of bacterial CNS infections are largely mediated by host immune responses and leukocytes. An estimated 50% of neuronal cell loss occurring in the context of *Streptococcus pneumoniae* meningitis is the result of bacterial toxins (pore-forming pneumolysin, hydrogen peroxide); the other half is mediated by the inflammatory process [9-11]. Endogenous inflammatory mediators, such as interleukin IL-1, IL-6, and tumor necrosis factor TNF-α, which are part of the host immune response, contribute to neurologic injury by stimulating migration of neutrophils into the CSF. Proinflammatory cytokines (IL-1a, IL-1b, TNF-α, IL-6, granulocyte-macrophage colony-stimulating factor), produced by these invading leukocytes, activated endothelial cells, astrocytes, and perivascular macrophages, regulate brain inflammation by altering brain endothelial cell junction complexes, which disrupts the BBB and results in the development of vasogenic brain edema, increased intracranial pressure, and disruptions in cerebral blood flow [12-15]. Intercellular adhesion molecules, vascular cellular adhesion molecules, and selectins alter tight junction complexes by regulating leukocyte and endothelial cell interactions, and leukocytes themselves increase vascular permeability through interactions with endothelial cells and release of proinflammatory mediators [15-17]. Finally, chemokines and chemoattractant cytokines such as IL-8, monocyte chemoattractic protein-1, and chemokine ligand (CCL2) are proinflammatory mediators that selectively drive leukocytes into brain parenchyma and can regulate BBB permeability by expressing specific receptors on brain endothelial cells and by producing other proinflammatory agents [18].

Stimulation of the host immune response depends on components of the bacterial cell wall and lipopolysaccharide surface proteins [19]. Because levels of complements, immunoglobulins, and polymorphonuclear leukocytes are lower in the CSF than the serum, opsonic activity is inferior, and therefore bactericidal as opposed to bacteriostatic agents must be used to control infection [20,21].

There are also factors limiting excessive host immune responses. The TNF-related apoptosis-inducing ligand (TRAIL) appears to modify the inflammatory response and reduce neuronal cell death. Soluble TRAIL levels are elevated in the CSF of patients with bacterial meningitis [22]. In experimental meningitis, using intrathecal administration of pneumococcal cell wall (a TRAIL receptor ligand), TRAIL deficient mice had protracted inflammation, clinical impairment and increased apoptosis in the hippocampus. These changes were reversed by administration of recombinant TRAIL (rTRAIL) into the subarachnoid space of $TRAIL^{-/-}$ mice or by transplanting TRAIL-expressing bone-marrow cells into a chimeric mouse model. Therefore, TRAIL is an anti-inflammatory cytokine that limits the lifespan of activated leukocytes, mediates neuronal injury in meningitis, and may be useful as a therapeutic agent to reduce the acute inflammatory response and improve outcomes in invasive CNS infections [23].

Removing cytokine and chemokine activity with neutralizing antibodies to cytokines and chemokine receptor antagonists, respectively, has been shown experimentally to reduce brain edema formation. This may represent a new strategy for treating vasogenic brain edema, which causes significant morbidity in CNS infections [18,23,24]. Blockade of TNF-α, which contributes to cochlear injury, reduced postmeningitic hearing loss, and cochlear injury after *Streptococcus pneumoniae* meningitis [25]. Brain-derived neurotrophic factor, which has marked antiapoptotic effects in hypoxic ischemic injury, significantly reduced the extent of brain cell injury in experimental meningitis [26]. These therapies may become useful as adjunctive treatments for bacterial meningitis.

Also of importance is the blood-CSF barrier. The choroid plexi in the ventricles are perfused by unique fenestrated capillaries. The barrier function is produced by tight junctions between ependymal cells separating these capillaries from the ventricular cavity. The BBB and blood-CSF barrier have different physiology, but they both restrain CNS drug distribution [27-29]. Altered permeability of these barriers during meningeal inflammation can significantly increase drug penetration into the brain parenchyma and CSF, especially those that are poorly lipid-soluble [30].

57.4 Pathogenesis of Encephalitis

Encephalitis is an acute inflammation of the brain parenchyma. The most common causative agents are viruses including mumps, herpes simplex virus (HSV), cytomegalovirus (CMV), varicella zoster virus (VZV), enteroviruses, togaviruses (eastern and western equine viruses), and lymphocytic choriomeningitis virus. Recently West Nile virus (WNV) and monkeypox in North America, and Chandipura viruses in the developed world have emerged as important causes of viral encephalitis [31]. Also, encephalitis caused by CMV, Epstein-Barr virus (EBV) and human herpes virus (HHV)-6 has increased with increasing populations with immunocompromised states, including HIV, organ transplantation, and cancer chemotherapy [32]. Immune-mediated conditions associated with encephalitis include acute disseminated encephalomyelitis, paraneoplastic limbic encephalitis, and voltage gated potassium channel limbic encephalitis [32]. Other microorganisms that can cause encephalitis include protozoa, such as *Toxoplasma gondii*, and bacteria, such as *Listeria monocytogenes* and *Mycobacterium tuberculosis*.

Viruses enter the CNS via reactivation of latent virus within the CNS or by viremia, followed by migration across the blood-brain barrier. Blood transfusions and donated organs are also increasingly recognized as sources of transmission [31]. Virus enters brain cells by adhesion to specific cell surface receptors on glia and neurons. Once inside the cell, the virus expresses proteins which inhibit apoptosis and complement opsonization which allows the virus to prevent detection by glia. Pathology occurs due to viral destruction of cells, para- or post-infectious inflammation, and by immune mediated responses [32]. Although neurons are primarily affected, blood vessels may be involved, causing vasculitis. Other associated features include meningitis, myelitis, radiculitis, and demyelination. Cerebral edema and raised intracranial pressure can result due to induction of perivascular lymphocytic inflammation, primarily in the gray matter and at the gray-white matter junction [33].

57.5 Clinical Evaluation of Patients With Suspected Central Nervous System Infection

Critical information leading to etiologic diagnosis can be obtained from a thorough examination of clinical features [34]. Identification of infectious agents in CNS is highly dependent on the CSF analysis, and occasionally serum or biopsy data. Neuroimaging also plays an important role in diagnosis and therapeutic decision-making.

57.5.1 Clinical Presentation

Acute Septic Meningitis

Acute bacterial meningitis is a neurologic emergency, with mortality and morbidity rates as high as 25% and 60% respectively, despite improvements in critical care [35,36]. In adults, the classic triad of fever, neck stiffness, and altered mental status has a low sensitivity for diagnosis of bacterial meningitis. A Dutch study of 696 episodes of adult community-acquired acute bacterial meningitis confirmed by CSF cultures reported the full triad in only 44% [37]. More sensitive was the finding of at least two of the four symptoms of headache, fever, neck stiffness, and altered mental status which occurred in 95% of episodes. On admission, 14% of patients were comatose, and 33% had focal neurologic deficits. A retrospective French study investigated factors distinguishing between bacterial and viral meningitis in 90 patients with confirmed bacterial meningitis and 54 patients with untreated viral meningitis [34]. The presence of one of four findings at admission, among altered consciousness, seizures, focal neurologic findings or shock, and CSF absolute neutrophil count above 1,000/mm^3 was predictive of bacterial meningitis. CSF glucose less than 2 mmol/l and CSF protein above 2 g/l did not distinguish between bacterial and viral meningitis.

It is important to remember that patients who are elderly, immunocompromised, or previously treated with antibiotics may not manifest a febrile response. The combination of altered mentation and fever should alert the clinician to the possibility of meningitis in any elderly patient [38]. Other common findings are nuchal rigidity (30%) and focal cranial nerve palsies, including gaze paresis caused by hydrocephalus [39]. Seizures are reported to occur in 5% to 28% of meningitis cases and are a sign of cortical irritation, possibly due to a cortically based complication such as empyema, stroke, or venous thrombosis [40-42]. Seizure activity is an independent predictor of mortality [42].

In a review of 103 episodes of acute bacterial meningitis in adults, 34% of patients who had seizures died compared with 7% without seizures. Decreased level of consciousness on presentation is also predictive of mortality (26% versus 2%). Altered mental status is common in bacterial meningitis. The average Glasgow Coma Scale (GCS) score on admission is 10-11, of which 10-20% of patients are comatose [37]. It should be remembered that recovery is possible after prolonged deep coma, depending on the degree of structural brain pathology. Coma caused by diffuse cerebral edema can lead to cerebral herniation. Coma may also be caused by hydrocephalus and by multiple cerebral infarcts secondary to vasculitis [43].

Raised intracranial pressure is likely common in bacterial meningitis, but not frequently monitored. Intracranial hypertension in meningitis can occur due to cytotoxic edema, vasogenic edema and communicating hydrocephalus [44]. From van de Beek et al., mean opening pressure at time of diagnostic lumbar puncture was significantly elevated at 37 mmHg and was greater than 40 mmHg in 39% of patients, many of whom were comatose [37]. From a small Swedish study of patients with bacterial meningitis and GCS <8, 60% had raised intracranial pressure (ICP) on admission and 14/15 developed intracranial hypertension [45]. The mean initial ICP was higher in non-survivors (46 mmHg) compared to survivors (20 mmHg). No randomized controlled trials have investigated the potential benefit of ICP monitoring in comatose patients with CNS infeciton. Elevated ICP induces secondary brain injury by reducing cerebral perfusion pressure (CPP) leading to ischemia and by causing brain shifts leading to herniation syndromes.

Abnormal cerebral blood flow (CBF) autoregulation is common in patients with bacterial meningitis [46]. This implies that the cerebral circulation is directly dependent on blood pressure and therefore vulnerable to ischemia under conditions of low systemic blood pressure. Cerebral vasculopathy has also been documented in patients with bacterial meningitis which increases risk of ischemic stroke [47]. Other vascular complications of meningitis are cerebral venous thrombosis, venous infarction and intracerebral hemorrhage. Arterial or venous vascular complications are reported in up to 20-30% of patients [48].

A few rare manifestations of meningitis may provide clues to the causative organism: petechial or purpural rash in meningococcal meningitis, ataxia and labyrinthitis in *Haemophilus influenzae* meningitis, and cough, weight loss, night sweats, and cranial nerve deficits in tuberculosis meningitis (TBM). Systemic complications in bacterial meningitis include septic shock in 12%, pneumonia in 8%, and disseminated intravascular coagulation in 8% of cases [41]. Mortality is often related to systemic complications rather than neurologic causes, especially in the elderly, emphasizing the importance of critical care management of these patients. Risk factors for unfavorable outcome from 696 episodes of adult bacterial meningitis in the Netherlands treated between 1998 and 2002 included the following [37]:

- Advanced age.
- Presence of osteitis or sinusitis.
- Absence of rash.
- Low admission Glasgow Coma Score.
- Tachycardia.
- Positive blood culture.
- Elevated erythrocyte sedimentation rate.
- Thrombocytopenia.
- Low CSF white cell count.

The major risk factors for mortality are: seizure activity, decreased level of consciousness (LOC), Inadequate antibiotic therapy and gram-negative meningitis.

Encephalitis

The clinical scenario of encephalitis is a febrile patient who presents with altered mental status or other signs of diffuse cerebral dysfunction. A prodrome with fever, headache, myalgia, and mild respiratory infection is often present. Changes in level of consciousness with focal neurologic deficits may follow. Seizures are common, both focal and generalized; occurrence depends on the etiological agent [49,50]. Some characteristic presentations are parotitis associated with mumps and herpetic rash with *Herpes simplex* encephalitis (HSE) although the latter is rare. Immunocompromised patients with brainstem HSE may present with cranial nerve palsies such as diplopia, dysarthria, and ataxia [51,52].

HSE is the most important form of treatable encephalitis. The clinical picture is altered consciousness, memory loss, personality change, and confusion or olfactory hallucinations, following a prodrome of headache and fever [53]. About two thirds of patients have seizures, often focal motor seizures affecting the face and upper extremities due to frontal and temporal lobe involvement. Focal neurologic signs like hemiparesis and aphasia are more common with HSE than other encephalitides. HSE is a medical emergency, and it is associated with a high mortality rate and numerous sequelae. Over 20% of survivors have severe disability which includes cognitive and behavioral disorders, seizures, and postinfectious encephalomyelitis [54,55].

Most cases of adult HSE appear to be caused by reactivation of HSV-1, either in the trigeminal ganglion or latent virus in the brain itself [56] although more recently it is unclear if HSE represents primary or recurrent infection and strains of HSE and cutaneous herpes simplex may be different. HSE has no identified triggering factors and although immunosuppression is associated with more aggressive disease and worse outcome, it does not predispose patients to the disease [57]. HSV-2, which causes genital herpes in adults, accounts for approximately 10% of HSE, mostly in neonates and the immunocompromised. Most cases of recurrent meningitis (previously called Mollaret's meningitis) are thought to be caused by HSV-2 [50].

West Nile virus encephalitis (WNVE), caused by a single-stranded RNA virus of the *Flavivirus* family appears to only cause severe human disease in the United States and Israel [58]. The disease usually affects persons over age 55, and has a 15% mortality rate [59,60]. Neuroinvasive WNV only occurs in an estimated 1% to 2% of infections, but the risk of encephalitis increases with age and in immunocompromised states [49]. Without encephalitis, WNV represents a flu-like illness. Signs of encephalitis are typical: fever, fatigue, nausea/vomiting, headache and altered mental status. WNVE presents with delirium in 38%, stupor in 27% and coma in 22% [61]. Other neurologic features include movement disorders, sometimes with Parkinsonian features, postural tremor, and myoclonus and cerebellar signs [61-63]. Seizures are infrequent. WNV can cause an acute flaccid limb paralysis in 10% of neuroinvasive cases, caused by infection of the anterior horn cells of the spinal cord, causing profound weakness and respiratory failure [64]. This poliomyelitis-like illness also occurs in other *flavivirus* encephalitides (*Japanese encephalitis virus* and *St. Louis encephalitis virus*) and *enteroviruses* [61-65]. The mortality in WNV is caused by respiratory failure in half of such cases. Morbidity is high, due to long-term limb weakness and functional disability [64]. Ophthalmologic disease, such as chorioretinitis and vitritis, and rhabdomyolysis are associated findings [66,67]. Pediatric WNV has similar manifestations and infection rates to adults and accounted for 12% of all neuroinvasive cases in the United States in 2004 [68,69].

Brain Abscess

Brain abscesses are focal, purulent infections of brain parenchyma. Site-specific focal neurologic deficits, such as aphasia and weakness are common although signs of in-

creased intracranial pressure may be the only presenting feature [70]. Fever is less common than in meningitis and when neck rigidity is present (25% of cases) it may indicate associated meningitis [38]. Seizures occur in up to 40% of cases and are often generalized tonic-clonic [71]. The route of transmission is usually contiguous spread from a local primary focus (paranasal sinusitis, otitis media, mastoiditis, penetrating head trauma (10%)). Twenty percent of cases spread hematogenously from either a pulmonary source (bronchiectasis, lung abscess), cardiac source (heart valve – infective endocarditis), or conditions with right to left shunt. The mouth, skin, and gastrointestinal tract may also be sources. In cases of hematogenous seeding, multiple abscesses are seen in 20%. Polymicrobial infections are not uncommon. *Staphylococcus pyogenes* is common in penetrating skull injuries. Organisms to consider in immunocompromised patients are *Listeria*, mycobacteria, fungi, and parasites. The important complications from abscess to watch for include strokes caused by cortical thrombophlebitis, rupture of abscess into ventricle or subarachnoid space causing meningitis or ventriculitis and increased intracranial pressure. The mortality from brain abscess is 10% overall.

Cranial Epidural Abscess

Cranial epidural abscess is an extra-axial infection occurring in the virtual space between the dura mater and the skull. It is most often located in the frontal region, and presents with headache, fever, and nausea, but rarely focal neurologic signs. Spread of infection is limited by tight adherence of dura to the overlying skull. These infections are usually related to trauma and neurosurgery, but can occur secondary to meningitis, sinusitis, and other extra-cranial sources. The most common infectious etiologies are streptococci, staphylococci, and anaerobes, with many infections being polymicrobial [72,73].

Subdural Empyema

Subdural empyema occurs in the potential space between the dura mater and the arachnoid, most commonly over the cerebral convexity. Unlike epidural infections, subdural empyema can spread more diffusely and cause inflammation of the brain parenchyma, edema, mass effect, elevated intracranial pressure, septic thrombophlebitis, and venous infarction [72,74]. Findings are therefore more severe including altered level of consciousness, focal neurologic deficits, and seizures. The sources of infection are the para-nasal sinuses, hematogenous spread via emissary veins in the subdural space, and extension of an epidural abscess into the subdural space [72,75].

Infratentorial empyema is a rare complication of bacterial meningitis. It presents as subacute meningitis with neck stiffness and decreased consciousness and should be suspected in a patient with recent history of otitis, sinusitis, or mastoiditis (especially after surgery) and findings suggesting meningitis and a posterior fossa lesion [76]. The preferred method of diagnosis is MRI with diffusion-weighted imaging (DWI) based on several reported cases of delayed diagnosis with CT which failed to visualize the lesions. DWI can distinguish subdural empyema from reactive subdural effusion [77]. The high mortality rate of this condition (34%) is due to its subdural location, hydrocephalus, and delayed detection. The management is antimicrobial therapy and a low threshold for neurosurgical exploration.

Ventriculitis

Ventriculitis is an infection of the ventricular system of the brain. The ventricles act as a reservoir of infection and inflammation, which causes blockage of CSF outflow tracts and hydrocephalus [78]. Ventriculitis complicates meningitis in 30% of adult cases, and up to 90% of neonatal cases [74]. It is clinically important when inflammation and bac-

terial load in the ventricles exceed those in the paraspinal space [78]. It is often a late complication of meningitis, when patients fail to improve with conventional therapy, but it can occur as a primary process [79,80]. Ventriculitis is frequently associated with intracranial devices, namely a CSF shunt or external ventricular drain (EVD). The risk of ventriculitis or meningitis with an EVD in place is most commonly reported in the 10% to 15% range, and depends on the type of EVD, insertion technique, management, and duration [81-84]. Blood in the CSF is a significant risk factor for ventriculostomy-related infections, and contributes to the high incidence of these infections in aneurysmal subarachnoid hemorrhage patients (10%) and patients with intraventricular hemorrhage (IVH) (13.7%) who have EVDs [83-85]. Other significant risk factors for infection are protocol violations in EVD care and CSF leaks [86]. Infection is reported to occur in 8% to 40% of patients receiving a CSF shunt, most within the first month after implantation [72]. Common pathogens causing EVD and CSF shunt infections are gram-positive organisms, such as *Staphylococcus epidermidis* and *Staphylococcus aureus*. Up to 25% of infections, however, are caused by gram-negative organisms, such as *Escherichia coli*, *Klebsiella* species, *Acinetobacter*, and *Pseudomonas* species [72].

57.5.2 Cerebrospinal Fluid Analysis

Diagnosis and management of CNS infection largely relies on CSF analysis. It is important to obtain CSF access as soon as it is safe. Concerns about uncal or cerebellar tonsillar herniation and the need to initiate empiric antibiotics emergently are often competing demands. The literature supporting necessity of doing a head CT scan prior to lumbar puncture (LP) is minimal while the evidence in favor of not delaying antibiotics in suspected meningitis is significant. Unfortunately the availability of CT frequently delays starting antimicrobial therapy [87]. In van de Beek's study of 696 episodes of community-acquired acute bacterial meningitis [37], CT was performed before LP in 48%, and in 63% of subjects presenting with impaired consciousness or neurologic deficits. In two thirds of subjects who had a CT scan, antimicrobial therapy was not started until after CT results were obtained. In many countries it is common practice to perform a head CT before performing LP in patients with suspected meningitis, due to a perception that this is a standard of care or because of fear of litigation [88]. In fact, only 1-2% of patients with meningitis herniated, and a much smaller percentage do so within hours of LP [44]. A normal CT does not eliminate risk for herniation. Criteria for performing head CT to assess risk for cerebral herniation prior to CSF access are the following [89,90]:

- Immunosuppression (to rule out *Toxoplasma encephalitis* or lymphoma).
- Significant alteration in mentation or comatose patient.
- Focal neurologic deficits.
- Seizures.
- Papilledema, poorly reactive pupils, or ocular palsies.
- Bradycardia or irregular respirations.
- Sedation or muscle paralysis.

In a prospective study of 301 adults with clinically suspected meningitis, 78% of subjects underwent CT before LP [88]. Of these, 24% had an abnormal finding and 5% had mass effect. Abnormal findings on CT were associated with the following clinical features at baseline:

- Age greater than 60 years.
- Immunocompromised state.
- History of a CNS lesion.
- History of seizures within 1 week before presentation.

- Abnormal level of consciousness.
- Inability to answer two consecutive questions correctly or follow two consecutive commands.
- Focal neurologic deficits including gaze palsy, abnormal visual fields, facial palsy, arm drift, leg drift, and abnormal language.

Of the 96 subjects who had none of these findings, only three had abnormal findings on CT and underwent LP without subsequent herniation (negative predictive value of 97%). The delay from admission to time of lumbar puncture in patients who first underwent CT resulted in a greater delay in administering empiric antibiotic therapy in this group [88]. It is well-described that the diagnostic sensitivity of CSF is not decreased by delaying LP by 1 or 2 hours after starting antibiotics [91]. If available, CSF counterimmunoelectrophoresis, CSF latex agglutination and coagulation tests detect common bacterial antigens in 70-100% of cases [92].

It is recommended that in all patients with clinical signs suggestive of increased ICP, even without abnormalities on head CT, one must exercise caution in performing an LP, or use a small 22- or 25-gauge needle to remove the smallest amount of CSF possible and minimize CSF leakage [89]. In a review of lumbar puncture associated with brain herniation in acute bacterial meningitis, the incidence of cerebral edema with brain herniation was 5%, accounting for approximatetly 30% of the mortality [93]. Many such reports describe a temporal association between the LP and the herniation event although herniation may also occur gradually due to ongoing CSF leakage from the LP site or due to cerebral vascular engorgement. The best clinical indication to delay the LP are clinical signs of ''impending'' herniation rather than CT findings. Aggressive treatment of herniation has been reported to produce good outcomes. Therefore, a high-risk patient should have blood drawn for culture and empiric antibiotic therapy initiated prior to CT.

Typical CSF findings in various CNS infections are presented in Table 57.1. Gram's stain of CSF will show organisms in 60% to 90% of bacterial meningitis cases and cultures are positive in 80% [38]. Most patients will have a CSF white blood cell count greater than 100 WBC/mm^3 in 90% of cases and greater than 1,000 WBC/mm^3 in 60%.

CSF glucose levels are less than 40 mg/dl in 50% to 60% of patients. The CSF to serum glucose ratio of less than 0.4 is 80% sensitive and 98% specific for bacterial meningitis in children over 2 months of age [92]. Decreased CSF glucose is also seen in fungal, tuber-

Infection	Cell count (cells/mm^3)	Glucose	Protein
Bacterial meningitis	Elevated (100-5000) PMNs predominate	Decreased	Elevated
Viral meningitis	Elevated (10-500) Lymphocytes predominate	Normal	Elevated
Fungal meningitis	Normal to elevated (0-500) Lymphocytes predominate	Normal to decreased	Elevated
Tuberculous meningitis	Normal to elevated (0-1000) Lymphocytes predominate	Decreased	Elevated
Brain abscess	Normal to elevated (0-500) Mixed differential	Normal	Elevated
Ventriculitis	Elevated (100-5000)* PMNs predominate	Decreased	Elevated

Table 57.1. Cerebrospinal fluid findings in CNS infections.

* Note: in post-neurosurgical patients, or patients with a ventriculostomy, the CSF cell count may be elevated as a result of surgical manipulation and inflammation. Reduction in CSF glucose may be a more sensitive indicator of infection.

PMNs = Polymorphonuclear leukocytes

culous, or carcinomatous meningitis. The CSF protein level is the most resistant to rapid change after starting treatment; levels remain elevated for 10 days or longer [94]. The CSF findings in subdural empyema and epidural abscess typically show a polymorphonuclear pleocytosis (10-500 WBC/mm^3), normal glucose, increased protein, and often negative Gram's stain and culture [71]. Blood cultures are positive in up to 50% of cases of meningitis [72]. Hyponatremia is common in both meningitis and encephalitis and is caused by the syndrome of inappropriate antidiuretic hormone (SIADH). CSF lactate concentrations are non-specific for suspected community-acquired bacterial meningitis, but may be useful for diagnosis of post-neurosurgical meningitis where a CSF lactate concentration cut-off of 4 mmol/l was superior to the CSF:serum glucose ratio [92,95]. This cut-off had a sensitivity of 88%, specificity 98%, positive predictive value 96% and negative predictive value 94%. Routine use of latex agglutination tests for bacterial antigens is not in common use because it does not appear to modify the decision to administer antimicrobials. Additionally, false-positive results have been reported [92]. They may be useful for patients pretreated with antibiotics with negative Gram's stain and CSF cultures. Bacterial DNA detection by polymerase chain reaction (PCR) for common meningeal pathogens has relatively limited availability, but should increase with further refinements which improve sensitivity and specificity [92]. Broad-range real-time PCR and DNA sequencing for bacterial meningitis detects virtually all pathogenic bacteria and has a sensitivity between 86% to 100% and specificity of 98% when compared with culture [96,97].

Laboratory diagnosis of tuberculous meningitis (TBM) remains challenging. The typical CSF profile is a lymphocytic predominant pleocytosis with elevated protein and low glucose, but has many exceptions, especially in HIV-positive patients [98-100]. The acid-fast stain for tuberculosis (TB) has sensitivity as low as 30%, which can be improved to about 80% with repeat CSF sampling and meticulous examination [72]. Culture, the gold standard, is only positive in 40% to 70% of cases and, even with fully automated liquid culture systems, takes from 1 to 3 weeks to a positive result. Several mycobacterial antigen and antibody kits have been designed but lack adequate sensitivity and specificity to gain wide acceptance [98,101,102]. CSF adenosine deaminase activity (ADA), a biomarker, is elevated in TBM and in developing countries the CSF ADA activity at a cut-off value of 6.97 IU/l has a reported sensitivity and specificity of 85% and 88%, respectively, for distinguishing TBM from non-TBM or nonmeningitis [103]. CSF ADA levels are also elevated in conditions such as lymphoma and sarcoidosis. Molecular diagnosis with commercial nucleic acid amplification tests for diagnosis of TBM have a sensitivity of 60% to 83% and specificity of 98% to 100% [102,104]. Real-time PCR is fast and has greater sensitivity than conventional PCR, but still cannot be used reliably to rule out TBM [105]. Nucleic acid amplification tests, if available, should be the first-line test to rule in TBM due to their high specificity [105]. Radioimmunoassay detection of interferon-gamma release measures a major mediator of the immune response in TB, affecting macrophage stimulation and lymphocyte Th1 transformation [106]. Interferon-γ assays in CSF were compared with PCR for diagnosis of TBM and had a higher sensitivity (70% versus 65%) with a specificity of 94% [107]. Combination of PCR and interferon-γ improved sensitivity to 80% and the incremental value of test combinations such as these shows promise, although further prospective studies should be performed. Currently, careful bacteriology is as good as or better than molecular methods, although the latter are sensitive for longer when anti-TB drugs have been started [103,108].

Acute-phase reactants have been examined for their usefulness in diagnosing acute bacterial meningitis, but appear to have limited usefulness in the intensive care unit. Elevated procalcitonin (PCT) concentrations can differentiate between bacterial and viral meningitis in children (cut-off 0.5 mg/l; sensitivity 94%; specificity 100%) and adults (cut-off

0.2 ng/ml; sensitivity and specificity up to 100%) [109-111]. Of 48 adult patients with acute bacterial meningitis and a serum PCT level on admission above 0.5 ng/ml, serum PCT levels decreased rapidly (from 4.5 to 2 mg/ml) (within 24 hours) with appropriate antibiotic treatment, suggesting this test may replace repeat lumbar puncture at 48 to 72 hours to assess antibiotic therapy [112]. Alternatively, in patients with ventriculitis and a ventricular catheter, PCT levels usually remain within the normal range, even with positive bacterial cultures [113,114].

Nosocomial EVD-related infections are difficult to diagnose because of lower diagnostic value of CSF values, less specific clinical signs of infection, and slow-growing and fastidious organisms [115]. Broad-range real-time polymerase chain reaction (RT-PCR) may have a role in producing faster diagnosis (about 4 hours) with probable increased sensitivity over cultures after antibiotic treatment and ability to detect bacteria, especially gram-negatives that are difficult to isolate [96]. Disadvantages of PCR include inability to identify antibiotic sensitivities, false negative results, and contamination issues. The ratio of leukocytes:erythrocytes in CSF divided by leukocytes: erythrocytes in peripheral blood (called the cell index) has been used to detect EVD-related infection in patients with IVH [116]. At IVH onset, the CSF relationship of leukocytes to erythrocytes should be equal to that in peripheral blood; the cell index should be 1. In 7/13 patients with definitive ventriculitis, the cell index showed a significant rise 3 days before the conventional diagnosis of catheter-related ventriculitis. Antimicrobial therapy led to a rapid decrease of both the cell index and usual infection parameters [116].

Viral CNS infection is associated with normal-to-mild ICP elevation, CSF lymphocytosis (neutrophils if tested early), WBC counts of 50/mm^3 to 2000/mm^3, normal glucose, and elevated protein [71]. HSV-1 encephalitis is typically associated with hemorrhagic CSF and very high CSF red cell count. CSF culture and serologic testing of acute and convalescent serum may be beneficial. For HSE, the sensitivity and specificity of PCR in CSF are 98% and 94%, respectively. One third of cases remains PCR-positive long after starting acyclovir treatment [117]. It is recommended to repeat LP at 24-48 hours and continue treatment for 10 days, due to the possibility of false negative PCR for HSV with early testing if features are consistent with HSE [118,119]. PCR has good specificity for CMV (95%) and *Toxoplasma* (100%), but lower sensitivity (79% and 42%, respectively) [71]. In patients with suspected enteroviral meningitis, enteroviral RT-PCR is more sensitive than viral culture for detecting enteroviruses (sensitivity 86% to 100%; specificity 92% to 100%) [120]. The diagnosis of most important viruses, as well as *Mycoplasma pneumoniae* can be determined by detection of IgM (and IgG) antibodies in CSF (and relative to serum) by an enzyme-linked immunosorbent assay. Oligoclonal bands may distinguish inflammatory from noninflammatory causes of encephalopathy. Anti-HSV-1 antibody in CSF can be detected at 10 days, with 50% sensitivity [32]. Immunocompetent patients should be initially tested with PCR for HSV, VZV (both potentially treatable with antiviral therapy), and enterovirus [32]. For immunocompromised patients, EBV and CMV PCR should be added and HHV-6 and HHV-7 considered. Other PCRs to send depend on clinical indication. Quantitative PCR (comparing virus in CSF with that in blood) may be required to determine the significance of a positive PCR assay, especially in HIV patients who may carry infected lymphocytes without representing pathogenic infection.

Findings in viral CNS infection on peripheral blood count are leukocytosis or leukopenia, atypical lymphocytes (EBV), or eosinophilia (eosinophilic encephalitis) [32]. Serum amylase may be elevated in mumps; cold agglutinins occur in mycoplasma, upon which serologic investigations are indicated for mycoplasma and *Chlamydia*; infiltrates on chest X-ray in atypical pneumonia should be followed by investigation for *Mycoplasma*, *Legionella* or *Lymphocytic choriomeningitis virus*. HIV testing should be performed for uncertain causes of CNS infection [32].

In fungal meningitis, in immunosuppressed patients, CSF may appear normal, although opening pressure may be high. In cryptococcal meningitis in HIV-positive patients a predominantly lymphocytic pleocytosis with low CSF glucose and high protein levels is common [39]. The encapsulated fungus can be identified by India ink examination of CSF, and serologic detection of cryptococcal antigen is sensitive and relatively specific for CNS cryptococcal infection. Repeat LP and CSF analysis to document CSF sterilization is not indicated routinely [92].

A patient who does not respond clinically after 48 hours of appropriate antimicrobial therapy, especially in cases of penicillin- or cephalosporin-resistant pneumococcal meningitis, and adjunctive dexamethasone therapy, should undergo repeat CSF analysis [92,121].

57.6 Neuroimaging Findings in Central Nervous System Infections

In uncomplicated bacterial meningitis, CT scans are usually sufficient for clinical management to assess cerebral edema, hydrocephalus, and base of skull pathology such as fractures, inner ear infection, or mastoiditis. Other important findings include subdural effusions, brain stem encephalitis (rhombencephalitis) with *Listeria* infection, and cortical infarcts secondary to vasculitis (20% of cases) [122]. CT or MR venography should be used to diagnose cerebral venous sinus thrombosis. MR DWI shows parenchymal complications of meningitis, such as infarcts of septic vasculitis earlier than other sequences. Encephalitis, cerebritis, and TB are DWI-hyperintense; neurocysticercosis lesions are DWI-hypointense. Toxoplasmosis is variable, whereas lymphoma shows no restriction of water diffusion [122]. MR angiography can suggest vasculitis. Ventriculitis is detected best by T2 fluid-attenuated inversion recovery (FLAIR) images showing periventricular hyperintensity or ependymal enhancement and irregular intraventricular debris [122]. In TBM, basal meningeal enhancement, hydrocephalus, tuberculoma, and infarction are all more common than in bacterial meningitis, where subdural collections are more common [123]. Based on a CT study of 94 children with TBM [123] basal meningeal enhancement or tuberculoma was 89% sensitive and 100% specific for diagnosis of TB. Precontrast hyperdensity in the basal cisterns on cranial MRI may be the most specific radiologic sign of TBM in children [124]. In Lyme disease, multifocal nonenhancing patchy lesions on T2 weighted images (T2WI) can be seen [122]. In acute HSE, FLAIR or T2WI show asymmetrical changes of necrotizing encephalitis in the first 48 hours and may be diagnostic. Diffusion abnormalities disappear within 14 days after symptom onset, while T2 hyperintensities persist [122]. Single photon emission CT (SPECT) may indicate hyperperfusion suggesting inflammation and neuronal injury in the temporal and frontal lobes relatively early, although half of scans are normal in the acute stage, and hyperperfusion is a nonspecific finding [71].

Bacterial abscesses are hyperintense on DWI with reduced apparent diffusion coefficient (ADC) in contrast to nonpyogenic lesions, which are generally hypointense or mixed-signal. Proton MR spectroscopy shows lactate, cytosolic amino acids, and absence of choline [122]. Extra-axial bacterial empyemas appear slightly hyperintense relative to CSF and hypointense to white matter on T1WI and hyperintense on T2WI, distinguishing them from sterile effusions and chronic hematomas [122]. Epidural hematomas can be distinguished from subdural empyema by a hypointense rim representing displaced dura in the former. On DWI, subdural empyema is usually hyperintense, whereas epidural hematoma usually has a low or mixed-signal intensity [122].

57.7 Antimicrobial Therapy

57.7.1 Distribution of Drug Into the Central Nervous System

Antimicrobial distribution into the CNS is influenced by physical barriers, and physiochemical properties of the antimicrobial itself. The major physiochemical factors governing antimicrobial penetration into the CNS are listed in Table 57.2. Only the unbound concentration of drug is available to diffuse across the BBB and blood-CSF barrier. Therefore highly protein-bound agents have limited ability to penetrate the CNS [125].

The tight junctions within the BBB and blood-CSF barrier limit diffusion of large molecular weight substances (>500 daltons). Anti-infectives with larger molecular weights such as vancomycin or amphotericin B have limited ability to penetrate an intact barrier [27,125]. More lipophilic agents (defined by a high octanal-to-water partition coefficient) will penetrate the CNS more readily than hydrophilic compounds. Lipophilicity can also affect the distribution of drugs within the CNS. Highly lipophilic agents accumulate in the lipid-rich brain structures, with a resultant lower concentration in the CSF and extracellular fluid. CSF levels may therefore underestimate overall CNS penetration [125]. The degree of ionization at physiologic pH also affects penetration of the BBB. Most drugs are weak acids or weak bases, and therefore polarity can vary depending on the pH. The pH of blood, CSF, and extracellular fluid changes with infection, and this can influence the polarity and, therefore anti-infective penetration of the CNS [125].

The choroid plexus contains specialized active transcellular transport systems involved in the excretion of drugs across the cerebral vessel wall [27]. During active CNS infection, impaired CSF excretion systems may result in higher CSF concentrations of antibiotics. As inflammation diminishes, antibiotic concentrations may subsequently decrease [28]. Disruption of the BBB during inflammation also affects antibiotic penetration. Hydrophilic agents such as vancomycin rely on passive diffusion through opening of tight junctions in the BBB and therefore have increased penetration during meningeal inflammation [126]. Hydrophilic drugs which use active transport systems such as penicillin and ceftriaxone may have lower concentrations in brain tissue after BBB injury [127].

57.7.2 Timing and Appropriateness of Initial Antimicrobial Therapy

Mortality from delaying antibiotic treatment for CT and LP is estimated at 10 to 20 times the risk of complications associated with lumbar puncture. A prospective multicenter

Physiochemical property	Effect on CNS penetration
Lipophilicity	Highly lipophilic drugs more readily penetrate the CNS
Protein binding	Highly protein bound drugs have reduced CNS penetration
Molecular weight	Substances >500-800 daltons have reduced ability to penetrate the BBB
Ionization	Polar, ionized compounds are less likely to cross the BBB. Polarity can vary for many drugs with changes in physiologic pH
Active transport	Specialized active transport cells in the choroid plexus may excrete drugs across the vessel wall

Table 57.2. **Physiochemical properties influencing antimicrobial penetration into the CNS.**

observational study of 156 adults hospitalized for pneumococcal meningitis found three factors independently associated with 3-month mortality: simplified acute physiology score II, isolation of a nonsusceptible strain, and an interval of greater than 3 hours between hospital admission and administration of antibiotics [128]. A retrospective cohort study of 286 adults with community-acquired bacterial meningitis assessed causes of unfavorable outcomes [129]. The major finding was that time to starting appropriate antibiotic treatment relative to the onset of first symptoms and particularly to the onset of consciousness disturbance was significantly delayed in the poor outcome group. Practice guidelines for the management of bacterial meningitis recommend that patients with purulent meningitis receive the first dose of antibiotics as soon as possible, and that antibiotic administration not be delayed for an LP [92]. The appropriate selection of initial antibiotics is also crucial. In a retrospective review of 109 subjects with community-acquired meningitis, 22 subjects did not receive appropriate initial antibiotic coverage, of whom 100% died, as compared with 23% of patients receiving appropriate therapy [130].

57.7.3 Antimicrobial Selection and Dosing

Meningitis

Empiric therapy of meningitis must consider patient age, immune status, and whether the infection is acquired in the community or nosocomial setting. Recommendations for empiric therapy of meningitis are listed in Table 57.3. Organism-specific recommendations are provided in Table 57.4.

Before the availability and widespread use of the *H. influenzae* type B vaccine, *Haemophilus influenzae* accounted for nearly 50% of bacterial meningitis cases (most being in children) in the United States [1,132]. Now, *H. influenzae* causes only a small percentage of cases, with the median age of patients with bacterial meningitis shifting from 15 months to 25 years [133]. In the United States and many countries, most cases of community-acquired bacterial meningitis are caused by *Streptococcus pneumoniae* (47%), followed by *Neisseria meningitidis* (25%), group B *Streptococcus* (13%), *Listeria monocytogenes* (8%), and *H. influenzae* (7%) [133]. More recently traditionally nosocomial gram-negative organisms (e.g., *Klebsiella* species, *Serratia* species, *Pseudomonas* species, and *Acinetobacter* species) are becoming increasingly common [134]. Such trends reflect a shift in the epidemiology of meningitis from a disease of the young and otherwise healthy to a disease of the elderly and immunocompromised. The immunocompromised are especially susceptible to meningitis caused by *Listeria monocytogenes* and gram-negative bacilli.

Of even greater concern is the emergence of resistance of both gram-negative organisms to 3rd and 4th generation cephalosporins and to carbapenems [135-137] and of gram-positive organisms to methicillin (methicillin-resistant *Staphylococcus aureus* – MRSA) and vancomycin (vancomycin-resistant *Enterococcus* – VRE). Multidrug resistant (MDR) gram-negative bacteria, including *Acinetobacter* spp. and *Citrobacter* spp. [138,139], and gram-positives such as *Staphylococcus epidermidis* are becoming more common. Even *Streptococcus pneumoniae* is developing reduced sensitivity to cephalosporins and even carbapenems [140].

In the setting of neurosurgery, head trauma and CSF leak, and cerebrospinal shunts, the most common organisms are *S. aureus* and gram-negative bacilli. Effective source control is critical, which often necessitates surgical removal of foreign materials. In patients with CSF shunts who are shunt-dependent, removal of the shunt often necessi-

tates placement of a temporary EVD. For TBM, the Infectious Diseases Society of America and American Thoracic Society recommend a similar regimen as for pulmonary TB [141]. An intensive 2-month phase with four drugs (isoniazid, rifampin, pyrazinamide, and ethambutol) is followed by a continuation phase for 6 to 9 months.

Patient-specific factor	Common pathogens	Preferred regimen	Alternative regimens
18-50 years	*S. pneumoniae, N. meningitidis, H. influenzae* (non-immunized patients)	Ceftriaxone[1] 2 g IV q 12 hrs ***or*** cefotaxime[2] 2 g IV q 6 hrs	Meropenem[2] 2 g IV q 8 hrs ***or*** chloramphenicol[3,4] 50 to 100 mg/kg/day in 4 divided doses ***or*** moxifloxacin[3] 400 mg IV daily
		plus vancomycin[2,5] 15 mg/kg IV q 8-12 hrs	***plus*** vancomycin[2,5] 15 mg/kg IV q 8-12 hrs

Ventriculitis and Cerebrospinal Fluid Shunt Infections

Ventriculitis and EVD and CSF shunt infections frequently involve gram-positive organisms, such as *S. epidermidis* and *S. aureus* (including MRSA). Up to 25% are caused by gram-negative organisms. The enteric gram-negative bacilli are of concern in patients who have a ventriculoperitoneal shunt, due to the risk of contamination of the peritoneal end of the catheter [72,81]. Initial broad-spectrum antibiotic selection should include coverage for resistant gram-positive organisms (such as MRSA) and resistant gram-negative organisms (such as *Pseudomonas* and *Acinetobacter* species). Vancomycin combined with a cephalosporin with antipseudomonal activity (e.g., cefepime or ceftazidime) or vancomycin plus meropenem are recommended. Infected hardware should be removed, replaced, or externalized when appropriate.

For ventriculitis, there is scientific rationale for installation of antibiotics directly into the ventricles: meningeal inflammation, which enhances the ability of antimicrobials to penetrate the BBB is less pronounced in ventriculitis [142]; and the ventricles can act as a persistent reservoir of infection and inflammation, causing difficulty with eradication and potential blockade of CSF outflow tracts [143]. Under these conditions, the penetration of systemic β-lactams and glycopeptides into the CSF is poor and results in subtherapeutic concentrations in the CSF and high failure rates [144-146].

Intraventricular administration of antibiotics may be necessary in some circumstances in an effort to overcome these difficulties [147,148].

Brain Abscess

The type of pathogen associated with brain abscess depends on patient-specific risk factors. Immunocompromised patients and patients undergoing recent neurosurgery or head trauma (especially penetrating brain injury) are at higher risk [149,150]. Brain abscesses are often polymicrobial (up to 60% of cases), with anaerobic bacteria in up to 49% of cases [151,152]. Frequently isolated organisms include *Streptococcus milleri, Bacteroides* species, *Enterobacteriaceae,* and *S. aureus*. Immunocompromised individuals are at risk for brain abscess from fungi, *Nocardia*, and *Toxoplasma*. Optimal treatment involves a combination of antibiotics and surgical intervention to obtain source control. Surgical approaches include stereotactic aspiration or excision. Stereotactic aspiration may be preferred if the abscess is in eloquent brain or an area unsuitable for excision (e.g. brainstem or diencephalon) [153]. Broad spectrum empiric therapy is indicated, the choice of which depends on risk factors for selected organisms (i.e. history, immune status, primary infection site). In immunocompetent patients, initial coverage with vancomycin, ceftriaxone (or cefotaxime), and metronidazole is recommended [150]. Antibiotics should be tailored to the causative organism when microbiologic data become available. Metronidazole often is continued, even if an anaerobic source is not identified on culture because anaerobes are fastidious and have a low culture yield. Patients with recent neurosurgery or head trauma and a presumed nosocomial source of infection should be treated with a third- or fourth-generation cephalosporin with antipseudomonal activity (ceftazidime or cefepime), along with vancomycin (to cover MRSA or methicillin-resistant *S. epidermidis*) and metronidazole. In HIV-positive patients empiric therapy to cover *Toxoplasma* with sulfadiazine and pyrimethamine (along with folinic acid) should be considered. Addition of amphotericin B should be considered in neutropenic and post-transplant patients to cover fungal sources, such as *Aspergillus*, *Cryptococcus*, and *Mucoracae.* If *Nocardia* is suspected, trimethoprim/sulfamethoxazole should be added to the empiric regimen [150,154]. In most cases of brain abscess, 6 to 8 weeks of treatment is required, depending on the clinical and radiographic response.

Epidural Abscess

Empiric treatment of cranial epidural abscess consists of broad-spectrum antibiotics, usually in combination with surgical drainage to prevent progression to subdural empyema. The most common etiologies include *streptococci, staphylococci*, and anaerobes. Infections are often polymicrobial [72,73]. Initial treatment with vancomycin, ceftriaxone (or cefotaxime), and metronidazole is appropriate in most cases. Substitution of ceftriaxone with ceftazidime, cefepime, or meropenem is recommended where *Pseudomonas aeruginosa* or other resistant gram-negative nosocomial pathogens are suspected, such as after recent neurosurgery or trauma. Metronidazole is not necessary in regimens containing meropenem which has adequate anaerobic coverage.

Spinal epidural abscess is usually caused by hematogenous spread, with direct seeding of the epidural space. It may also be a complication of adjacent discitis or vertebral osteomyelitis. Other causes of spinal epidural abscess include surgery of the spine, neuraxial anesthesia/analgesia, and LP [72,73,155]. The most common organism involved is *S. aureus*, occurring in 60% to 90% of cases [155,156]. Other causative organisms include aerobic and anaerobic streptococcal species, and gram-negative organisms such as *E. coli* and *P. aeruginosa* [72,73]. Urgent surgical decompression is usually indicated to prevent neurologic deficits. Empiric antimicrobials should be started immediately. In most instances, vancomycin combined with a cephalosporin with antipseudomonal activity (ceftazidime or cefepime) or meropenem is indicated until culture results are available. In selected cases where there are no risk factors for nosocomial drug-resis-

tant organisms, empiric therapy with nafcillin (or oxacillin), combined with a third-generation cephalosporin (ceftriaxone or cefotaxime) may be appropriate. Antibiotic coverage should be narrowed once culture data are available, and treatment should continue for 3 to 4 weeks. In the case of vertebral osteomyelitis or discitis, treatment for 4 to 6 weeks is indicated [72].

Subdural Empyema

Early surgical evacuation in addition to appropriate antibiotic therapy is usually required for successful management. Empiric antibiotic selection for subdural empyema is the same as that for intracranial epidural abscess, as the bacteriology of these infections is identical [75].

Viral Encephalitis

Treatment of viral encephalitis is largely supportive and includes optimization of fluid balance and electrolytes; symptomatic treatment of fever, headache, and nausea; airway protection; management of ICP; and management of seizures. For HSE encephalitis, early treatment (within 2 days of onset) with acyclovir (10 mg/kg intravenously every 8 hours for 14 to 21 days) is associated with improved mortality (70% versus less than 20%) and morbidity [157]. Some other herpes viruses (VZV and herpes B virus) also respond to acyclovir. Therapy usually is started empirically if encephalitis is suspected until diagnostic confirmation is obtained (usually by CSF PCR) [157-159]. Dose adjustment is required in patients with renal insufficiency. Adequate hydration should be maintained during treatment, because acyclovir can cause a crystal nephropathy that is usually reversible. Some recommend repeat CSF examination at completion of treatment and to continue acyclovir if HSV PCR is still positive [32]. Prolonged high dose oral valacyclovir for 3 months after 3 weeks of treatment is also being studied. Oral valacyclovir does not achieve adequate CSF levels to be considered a primary treatment for HSE.

Corticosteroids and mannitol are usually reserved for patients with cerebral edema and intracranial hypertension. However, a nonrandomized retrospective study of 45 subjects with HSE treated with acyclovir found that combination treatment with corticosteroids and acyclovir was an independent predictor of good outcome at 3 months [160]. An experimental encephalitis study showed reduced MRI abnormalities months after infection in animals treated with corticosteroids [161]. Despite the immunosuppressive effects of steroids, they do not enhance viral replication in experimental HSE [162]. For VZV encephalitis, steroids are sometimes used to treat the vasculitic component [32].

CMV encephalitis is an opportunistic pathogen most commonly seen in transplant recipients and other immunosuppressed patients [163]. Current recommendations for both CMV and HHV-6 encephalitis are a combination of ganciclovir (5 mg/kg intravenously every 12 hours) and foscarnet (90 mg/kg intravenously every 12 hours, or 60 mg/kg intravenously every 8 hours) [163-165]. Ganciclovir and foscarnet are associated with severe adverse effects, including renal insufficiency, bone marrow suppression, encephalopathy, and seizures. Both ganciclovir and foscarnet require careful monitoring and dose adjustment in the setting of renal dysfunction [166].

Treatment for severe adenovirus infections have included cidofovir or ribavirin. Patients with life-threatening enterovirus infections have been treated successfully with pleconaril on a compassionate-use basis, and it is deserving of further study [167,168]. Pleconaril is a novel antiviral that inhibits enteroviral replication by integrating into the capsid of picornaviruses and preventing the virus from attaching to cellular receptors and uncoating to release RNA into the cell. Treatment of WNV and other flaviviruses with interferon alpha for 7 days was studied in a randomized, controlled trial of Japanese encephalitis in Vietnamese children, which did not improve outcomes at 3 months [32].

Fungal Central Nervous System Infection

Fungal infections of the CNS are encountered more commonly as opportunistic infections in the immunocompromised. Fungi may cause meningoencephalitis and brain abscess or granuloma. Causative organisms include *Cryptococcus neoformans, Coccidioides immitis, Histoplasma capsulatum, Candida albicans, Sporothrix schenkii, Blastomyces dermatidis, Zygomycetes* species, and *Aspergillus* species, with the latter two more commonly causing brain abscess [169]. Optimal treatment of CNS fungal infections is ill defined. The incidence of invasive fungal infections is rising despite the emergence of newer antifungal agents, and outcomes in general are poor [170]. Most treatment regimens consist of an initial induction phase with an amphotericin-based regimen that lasts 2 to 6 weeks, depending on clinical response. This is followed by a chronic suppressive phase with a triazole antifungal with activity against the pathogen being treated (usually fluconazole or voriconazole) that can last from 6 weeks to lifelong suppression. Optimal treatment also should include management of risk factors for fungal disease, such as hyperglycemia, and minimizing immunosuppressant drugs where appropriate.

Although amphotericin B is considered the first-line agent for most CNS fungal infections, it has a large molecular weight and has poor penetration of the BBB. For this reason flucytosine is often added to amphotericin B in the treatment of cryptococcal, *Candida*, and *Aspergillus* CNS infections. The dose of amphotericin B deoxycholate (AmB) is 1 mg/kg intravenously daily, combined with flucytosine 25 mg/kg orally every 6 hours. Higher doses (1.5 mg/kg daily), however, are recommended in the setting of mucormycosis [171]. Flucytosine requires dose adjustment in the setting of renal insufficiency, and serum levels should be monitored. Levels greater than 100 mg/ml are associated with an increased risk of bone marrow depression, which can be irreversible and result in death [172,173]. The goal peak flucytosine level is 70 mg/ml to 80 mg/ml (drawn 4 hours after a dose at steady state), and the goal trough level is 30 mg/ml to 40 mg/ml.

In patients with renal insufficiency, a lipid-based amphotericin product is recommended. Both liposomal amphotericin B (L-amB) (5 mg/kg/d) and amphotericin B lipid complex (ABLC) (5 mg/kg/d) have been evaluated in a small number of patients, and they appear to have efficacy similar to conventional amphotericin B [174-176]. The amphotericin B products differ significantly with respect to particle size, electrical charge, and volume of distribution, all of which may influence CNS penetration and antifungal activity. Many animal studies show poor distribution of amphotericin products into the CSF; however, brain tissue concentrations appear to be adequate, and CSF concentrations do not appear to correlate with clinical efficacy [177]. An animal model of *C. albicans* CNS infection has demonstrated greater antifungal efficacy with AmB and L-AmB over ABLC and amphotericin B colloidal dispersion, but the clinical relevance of these findings has yet to be demonstrated [178].

Voriconazole is a promising therapy for susceptible CNS fungal infections, in particular invasive aspergillosis. Voriconazole penetrates the CSF well with a median CSF-to-plasma ratio of 0.5 [179]. Schwartz and colleagues [180] conducted a retrospective analysis of voriconazole in 81 subjects who had CNS aspergillosis; 35% had a complete or partial response. Thirty-one percent of subjects survived for a median of 390 days and 38% had neurosurgical intervention for the infection, which was associated with improved survival, making it difficult to clearly discern the impact of voriconazole on outcomes. Considering that reported mortality of CNS aspergillosis approaches 100% [181], this study suggests voriconazole is a reasonable option for CNS aspergillosis, and an alternative for other susceptible CNS fungal infections when an amphotericin-based regimen cannot be tolerated. Initial dosing of voriconazole is 6 mg/kg intravenously every 12 hours for two doses, followed by 4 mg/kg intravenously every 12 hours. Voriconazole is metabo-

lized by the hepatic CYP isoenzymes CYP2C9, CYP2C19, and CYP3A4 and is susceptible to numerous drug interactions, with many combinations being contraindicated.

Posaconazole is an extended spectrum triazole antifungal with in vitro activity against *Candida, Aspergillus, Zygomycosis,* and *Fusarium* species. In an open-label clinical trial in patients with refractory invasive fungal infection the subset of patients with CNS disease had mostly cryptococcal meningitis and were HIV-positive. Successful outcomes were observed in 14 of 29 (48%) of patients with cryptococcal disease, and 5 of 10 (50%) patients with other fungal infections [182]. Based on this report, and animal studies suggesting efficacy [183,184], posaconazole may be considered as salvage therapy in cryptococcal meningitis where other therapies have failed. Currently, posaconazole is only available as an oral medication (200 mg every 6 hours for 7 days, followed by 400 mg twice daily). It is highly lipophilic, with a very large volume of distribution (1,774 l), and is highly protein bound (>98%). It is an inhibitor of cytochrome P450 3A4, and is therefore subject to numerous clinically significant drug interactions.

Caspofungin and micafungin are the first of a new class of antifungals (echinocandins) that target the fungal cell wall through inhibition of β-1,3 glucan synthesis. Caspofungin is highly protein-bound and has a large molecular weight and a small volume of distribution, all of which indicate poor CNS penetration. From animal data the brain tissue-to-plasma ratio is approximately 0.1 [185]. Hsue and colleagues [186] reported a case of treatment failure associated with the use of caspofungin for meningeal coccidiomycosis. In this report, CSF concentrations were undetectable, despite adequate serum concentrations. In spite of sporadic reports of treatment successes [187,188], these agents cannot be recommended for CNS fungal disease at this time.

Given the poor CNS penetration of AmB and its significant systemic toxicities, there has been interest on the use of intrathecal AmB for treating invasive CNS fungal infections. It can be administered through a reservoir device or as an intraventricular injection, and is typically given in conjunction with systemic amphotericin and flucytosine. Dose ranges for intrathecal AmB range from 0.01 mg to 1.5 mg, and intervals range from daily to weekly [189,190]. Adverse effects associated with intrathecal AmB include arachnoiditis, paraplegia, paresthesias, nausea, vomiting, headache, and back pain. Hydrocortisone (15 mg to 25 mg) can be added to the intraventricular mixture to reduce toxicity. Prophylactic administration of antipyretics and antiemetics may also help alleviate some adverse effects. Although intraventricular AmB is usually reserved for patients who have not responded to systemic therapy, or have relapsed, limited evidence shows that early therapy with both systemic and intraventricular amphotericin B can lead to significant differences in survival, and CSF sterilization compared with systemic therapy alone [191,192].

57.8 Glucocorticoids for Bacterial Meningitis

Several meta-analyses regarding adjunctive corticosteroid therapy have been published, most of which include children as the majority of the studied population [193-200]. A Cochrane collaboration review including 18 clinical trials and 2750 people concluded that adjunctive steroid treatment is associated with a reduction in mortality and hearing loss in all patients (adults and children) with bacterial meningitis without major adverse events [193], a finding that concurs with the recommendations of the Infectious Diseases Society of America [92]. Subgroup analysis for causative organisms showed mortality benefit in patients with *S. pneumoniae*, and reduction in hearing loss in children with *H. influenzae*.Routine steroid therapy appears to be justified in most adults although

two more recent large randomized controlled clinical trials (RCTs) from Vietnam and Sub-Saharan Africa that evaluated the effectiveness of dexamethasone for adult bacterial meningitis concluded that adjunctive steroids were not associated with better survival or reduction in neurological deficits [201,202].

Despite relatively high dose, much of mortality benefit may be due to reduction in systemic rather than neurologic complications.

The rationale for use of steroids is based on experimental data showing that the inflammatory response in the subarachnoid space contributes significantly to the morbidity and mortality of bacterial meningitis [35]. De Gans and colleagues [203] demonstrated in a large prospective randomized, controlled trial that dexamethasone given before or with the first dose of antibiotic and then every 6 hours for 4 days improved the outcome in adults with acute bacterial meningitis, particularly pneumococcal meningitis, without serious adverse effects. Unfavorable outcomes were reduced from 25% to 15% and mortality from 15% to 7% in dexamethasone-treated subjects. On the basis of this study, the Infectious Diseases Society of America Practice Guideline recommends use of dexamethasone (0.15 mg/kg every 6 hours for 2 to 4 days) in patients with suspected meningitis [92]. Dexamethasone should be continued only in patients with gram-positive diplococci on Gram's stain or *S. pneumoniae* in CSF or blood cultures. It should not be given to patients with prior administration of antibiotics.

A major concern has been the rapidly rising incidence of highly resistant *S. pneumoniae* requiring combination therapy with vancomycin. Vancomycin penetration into the CNS is largely dependent upon meningeal inflammation, and some experimental studies show that dexamethasone significantly decreases the achievement of therapeutic vancomycin concentrations in the CSF [204,205], resulting in clinical treatment failure in adults [206]. In contrast, more recent data suggest this can be overcome by giving higher doses of vancomycin via continuous infusion (15-mg/kg loading dose followed by 60-mg/kg per day infusion) [207]. Expert opinion recommends adjuvant dexamethasone even in patients with highly resistant pneumococcal isolates [92,208]. There are no data to support adjunctive steroids in patients who have nosocomial and postneurosurgical meningitis, and meningitis related to CSF shunts.

In patients who have TBM, a randomized, double-blind, placebo-controlled study of 545 subjects conducted in Vietnam demonstrated that adjunctive treatment with dexamethasone reduces mortality (31.8% versus 41.3%), but probably does not prevent severe disability (18.2% versus 13.8%) [209]. The prespecified subgroup analysis of patients with HIV demonstrated a nonsignificant reduction in the risk of death, although none were treated with antiretroviral drugs, and the results may not be generalizable to populations with access to antiretroviral treatment. The results of this trial suggest that for non-HIV patients with TBM, 4 to 8 weeks of dexamethasone should be administered (2 to 4 weeks of tapering intravenous steroids followed by tapering oral therapy).

57.9 Management of Complications of Acute CNS Infection

57.9.1 Elevated Intracranial Pressure

The management of elevated ICP in conditions such as bacterial meningitis or encephalitis should follow the same principles as for other etiologies. Osmotic therapy with mannitol or hypertonic saline has not been adequately studied in CNS infections. Small doses of mannitol (0.25 to 0.5 mg/kg) appear to be equally effective to larger doses. If mannitol is used, the serum osmolar gap should be followed to ensure accumulation is not oc-

curring [210]. Hypertonic saline may be required to treat SIADH associated with bacterial meningitis given that low serum osmolarity can worsen cerebral edema. Fever may not only raise ICP but also worsen secondary brain injury and should always be aggressively managed [211]. It is recommended to use surface cooling or endovascular methods as antipyretics and cooling blankets have limited efficacy. Steroids may reduce inflammation in the subarachnoid space and lessen cerebral edema. Effect of steroids on ICP in this condition has not been studied. When patients arrive in the ICU having already received antibiotics, but not steroids, it is of questionable benefit to introduce steroids at this time because much of inflammation with meningitis occurs in response to destruction of bacteria by antibiotics [212]. Mechanical interventions to reduce ICP may be warranted provided that a mass lesion has been excluded and risk for cerebral herniation from CSF drainage is minimal. Options include repeat large volume lumbar puncture, lumbar drain placement, ventriculostomy and decompressive craniectomy. Clinicians should have a low threshold to re-image the brain to rule out hydrocephalus (occurs in 20% of acute bacterial meningitis).

57.9.2 Cerebrovascular Complications

Although the lower limit of safe cerebral perfusion pressure is unknown in CNS infections, CPP should be maintained >60 to 70 mmHg to avoid cerebral ischemia even in patients with intact autoregulation. Due to the high incidence of arterial or venous complications in acute bacterial meningitis, computed tomographic venography (CTV), magnetic resonance angiography (MRA), or magnetic resonance venography (MRV) should be considered in patients who deteriorate or fail to improve with antibiotic therapy. Careful anticoagulation appears safe in patients with cerebral venous sinus thrombosis in the setting of CNS infection [213].

57.9.3 Severe Sepsis and Septic Shock

In patients with severe sepsis or septic shock, early goal-directed therapy including aggressive fluid resuscitation reduces mortality and is not associated with worsened cerebral edema [214,215]. In experimental bacterial meningitis it was demonstrated that fluid restriction can decrease cerebral blood flow and worsen cerebral ischemia [216]. This suggests that hypovolemia and hypotension should be avoided in patients with CNS infection. Preference for systemic vasopressors in the setting of meningitis has not been studied. Norepinephrine appears to improve CBF more effectively than dopamine at least in head-injured patients [217]. Vasopressin has been studied in experimental traumatic brain injury and appears to be equally as effective as phenylephrine for maintaining cerebral perfusion pressure, improved intracranial pressure, and brain tissue oxygenation compared with phenylephrine [218]. Based on combined data from 4 clinical trials of drotrecogin alfa, which found that the median APACHE II score of enrolled patients with meningitis was 22, it appears unlikely that patients with meningitis and septic shock should be treated (scores >25 derive benefit). Furthermore, 5.7% of patients with bacterial meningitis had intracerebral hemorrhage as a complication of drotrecogin alfa compared with 1% control patients [219]. The role of systemic corticosteroids in CNS infection with septic shock is unclear at this time. In this regard it is noteworthy that in a post-hoc analysis of the European Dexamethasone in Adulthood Bacterial Meningitis Study [203], investigating only patients with pneumococcal meningitis who died within 14 days, mortality benefit from steroid therapy was attributable to a beneficial effect on systemic complications with no significant reduction in mortality due to neurologic causes [220].

57.9.4 Intraventricular and Intrathecal Antibiotics

The clinical situations in which intraventricular antibiotics have been studied include: 1) severe meningitis with associated ventriculitis; 2) intraventricular rupture of a purulent brain abscess; and 3) cerebrospinal fluid shunt infections. For the latter, there is reasonable evidence for the instillation of antimicrobial agents into the ventricles in difficult-to-eradicate shunt infections or in patients who cannot undergo surgical management [92]. Success rates of conservative management of patients with CSF shunt infections caused by coagulase-negative Staphylococci appears to be comparable to conventional management with shunt replacement [221].

Intraventricular instillation of most antimicrobials has been viewed as associated with significant toxicity, although most recent reports suggest that intraventricular/intrathecal administration with agents such as polymyxin B, colistin and vancomycin is not associated with severe or irreversible toxicity [222]. Toxicity appears to be dose-related and early reports may have been associated with inappropriate dosing. Moreover, systemic toxicity of the intravenous route of these same agents may be offset by using the CSF route. Exact therapeutic doses and the role of adjuvant systemic or local CSF therapy are not well understood at this time.

There is a positive publication bias in the literature as almost all reports are case reports or small case series and there are no randomized clinical trials of intraventricular antimicrobial use in adult CNS infection. The success rates of CSF sterilization suggest that therapy with intraventricular antimicrobials is a potentially effective treatment against both gram-negative and -positive MDR meningitis as well as fungal meningitis. In a review by Falagas et al. [223] of intraventricular/intrathecal use of polymyxins in 64 patients (31 case reports/series) with gram-negative meningitis, an overall cure rate of 80% was reported including 91% of CNS infections due to *Acinetobacter* spp. As mentioned earlier, therapy with both systemic and intraventricular amphotericin B in fungal CNS infection can improve survival, and CSF sterilization compared with systemic therapy alone [191,192]. For tuberculous meningitis the addition of intraventricular rifampin or isoniazid has anecdotal reports of efficacy [224,225], whereas multidrug resistant *Mycobacterium tuberculosis* appears to respond favorably to intraventricular amikacin and levofloxacin [226,227].

Although no antimicrobial agent is approved by the Food and Drug Administration for intraventricular use, commonly used agents (depending on the causative organism) include vancomycin, gentamicin, tobramycin, and polymyxins. The usual dose of intraventricular vancomycin is 10 mg to 20 mg per day, continued for 48-72 hours after CSF cultures become negative. Potential adverse effects of intraventricular vancomycin include ototoxicity, CSF eosinophilia, seizures, altered mental status, and local tissue irritation [147,228]. The usual daily dose of intraventricular gentamicin and tobramycin is 5 mg to 10 mg, and that of amikacin is 10 mg to 20 mg [229,230]. Toxicities for these aminoglycosides are similar to those of vancomycin.

Redosing is determined by calculation of the inhibitory quotient (trough CSF concentration divided by the minimum inhibitory concentration of the agent for the isolated pathogen). This number should exceed 10 to 20 for consistent CSF sterilization [231]. Polymyxins (polymyxin B and colistimethate) have been used in ventriculitis caused by multi-drug resistant *Acinetobacter* and *Pseudomonas* species, with the most common adverse effect of meningeal irritation being dose-dependent and reversible [232]. Dosing has varied substantially (5-20 mg of colistimethate daily), and as for all of the above regimens, the optimal duration is unknown. Preservative-free formulations should always be used for intraventricular administration.

57.10 Prophylactic and Periprocedural Antibiotics for Neurosurgical Procedures and External Ventricular Drains

Nosocomial meningitis accounted for 40% of acute adult bacterial meningitis in a review of 493 episodes, of which 81% occurred within 1 month of neurosurgery or head injury [40]. A retrospective study reported an overall meningitis rate of 1.52% [86] in 6243 subjects undergoing craniotomy, of whom 17% did not receive perioperative antibiotics. Independent risk factors for meningitis were CSF leakage, concomitant incision infection, male sex, and duration of surgery. Perioperative antibiotic prophylaxis reduced incidence of incision infections significantly from 8.8% to 4.6%, but did not prevent meningitis. In patients receiving antibiotics, organisms were mainly noncutaneous and tended to be less susceptible to the prescribed prophylactic antibiotics. Meningitis from noncutaneous organisms were associated with a higher mortality rate compared with cutaneous organisms. The investigators recommended use of narrow-spectrum antibiotics for prevention of surgical site infections without any effect on the risk of meningitis.

Ventriculostomy-related infection (VRI) rates are generally 5% to 10%, with a range of 0% to 22% [81]. Definition of CSF infections related to ventriculostomies is important. The following categories of VRI are potentially useful [85]:

- **Confirmed VRI:** positive CSF culture obtained from ventricular or lumbar catheter associated with CSF pleocytosis and clinical symptoms not related to other causes.
- **Suspected VRI:** positive CSF culture and CSF pleocytosis without clinical symptoms or with other likely source of infection.
- **Contaminant:** isolated positive CSF culture in conjunction with negative Gram's stain, normal CSF cell counts and absent clinical symptoms.

Some researchers accept CSF pleocytosis or low CSF glucose alone as evidence of CSF infection, although positive cultures are considered the gold standard. Others apply more stringent criteria, requiring an initial sterile CSF culture at time of EVD insertion, two separate CSF cultures on separate days, and assess the number of risk factors to determine whether infections are related to the catheter or not. Risk factors that predispose patients with ventriculostomies to ventriculitis or meningitis are intraventricular hemorrhage, subarachnoid hemorrhage, cranial fracture with CSF leak, craniotomy, systemic infection and catheter irrigation [81]. Because CSF surveillance may increase the risk of VRI, clinicians often collect CSF only at time of EVD insertion, removal, and when clinically indicated. The value of routine CSF surveillance has been questioned as it has not been shown to predict VRI before actual positive culture with clinical symptoms [232]. However, some studies suggest that accessory tests, including cell index, lactate level, and IL-1B may be helpful in diagnosing VRI before the onset of ventriculitis [116,233].

The data on duration of EVD as a risk factor for VRI is controversial. In Lozier's analysis [81], ten studies (2046 EVDs in 1698 subjects) reported a positive association, and seven studies (2199 EVDs in 2113 subjects) reported no association between duration of catheterization and CSF infection. There is a likely relationship between duration of EVD and infection, but it may not be a continuous rise. Holloway and colleagues [83] reported an increasing risk of infections during the first 10 days of EVD, followed by a significant decrease afterwards despite the population still being at risk. This has been the authors' experience as well. While EVD duration may not be easily modified, other potential prevention strategies are antibiotic prophylaxis and routine EVD change. The data on antibiotic prophylaxis (none versus periprocedural versus continuous) is conflicting. One randomized, controlled trial [234] randomized 228 subjects to either perioperative anti-

biotics only (ampicillin/sulbactam) or prolonged antibiotics for the duration of the ventricular catheter (ampicillin/sulbactam and aztreonam). Prolonged antibiotic prophylaxis significantly reduced the incidence of both CSF and extracranial infection, but selected resistant or opportunistic pathogens, such as *Candida* and MRSA. The mortality of patients with CSF infection in the continuous antibiotic group was significantly higher than in the perioperative antibiotic-only group. A retrospective study of 308 subjects compared prophylactic antibiotics administered for the duration of the EVDs with periprocedural antibiotics, and found no difference in the overall rate of ventriculitis [235]. The use of continuous prophylactic antibiotics is therefore discouraged based on the risk of selecting resistant organisms.

It has been argued based on retrospective data that EVDs should be changed around day 5, when the infection risk starts to go up. Based on the majority of retrospective evaluations, however, prophylactic catheter exchange has not been effective in preventing VRI, and has been associated with increased risks of ventriculostomy associated hemorrhage and poor catheter positioning [236].

Finally, a comment on the efficacy of antimicrobial-impregnated EVDs. A prospective randomized, controlled trial evaluated EVDs impregnated with minocycline and rifampin in 288 subjects (mainly subarachnoid hemorrhage and trauma) requiring EVDs [237]. The antibiotic-impregnated catheters were half as likely to become colonized as the control catheters (17.9% versus 36.7%) and seven times less likely to be associated with positive CSF cultures (1.3% versus 9.4%). Heparin-coated catheters, which have been shown to lower the incidence of bacterial colonization and septicemia in central venous catheters [238], have also been evaluated in a randomized, controlled study of 198 subjects requiring EVDs (mostly with subarachnoid hemorrhage and trauma), but demonstrated no benefit in catheter colonization when compared with non-heparin-coated EVDs. Finally, a hydrogel-coated EVD, which has a proposed advantage of reducing clot and bacterial adhesion, was evaluated in a prospective randomized trial [239]. This also failed to demonstrate reduction in bacterial colonization. At this time it appears that the antibiotic impregnated EVDs are effective in reducing the likelihood of VRI. A large bore antibiotic impregnated catheter for drainage of intraventricular hemorrhage is not available at present.

Acknowledgments

The authors would like to gratefully acknowledge the contribution of Brian Cole for his drawing of Figure 57.1.

58 Tuberculous Meningitis: The Critical Issues

J.M.K. Murthy [1]

[1] Chief of Neurology, The Institute of Neurological Sciences, CARE Hospital, Nampally, Hyderabad, India

58.1 Introduction

The global burden of tuberculosis is still high, particularly in the developing world. Tuberculosis is a leading cause of death from infectious disease, second only to human immunodeficiency virus (HIV) infection and the acquired immunodeficiency syndrome (AIDS) [1]. Globally there were an estimated 9.27 million new cases (139 per 100,000 population) of tuberculosis in 2007 and the number of prevalent cases was 13.7 million (206 per 100,000 population). Some 22 high-burden countries, most of them in the developing world, collectively account for 80% of the global tuberculosis burden. An estimated 1.3 million deaths occurred among HIV-negative incident cases of tuberculosis (20 per 100,000 population) and an additional 456,000 deaths among incident cases of tuberculosis that were HIV-positive [2]. Human immunodeficiency virus infection increases the lifetime risk of developing clinical tuberculosis post-infection to 1 in 3 [3].
The incidence of central nervous system (CNS) tuberculosis is not well studied. The incidence of CNS tuberculosis generally reflects the incidence and prevalence of tuberculosis in the community. About 10% of patients who have tuberculosis develop CNS disease [4]. HIV infection predisposes to the development of extra-pulmonary tuberculosis, particularly tuberculous meningitis [5]. There were 206 per 100,000 prevalent cases of tuberculosis in 2007 [1] and the projected incidence cases of CNS tuberculosis would be 20.6 per 100,000 population in the year 2007, most of it would be in the high-burden countries. The incidence rates of tuberculous meningitis are age-specific and range from 31.5 per 100,000 (<1 year) to 0.7 per 100,000 (10-14 years) in the Western Cape Province, South Africa [6]. There are no community-based mortality studies in CNS tuberculosis. The estimated mortality due to tuberculous meningitis in India is 1.5 per 100,000 population [7]. HIV co-infection is associated with higher complication and case fatality rates [8,9].

58.2 Pathogenesis and Pathology

Lymphohematogenous spread of *M. tuberculosis* from a primary focus leads to the development of a Rich focus in the brain. Tuberculous meningitis results from the release of *M. tuberculosis* into the subarachnoid space from a meningeal or subcortical Rich focus. This results in a local T-lymphocyte-dependent response, caseating granulomatous inflammation [10,11]. The cytokine tumour necrosis factor alpha (TNF-α) is critical in the neuropathogenesis of *M. tuberculosis*. TNF-α plays a role in granuloma formation and also in host-mediated destruction of infected tissue [12,13]. However, TNF-α concentrations in the cerebrospinal fluid (CSF) have not correlated with disease severity and outcomes in humans [14,15]. Tuberculous meningitis is also characterized by an increased CSF expression of other pro-inflammatory cytokines such as interferon (INF)-γ, interleu-

kin (IL)-1β, IL-8, and the anti-inflammatory cytokine IL-10 [14,16]. There is evidence of significant blood-brain-barrier (BBB) breakdown in patients with tuberculous meningitis [14,17] and this has been attributed to matrix metalloproteinases (MPP) [18].

The pathological process of tuberculous meningitis includes basal exudate formation, an obliterative vasculitis, encephalitis and tuberculoma formation. The release of *M. tuberculosis* into the subarachnoid space results in the development of inflammatory exudate that affects mostly the sylvian fissures, basal cisterns, brainstem, and cerebellum. Blockage through adhesion formation of the basal subarachnoid cisterns can result in hydrocephalus. The adhesive exudate envelops the arteries and compromises the cranial nerves. The latter may explain the cranial nerve palsies seen in tuberculous meningitis. An obliterative vasculitis of both large and small vessels, perforating vessels, commonly results in infarction in the territory of the affected vessel [10,11]. In an autopsy study of 190 cases of neurotuberculosis, hydrocephalus was noted in 71% and it was severe in 36%. Vasculitis and infarcts were noted in 70% of cases, whereas large infarcts involving the middle cerebral artery territory were noted in only 3.2% of cases. Perforating vessels to the basal ganglia are most commonly occluded [11]. Tuberculomas often occur in the absence of tuberculous meningitis but may occur along with tuberculous meningitis. Tuberculomas are thought to arise when tubercles in the brain parenchyma enlarge without rupturing into the subarachnoid space [13]. The reported frequency of tuberculomas on the initial computed tomography (CT) scan in patients varies between 2 and 38% and they are often multiple [19].

58.3 Clinical Features

Tuberculous meningitis is difficult to diagnose as the clinical features are non-specific and vary widely and are often diagnosed when brain damage has already occurred [12,20,21]. The variables that may determine disease evolution and clinical presentation include age and HIV co-infection. Patients with HIV co-infection may less commonly have fever, headache, and meningismus and they are more likely to have an altered mental status [22,23].

Tuberculous meningitis often presents with meningitis symptoms of fever (60-95%), headache (50-80%), and signs of meningismus (40-80%), focal neurologic deficits (hemiplegia 10-20%, paraparesis 5-10%, any cranial palsy 30-50%), behavioural changes (10-30%) and altered mental status (30-60%). Seizures can complicate the disease: 50% in children and 5% in adults [12]. In a large cohort of children, the common clinical characteristics on admission were fever (67%), headache (25%). meningismus (98%), altered mental state (96%), motor deficit (63%), brainstem dysfunction (39%), cranial nerve palsies (27%), and elevated intracranial pressure (23%). Seizures were present on admission in 47% of children and 97% of the children presented with severe grade disease (stage II and III) [21]. A rare clinical syndrome, tuberculous encephalopathy has been described in children. The syndrome is characterized by coma, convulsions, involuntary movements, and pyramidal signs with normal CSF. Post-mortem pathology showed diffuse cerebral edema and demyelination and was presumed to be due to allergic encephalomyelitis [24]. Other unusual clinical features include movement disorders, tremor, chorea, ballismus, and myoclonus [25].

The severity of tuberculous meningitis at presentation is classified into three grades according to the patient's Glasgow Coma Scale (GCS) score and the presence or absence of focal neurological signs, the modified British Medical Research Council criteria [26]: Grade I. alert and orientated without focal neurological deficit; Grade II. GCS score 10-

14 with or without focal neurological deficit or GCS score 15 with focal neurological deficit; Grade III. GCS <10 with or without focal neurological deficit. Severe grade disease is associated with high mortality and morbidity [21].

Some clinical and CSF findings are predictive of a diagnosis of tuberculous meningitis. In children the clinical variables predictive of tuberculous meningitis include: symptoms lasting longer than 6 days, optic atrophy, focal neurologic deficits, abnormal movements, and a CSF leukocyte differential <50% neutrophils. The diagnostic sensitivity is 98%, the specificity is 44% when at least one feature is present, the sensitivity is 55% and the specificity is 98% if three or more features are present [27]. The adult study in Vietnam identified five clinical variables predictive of diagnosis of tuberculous meningitis: age (<36 years: 2, >36 years: 0); white cell count (>15000: 4, <15000: 0); history of illness (>6 days: -5, <6 days: 0); CSF leukocyte count (>750: 3, <750: 0), and percent of CSF neutrophils (>90: 4, <90: 9). A maximum score of four or more on admission was diagnostic of tuberculous meningitis. This diagnostic rule had a sensitivity of 86% and a specificity of 79% [28].

58.4 Laboratory Diagnosis

Tuberculous meningitis cannot be diagnosed clinically with certainity as the presenting features of the disease are often non-specific. Rapid diagnosis, particularly in grade II and III disease, is critical for instituting appropriate management interventions to prevent complications and reduce morbidity and mortality. Unfortunately, there is still no single diagnostic method that is both sufficiently rapid and sensitive.

CSF of untreated tuberculous meningitis typically shows moderate lymphocytic pleocytosis, moderately elevated protein concentration, and low glucose levels. The opening pressure, in the absence of spinal block, is usually moderately elevated (180-300 mm-H_2O). Acellular CSF has been reported in the elderly and in patients with HIV co-infection [12,13,21,29]. Adenosine deaminase (ADA) enzyme is primarily associated with T cells and monocytes and is elevated >15 IU/l in the CSF in tuberculous meningitis, (sensitivity 50-83% and specificity 95%). The test results can be obtained within a few hours [29]. Tuberculostearic acid, a fatty acid component of the *M. tuberculosis* cell wall, has been detected in the CSF of patients with tuberculous meningitis. Although the method has good sensitivity (95-100%) and specificity (91-99%), its limitations are that it requires expensive equipment and considerable expertise [13].

Bacteriological diagnosis, demonstration of acid-fast bacilli (AFB) of *M. tuberculosis* by Ziehl-Neelsen staining (sensitivity 25%) and culture (sensitivity 18-83%) is highly specific (100%) [21]. Multiple samples of CSF enhance the sensitivity up to 86% [30]. A study from Vietnam reported a bacteriological diagnosis of tuberculous meningitis in 81% of adults with the disease; acid-fast bacilli were seen in 58% patients and cultured from 71% patients. CSF volume, duration of symptoms, CSF neutrophil count, lactate, and glucose were all independently associated with bacteriological confirmation [31]. Semi-automated radiometric culture systems such as Bactec have reduced culture times.

Tests to detect *M. tuberculosis* specific antibodies and antigen in the CSF of patients with tuberculous meningitis are rapid and less expensive. But the techniques are limited by the inability to differentiate acute infections from previous infection and problems with cross-reactivity, in addition to variable and often poor sensitivity and specificity. For the antibody assays the reported sensitivity (52-93%) and specificity (58-199%) were quite variable Similarly for the antigen assays, the sensitivity and specificity were 38-94% and 95-100%, respectively [13].

Commercially available nucleic-acid amplification and other polymerase chain reaction (PCR) assays may provide a screening tool for the diagnosis of tuberculous meningitis. The value of these assays lies largely in the rapidity with which results can be obtained and the very good specificity of these tests [29]. A systematic review of the diagnostic sensitivity and specificity of commercially available nucleic-acid amplification assays for tuberculous meningitis estimated 56% sensitivity (95% confidential interval [CI], 46-66) and 98% specificity (95% CI, 97-99) and the negative predictive value and positive predictive value were 44% and 35.1%, respectively. The sensitivity of these assays is too low, and about half those testing negative will have the disease [32].

58.5 Neuroradiology

Neuroimaging, both contrast computer tomography (CT) and magnetic resonance imaging (MRI), reveals the pathology and the complications of tuberculous meningitis. Though the image characteristics are nonspecific, the findings when correlated with the given clinical features may give a clue for the diagnosis [33]. The imaging characteristics include basal meningeal enhancement (Figures 58.1a and 58.2), hydrocephalus (Figures 58.1a and b), tuberculoma(s), and infarcts (Figure 58.3). Hydrocephalus and basal meningeal enhancement are the most common findings [33-39]. In a large cohort of children (554 patients) from South Africa, the common features on CT were hydrocephalus (82%), basal meningeal enhancement (75%), infarctions (32%), and tuberculomas (13%) [21]. The data in a recent study by Thwaites et al. [38] suggest tuberculomas form in most patients during treatment, predominantly within the meninges (Figure 58.4). Certain neuroimaging findings seem to be specific for the diagnosis of tuberculous meningitis in children: basal meningeal enhancement, tuberculomas, or both on contrast CT (sensitivity 89% and specificity 100%) [34] and the presence of hyperdensity in the basal cisterns on non-contrast CT scans [35].

58.6 Treatment of Tuberculous Meningitis

58.6.1 Antituberculous Drug Treatment

There is a scarcity of controlled trials of antituberculous drugs in CNS tuberculosis. Most of the guidelines follow the model of short-course chemotherapy of pulmonary tuberculosis: an "intensive phase" of treatment with four drugs, followed by treatment with two drugs during a prolonged "continuation phase" [12]. The Infectious Disease Society of America, the Center for Disease Control and Prevention, and the American Thoracic

Drug	Blood-brain Barrier Permeability	Mechanism	Dose Children	Adult
Isoniazi	Yes	Bactericidal (Intra-extracellular)	10-15 mg/kg	300 mg
Rifampin	Yes inflamed	Bactericidal (intra-extracellular)	10-20 mg/kg	600 mg
Pyrazinami	Yes	Bactericidal (intracellular)	15-30 mg/kg	2000 mg
Ethambutol	Yes inflamed	Bacteriostatic	15-20 mg/kg	1000 mg

Table 58.1. **First-line antituberculous drugs.**

Society guidelines recommend an initial 2-month induction therapy with isoniazid, rifampin, pyrazinamide, and ethambutol, followed by 7 to 10 months of additional isoniazid and rifampin for an isolate that is sensitive to these drugs (Table 58.1). Recent a systemic review suggests that a 6-month regimen might be sufficient if the likelihood of drug resistance is low [40].

58.6.2 Multi-drug Resistant Tuberculosis

Multi-drug resistant (MDR) (resistant to both isoniazid and rifampin) tuberculosis is a concern in high-burden countries. There were an estimated 500,000 cases of MDR tuberculosis in 2007, mostly from high-burden countries: 131,000 in India, 112,000 in China, 16,000 in South Africa, and 15,000 in Bangladesh. Furthermore, 55 countries had reported cases of extensively drug resistant (EDR) tuberculosis defined as MDR tuberculosis plus resistance to a fluoroquinolone and injectable second-line drugs by the end of 2008 [2]. In high-burden countries, the proportion of tuberculosis cases that are MDR may range from 1 to 14% or more [41]. Thus the probability of a patient with tuberculous meningitis in high-burden countries having MDR tuberculosis would be 0.1 to 1.4%. It will be extremely difficult clinically to suspect MRD tuberculous meningitis. MDR tuberculous therapy should be considered if there is a history of prior exposure to antituberculous drugs, contact with a patient with MDR tuberculosis, or poor clinical response to first-line drugs [13]. Resistance to isoniazid was associated with significantly longer times to CSF bacterial clearance [42]. In a prospective study of Vietnamese adults with tuberculous meningitis, isoniazid and/or streptomycin resistance was associated with slower CSF bacterial clearance but not with any difference in clinical response or outcome. However, combined isoniazid and rifampicin resistance was strongly predictive of death (RR of death 11.63, 95% CI 5.21-26.320) [43]. MDR tuberculosis requires extended treatment with second-line drugs that are less effective and have more adverse effects than isoniazid-based and rifampin-based regimens [44]. With the emergence of EDR tuberculosis, even the second-line drugs will be ineffective. Ethinomide and cycloserine have good CNS penetration and may be used as part of an “intensive phase” treatment regimen in patients with suspected MDR tuberculous meningitis [13]. Therapeutic drug monitoring has been used to assist in the management of MDR tuberculosis [45,46].
TMC207, an investigational diarylquinoline compound, acts by specifically inhibiting mycobacterial ATP synthase. In vitro, it inhibits drug-sensitive and drug-resistant *M. tuberculosis* isolates and is also bactericidal against dormant tubercle bacilli [47-50]. In a two-stage, phase 2, randomized, placebo-controlled trial consisting of an exploratory stage (8 weeks) followed by a separate proof-of-efficacy stage (24 weeks) in patients with newly diagnosed, smear-positive pulmonary infection caused by MDR *M. tuberculosis*, the addition of TMC207 to standard therapy reduced the time to conversion to a negative sputum culture as compared with placebo and increased the proportion of patients with conversion of sputum culture. The drug was well tolerated except for significant nausea [51].

The in-hospital case-fatality rate was 57% in patients with MDR tuberculous meningitis, with significant functional impairment in most of the survivors (Patel 2004) [52]. The morality was near 90% in patients with HIV-associated MDR tuberculous meningitis [53].

58.6.3 Adjunctive Steroid Therapy

A Cochrane systematic review concluded that overall adjunctive therapy with corticosteroids reduces the risk of death (RR, 0.78, 95% CI, 0.67-0.91). Data on disabling residual neurological deficits from three trials showed that corticosteroids reduce the risk of death or disabling residual neurologic deficit (RR, 0.82, 95% CI, 0.70-0.97). The review recommends the routine use of corticosteroids in HIV-negative people with tuberculous meningitis to reduce death and disabling neurological deficits amongst survivors. Corticosteroids should be used irrespective of age and disease stage [54]. A recent Vietnam adult study of adjunctive dexamethasone therapy in tuberculous meningitis demonstrated a significant reduction in mortality but not in morbidity [55]. A further subgroup analysis revealed that this benefit occurred among all severe grades of CNS tuberculosis and that this benefit was not seen in patients with HIV co-infection. The study also found that treatment with dexamethasone was associated with less severe adverse events, particularly hepatitis. The mechanism by which dexamethasone exerts its survival benefit is uncertain. Two possible mechanisms have been proposed: 1) the effect of dexamehasone on the deleterious aspects of the immune response in the CNS; and 2) the ability of dexamehtasone to prevent hydrocephalus and/or infarction [13,38]. Dexamethasone does not seem to improve outcome by attenuating immunological mediators of inflammation in the subarachnoid space or by suppressing peripheral T-cell response to mycobacterial antigens [15]. There is some evidence to suggest that adjunctive dexamethasone may affect outcome from tuberculous meningitis by reducing hydrocephalus and preventing infarction [38].
The initial dose of dexamethasone is 8 mg/day for children weighing <25 kg and 12 mg/day for children weighing ≥25 kg and for adults for 3 weeks and then decreased gradually during the following 3 weeks [56]. In the trails by Thwaites et al. [55], the initial dose was 0.3 mg/kg/day for grade I and 0.4 mg/kg/day for grades II and III, followed by gradual tapering over 6 weeks.

58.7 Treatment of Complications

In patients with tuberculous meningitis, potential neurologic complications requiring careful attention include altered mental status, elevated intracranial pressure (eICP), hydrocephalus, vasculitis, and acute seizures. Critical care of these patients should focus not only on treatment of the underlying infection and its immediate complications but also on minimizing secondary brain injury. Aggressive and appropriate care within the intensive care unit setting can minimize these complications and improve the chance of a good outcome [19].

58.7.1 Fever

Fever is a common feature in patients with tuberculous meningitis and the reported frequency varies between 60 and 95% [12]. Fever is regarded as a fundamental component of the acute-phase response to infection. Despite considerable research, it remains un-

clear whether infection-related fever is globally beneficial or harmful [57]. No data exist to determine the effect of fever on the pathology and ICP in tuberculous meningitis.
Fever management has become a common practice in neurologic and neurosurgical ICUs in patients with acute brain insult [58]. Fever exacerbates the degree of resulting neuronal injury in the presence of acute brain insult [58-60] and it also raises ICP [61]. However, there are several uncertainties with regard to infection-related fever management. There are very few studies that have looked into the effect of infection-related fever in patients with acute brain insult. Retrospective data indicate that stroke patients with preceding bacterial infections have poorer neurological and behavioural outcomes than do their uninfected counterparts [62,63]. In one experiment in which rats were injected with *E. coli* lipopolysaccharide prior to the induction of global brain hypoxia, fever was associated with increased neural damage [64]. Thus, fever management to achieve normothermia might be warranted in patients with severe grade tuberculous meningitis. However, one has to exercise caution in patients with associated sepsis. Low or normal temperature during bacteraemia has been shown to be associated with poor outcome [65]. Standard fever management consists of antipyretic drug therapy and external/physical cooling. Newer methods with surface cooling and intravascular cooling devices are more effective in lowering fever than standard fever management protocols [58].

58.7.2 Fluid and Sodium Disturbances

Disturbances of sodium, intravascular volume, and water are common in tuberculous meningitis. The reported frequency of hyponatremia in patients with tuberculous meningitis varies between 35 and 65% [66-68]. Hypotonic hyponatremia causes the entry of water into the brain, resulting in cerebral edema [69]. Hyponatremia without eICP may be associated with altered mental status. In patients with tuberculous meningitis, both hyponatremia and altered mental status are independent predictors of death or severe disability [70].
In tuberculous meningitis it is often difficult to precisely determine the cause of hyponatremia. The differential diagnosis includes the central salt wasting syndrome (CSWS), the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), and adrenal insufficiency. The CSWS is defined as renal loss of sodium during intracranial disease, leading to hyponatremia, excessive natriuresis, volume depletion and clinical response to volume and salt replacement [71]. The available evidence suggests that the cause of hyponatremia in tuberculous meningitis is due to CSWS [72-77]. The CSWS involves renal salt loss resulting in hyponatremia and hypovolaemia, whereas SIADH involves a physiologically inappropriate secretion of ADH or increased renal sensitivity to ADH, leading to renal conservation of water and euvolaemic or hypervolaemic hyponatremia [71].
At presentation, many patients with tuberculous meningitis have compromised volume status. The first step is to assess the volume status and replace the volume with normal saline and simultaneously investigate the patient for hyponatremia. The therapy in CSWS is volume and sodium replacement (0.9% sodium chloride or 3% if necessary). The rapidity of sodium replacement depends on the rate at which the hyponatremia developed. Treatment of hyponatremia developing at a rate of >0.5 mmol/l/h should be aggressive, as it is a life-threatening complication and may cause death from severe cerebral edema and herniation (Kroll 1992) [78]. Mineralocorticoid or fludrocortisone supplementation has also been shown to be effective in returning serum sodium levels to normal [79,80]. Volume restriction is the treatment of choice in SIADH and in pa-

tients with symptomatic hyponatremia; 3% sodium chloride is usually combined with frusemide to facilitate free water excretion and correct hyponatremia.

58.7.3 Acute Seizures

Acute seizures occur in about 50% of children with tuberculous meningitis and in 5% of adults [12]. New-onset acute symptomatic seizures are not uncommon in patients with HIV-associated tuberculous meningitis [81]. Rarely convulsive status epilepticus (CSE) [82] and non-convulsive (NCSE) [83] status epilepticus (SE) may complicate tuberculous meningitis. Patients with the first acute symptomatic seizure caused by CNS infection are at a higher risk for 30-day mortality [84].

In patients with CNS infections, recurrent seizures are common after the first acute seizure [85]. Probably, these patients will need AED prophylaxis to prevent seizure recurrence, at least for the period of resolution or stabilization of an acute CNS insult. The plan in such patients would be acute abortive treatment with benzodiazepines, followed by a loading dose of phenytoin/fosphenytoin and subsequent maintenance therapy. An alternative drug is levetericetam. Studies using levetericetam in SE and NCSE, both in children and adults, suggest the efficacy of the drug when administered early, and a dose of <3000 mg daily is likely to provide benefits [86-88]. AEDs may be continued if there is a high risk of recurrence for a period of 3 to 6 months [89].

While using AEDs, interactions with other co-medications, particularly anituberculous drugs, should be considered. Isoniazid inhibits phenytoin, carbamazepine and valproic acid, producing high serum levels of these AEDs and thus toxicity [90,91]. Rifampin lowers the concentration of valproic acid, phenytoin, carbamazepine, lamotrigine, making some of these drugs relatively ineffective [90]. When combined with isoniazid, rifampicin counters the former's inhibitory effect on the metabolism of phenytoin. Isoniazid, rifampin, pyrazinamide and valproic acid are all hepatotoxic drugs. When used together, they may potentiate hepatotoxicity. Preferably, valproic acid should be avoided; if given, liver function should be monitored at regular intervals.

58.7.4 Vasculitis

Vascular pathology associated with tuberculous meningitis, arteritis, arterial spasm, intraluminal thrombus, and external compression of proximal vessels by exudates in the basal cisterns, all compromise cerebral perfusion and oxygen delivery to the brain [10,11,92]. In an autopsy study, arteritis and infarcts were seen in 70% of brains. Arteritis mostly involved the perforating branches of the major arteries at the base of the brain [10,11].

It is not clear how to treat this serious complication of tuberculous meningitis or the compromised cerebral perfusion and infarction. Recently delayed abnormalities of cerebral oxygenation, despite ICP control and full conventional therapy, have been shown in two patients with tuberculous meningitis, confirming the progressive nature of the vascular insult [93]. Corticosteroids may be beneficial. How corticosteroids exert their beneficial effect in tuberculous meningitis is not clear. One of the mechanisms may be an anti-inflammatory effect. However, this effect is difficult to prove [94]. The Vietnam adult study suggests that dexamethasone might improve survival from tuberculous meningitis by reducing the incidence of infarction and speeding the resolution of hydrocephalus [38]. Corticosteroids might antagonize vascular endothelial growth factor (VEGF) β and thereby reduce vasogenic cerebral edema [95]. Gujjar et al. [96] studied the efficacy of triple-H therapy in patients with tuberculous arteritis and suggested that it is safe and may be beneficial in the management of patients with tuberculous arteritis.

58.7.5 Intracranial Pressure

In patients with tuberculous meningitis, elevated intracranial pressure (eICP) is one of the predictors of poor outcome. The relative risk of poor outcome in children with clinical features of eICP was 1.7 (95% CI, 1.7–2.2; p 0.002). In this study, the stage of the disease at admission was found to be an independent risk factor for poor outcome (odds ratio [OR], 4.8, 95% CI, 2.7-8.7; p <0.001) [21]. The presence of hydrocephalus usually signifies eICP; in patients with hydrocephalus, the stage of the disease at admission is a predictor of poor outcome [97-100].

Pathogenesis of ICP

Understanding the pathogenesis of eICP is essential for formulating appropriate therapeutic interventions. The pathological substrate of eICP includes: 1) diffuse edema consequent to encephalitic processes; 2) micro- and macroinfarcts secondary to vasculitis of both small and large vessels and the associated edema and space-occupying effect; 3) hydrocephalus due to CSF blockage by adhesion formation of the basal subarachnoid cisterns; 4) a space-occupying effect of associated tuberculoma(s) [10,11]. Rarely, mostly in children, tuberculous encephalopathy may contribute to eICP. Tuberculous encephalopathy is an immune-mediated allergic process with no appreciable inflammatory reaction; the pathology includes demyelination and edema [24].

In addition to the pathological substrate, other players in the pathogenesis of eICP in tuberculous meningitis include fever and hyponatremia. Hyponatremia is a common finding in such patients and results in osmotic water shifts, leading to an increase in intracellular fluid (ICF) volume, especially brain cell swelling or cerebral edema [69]. An increase in brain temperature in the presence of acute cerebral damage is associated with a significant raise in ICP [61].

Management

The clinical presence of papilledema may help to diagnose eICP. The GCS is a reliable scale to assess brain injury severity. A GCS <8 suggests serious pathology and possible eICP. In addition to clinical evaluation, neuroimaging is an essential component in the management of eICP in patients with tuberculous meningitis. It provides a good idea about the possible pathological substrate of eICP. The imaging evaluation usually begins with a contrast CT scan as an emergency procedure: 1) to identify intracranial lesions, tuberculomas and space-occupying infarcts that may need surgical correction; 2) to identify CSF obstruction, hydrocephalus; and 3) to appreciate the severity of cerebral edema or the presence of brain shift.

There are no established guidelines for when to institute ICP monitoring in patients with tuberculous meningitis and eICP. In one study in children with hydrocephalus and eICP, response to therapy was assessed by means of repeated lumbar CSF pressure monitoring and CT scanning. No correlation was observed between lumbar opening pressure and the degree of hydrocephalus as measured by CT [101]. Studies in children with other CNS infections, encephalitis and bacterial meningitis have shown the usefulness of ICP monitoring in the optimal management of ICP [102,103]. It will be appropriate to monitor ICP in patients with tuberculous meningitis with features of ICP and grade II and III disease.

Management of eICP should be carried out in a stepwise fashion as in any other clinical setting. The initial steps should include optimal head positioning to allow for venous drainage and adequate analgesia and sedation. Additional basic measures should focus on optimizing hemodynamic status and oxygenation (airway and ventilation control).

Osmotherapy

The administration of osmotic agents is one of the principal strategies to lower eICP. Commonly used agents are mannitol and hypertonic saline. Osmotic agents, most often mannitol, have been used in patients with CNS infections to treat eICP [104-106]. But none of the studies systematically evaluated the efficacy of the osmotic agents. Similarly, there are few studies in which eICP was treated with an ICP-targeted approach [107]. Hypertonic saline can be used as an alternative to mannitol. It may also be used in otherwise refractory intracranial hypertension to treat eICP. The safety and efficacy of hypertonic saline in the treatment of eICP in other clinical settings has been well established. However, caution is advised with high osmolar loads because they carry an increased risk for potentially deleterious consequences of hypernatremia or may induce osmotic blood-brain barrier opening, with possibly harmful extravasation of the hypertonic solution into the brain tissue [108].

Hyponatremia is a common complication of tuberculous meningitis, and hypovolaemia is often present early in the course of the disease. Fluid therapy should aim at avoiding hypovolaemia and hypo-osmolality. When such a clinical situation is associated with eICP, hypertonic saline may be an appropriate choice [19]. Hypertonic saline is devoid of the risks of dehydration and tubular damage as occur with mannitol.

Hydrocephalus

Hydrocephalus can be treated with diuretics, osmotic agents, serial lumbar puncture, external ventricular drainage or ventriculoperitoneal shunt. The addition of acetazolamide and furosemide was significantly more effective in achieving normal ICP than antituberculous drug treatment alone [109]. In a series of 217 children with tuberculous meningitis and hydrocephalus, medical treatment obviated the need for shunt surgery in over 70% of children [110]. However, patients on medical treatment should be closely monitored to detect worsening or lack of improvement, and shunt surgery should be considered if medical management fails. Ventriculoperitoneal shunt is associated with favourable outcome. The grade of the disease at presentation is a predictor of outcome after shunt surgery [97-100]. In mild and moderate hydrocephalus, early shunt surgery (2 days after diagnosis) was associated with better outcomes compared with delayed surgery (3 weeks after diagnosis [111].

Tuberculomas

The reported frequency of tuberculoma(s) on the initial CT scan varies between 2 and 38% [19]. A growing body of evidence suggests that most often tuberculomas resolve with antituberculous treatment [19].Surgical excision is indicated in: 1) tuberculomas causing obstructive hydrocephalus and significant eICP; 2) tubuerculomas causing obstructive hydrocephalus and not resolving on medical treatment; 3) large space-occupying tuberculomas with eICP; 4) tuberculomas with associated compartmental shifts and not resolving with medical treatment [19].

Prognosis

The reported mortality associated with treated tuberculous meningitis varies between 20 and 50% [13]. In a recent, large retrospective cohort study of all the children with tuberculous meningitis in the Western Cape of South Africa, the mortality was 13% [21]. This very low mortality has been explained by directly observed treatment, active treatment of hydrocephalus, and low rate of HIV co-infection and MDR tuberculosis in the study population. However, the morbidity was quite high, and only 16% of patients had a normal outcome. The morbidity reported in other series varied between 20 and 30%

[13]. A major prognostic indicator for mortality and morbidity was disease stage at presentation [21,112]. In the South African study in children, ethnicity, disease stage, headache, convulsions, motor function, brainstem dysfunction, and cerebral infarction were independently associated with poor outcome on multivariate logistic regression analysis. The area under curve (AUC) of the model was 0.84 (95% CI, 0.80-0.89) [21].

58.8 Conclusion

Tuberculous meningitis is a serious CNS infection with significant mortality and high morbidity among survivors. Most factors found to correlate with poor outcome can be directly traced to the degree of disease progression at the time of diagnosis. The only way to reduce mortality and morbidity is by early diagnosis and timely recognition of complications. Aggressive and appropriate care within the intensive care unit setting can minimize associate brain injury and improve the chance of a good outcome.

59 *Acinetobacter* Infections: An Emerging Problem in the Neurosurgical Intensive Care Unit

A. Rodríguez-Guardado [1], A. Blanco [2], F. Pérez [3], M. Álvarez Vega [4], JM Torres [4], JA Cartón [1]

59.1 Introduction

Interest in *Acinetobacter* spp. has been growing for the past 30 years. One of the main reasons for the present increased interest in this genus is the emergence of multiresistant strains, several of which are pan-resistant to antibiotics and suddenly cause an outbreak of infection [1]. Some of these outbreaks of nosocomial infections have occurred in intensive care units (ICUs) where treatment and control are difficult.

Multidrug-resistant *Acinetobacter baumannii* is a rapidly emerging pathogen in the healthcare setting, where it causes infections including bacteraemia, pneumonia, meningitis, urinary tract infections, and wound infections. The associated mortality is high. The crude mortality rate associated with bacteraemia is approximately 52% and that associated with pneumonia ranges from 23 to 73% [2,3]. It is among the most difficult antimicrobial-resistant Gram-negative bacilli to control and treat due to its ability to survive under a wide range of environmental conditions and to persist for extended periods of time on surfaces, making it a frequent cause of outbreaks of infection and an endemic healthcare-associated pathogen.

Recently, an increased rate of infections caused by *A. baumanii* strains resistant to antibiotics traditionally used in therapy has been reported [3-5]. This is an especially severe event in such infections as post-surgical meningitis because the choice of an antibiotic depends not only on the sensitivity of *A. baumanii* but also on the antibiotic's penetrability through the blood-brain barrier. Multidrug-resistance complicates the treatment of infection, making the search of new agents imperative and the return to old drugs for optimal treatment of this multidrug-resistant organism.

The focus of this review is to summarize the current state of knowledge regarding *A. baumannii* in relation to its taxonomy, identification, microbiology, epidemiology, infections, resistance to antibiotics, and the potential therapeutic approaches to postsurgical meningitis in particular.

59.2 Microbiological Characteristics

The genus *Acinetobacter* comprises ubiquitous Gram-negative bacilli that were originally identified in the 1930s [3,6]. Subsequently, several changes were introduced into the taxonomic classification of *Acinetobacter* spp. The genus *Acinetobacter* initially en-

compassed a heterogeneous collection of non-pigmented, oxidase-positive and oxidase-negative Gram-negative rods [3,6-8]. The genus *Acinetobacter* is now defined as including Gram-negative (but sometimes difficult to stain) coccobacilli, with a DNA G1C content of 39 to 47 mol%, that are strictly aerobic, nonmotile, nonfermentative, catalase-positive and oxidase-negative. Good growth occurs at 40°C without the need for growth factors, while nitrates are reduced only rarely [3]. It appears as bacilli during the rapid growth phase and as cocobacilli in the stationary phase [9].

Over 20 species belonging to the genus *Acinetobacter* have been identified [10]. *A. baumannii* (two genomic species) is the species of greatest clinical relevance, and it is typically associated with outbreaks in the hospital setting [11]. Other species that have been associated with disease in humans belong to the *A. calcoaceticus-A. baumannii* complex that includes three *Acinetobacter* genomic species: *A. johnsonii, A. wolffii, and A. calcoaceticus* subsp*. anitratus* [9].

59.3 Epidemiology

Increasing isolation of multidrug-resistant (MDR) *A. baumannii* has been reported worldwide, and it is now one of the most difficult nosocomially acquired Gram-negative pathogens to control and treat [12]. *A. baumannii* has the ability to utilise various sources of nutrition, which accounts for its growth on routine laboratory media. This explains its survival as an environmental pathogen. Some strains can survive environmental desiccation for weeks, a characteristic that promotes transmission through fomite contamination in hospitals [13]. The capacity of *Acinetobacter* spp. to survive on most environmental surfaces for long periods of time suggests that all animate and inanimate entities should be considered reservoirs.

In healthcare settings, colonized and infected patients are often the sources of *A. baumannii* infections; however, the ability of the organism to survive for prolonged periods on environmental surfaces has also contributed to protracted outbreaks in these settings [12]. *Acinetobacter* has been isolated from pasteurized milk, frozen foods, chilled poultry, foundry, and hospital air, vaporizer mist, tap water faucets, peritoneal dyalisate baths, bedside urinals, washcloths, door handles, keyboards, angiography catheters, ventilators, contaminated gloves, duodenoscopes, laryngoscope blades, plasma protein fraction, and hospital pillows [14-16]. This ability to grow on medical equipment and throughout the hospital environmental emphasizes the need for special attention to disinfection [17-20].

Multidrug-resistant *Acinetobacter* spp. infections have been described in patients admitted to rehabilitation centres and long-term care facilities, as well as in patients hospitalized for acute illnesses [21-26]. The origin of a particular epidemic strain of *A. baumannii* in a hospital is often unknown [21]. There are several factors that maintain the presence of *Acinetobacter* spp. in the healthcare environment, including the presence of susceptible patients or health workers colonized or infected by the microorganism. *Acinetobacter* spp. can colonize the skin, wounds, and the respiratory and gastrointestinal tracts. Up to 25% of healthy ambulatory adults exhibit cutaneous colonization and 7% of adults and children have transient pharyngeal colonization. It is the most common Gram-negative organism persistently carried on the skin of hospital personnel and it has been found to colonize 45% of inpatient tracheostomy sites and 41% of faecal samples in ICUs [22-23]. Differentiating between colonization and infection has clinical and therapeutic relevance because the presence of colonized or infected patients is important in maintaining the organism in the hospital. According to Landman et al. [27], 31-50%

of patients admitted to ICUs have clinical samples testing positive for *A. baumannii* but only between 10-35% show clear signs of infection.

Acinetobacter baumannii can cause community-acquired infections although less frequently than nosocomial infections. Multidrug-resistant *Acinetobacter* infection has been reported among patients residing in rehabilitation and long-term care facilities, as well as in acute care hospitals [24-26]. Several factors maintain the presence of multidrug-resistant *Acinetobacter* spp. in the healthcare setting, including the presence of susceptible patients, the presence of patients already colonized or infected with the organism, selective pressure from antimicrobial use, and incomplete compliance with infection control procedures [28].

In addition to transmission, the emergence of resistance occurs in the context of selective pressure from broad-spectrum antimicrobial therapy with carbapenems or third-generation cephalosporins. The relative contribution of antimicrobial selective pressure and transmission between patients to the emergence of multidrug-resistant *Acinetobacter* spp. is not known [29-31].

59.4 Antimicrobial Resistance

Various terms have been used (sometimes interchangeably) to denote antimicrobial-resistant phenotypes of *Acinetobacter* spp. The most common definitions of multidrug resistance are carbapenem resistance or resistance to more than three classes of antimicrobials [32].

The emergence of multiresistance in *Acinetobacter* spp. complicates the choice of antibiotic treatment and is associated with significant morbidity (63.4%) and mortality (44.2%) [33]. The resistance rate varies between geographic areas, hospitals and even different hospital wards within the same hospital [34]. Some studies [35] found sensitivity rates of imipenem and amikacin of almost 74% in North America and Europe, 60% and 23%, respectively, in Latin America, and 69.2% and 59.6%, respectively, in the Asian region. According to the SENTRY study [36-38] involving 30 European centres from 2001 to 2004, the proportion of strains resistant to imipenem, meropenem, ampicillin-sulbactam and polymyxin B was 26.3%, 29.6%, 51.6%, and 2.7%, respectively. More recent data collected in the MYSTIC study (Meropenem Yearly Susceptibility Test Information Collection) involving 40 hospitals in 12 European countries showed higher rates of resistance to meropenen (43.4%) and imipenem (42.5%) [39]. These results may be even higher in ICUs where several studies have reported resistance to meropenem and imipenem of nearly 75-80% [40].

In several countries, the rate of resistance to colistin is now 2-3% in relation to previous use, and heteroresistant populations have emerged which can hinder its future use in monotherapy [41]. Although tigecycline once appeared to be a good alternative to conventional treatments, reports have increasingly described the emergence of resistant strains even during treatment with the drug, severely compromising its use in empirical therapy. A German study of 215 strains of *A. baumannii* found resistance rates to tigecycline of almost 6% compared to 2.8% for colistin [42]. Another recent study reported resistance rates of 25%, suggesting that the role of antibiotic therapy with these drugs should be carefully evaluated [40].

Several risk factors for the acquisition of multidrug-resistant strains have been identified. These include the previous use of antibiotic treatments, especially carbapenems and third-generation cephalosporins, followed by quinolones, aminoglycosides and metronidazole, and the number of previous antibiotics. The second most common risk

factor is the use of mechanical ventilation. Other factors include a stay in the ICU, duration of ICU stay and overall hospital stay, severity of the underlying disease, recent surgery and invasive techniques [43,44]. *Acinetobacter* spp. display mechanisms of resistance to all existing antibiotic classes, as well as a prodigious capacity to acquire new determinants of resistance [45]. The capacity of *Acinetobacter* spp. to develop extensive antimicrobial resistance may be due in part to the organism's relatively impermeable outer membrane and its environmental exposure to a large reservoir of genes.

59.4.1 Mechanisms of Resistance

Resistance mechanisms for *Acinetobacter* spp. generally fall into three categories: 1) antimicrobial-inactivating enzymes; 2) reduced access to bacterial targets; and 3) mutations that change targets or cellular functions. Because *Acinetobacter* spp. are Gram-negative organisms, they possess an additional outer membrane that acts as a permeation barrier [2,13,44].

59.4.2 Resistance to Beta-lactams

The mechanism of resistance to beta-lactams involves: 1) their hydrolysis by beta-lactamases; 2) changes in penicillin-binding proteins (PBPs) that inhibit their action; 3) alterations in the structure and number of porin proteins that result in decreased permeability to antibiotics through the outer membrane of the bacterial cell; and 4) the activity of efflux pumps that further decrease the concentration of an antibiotic within the bacterial cell [46,47].

The most important problem in multidrug-resistant *Acinetobacter* is its resistance to carbapenems. This resistance is mediated by various mechanisms:

- Metallo-β-lactamase (VIM, IMP).
- OXA carbapenemases (class D).
- Cell permeability changes.
- Target (PBPs) changes.

The metallo-β-lactamases and OXA carbapenemases are the most important mechanisms of resistance in *A. baumannii* because they confer resistance to carbapenems. These enzymes belong to either Ambler Class B (metallo-β-lactamases) or class D (oxacillinases) [48]. Metallo-β-lactamases are efficient carbapenemases. Three groups of this enzyme class have been found in *Acinetobacter* spp*:* IMP-like MBL, VIM-like MBL, and SIM-1. IMP and VIM confer high-level resistance to carbapenems and most other beta-lactams, with the exception of aztreonam. MBL are class-1 integrons and may be transferred and expressed along with resistance genes to other antimicrobials such as aminoglycosides [34,47,57-59].

The other group of enzymes (carbapenem-hydrolysing oxacillinases) consists of oxacillinases with intrinsic carbapenemase activity. The significant contribution of these enzymes to carbapenem resistance in *A. baumannii* has been emphasized, particularly when they are accompanied by IS*Aba1* and IS*Aba3* in the naturally occurring plasmid [60-62].

A third mechanism of carbapenem resistance involves porins, which are outer-membrane proteins that allow antimicrobials, such as beta-lactams, to permeate into the bacterial cell. Loss or modification of porin proteins has been shown to confer carbapenem resistance and high-level resistance is observed in the presence of both loss of porin function and expression and production of carbapenemases [47,63]. Another mechanism contributing to carbapenem resistance is the overexpression of bacterial efflux

pumps that decrease the concentration of beta-lactam antibiotics in the periplasmic space [64]. Efflux pumps cause clinical resistance in *Acinetobacter* spp. by acting in association with the overexpression of AmpC beta-lactamases or carbapenemases. With less beta-lactam entering the periplasmic space, the weak enzymatic activity of beta-lactamase is amplified. Besides removing beta-lactam antibiotics, efflux pumps can actively expel quinolones, tetracyclines, chloramphenicol, disinfectants, and tigecycline [66,62,47].

Various factors associated with the emergence of strains resistant to carbapenems and sensitive to colistin have been identified, including prior exposure to quinolones and antipseudomonal drugs and the number of antibiotics used previously [65].

59.4.3 Resistance to Aminoglycosides

Resistance to aminoglycosides is mediated by three mechanisms: alteration of the ribosomal target; reduction of uptake; and enzymatic modification of the drug. Alteration of the ribosomal target only affects streptomycin. The second mechanism is fairly common in *Acinetobacter* spp., but resistance to aminoglycosides in *A. baumannii* is mediated principally by aminoglycoside-modifying enzymes. These include aminoglycoside O-phosphotransferases, aminoglycoside N-acetyltransferases, and aminoglycoside O-nucleotidyltransferases. They are mediated primarily by plasmids or transposons that can play a role in the spread of resistance. These enzymes may also be chromosomally located [3,67,68].

59.4.4 Resistance to Quinolones

Resistance of *A. baumannii* to quinolones is often caused by modifications in the structure of DNA gyrase secondary to mutations in the quinolone resistance-determining regions of the *gyrA* and *parC* genes [69,70]. These changes result in a lower affinity for the binding of quinolone to the enzyme-DNA complex. As mentioned above, a second mechanism of resistance to the quinolones is mediated by efflux systems that decrease intracellular drug accumulation [48].

59.4.5 Resistance to Tetracyclines

Two different mechanisms of resistance to tetracyclines have been described in *A. baumannii*. TetA and TetB are specific transposon-mediated efflux pumps; TetB determines the efflux of both tetracycline and minocycline, whereas TetA drives only the efflux of tetracycline. The second mechanism is the ribosomal protection protein, which shields the ribosome from the action of tetracycline. The *tet*(M) gene encodes this protein, which serves to protect the ribosome from tetracycline, doxycycline, and minocycline [3,46].

Tigecycline is the first antibiotic of a new class called glycylcyclines that may be useful for multidrug-resistant *Acinetobacter* [71-73]. Tigecycline overcomes the two major mechanisms of resistance to tetracyclines (ribosomal protection and efflux), but tigecycline resistance emerging during therapy has been reported [72]. This resistance appears to be attributable to overexpression of the AdeABC multidrug efflux pump [73]. Probably this mechanism can be upregulated by the previous use of other antibiotics (e.g., fluoroquinolones, aminoglycosides) that are administered frequently in patients with serious infections [74].

59.4.6 Resistance to Polymyxins

There are several suggested mechanisms of resistance to colistin/polymyxin B in Gram-negative bacteria, most of which involve changes in the outer membrane. The mechanism of resistance to colistin likely resides in modifications in the lipopolysaccharide of *A. baumannii* (acidification, acylation, or presence of antigens that interfere with the binding of the antibiotic to the cell membrane) [3]. A strong association has been reported between the use of colistin and the development of resistance in clinical isolates of *A. baumannii* [75].

59.5 Virulence and Pathogenicity

A. baumannii is regarded as a low-grade pathogen with limited virulence. However, this microbe has certain features that allow it to increase the virulence of those strains implicated in infections. The bacteria's invasiveness may be related to substances that protect the surface of phagocytosis, i.e., the polysaccharide capsule. The presence of fimbriae allows adhesion to human epithelial cells. Studies have investigated the production of such enzymes as butyrate esterase, caprylate esterase, leucine and aryl amidase which may damage tissue lipids and the potentially toxic role of the lipopolysaccharide component of the cell wall and the presence of lipid A. Apart from sharing factors in common with other Gram-negative bacteria, *Acinetobacter* spp. produce a lipopolysaccharide that can exert an endotoxigenic effect through lipid A and that enhance the ability of these microorganisms to capture iron through the secretion of siderophores, which allows them to survive in the human body. Moreover, some strains of *Acinetobacter* spp. can produce slime which was considered to be the main factor responsible for the enhancement of virulence in mixed infections [1,3,76].

All these factors act together in the pathogenicity of *Acinetobacter* spp. The capsular polysaccharides and lipopolysaccharides (LPSs) act in synergy by blocking access of the human complement to the bacterial cell wall, thus preventing its lytic activity on bacterial membranes. Furthermore, the hydrophilicity conferred by the presence of capsular polysaccharides, together with other nonspecific adherence factors (i.e., fimbriae), prompts the colonization of human epithelial cells by pathogenic strains [77]. Enzymes able to damage tissue lipids are also produced during the infectious stages of colonization. Interestingly, the action of LPSs in the pathogenicity of *Acinetobacter* is not limited to the protection of bacterial cells from host defences; these molecules are, in fact, provided with a powerful endotoxic activity, and their production in vivo is thought to be related to *Acinetobacter* septicaemia symptoms [78,79].

59.6 Useful Antibiotics for *Acinetobacter* Infections

Distinct classes of antimicrobial agents considered potentially effective in the treatment of *A baumannii* infection include: sulbactam; antipseudomonal penicillins or cephalosporins; carbapenems; monobactams; aminoglycosides; fluoroquinolones; glycylcyclines; and colistin [80]. However, the emergence of strains with high resistance to carbapenems, aminoglycosides and fluoroquinolones [35,36,81] poses a challenge to the clinician; therefore, sulbactam, tigecycline and colistin represent the current therapeutic approaches associated with satisfactory efficacy.

59.6.1 Carbapenems

Imipenem and meropenem have been regarded as the treatment of choice for severe *A. baumannii* infections, although the increase in resistance rates of *A baumannii* isolates to carbapenems, especially in Europe and North America, have diminished their usefulness [35]. Furthermore, carbapenem-resistant *A. baumannii* strains might only rarely be susceptible to other antipseudomonal agents [80], making treatment very difficult.
As described above, carbapenem resistance in *A. baumannii* is mediated by several mechanisms, including plasmid or chromosomally encoded carbapenemases (mainly OXA-23-like, OXA-24-like, or OXA-58-like class D β-lactamases), as well as metallo-β-lactamases (class B β-lactamases), efflux pump mechanisms, penicillin-binding protein alterations, and modifications or loss of outer membrane proteins (porins) [48,80]. More than one of these resistance determinants could be present in the same strain, thus conferring it high-level resistance.
A recently developed carbapenem is Doripenem, a novel, forthcoming carbapenem that possesses a broad spectrum of activity against Gram-negative bacteria similar to that of meropenem, while retaining the spectrum of imipenem against Gram-positive pathogens [82]. It is approved for the treatment of complicated urinary tract and complicated intra-abdominal infections. An indication for hospital-acquired pneumonia including ventilator-associated pneumonia is pending. Its principal features are: 1) bactericidal action against most species; 2) β-lactamase stability to commonly occurring enzymes, including the emerging extended-spectrum β-lactamases (ESBLs); 3) pharmacokinetic and pharmacodynamic qualities similar to those of meropenem (half-life of 1 h) with minimal risk of convulsive adverse reactions; 4) postantibiotic effects of nearly 2 h in vitro for *Pseudomonas aeruginosa*; and 5) low serum protein binding (8.9%). Doripenem is stable enough in the presence of renal dehydropeptidase I that it need not be coadministered with a dehydropeptidase I inhibitor such as cilastatin. Pharmacokinetic studies have supported a 3-times-daily dosing schedule [83].
The most frequent adverse reactions are: nausea, diarrhoea, headache, phlebitis, hypersensitivity reaction, and *C. difficile*-associated colitis. In contrast to imipenem, doripenem did not cause electroencephalographic changes or seizures in animal studies [84-86]. Doripenem may be have a important role in the treatment of *Acinetobacter* infection because it has a lower minimum inhibitory concentration (MIC) than ertapenem or imipenem when tested against *Acinetobacter* spp. [85,86] and some isolates that are intermediate or resistant to other carbapenems may be susceptible to doripenem [85,86]. In a recent study 86 on 12,581 isolates collected between 2005 and 2006 and tested with doripenem, imipenem and meropenem, the MIC(90) of doripenem (0.12) was comparable to that of meropenem (0.12) and superior to that of imipenem (2), though the susceptibility of the isolates exceeded 99% for all evaluated carbapenems. Doripenem (MIC(90) = 2, 89.1%S) was twice as active at MIC(90) against imipenem-susceptible *Acinetobacter* spp. as imipenem or meropenem. However, none of the carbapenems was active against A*. baumannii* strains expressing plasmid-mediated carbapenemases [86,87].

59.6.2 Colistin

Colistin belongs to the Polymyxins group and is available in two forms, colistin sulphate and colistimethate sodium. Colistimethate sodium is a non-active prodrug that is hydrolyzed in vivo to the active form and used for parenteral administration due to its lower toxicity [89]. Polymyxins show bactericidal activity against A *baumannii* by interacting

with anionic lipopolysaccharides on the bacterial cell membrane, leading to an increase in membrane permeability [36,90]. Resistance rates against these agents have remained low despite their more frequent use and the presence of carbapenem-resistant strains [37,91,92].

The usual dose of colistin is 2.5-5 mg/kg/day in 2 to 4 divided doses. In persons weighing >60 kg, the most frequent dose is 80-160 mg/8 h. Dose adjustment is required in the presence of renal failure. Since the bactericidal activity of colistin is concentration-dependent, administering large doses over less frequent intervals may be a favourable approach [93-97]. Isolated case reports described the cure of A. baumannii bacteraemia with continuous intravenous colistin (2,000,000 IU/24 h) in patients with allergic reactions to other treatment [96]. However, the emergence of heteroresistant strains with increasing frequency, along with the pharmacodynamic characteristics of the drug, appear to discourage their use in 24-hour intervals. Owen et al. [97] showed a rapid bactericidal concentration-dependent effect, with regrowth at 3 hours after administration that was clearly significant at 24 hours, even at concentrations 32 and even 64 times above the MIC in some isolates, which advises against its use as monotherapy, and at 24-hour intervals in the presence of heteroresistant strains.

Colistin alone or in combination with other antimicrobials like rifampicin demonstrated its usefulness in several infections due to *A. baumannii* such as ventilator-associated pneumonia, meningitis, and bacteraemia, with rates of clinical and microbiological response close to 80% and 95%, respectively, depending on the type of infection [98-102] It has sometimes been used in nebulized form in variables doses, although the most common are 2-4 million IU with conventional intravenous treatment. The response rate was 85.7% after a single treatment. More studies are needed to clarify its role [103].

The most common toxic effects of colistin are nephrotoxicity and polyneuropathy. For this reason, the systemic administration of polymyxins was abandoned for about 20 years in most areas of the world. However, the problem of infections due to multidrug-resistant Gram-negative bacteria such as *P. aeruginosa* and *A. baumannii* has led to the re-use of polymyxins. Most non-comparative studies have reported an 8-21% rate of renal toxicity associated with polymyxin therapy which appears to be correlated with the cumulative dose, although recent studies using doses of 225 mg/8 h did not observe the occurrence of nephrotoxicity. Patients with pre-existing renal dysfunction in any stage including hemodiafiltration or hemodialysis seem to be more susceptible to the renal adverse effects of polymyxins [102,104-109]. However, a recent study by Hartzell et al. [110] reported a higher percentage of nephrotoxicity (45%), with interruption of therapy in 21% of patients. This study evaluated nephrotoxicity according to the RIFLE criteria (risk, damage, failure, loss and end stage renal disease), and the higher toxicity was possibly related to greater rigor in applying the criteria. Other side effects are neurotoxicity, bronchoconstriction, chest tightness or cough following administration via the respiratory tract. Chemical meningitis with intraventricular or intrathecal use has been infrequently reported [111-112].

Resistance to colistin is low but it has already been reported. The risk factors significantly associated with the isolation of colistin-resistant isolates were age, length of ICU stay, surgical procedures, use of colistin, use of monobactams, and duration of use of colistin. Although the use of colistin was identified as the only independent risk factor in the multivariable model [113]. To prevent this phenomenon, colistin should be used judiciously, given that treatment options for colistin-resistant Gram-negative bacteria are limited. However, in many occasions it must be used as empirical therapy. Falagas et al. [114] estimated that between 4 and 5 of 100 patients admitted to the ICU will die if colistin is not included in empirical antibiotic treatment. Colistin should probably be included as

empirical antibiotic therapy in those ICUs where the probability of contracting a microorganism sensitive only to colistin is close to 50%.

59.6.3 Ampicillin-sulbactam

Sulbactam was introduced in the 1980s as a beta-lactamase inhibitor in combination with beta-lactamic antibiotics [4,5]. Sulbactam exerts its bacteriostatic activity against *Acinetobacter* spp. by binding to PBP2. The most frequently used combination is ampicillin/sulbactam (ratio 2:1), although the two agents are not synergetic [115-117]. The combination of ampicillin-sulbactam has been used by some authors in doses of 2 g/6-8 h [34,115]. The use of ampicillin/sulbactam had been described in retrospective series. Combination therapy has shown effectiveness similar to imipenem therapy in *A baumannii* ventilator-associated pneumonia or bacteraemia caused by multidrug-resistant drugs [115-122]. Favourable clinical outcomes have also been reported with sulbactam or combination ampicillin/sulbactam therapy in patients with other types of nosocomial infections like meningitis [101,121]. Therefore, ampicillin-sulbactam is a sensible option for the treatment of life-threatening *Acinetobacter* infections. However, the role of sulbactam in the treatment of *Acinetobacter* infections is limited due to the development of multidrug-resistant strains.

59.6.4 Glycylcyclines

Glycylcyclines are a novel class of antimicrobial agents related to the tetracyclines. Tigecycline was the first commercially available agent in this class. Tigecycline is a semisynthetic derivative of minocycline that arises from the incorporation of the t-butyl glycylamide radical in position 9 of minocycline, a structural change that enhances its spectrum and provides a better resistance profile. Its mechanism of action is like that of tetracycline: it inhibits protein translation by binding reversibly to the 30S subunit of the bacterial ribosome. This binding blocks the entry of aminoacyl t-RNA to the site of the ribosome, thus preventing the incorporation of amino acids and the subsequent formation of long-chain peptides [123-125]. Glycylcycline binds five times more effectively than tetracycline, which may affect its ability to overcome resistance to tetracyclines from the protection of the ribosome. Moreover, it seems that the mode of interaction of tigecycline with the ribosome is different from that of tetracyclines. It shows bacteriostatic activity against *A baumannii* because it interferes with bacterial protein synthesis through ribosomal binding and thus exhibits its time-dependent bactericidal activity. Tigecycline is extensively distributed into many tissues, resulting in a prolonged half-life that justifies twice-daily dosing. Fifty-nine percent of a tigecycline dose is excreted through the liver, and 33% is excreted through the kidney. In patients with severe hepatic impairment (Child's class C), the normal dose of tigecycline (100 mg initial dose, then 50 mg twice daily) should be reduced to 25 mg twice daily after the normal loading dose. No adjustments are required for any level of renal impairment [124].

Tigecycline is able to evade the most common mechanisms of resistance to tetracyclines in *A baumannii*, including efflux pumps encoded by the *tet*(A) and *tet*(B) determinants, and ribosomal protection mechanisms. Nevertheless, several unique multidrug efflux pumps have been shown to reduce the organism's susceptibility to tigecycline and the rate of resistance is nearly 6% [126,127].

Clinical experience with the use of tigecycline for the treatment of patients with multidrug-resistant *A baumannii* infections is accumulating. Tigecycline has been used in a small number of critically ill patients – mainly as part of combination antibiotic regi-

mens—for the treatment of various types of infections, including ventilator-associated pneumonia and primary or secondary bacteraemia [128-132]. In early case series, most patients had a good clinical outcome. However, the failure of tigecycline to clear *A. baumannii* bacteraemia was reported in a few cases [132]. Furthermore, pharmacokinetic and pharmacodynamic data indicate that tigecycline blood concentrations seem to be suboptimal for maximal antibacterial activity to be exerted in this compartment. There are increasing reports indicating that resistance to tigecycline developed during treatment. In a recent review of retrospective data on 42 severely ill patients, 31 of which had a respiratory tract infection (in 4 cases with secondary bacteraemia) and 4 had bacteraemia, tigecycline therapy (in combination with other antibiotics in 28 patients) was effective in 32/42 cases, but resistance developed in 3 cases during the treatment [128].
Clinicians should be aware that tigecycline MICs for *A. baumannii* isolates may increase during therapy after brief exposure to the drug. Patients receiving tigecycline for *Acinetobacter* infection should be monitored for the development of clinical resistance, and isolates should be monitored for evidence of microbiologic resistance.

59.6.5 Aminoglycosides

Aminoglycosides have shown moderate rates of antimicrobial activity against *A baumannii.* In worldwide collections of *Acinetobacter* spp. isolates, susceptibility rates to amikacin were approximately 60% [36] and the activity of aminoglycosides is lower for multidrug-resistant isolates of *A baumannii* compared with non-multidrug-resistant ones [133]. Reports on the clinical use of aminoglycosides in human beings are scarce and refer to cases of bacteraemia [134] or meningitis [101] in which aminoglycosides have been used in combination with other classes of antimicrobial agents.

59.6.6 Fluoroquinolones

Fluoroquinolones have moderate antimicrobial activity against *A baumannii.* Although levofloxacin has been shown to yield a lower MIC compared with ciprofloxacin and ofloxacin against *Acinetobacter* spp., overall resistance rates to ciprofloxacin and levofloxacin in clinical isolates are around 50% [135]. Nonetheless, the activity of fluoroquinolones against recent multidrug-resistant or imipenem-resistant isolates has been reported to be low [36,133]. The clinical data are based on in vitro studies where levofloxacin showed effectiveness similar to imipenem in a mouse pneumonia model against a strain susceptible to both agents [135]. However, no comprehensive evidence exists for the effectiveness of fluoroquinolones in the treatment of human infections caused by *A baumannii.*

59.6.7 Combination Therapy

Several novel antibiotic combinations demonstrated increased activity in vitro compared with that of any single agent against multidrug-resistant *A. baumannii* isolates. Whether these combinations yield improved outcomes over those seen with a polymyxin or another agent alone remains to be determined. However, against infections with species resistant to all antibiotics, including polymyxins, novel combinations are the only remaining therapeutic option. Several drug combinations have been tested, mostly involving colisitin, carbapenems, rifampicin, fluoroquinolones and sulbactam [136].
Although most of the studies were done in vitro and in animal models of pneumonia, they show that combined therapy, especially the combination with rifampin, obtained

better results than monotherapy with carbapenems or colistin [137-141]. The colistin and rifampicin combination (colistin sulphomethate sodium (2 million IU 3 times a day and intravenous rifampicin 10 mg/kg every 12 h) in the treatment of ventilator-associated pneumonia or bacteraemia caused by carbapenem-resistant *A. baumannii* demonstrated a clinical response of 76% and mortality of 21% [139].

The combination of imipenem and ripampicin has been investigated in some clinical studies; however, the published data are contradictory. Although the combination is synergistic, in vitro studies indicate that because 70% of patients develop high rates of resistance to rifampicin, this combination cannot be recommended [142]. The combination of imipenem with sulbactam has demonstrated synergistic activity in vitro, although some work indicates that the association of carbapenem with ampicillin-sulbactam is associated with better outcomes than the combination of imipenem with amikacin or carbapenems alone. The clinical utility of this combination in patients infected with carbapenem-resistant *A. baumannii* is not well established [91,143].

The assessment of *in-vitro* synergy of the combination of imipenem with a polymyxin against carbapenem-resistant *A baumannii* strains has provided mixed findings. Among other polymyxin-based combination regimens for multidrug-resistant *A baumannii*, the combination of colistin with a carbapenem has shown in vitro either synergistic or indifferent activity [144,146] but clinical effectiveness has not been substantiated [145]. Tigecycline has demonstrated synergy with levofloxacin, amikacin, imipenem and colistin, but there are few data at present to recommend its systematic use [147].

59.7 Specific Infections Due to *A. Baumannii* in Neurosurgery Intensive Care Units

Acinetobacter baumannii is an important cause of nosocomial infections. Risk factors specific for nosocomial infection include length of hospital stay, surgery, wounds, severity of underlying diseases, previous infection, faecal colonization with *Acinetobacter*, treatment with broad-spectrum antibiotics, especially amikacin and imipenem, parenteral nutrition, indwelling central intravenous or urinary catheters or other invasive procedures, admission to a burn unit or ICU, and mechanical ventilation or tracheostomy [28,148].

In many cases, these infections have significant morbidity and mortality. Some studies report an overall mortality rate of 43.3%, a related mortality of 30%, and attributable mortality of 24.3%, with a worse prognosis for critical ICU patients infected by this bacterium compared to those infected by other microorganisms [149].

59.7.1 Postsurgery Nosocomial Meningitis. General Characteristics

A. baumannii meningitis is an infrequent infection mostly associated with intraventricular catheters, cerebrospinal fluid (CSF) fistula or head trauma [148,149]. It is a serious problem in the neurosurgical ICU, especially in patients with intraventricular catheters where the incidence of infection varies from 0 to 27% [150-152].

The risk of nosocomial meningitis in these patients is related to [155-157]:

- Type of neurosurgical procedure.
- Glasgow Coma Scale <10.
- Emergency surgical procedure.
- Presence of surgical wound infection.

- Presence of an external CSF drain.
- Duration of an intraventricular catheter >5 days.
- Absence of antibiotic prophylaxis.

The average incidence is around 2.3% (0.5-11%) and varies with the type of intervention [156]:

- Clean 0.8-5%.
- Clean with insertion of foreign material 6.9%.
- Clean-contaminated 6.8%.
- Contaminated 9.7%.
- Dirty-infected 9.1%.

The most frequent mode of acquisition of nosocomial meningitis is direct transmission during invasive neurosurgical procedures (80%). The extension from a contiguous focus (otitis, mastoiditis, sinusitis, subdural empyema and epidural abscess) and cases secondary to bacteraemia from a distant focus only account for 20% of nosocomial bacterial meningitis [156]. Some studies indicate that up to 40% of patients harbour colonization or infection by the microorganism in places other than the central nervous system (CNS) before the onset of meningitis [153]. Given that the main route of acquiring meningitis is through surgical wounds or intraventricular catheters, this situation is of great importance. Hence, these patients should be monitored systematically for colonizing flora and measures of asepsis applied in their care.

The clinical manifestations of postsurgical meningitis caused by *A. baumannii* are unremarkable, mostly fever and progressive loss of consciousness. Therefore, these manifestations are attributed to the underlying disease, subsequently delaying the final diagnosis of meningeal infection, and representing a prognostic factor of mortality [105,157]. CSF data are consistent with an increased leukocyte count (75-100% polymorphonuclear leukocytes) accompanied by elevated protein with normal or decreased blood glucose levels. Due to the poor specificity of clinical and laboratory data, routine Gram staining and culture are essential in patients with fever of unknown origin and intraventricular catheter.

Infection of CSF shunts carries high morbidity and, above all, taken together, high mortality, which has been estimated to be 15-20%, which may even be higher in certain risk groups, such as preterm infants. The average incidence is 2.6% (range, 4.5-14%) [157,158]. CSF shunts can be divided into two groups: internal referrals or referral shunts and external ventricular drain or external lumbar drain.

- The most commonly used internal shunts are ventriculoperitoneal devices which drain into the abdominal cavity. Ventriculoatrial shunts are used less frequently and tend to be placed in patients in whom the abdominal route is not feasible. The incidence of infection in CSF internal shunts is between 1.5 and 39% (mean, 10%) according to the series. The most important factor associated with infection is the technical expertise of the neurosurgeon. Arguably, following the largest series, overall infection rates >10-15% are hardly admissible and demand the implementation of preventive strategies. The organisms involved are usually skin flora. Coagulase-negative *Staphylococci* (mainly *S. epidermidis*) are the most common pathogens, followed by *S. aureus*
- External shunts are catheters that communicate the subarachnoid or ventricular space with the outside. The main therapeutic indications are: acute hydrocephalus, massive intraventricular hemorrhage, intracranial pressure measurement, closure of CSF leaks, and occasionally drug administration. The incidence of infection differs depending on the device: in the case of an external shunt or peripherally inserted central catheter (PICC) it ranges from 5 to 7% and 3-5% for the Ommaya reservoir. In this case, the causal organisms are almost always, *Staphylococci* and Gram-

Type of surgery	Type of complication	Risk factors
Ventriculostomy	Meningitis	Previous surgery Shunt >5 days ICP >20 mmHg Irrigations Extensive dural lesion
ICP catheter	Meningitis Supuration	Age Duration of ICP monitoring Steroid treatment
Ommaya reservoir	Meningitis	Aspiration of CSF

Table 59.1. **Risk factors associated with external shunts.**

negative pathogens. Patients with this type of drainage are frequently admitted to ICUs where the prevalence of nosocomial infection, especially from often multiresistant gram-negative bacilli, is high. Infection rarely occurs at the time of catheter insertion, but rather over subsequent days. External catheters remaining in place beyond 5-7 days are at highest risk.

Several risk factors associated with infection of internal shunts are: duration of surgery, vascular thrombosis, age, resurgery, ventriculoatrial > ventriculoperitoneal.

Risk factors associated with infection of external lines are shown in Table 59.1.

The most common clinic manifestation [155,156] is shunt malfunction syndrome, consisting of headache, nausea or vomiting, behavioural changes or gradual decrease in level of consciousness, with or without fever. These symptoms are attributable to intracranial hypertension and are suspicious of infection.

In peritoneal shunts, abdominal clinic is common (up to 40% of cases), often presenting as pain in the right lower quadrant, with or without signs of peritoneal irritation. Other complications include intestinal perforation or pseudo-obstruction symptoms. Any abdominal symptoms in a patient with a peritoneal shunt should suggest the possibility of infection. Abdominal ultrasound may reveal a cystic image or inflammatory liquid mass in the distal insertion of the catheter.

Ventriculoatrial shunt infection manifests mainly with fever, which can be elevated and accompanied by chills and even sepsis. Potential complications are severe, such as tricuspid endocarditis, septic pulmonary embolism, paradoxical cerebral embolism, mycotic aneurysm in the territory of the pulmonary artery, cardiac tamponade, myocardial perforation, pseudotumour right atrial thrombosis *in situ* or diffuse glomerulonephritis associated with hypocomplementemia and nephritic syndromes.

Contamination	Culture of CSF + normal CSF + no symptoms
Colonization ventriculostomy	• Positive cultures • Normal CSF • No symptoms. Possible fever
Possible infection Ventriculostomy	• Negative culture • CSF: ↓ glucose, ↑ proteins, ↑ leucocytes
Ventriculostomy infection	• CSF: ↓↓↓ glucose, ↑↑↑ proteins, ↑↑↑ leucocytes • Positive culture • Fever and other symptoms
Ventriculitis	• All the anterior • Fever and meningitis symptoms

Table 59.2. **Diagnostic criteria for external shunt infection.**

External shunt ventricular catheter infection manifests with the development of ventriculitis, fever and altered mental status. As in shunt infection, meningitis can occur if ventriculitis is severe. Sometimes, there are signs of infection at the catheter insertion point. Occasionally, an abscess may occur in the intracerebral route of the catheter. The infection of external lumbar drainage catheters may lead to predominantly purulent meningitis and spinal cord that, if severe or not treated promptly, will also cause ventriculitis.

Diagnostic criteria for postoperative meningitis secondary to external shunts have been developed [159].

The final diagnosis is based on clinical and CSF cytochemical findings of a microorganism isolated in the CSF culture. If necessary, the catheter is removed (all CSF shunts, internal or external, are removed, whatever the reason, and a culture from the catheter tip is obtained). In external lines, the fluid sample is obtained through a ventricular or lumbar catheter. In an internal line, CSF is usually obtained by puncturing the reservoir or valve, or sometimes through the exteriorized distal catheter. In patients with a permanent ventriculoperitoneal shunt, lumbar puncture is contraindicated, as there is danger of locking, and the CSF sample taken by lumbar puncture may differ biochemically and biologically from that taken from the reservoir (infection site).

CSF samples must be grown in aerobic and anaerobic conditions. In some slow-growing infections, the fluid characteristics may be normal and the cultures negative or take long to grow, so that infection is sometimes determined only when culture of the catheter, once removed, is positive (5-10% cases). Lumbar CSF culture offers maximum sensitivity in lumboperitoneal shunts (80-90%) but decreases significantly in ventriculoperitoneal shunts (50-60%) and even more in ventriculoatrial shunts (40%). Ventricular CSF generally shows an inflammatory response with pleocytosis of variable intensity, but in general an average of 100-150 cells. Glucose may be decreased and protein is usually elevated, although usually mild to moderate. The infection of a derivation can be mildly or asymptomatic and present with normal biochemical CSF characteristics, so that only microbiological study can document its existence. In such cases, the results of Gram staining and density of bacterial growth need to be assessed and doubtful cultures repeated, given that contamination may occasionally occur.

Blood cultures must be obtained if the patient is septic. The positivity of blood cultures is <20% in ventriculoperitoneal shunts but up to 95% in ventriculoatrial shunts. A surgical wound or decubitus skin ulcer in the path of the catheter must also be cultivated if it shows signs of infection. Characteristics of meningitis secondary to CSF leak are different from ventricular shunts [160]. The occurrence of CSF leaks is relatively common after traumatic brain injury and certain types of surgical procedures. The incidence of CSF leaks following head injury varies from 2.6 to 30% depending on the type and location of injury. The cumulative incidence at 10 years of meningitis in untreated CSF leakage ranges from 10 to 30% and mortality can be >10% [160]. The most common causative agent in meningitis associated with CSF fistulas is *S. pneumoniae* [161,162].

59.7.2 Postneurosurgery Meningitis Caused by *A. baumannii*

Nosocomial meningitis caused by *A. baumannii* is a major problem in the ICU, especially in patients with intraventricular catheters where the incidence of infection varies from 0 to 27% depending on the study [150-152]. Meningitis is more common in patients with intraventricular hemorrhage, head trauma, prolonged hospital stay and ICU stay [101,150-153]. Other risk factors are the presence of intraventricular catheters for more than 7 days in all postsurgical meningitis [154], and previous antibiotic therapy.

The incidence of nosocomial meningitis caused by *A. baumannii* varies across different series. In large series, it ranks as the fifth major cause of nosocomial meningitis and in recent series it is the second leading cause of infection in patients with ventricular shunts in some ICUs [163-165].

Nosocomial meningitis caused by *A. baumannii* often has a subacute onset with a longer course than community-acquired meningitis [166]. The clinical manifestations of postoperative meningitis caused by *A. baumannii* are mainly subacute fever and progressive loss of consciousness. In many cases these manifestations are attributed to the underlying disease, thus delaying the final diagnosis of meningeal infection, which is a predictor of mortality [101,153]. A small number of patients may show meningeal signs, neurological or seizure focus; however, since many cases occur in sedated patients under mechanical ventilation these data are difficult to assess. CSF data are consistent with increased leukocyte count in f late diagnosis with a 75-100% polymorphonuclear leukocyte count, accompanied by elevated protein with normal or decreased blood glucose levels. There are reports of contamination, so that in suspicious cases repeated lumbar puncture may be useful [167]. The nonspecific clinical and laboratory data make routine performance of Gram staining and culture essential in patients with fever of unknown origin, intraventricular catheter carriers or those admitted to a neurosurgical ICU.

The published mortality rate is 15-71% and 33% in our own experience [101,153]. In some reviews the patients who died had significantly increased pleocytosis and elevated protein, which would seem a worse prognostic sign although not statistically significant [153]. What is clearly established is that the main determinants of mortality are the absence of foreign material removal and the delay of appropriate treatment. Early intraventricular catheter removal with adequate empirical therapy are essential for the survival of patients.

59.7.3 Agents in the Treatment of Meningitis Caused by *A. baumannii*

Acinetobacter spp. quickly develop resistance to multiple antimicrobials. This complicates the treatment of these infections, making the search of new agents and the return to old drugs imperative.

Cephalosporins

The current Infectious Diseases Society of America (IDSA) guidelines recommend as empirical treatment of postsurgical meningitis a combination of vancomycin plus cefepime, ceftazidime or meropenem [168]. But current resistance rates of *Acinetobacter* spp. to both cefepime and ceftazidime are >50% and in some hospitals even approach 100% for strains resistant to carbapenems. These data currently discourage their use as empirical treatment. In the few cases where they may be used, the usual dose should be increased to supply 12 g/day of ceftazidime and 2 g/8 h of cefepime [163].

Carbapenems

Until the emergence of resistance, carbapenems alone or in combination with amikacin were the first-line treatment for this type of infection. However, resistance to the new antibiotics in recent years has led to the use of alternative agents such as ampicillin-sulbactam or colistin [152]. Meropenem is preferred over imipenem given the risk of imipemem-associated convulsions at doses necessary for treating meningitis [84,86,87]. It is sometimes difficult to distinguish drug-induced seizures from those produced by the disease causing meningitis. Given that many of these patients have potentially epileptogenic lesions, it seems recommendable to avoid the use of this drug. Doripenem has some epileptogenic activity in animals, so its use is discouraged in the absence of new

data. However, meropenem is associated with a very low risk of seizures even in the presence of meningitis, making it the carbapenem of choice in this infection [169].
Several studies have investigated the most effective meropenem dose in meningitis. The most commonly used dose is 2 g/8 h administered intravenously over 30 minutes and it has been compared against infusion of 2 g/8 h over 3-4 hours. One of the problems of treatment with carbapenems is not only the increasing emergence of resistant strains but also the emergence of resistance during treatment. What the scarce literature data seem to show is that 3-hour infusion is associated with less emergence of resistance during treatment, as this is the currently recommended route in this treatment.

Ampicillin-sulbactam

Sulbactam was introduced in the 1980s as a beta-lactamase inhibitor in combination with beta-lactamic antibiotics [5] with in vitro activity against *Acinetobacter* spp. enhanced by its affinity for penicillin-binding proteins. Intravenous sulbactam penetrates only 1% of the blood-brain barrier but increases up to 32% in meningeal inflammation [121,172]. The combination of ampicillin-sulbactam has been used in doses of 2 g for 6-8 hours, with a mortality rate of 20-25% [101,121].
In our experience, the mortality was 33% in about 4 cases treated with 3 g/8 h and it was significantly lower than with other treatments, except for a combination of intrathecal and intravenous colistin [101]. In a series of 8 cases published by Jimenez Mejias et al. [121], doses of 1 g/6-8 hours led to the death of patients receiving treatment every 8 hours. A dose of 2 g/6 h is now considered more suitable for the treatment of meningitis [163].

Fluoroquinolone

Quinolones, especially levofloxacin, exhibit in vitro activity against *Acinetobacter* spp. [173], but problems such as high resistance rates (over 60%), scarce clinical experience, and reduced penetration across the blood-brain barrier limit their role in the treatment of meningitis. Experience in the treatment of *A. baumannii* meningitis is limited to only four isolated cases but with therapeutic success [174,175]. Quinolones penetrated 6-37% of the blood-brain barrier [176], so that it may be necessary dose to 800 mg/8 h with ciprofloxacin. However, this higher dose in treating meningitis could be accompanied by a theoretical risk of seizure [177].
Current recommendations [163,168] advise quinolones only as an alternative treatment in the absence of other options. The recommended doses are 400 mg/8 h or more with ciprofloxacin and 750 mg/24 h or 500 mg/12 h for levofloxacin.

Aminoglycosides

Bacterial multiresistance and the poor penetration of many drugs across the blood-brain barrier have led to the use of intrathecal therapies initially with aminoglycosides and most recently with colistin. The use of intrathecal and intravenous amikacin has been reported in the treatment of meningitis refractory to standard therapy in a small number of cases with cure rates of 50-60% [171,178]; however, given the low penetration of aminoglycosides in the CSF, it must be administered only by intrathecal route. The exact dose of intrathecal amikacin has not been established and varies between 5 and 50 mg/24 h. The most frequent dose is 30 mg/24 h [163]. In recent study a 20 mg/day dose achieved cure rates of 83.4% without causing side effects [101].
Recent studies on 55 episodes of meningitis caused by *A. baumannii* found that patients who had received intravenous and intrathecal treatment had better outcomes than those receiving only parenteral treatment, although the small number of cases did not allow for statistically significant differences [101].

Study	Design	Patients	Treatment	Dosing	Cure
Levin et al., 1999 [182]	Prospective nonrandomized	5 CNS infections	Colistin	2.5-5 mg/kg/day iv divided in 3 doses	80%

Table 59.3. **Main clinical studies on *A. baumannii* meningitis treatment.**

Colistin

The role of colistin in the treatment of meningitis was initially limited due to its poor CSF penetration (25% of serum levels) without modifications in the presence of meningeal inflammation [179]. However, it has been administered in isolated clinical cases by intrathecal and intravenous routes with good results [101,180]. It is the first-line treatment in multidrug-resistant *A. baumannii* strains [184]. Recent series described the cure of 8 cases of nosocomial meningitis at a dose of 225 mg/8 h by the intravenous route. However, the use of high doses of colistin increases the risk of nephrotoxicity [179,180,182]. Due to the suboptimal penetration of colistin through the blood-brain barrier [179], the drug is administered by the intraventricular or intrathecal route [101,111,63,183,184] or in combination with other antibacterial agents such as aminoglycosides [11,16,101,184].The dose of intrathecal colistin is generally 5 mg/12 h. In recent study the dose was 10 mg/12 h without increasing side effects [101]. In this review, all patients treated with intravenous and intrathecal colistin survived without evidence of local toxicity. Although the small number of cases studied limits the statistical significance of the results, the present data show that combined colistin by either route can be both safe and effective for this infection [101]. These findings support evidence that intravenous treatment alone should not be recommended. Recently, some cases have been successfully treated with intrathecal colistin alone, although at present there are few data to support such therapy. Treatment regimens for nosocomial meningitis that don't include intravenous colistin with intrathecal colistin should be considered suboptimal [101,163].

The duration of treatment is controversial, but it should be continued for at least 3 weeks after the withdrawal of foreign bodies or after two consecutive negative cultures.

Rifampicin

Rifampicin may be useful in combination with various other drugs used in meningitis treatment like colistin, ampicillin-sulbactam or carbapenems. It has in vitro synergy with colistin and its use could be considered as adjuvant treatment. However, intravenous rifampicin alone without other treatment is discouraged.

Tigecycline

New antibiotics include tigecycline, a member of a new class of antibiotics, the glycines. In animal studies of meningitis, tigecycline at a single dose of 20 mg/kg/day showed CSF concentrations >1 µg/ml 3 h after infusion. The CSF penetration of tigecycline is minimal, with concentrations of 0-15 µg/ml at 90 minutes after the administration of a dose of 100 mg far under the required MIC, so its use cannot be recommended [187], although an isolated cases of cure of meningitis with tigecycline have been described [188].

59.7.4 Empiric Treatment of Nosocomial Meningitis Due to *A. baumannii*

Nosocomial meningitis is an important cause of morbidity and mortality; it requires urgent and effective treatment, including antibiotic therapy and general supportive measures of the critically ill patient. Delay in the diagnosis and inadequate treatment are the most important factors of mortality. For this reason, in the early diagnosis of meningitis it is very important to perform complementary techniques and quickly initiate appropriate antimicrobial therapy to prevent worsening of the patient's condition.

Kind of risk	Therapy
If risk factors of *Acinetobacter* spp. infection: • Previous colonization or infection • Previous use of carbapenems or cephalosporins	Meropenen 2 g/8 h IV plus intrathecal amikacin 30 mg/day
If risk factors of carbapenems resistance: • Previous use of antibiotics (quinolones, carbapenems) • Admission to ICU • Mechanical ventilation • Previous surgery	Colistin 2-5 mg/kg/8 h plus intrathecal colistin with or without rifampicin 600 mg/24 h orally

Table 59.4. **Empirical treatment of** *A. baumannii* **nosocomial meningitis. Modified from [163].**

It is therefore recommended that in patients with suspected meningitis (and before administering antibiotics, except in selected cases as detailed below), blood samples and lumbar puncture (unless contraindicated) should be taken and sent to the microbiology laboratory for culture. If a CT of the head is required prior to lumbar puncture, this should not delay the delivery of treatment, so that blood cultures will be done and the appropriate therapeutic regimen initiated. Once the CT is obtained, if there are no contraindications, a lumbar puncture will be carried out. We recommend Gram staining of the CSF sample in suspected cases of nosocomial meningitis.

The aim of antibiotic treatment should be to achieve rapid sterilization of the CSF. Antibiotics should have rapid bactericidal activity, as bacteriostatic action is not enough to clear the infection and delayed sterilization of CSF has been associated with an increased incidence of neurological sequelae. It is essential that the antibiotic concentration in the CSF is greater than the minimum bactericidal concentration (MBC), and that the ratio between both concentrations (the bactericidal index) exceeds 1. Bactericidal activity in the CSF is optimal if the bactericidal rate is about 10. When the antibiotic does not reach the necessary concentration in the CSF through systemic administration, direct administration by the intraventricular or intrathecal route is necessary. The initial antibiotic dose must be maintained throughout the entire course of therapy without reducing the dose when the patient improves, since the penetration of the antibiotic across the blood-brain barrier normalizes as the CSF decreases. In nosocomial meningitis, empiric therapy should cover *P. aeruginosa* and *A. baumannii* and *Staphylococcus* spp., especially if an intraventricular catheter is present. Empirical treatment for nosocomial meningitis due to *A. baumannii* is illustrated in Table 59.4.

59.7.5 Definitive Treatment

Medical treatment alone is not considered the most appropriate at this time. The cure (or at least a prolonged remission of infection) occurs in approximately 25-40% of cases and mortality is high (24-53%), so this treatment option is not recommended in all cases. The combination of systemic and intrathecal antibiotics produces more efficient results, with remission rates of 75%; however, given the significant morbidity and mortality associated with this infection, the level of recommendation remains low, unless accompanied by withdrawal of foreign material.

Medical and Surgical Treatment

The use of intravenous and intrathecal antibiotics has cure rates of 40%, which increases to 70% if accompanied by withdrawal of an intraventricular catheter. It has been shown that catheter-related meningitis caused by *A. baumannii* is related to biofilm formation

[196]. There is universal agreement that the removal of foreign devices is critical to healing and one of the main factors influencing mortality. Hence, unless absolutely contraindicated, the removal of all shunt components should be advised. Depending on whether or not maintaining continuous CSF drainage is essential, the type of hydrocephalus that led to shunt insertion, and preferences of the surgical team, there are different treatment options:

- If the patient's condition requires a permanent shunt and the cause that led to the shunt was obstructive hydrocephalus, the following options can be chosen:
  - Externalization of the distal catheter to reduce intracranial hypertension and to drain the infected CSF. After 3-5 days of appropriate antibiotic therapy for sterilization of the ventricles, the rest of the system is withdrawn and an external ventricular drain is placed in the contralateral ventricle while continuing antibiotic treatment.
  - Removal of the infected catheter and insertion during the same surgical procedure of an external ventricular catheter on the contralateral side.
- If the patient needs permanent derivation and the cause that led to the shunt was a communicating hydrocephalus, we recommend entirely removing the infected system and placing a lumbar catheter for external CSF drainage.
- If the patient can remain without CSF drainage, at least temporarily, we recommend early removal of the infected catheter and appropriate antibiotic treatment. Once the infection has been cleared, or at least controlled with antibiotic treatment, a new system can be placed on the contralateral side.

The appropriate time for the final relocation of the shunt depends on the etiological agent of infection, initial response to antibiotic treatment, and removal of the infected system. To this end, the patient's progress should be monitored every 3 days by cytological analysis, biochemical and CSF culture. In infections caused by Gram-negative or mixed flora, we recommend a period at least 14 days. In brief, the recommendation for medico-surgical treatment is based on:

- Removal of foreign material.
- Removal of all system components at the start of treatment.
- An external device must be placed elsewhere. The new system will be placed in a permanent place at a second time.

59.7.6 Duration of Antibiotic Treatment and Indications for Lumbar Puncture Control

The duration of antimicrobial therapy should be individualized and based on clinical response. Furthermore, the recommended duration of antimicrobial therapy in many cases is not based on controlled studies (which is very difficult in this type of illness) and recommendations are often taken from various different studies. The general recommendation is to continue treatment for 21 days according to the IDSA guidelines or to maintain therapy until microbiological cultures test negative.

The optimal number of negative cultures to ensure clearance of infection is unknown, but treatment must usually continue until three consecutive negative cultures have been obtained. Intravenous therapy should be maintained until after completing intraventricular culture [197]. In noncarriers of intraventricular catheters a lumbar puncture should be done within 4 days of starting treatment and the treatment changed if cultures remain positive. A control culture should be obtained if there is no evidence of improvement at 72 hours of starting treatment.

59.7.7 Indications and Dosing Schedules of Intrathecal Antimicrobial Therapy

As previously discussed, intrathecal therapy seems essential in infections with *A. baumannii*. The usual dosage of the drugs most commonly used intraventricularly is shown in Table 59.5.

Antibiotic	mg/day
Gentamycin	5-10
Tobramicin	5-10
Amikacin	10-50
Colistin	10-20

Table 59.5. **Recommended daily intraventricular drug dose.**

Steroid Treatment

The benefit of adjunctive therapy with dexamethasone has been well established in meningitis caused by *Streptococcus pneumoniae* or *Haemophilus influenzae* [198,199], although its role in Gram-negative meningitis is more controversial. However, many of these patients may require steroids for their underlying disease, and it should be borne in mind that whenever indicated the drug should be administered concomitantly or 15-20 minutes before antibiotic treatment.

59.7.8 Hospital-acquired/Ventilator-associated Pneumonia (VAP)

Pneumonia is the most common infection in ICUs, accounting for 31-47% of nosomial infections. Pneumonia develops in 8-28% of patients on mechanical ventilation and is responsible for more than 50% of antibiotic use in ICUs. Mortality rates vary from 20 to 70%, with a worse prognosis after inappropriate empirical therapy. It can also prolong the hospital stay from 6 to 30 days and represents a significant increase in hospital costs [200].

Acinetobacter spp. are a major cause of VAP and are associated with mortality rates of 50-70% [201] in some cases associated with inappropriate initial antibiotic therapy [202]. The incidence of the microorganism varies, but it is the second commonest etiological agent among the Gram-negative bacteria. Longer periods of hospitalization, longer time on mechanical ventilation, and prior use of antibiotics are the major factors that increase the risk of VAP due to *Acinetobacter* spp [203].

The occurrence of VAP due to *A. baumannii* sensitive only to colistin is associated with previous treatment with carbapenems [204], previous episodes of VAP, and prior antimicrobial therapy for >10 days [205,206]. It is necessary to differentiate between true infection and colonization to avoid introducing unnecessary treatments.

The agents with the greatest antimicrobial activity are imipenem/cilastatin, amikacin, colistin, ampicillin/sulbactam and tigecycline. Treatment with imipenem is considered the treatment of choice in carbapenem-susceptible strains. However, the increase of strains resistant to carbapenems has promoted the use of alternative antibiotic treatments. As in the case of meningitis, prolonged infusion of meropenem 2 g/8 h for at least 3 hours seems to be associated with lower rates of resistance. An experimental study investigating the utility of combination treatment with amikacin showed that the combination of imipenem plus amikacin was inferior to imipenem alone with the imipenem-susceptible strain, despite their in-vitro synergy, and was inferior to amikacin alone with the imipenem-resistant strain. The combined use of imipenem with amikacin was less efficacious than monotherapy, probably because of a drug-drug interaction that resulted in decreased pharmacokinetic and pharmacodynamic parameters for both antimicrobial agents. Further studies assessed prospectively or retrospectively treatment

with colistin in patients with VAP caused by *A baumannii* [94,98,100]. Specifically, no difference in clinical response was reported between patients treated with intravenous colistin for infections caused by organisms susceptible only to polymyxins and those treated with other agents, mainly carbapenems, for infections caused by carbapenem-susceptible organisms.

Colistin may also be administered by inhalation. The dose of aerosolized colistin may range between 500,000 IU every 12 h and 2,000,000 IU every 8 h. Several studies have reported favourable clinical outcomes with the use of aerosolized colistin along with intravenous colistin or other parenteral antimicrobial agents for nosocomial pneumonia caused by multidrug-resistant *A baumannii* [100,204]. In a recent study involving 60 critically ill patients who received aerosolized colistin (2,000,000 IU) over 16 days in concomitant intravenous treatment with colistin or other antimicrobial agents, bacteriological and clinical response of VAP was observed in 83.3% patients. No adverse effects related to inhaled colistin were recorded. Aerosolized colistin may be considered as an adjunct to intravenous treatment in patients with VAP due to multidrug resistant, Gram-negative bacteria susceptible to colistin in critically ill patients [205,206]. Data on patients treated with inhaled colistin are scarce. In a recent study by Falagas et al., 4 of 5 patients treated with inhaled colistin showed healing and one died. Although the results are promising, a greater number of cases are needed to assess its future role [207].

The efficacy and safety of ampicillin-sulbactam for VAP caused by multidrug resistant *A. baumannii* have been evaluated in a few reports, with a clinical improvement of 67% [120]. High-dose ampicillin/sulbactam was comparably safe and effective with respect to colistin in critically ill patients with multidrug resistant *A. baumannii* VAP [208].

The role of tigecycline alone or in combination with other antimicrobials for the treatment of VAP showed best clinical response (84%) in a small retrospective case series. However, 4 patients had clinical failure: 3 with VAP and 1 with VAP plus bacteraemia that developed resistance to tigecycline during therapy, and 3 patients with VAP had a recurrence of infection Tigecycline may be effective when used alone or in combination with other antimicrobials for VAP caused by multidrug resistant *A. baumannii*. However, the emergence of a resistant strain while one patient was receiving therapy raises concern [126,209].

The treatment of VAP caused by *A. baumannii* should be based on microbiological results; however, until these are obtained, appropriate empirical therapy should include two intravenous agents active against the most common local flora or an intravenous agent and one inhaled. The presence of *A. baumannii* susceptible only to colistin should be suspected in patients with VAP, previous antibiotic treatment in the 10 days preceding the new episode [210] and in this case the best option would probably be the use of systemic and inhaled colistin combined.

A very important issue in hospital-associated pneumonia (HAP) is its prevention. There is convincing evidence that specific interventions can be employed to prevent HAP/VAP. Evidence-based interventions focus on the prevention of aerodigestive tract colonization (avoidance of unnecessary antibiotics and stress ulcer prophylaxis, use of sucralfate for stress ulcer prophylaxis, chlorhexidine oral rinse, selective digestive decontamination, short-course parenteral prophylactic antibiotics in high-risk patients) and the prevention of aspiration of contaminated secretions (preferred oral intubation, appropriate ICU staffing, avoidance of tracheal intubation with the use of mask ventilation, application of weaning protocols, and optimal use of sedation to shorten the duration of mechanical ventilation, semirecumbent positioning, minimization of gastric distension, subglottic suctioning, avoidance of ventilator circuit changes/manipulation, routine drainage of ventilator circuit condensate) [211].

59.7.9 Bloodstream Infections

Bacteraemia, followed by respiratory tract and surgical wound infections, is the most significant infection caused by *A. baumannii* [212]. The known risk factors for *A. baumannii* bacteraemia are previous colonization with *A. baumannii*, invasive procedures, and the use of broad-spectrum antimicrobials. Other risk factors are immunosuppression and mechanical ventilation [213,214]. Consequently, episodes of bacteraemia due to *A. baumannii* occur most frequently in critically ill patients admitted to an ICU [201]. The clinical manifestations of bacteraemia caused by *A. baumannii* are not specific. The most common sources of bacteraemia are intravascular catheters and the respiratory tract [215-217]. *A. baumannii* bacteraemia is associated with a high crude mortality rate, but it is difficult to distinguish morbidity and mortality attributable to *A. baumannii* from that attributable to the common and severe co-morbidity in these patients. The risk factors associated with higher mortality are: presence of inappropriate antimicrobial treatment, age >65 years, development of septic shock, and severity of the underlying disease [218-221].
Generally, imipenem is the most active agent against *A. baumannii*. However, the description of imipenem-resistant *A. baumannii* strains is becoming increasingly common. Among the different antimicrobial regimens prescribed, the combination of a carbapenem and ampicillin-sulbactam was associated with a better outcome than the combination of a carbapenem and amikacin, or a carbapenem alone. Colistin has shown efficacy in bacteraemia, unlike the resistance to tigecycline described during treatment [222-225].

59.8 Infection Control and Prevention

Several studies have indicated that colonization with multidrug-resistant Gram-negative bacilli is a frequent precursor of true infection. Specific sites of colonization may be amenable to eradication strategies. Hand colonization contributes significantly to *Acinetobacter* transmission and can be controlled by proper handwashing, glove use, and use of antiseptic- or alcohol-based soaps [226]. The duration of colonization is controversial but important because it is crucial to decide the time of isolation of patients, the potential transmission time, and other steps to follow. The duration of colonization is unknown but it should be considered that isolation is no longer necessary after three consecutive negative cultures obtained 1 week apart. It is also important to consider the number of patients colonized at any given time. The greater the number of patients colonized, the greater the risk of transmission between patients, increasing both environmental pollution and health personnel [226].
The digestive tract has only rarely been implicated as a major site for *Acinetobacter* colonization [227,228]. If this is documented during an outbreak, selective decolonization with polymyxin B or aminoglycosides could be attempted [229].
The strategies for infection control and prevention of outbreaks caused by multiresistant *A. baumanii* need to be simultaneous and multiple to be useful. Identification of colonized and infected patients, combined with implementation of infection control measures such as hand hygiene and contact isolation precautions might help prevent transmission of this organism within medical facilities. These strategies have included [230-234]:

- Institute active surveillance of groin, axillary, and/or wound cultures for *A. baumannii* in all patients.
- Use contact precautions for colonized or infected patients.

- Increase the availability and use of alcohol-based hand rubs, with daily review of antibiotic susceptibility of all clinical isolates.
- Select cefepime or carbapenem-resistant isolates.
- Review patient records prospectively to determine geographic location, nosocomial acquisition, and presence of clinical infection.
- Emphasize contact precautions to prevent transmission of isolates.
- Assign a dedicated infection-control nurse to affected area or areas.
- Use polymyxin B to selectively decontaminate colonized wounds.
- Consider inhaled polymyxin B for pulmonary colonization or infection (to supplement parenteral therapy).
- Use surveillance techniques to monitor personnel, equipment, and environmental contamination.
- Instruct housekeeping staff to decontaminate the inanimate environment on a regular schedule.
- Close the contaminated unit if necessary.
- Use molecular epidemiologic techniques to determine clonality of isolates.

59.9 Conclusion

- *A. baumannii* is an increasingly important emerging pathogen associated with significant morbidity and mortality. The increasing rate of resistance has made its treatment difficult, especially in neurosurgical infections.
- *A. baumannii* infections are of growing importance in neurosurgical ICUs not only because of the occurrence of nosocomial meningitis but also because of other infections such as ventilator-associated pneumonia or bacteraemia.
- There are several factors that maintain the presence of *Acinetobacter* spp. in the healthcare environment, including the presence of susceptible patients or health workers colonized or infected by the organism. *Acinetobacter* spp. can colonize the skin, wounds, and the respiratory and gastrointestinal tracts. Over 25% of healthy adults have cutaneous colonization and 7% of adults and children have transient bacterial colonization. Gram-negative bacillus is most frequently isolated from the skin of healthcare workers and colonizes 45% of tracheotomised patients and 41% of stool samples from ICU patients. Differentiating between colonization and infection is of particular clinical and therapeutic relevance in view of the multidrug resistance of this organism and the limited therapeutic options available.
- Both imipenem and meropenem have been considered as the treatment of choice for serious infections due to *A. baumannii*. Doripenem is a new carbapenem which may have an important role in the treatment of *Acinetobacter* infection, and its MIC is lower than that of ertapenem or imipenem against *Acinetobacter* spp. However, meropenem is the only suitable drug for the treatment of meningitis.
- Colistin is a polymyxin and is available in two forms, colistin sulphate and sodium colistimethate. The usual dose is 2.5-5 mg/kg/day divided into 2 to 4 doses. In patients with >60 kg body weight, the most commonly used dose is 80-160 mg/8 h, taking into account that dose adjustment in renal insufficiency is required.
- Colistin is useful alone or in combination with other antibiotics such as rifampicin in ventilator-associated pneumonia, meningitis, bacteraemia, and so on. The most common side effects are nephrotoxicity and polyneuropathy.
- Tigecycline may be useful in ventilator-associated pneumonia but currently cannot be recommended as empirical or direct treatment or in bacteraemia and postsurgi-

cal meningitis, given the low levels reached in the blood and CSF. Patients receiving tigecycline as treatment for *A. baumannii* should be monitored for the clinical development of resistance and isolates should be checked by testing for microbiological resistance.

- Nosocomial meningitis caused by *A. baumannii* is associated with the presence of intraventricular catheters, CSF fistula or head injury. It is a serious problem in the neurosurgical ICU, especially in patients with intraventricular catheters.
- Nonspecific clinical and laboratory data should be integrated with Gram stain and culture in patients with fever of unknown origin, intraventricular catheter carriers, or those admitted to the neurosurgical ICU.
- Mortality is associated with the absence of foreign material removal and delays in the institution of proper treatment; therefore, early removal of intraventricular catheters with adequate empirical therapy are essential for the survival of patients.
- The duration of treatment should be at least 3 weeks after the removal of foreign material or after two consecutive negative cultures.
- The recommended treatment is medico-surgical and is based on the use of meropenem 2 g/8 h by infusion for least 3 h in strains sensitive to carbapenems or intravenous and intrathecal colistin or strains with suspected resistance to carbapenems. Antibiotic treatment should always be accompanied by the removal of foreign material. If required, an external device should be placed elsewhere. A new system should be placed at a later time.

60 Multiple Organ Dysfunction in Patients With Brain Injury

Antonio Capone Neto [1]

[1] Associate Professor, Intenvive Medicine Department, Sunnybrook Hospital, Toronto University, Canada. Intensive Care Unit, Hospital Israelita Albert Einstein, São Paulo, Brasil

60.1 Introduction

Like any other critically patient in intensive care, patients with severe head trauma are at risk of developing multiple organ dysfunctions. Despite being common, the interactions between neurological disorders and non-organic neurological disorders are not completely certain. It is known, however, that the development of non-neurological organ dysfunction appears to be associated with adverse functional outcomes and higher mortality in both traumatic neurological injury and non-traumatic injury.

In a recent observational study, respiratory dysfunction was the most common dysfunction, occurring in 23% of patients with severe traumatic brain injuries (TBI), followed by cardiovascular dysfunction in 18%, and coagulation disorder in 4%. The development of a non-neurological organ dysfunction was independently associated with increased hospital mortality and worse functional outcome as assessed by the Glasgow Outcome Scale (GCS). Other studies found that the mortality of TBI patients appears to increase significantly when there is another associated organ dysfunction (65% vs. 17%).

In addition, extra-cerebral organ dysfunctions have been reported in severely ill neurological patients in the absence of other commonly associated risk factors such as systemic trauma, shock or infection. This indicates that the severe neurological injury can itself be a risk factor for the development of multiple organ dysfunctions.

Morevoer, several studies indicate that the inflammatory brain response can produce systemic immune and inflammatory changes and that this pro-inflammatory state characterizing TBI can have a significant role in the development of other organ dysfunctions.

Among the various organic dysfunctions that can occur in patients with severe TBI, we will discuss in more detail the pulmonary, cardiovascular and changes in coagulation because they are more directly related to the neurological event itself by how often that happens and the impact that they may have on the outcome of these patients.

60.2 Changes in Pulmonary Function

Among the various organic dysfunctions that can occur in a TBI patient, pulmonary complications are the most frequent, especially pulmonary infections and pulmonary edema. It is also unclear whether the pulmonary abnormalities are directly or indirectly caused by neurological damage and if the mechanisms involved change according to the neurological pathology. The clinical relevance of these complications was evaluated in a study which estimated that pulmonary changes are responsible for up to 50% of deaths after TBI.

- Bronchial aspiration
- Pulmonary infection
- Atelectasis
- Pulmonary edema (neurogenic, cardiogenic or inflammatory)
- Inflammatory mediators released by the brain (?)
- Massive release of catecholamines (sympathetic "storm")
- Pulmonary thromboembolism
- Central alteration of respiratory pattern
- Adverse effects of treatment for "neuroprotection"
- Adverse effects of treatments for control of intracranial hypertension

Table 60.1. **Possible mechanisms involved in pulmonary alterations in neurological patients.**

Several mechanisms are involved in the respiratory failure of patients with TBI (Table 60.1). Brain damage may also increase pulmonary vulnerability to mechanical ventilation injury or to ischemia and reperfusion. These mechanisms, associated or not, usually culminate in changes in ventilation-perfusion and consequent hypoxia.

The development of neurogenic pulmonary edema is a recognized complication and probably frequent among severe acute brain injuries, but underdiagnosed. Its pathophysiology is unknown but believed to involve a massive discharge of catecholamines, leading to a consequent hypertensive crisis and increased inflammatory response and resulting in increased pulmonary capillary permeability. Experimental and clinical studies have observed that the mere elevation of intracranial pressure (ICP), even without significant hemodynamic changes, increases the protein content in the lung's lymph. Experimentally, neurogenic pulmonary edema can be prevented with prior use of alpha-adrenergic blockers, which favours this hypothesis. Neurogenic pulmonary edema usually appears suddenly and very quickly (minutes or hours) after injury of the central nervous system, although there are reports of later onset. Another clinically relevant aspect is that neurogenic pulmonary edema is often confused with pulmonary edema caused by fluid overload, acute respiratory distress syndrome or aspiration pneumonia. It is likely that non-serious forms with fewer manifestations ("subclinical") are very common, while severe neurogenic pulmonary edema is rarer. The diagnosis should be made by history and exclusion of other causes since there are no specific tests for it.

The real impact of neurogenic pulmonary edema on the morbidity and mortality in severe neurological patients is unknown. The fact that this complication usually occurs in severe cases makes it difficult to evaluate their influence on the final results. It is known, however, that hypotension, low cardiac output and hypoxemia are determinants of secondary brain injury, with consequent worsening of morbidity and mortality. Treatment is supportive, with mechanical ventilation in severe cases. The use of positive end-expiratory pressure (PEEP) may be beneficial, but ICP must be monitored. The use of vasodilators, inotropes and diuretics is controversial.

Table 60.2 lists the risk factors of ventilator-associated pneumonia (VAP) in severe neurological patients. In TBI patients the incidence of VAP is estimated to be 30-50% and most of these infections are not serious. However, it is important to note that some studies have shown that the early development of pneumonia in neurological patients significantly increases mortality even after adjusting for the severity of neurological pathologies and co-morbidities.

- Altered level of consciousness
- Bronchial aspiration
- Emergency tracheal Intubation
- Deep and prolonged sedation
- Prolonged mechanical ventilation
- Re-intubation
- Previous use of antibiotics (?)
- Immunosuppression (?)

Table 60.2. **Risk factors of ventilator-associated pneumonia in TBI patients.**

The most commonly isolated agent in VAP during the first week (early onset) is *Staphylococcus aureus*. In such cases, the

upper airways seem to be subject for tracheobronchial colonization and therefore VAP. In cases of late-onset VAP, Gram-negative bacteria predominate and the possible sources of colonization would be not only the upper airways but also the stomach.

Although most available studies have been in stroke patients, the prevention of respiratory infections in neurological patients in general has been underscored as a strategy to improve prognosis. In TBI patients, measures are applied to prevent VAP used for all critical patients, especially protocols to reduce the time on mechanical ventilation, reduction of atelectasis and lung collapse. The use of early tracheotomy in the prevention of VAP is controversial, but it seems to favour a more rapid weaning from mechanical ventilation. It is important to note that the parameters commonly used for weaning from mechanical ventilation generally do not apply to TBI patients.

The use of prophylactic antibiotic therapy or selective decontamination to reduce the incidence of VAP in severe neurological patients is controversial. Although some studies have shown benefit, others did not show any effect or even a worsening in outcome with the use of these preventive strategies.

Development of the acute respiratory distress syndrome (ARDS) in TBI patients poses a major challenge because the hypoxemia resulting from the manoeuvres intended to improve it (e.g., increase in PEEP, alveolar recruitment or permissive hypercapnia) may aggravate brain injury.

The impact of PEEP on ICP is not linear and is often unpredictable. There are evidences that the impact of PEEP on ICP is related more to variations in $PaCO_2$ and pulmonary compliance than with the PEEP value itself. Several studies have shown that values of up to 15 cmH_2O of PEEP do not cause significant changes in ICP or cerebral perfusion pressure (CPP). Lung recruitment manoeuvres using pressures up to 60 cmH_2O were associated with worsening hemodynamics and cerebral oxygenation. Also during bronchoscopy in patients with severe TBI it has been shown that major changes occur in ICP and CPP, although transitory, and that the use of intra-tracheal lidocaine did not abolish these effects.

Thus, there is a linear correlation between PEEP and ICP. ICP monitoring in all patients with severe TBI and respiratory failure is recommended, which may be necessary in the use of PEEP >8-10 cmH_2O. Special care should be taken with the use of alveolar recruitment manoeuvres or bronchoscopy.

Furthermore, there is evidence that patients ventilated without PEEP show progressive deterioration of lung compliance. Thus, we have routinely used PEEP of around 8-10 cmH_2O for all serious neurological patients. This strategy seems to be beneficial for preventing progressive lung collapse without causing significant negative effects on cerebral hemodynamics. Although it is essential to avoid hypovolemia and hypotension in severe neurological patients, it is also essential to avoid fluid overload, especially in patients with ARDS. In cases where there is a deterioration in lung function, one should not delay the use of measures to reduce the total volume of fluid infused or the use of diuretics in patients who are hemodynamically stable.

However, not only does brain injury impact on the lungs, but also severe lung injury has an impact on the brain. Recent studies have shown that patients who were on mechanical ventilation, especially those with ARDS, were noted to have cognitive dysfunction that resembles cases of mild dementia and that persist for several years after discharge. The pathophysiology of these cognitive changes is unclear but probably has multiple etiologies such as hypoxemia, hypotension, delirium and sepsis, among other factors.

The incidence of deep vein thrombosis (DVT) in trauma patients varies from 6 to 58% and several studies have identified severe TBI as an independent risk factor for DVT. A recent study evaluating 2000 TBI patients showed that they are 3 to 4 times more likely to develop DVT. However, there is no consensus on strategies for DVT prophylaxis in head-

injured patients nor has its impact on the outcome of these patients been determined. The possible mechanisms involved in an increased risk for DVT include: immobilization, activation of the extrinsic coagulation pathway, elevated levels of circulating tissue factor, and high levels of von Willebrand factor.

60.3 Cardiovascular Dysfunction

Serious injury of the central nervous system can trigger important cardiocirculatory changes, even in patients without previous heart disease. Such changes may increase cardiac morbidity and mortality not only by damaging the heart itself but also by secondary brain damage that may occur as a result of reduced cerebral perfusion. Although the true incidence of these complications is not known, it is known that they can hap-

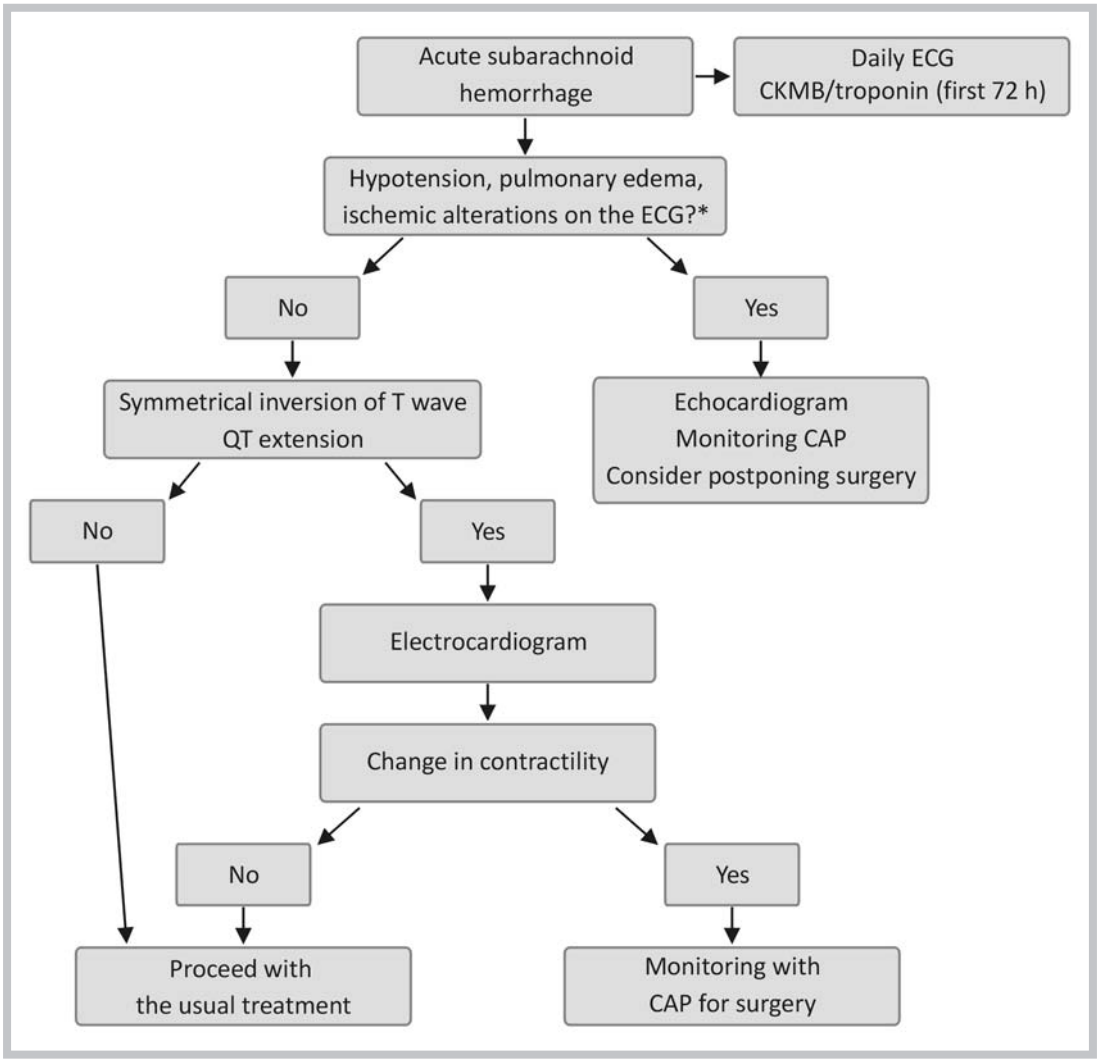

Figure 60.1 **Algorithm for the diagnosis of left ventricular dysfunction in severe neurological patients. Modified from [Mayer, 1995].**

*Q waves, ST elevation or other changes diagnostic of acute ischemia

pen in any severe acute neurological condition, especially in cases of subarachnoid hemorrhage. Cardiovascular complications secondary to neurological events are usually divided into cardiac arrhythmias, myocardial ischemia, neurogenic pulmonary edema and hypertension.

Cardiac arrhythmias are the most frequent. However, these rhythm changes are not always purely electrical phenomena and many patients have evidence of myocardial damage and structural enzyme elevation (4-25% of cases), changes in global and segmental myocardial contractility on the echocardiogram ("stunned myocardium") and myocardial necrosis in clinical pathology. Echocardiographic studies in patients with subarachnoid hemorrhage have demonstrated reversible changes in myocardial contractility and in almost all of them no pathology was detected on either coronary angiography or at autopsy studies. Myocardial lesions described in anatomopathological examination include: subendocardial and intramyocardial hemorrhage, myocardial necrosis, and myofibrillar degeneration. These changes were given different names such as myocytolysis, myofibrillar necrosis, myofibrillar degeneration, and necrosis in bands. They are distributed throughout the myocardium, more concentrated in the subendocardial region and often involve the conduction system.

A suggested algorithm for diagnosing changes in ventricular function in patients with subarachnoid hemorrhage can be used in other neurological patients who have severe hemodynamic instability or suspected cardiac dysfunction (Figure 60.1). Clinically, patients with alterations of myocardial contractility will also frequent present hemodynamic instability and pulmonary edema, supporting the concept that these lesions contribute to increased morbidity and mortality. Treatment is supportive only, with emphasis on the maintenance of cardiac debt and adequate pressure levels. In the presence of significant hemodynamic instability, one should consider the early use of invasive hemodynamic monitoring.

60.4 Coagulopathy

It is known that coagulopathy is associated with severe TBI, particularly penetrating injuries. It is also believed that the presence of coagulopathy worsens the prognosis of these patients, being an unfavourable outcome. However, the features, the pathophysiology, and the real incidence of coagulopathy associated with severe TBI are not fully understood. Some studies showed an initial state of hypercoagulability, followed by a state of increased fibrinolysis or disseminated intravascular coagulation. This last possibility could predispose or aggravate a multiple organ failure.

A recent study evaluating 436 patients with severe TBI noted coagulopathy associated in 36% of cases, being more frequent in the more severe cases and penetrating injuries. This study also showed that this combination significantly increases mortality. What complicates the analysis of studies on coagulopathy associated with severe TBI is the lack of consistency in diagnostic criteria for coagulopathy, whether they are clinical, laboratory, or temporal. Besides, it is unclear whether correction of coagulation abnormalities improves the outcome of these patients.

60.5 Key Concepts

Non-neurological organ dysfunction is common in patients with severe TBI and is independently associated with worse functional outcome and higher mortality.

Pulmonary dysfunctions are more common in TBI patients, occurring in 25-50% of patients. The etiology of these changes is multifactorial, which complicates specific preventive strategies.

The impact of PEEP on ICP is not linear and is unpredictable. Generally, PEEP up to 15 cmH_2O does not cause significant changes in ICP. However, ICP monitoring is recommended in all cases of severe TBI in which PEEP >8-10 cmH_2O may be necessary.

Cardiovascular disorders are also frequent and, especially when triggered states of low cardiac output have a significant impact on morbidity and mortality.

Although the pathophysiology of coagulation disorders associated with TBI is not fully understood, it is well recognized that these changes are indicators of an unfavourable outcome.

61.1 Introduction

Tetanus and botulism are infectious, non-contagious diseases caused by neurotoxins produced by anaerobic bacteria *Clostridium tetani* and *Clostridium botulinum*. These neurotoxins are highly neurotropic and are among the most violent and powerful toxins known. Tetanus is characterized by spastic paralysis due to blockage of inhibitory circuits in the spinal cord, while botulism is characterized by flaccid paralysis due to inhibition of the release of acetylcholine at the neuromuscular junction. Both conditions are associated with high mortality and rapid progression to severe forms, and should therefore be treated in intensive care units (ICUs), preferably in reference services.

61.2 Development

Tetanus results from contamination of a wound by *Clostridium tetani* spores that, under anaerobic conditions, convert to the vegetative form and thus can multiply, producing tetanospasmin. The toxin initially circulates through the bloodstream before migrating over hours or days by motor nerve fibres to the central nervous system (motor neurons of the spinal or cranial nerve nuclei), blocking the inhibitory interneurons of Rushaw and allowing stimulation of the lower motor neurons by impulses coming from the brain and sensory regions. The result is spasticity and muscle spasms. Manifestations of hyperexcitability are due to the action of tetanospasmin which increases acetylcholine release and decreases the levels of glycine.

In botulism the toxin absorbed in the gastrointestinal tract or in a wound spreads via hematogenous route to the nerve endings, more specifically the presynaptic membrane of the neuromuscular junction, blocking the release of acetylcholine, resulting in flaccid paralysis. Botulinum toxin most often it is ingested in food contaminated by *Clostridium botulinum*, although in special situations, the toxin can be produced after the ingestion of spores that germinate in the faeces or the contaminated wound under anaerobic conditions.

With tetanus the diagnosis is based exclusively on the clinical picture and history of injury and requires a high index of suspicion to identify the early signs and symptoms and disease progression. The diagnosis of botulism is based on the history and clinical picture and specific laboratory tests, although the early recognition of initial clinical manifestations, enabling immediate therapeutic intervention, is critical in the prognosis of the disease, especially when it is the index case of a foodborne outbreak.

Tetanus is characterized by the prolonged contraction and spasms of skeletal muscles. The generalized form of tetanus is the most common. Usually, the first clinical manifestation of tetanus is contracture of the muscles of mastication, which progresses to trismus (lockjaw). Dysphagia may also appear at the initial stage and is characterized by "choking" when the patient tries to swallow. Stiffness of the facial muscles causes accentuation of the natural creases of the face, twitching of the nostrils and lips (sardonic smile), wrinkled forehead, arching eyebrows, and closed eyelids, giving a characteristic expression known as *tetanic facies*. In this descending pattern of manifestations, the neck muscles are the next involved, with stiff neck, then the paravertebral muscles, the chest and the intercostal muscles, which can make breathing difficult. In this phase the most frequent complaint is neck and back pain. Stiffness may also involve the abdominal muscles and limbs. As the condition progresses, spasms can increase in intensity and duration and may be triggered by various stimuli (light, noise, urination, defecation, accumulation of bronchial secretions, etc.) or arise spontaneously. Paraspinal muscle spasm may cause crushing and fracture of vertebrae. The most serious signs of progress are dysfunctions of the autonomic nervous system: profuse sweating; fluctuations in blood pressure that can be rapidly followed by cardiovascular collapse, instability of the heart; ileus; and fluctuations in blood glucose levels. The patient remains lucid throughout the course of the illness. Fever is uncommon and usually occurs when there is secondary infection in the "gateway" or, more frequently in the respiratory tract. The incubation period (time between injury and appearance of the first symptom) is ≤10 days and the period of progression (time between the first symptom and the first spasm) ≤48 hours, the time elapsed between the occurrence of the first tetanus symptom and admission ≤36 hours and the occurrence of spasms in the first 24 hours of hospitalization are indicators of poor prognosis and may be useful to guide treatment choice. Before intensive care became available, mortality due to tetanus was caused by spasms of the glottis, aspiration and respiratory infection. Since the wider availability of intensive care, complications associated with disruption in the autonomous nervous system have become the leading causes of death. The course of the illness begins to decline 2 to 4 weeks after onset, initially with improved autonomic nervous system function, followed by cessation of spasms, and slow and gradual reduction of muscle contracture. Remission usually occurs within days or weeks.

The hallmark of botulism is descending flaccid paralysis that usually begins in the territory of cranial nerves and manifesting as blurred vision, unilateral or bilateral palpebral ptosis, difficulty converging the eyes, double vision and ophthalmoplegia, weakness of the mastication muscles, swallowing and speech, with consequent dysarthria and dysphasia. Muscle weakness may progress symmetrically to neck muscles, trunk and limbs, causing difficulty sustaining the neck, dyspnea, respiratory failure and flaccid quadriplegia. Autonomic nervous system dysfunction is characterized by dilated pupils and absence of photoreactivity, dry mouth, ileus, fluctuations in blood pressure and heart rate, sweating and urinary retention. As with tetanus, the patient with botulism retains clear senses and mental status during the course of the disease. In foodborne botulism, the most common form in adults, the intoxication results from the ingestion of botulinum toxin and can start with nausea, vomiting, diarrhoea and abdominal pain, with or without concomitant neurological symptoms. In wound botulism, as the toxin is produced and absorbed at the wound site, there is no gastrointestinal symptoms, but fever may occur. Intestinal botulism is more common in children and occurs after the ingestion of *Clostridium botulinum* that start toxin production. The initial symptoms are constipation and irritability, followed by neurological symptoms. In untreated cases, death can result from airway obstruction or respiratory failure. The disease can progress over 1-2 weeks and stabilize for more than 2 or 3 weeks. The recovery phase can be very slow in severe cases and last for several months.

Although the diagnosis of tetanus is exclusively clinical and epidemiological, with botulism the laboratory may have fundamental importance in confirmation of diagnosis, identify the type of toxin, and in some cases, isolate *Clostridium botulinum*, although the presence of the bacterium is not conclusive for diagnosis. The detection of toxin in serum or in the content of vomiting, gastric lavage and/or intestinal tract and faeces remains the standard method for diagnosis. Considering that this is a life-threatening intoxication and that early treatment can define therapeutic success, collecting and sending biological material for laboratory examination should be done as soon as possible, preferably within the first 7 days of illness and before the administration of antibotulinic serum. The most widely used diagnostic test is still the mouse bioassay, although a more rapid immunoassay for the detection of botulinum neurotoxin has recently been developed. Electromyography may be useful in identifying the location of involvement, the characteristic lesion being at the neuromuscular junction. Repetitive nerve stimulation shows an increase in the amplitude of the motor potential, and these changes disappear after clinical recovery.

The differential diagnosis for tetanus should include strychnine poisoning; bacterial meningitis; tetany due to hypocalcemia; rabies; hysteria; intoxication from metoclopramide and neuroleptics; inflammation of the mouth and pharynx that can be accompanied by trismus; peritonitis; neck stiffness due to acute cervical osteoarthritis; neck stiffness; septicaemic spondylitis; and seizures.

The differential diagnosis for botulism is with the Guillain-Barré and Müller Fisher syndromes, myasthenia gravis, stroke, central nervous system tumours and alcoholic coma.

Any case of botulism should be reported immediately to health authorities so that measures of investigation and containment of outbreaks can be promptly adopted. Even small outbreaks of foodborne botulism can precipitate a national emergency and overload the ICU.

61.3 Treatment

Because both are potentially life-threatening conditions with an unpredictable evolution, tetanus and botulism should be treated at an ICU, preferably with trained and qualified medical and nursing staff. In Pernambuco, Brazil, the centralization of care in the ICU with an experienced team specializing in the treatment of tetanus has resulted in a significant reduction in mortality.

The treatment of tetanus has the following objectives: neutralization of the toxin, elimination of focus, and symptomatic treatment.

61.3.1 Neutralization of the Toxin

Human anti-tetanus immunoglobulin (HTIG) is given intramuscularly (IM) at a dose of 1000 IU to 3000 IU, although Blake and Feldman (1976), in a retrospective study, found the same efficacy with 500 IU. HTIG should not be administered intravenously (IV). The anti-tetanus serum (ATS) can be used as a second choice at a dose from 10,000 to 20,000 IU IM or IV at any age. The administration of the ATS should be preceded by a skin sensitivity test. If the patient tests negative, promethazine is administered IM 15 minutes before injecting the serum. If the test is positive, ATS cannot be administered and HTIG is given.

A randomized clinical trial conducted by the authors of this chapter compared patients who received HTIG by intrathecal and intramuscular routes with a group treated with

HTIG intramuscularly. The group that received HTIG via intrathecal and IM benefited from a better response in relation to various criteria: better clinical outcome; shorter hospitalization time and fewer spasms; lower proportion of overall complications such as respiratory infection and need for artificial ventilation; shorter time on ventilation and lower mortality rate, although for this last variable the difference was not statistically significant. The HTIG was preservative-free, at a dose of 1000 IU, injected into the subarachnoid space by suboccipital or lumbar puncture. In a recent meta-analysis, Kabura et al. (2007) found the intrathecal administration of antitoxin was more beneficial than IM administration for the treatment of tetanus.

61.3.2 Elimination of Focus

The suspicious focus should be widely debrided to remove foreign bodies and necrotic tissue. Prior systemic administration of tetanus antitoxin is recommended. The wound should be cleaned with oxidant liquids such as hydrogen peroxide, potassium permanganate 1: 5000 or aqueous solution of iodine.
Antibiotic treatment can be done with metronidazole at a dose of 1-1.5 g day (15-30 mg/kg/day) divided into 3 parts (8/8 hours) or even a single dose/day for 7-10 days or crystalline G penicillin at a dose of 12-15 million IU/day (200,000 IU/kg/day) in equal fractions of 4/4 hours for 7-10 days. Other alternatives are clindamycin, ampicillin-sulbactam and erythromycin.

61.3.3 Symptomatic Treatment

Among muscle relaxants and sedatives, benzodiazepines, barbiturates and phenothiazines have been used more frequently. The diazepines are considered by most authors as the drug of choice as they have a sedative and relaxant action and are inexpensive. The initial dose is 10 mg IV at intervals ranging from 12/12 hours to 1/1 hour. Attention should be paid to the level of consciousness and respiratory depression, especially among the elderly. Doses should be adjusted according to the patient's response and severity of the case. The observed side effects are: behaviour disorders, diplopia, dizziness and ataxia. Cases of prolonged coma due to residual effect have been observed in tetanus treated with diazepines, especially among elderly patients. Chlorpromazine also has a sedative and relaxant action and can be combined with diazepines in severe cases (dose of 25 mg IV with a minimum interval of 6 hours). The most frequent side effects include tachycardia, pallor, hypotension, glucosuria, jaundice and sweating.
In cases of serious illness in which muscle spasms do not remit with high-dose muscle relaxants, pancuronium or vecuronium can be used. The use of neuromuscular blocking requires that the patient is mechanically ventilated and sedated. Pancuronium is most widely used because of its low cost and long half-life, at a dose of 0.1 mg/kg, which may be repeated up to 1/1 hour. In cases of severe cardiovascular instability, vecuronium is preferred due to its lack of cardiovascular side effects. Atracurium can also be an alternative, although it is more expensive and can cause cardiovascular instability.
There is no consensus on the most appropriate way to treat autonomic nervous system dysfunctions and most publications are based on case reports or small series. It is expected that an ideal treatment regimen will be effective in stabilizing the cardiovascular system, while preserving compensatory functions to prevent sudden death. In cases of severe, prolonged tachycardia, associated with consistently elevated blood pressure or blood pressure instability, morphine can be used at an initial dose of 5-10 mg 8/8 or even 4/4 hours, SC or IV. In more severe cases, the dose can vary from 240 to 2500 mg/

day or 0.01 to 0.1 mg/kg/minute with continuous infusion. However, when very high doses are needed, its use should be limited to short periods of time.

Thwaites et al. (2006), in a randomized and double-blind study testing the effect of magnesium sulphate in an IV solution for the control of spasms and autonomic nervous system dysfunction, observed a reduction in the need for verapamil to control the tachycardia associated with autonomic nervous system dysfunction.

A number of patients with tetanus will require tracheostomy during its clinical course, even though some may not require mechanical ventilation. Tracheostomy should preferably be performed before intubation, although orotracheal intubation is rarely used in patients with tetanus. The most frequent indications for tracheostomy include:

- Apnea attack.
- Dysphagia preventing the patient from swallowing saliva and/or expel secretions.
- Marked trismus obstructing the ability to swallowing saliva.
- Frequent and intense muscle spasms (neuromuscular blocking + mechanical ventilation).
- Signs of bronchoaspiration or “choking”.
- Lower respiratory tract infection/secretion in the lower airways.
- Pulmonary atelectasis.

Attention should be paid to the need for early tracheostomy in patients with clinically rapid progression or more indicators of severity: period of onset 48 hours; incubation period ≤10 days; time between symptom onset and hospital admission ≤36 hours; presence of spasms on admission or within 24 hours; and in the elderly. The early indication for tracheostomy may reduce the occurrence of aspiration and apnea and avoid the need for mechanical ventilation. The early indication also prevents an emergency procedure with a higher risk of complications.

Outcomes after botulism treatment are directly related to early diagnosis and site conditions. Treatment should be performed in a hospital with an ICU and supported by two sets of actions: supportive care and specific treatment.

The general measures of cardiorespiratory support and monitoring are the mainstays in the treatment of botulism. Respiratory care is essential and respiratory failure may occur early, owing to impairment of swallowing, obstruction by viscous mucus or the progression of muscle paralysis. Also, cardiac monitoring is essential, since in severe forms of the disease autonomic nervous system dysfunction is frequent. Critically sick patients may need a neurologist, infectivologist, cardiologist, pulmonologist and intensivist, as well as rehabilitation specialists.

Specific treatment relies on heterologous antitoxin to neutralize the circulating toxin that has not yet reached the nerve endings. The decision to administer antitoxin must be based on clinical findings, history and physical examination but should not be delayed while awaiting laboratory tests results, as this is the only specific treatment and its early use is essential. On the other hand, its indication should be carefully weighed because it is not devoid of risk, as some patients are hypersensitive to the serum of other animals. The serum may be specific to the toxin subtype or polyvalent (combination of 2-4 antitoxins A, B, E and F). Each country has its own system of distribution of botulinum antitoxin to reference units. The dose is one ampoule intravenously diluted in 0.9% saline at a ratio of 1:10 and infused approximately over 1 hour. All biological material for testing should be collected before administrating the antitoxin. In a large outbreak of foodborne botulism in Thailand, botulinum antitoxin was given to some patients on the fourth day of illness and to others on the sixth day, with an inadvertent 2-day delay due to a temporary unavailability of the serum in the country. There was a statistically significant difference between the two groups in the duration of mechanical ventilation and time to extubation, favouring the group that had received the antitoxin earlier.

In cases of foodborne and intestinal botulism, there is no indication for antibiotic treatment because its use can increase the release of toxins into the intestinal lumen. In wound botulism, antibiotic therapy can be given with crystalline penicillin (10-20 million IU/day IV in divided doses of 4/4 hours) or metronidazole (2 g/day IV, 6/6 hours for 7-10 days). Antibiotic therapy for other infections that may occur during the course of the disease should be selected cautiously when using aminoglycosides and tetracyclines, because they can potentiate the neuromuscular blockade by reducing the entry of calcium into the neuron.

62 Neurological Complications of HIV

Tracey A. Cho [1], Nagagopal Venna [2]

62.1 Introduction

HIV and AIDS cause significant morbidity and mortality worldwide, including Latin America. In 2007, estimates of adult HIV prevalence rates in Latin American ranged from 0.2 in Bolivia to 2.5 in Guyana. While the incidence of many neurological complications of HIV has decreased with potent antiviral therapy (ART), central nervous system (CNS) complications remain a significant burden. This is due to poor compliance, lack of access to medications, viral resistance, immune dysregulation despite viral control, and changing patterns of illness. The neurological intensivist must be able to diagnose and manage the varied CNS manifestations of HIV.

The first step is to consider the possibility of or recognize the existence of underlying HIV as a factor in the patient's presentation. Because the differential is so broad in someone with advanced HIV, the neurological ICU patient's HIV status should be routinely assessed. Once a patient tests positive for HIV, the level of immunosuppression should be quantified with viral load and T cell subsets. Those patients with CD4 counts >500 cells/µl for the most part carry the same risks as non-HIV infected patients. Those with mild reductions in CD4 counts to 200-500 cells/µl have an increased risk for tuberculosis, syphilis, varicella zoster, and cognitive impairment.

Most of the severe neurological complications of HIV occur at CD4 counts <200 cells/µl. In patients with a marked virologic and/or immunologic response to ART (precipitous drop in HIV viral load or in-

Focal brain lesions	With mass effect: • Toxoplasma • Primary CNS lymphoma • PML immune reconstitution inflammatory syndrome • Tuberculoma • Fungal abscess • Neurocysticercosis • Pyogenic abscess
	Without mass effect: • PML • HIV-associated stroke • HIV-associated dementia
Diffuse brain lesions	• HIV meningoencephalitis • Post-infectious encephalomyelitis • CMV encephalitis • VZV encephalitis • Neurosyphilis • Neurodegenerative diseases
Meningitis	• Cryptococcal • HIV • Coccidioidal • Tuberculous • Neurosyphilis • HSV-2 • VZV • Pyogenic • Neoplastic
Myeloradiculitis	• HIV vacuolar myelopathy • CMV myeloradiculitis • HTLV-1 myelopathy • Neurosyphilis myelitis • Tuberculous myelitis • VZV myelitis • HSV-2 myeloradiculitis • Toxoplasma myelitis • Epidural lymphoma • Subac. combined degeneration (B12 defic.)

Table 62.1. Central nervous system complications of HIV.

crease in CD4 cell counts), previously asymptomatic or successfully treated neurological infections may worsen due to an exuberant immune response to residual infectious antigens. This immune reconstitution inflammatory syndrome (IRIS) can cause atypical presentations of neurologic disease.

As with any neurological disease process, the initial step is to localize the disease within the nervous system. HIV and the opportunistic infections associated with it can affect virtually any part of the central (Table 62.1) or peripheral nervous system (Table 62.2). Furthermore, more than one process may be active simultaneously, which can be challenging for localization. For the purposes of this chapter, the most important complications will be reviewed with a view to the neuro-ICU practitioner.

Neuropathy	• HIV distal symmetric polyneuropathy • Antiretroviral drug toxic polyneuropathy • Acute inflammatory demyelinating polyneuropathy • Chronic inflammatory demyelinating polyneuropathy • Mononeuritis multiplex (HIV, CMV, VZV, HBV, HCV) • Diffuse infiltrative lymphocytosis syndrome
Myopathy	• HIV myopathy (polymyositis) • Zidovudine myopathy • Pyogenic myositis • Toxoplasma myositis
Other	• HIV-associated neuromuscular weakness syndrome (lactic acidosis)

Table 62.2. **Peripheral nervous system complications of HIV.**

62.2 Focal Brain Lesions

The most common causes of focal brain lesions specific to HIV+ patients are toxoplasma encephalitis (TE), primary CNS lymphoma (PCNSL), and progressive multifocal encephalopathy (PML). In two large series from the United States and Italy, among those HIV patients in whom diagnosis was confirmed, approximately 45% were due to TE, 30% to PCNSL, 20% to PML, and the remainder to other causes, including tuberculous and fungal infection. In certain parts of the world including Latin America, tuberculoma is not an infrequent cause, with an increased incidence of tuberculosis co-infection with HIV. In one study from South Africa, tuberculosis was the most common cause of focal brain lesion in patients with HIV. Patients who are also intravenous (IV) drug users are also at higher risk of pyogenic abscess with typical organisms, as well as mycotic abscess. While the incidence is not increased in HIV patients, neurocysticercosis (NCC) remains an important infectious cause of focal brain lesions in Latin America and should be considered in all patients with cystic brain lesions regardless of their HIV status. HIV may be associated with stroke, either directly (through a large vessel vasculopathy) or due to opportunistic organisms causing infectious vasculitis. Hence, HIV should be considered in the differential diagnosis of stroke in young patients. The clinical syndrome, radiographic appearance, serological and DNA studies, and – in the case of TE – response to treatment, can help to distinguish the three most common HIV-specific causes of focal brain lesions.

TE is caused by the intracellular protozoan parasite *Toxoplasma gondii* which may be transmitted by ingestion of food or water contaminated with the faeces of infected cats or by ingestion of infested undercooked pork and lamb. Once infected, humans carry the parasite in cyst form for life, with reactivation occurring in the setting of immunosuppression, usually with CD4 counts <100 cells/µl. Toxoplasma is found worldwide but certain areas, including Latin America, have increased seroprevalence. In certain parts of Brazil, antibodies to *T. gondii* are found in up to 80% of adults. TE tends to present acute-

ly over a period of days. The most common presenting symptoms and signs include headache, confusion, fever, and focal deficits including hemiparesis, ataxia, and psychomotor retardation. Seizures are also a frequent complication. Untreated, the infection is uniformly fatal. The classic appearance on imaging with computed tomography (CT) and magnetic resonance imaging (MRI) is that of multiple ring-enhancing lesions with surrounding edema, although solitary lesions may rarely occur (Figures 62.1 and 62.2). It most commonly affects the hemispheres and basal ganglia. Serologic testing for antibodies to toxoplasmosis is highly sensitive, with only rare false negative results in the setting of profound immunosuppression (CD4 count <50 cells/µl). Hence, negative toxoplasma serology should suggest an alternative diagnosis in most cases. Many patients with CD4 counts <100 cells/µl are placed on trimethoprim-sulfamethoxazole (TMP-SMX) for prophylaxis of *Pneumocystis* pneumonia and TE, so the current use of TMP-SMX reduces the probability of a focal brain lesion being due to TE. The recommended primary treatment of TE includes oral pyrimethamine (200 mg loading dose, then 75mg/day) plus folinic acid and either sulfadiazine (6-8 g/day orally in 4 divided doses) or clindamycin (600-1200 mg IV or 450 mg orally 4 times daily) for six weeks. Combination anti-retroviral therapy should be initiated after clinical and radiographic response. Maintenance dosing of pyrimethamine 25-50mg daily and sulfadiazine (2-4 g daily in 4 divided doses)

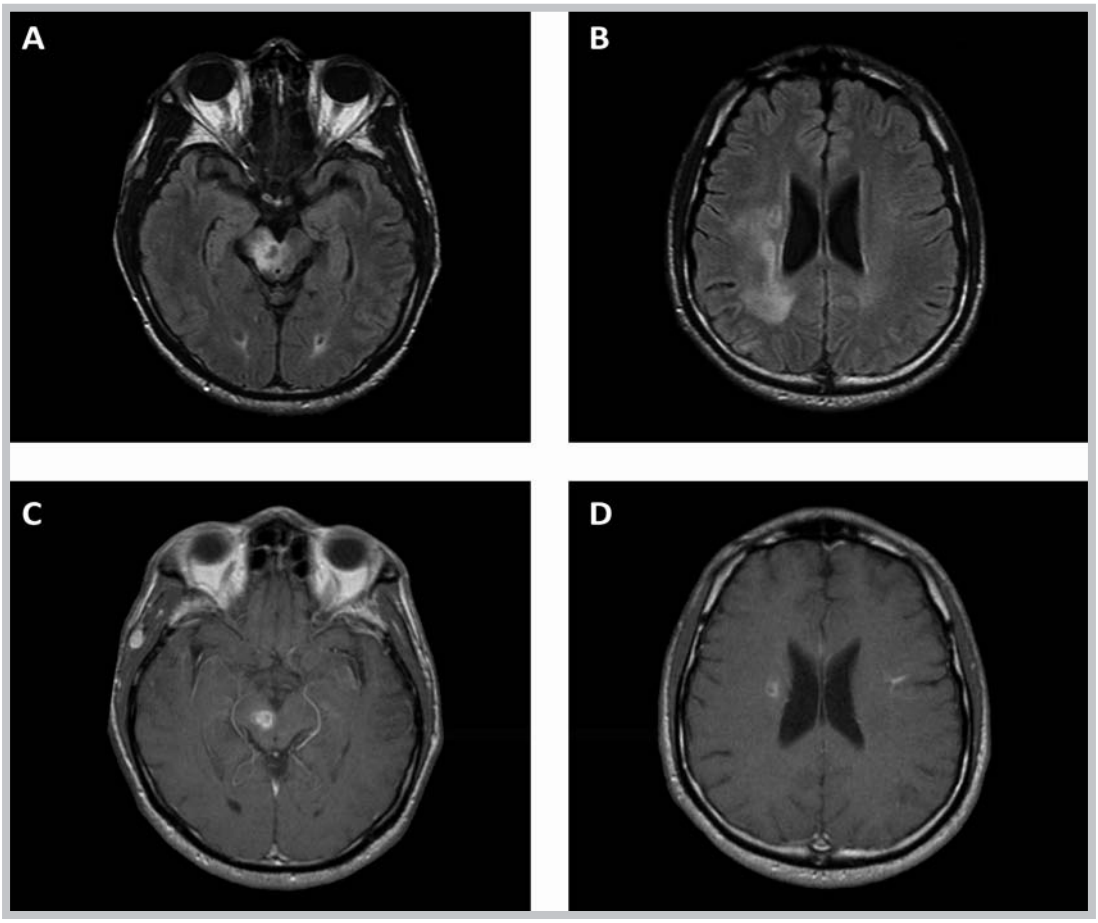

Figure 62.3. **Toxoplasmosis. Fluid attenuated inversion recovery (A, B) and T1 post contrast (C, D) MRI showing improvement in T2 hyperintensity in the right cerebral peduncle and periventricular corona radiata with mild mass effect and patchy rim enhancement 4 weeks after starting treatment.**

is continued until at least 6 months after CD4 counts rise above 200 cells/µl. Steroids (dexamethasone 4 mg every 6 hours) may be used in extreme cases associated with significant midline shift or signs of herniation but it should be avoided in most cases to prevent confusion regarding the specificity of response to TE treatment.

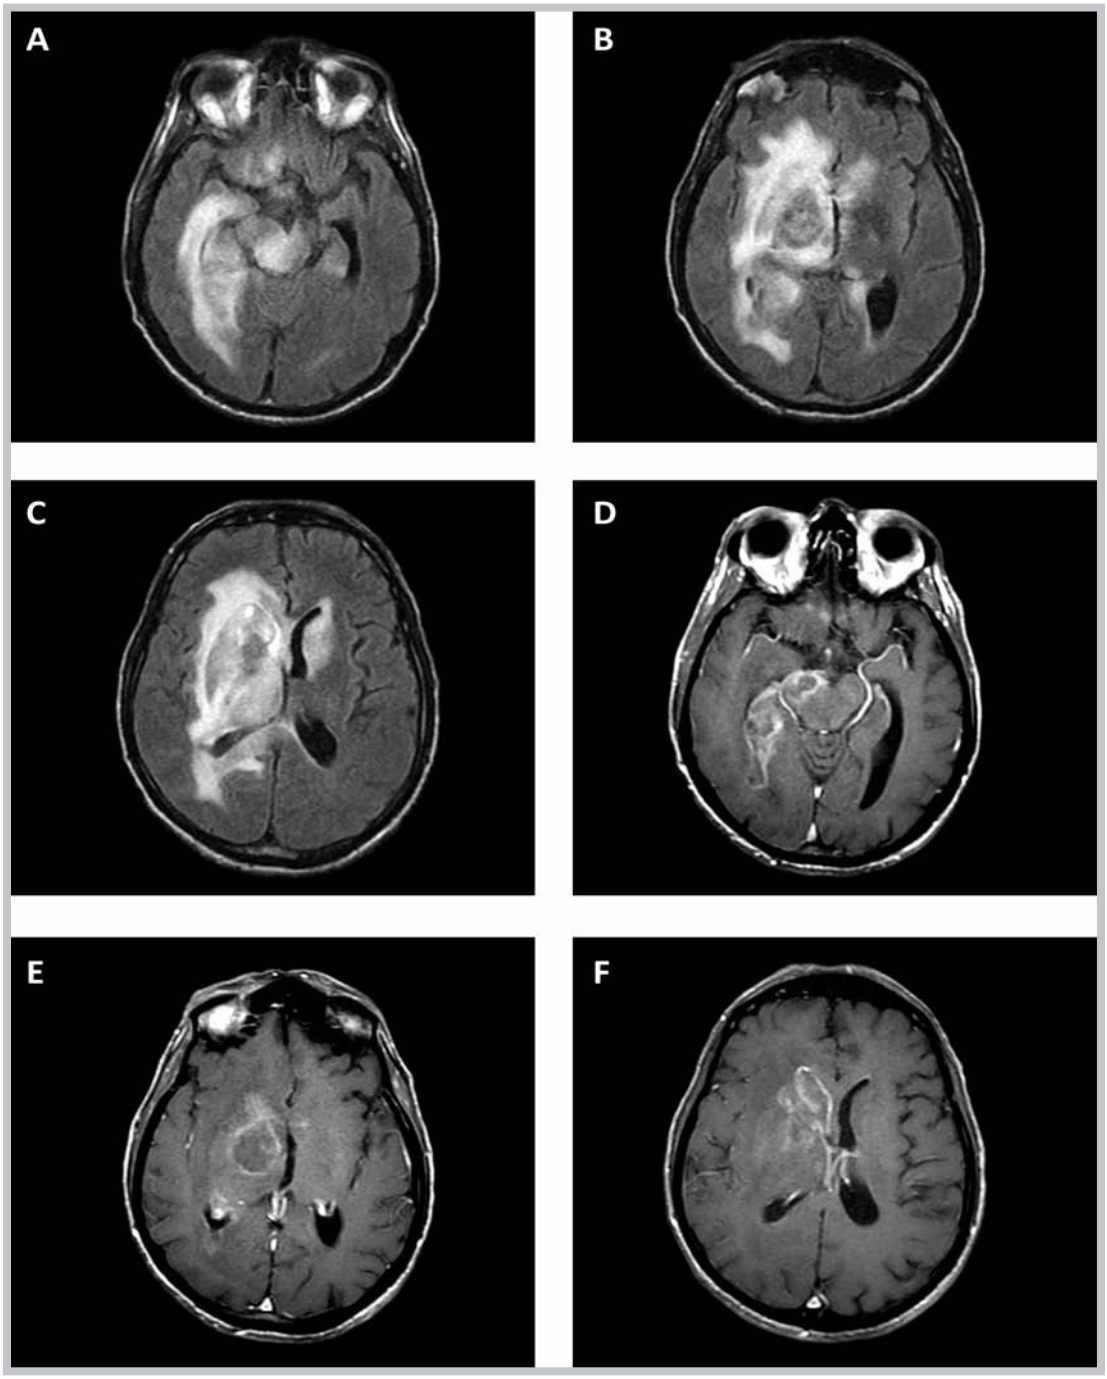

Figure 62.4. **Primary central nervous system lymphoma. FLAIR (A, B, C) and T1 post-contrast (D, E, F) MRI showing T2 hyperintense lesion with patchy rim enhancement and surrounding edema in the right midbrain and basal ganglia with extension across the genu and splenium of the corpus callosum.**

Antiepileptic drugs (AEDs) may be used for secondary prophylaxis but they are not routinely used for primary prophylaxis. Given the hepatic metabolism and toxicity of the TE antimicrobials, AEDs with lower hepatic toxicity and enzyme induction should be preferred (i.e., levetiracetam). The vast majority of patients will show significant improvement clinically and radiographically within 2-3 weeks (Figure 62.3). Failure to do so should strongly suggests an alternative diagnosis.

Primary CNS lymphoma is the second most common cause of focal brain lesions in HIV. In patients with HIV, PCNSL is associated with Epstein-Barr virus (EBV) infection, as opposed to PCNSL in non-immunocompromised patients. Histopathology typically reveals a large B-cell lymphoma. Presenting symptoms are nonspecific; a majority of patients present with mental status changes such as lethargy, confusion, memory loss, and behavioural changes. Furthermore, up to 80% of patients have a history of constitutional symptoms, including fever, night sweats, weight loss, and fatigue (which are common in advanced HIV as well). Focal symptoms, including hemiparesis, aphasia, ataxia, and cranial nerve deficits are also common, but patients may lack clear localizing symptoms and signs. Symptoms are typically present for days to weeks before diagnosis. Patients are profoundly immunosuppressed with CD4 usually <50 cells/μl. CT and MRI reveal a wide spectrum of findings, including solitary or multifocal lesions; ring, patchy, or homogenous enhancement; and cortical or subcortical location (Figure 62.4).

Compared to non-immunocompromised patients, PCNSL in HIV is more likely to be multifocal, found in cortical as well as deep locations, and with less homogenous enhancement (due to central necrosis from rapid growth). Radiographic appearance is not reliable in terms of differentiating PCNSL from TE or other infections, but in general PCNSL is more likely to involve periventricular and corpus callosum white matter and less likely to involve the posterior fossa than TE. Metabolic imaging including single-photon emission computed tomography (SPECT) has been used in some studies to differentiate PCNSL from other causes of mass lesions, but these technologies are not widely available or validated. Given the strict association with EBV, the presence of EBV DNA on PCR assay of cerebrospinal fluid (CSF) lends strong supportive evidence for PCNSL. CSF cytology may be diagnostic, but its sensitivity is poor as only a minority of PCNSL have leptomeningeal involvement. While up to 25% of non-HIV-associated PCNSL may include ocular involvement, ocular spread is not well established in HIV so that the yield of ophthalmological examination is low. Some clues in favour of PCNSL over TE include negative toxoplasma serology, adherence to prophylactic TMP-SMX, and lack of response to specific treatment for TE. The combination of negative toxoplasma serology and positive CSF EBV DNA PCR should strongly support the diagnosis of PCNSL in these patients. In many cases, however, biopsy is necessary to confirm the diagnosis prior to initiating potentially toxic therapies. It is important to note that the administration of corticosteroids prior to biopsy to reduce mass effect may compromise the diagnostic yield as PCNSL may rapidly but temporarily shrink in response to corticosteroids. HIV-related PCNSL has traditionally been treated with whole brain radiation combined with corticosteroids with modest benefit and significant neurotoxicity in the few who survive long enough. The median survival in untreated PCNSL is 1 month, and with radiation this is extended to 2-5 months (often due to other opportunistic infections). Chemotherapy has been avoided due to the already profound immunocompromised state of these patients. However, with the advent of effective combination antiretroviral therapy (cART), survival in PCNSL has improved. Furthermore, high-dose methotrexate, which has become standard therapy in non-HIV PCNSL, has also been shown to improve survival with fewer neurotoxic effects compared to radiation. In practice, some combination of cART, methotrexate, and radiation is often used, depending on patient characteristics.

The third most frequent cause of focal brain lesions in HIV is PML. The JC virus (or John Cunningham virus) is a polyomavirus typically acquired in childhood and which remains latent in the kidneys, blood, and lymphoid organs. Up to 86% of normal subjects in Europe had antibodies to JCV. In the setting of immunocompromisation from HIV (also in hematologic malignancy or treatment with immunosuppressive medications), JCV may reactivate with a tropism for the cerebral white matter. This usually occurs with CD4 counts <200 cells/µl. It infects the oligodendrocytes, causing lysis and demyelination. Compared to TE and PCNSL, PML presents more insidiously over weeks to months. Patients present with focal deficits, including hemiparesis, ataxia, visual field deficits, and diplopia. Altered mental status is common, but cognitive impairment in the absence of focal findings on exam or imaging is unusual. Cortical symptoms and signs, including seizures, frequently occur due to involvement of the juxtacortical white matter and the gray matter itself. While TE and PCNSL are characterized by contrast enhancement and mass effect on neuro-imaging, PML typically lacks these features. Classically, PML appears as asymmetric multifocal white matter lesions which do not respect vascular territories and lack contrast enhancement or mass effect. Lesions are hypodense on CT; MRI reveals hyperintense lesions on T_2-weighted and hypointense lesions on T_1-weighted images (Figure 62.5).

While lesions most commonly involve the periventricular and subcortical white matter, posterior fossa and basal ganglia lesions frequently occur. Brain biopsy reveals gross demyelination and histopathology shows oligodendrocytes with nuclear inclusions and atypical astrocytes. Immunohistochemistry staining for JCV identifies infected oligodendrocytes. Development and validation of PCR for CSF JCV DNA has obviated the need for brain biopsy in most HIV patients with PML. Before the advent of highly active antiretroviral therapy (HAART), CSF PCR for JCV had 72-92% sensitivity and 92-100% specificity; sensitivity is decreased in patients on ART. In cases with typical clinical and radiographic features, positive CSF JCV PCR is considered diagnostic. Even when CSF is negative, a presumptive diagnosis may be given if other etiologies are excluded. There is no effective JCV specific treatment available, but in HIV patients, reconstitution of the

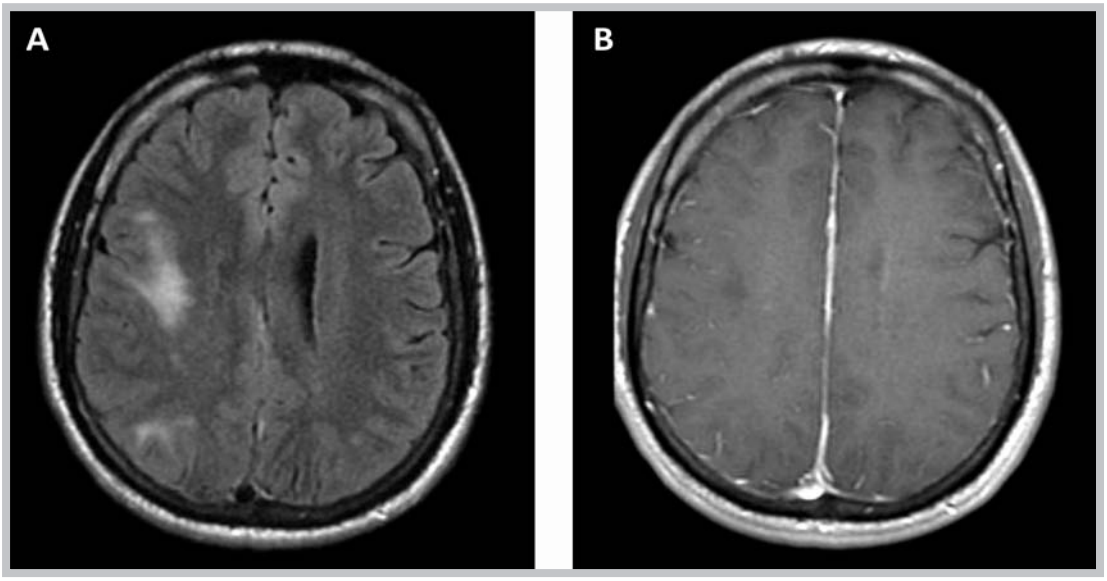

Figure 62.5. **Progressive multifocal leukoencephalopathy. FLAIR (A) and T1 post-contrast (B) MRI showing multifocal T2 hyperintense lesion in the right frontal and parietal subcortical white matter, with corresponding T1 hypointensity but no enhancement or mass effect.**

immune system with effective ART has led to great improvements in survival. Prior to HAART, the 1-year survival rate in patients with PML was only 10%; more recently this has improved to at least 50%. Even with longer survival, however, lesions caused by PML tend to persist, leaving residual deficits. A more recently recognized presentation occurs when there is a robust immune response – in the setting of IRIS from effective ART – which leads to symptomatic presentation of previously undiagnosed PML or worsening of known PML, with enhancement and edema on neuro-imaging. Although symptoms may worsen, this inflammation confers an improved prognosis for survival. Corticosteroids may be used cautiously in cases where this inflammation threatens essential neurological structures.

Although TE, PML, and PCNSL constitute the most common etiologies for focal brain lesions in patients with HIV, such patients are also at increased risk for other infections and for unusual manifestations of non-HIV-related infections. In many parts of the world, tuberculosis is an important cause of focal CNS lesions. Its incidence is increased further in patients with HIV, even at CD4 counts >200 cells/µl. Patients with HIV started on ART with virologic and immunologic improvement may unmask a previously asymptomatic tuberculoma. Distinguishing these lesions from toxoplasmosis or neurocysticercosis can be particularly difficult, and biopsy is often required. While HIV does not increase the

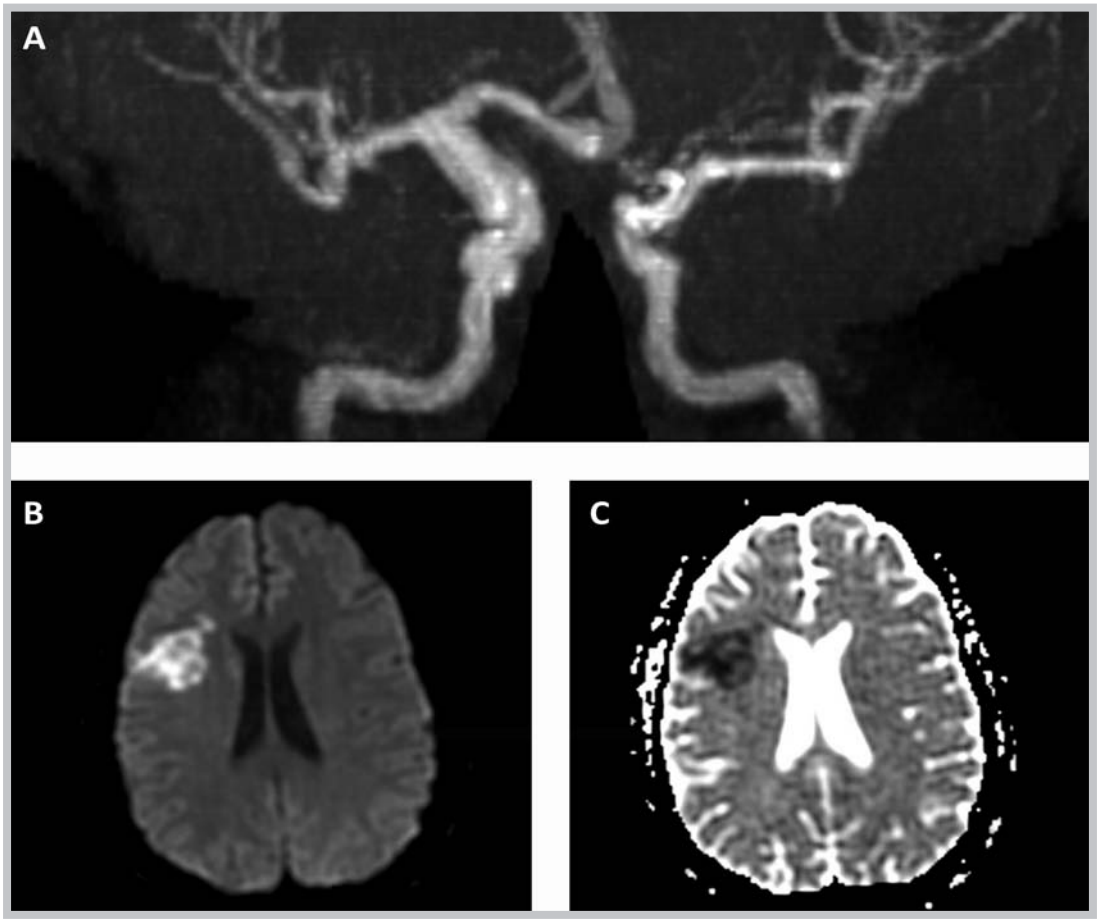

Figure 62.6. **HIV-arteriopathy. MRA circle of Willis (A) showing distal right ICA and proximal right MCA fusiform dilatation; diffusion weighted imaging (B) and apparent diffusion coefficient (C) sequences showing right MCA territory acute infarction.**

risk for neurocysticercosis, it may alter the presentation of this disease endemic to Latin America. There is some evidence suggesting that giant cysts and the racemose form of neurocysticercosis are more common in HIV-positive patients, possibly due to reduced immunity that allows for more chronic expansion of the cysts. In some cases, neurocysticercosis may be incidentally noted when imaging is obtained due to another HIV-related focal brain lesion. Rarer causes of focal brain lesions in HIV include fungal abscesses, including cryptococcus and histoplasmosis; aspergillosis may rarely cause a brain abscess in patients with HIV. Pyogenic bacteria, as well as atypical bacteria such as nocardia, are infrequent causes of focal brain lesions in HIV patients but are more common in injection drug users.

Occasionally, cerebral infarction is the presenting symptom of HIV or occurs in the course of known HIV infection. Basal meningitis/vasculitis due to tuberculosis, syphilis, and fungal infections – along with intracerebral vasculitis due to varicella-zoster virus (VZV) – are the usual etiologies for infarction. An unusual dilated cerebral arteriopathy affecting the extracranial and intracranial arterial stems and causing fusiform aneurysms has been increasingly recognized in patients with HIV and should be considered in the differential diagnosis of stroke of unknown etiology in young adults (Figure 62.6).

62.3 Diffuse Encephalitis

In addition to focal brain lesions, HIV patients are at risk for a number of more diffuse encephalitic processes. Acute HIV infection (or viral rebound from poor adherence or viral resistance) may rarely manifest with a fulminant HIV encephalitis (direct infection) or a peri- or post-infectious acute demyelinating encephalomyelitis (ADEM). Patients with more advanced HIV often develop HIV-associated dementia (HAD). Rarer causes of diffuse encephalitis in late HIV include cytomegalovirus (CMV), varicella-zoster virus (VZV), and neurosyphilis. Finally, in settings where patients have access to effective ART, longer survival has led to more typical causes of dementia in aging populations.

Among the processes that cause diffuse encephalitis in patients with HIV, the most frequent is HAD. This is typically a slowly progressive subcortical dementing process. As such, neurological sequelae from HAD will rarely require neurological-ICU care. Familiarity with this entity is nonetheless important for intensivists as these patients often have advanced disease and multiple simultaneous processes. HIV gains access to the CNS early in the course of infection via migration of infected monocytes. Replication within the CNS occurs in the microglia and macrophages. Damage occurs indirectly from cytokine-induced cytotoxicity. Early in the course of HAD, deficits develop in concentration, short-term memory, cognitive slowing, apathy, reading, and comprehension. Later on, patients may develop more florid dementia and frontal release signs. These are often accompanied by motor deficits which are predominantly extra-pyramidal. Neuro-imaging may reveal cortical and periventricular atrophy; often there is diffuse, symmetric subcortical white matter hypodensity on CT or hyperintensity on T_2-weighted MRI (Figure 62.7). Compared to PML, lesions due to HAD are more often symmetric, may be isointense on T_1-weighted MRI, and are potentially reversible. In untreated patients, HAD usually presents in advanced disease (CD4 count <150 cells/µl). But more recently with ART the proportion of cases presenting with CD4 counts of 200-350 cells/µl is increasing. CSF studies are nonspecific and may even be normal. The HIV viral load may be detectable, sometimes at high titres, in the CSF. In patients on ART, however, the CSF viral load does not correlate with HAD. Although biopsy may be unnecessary, classic pathology on brain biopsy or autopsy reveals multinucleated giant cells and myelin pallor.

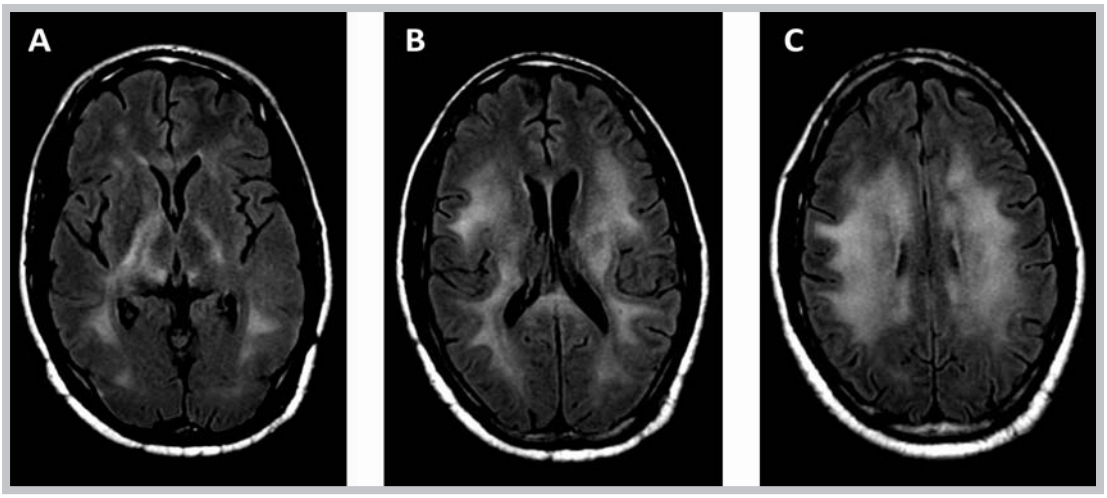

Figure 62.7. HIV-associated dementia. FLAIR MRI showing symmetric, confluent T2 hyperintense signal in subcortical white matter (A, B, C); there was no corresponding enhancement or mass effect.

While there are proposed criteria for diagnosis, HAD is ultimately a diagnosis of exclusion. Treatment with ART with suppression of serum viral load may lead to stabilization or even reversal; treatment is less effective late in the disease when significant atrophy is already present. There is ongoing debate on whether ART regimens with better CNS penetration (as measured in CSF) improve outcome.

Rarely HIV can cause a more fulminant meningoencephalitis. In HIV seroconversion, patients may present with an acute disseminated encephalomyelitis (ADEM)-like illness. In addition, in the setting of viral rebound due to cessation of ART or viral breakthrough due to the development of resistance to ART, patients may develop meningoencephalitis with a high CSF viral load. In both these scenarios, patients may improve rapidly with (re-)initiation of ART. More recently, it has been recognized that immune reconstitution from effective ART can lead to an exaggerated inflammatory response in the CNS, often in a similar but more fulminant pattern to HAD. This process often proves rapidly fatal, and steroids may be given in an attempt to attenuate the exaggerated immune response.

Cytomegalovirus (CMV) is a herpes virus that may be reactivated in profoundly immunocompromised patients (CD4 count <50 cells/μl) to cause neurologic disease in the retina, brain, spinal cord, nerve root, or peripheral nerves. Non-nervous system involvement includes colitis, esophagitis, and rarely pneumonitis. While the incidence of CMV disease in HIV has declined in populations with access to ART, it remains an important consideration in cases of diffuse encephalitis in immunocompromised patients. CMV encephalitis may present with subacute dementia similar to HAD but usually more rapid and more likely to have accompanying focal symptoms and signs. CMV ventriculo-encephalitis is a more fulminant syndrome, with accompanying focal signs including cranial nerve palsies, and is rapidly fatal. Patients with CMV encephalitis often have evidence of CMV disease elsewhere, especially retinitis. CT and MRI may reveal periventricular enhancement. The typical CSF profile is nonspecific, usually with mild-moderate pleiocytosis, normal to low glucose, and moderately elevated protein. In the appropriate clinical context, diagnosis is made by CSF CMV antigen testing or DNA PCR. Treatment consists of intravenous ganciclovir 5 mg/kg q12 and foscarnet 60 mg/kg q12 until improvement, with initiation of ART if there is a clinical response. Lifelong maintenance consists of oral valacyclovir 900 mg daily.

VZV is ubiquitous throughout temperate climates. Primary infection causes chicken pox, with latent virus persisting in the dorsal root and cranial nerve ganglia. Reactivation in the elderly and immunocompromised leads to herpes zoster or shingles. Patients with HIV have a 15-fold increase in zoster, which may occur at any CD4 count but usually when <200 cells/μl. VZV may rarely manifest as a neurologic syndrome, including encephalitis, myelitis, meningitis, retinitis, cranial nerve palsy, CNS vasculitis, or a combination thereof. Neurological involvement in zoster is more common in HIV than in other patients. Rash may not be present in a significant minority, so its absence does not exclude VZV as a cause of neurological symptoms. CSF typically reveals a mild lymphocytic pleiocytosis, moderately elevated protein, and normal glucose. CSF VZV DNA PCR or antibodies confirm the diagnosis. MRI may show multifocal T_2 hyperintensities and leptomeningeal enhancement, but such findings are nonspecific and may be normal. In VZV vasculitis, MRI may show single or multifocal cerebral infarctions, so VZV should be considered in the differential diagnosis of stroke syndromes in HIV patients. Treatment with intravenous acyclovir usually leads to recovery, except for visual loss from retinitis and infarctions from vasculopathy.

62.4 Meningitis

Meningitis is a frequent complication of advanced HIV. In patients with CD4 counts <200 cells/μl, the most common cause of meningitis is *Cryptococcus neoformans*, followed by tuberculosis and syphilis. HIV itself causes aseptic meningitis at seroconversion in up to one third of patients, which is usually self-limiting, as well as a rebound meningoencephalitis as noted above. Less common causes of meningitis include coccidioides, VZV, HSV-2, and pyogenic bacteria. Non-infectious meningitis may occur with leptomeningeal spread of systemic non-Hodgkin's lymphoma. Patients with advanced HIV may not present with classic symptoms and signs of meningitis, so the threshold for performing lumbar puncture to assess neurological symptoms should be lower for these patients. As these patients may also have multiple simultaneous neurological processes, neuro-imaging should be performed prior to lumbar puncture when possible to exclude mass lesions which might lead to downward herniation if CSF pressure is decreased.

C. neoformans is a ubiquitous encapsulated yeast found in the soil worldwide, as well as in pigeon droppings. This invasive fungus infects humans through the lungs, but the most common clinical manifestation is meningitis (meningoencephalitis), likely related to decreased complement activation and other factors that allow more growth in the CSF. It predominately affects immunocompromised patients; HIV patients with cryptococcal meningitis typically have CD4 counts <100 cells/μl, although it can rarely occur at higher counts. The incidence has decreased in populations with access to ART. Due to the lack of appropriate immune response, patients develop symptoms over days to weeks. Fever, malaise, and headache are the most common presenting symptoms, with classic symptoms of meningitis, as well as altered mental status, occurring in only about 25% on presentation. Rarely, patients may present with focal findings due to a mass lesion or cryptococcoma, usually in the deep white matter or basal ganglia, which occurs more often in non-HIV patients. Hence, mass lesions in patients with cryptococcal meningitis are more likely to be due to one of the causes listed in the section above. In some patients, cranial nerve palsies such as bilateral blindness and deafness can be presenting symptoms with only slight meningeal symptoms, due to the predilection of the infection to the CSF cisterns at the base of the brain. CT and MRI may be normal, but contrast studies may reveal perivascular nodules. CSF opening pressure is almost always elevat-

ed, often markedly so. CSF is often bland, with up to 30% of patients having normal CSF profiles. CSF India ink stain reveals numerous encapsulated yeast in 80% of cases. CSF cryptococcal antigen assay is highly sensitive and specific and is much more rapid than culture. Serum cryptococcal antigen assay is similarly sensitive in HIV patients and useful when lumbar puncture cannot be done immediately. Cryptococcal meningitis in HIV is treated with intravenous amphotericin B (0.7 mg/kg/day) plus oral flucytosine (100 mg/kg/day in 4 divided doses) for 14 days as induction. Consolidation treatment consists of oral fluconazole (400 mg/day) for at least 8 weeks. Once there is clinical improvement after 10 weeks, oral fluconazole (200 mg/day) provides maintenance therapy, which is continued indefinitely although discontinuation may be considered after ART leads to CD4 counts >100 cells/μl for at least 12 months. Even with successful chemotherapeutic treatment of cryptococcus, increased intracranial pressure (ICP) can pose ongoing problems. Patients may require daily lumbar puncture to remove enough CSF to maintain closing pressure <200 mmH_2O; patients who have ongoing elevated ICP after 4 weeks often require a ventriculoperitoneal shunt. Some patients without known cryptococcal meningitis, or with previously treated disease, may show worsening meningitis with inflammatory CSF in the setting of effective ART. This IRIS meningitis may be difficult to distinguish from worsening infection, but usually the organism burden is lower or undetectable in CSF and virologic and immunologic parameters show marked improvement. The timing of initiating ART in patients treated for cryptococcus is controversial, but waiting 2 weeks after specific cryptococcal treatment is reasonable.

HIV itself causes self-limiting aseptic meningitis in up to 30% of cases during acute seroconversion, but it may also persist as a low-grade chronic meningitis that is often asymptomatic. Symptoms include headache, meningismus, malaise, and photophobia. Focal symptoms are rare but may include cranial nerve deficits including bilateral facial palsies; few cases of encephalopathy have been reported. CSF reveals a mild lymphocytic pleiocytosis, normal glucose, and normal to mildly elevated protein. The CSF HIV viral load may be detectable and markedly high in some cases. Except in severe cases, the course is self-limiting and not an indication for initiation of ART (although the issue of starting ART early to reduce CNS penetration is under debate). As mentioned above, rebound HIV meningitis may occur in the setting of viral breakthrough from ART discontinuation or development of resistance. It is rapidly reversible with appropriate ART.

Coccidioides (*C. immitis* in California and *C. posadasii* in the American southwest, and Central and South America) are dimorphic fungi limited to arid and semi-arid regions of the Western hemisphere which infect humans by inhalation of spores. In normal hosts, it may cause a self-limiting respiratory illness. In immunocompromised patients, however, there is an increased risk for extrapulmonary dissemination during primary infection or through reactivation. Of these, meningitis is the most serious. Patients may present weeks to months after initial infection, most often with persistent headache. Tremor may be the only other neurological symptom, and overt signs of meningismus are often lacking. Later in the course of disease, cranial neuropathies and focal infarct may occur due to inflammation at the base of the brain with vasculopathy of the basal vessels. MRI may show nonspecific signs of basal meningitis, including leptomeningeal enhancement, infarction, and hydrocephalus. CSF studies show a mild to moderate lymphocytic pleiocytosis; although there may be neutrophilic predominance, early and mild eosinophilia is common. Compared to most other causes of aseptic meningitis, CSF glucose is more often depressed, sometimes markedly. CSF protein is moderately to severely elevated. Coccidioides symptoms and CSF profile can mimic tuberculosis and are both endemic in certain areas of Central and South America, so caution is warranted in the diagnosis. CSF culture of coccidioides is diagnostic but insensitive. Detection of antibodies to coccidioides more often yields the diagnosis, and rarely infection must be inferred from

detection at another site or in serum. Meningitis is treated with intravenous or oral fluconazole 400-800 mg daily acutely and 400 mg daily for life thereafter.
Meningitis is the most common CNS manifestation of tuberculosis and it is a major cause of HIV-associated meningitis in endemic areas. Syphilis more often progresses to early neurosyphilis in patients with HIV, requiring more aggressive diagnosis and treatment of syphilis in these patients. Organisms causing meningitis in immunocompetent hosts may also affect patients with HIV, and CSF should be routinely checked for pyogenic bacteria, mycobacteria, venereal disease research laboratory (VDRL) test, VZV, and HSV-2 as these have specific treatments. In addition, neoplastic meningitis – in particular leptomeningeal spread of systemic lymphoma – may cause subacute meningitis with cranial nerve palsies and/or polyradiculitis. CSF should be sent for cytology and flow cytometry where available. Unfortunately, leptomeningeal spread portends a poor prognosis even with appropriate treatment.

62.5 Myeloradiculitis

The most common myelopathy in patients with advanced disease is HIV vacuolar myelopathy. It has been detected in 25-50% of patients with AIDS, although it is symptomatic in only 5-10%. CMV is a rare but important cause of acute myelopathy in patients with advanced HIV and may cause conus medullaris or cauda equina syndrome. Other causes of myelopathy include human T-cell lymphotrophic virus-1 (HTL-1), tuberculosis, syphilis, toxoplasmosis, VZV, HSV-2, vitamin B12 deficiency, and lymphoma.
HIV vacuolar myelopathy shares features in common with subacute combined degeneration. HIV causes vacuolization of the lateral and posterior columns – particularly in the thoracic region – through unknown but indirect mechanisms rather than direct infection. It usually accompanies HIV-associated dementia. Patients present with slowly progressive but painless spastic paraparesis, sensory ataxia, and neurogenic bladder and sexual dysfunction. Rarely acute HIV infection is associated with an acute transverse myelitis, likely due to immune dysregulation. As with encephalitis, rebound viraemia in the setting of ART cessation or development of resistance may occasionally cause an acute myelitis. MRI in vacuolar myelopathy is most often normal but early in the process may show increased signal in the posterior and lateral columns and later may show atrophy of the thoracic cord. CSF typically reveals no white blood cells and mildly elevated protein. There is no specific treatment for HIV vacuolar myelopathy. By the time it is clinically manifest, irreversible damage has occurred. ART may help prevent progression, and typical symptomatic treatments for myelopathy should be applied. There is some evidence that methionine may offer some modest benefit.
CMV may cause axonal destruction, demyelination, or perineural vasculitis. Patients with CMV myeloradiculitis present over days to weeks with lower extremity weakness, saddle anaesthesia, and bowel and bladder paresis producing an acute conus medullaris or cauda equina syndrome. Reflexes are increased in myelitis and absent in polyradiculitis, which is often painful. Patients may have concomitant retinitis or encephalitis. MRI may be normal or show enlargement and enhancement of conus medullaris or cauda equina. CSF studies reveal moderate pleiocytosis (may be neutrophilic or lymphocytic), elevated protein, and normal to low glucose. Diagnosis is confirmed by CSF CMV DNA PCR, which has high sensitivity and specificity in the appropriate clinical setting. Treatment is the same as for CMV encephalitis (see above).
HTLV-1 causes a myelopathy which progresses over many years, ultimately resulting in symmetric spastic paraparesis, bladder dysfunction, and often lumbar and radicular

pain. Other causes of chronic myelopathy include tuberculosis, syphilis, subacute combined degeneration, and epidural compression from lymphoma. Acute myelitis may occur in the setting of infection with VZV, HSV-2, and syphilis. Appropriate serum and CSF studies should be sent to assess for these.

62.6 Peripheral Nervous System

While peripheral nervous system disease rarely causes acute critical illness, these syndromes are important to recognize. They may complicate the evaluation of weakness or sensory change in critically ill patients, and rarely may progress rapidly, leading to respiratory weakness and other serious complications.

The most common neurological complication of HIV infection is a distal symmetric polyneuropathy (DSPN) which primarily affects the sensory nerves. The virus causes a toxic dying back neuropathy through indirect immune activation and inflammation. Patients present with burning dysesthesias on the soles of the feet, decreased sensation in the distal lower extremities (especially vibration), and loss of ankle deep tendon reflexes. Certain ART medications – especially the dideoxnucleosides stavudine (d4T) and didanosine (ddI) – cause a toxic neuropathy indistinguishable from DSPN. The frequency with which this complication occurs may obscure the diagnosis of other causes of sensory loss, weakness, or ataxia such as myelopathy or critical illness neuropathy or myopathy.

Both acute and chronic demyelinating polyradiculoneuropathies occur in patients with HIV. Early in the infection, Guillain-Barré syndrome (GBS) may occur in the setting of seroconversion or as the first sign of HIV. GBS may rarely result from immune reconstitution with effective ART. In more advanced HIV infection, patients more often develop chronic inflammatory demyelinating polyradiculoneuropathy (CIDP). The clinical presentation of GBS and CIDP in patients with HIV is similar to that in non-infected patients, and the treatment and favourable response are the same. Clinical features and treatment of inflammatory demyelinating polyradiculoneuropathies are discussed elsewhere.

Mononeuropathy is rare but may occur at any point in the course of HIV infection. Compression may be related to cachexia or in presymptomatic nerve toxicity as in diabetes. Mononeuropathy may also develop into mononeuritis multiplex. Early in HV infection it is likely due to autoimmune vasculitis and has a good prognosis. In more advanced HIV, opportunistic infections including CMV, VZV, and hepatitis B and C play a more prominent role. These viruses should be sought and treated if present. If no explanation is found, biopsy may be necessary to assess for CMV inclusions or vasculitis. In more severe disease associated with vasculitis, treatment with immunomodulation (plasma exchange, intravenous immune globulin, or prednisone) may be helpful but prognosis is poor.

Some patients with HIV develop sicca symptoms with a Sjögren's-like syndrome with a CD8+ lymphocytosis infiltrating various tissues, including parotid gland, lung, kidney, and peripheral nerve. This diffuse infiltrative lymphocytosis syndrome (DILS) can cause an axonal neuropathy with pain and symmetric sensory loss or a picture of painful mononeuritis multiplex. Blood CD8 counts are elevated above 1200 cells/μl with a CD8 percentage >60%. Treatment consists of ART and/or steroids with typically good response.

Myopathy in HIV may be due to several different processes. HIV myopathy is a presumably immune mediated inflammatory myopathy which may occur at any point in the course of infection. It has clinical and pathologic characteristics similar to non-HIV polymyositis. Patients present with proximal lower more than upper extremity weak-

ness, muscle pain, and tenderness. Creatinine kinase (CK) is often elevated but may be normal. Electromyography (EMG) may be normal but often reveals changes consistent with necrotic myopathy (increased insertional activity, fibrillations, and polyphasic potentials). Muscle biopsy reveals mononuclear endomysial infiltrate, with predominantly CD8+ T cells and macrophages. Once other causes are excluded, treatment is similar to non-HIV polymyositis with high-dose prednisone slowly tapered after maximal response.

Zidovudine, a nucleoside reverse transcriptase inhibitor, may cause a toxic myopathy clinically indistinguishable from HIV myopathy. The pattern of weakness and CK elevation are similar. EMG and basic histopathology are typically milder than HIV myopathy, although evidence of mitochondrial toxicity may be apparent, with ragged red fibres on trichome stain and ultrastructural damage in electron microscopy. Cessation of the offending agent generally leads to recovery over many weeks.

Bacterial pyomyositis usually causes more focal muscle disease, and inflammatory changes overshadow any accompanying weakness. Toxoplasmosis may cause a more diffuse myositis, usually in the setting of disseminated disease including encephalitis. Muscle biopsy reveals more neutrophilic infiltrate and intracellular cysts containing the parasite, if seen, are diagnostic. Treatment is similar for CNS disease (see above).

A rare complication of the nucleoside reverse transcriptase inhibitor stavudine is HIV-associated neuromuscular weakness syndrome. Patients develop acute ascending weakness and respiratory failure over several days to weeks, with accompanying fatigue, abdominal pain, nausea, and vomiting. Weakness may be due to neuropathy, myopathy, or both. The clinical picture resembles Guillain-Barré syndrome, except for the accompanying systemic illness. Serum lactate is invariably elevated, and the mechanism is believed to be mitochondrial toxicity. Stavudine should be discontinued immediately and treatment is supportive. Prompt recognition in the early phase of this syndrome can result in marked improvement in the disorder which otherwise has high mortality.

62.7 General Issues

The optimal timing of initiating combination antiretroviral therapy has been an area of active research and ongoing debate. One issue is the possibility of worsening neurological outcome due to IRIS. Some argue that cART should be delayed until after specific antimicrobial treatment for opportunistic infections has obtained control of the infection, typically within 4-6 weeks. However, recent evidence suggests no difference if cART is started earlier. Although the evidence is mixed, a reasonable approach is to treat for any specific opportunistic infections for 2 weeks prior to initiating cART. For neurological infections, this primarily includes cryptococcal meningitis and toxoplasma encephalitis. Since PML and PCNSL have no effective specific antimicrobial therapy, cART should be initiated as soon as possible in these patients. An exception to this guideline is tuberculous involvement of the CNS, in which the risk for paradoxical worsening in the short term with cART is higher than for other opportunistic infections. For those with CD4 counts <100 cells/µl, cART should be started after 2 weeks of anti-Tb therapy. For those with higher CD4 counts (100-350 cells/µl), most recommend waiting until after the 2-month intensive phase of anti-Tb treatment before starting cART. For those with CD4 counts >350 cells/µl, cART may be delayed until Tb treatment is complete. For patients who develop CNS symptoms while on cART, this therapy should be continued and IRIS should be considered.

In addition to the neurological complications of HIV noted above, there are other important considerations in the neurological care of patients with HIV. Seizures are common in HIV, present in approximately 5-15% of HIV-positive patients. Conversely, patients with underlying seizure disorders – as from neurocysticercosis – may contract HIV. This poses particular challenges in treatment. Although data are limited, there does not appear to be any major effect of antiepileptic drugs (AEDs) on HIV or its course. AEDs, however, can have significant interactions with ART. Both the older AEDs (phenytoin, phenobarbital, carbamazepine, valproate) and certain antiretrovirals (protease inhibitors [PI's] > non-nucleoside reverse transcriptase inhibitors [NNRTIs] >> nucleoside reverse transcriptase inhibitors [NRTIs]) are significantly protein-bound and metabolized by the hepatic cytochrome P450 system.

Hence, while NRTIs may be safely co-administered with older AEDs, the use of protease inhibitors and NNRTIs with older AEDs poses the risk of increased AED toxicity due to protein displacement and enzyme inhibition, as well as subtherapeutic ART levels due to enzyme induction by the AEDs. When available, newer AEDs with effectiveness for the clinical context should be used when patients are taking concurrent ART. Levetiracetam, which has effectiveness in both generalized and partial seizures and is not hepatically metabolized or significantly protein bound, is a particularly useful agent in this situation.

62.8 Key Concepts

HIV infection can affect every part of the nervous system from focal brain lesions to inflammatory myopathy. The most frequent HIV-related syndromes seen in the ICU setting are focal brain lesions, diffuse encephalitis, and meningitis. In many instances, the neurological syndromes can be the presenting manifestations of AIDS. The accompanying symptoms and signs of systemic illness, such as weight loss, oral thrush or other systemic opportunistic infections and unexplained lymphopenia on routine blood count, provide clues to the diagnosis. Based on the clinical presentation, radiographic findings, and serological and antigen testing, the diagnosis is usually possible without resorting to biopsy. In cases where the clinical context so allows, an empiric trial of treatment for toxoplasmosis is reasonable given the usually quick response to treatment. If there is no response, other entities must be considered and sought aggressively.

Patients with advanced HIV may have more than one process occurring simultaneously, and typical presenting symptoms and signs may be lacking given the lack of immune activation. Furthermore, patients with HIV are also susceptible to neurological infections which occur in the immunocompetent host, in particular tuberculosis, syphilis, and neurocysticercosis. Once diagnosis is made in an ART-naïve patient, specific antimicrobial agents should be initiated in advance of ART to help avoid IRIS. In treating patients with comorbid HIV and epilepsy, newer AEDs pose less risk of harmful drug interactions.

The pathophysiology, diagnosis, and treatment of HIV-associated neurological disease are complicated and evolving. In this context, the increasingly recognized role of immune reconstitution in neurological disease should be considered in unusual cases. Consultation with infectious disease experts when possible is helpful to address the unique aspects of neurological complications in the setting of HIV, but the neurological intensivist should maintain a working knowledge of the most common and most devastating neurological manifestations of HIV and their treatment.

Frequent Problems

63 Cerebral Protection

Pablo Rama-Maceiras [1], **Óscar Pato López** [1]

[1] Department of Anesthesiology and Perioperative Medicine, Complejo Hospitalario Universitario A Coruña, A Coruña, Spain

63.1 Introduction

Acute brain Injury is due to several causes: traumatic brain injury (TBI), different medical conditions, such as subarachnoid hemorrhage (SAH), central nervous system infections or stroke, and some surgical procedures (mainly cardiothoracic, neurosurgical and vascular). Primary brain injuries can be divided into two major categories: focal injuries, stroke being the most representative example, and diffuse injuries, for instance patients who suffer coma following a cardiac arrest. In spite of considerable differences in clinical features and initial prognosis of primary lesions, all of them trigger a wide variety of secondary injuries, both at a systemic level (hypotension, hypoxemia, ventilatory and hydroelectrolitic alterations), and at a cerebral level (swelling, intracranial hypertension or seizures). These secondary injuries are responsible for the onset of ischemia.

Neurons are extremely sensitive to ischemia due to a low energy substrate disposal in the brain. Moreover, neuronal hypoxia-ischemia occurs not only because of cellular energy failure, but also because of the activation of the genetic transcription that contributes to apoptosis and inflammation, protein synthesis inhibition and oxidative stress. Consequences of neuronal ischemia vary from subtle neurocognitive deficits to catastrophic neurological morbidity. In any case, the result of the secondary injury is neuronal death, neurological deterioration and a worse functional outcome than those solely induced by the primary injury.

Cerebral protection can be defined as a set of interventions aimed at maintaining the integrity of neuronal interactions. In other words, it comprises any strategy, or combination of strategies, that antagonizes, interrupts, or slows the sequence of injurious biochemical and molecular events that, if left unchecked, would eventuate in irreversible ischemic injury [1]. This concept has been evolving as our knowledge of cerebral physiology and physiopathology has improved. Such knowledge is relevant to understanding the relevance of the interventions adopted, as well as the reasons why they are successful or not. **Neuroprotection** is the group of strategies applied before brain injury takes place, in order to modify the following cascade of events. The treatment that focuses on restoring normal homeostasis of cells already exposed to the insult is referred to as **neuro-resuscitation**. Although primary injury is often difficult to predict, cerebral protection should ideally be started before its appearance, and should be maintained during the phase of tissular reperfusion.

63.2 Pathophysiology of Brain Injury

Ischemia initiates a complex cascade of cellular events, encompassing many different pathways, that ultimately leads to irreversible tissue injury. It usually starts with rapid depletion of adenosine triphosphate (ATP) – which is synthesized by aerobic glucose metabolism –, and activation of anaerobic metabolism [2].

Extracellular liberation of excitatory mediators – mainly glutamate – is induced. These substances cause neuronal depolarization, via activation of N-methyl-D-aspartate (NMDA) and α-amino-3-hidroxy-5-methylisoxazole-4-propionic acid (AMPA) type of glutamate receptor, allowing calcium to enter the intracellular compartment. Dysfunction of ATP-sodium-potassium pumps facilitates this process. Water entering the cell together with sodium induces cytotoxic edema, while calcium acts as a coenzyme, and facilitates enzymes activation -proteases and lipases-, which are ultimately responsible for cellular membrane destruction and liberation of fatty acids, prostaglandins and thromboxanes.

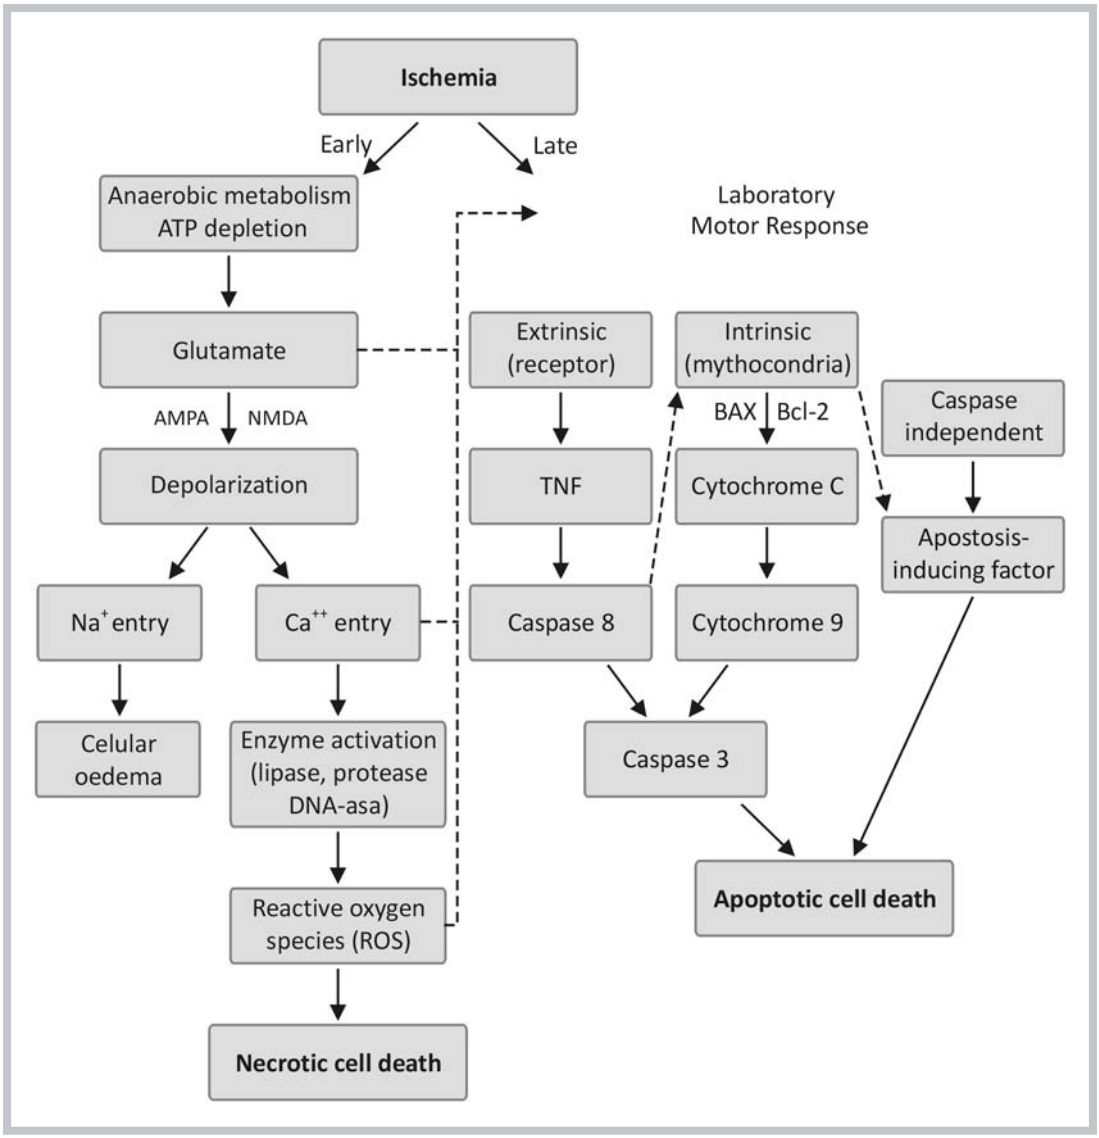

Figure 63.1. **Pathophysiology cascade of ischemic neuronal death associated to secondary brain damage.**

AMPA = α-amino-3-hidroxy-5-methylisoxazole-4-propionic acid type of glutamate receptors
ATP = Adenosin-triphosphate
BAX / Bcl-2 = pro and anti-apoptotic proteins in mytochondrial membrane
Ca^{++} = calcium
Na^{+} = sodium
NMDA = N-methyl-D-aspartate receptors
ROS = reactive oxygen species
TNF = Tumor necrosis factor

Oxidative stress is also induced by interrupting mitochondrial respiratory chain. It consists of an imbalance in the production and degradation of reactive oxygen species (ROS), which aggravates the ATP-sodium-potassium pump inhibition, lipid peroxidation, mitochondrial and cellular membrane disintegration, protein oxidation and nuclear DNA fragmentation.

The final result is cellular death due to necrosis (Figure 63.1). Activation of anaerobic metabolism generates acidosis, increasing neuronal damage. This type of cellular death is morphologically characterized by swelling and cellular pyknosis, karyolysis, cytoplasmic eosinophilia and inflammatory response [3].

Once ischemic insult ceases, perfusion is restored, and oxygen and glucose tissular deliveries are recovered. Nevertheless, reperfusion induces some adverse effects that worsen ischemic injury (largely the formation of more ROS). Moreover, a relative hypoperfusion state remains after reperfusion, due to platelet aggregation (mediated by thromboxane A2), calcium influx in endothelial cells (which causes vasoconstriction), cytotoxic edema, loss of red blood cells shape, and vasogenic swelling, generated by the blood brain barrier (BBB) disruption [4].

Free radicals and metalloproteinases (MMP) play a key role in the BBB alteration. The latter are synthesized by neutrophils, and alter the tight junctions which are present in the BBB. An initial disturbance of the BBB develops following an ischemic event. Such disturbance is usually repaired in the first 2 or 3 hours within reperfusion, and it may not be evident again until 24-48 hours later. This second disruption is related to vasogenic edema and haemorrhagic transformation in case of ischemic stroke, and has been associated with MMP-3 and MMP-9 [5].

Those strategies focused on interrupting or slowing down the aforementioned chain of events have a potentially protective role. In that sense, several techniques or pharmacological agents have demonstrated positive outcomes in neuroprotection, when evaluating short term histological parameters of neuronal loss (less than 15 days). On the other hand, many of those interventions failed to obtain a clinical benefit when evaluated at a longer term. This feature has lead to the discovery of a second pathway of ischemic neuronal death, which occurs at a later stage to necrosis. This pathway is more frequently present in the ischemia-penumbra areas. Ischemia is not critical enough to induce cellular necrosis in these penumbra areas; however a considerable degree of hypo perfusion may be still present. Apoptosis, a type of cellular death “genetically programmed”, is activated in these areas in response to stimuli as calcium, glutamate, ROS storage or ATP depletion. Important contributors to late apoptosis are cellular mitochondria and some enzymes, named caspases, which are ultimately responsible for that process [3].

This sort of cellular death is morphologically characterized by nuclear chromatine degradation, cytoplasmic and nuclear condensation and, finally, cellular fragmentation into “apoptotic bodies”. Apoptosis has also been described in functional cells, and it is originated inside the nucleus during certain cellular phases. Signals which trigger ischemic apoptosis include several pathways [6] (Figure 63.1):

- Intrinsic pathway, mediated by the mitochondria. It is characterized by cytochrome-C release, which activates caspase-9 that, in turn, activates caspase-3 and induces DNA fragmentation. This pathway can be early initiated, within 2 hours from onset of the injury, and it is modulated by mitochondrial membrane proteins, such as Bax (pro-apoptotic) or Bcl-2 (anti-apoptotic).
- Extrinsic pathway is characterized by receptor activation, mediated by binding molecules, such as tumor necrosis factor, which activates caspase-8 and this enzyme, in turn, activates caspase-3. Extrinsic pathway is established later than the intrinsic one.

- The third pathway is triggered by storage of anomalous proteins inside the endoplasmic reticulum. This phenomenon activates caspases 12 and 4, which are associated to caspase-3 activity.
- The fourth apoptotic pathway is caspase-independent. It is mediated by apoptosis induction factor, which is released in response to oxidative stress. This factor binds to DNA, promoting chromatine condensation and cellular death.

Apoptosis-mediated dead cells are phagocytized by cerebral microglia. This ends cellular death expansion and avoids response amplification. However, necrotic cells are phagocytized by macrophages, inducing a propagation reaction in the surrounding tissue. For some authors, changing from a necrotic cellular death to an apoptotic one could be a relevant cerebral-protective mechanism, due to its ability to control neuroinflammation spread. However, this is still a point of debate.

Observing this complex process of ischemic neuronal death helps us to understand some key issues. Firstly, different ischemia-mediated cellular death pathways are intimately related or at least, necrosis and apoptosis are. Secondly, strategies that seemed effective blocking necrotic cellular death may not be relevant in the long term with regards to patient outcome, since apoptotic mechanisms induce late cellular death (this is probably the case of anesthetics-mediated neuroprotection). Finally, it is difficult to imagine a single protective measure capable of slowing down all these events, or altering early features induced by ischemic cascade, owing to the fact that many patients arrive at the emergency area several hours after the onset of the ischemic injury.

In addition to negative effects, ischemia also activates repairing mechanisms. Thus, many processes which result harmful at one point in time can be beneficial at another. For instance, MMPs alter BBB in the early phases of an ischemic event, and therefore inhibition is beneficial at that moment. However they are associated with neurogenesis and angiogenesis later on, and consequently, late treatments based on MMPs-inhibitors might delay reparation mechanisms.

63.3 Cerebral Protection Goals

During early resuscitation, surgery or Intensive Care Unit (ICU) admission, our interventions in an acute brain injury, should focus on preventing and treating cerebral ischemia associated with secondary injury. The final purpose is to minimize cerebral damage and maximize neurological recovery. This objective is based on the fact that primary injuries – with the exception of those caused by some surgical procedures – are seldom predictable (traumatism, stroke, cardiac arrest, etc.) and thus, the initial damage cannot be avoided. Furthermore, secondary injury will decisively contribute to final neurological outcome unless effective neuroprotective measures are implemented. Finally, secondary injury consequences have probably been underestimated in the past. There is evidence supporting the hypothesis that cognitive dysfunction associated with mild cerebral injuries may be due to this secondary injury.

As well as precociousness, other factors seem to be of crucial importance for protective measures to be effective: intensity with which a treatment is applied (drugs given at different doses, levels of hypothermia, etc.), duration of the treatment, severity of primary injury and finally, injury extension – focal or diffuse. Moreover, neurons represent only 5% of cells in cortical grey matter, with glia and astrocytes being much more numerous. Accordingly, another field of interest is neuroprotection "beyond the neuron", focused on the so called "neurovascular unit" (neurons, muscular brain vessels cells, and support cells – astrocytes, oligodendrocytes and microglia).

Those strategies or treatments which have demonstrated major clinical impact and their applicability will be described hereafter, as well as clinical investigation lines which are currently being developed.

63.4 General Neuroprotection Strategies

Three different groups of neuroprotection strategies can be distinguished:
Neuronal loss reduction. This goal can be achieved by increasing tissular oxygen delivery and decreasing metabolic demands. Traditional neuroprotection was based on decreasing brain metabolism, i.e. administering high doses of barbiturates after an ischemic event. Nevertheless, this pathway is neither the only, nor the most relevant in order to establish neuroprotection. Consequently, other strategies aimed at modifying ischemic neuronal death cascades have been developed:

- Glutamate receptor inhibition (NMDA and AMPA).
- Gamma-amino butyric acid (GABA) system stimulation.
- Anti-inflammatory mechanisms.
- Apoptosis inhibition.
- Mitochondrial dysfunction prevention.
- Cellular hyperpolarization.

Ischemic preconditioning. It is an innate protective mechanism which reduces damage induced by ischemia-reperfusion. Basically, it consists of inducing cellular tolerance by provoking ischemic situations previous to a severe injury that otherwise would be lethal. It has been observed that patients who had suffered from transient ischemic events prior to a serious stroke showed better recovery than those who had not. Two different preconditioning types can be distinguished: early and late preconditioning. The former is developed within minutes to hours after the initial insult, and it is independent of protein synthesis, whilst the latter takes place between 12 and 24 hours after the preconditioning stimulus, lasts for 2 or 3 days, and depends on genetic regulation and protein synthesis.
Neuroprotection can be elicited by certain drugs such as inhaled anesthetics, opioids, adenosine, statins, etc.). They interfere with energetic cellular metabolism and are able to reproduce cellular responses similar to those occurring during preconditioning, such as vasodilatation, angiogenesis, neurogenesis reduction in energy consumption, antagonism of NMDA and AMPA glutamate type receptor [7].
Recently, two additional preconditioning pathways have sparked great interest. On the one hand, **remote preconditioning** can be elicited by applying brief periods of ischemia to tissues with ischemic tolerance, thus protecting vital organs more susceptible to ischemic damage. For instance, skeletal muscle ischemia is a potent preconditioning stimulus for heart and probably, for brain too [8]. It can be performed quickly and inexpensively, requiring only a blood pressure cuff applied in an arm or a lower limb. Some clinical trials are being carried out in order to test the neuroprotective effect of remote ischemic preconditioning on cardiac surgery (NCT 01231789) and for SAH (NCT01110239).
On the other hand, **postconditioning** entails brief ischemia periods (10 seconds approximately) applied during reperfusion and separated by 30-second intervals. It appears to be a promising strategy after myocardial ischemia, and its role in cerebral protection is being studied, since cellular injury mechanisms are similar. However, results in neuroprotection are less satisfactory than in the heart, so postconditioning might only be applicable to mild or moderate injuries. This fact might due to a greater cerebral sensitivity towards ischemia [9].

Neuronal reparation. It is mainly caused by a genetic upregulation, between 4 and 24 hours after reperfusion, which induces greater production of endothelial growth factor and erythropoietin (EPO). EPO stimulates neurogenesis in animal ischemia-reperfusion models, decreases neuronal damage and improves long-term cognitive outcomes. EPO and EPO-receptors have been detected throughout the central nervous system, as well as an increase in their levels following hypoxic events. EPO crosses BBB (despite a large molecular weight) and has a very interesting therapeutic window in ischemic events. Its effects involve several cellular levels in the brain: it increases tolerance to ischemia and regeneration of astrocytes, improves differentiation, regeneration and survival of neurons; increases regeneration of oligodendrocytes and preserves vascular regeneration as well as the integrity of the BBB following an ischemic vascular event [10].
GABA-A agonists, such as pregnanolone – a steroid with anaesthetic effects – and sevoflurane are other drugs with neuronal regeneration properties.

63.5 Concrete Strategies for Cerebral Protection

Global strategies for neuroprotection have been described in the section above. Nevertheless, from a practical point of view, it is more useful for physicians to know the potential and applications of measures at their disposal.

63.5.1 Control of Physiological Parameters

At present, this is probably the best modality of cerebral protection [11]. Control and maintenance of arterial pressure, oxygenation, hydroelectrolitic balance and CO_2 exchange are key points for final outcomes in several neurocritical pathologies; regardless of whether they are focal or diffuse. However, there is less clear evidence that ideal values of these parameters should be generalized for all patients. That is the reason why cerebral monitoring represents a helpful complement. Neuromonitoring – cerebral perfusion pressure (CPP), jugular bulb oxygen saturation (SjO_2), tissue oxygen pressure ($ptiO_2$), transcranial Doppler, cerebral microdialysis, electroencephalography, etc. – should be used, where possible, according to each patient's pathology, in order to optimize physiological parameters. Since the development of specific neurocritical ICUs has been shown to improve the prognosis of many of these pathologies when compared with general ICUs, admitting neurocritical patients into specialized units could be considered a neuroprotective measure.

Hypoxemia and Hypotension

Hypoxemia and hypotension during the acute phase of cerebral injury are associated with poor prognosis and should be treated aggressively [12]. Oxygen therapy should be focused on maintaining normal oxygenation ranges (SpO_2>94%) as hyperoxia during reperfusion may stimulate ROS synthesis and oxidative stress. Hyperoxia has also been shown to reduce lactate levels in cerebral microdialysis, but not the lactate/piruvate rate, which is a more reliable indicator of the energetic state. In addition, lactate may be used as an energetic substrate in case of severe metabolic depletion in the brain. These findings explain why hyperoxia may be harmful in this setting.
Hypotension induces a global reduction in CPP and cerebral blood flow. The initial objective should be to maintain CPP within a target range of 60 to 70 mmHg. Excessive fluid administration may be harmful, due to increased cerebral swelling in case of BBB disrup-

tion. Furthermore, arterial hypertension may contribute to vasogenic cerebral swelling in the case of cerebral autoregulation abnormalities, which are frequently established following severe acute injuries. Nevertheless, mild hypertension may be recommended after SAH secondary to cerebral aneurysm rupture, once endovascular coiling or surgical clipping has been performed, in an attempt to avoid vasospasm [13].

Control of arterial blood pressure may reduce cerebral swelling and the risk of hemorrhagic transformation following stroke. Nevertheless, this effect must be balanced against the risk of decreasing perfusion in the penumbra areas. Antihypertensive treatment is discouraged for patients who are non-candidate for thrombolytic therapy, unless diastolic blood pressure is above 120 mmHg or systolic above 220 mmHg. Anti-hypertensive drugs are recommended for patients following thrombolytic treatment, within the first 24 hours, if diastolic or systolic blood pressure are above 110 or 185 mmHg respectively [14]. Despite the lack of clear evidence in spontaneous cerebral hemorrhage, recent studies suggest that maintaining systolic blood pressure below 140 mmHg may reduce hematoma growth [15].

Fluid Management and Transfusion

As a rule, normovolemia is the therapeutic target and, in any case, hypovolemia and hypo-osmolarity should be avoided. Since the brain is very sensitive to secondary injury induced by ischemia, anemia should also be avoided. Hemoglobin levels of 7-8 g/dl appear to be safe for stable patients. On the other hand, acute patients may have a reduced tolerance to anemia. In those cases, the risk-benefit ratio of blood transfusion versus anemia should be assessed [16].

Recent studies have suggested that anemia can foster protective responses in the brain, mediated by ischemic preconditioning, EPO release, β2-adrenergic stimulation, and nitric oxide synthase; but these hypotheses still need clinical confirmation [17]. Monitoring can help in taking individualized decisions for these patients regarding transfusion therapy. Some coexisting diseases (such as coronary disease) may also affect the transfusion threshold.

Concerning osmotic treatment, mannitol is still the most used drug for neurocritical patients, particularly for treating intracranial hypertension [18]. Hypertonic saline solutions are a point of debate: they improve hemodynamic and blood viscosity, reduce endothelial swelling and capillary resistance, but they may cause renal failure, rebound intracranial hypertension, coagulopathy, hypervolemia and electrolytic disturbances [19].

Ventilation

Neurological patients frequently need mechanical ventilation, sometimes for long periods. Ventilation strategies should be aimed at maintaining an adequate gas exchange, minimizing the risk of ventilation-associated lung injury. Cerebral vessels are sensitive to extracellular pH changes caused by ventilation, thus in the range of a $paCO_2$ of 20 to 60 mmHg, cerebral blood flow varies about 3% per mmHg of $paCO_2$. Hypercapnia causes cerebral vasodilatation and, consequently, an increase in cerebral blood volume and blood flow, as well as in intracranial pressure. Hypocapnia (hyperventilation) induces the opposite effects; however, the possibility of critical reductions of blood flow in areas at risk of ischemia should be taken into account. Hyperventilation is effective during brief periods, because extracellular pH tends to normalize a few hours after its instauration, and a rebound phenomenon can even develop once intentional hypocapnia has ceased. After acute neurological injuries, normocapnia is generally recommended, with short periods of hypocapnia in case of severe neurological compromise, whenever unrespon-

sive to other therapies, and preferentially guided by cerebral oxygenation monitoring (SjO_2, $ptiO_2$) and/or microdialysis. Reducing ventilatory dead space, avoiding patient fight against the ventilator, checking permeability of orotracheal tube and procedures directed at increasing lung compliance (i.e. evacuating pleural effusions or severe ascites) are relevant issues for maintaining normocapnia. Hypercapnia is counterproductive and, basically, it should be avoided [20], although some recent investigations have suggested some neuroprotective effects of mild hypercapnia after global cerebral ischemia, possibly via the activation of the hypothalamic-pituitary-adrenal axis, exertion of anti-inflammatory and antioxidant effects, and release of neurotransmitters. However, the real role of hypercapnia in brain injuries remains to be clarified, since deleterious effects may outweigh the possible benefits [21].

There is controversy regarding the use of protective ventilation in patients with neurological injuries, based on a low fraction of inspired oxygen, low tidal volumes and high positive end-expiratory pressure (PEEP). This pattern is often associated to hypercapnia and decreased venous return – the latter mediated by high intrathoracic pressures –, both of which may increase intracranial pressure. PEEP can provide cerebral benefits when its value is lower than intracranial pressure and it enhances pulmonary compliance, thus improving CO_2 exchange -via alveoli recruitment- and contributing to cerebral blood flow redistribution (mainly venous). Nevertheless, if PEEP provokes pulmonary overdistension, the net effect can be deleterious [12]. In case of "conflict of interest" between the brain and the lung, putting cerebral protection before protective ventilation is highly recommended [22].

Glucose

Hyperglycemia could simply be a marker of severity of the brain injury; however, without an adequate oxygen supply, its presence increases anaerobic metabolism thus generating acidosis and worsening ischemic injury. Some clinical trials carried out in critical care populations showed a lower intracranial pressure, fewer complications and even lower mortality, when comparing a tight control of glucose blood level versus a liberal one. Whether glucose value *per se* is more relevant than the insulin administered to maintain that glucose blood level is still controversial, and so is the ideal glucose value (microdialysis patterns characteristic of metabolic neuronal suffering have been observed in patients with glucose levels considered normal in other critical patients) [23]. The glucose threshold in neurocritical patients might be about 140 mg/dl but no definitive data are available on this point.

63.5.2 Therapeutic Hypothermia

Despite not being a drug, it is considered a medical treatment. Its protective effect is beyond decreasing metabolic requirements since it reduces extracellular acidosis, swelling and the release of excitatory aminoacids and free radicals. Besides, it may play a role in repairing BBB integrity, reducing apoptosis and eliminating intracranial gradients of temperature [24]. Cerebral temperature is usually 1°C above core temperature, but differences up to 2°C among different areas of the brain can be observed [25].

Clinical benefits derived from hypothermia probably depend not only on the type of neurological pathology, but also on the precociousness and speed of cooling, the temperature achieved (the protective effect seems to disappear above 35°C, and the complications rate increases below 32°C), the method used for cooling, the duration of hypothermia – which should be guided by clinical targets such as the control of intracranial pressure – and finally, the rewarming rate (much of the benefit can be lost if the patient

is rewarmed too fast, independently of the nature of injury) [26]. Therefore, the experience of the centre where therapeutic hypothermia is instituted may be a critical factor.
Mild to moderate hypothermia (33-34°C) in comatose survivors of out-of-hospital cardiac arrest, induced within hours of resuscitation and maintained for 12-24 hours, has demonstrated a reduction in mortality [27]. One meta-analysis showed that the number of patients needed to be treated (NNT) in order to prevent one death was 6, and NNT in order to obtain an optimized neurological recovery was 7. According to this evidence, the 2010 American Heart Association guidelines for cardiopulmonary resuscitation and emergency cardiovascular care included the following recommendations [28]:

- Comatose (i.e., lack of meaningful response to verbal commands) adults patient, with return of spontaneous circulation (ROSC) after out-of-hospital ventricular fibrillation cardiac arrest should be cooled to 32°C-34°C for 12-24 hours.
- Induced hypothermia may also be considered for comatose adult patients with ROSC after in-hospital cardiac arrest of any initial rhythm or after out-of-hospital cardiac arrest with an initial rhythm of pulseless electric activity or asystole.
- Active rewarming should be avoided in comatose patients who spontaneously develop a mild degree of hypothermia (>32°C) after resuscitation from cardiac arrest during the first 48 hours after ROSC.
- Patient core temperature should be closely monitored after ROSC and interventions should be performed to avoid hyperthermia.
- Additionally, the 2010 European resuscitation council guidelines for resuscitation stated that a child with ROSC but remaining comatose after cardiopulmonary arrest might benefit from being cooled to a core temperature of 32-34°C for at least 24 h. The successfully resuscitated child with hypothermia and ROSC should not be actively rewarmed unless the core temperature is below 32°C. Following a period of mild hypothermia, the child should be rewarmed slowly (at 0.25-0.5°C/h) [29].

Moderate whole-body hypothermia (rectal temperature of 33.5-34.5°C) for 72 hours in term neonates with clinical and electrophysiological evidence of perinatal hypoxic-ischemic encephalopathy attributable to perinatal asphyxia showed a strong neuroprotective effect [30], and substantially – although incompletely – reduces neurological disability [31]. Hypothermia must be started within 6 hours of birth and rewarming should last at least 4 hours
The NABISH study, one of the biggest trials run on moderate hypothermia (32.5-34°C), failed to demonstrate either reduction of mortality or functional improvement in adult patients suffering from severe TBI, except for the subgroup of patients younger than 45 who were hypothermic on admission [32]. The recently published NABISH II clinical trial, which evaluated moderate early hypothermia (33°C) for 48 hours in adults younger than 45, has been cancelled without completion of the estimated sample size due to futility, although the subgroup of patients with drainable mass lesions might benefit for hypothermia effect [33].
The methodology of the NABISH trials has been criticized, especially by those who claim that hypothermia contributes to better outcomes provided that it is used with a concrete therapeutic goal (i.e., control of intracranial pressure), without a pre-established duration and checking adverse effects. A systematic literature review concluded that there may be a trend to therapeutic benefits when using hypothermia in patients with severe head injury, but the recommendations are not strong enough due to a lack of studies with adequate methodological quality. The Cochrane Collaboration corroborated these findings [34] and showed an increased rate of pneumonia in TBI patients treated with hypothermia, especially when it was associated to barbiturates. Results for pediatric severe trauma are also contradictory: it appears to improve intermediate outcomes, such as intracranial pressure or cerebral edema, but it has not shown any definitive benefit in

terms of survival. Regarding spinal cord injury, there is not clear evidence to recommend for or against the practice of therapeutic hypothermia as a treatment [35]
Indeed, one of the major limitations of hypothermia as a therapeutic measure is the development of complications, especially infectious ones, but also thrombocytopenia, acidosis, insulin resistance, and pancreatitis, which appear to increase the deeper and the longer the hypothermia is. Consequently, physicians should be aware of these complications and treat them early. At present, at least two large randomized clinical trials for evaluating hypothermia in severe TBI patients are being developed: one in Japan and the European Eurotherm trial. Their results will clarify the role of hypothermia as a cerebral protective measure in this disease.
Concerning stroke, current evidence for hypothermia is still scarce and limited to case series and pilot studies. In these patients, hypothermia presents another limitation to its use, as most of them are conscious at the time of hospital admission and do not tolerate cooling. Furthermore, whether or not the association of hypothermia with fibrinolytic therapy enhances neuroprotection is currently being studied [24].
As far as HSA treatment and surgical aneurysm clipping are concerned, a clinical trial which included 1001 patients (IHAST trial), failed to demonstrate any benefit of intraoperative hypothermia in terms of mortality or neurological recovery. Moreover, an increase in the rate of bacteriemia, close to statistical significance, was found in the hypothermia-treated group, discouraging routine use for this indication [36].
Leaving aside the possible beneficial effect of hypothermia, it seems that hyperthermia in patients with neurological injuries is detrimental. Fever increases metabolic rate, triggers the release of excitatory aminoacids and free radicals, and aggravates the damage of the BBB and proteolysis of cellular cytoskeleton. Besides, fever duration influences both vital and neurological prognosis. Therefore fever should be prevented and treated [37], although each type of injury may have an optimal time-window for fever control.
Because we need a balance between limiting secondary injury and impairing the ability to fight against infections, it seems reasonable to control fever aggressively during the first hours to days after spinal cord injury, intracerebral hemorrhage and TBI. In SAH patients the risk period for hyperthermia consequences is more prolonged, since fever can favour vasospasm even some weeks after the hemorrhage [25]. Pharmacologic interventions (mainly acetaminophen), external cooling, maintaining infections surveillance and avoiding shivering can be an appropriate approach to fever prevention and management.

63.5.3 Thrombolysis, Anticoagulants and Antiplatelet Drugs

The main priority in the treatment of stroke is restoring normal cerebral blood flow. The only widely accepted treatment is reperfusion, mediated by intravenous administration of recombinant tissue plasminogen activator (r-tPA) at a dose of 0.9 mg/kg, with a maximum of 90 mg (10% administered as a bolus and the remainder as a continuous infusion for 1 hour). Nevertheless, few patients admitted to hospital with stroke may benefit from reperfusion due to the strict inclusion criteria for therapy that excludes the majority of patients from effective therapy [38] (Table 63.1).
Despite improvement in care after reperfusion, experimental and clinical data indicate that the benefits of thrombolysis with r-tPA are limited due to the narrow therapeutic range. The earlier the treatment is administered, the more effective it is. It has been approved for use within 3 hours from stroke onset. It should neither be given neither more than 4.5 hours after onset, nor in cases of extensive infarctions involving the middle cerebral artery. Elderly patients (>80) also benefit from thrombolysis, although they showed worse outcomes after the treatment than younger patients [39].

Inclusion criteria	Exclusion criteria
• Ischemic stroke with specific start point • Measureable neurological damage • Radiologic evidence ruling out hemorrhage	• Stroke or severe traumatic brain injury in the previous 3 months • Major surgery in the previous 14 days • Previous history of intracranial hemorrhage • SBP >185 mmHg or DBP >110 mmHg • Symptoms suggesting subarachnoid hemorrhage • Digestive bleeding or gross hematuria in the previous 21 days • Non-compressive arterial puncture in the previous 7 days • Seizures as the initial clinical presentation of stroke • Increase in aPTT, PT >15 seconds or INR >1.4 • Platelet count $<100x10^9/mm^3$ • Glucose blood level below 50 mg/dl or above 400 mg/dl

Table 63.1. **Criteria for intravenous tissue plasminogen activator administration after stroke.**

aPTT = activated partial thromboplastin time
DBP = diastolic blood pressure
INR = international normalized ratio
PT = prothrombin time
SBP = systolic blood pressure

Patients must be monitored intensively at least 24 hours after thrombolysis. Cerebral hemorrhage is the main adverse effect (6.4% versus 0.6% of patients not receiving r-tPA). If thrombolysis is delayed, the risk of bleeding increases, especially more than 3 hours after stroke, although, mortality does not appear to increase. Induced upregulation of MMP-9 alters BBB, facilitating bleeding. Despite these adverse effects, NNT of r-tPA to produce significant improvement in functional outcome is 3, while NNT to cause damage is 30 [40]. Induced hypothermia may have a preventive effect on hemorrhagic conversion after r-tPA administration, although results of studies in this regard are not conclusive; as well as minocycline, which reduces the activation of microglia and cytokines production, and inhibits MMPs. In the event that bleeding is suspected, r-tPA should be stopped (if still running) and CT-scan should be performed, as well as a blood cell count and a coagulation test. In addition to platelets, fresh frozen plasma or cryoprecipitate must be available. If CT-scan rules out hemorrhage, r- tPA infusion can be restored. When cerebral hemorrhage is confirmed, laboratory tests must be checked, plasma and platelets must be administered, and the neurosurgeon must be alerted.

Another relevant adverse effect of r-tPA is orolingual angiedema (5%). Antihistamines and corticosteroids may be effective in this case. Finally, it may have neurotoxic potential due to the activation of glutamate receptors, especially in astrocytes.

Use of anticoagulants is not recommended for stroke, except in cases of cerebral venous sinuses thrombosis. Unfractionated heparin is indicated for this particular condition during the acute phase, even in the presence of hemorrhagic infarction, continuing treatment with vitamin K antagonists for up to 12 months and maintaining an international normalized ratio (INR) of 2.0-3.0. In those patients suffering a stroke, who are not candidates for thrombolysis, antiplatelet drugs may be used. Acetylsalicylic acid at doses of 300 mg reduces the recurrence of ischemic stroke without increasing bleeding risk. Due to lack of evidence, neither clopidogrel nor platelet receptors inhibitors IIb/IIIa (e.g. abciximab) are recommended. After non-cardioembolic stroke, preventive treatment with an antiplatelet agent is encouraged. In cases of atrial fibrillation in patients who have suffered stroke or recent transient ischemic attack, anticoagulation (INR 2.0-3.0) is recommended. If anticoagulation is contraindicated, aspirin 75-325 mg a day may be a valid alternative. In patients with mitral valve prolapse and transient ischemic attack or stroke, antiplatelet therapy is encouraged.

Antiplatelet agents and intrathecal fibrinolytic agents have also been tested in SAH in order to reduce the risk of delayed cerebral ischemia secondary to vasospasm, although current evidence does not support the routine administration of these drugs [41,42].

63.5.4 Anesthetics

Anesthetics have the potential to reduce cerebral metabolism. In this respect, the mechanism of action of barbiturates, propofol or halogenated inhalational agents (isoflurane, sevoflurane, desflurane) is based on enhancing GABA stimulation – which is the main inhibitory neurotransmitter in the brain –, and counteracts the deleterious effects of glutamate. Nitrous oxide, ketamine and xenon act by inhibiting the NMDA receptor, which mediates the effect of glutamate. Thiopental and propofol may also act by reducing free radicals; and the latter exerts antiapoptotic and anti-inflammatory properties [43].
When administered before an ischemic event, and given at usual clinical doses, anesthetics can contribute to preconditioning, by opening potassium channels, thus hyperpolarizing the cell.
Thiopental is still considered the anesthetic benchmark in terms of protection, being the only one to have demonstrated neuroprotective efficacy in a clinical trial. That study included patients who underwent heart valve surgery with cardiopulmonary bypass [44]; but the result could not be replicated in other surgical populations or in patients who had suffered a cardiac arrest. Barbiturates are used for cerebral protection in many circumstances, including trauma, stroke, carotid endarterectomy and even the clipping of cerebral aneurysms, although benefits are not as obvious as it was thought in the past. Moreover, their use delays postoperative recovery and has immunosuppressive effects, due to which interest in these agents has declined.
Many authors support the effectiveness of anesthetics in neuroprotection based on two facts: firstly, the reduced incidence of stroke occurring during the intraoperative period. Secondly, the effectiveness of anesthetics in the prevention of neuronal death by necrosis and to a lesser extent, to apoptosis, has been demonstrated at an experimental level. Nevertheless, critics argue that these results have not been clinically proven yet, and that anesthetics may promote neuronal degeneration and apoptosis by altering the GABA-glutamate balance needed for an adequate neuronal maturing. More conciliatory positions suggest that anesthetics delay neuronal death by enhancing the ischemic threshold, thus they may be effective in protecting against mild brain damage and, in any case, they can increase the margin of time in order to implement other protective measures [3].
Lidocaine, administered at usual antiarrhythmic doses (1 mg/kg bolus and infusion at 1-2 mg/h), acts by blocking sodium channels which, added to its inhibitory effects on cerebral metabolism and leukocytes activation, confers neuroprotective potential. However, results in clinical trials, basically in cardiac surgery, have not been conclusive [45].

63.5.5 Corticosteroids

Corticosteroids exert anti-inflammatory properties and stabilize membranes; decrease brain edema and foster regeneration of the BBB. However there is only evidence of neuroprotective effectiveness in the peritumoral brain edema (mainly metastatic), in bacterial meningitis (mainly in children) and probably in tuberculosis meningitis [46].
The Cochrane Collaboration reviews have shown a lack of protection of corticoids after an acute ischemic or hemorrhagic stroke, although a recent trial has suggested an improvement in the functional outcome after SAH for patients receiving 16 mg/kg of meth-

ylprednisolone for three days [47]. In TBI, the CRASH trial had to be cancelled after the randomization of 10,000 patients (half of the estimated sample size), because one interim analysis reflected an increase in mortality for those patients receiving high doses of methylprednisolone, compared to those receiving placebo [48].
Concerning traumatic spinal cord injury, the NASCIS trials concluded with this recommendation: "Early administration of high doses of methylprednisolone (30 mg/kg bolus in 30 minutes + 5.4 mg/kg/h) for 24-48 hours can be used, considering that related complications might overcome anticipated benefits of this treatment" [49].
However, we should not confuse the protective and the therapeutic role of steroids. One systematic review of the literature suggests that pituitary dysfunction after TBI and SAH occurs about 27.5% and 47% respectively, although most of them can go unnoticed. The most common deficits are growth hormone and ACTH related. Diagnosis is based on stimulation tests, which are often not feasible in the neurocritical patient. However, cortisol basal levels can even be obtained in the acute phase of the injury. Cortisol levels below 7.2-18 μg/dl (200-500 mmol/l), when associated to adrenal gland deficit signs and symptoms (such as hyponatremia, hypoglycemia or hypotension), can be inadequate, and those patients might be good candidates to receive steroid therapy [50]. Finally, we should not forget that steroid therapy is considered an independent risk factor for the development of hyperglycemia, myopathies and critical patient neuropathy, which suggests that corticosteroids may have a harmful role for the Peripheral Nervous System.

63.5.6 Calcium Channel Blockers and Magnesium

Calcium channel blockers mainly exert their effect through decreasing the contraction of the vascular smooth muscle, promoting vasodilatation, increasing cerebral blood flow and avoiding vasospasm. Vasospasm is closely linked to the development of delayed ischemic deficits after a brain injury. Nimodipine 60 mg/4h per os has been associated to a decrease in vasospasm and improvement in the outcome of patients after SAH, with few side effects [51]. Nimodipine effectiveness has also been shown in patients suffering vasospasm after TBI, although the evidence is weaker in this pathology.
Most brain injuries are associated to low serum levels of magnesium and the benefit of maintaining blood values over 1.5 mmol/l for this group of patients has been proposed. On the one hand, magnesium acts by blocking glutamate in the NMDA receptor, lowering intracellular calcium concentration, and thus limiting enzyme activation and ischemic cellular necrosis. On the other hand, it enhances nimodipine action, and inhibits platelet aggregation and ROS liberation.
The effectiveness of magnesium sulphate was evaluated in the IMAGES trial, involving 2,589 patients, who were treated with magnesium or placebo in the following 12 hours after an acute ischemic stroke. After 90 days, there were no differences between groups in mortality or neurological recovery, even in the subgroup of patients treated in the first 6 hours after the stroke [18]. FAST-MAG trial, to evaluate field initiation (within 2 hours) of magnesium sulphate neuroprotective therapy after acute stroke (16 mmol over 15 minutes + 65 mmol over 24 hours) has reached 75% of enrolment by the end of May 2011 [52].
For patients suffering SAH, there is some evidence that after treatment of the aneurysm, daily intravenous infusion of 64-96 mmol of magnesium (8-12 g) for 14-21 days decreases the number of 90 days-delayed ischemic deficits and improves functional recovery, although no effect has been proven in terms of mortality [53]. However, the recently published data of the IMASH trial, which compared magnesium sulphate infusion

with placebo do not support a clinical benefit of magnesium sulphate infusion over placebo [54].
Regarding TBI, one recent trial involving more than 500 patients assessed the administration of magnesium in the first hours after injury. No benefit has been shown with magnesium treatment, and even those patients receiving higher doses of the drug developed a worse functional outcome. Currently there is no evidence to support the use of magnesium salts in patients with TBI [55].
Magnesium neuroprotective effects have been also tested in patients at risk for preterm delivery. The available evidence suggests that magnesium sulphate given before anticipated early preterm birth reduces the risk of cerebral palsy in surviving infants. Ideal candidates [56] and the dose regimen remain still unclear [57].
Magnesium related adverse effects are scarce: muscular weakness, areflexia, bradycardia and hypotension when magnesium blood level is over 3-5 mmol/l have been described. Minor reactions, such as pain on injection or nausea are more frequent, but they can be avoided by diluting the drug (<0.5 mmol/ml) and administering it slowly (<30 ml/h).

63.5.7 Statins

Statins are 3-hydroxy-3-methylglutaryl co-enzyme A (HMG-CoA) reductase inhibitors used in the prevention of cardiovascular diseases and atherosclerosis associated to hypercholesterolemia, and they show high affinity with the enzyme about 1000 times higher than the natural particle HMG-CoA [18].
Statins treatment seems to develop protective properties in strokes, especially for high-risk patients (those with coronary artery disease, diabetes or hypertension). In a recent meta-analysis, a reduction of 21% of these events has been shown. These data have increased the interest in this group of drugs as neuroprotective. Several mechanisms have been proposed to explain this protective effect. Lipid metabolism effects, especially reduction in LDL lipoproteins and cholesterol have been associated to a reduction in the vascular wall thickness and platelet aggregation. Besides, statins cause an up-regulation in the endothelial nitric-oxide synthase, and they inhibit the activation in astrocytes of inducible nitric-oxide synthase, which exerts neurotoxicity. They enhance the activation of the plasminogen tissular activator and the inhibition of the plasminogen inhibitor, decreasing hypercoagulability states. Lastly, they exert antioxidant and anti-inflammatory properties, as well as fostering regeneration and neuronal plasticity by mobilizing endothelial stem-cells [58].
Due to this potential, these drugs are being tested in several studies. Recent evidence across phase II studies suggest a reduction in the incidence of vasospasm, and better outcome, after the administration of pravastatin 40-80 mg for 14-21 days after SAH. One recent meta-analysis dealing with statins therapy for SAH concludes that they reduce the incidence of vasospasm, with a NNT of 6.1 patients; the incidence of delayed ischemic deficits related to vasospasm (NNT of 5.0), and even mortality (NNT 6.7). The authors of this meta-analysis recommend the administration of statins to all patients, after SAH, where there is no contraindication, although there is a lack of knowledge of the ideal treatment length [59]. However, the small number of patients included in this meta-analysis (158) suggests that before extending statins administration on this indication, we should wait for the results of the large STASH trial, which is currently running. It seems suitable to maintain statin therapy in those patients previously taking these drugs, when admitted with acute neurological damage, especially in those patients suffering hemorrhagic or ischemic strokes.

Several adverse effects of statins have been described, but only liver enzymes elevation and myopathies seem relevant. These effects are mainly produced in elderly patients, those with liver failure or hypothyroidism, and those taking fibrates, cyclosporine, and antifungal drugs containing the azolic ring, macrolides, verapamil, diltiazem or amiodarone.

63.5.8 Erythropoietin (EPO)

EPO and its receptor are expressed in almost all cells within the Central nervous System. EPO improves tolerance to ischemia due to anti-apoptotic and preconditioning properties; acts as a free-radical scavenger of ROS and suits cellular regeneration. Weekly subcutaneous injection of 40,000 UI of EPO up to three doses is being tested in a phase III trial in TBI patients (NCT00987454). A German phase II study has shown positive results after the administration of recombinant EPO 33,000 IU/day for three days in stroke patients [60], but these results have not been confirmed in a subsequent trial using 40,000 IU/day for three days, and even mortality was increased in the EPO arm of the trial [61]. Three doses of 30,000 IU every 48 hours were associated with a reduction in the incidence of severe vasospasm and in the development of delayed ischemic deficits compared to placebo in patients suffering SAH [62], but 6 months outcome was not different between groups. Younger patients taking statins simultaneously seemed to get the most benefit from the EPO protective effect [63].

EPO studies are also being carried out after perinatal hypoxic encephalopathy. There seems to be a positive effect after the administration of 300-500 IU/kg of EPO every 48 hours for two weeks in terms of the neurological outcome; however, these results are awaiting confirmation in phase III studies.

Overall, high and repeated doses seem to be associated to better results in terms of neuroprotection, because of the low capability of EPO for BBB penetration. Potential thrombotic adverse effects of high doses of this drug, through an increase in blood viscosity and platelet activation, might stop the development of this treatment. That is why we cannot recommend the systematic administration of EPO for neuroprotection while waiting for the results of larger randomized clinical trials. Development of new recombinant forms of EPO, free of the hematopoietic properties might minimize side effects of this drug [64].

63.5.9 Antiepileptic Drugs

Seizures can be included in the clinical presentation of several injuries in neurocritical patients. Seizures worsen secondary brain injury because they increase oxygen consumption and intracranial pressure, and can impair the outcome, as well as delay recovery [65]. An electroencephalogram should be performed to every patient with high suspicion of seizures, and should be considered in patients without improvement in the level of consciousness after a neurological event, to rule out non-convulsive status epileptic.

Every clinical condition and even every patient needs an individual evaluation to start antiepileptic treatment. As a rule, we can say that prophylaxis or treatment is indicated for patients with witnessed seizures, or patients with high risk of development of seizures. However we should neither establish prophylactic treatment systematically to all neurocritical patients, nor extend treatment, since short-term adverse events and long term cognitive dysfunction associated to antiepileptic drugs, may overcome benefits of the treatment in low risk seizures patients.

Antiepileptic drugs can be used in addition to hypothermia in children with hypoxic perinatal encephalopathy.

63.5.10 Other

Several other drugs are being studied in order to evaluate their role as neuroprotection agents. Some examples are:

- **Caspase inhibitors**. Caspases are the enzymes in charge of apoptosis mechanisms. Minocycline and dexamethasone can act at this level. Promising results have been obtained with minocycline [66], and there are at least three clinical trials under investigation to evaluate its effects after an acute ischemic stroke.
- **Prevention of mitochondrial dysfunction**. The role that experts give to mitochondria in the maintenance or derangement of the cellular structure is becoming more and more relevant. Cyclosporine A might preserve the integrity of the transitional pore in mitochondrial membrane, avoiding the entry of calcium, edema and destruction. The optimal dose seems to be 2.5 mg/kg over two hours followed by a continuous infusion of 5 mg/kg/day for 72 hours [67]. Phase III studies with cyclosporine A are currently being developed in severe TBI. Voltage dependent calcium channel blockers may also act at the mitochondrial level, and they are being tested in some experimental studies.
- **Scavengers of free radicals**. After the failure of clinical trials with tirilazad [68] and NXY-059 [69] in patients with stroke, there are other promising scavengers being studied, such as edaravone and albumin, which in addition might decrease cerebral edema after an ischemic event. Its protective effects is being currently tested in the ALIAS trial (NCT 00235495), comparing 2.0 g/kg of iv albumin 25% and equivalent volume of saline control, infused over 2 hours, started within 5 hours of stroke onset [70].
- **Female hormones**. Oestrogens might inhibit apoptosis and promote vasodilatation, improving blood flow. Progesterone may improve brain edema by collaborating in the repair of the BBB, upregulating GABA receptors and inhibiting apoptosis. Current clinical evidence from three small randomized clinical trials indicates progesterone may improve the neurologic outcome of patients suffering TBI [71]. This evidence is still insufficient, and a multicentre, randomised double blind study is currently underway (NCT00822900).
- **Nitric oxide and nitric oxide synthase inhibitors**. Nitric oxide is produced from L-arginine, through different types of nitric oxide synthase (inducible, endothelial and neuronal), and plays a key role in the regulation of vascular tone. High concentrations of nitric oxide may be excitotoxic, damaging DNA and promoting apoptosis, as well as ROS. Therefore, blocking the inducible form of nitric oxide synthase may be beneficial.
- **Antagonism of bradykinins**. After cerebral damage, inflammatory kinins are released, worsening secondary brain damage. Therefore, blockade of bradykinin B2R might represent a therapeutic approach in the pharmacological treatment of TBI, however, there is no reliable evidence that B2R antagonists are effective in reducing mortality or disability after TBI, although well-designed randomized clinical trials are needed [72].
- **Neurotransmitters blockade**, neurotrophic factors and some proteins of coagulation cascade are also neuroprotective targets, which are being investigated in different pathologies.

63.6 Cerebral Protection in Cardiovascular Surgery

Patients undergoing cardiac surgery have a considerable risk of neurological injuries, due to embolic strokes, and the inherent risks of cardiopulmonary bypass, which is associated to hypoperfusion, ischemia-reperfusion injury, cellular edema and cerebral swelling. Stroke after cardiac surgery is below 1% in patients younger than 65 years old under coronary bypass, about 5% in patients between 65 to 75, and 7-9% in those above 75.

About 30-40% of cardiac surgery patients develop postoperative cognitive dysfunction several weeks after the surgical procedure. Apart from previous cerebral vascular diseases, advanced age and female sex are well known, but unmodifiable risk factors for neurological complications. Protective approaches in this setting are based on reducing sources of damage (embolism and hypoperfusion), as there is no current evidence of the effectiveness of any neuroprotective drug. Barbiturates have been the only agents showing protection in a randomized clinical trial, the methodology of which has been questioned [45].

The incidence of stroke for patients younger than 60 years old, undergoing aortic arch surgery is about 1%, but it rises to 20% in older patients. The traditional approach to brain protection used in this surgical procedure was deep hypothermic circulatory arrest (≤20°C). Brief periods of circulatory arrest (less than 20-25 minutes preferably) and deeper hypothermia improve the effectiveness and safety of this technique without the development of neurological damage in most patients. Rewarming must also be carefully carried out, taking at least 20-30 minutes to complete, and avoiding hyperthermia.

Alternatives that are more recent allow an increase of the period of circulatory arrest; such as antegrade brain perfusion (via arterial perfusion) or retrograde brain perfusion (via venous perfusion). These techniques decrease the risk of global cerebral hypoperfusion, but they also have some limitations. Retrograde perfusion has been associated to cerebral swelling, intracranial hypertension or hemorrhages, whilst antegrade perfusion extends the time period needed to control vessels in order to be perfused and increases the risk of embolic events because of dislodgement of a calcium plaque [73].

Antegrade perfusion may extend safety time for circulatory arrest up to 80 minutes. Blood flow should be started with 10 ml/kg/min and must be adjusted to maintain a cerebral perfusion pressure of 40-60 mmHg, at a temperature of 10-13°C. During this period, electroencephalographic burst suppression should be maintained, as well as jugular blood oxygen saturation, when available, above 90-95%. Transcranial Doppler monitoring of the flow in the medium cerebral artery is advisable. Retrograde perfusion can get homogeneous brain cooling, but it does not seem to extend the safety period for circulatory arrest longer than 30 minutes. Blood temperature should be 10-12°C and flow should avoid a pressure in the superior cava vein greater than 20-25 mmHg (100-150 ml/min) in order to decrease the risk of brain edema.

Different drugs have been used regarding pharmacological protection for aortic arch surgery. Some of them are barbiturates (5 mg/kg before circulatory arrest), lidocaine 200 mg to stabilize the neuronal membrane, 2 g of magnesium sulphate; mannitol (0.25-0.5 mg/kg) to decrease brain edema, steroids for stabilizing the BBB, nimodipine, aprotinine and even beta-blockers; but none of them is supported by evidence enough for the systematic administration to be recommended.

In carotid surgery, stroke incidence ranges between 1.5-2.8% of patients. Endovascular treatment (arterial dilation and stent placement) has not shown any definitive bene-

fit in terms of stroke or death, compared to open surgery, although the development of filters to capture embolic particles can improve the outcome after endovascular treatment. Patients undergoing stent placement must be treated with double antiplatelet drugs (acetylsalicylic acid + clopidogrel), while those undergoing open surgery may benefit from treatment with acetylsalicylic acid 50-100 mg/day.

Anesthetic technique is also a source of debate, because local anesthesia allows the early detection of intraoperative neurological deficits and optimizes shunt usage. In spite of some observational studies suggesting benefits with regional anesthesia in terms of mortality and cerebral stroke reduction, the GALA trial -which included more than 3,000 patients under carotid endarterectomy- has not demonstrated any benefit of regional anesthesia compared to general anesthesia in terms of stroke, myocardial infarct or mortality [74].

Blood pressure control after carotid procedures is very relevant. Pressure should be maintained at about 10-20% of baseline values, because hypertension can be associated to cerebral hyperperfusion injury, including frontal headache, focal seizures, edema and hemorrhage. Its incidence is about 0.2-0.7%, but it is associated with a high mortality rate. Etiology is probably linked to an increase in flow after the re-establishment of "normal" perfusion in a chronically maximally dilated arterial bed (hypoperfused brain).

63.7 Neuroprotection. From Past Failure to Future

Many potential neuroprotective therapies tested successfully in experimental models have failed when applied to humans in clinical trials. There are several explanations for this lack of positive results [1]. Firstly, there is great variability in the quality or scope of these pre-clinical studies as reflected in their adherence to the Stroke Therapy Academic and Industry Roundtable (STAIR) guidelines.

Secondly, some consequences triggered after a brain injury might be beneficial in the long term, such as the removal of dysfunctional tissue or ischemic preconditioning, and so, they should not be avoided, but rather promoted.

Thirdly, inappropriate dosage or temporary administration of neuroprotective therapies might mask beneficial effects. Besides, there is a chance that the design and statistical management of clinical trials may not be optimal. Furthermore, in preclinical studies, the targeted variable is usually a reduction in the damaged tissue, while in clinical studies we look for a reduction in mortality or an improvement in neurological outcomes, which are complex objectives, affected by a great number of variables.

Finally, the way of evaluating the outcome might not be the most adequate as it is usually based on "all or nothing type" variables (dead or alive, favourable or unfavourable outcome). New ways of evaluating the outcomes are being currently proposed, based on scales that combine several parameters, on secondary markers of patient outcome or on the "sliding dichotomy" (evaluate the outcome based on the initial severity of the patient). All these measures try to detect possible benefits for patients receiving neuroprotective therapies.

One less pessimistic view of neuroprotection points out that there is still a lack of knowledge about relevant aspects related to the complex progression of neuronal damage. That may be the reason why no one single therapy may provide adequate neuroprotection in all the circumstances, maintaining a reasonable therapeutic window and being free of adverse effects in humans. In the future, neuroprotection may turn towards the judicious combination of therapies at safe and lowest effective doses in order to get better results.

63.8 Summary and Key Points

- Neuroprotection is a challenge for critical care professionals.
- Pathophysiological knowledge of secondary brain damage plays a key role in understanding and applying neuroprotective therapies.
- Several potentially protective therapies or drugs have failed when applied to large populations of patients. For this reason, the development of clinical guidelines for neuroprotection is complex.
- According to the best evidence available, an adequate hemodynamic and respiratory management, cerebral monitoring, and the prevention and active treatment of hyperthermia are key factors in achieving a good outcome in neurocritical patients.
- According to phase III randomized clinical trials, mild hypothermia has proven neuroprotective properties in brain injury after cardiac arrest, in neonatal hypoxic encephalopathy and possibly in selected groups of TBI (young patients who are hypothermic on arrival to the hospital and patients with refractory intracranial hypertension unresponsive to conventional treatment).
- Anesthetic drugs may delay and reduce ischemic neuronal damage, especially when the damage is mild or moderate. They can also show preconditioning properties
- Corticosteroids have not been proven effective in TBI, nor in ischemic or hemorrhagic stroke, and so they should be restricted to tumour-related brain edema.
- Reperfusion with thrombolytic agents is the indicated treatment in the first 3 to 4.5 hours after an ischemic stroke. Early treatment is essential, because a delay impairs effectiveness and increases the risk of hemorrhagic complications.
- Statins may reduce the incidence of stroke and they might be effective in preventing vasospasm after SAH. Consequently, they could be used in the future for prevention of delayed ischemic injuries after SAH hemorrhage, in addition to nimodipine.
- Other potentially effective drugs in terms of neuroprotection are under clinical or preclinical studies.

64 Antithrombotic Therapy for Secondary Stroke Prevention

Mario Di Napoli [1], Francesca Papa [1] Luca Masotti [2]

[1] Neurological Service, San Camillo de'Lellis General Hospital, Rieti, Italy
[2] Internal Medicine, Cecina Hospital, Cecina, Italy

64.1 Introduction

Stroke is the leading cause of morbidity and long-term disability in Europe such as the third cause of death in United States [1]. The minimization of the very high risk of a recurrent stroke in the first 3 months (about 17% [95% confidence intervals (CI) 14-21]) represents an important aspect in the management of ischemic stroke patients [2] such as the reduction of long-term risk of recurrent stroke, myocardial infarction (MI), and death due to major vascular events, which is about 44% (95% CI 42-46) over 10 years [3]. Stroke patients show a high prevalence of coronary or peripheral artery disease (PAD), and an increased risk cardiovascular death [4].

Recurrent strokes are extremely dangerous [5]. Approximately 6-70% of first recurrent strokes have the same mechanism as the incident stroke [6]. Secondary stroke prevention depends on concomitant cardiovascular disorders and stroke subtypes [7]. Hypertension is the main stroke risk factor for intracerebral hemorrhage (ICH) and blood pressure control represents a valid prevention strategy. Risk factor associations differ in ischemic stroke subtypes. Hypertension, smoking, abdominal obesity, dyslipidemia and diabetes are common risk factors for small vessel disease (SVD) strokes [7]. Although the differences between SVD and the other ischemic stroke subtypes are not as great as previously suspected [8], the risk of recurrence varies between stroke subtypes, as well as the differences in degrees of severity and impairment. Lacunar (SVD) stroke shows lower 30-day risk of recurrence, lower 5-year mortality, and better functional outcomes when compared with other subgroups [9]. Large vessel disease (LVD) stroke presents the highest 30-day recurrence of ischemic stroke subtypes while cardioembolic stroke the highest (>80%) 5-year mortality [9].

In secondary stroke prevention, the different vascular mechanisms of stroke must have importance in the choice of strategies to reduce ischemic stroke risk; they depend on the underlying cause of ischemic stroke, and include carotid revascularization, vascular risk factor control, and antithrombotic therapy. Lifestyle and risk factor modifications such as low- fat and low-salt diet, exercise, smoking cessation, and control of blood pressure, glucose, and lipids are appropriate initiatives in all stroke patients who can benefit from them [10]. Endarterectomy or endovascular procedures such as angioplasty and stenting are appropriate procedures in patients with LVD strokes related to severe, extracranial internal carotid artery stenosis. Similarly, those with large vessel disease involving the extracranial vertebral arteries or intracranial arteries may also benefit from angioplasty and stenting, but these procedures are still considered investigational.

Antithrombotic therapy is a key component of any strategy for the secondary prevention of ischemic stroke. A better understanding of the various therapeutic options will lead to improved stroke prevention, better medication adherence, and fewer complications. Antiplatelet agents and anticoagulants are the two major classes of antithrombotic therapy used for stroke prevention. The etiology and mechanism of the stroke must be con-

sidered in order to make the best decision regarding which agent(s) to use for secondary stroke prevention. Antiplatelet therapy is recommended in patients with ischemic stroke of non-cardiac origin decreasing the stroke risk of 11-15% and the composite risk of stroke, MI, and vascular death of 15-22% [11]. Anticoagulant agents are indicated in patients with a high-risk source of embolism such as atrial fibrillation (AF) or prosthetic heart valves and cardioembolic stroke [12].

This chapter will review antithrombotic treatment strategies for secondary ischemic stroke prevention in the context of current best evidence and examine how they may affect the prophylactic antithrombotic management of patients with ischemic stroke.

64.2 Antiplatelet Regimens: Prevention of Recurrent Ischemic Stroke of Non-cardioembolic Stroke (Atherosclerotic, Lacunar, or Cryptogenic Infarcts)

The best antithrombotic regimen is antiplatelet therapy, of which aspirin (ASA) has been the mainstay for the prevention of recurrent ischemic stroke of arterial origin. The AHA/ASA guidelines [12-14] together with other international guidelines recommend antiplatelet agents rather than OAT in patients with non-cardioembolic ischemic stroke or transient ischemic attack (TIA) to reduce the risk of recurrent strokes. For patients with non-cardioembolic stroke, oral anticoagulants are generally not recommended because of both the lack of evidence of greater efficacy and the increased risk of bleeding complications (Table 64.1).

ASA, ticlopidine, clopidogrel, and a combination of ASA plus extended release dipyridamole (ER-DP) (ASA+ER-DP) are the four antiplatelet regimens approved by the US Food and Drug Administration (FDA) for secondary prevention of ischemic stroke. Ticlopidine is virtually no longer used because of its side-effects such as neutropenia, thrombotic thrombocytopenic purpura, gastrointestinal side effects. ASA, clopidogrel, and ASA+ER-DP are currently the recommended antiplatelet agents for secondary stroke prevention (Table 64.1).

Aspirin

Aspirin (ASA) reduces adverse cardiovascular events but increases bleeding in patients with stable cardiovascular disease [17,18]. In doses as low as 75 mg/day it reduces risk of vascular events in patients with previous stroke or transient ischemic attack [19]. Low-dose ASA are associated with low risk of major bleeding (NNH 769 per year) [20]. ASA increases risk of hemorrhagic stroke, but overall benefit on myocardial infarction and ischemic stroke incidence may outweigh its adverse effects on risk of hemorrhagic stroke in most populations [21]. Laboratory ASA resistance associated with increased risk of recurrent cardiovascular events in patients taking ASA for secondary prevention [22]. Concomitant nonsteroidal anti-inflammatory drugs (NSAID) may be associated with ASA resistance [23].

ASA inhibition of COX-1 decreases TXA2 production (Table 64.2) [24]. Like most other NSAIDs, ASA exerts its therapeutic effects by inhibiting prostaglandin G/H synthase 1 and 2, better known as cyclooxygenase-1 and -2 or simply COX-1 and -2. COX-1 and -2 catalyze the conversion of arachidonic acid to prostaglandin G2 and prostaglandin G2 to prostaglandin H2. ASA differs from other NSAIDs because it is an irreversible COX inhibitor. ASA irreversibly acetylates a serine side chain of COX rendering the enzyme inactive. Enzyme activity can only be regained by production of more cyclooxygenase. This

For patients with non-cardioembolic stroke or transient ischemic attack (TIA)	Antiplatelet agents recommended over anticoagulation (ACCP Grade 1B, AHA/ASA Class I, Level A, CSN Grade A). Options include: • Clopidogrel (Plavix) 75 mg once daily (AHA/ASA Class IIa, Level B) • Combination of ASA 25 mg plus extended-release DP 200 mg (Aggrenox, Asasantin) twice daily (AHA/ASA Class I, Level B) • ASA 50-325 mg/day (AHA/ASA Class I, Level A) • cilostazol (Pletal) 100 mg twice daily • Clopidogrel or combination ASA plus extended-release DP suggested over ASA alone (ACCP Grade 2B) • Combination of ASA plus clopidogrel not usually recommended (ACCP Grade 1B, AHA/ASA Class III, Level A, CSN Grade B)
For patients with cardioembolic stroke and contraindications to anticoagulant medication	Use ASA 75-325 mg daily (AHA/ASA Class I, Level A) or combination of ASA plus clopidogrel (ACCP Grade 1B) • Supporting evidence: ▪ ASA in doses as low as 75 mg/day reduces risk of vascular events in patients with previous stroke or TIA (Level 1 [likely reliable] evidence) ▪ Clopidogrel may be slightly more effective than ASA at reducing ischemic events (Level 2 [mid-level] evidence) ▪ Addition of DP to ASA reduces risk of vascular events after stroke or TIA (Level 1 [likely reliable] evidence) ▪ ASA plus extended-release DP appears similar to clopidogrel for prevention of recurrent stroke but may have slightly more major hemorrhagic events (Level 2 [mid-level] evidence) ▪ Combination of ASA plus clopidogrel for secondary stroke prophylaxis increases risk of life-threatening or major bleeding (level 1 [likely reliable] evidence) ▪ Cilostazol decreases risk of hemorrhagic stroke but increases risk of adverse events compared with ASA in patients with previous cerebral infarction (Level 1 [likely reliable] evidence); Pletal approved only for intermittent claudication • Other antiplatelet agents: ▪ Triflusal (Aflen, Disgren, Grendis, Triflux) appears as effective as ASA for secondary prevention of vascular events with lower risk of hemorrhage (level 2 [mid-level] evidence) ▪ Ticlopidine (Ticlid, Tiklid) may be slightly more effective than ASA at reducing ischemic events (Level 2 [mid-level] evidence), but less commonly used due to life-threatening hematologic toxicity
For patients who have ischemic stroke on antiplatelet therapy	No evidence to guide changing antiplatelet regimen (AHA/ASA Class IIb, Level C)
Use of antithrombotic therapy following intracerebral hemorrhage	Depends on risk for recurrent hemorrhage and risk for ischemic events (AHA/ASA Class IIb, Level B); antiplatelet therapy may not increase risk for recurrent hemorrhage after intracerebral hemorrhage (Level 2 [mid-level] evidence)

Table 64.1. **International recommendations of American College of Chest Physicians (ACCP) [15], American Heart Association (AHA) [13] and Canadian Stroke Network (CNS) [16] in noncardioembolic stroke about the use of antiplatelet therapy.**

unique property of ASA and its higher selectivity for COX-1 over COX-2 makes it an effective antiplatelet agent. Platelets contain COX-1, a key enzyme in the production thromboxane A2 (TXA2), which is a potent inducer of platelet aggregation. Since platelets lack the ability to make more enzyme, TXA2 production is inhibited for the lifetime of the platelet (approximately 8-12 days) [24]. It has a rapid effect, and antiaggregate activi-

ty occurs within 1 hour of administration. These effects last for the life of the anucleate platelet, approximately 7 to 10 days. Prostaglandin systems in the vessel wall, which produce prostacyclin, a vasodilator and platelet inhibitor, can recover after low-dose ASA.

Structure	 Chemical formula: $C_9H_8O_4$ SMILES: CC(=O)OC1=CC=CC=C1C(O)=O
Pharmacodynamics	ASA is an analgesic, antipyretic, antirheumatic, and anti-inflammatory agent. ASA's mode of action as an antiinflammatory and antirheumatic agent may be due to inhibition of synthesis and release of prostaglandins. ASA appears to produce analgesia by virtue of both a peripheral and CNS effect. Peripherally, ASA acts by inhibiting the synthesis and release of prostaglandins. Acting centrally, it would appear to produce analgesia at a hypothalamic site in the brain, although the mode of action is not known. ASA also acts on the hypothalamus to produce antipyresis; heat dissipation is increased as a result of vasodilation and increased peripheral blood flow. ASA's antipyretic activity may also be related to inhibition of synthesis and release of prostaglandins
Mechanism of action	ASA directly and irreversibly inhibits the activity of both types of cyclooxygenase (COX-1 and COX-2) to decrease the formation of precursors of prostaglandins and thromboxanes from arachidonic acid. This makes ASA different from other NSAIDS (such as diclofenac and ibuprofen) which are reversible inhibitors. Salicylate may competitively inhibit prostaglandin formation. ASA's antirheumatic (nonsteroidal anti-inflammatory) actions are a result of its analgesic and anti-inflammatory mechanisms; the therapeutic effects are not due to pituitary-adrenal stimulation. Platelet-derived COX-1 generates thromboxane A2 (TXA2), a potent vasoconstrictor and platelet agonist. In contrast, endothelial cell COX-1 generates prostacyclin which possesses vasodilatory and antiplatelet actions. Platelet COX-1 is more sensitive than endothelial cell COX-1 is to this effect of ASA and this distinction explains the recommendation for using very low doses of ASA to retard platelet aggregation. Inhibiting platelet COX-1 without diminishing endothelial cell COX-1 is desirable in patients with cardiovascular disease Inhibition of platelet COX-1 results in decreased platelet aggregation, leading to a prolonged bleeding time. Hemostatic effects return to normal roughly 36 hours after the last dose of the drug. The platelet aggregation-inhibiting effect of ASA specifically involves the compound's ability to act as an acetyl donor to COX; the nonacetylated salicylates have no clinically significant effect on platelet aggregation. Irreversible acetylation renders COX inactive, thereby preventing the formation of the aggregating agent TXA2 in platelets. Since platelets lack the ability to synthesize new proteins, the effects persist for the life of the exposed platelets (7-10 days). ASA may also inhibit production of the platelet aggregation inhibitor, prostacyclin (prostaglandin I2), by blood vessel endothelial cells; however, inhibition prostacyclin production is not permanent as endothelial cells can produce more cyclooxygenase to replace the non-functional enzyme. ASA has little effect on thrombin-induced platelet aggregation. More recently, it has been proposed that the beneficial effect of ASA might be related to its ability to reduce circulating levels of C-reactive protein. In very high and toxic doses, ASA also exerts a direct inhibitory effect on vitamin K-dependent hemostasis. Prothrombin synthesis is impaired, resulting in hypoprothrombinemia

Absorption	Absorption is generally rapid and complete following oral administration but may vary according to specific salicylate used, dosage form, and other factors such as tablet dissolution rate and gastric or intraluminal pH	
Volume of distribution	Not available	
Protein binding	High (99.5%) to albumin. Decreases as plasma salicylate concentration increases, with reduced plasma albumin concentration or renal dysfunction, and during pregnancy	
Metabolism	ASA is rapidly hydrolyzed primarily in the liver to salicylic acid, which is conjugated with glycine (forming salicyluric acid) and glucuronic acid and excreted largely in the urine	
Route of elimination	Not available	
Half life	The plasma half-life is approximately 15 minutes; that for salicylate lengthens as the dose increases: doses of 300 to 650 mg have a half-life of 3.1 to 3.2 hours; with doses of 1 gram, the half-life is increased to 5 hours and with 2 grams it is increased to about 9 hours.	
Clearance	Not available	
Toxicity	Oral, mouse: LD_{50}=250 mg/kg; Oral, rabbit: LD_{50}=1010 mg/kg; Oral, rat: LD_{50}=200 mg/kg. Effects of overdose include: tinnitus, abdominal pain, hypokalemia, hypoglycemia, pyrexia, hyperventilation, dysrhythmia, hypotension, hallucination, renal failure, confusion, seizure, coma, and death.	
Drug Interactions	**Drug**	**Interaction**
	Acenocoumarol	Acetylsalicylic acid increases the effect of the anticoagulant, acenocoumarol
	Acetazolamide	Acetylsalicylic acid at high dose increases the effect of the carbonic anhydrase inhibitor, acetazolamide
	Acetohexamide	Acetylsalicylic acid increases the effect of sulfonylurea, acetohexamide
	Anisindione	Acetylsalicylic acid increases effect of the anticoagulant, anisindione
	Betamethasone	The corticosteroid, betamethasone, may decrease the effect of the salicylate, acetylsalicylic acid
	Chlorpropamide	Acetylsalicylic acid may increase the effect of the sulfonylurea, chlorpropamide
	Cortisone acetate	The corticosteroid, cortisone acetate, may decrease the effect of the salicylate, acetylsalicylic acid
	Dexamethasone	The corticosteroid, dexamethasone, may decrease the effect of the salicylate, acetylsalicylic acid
	Dichlorphenamide	Acetylsalicylic acid at high dose increases the effect of the carbonic anhydrase inhibitor, dichlorphenamide
	Dicumarol	Acetylsalicylic acid increases effect of the anticoagulant, dicumarol
	Fludrocortisone	The corticosteroid, fludrocortisone, may decrease the effect of the salicylate, acetylsalicylic acid
	Ginkgo biloba	Additive anticoagulant/antiplatelet effects may increase bleed risk. Concomitant therapy should be avoided
	Gliclazide	Acetylsalicylic acid increases the effect of the sulfonylurea, gliclazide
	Glipizide	Acetylsalicylic acid increases the effect of the sulfonylurea, glipizide
	Glisoxepide	Acetylsalicylic acid increases the effect of the sulfonylurea, glisoxepide

	Glyburide	Acetylsalicylic acid increases the effect of the sulfonylurea, glibenclamide
	Glycodiazine	Acetylsalicylic acid increases the effect of sulfonylurea, glycodiazine
	Griseofulvin	Griseofulvin may decrease the efficacy of acetylsalicylic acid
	Heparin	Increased risk of bleeding
	Hydrocortisone	The corticosteroid, hydrocortisone, may decrease the effect of the salicylate, acetylsalicylic acid
	Ibuprofen	Concomitant therapy of the NSAID, ketoprofen, and acetylsalicylic acid may result in additive adverse/toxic effects (e.g. GI bleeding). The NSAID may also limit the cardioprotective effect of acetylsalicylic acid. Occasional concomitant use may not cause clinically significant problems, but regular, frequent concomitant therapy is not recommended
	Ketoprofen	Concomitant therapy of the NSAID, ketoprofen, and acetylsalicylic acid may result in additive adverse/toxic effects (e.g. GI bleeding). The NSAID may also limit the cardioprotective effect of acetylsalicylic acid. Occasional concomitant use may not cause clinically significant problems, but regular, frequent concomitant therapy is not recommended
	Ketorolac	Acetylsalicylic acid may increase the adverse GI effects ketorolac
	Methazolamide	Acetylsalicylic acid at high dose increases the effect of the carbonic anhydrase inhibitor, methazolamide
	Methotrexate	Acetylsalicylic acid increases the effect and toxicity of methotrexate
	Methylprednisolone	The corticosteroid, methylprednisolone, may decrease the effect of the salicylate, acetylsalicylic acid
	Paramethasone	The corticosteroid, paramethasone, may decrease the effect of the salicylate, acetylsalicylic acid
	Prednisolone	The corticosteroid, prednisolone, may decrease the effect of the salicylate, acetylsalicylic acid
	Prednisone	The corticosteroid, prednisone, may decrease the effect of the salicylate, acetylsalicylic acid
	Probenecid	Acetylsalicylic acid decreases the uricosuric effect of probenecid
	Sulindac	Risk of additive toxicity (e.g. bleed risk). Acetylsalicylic acid may decrease the serum concentration of sulindac. Sulindac may counteract the cardioprotective effects of acetylsalicylic acid. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of both agents if the interacting agent is initiated, discontinued or dose changed
	Telmisartan	Concomitant use of relmisartan and acetylsalicylic acid may increase the risk of acute renal failure and hyperkalemia. Monitor renal function at the beginning and during treatment
	Tiaprofenic acid	Increased risk of gastrointestinal bleeding

	Ticlopidine	Increased effect of ticlopidine
	Tolazamide	Acetylsalicylic acid increases the effect of the sulfonylurea, tolazamide
	Tolbutamide	Acetylsalicylic acid increases the effect of the sulfonylurea, tolbutamide
	Tolmetin	Additive adverse effects increase the risk of gastrointestinal bleeding. Possible decrease in the cardioprotective effect of acetylsalicylic acid. Monitor for increased bleeding risk during concomitant therapy
	Trandolapril	Acetylsalicylic acid may reduce the efficacy of Trandolapril. Monitor for changes in Trandolapril efficacy if acetylsalicylic acid is initiated, discontinued or dose changed
	Treprostinil	The prostacyclin analogue, Treprostinil, increases the risk of bleeding when combined with the antiplatelet agent, Acetylsalicylic acid. Monitor for increased bleeding during concomitant thearpy
	Triamcinolone	The corticosteroid, triamcinolone, may decrease the effect of the salicylate, acetylsalicylic acid
	Valproic acid	Acetylsalicylic acid increases the effect of valproic acid
	Warfarin	The antiplatelet effects of acetylsalicylic acid may increase the bleed risk associated with warfarin
Food interactions	• Avoid alcohol, alcohol appears to cause a 50 to 100% increases in ASA serum levels • Take with a full glass of water • Take with food to reduce gastric irritation	

Table 64.2. **Aspirin (ASA) overview. SMILES indicates simplified molecular-input line-entry system [25].**

Effectiveness of ASA

ASA reduces the risk of recurrent stroke and other major vascular events of approximately 13-22% (mean 13%; 95% CI 6-19%) compared with control, when administered acutely and over the long-term (Figure 64.1) [26-36]. Antiplatelet therapy reduced the risk of secondary stroke, MI, or vascular death by 22% among the subset of patients with prior cerebrovascular disease (TIA or stroke) in the 2002 ATC; the absolute benefit was 36 events prevented per 1000 patients treated for 29 months [19]. The benefit was independent of age (greater or less than 65), sex, diabetes, or hypertension. These results were further confirmed in an implemented 2009 ATC meta-analysis of 16 placebo-controlled secondary prevention trials. ASA reduced the risk of any serious vascular event and the risk of ischemic stroke of 19% and 22%, respectively [37]. In high-risk patients, stopping antiplatelet therapy may increase the risk of stroke. In one study of patients hospitalized with cerebral infarction 4.5% patients (n=13 of 289) had recently stopped antiplatelet therapy. Most had been taking ASA and in all patients, the antiplatelet agent had been discontinued within 6 to 10 days of stroke onset, consistent with the known lifespan (about 10 days) of inhibited platelets [38]. Similar results were found in a case-control study comparing 309 patients with stroke to 309 matched controls. ASA discontinuation was associated with a significantly increased risk of a recurrent cerebrovascular event (TIA or ischemic stroke; OR 3.4, 95% CI 1.08-10.63) [39]. In addition, ASA decreases the risk of other cardiovascular events in a wide range of patients with established cardiovascular disease and the risk of death from certain cancers in the long-term use. However, ASA shows a limited efficacy and treatment failures should be expected in

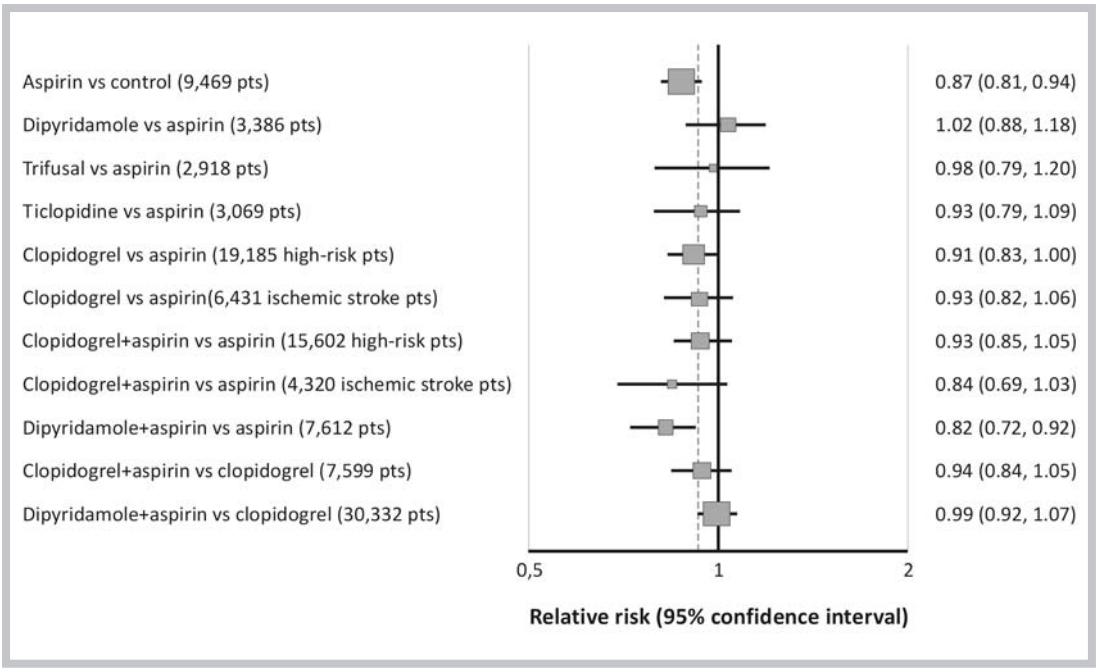

Figure 64.1. **Summary of the results of RCTs of antiplatelet drugs in patients with TIA or ischemic stroke of presumed arterial origin. Relative effects of antiplatelet regimens vs.placebo, aspirin, and clopidogrel in reducing the risk of stroke, myocardial infarction, or vascular death (major vascular events). The x-axis shows the degree of relative risk of stroke, myocardial infarction, or vascular events/death with each antiplatelet regimen. Point estimates and 95% CIs are shown. The data derived from a systematic review of all trials [26-31,33,35,36].**

most patients with TIA and stroke. The modest treatment effect of ASA in many patients may be attributable to non-compliance [40], and in some patients to suboptimum platelet inhibition by ASA, as shown by incomplete inhibition of TXA2 production or of platelet activation and aggregation [41,42].

Dose of ASA

The lack of proof of an optimal dose is a controversial issue concerning the efficacy of ASA in stroke prevention. In secondary stroke prevention studies, ASA doses range between 20 to 1300 mg; however, 50 to 325 mg/day of ASA is as effective as higher dose in most studies [11,43-48]. Lower doses within this range appear to provide the same benefit as higher doses [43-48]. Doses of 75 to 150 mg/day produced the same risk reduction, compared with placebo, as doses of 150 to 325 mg/day according to a review of 195 trials of secondary prevention by the ATC [11]. The ATC analysis of trials directly comparing ASA<75 mg/day to ASA ≥75 mg/day, showed comparable effectiveness between the two regimens. However, the ASA doses of<75 mg/day have been less widely assessed than doses of 75 to 150 mg/day, so uncertainty remains regarding the effectiveness of doses<75 mg/day compared with higher ASA doses in the ATC meta-analysis. No additional benefit with a greater risk of non-fatal major gastrointestinal hemorrhage was demonstrated in two further trials comparing higher with lower doses of ASA regimens [45,49]. The risk of major stroke, MI, or vascular death was 15% less with ASA than with placebo in the United Kingdom Transient Ischemic Attack trial (UK-TIA); in this trial, patients with minor ischemic stroke or TIA were randomized to 600 mg ASA twice daily, 300 mg ASA once daily, or placebo. The two ASA doses were equal in efficacy. Also in the Dutch TIA trial of patients with TIA or non-disabling stroke, there was no difference

in stroke prevention between the two doses of ASA 30 mg ASA vs. 283 mg in preventing vascular death, non-fatal stroke, or non-fatal MI. Again, however, the 30 mg dose group had fewer bleeding complications [45]. No clinical trial evidence supports an increase in the ASA dose for patients who have a stroke while receiving ASA. Lower doses may also be effective. The Dutch TIA Trial [49] demonstrated a similar efficacy for stroke prevention with 30 mg compared with 283 mg of ASA per day in patients who had had a TIA or minor ischemic stroke. Similarly, in the European Stroke Prevention Study-2 (ESPS-2), 50 mg of ASA daily reduced stroke risk by 18% compared with placebo (29 strokes prevented per 1000 treated), an effect of comparable magnitude to the other trials cited above [47]. This benefit is consistent with laboratory observations that 30 mg of ASA per day results in complete suppression of TXA2 production [50]. Both the Food and Drug Administration and the American College of Cardiology now support ASA doses between 50 and 325 mg, either alone or in combination with extended-release DP (ER-DP) for prevention of recurrent noncardioembolic TIA or stroke [51,52]. ASA in doses as low as 75 mg/day reduces risk of vascular events in patients with previous stroke or TIA [17,18].

Toxicity and Risk of Bleeding

Low-dose ASA are associated with low risk of major bleeding (number needed to harm [NNH] 769 per year) [20]. In the UK TIA trial, for example, gastrointestinal hemorrhage occurred in 1.6% of patients on placebo, 2.6% on 300 mg ASA, and 4.7% on 1200 mg ASA [43]. ASA doses ≤200 mg/day were associated with a significantly lower rate of major bleeding events compared with higher doses in an analysis of data from 31 randomized, controlled trials [53]. However, major bleedings were similar when ASA <100 mg/day was compared with 100 to 200 mg/day, the overall rate of bleeding complications (including major, minor and insignificant events) was associated with a lower risk in ASA <100 mg/day group compared with the 100 to 200 mg/day and >200 mg/day groups. A later meta-analysis of 22 randomized trials of low-dose ASA (75 to 325 mg/day) vs.placebo for cardiovascular prophylaxis reached similar conclusions within the low-dose range [20]. Compared with placebo, ASA increased the relative risk of any major bleeding, major gastrointestinal bleeding, and intracranial bleeding by 1.7- to 2.1-fold. However, the absolute annual increase in risk for any major bleeding episode (mostly gastrointestinal) and for intracranial bleeding was 0.13 and 0.03%, respectively. Furthermore, there was no evidence of an increased risk of bleeding with “high” low-dose ASA (>162 to 325 mg/day) compared with “low” low-dose ASA (75 to 162 mg/day). Although ASA increases the risk of major bleeding by about 70% (risk ratio [RR] 1.71 [95% CI 1.41-2.08]), the absolute annual increase is modest (0.13% [0.08-0.20%]), indicating that one additional major bleeding episode will occur each year for every 769 patients (95% CI 500-1250) treated with ASA [20]. The increased risk of bleeding is mainly due to an increase in major gastrointestinal bleeding (RR 2.07 [95% CI 1.61-2.66]; absolute annual increase 0.12% [0.07-0.19]) and intracranial bleeding (RR 1.65 [1.06-5.99]; absolute annual increase 0.03% [0.01-0.08]) [20]. Gastrointestinal hemorrhage was more common with the 1200 mg dose than the 300 mg dose. ASA increases risk of hemorrhagic stroke, but overall benefit on MI and ischemic stroke incidence may outweigh its adverse effects on risk of hemorrhagic stroke in most populations. ASA use associated with absolute risk increase in hemorrhagic stroke of 12 events per 10,000 persons (NNH 833) [21].

Nonresponse/resistance

About 10% of general population is resistant to antiplatelet effects of ASA [54]. Decreasing response to ASA is correlated independently with increasing risk of cardiovascular events. In a systematic review of 13 prospective cohort studies and 3 case-control studies among patients treated with ASA for secondary prevention of cardiovascular events,

5% to 65% range of ASA resistance by *ex vivo* nonresponsiveness to ASA based on any test of platelet TXA2 synthesis or platelet function, in a meta-analysis of 12 studies with 1813 patients 30.4% patients with vs. 12.7% patients without ASA resistance had cardiovascular events ($p<0.001$) although this meta-analysis is limited by heterogeneity ($p=0.03$) [55]. Studies showing that ASA is unable to protect against the onset of thrombotic complications. A high percentage (up to a barely believable 45%, depending on the study) of patients presents "treatment failure" or "ASA resistance," being more common in elderly people and women [41]. The mechanisms involved in ASA resistance are probably multifactorial and include the factors shown in Figure 64.2.

Potential causes of a reduced response to ASA include inadequate dose, genetic polymorphisms of *PTGS1* (which encodes prostaglandin G/H synthase 1, formerly cyclo-oxygenase 1) and other genes involved in TX biosynthesis, upregulation of non-platelet sources of TX biosynthesis, increased platelet turnover, and drug interactions (eg, with non-steroidal anti-inflammatory drugs [NSAIDs]), and occasional ASA allergy. *C*oncomitant NSAIDs may be associated with ASA resistance. Concomitant NSAID use is associated with increased risk of ASA nonresponsiveness as determined by arachidonate acid agonist (OR 2.17, $p=0.036$) and by determined by collagen agonist (OR 2.67, $p=0.001$) [23,41,56]. The specific NSAIDs that may lead to a less than expected inhibition of platelet function by ASA are ibuprofen, naproxen, and possibly other non-selective NSAIDs, because they compete with ASA for access to its target (the active site at position 530 of

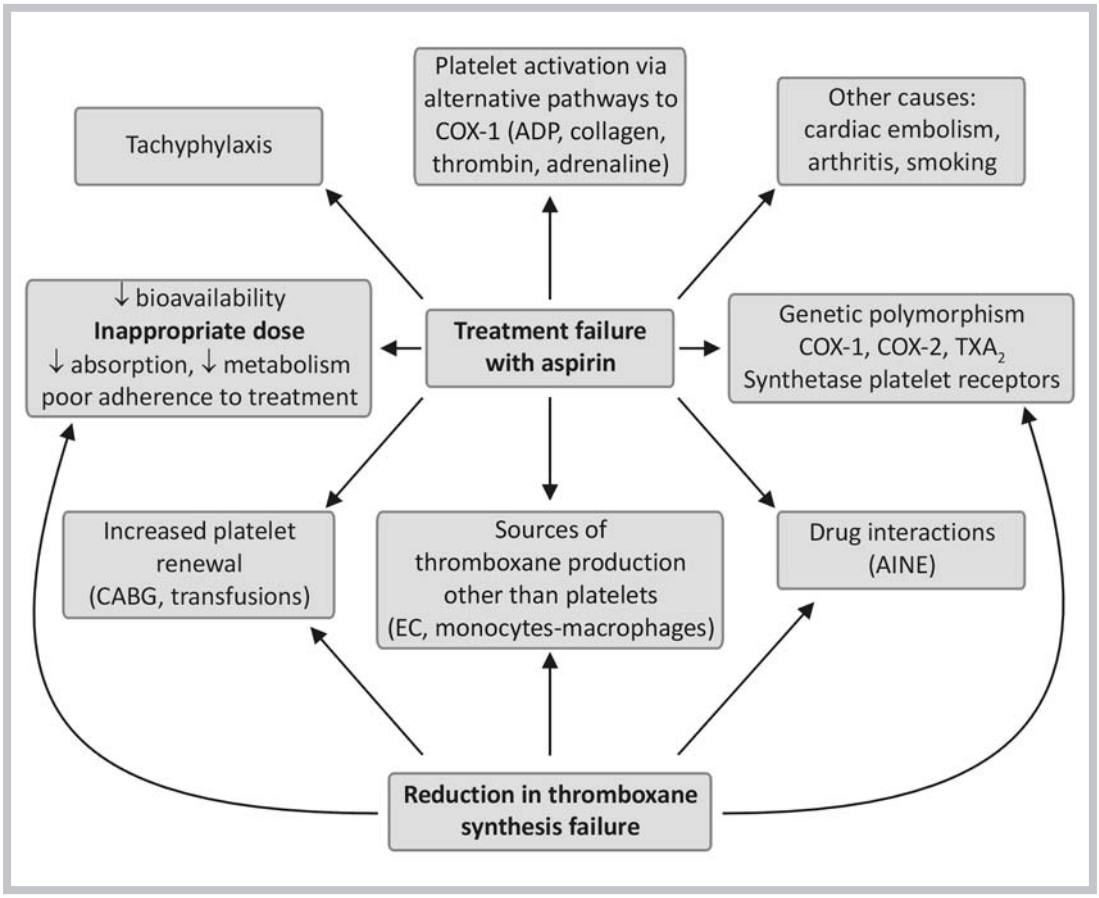

Figure 64.2. **Possible mechanisms involved in aspirin resistance. NSAIDS indicates non-steroid antiinflammatories; CABG, coronary artery bypass.**

a serine residue in the core of the cyclo-oxygenase enzyme) [57]. ASA hyporesponsiveness can potentially be overcome by increasing the dose or frequency of administration, and by avoiding drugs that interact with ASA. However, the benefit of these measures on clinical outcomes remains unproven. ASA resistance represents a controversial topic also because there is poor agreement on the best measurement of such resistance, as the methods of assaying platelet inhibition do not always agree, and there has also been little control for lack of adherence to the ASA regimen [40]. Likewise, switching to alternative antiplatelet agents has not been studied for ASA failures. In clinical practice ASACheck® and ASAWorks® are tests for ASA resistance which measure urine 11-dehydro-TXB2, high levels might suggest ASA resistance but could be due to other sources of TX production. Ultegra RPFA-ASA® is another point-of-care optical platelet function assay for ASA resistance. Laboratory ASA resistance is associated with increased risk of recurrent cardiovascular events in patients taking ASA for secondary prevention. To date, small studies have been conducted showing that incomplete TX synthesis suppression, despite sufficient doses (aspirin resistance), is a potential cardiovascular risk marker [58]. In the WARSS trial [59], a clinical trial of ASA vs. warfarin in non-cardioembolic stroke patients, the two agents had nonsignificant difference in efficacy. Moreover, patients who had already failed ASA when they had their index strokes had a higher risk of recurrent stroke in the course of the trial, but there was still no evidence of superior efficacy of warfarin over ASA. Established alternatives to ASA include clopidogrel and the combination of ASA and ER-DP.

Recommendations for ASA

American College of Chest Physicians (ACCP) (Ninth Edition) [15]

- Following noncardioembolic stroke or transient ischemic attack (TIA)
  - ASA 75-100 mg once daily recommended as an option for long-term antiplatelet therapy over: no antiplatelet therapy (ACCP Grade 1A), oral anticoagulants (ACCP Grade 1B), combination of clopidogrel plus ASA (ACCP Grade 1B), Triflusal (ACCP Grade 2B).
  - Among the recommended antiplatelet regimens, clopidogrel or combination of ASA plus extended-release DP suggested over ASA alone (ACCP Grade 2B) or triflusal (ACCP Grade 2C).
  - Benefit of clopidogrel over ASA for preventing major vascular events may be offset with long-term use (>5 years) by lower cancer-related mortality with ASA.
- Following cardioembolic stroke or TIA (that is, atrial fibrillation, including paroxysmal atrial fibrillation):
  - OAT recommended over: no antithrombotic therapy (ACCP Grade 1A), ASA (ACCP Grade 1B), combination therapy with ASA plus clopidogrel (ACCP Grade 1B).
  - For patients unsuitable for or who choose not to take an oral anticoagulant (for reasons other than concerns about major bleeding), combination therapy with ASA plus clopidogrel recommended over ASA (ACCP Grade 1B).
  - Use of ASA as bridging therapy suggested until anticoagulation reaches therapeutic level.

American Heart Association (AHA) [13]:

- For patients with noncardioembolic ischemic stroke or TIA, antiplatelet agents recommended rather than OAT (AHA/ASA Class I, Level A):
  - Acceptable options include: ASA 50-325 mg daily (AHA/ASA Class I, Level A), combination ASA 25 mg twice daily and extended-release DP 200 mg twice daily (AHA/ASA Class I, Level B), clopidogrel 75 mg daily (AHA/ASA Class iia, Level B).
  - Selection of antiplatelet agent should be individualized based on patient risk factors, cost, tolerance and other clinical factors.

  - Addition of ASA to clopidogrel increases risk of hemorrhage and is not routinely recommended for secondary prevention of stroke (AHA/ASA Class III, Level A).
  - Clopidogrel reasonable for patients allergic to ASA (AHA/ASA Class iia, Level C).
  - For patients who have ischemic stroke while taking ASA (AHA/ASA Class iib, Level C): no evidence for additional efficacy with increasing dose of ASA, alternative antiplatelet agents often considered, but no regimen specifically studied.
- For patients with ischemic stroke or TIA and paroxysmal or permanent atrial fibrillation:
  - If unable to take oral anticoagulants, ASA alone is recommended (AHA/ASA Class I, Level A).
  - Clopidogrel with ASA not recommended for patients with hemorrhagic contraindication to warfarin (AHA/ASA Class III, Level B).
- Optimal medical therapy for patients with extracranial arterial disease (carotid or vertebrobasilar) and TIA or stroke should include antiplatelet therapy (AHA/ASA Class I, Level B).
- For patients with stroke or TIA due to 50%-99% stenosis of major intracranial artery, ASA 50-325 mg/day is recommended over warfarin (AHA/ASA Class I, Level B).
- For patients with cardiomyopathy:
  - Insufficient evidence for use of warfarin in patients with prior stroke or TIA, sinus rhythm, cardiomyopathy and ejection fraction ≤ 35% (AHA/ASA Class iib, Level B).
  - Treatments to consider for patients with ischemic stroke or TIA and cardiomyopathy include (AHA/ASA Class IIb, Level B): warfarin (INR 2-3), ASA 81 mg/day, clopidogrel 75 mg/day, combination of ASA 25 mg twice daily and extended-release DP 200 mg twice daily.
- For patients with native valvular heart disease:
  - Antiplatelet therapy may be considered for patients with ischemic stroke or TIA and: native aortic or nonrheumatic mitral valve disease and no atrial fibrillation (AHA/ASA Class IIb, Level C), mitral annular calcification (AHA/ASA Class IIb, Level C), mitral valve prolapse (AHA/ASA Class IIb, Level C).
  - To avoid additional bleeding risk, antiplatelet agents should not be routinely added to warfarin (AHA/ASA Class III, Level C).
- For patients with ischemic stroke or TIA due to extracranial arterial dissection (carotid or vertebral):
  - Antithrombotic therapy for at least 3-6 months is reasonable (AHA/ASA Class IIa, Level B).
  - Relative efficacy of antiplatelet therapy vs. Anticoagulation is unknown (AHA/ASA Class iib, Level B).
- For patients with patent foramen ovale (PFO):
  - Antiplatelet therapy is reasonable for patients with ischemic stroke or TIA and PFO (AHA/ASA Class IIa, Level B).
  - Insufficient data to determine whether anticoagulation is as or more effective than ASA for secondary stroke prevention in patients with PFO (AHA/ASA Class IIb, Level B).

Canadian Stroke Network (CSN) [16]:

- All patients with ischemic stroke should be prescribed antiplatelet therapy for secondary prevention of recurrent stroke unless indication for anticoagulation (CSN Grade A).
- Medications include (CSN Grade A):
  - ASA 80-325 mg/day (1-5 mg/kg/day in children [CSN Grade B]).
  - Combined ASA (25 mg) and extended-release DP (200 mg) twice daily.
  - Clopidogrel 75 mg/day.

- Clopidogrel may be considered an alternative in pediatric patients with contraindication to ASA (CSN Grade C).
- Long term combination of ASA and clopidogrel is not recommended for secondary stroke prevention unless there is a compelling indication (CSN Grade B).

Thienopyridine Derivatives

Ticlopidine and clopidogrel decrease platelet aggregation by inhibiting the binding of adenosine 5'-diphosphate (ADP) receptor antagonists that inhibit ADP-induced fibrinogen binding to platelets [60]. Significant inhibition is present after 2 to 3 days of therapy with ticlopidine 500 mg/day or clopidogrel 75 mg/day, with maximal inhibition occurring between 4 and 7 days. As with ASA, the antiplatelet action persists for 7 to 10 days after therapy is stopped lasting for the lifespan of the platelet.

Ticlopidine

Ticlopidine is a thienopyridine structurally and pharmacologically similar to clopidogrel (Table 64.3) [25]. The active metabolite of ticlopidine prevents binding of adenosine diphosphate (ADP) to its platelet receptor, impairing the ADP-mediated activation of the glycoprotein GPIIb/IIIa complex. It is proposed that the inhibition involves a defect in the mobilization from the storage sites of the platelet granules to the outer membrane. No direct interference occurs with the GPIIb/IIIa receptor. As the glycoprotein GPIIb/IIIa complex is the major receptor for fibrinogen, its impaired activation prevents fibrinogen binding to platelets and inhibits platelet aggregation. By blocking the amplification of platelet activation by released ADP, platelet aggregation induced by agonists other than ADP is also inhibited by the active metabolite of ticlopidine.

Structure	 Chemical formula: $C_{14}H_{14}ClNS$; SMILES: ClC1=CC=CC=C1CN1CCC2=C(C1)C=CS2
Mechanism of action	The active metabolite of ticlopidine prevents binding of adenosine diphosphate (ADP) to its platelet receptor, impairing the ADP-mediated activation of the glycoprotein GPIIb/IIIa complex. It is proposed that the inhibition involves a defect in the mobilization from the storage sites of the platelet granules to the outer membrane. No direct interference occurs with the GPIIb/IIIa receptor. As the glycoprotein GPIIb/IIIa complex is the major receptor for fibrinogen, its impaired activation prevents fibrinogen binding to platelets and inhibits platelet aggregation. By blocking the amplification of platelet activation by released ADP, platelet aggregation induced by agonists other than ADP is also inhibited by the active metabolite of ticlopidine
Absorption	Absorption is greater than 80%. Food increases absorption
Volume of distribution	Not available
Protein binding	Binds reversibly (98%) to plasma proteins, mainly to serum albumin and lipoproteins. The binding to albumin and lipoproteins is nonsaturable over a wide concentration range. Ticlopidine also binds to alpha-1 acid glycoprotein. At concentrations attained with the recommended dose, only 15% or less ticlopidine in plasma is bound to this protein

Metabolism	Metabolized extensively by the liver; only trace amounts of intact drug are detected in the urine. At least 20 metabolites have been identified. It has been proposed that 1 or more active metabolites may account for ticlopidine's activity, because ticlopidine itself is an extremely weak platelet aggregation inhibitor in vitro at the concentrations achieved in vivo. However, no active metabolite has been identified	
Route of elimination	Ticlopidine hydrochloride is metabolized extensively by the liver; only trace amounts of intact drug are detected in the urine. Approximately 1/3 of the dose excreted in the feces is intact ticlopidine hydrochloride, possibly excreted in the bile	
Half life	Half-life following a single 250-mg dose is approximately 7.9 hours in subjects 20 to 43 years of age and 12.6 hours in subjects 65 to 76 years of age. With repeated dosing (250 mg twice a day), half-life is about 4 days in subjects 20 to 43 years of age and about 5 days in subjects 65 to 76 years of age	
Clearance	Not available	
Toxicity	Single oral doses of ticlopidine at 1600 mg/kg and 500 mg/kg were lethal to rats and mice, respectively. Symptoms of acute toxicity were GI hemorrhage, convulsions, hypothermia, dyspnea, loss of equilibrium and abnormal gait	
Drug Interactions	**Drug**	**Interaction**
	Acetylsalicylic acid	Increased effect of ticlopidine
	Alteplase	Increased bleeding risk. Monitor for signs of bleeding
	Ambrisentan	Ticlopidine may decrease the metabolism and clearance of ambrisentan. Consider alternate therapy or monitor for adverse/toxic effects of ambrisentan if ticlopidine is initiated, discontinued or dose changed.
	Aminophylline	Ticlopidine increases the effect and toxicity of theophylline
	Bortezomib	Ticlopidine may decrease the metabolism and clearance of bortezomib. Consider alternate therapy or monitor for adverse/toxic effects of bortezomib if ticlopidine is initiated, discontinued or dose changed
	Carbamazepine	Ticlopidine increases the effect of carbamazepine
	Carisoprodol	Ticlopidine may decrease the metabolism and clearance of carisoprodol. Consider alternate therapy or monitor for adverse/toxic effects of carisoprodol if ticlopidine is initiated, discontinued or dose changed
	Cilostazol	Ticlopidine may decrease the metabolism and clearance of cilostazol. Consider alternate therapy or monitor for adverse/toxic effects of cilostazol if ticlopidine is initiated, discontinued or dose changed
	Cimetidine	Cimetidine may increase ticlopidine levels. Avoid concomitant therapy.
	Citalopram	Ticlopidine may decrease the metabolism and clearance of citalopram. Consider alternate therapy or monitor for adverse/toxic effects of citalopram if ticlopidine is initiated, discontinued or dose changed
	Clobazam	Ticlopidine may decrease the metabolism and clearance of clobazam. Consider alternate therapy or monitor for adverse/toxic effects of clobazam if ticlopidine is initiated, discontinued or dose changed
	Clomipramine	Ticlopidine may decrease the metabolism and clearance of clomipramine. Consider alternate therapy or monitor for adverse/toxic effects of clomipramine if ticlopidine is initiated, discontinued or dose changed

	Cyclosporine	Ticlopidine decreases the effect of cyclosporine
	Diazepam	Ticlopidine may decrease the metabolism and clearance of diazepam. Consider alternate therapy or monitor for adverse/toxic effects of diazepam if ticlopidine is initiated, discontinued or dose changed
	Digoxin	Ticlopidine may decrease digoxin levels. Monitor for digoxin levels with ticlopidine is initiated, discontinued or dose changed
	Dyphylline	Ticlopidine increases the effect and toxicity of theophylline
	Escitalopram	Ticlopidine may decrease the metabolism and clearance of escitalopram. Consider alternate therapy or monitor for adverse/toxic effects of ambrisentan if escitalopram is initiated, discontinued or dose changed
	Ethotoin	Ticlopidine increases the effect of hydantoin
	Fosphenytoin	Ticlopidine may decrease the metabolism and clearance of fosphenytoin. Consider alternate therapy or monitor for adverse/toxic effects of fosphenytoin if ticlopidine is initiated, discontinued or dose changed
	Ginkgo biloba	Additive anticoagulant/antiplatelet effects may increase bleed risk. Concomitant therapy should be avoided
	Heparin	Increased bleeding risk. Monitor aPTT
	Ifosfamide	Ticlopidine may decrease the metabolism and clearance of ifosfamide. Consider alternate therapy or monitor for adverse/toxic effects of ifosfamide if ticlopidine is initiated, discontinued or dose changed
	Imipramine	Ticlopidine may decrease the metabolism and clearance of Imipramine. Consider alternate therapy or monitor for adverse/toxic effects of Imipramine if ticlopidine is initiated, discontinued or dose changed
	Mephenytoin	Ticlopidine increases the effect of hydantoin
	Methsuximide	Ticlopidine may decrease the metabolism and clearance of methsuximide. Consider alternate therapy or monitor for adverse/toxic effects of methsuximide if ticlopidine is initiated, discontinued or dose changed
	Moclobemide	Ticlopidine may decrease the metabolism and clearance of moclobemide. Consider alternate therapy or monitor for adverse/toxic effects of moclobemide if ticlopidine is initiated, discontinued or dose changed
	Nilutamide	Ticlopidine may decrease the metabolism and clearance of nilutamide. Consider alternate therapy or monitor for adverse/toxic effects of nilutamide if ticlopidine is initiated, discontinued or dose changed
	Oxtriphylline	Ticlopidine increases the effect and toxicity of theophylline
	Pentamidine	Ticlopidine may decrease the metabolism and clearance of pentamidine. Consider alternate therapy or monitor for adverse/toxic effects of pentamidine if ticlopidine is initiated, discontinued or dose changed
	Phenobarbital	Ticlopidine may decrease the metabolism and clearance of phenobarbital. Consider alternate therapy or monitor for adverse/toxic effects of phenobarbital if ticlopidine is initiated, discontinued or dose changed

	Phenytoin	Ticlopidine may decrease the metabolism and clearance of phenytoin. Consider alternate therapy or monitor for adverse/toxic effects of phenytoin if ticlopidine is initiated, discontinued or dose changed
	Reteplase	Increased bleeding risk. Monitor for signs of bleeding
	Sodium bicarbonate	Sodium bicarbonate may decrease ticlopidine levels. Administer agents 1 to 2 hours apart
	Streptokinase	Increased bleeding risk. Monitor for signs of bleeding
	Tamoxifen	Ticlopidine may decrease the therapeutic effect of tamoxifen by decreasing the production of active metabolites. Consider alternate therapy
	Tamsulosin	Ticlopidine, a CYP2D6 inhibitor, may decrease the metabolism and clearance of Tamsulosin, a CYP2D6 substrate. Monitor for changes in therapeutic/adverse effects of tamsulosin if ticlopidine is initiated, discontinued, or dose changed
	Tenecteplase	Increased bleeding risk. Monitor for signs of bleeding
	Theophylline	Ticlopidine increases the effect and toxicity of theophylline
	Thioridazine	Ticlopidine may decrease the metabolism of thioridazine. Concomitant therapy is contraindicated
	Tizanidine	Ticlopidine may decrease the metabolism and clearance of tizanidine. Consider alternate therapy or use caution during co-administration
	Tramadol	Ticlopidine may decrease the effect of tramadol by decreasing active metabolite production
	Treprostinil	The prostacyclin analogue, Treprostinil, increases the risk of bleeding when combined with the antiplatelet agent, Ticlopidine. Monitor for increased bleeding during concomitant thearpy
	Trimipramine	The strong CYP2C19 inhibitor, ticlopidine, may decrease the metabolism and clearance of trimipramine, a CYP2C19 substrate. Consider alternate therapy or monitor for changes in therapeutic and adverse effects of trimipramine if ticlopidine is initiated, discontinued or dose changed
	Warfarin	Increased bleeding risk. Monitor INR
Class effects	Thienopyridines may be slightly more effective than *ASA* for preventing serious vascular events in high-risk patients (Level 2 [mid-level] evidence) [35]	

Table 64.3. **Ticlopidine overview. SMILES indicates simplified molecular-input line-entry system.**

When taken orally, ticlopidine causes a time- and dose-dependent inhibition of both platelet aggregation and release of platelet granule constituents, as well as, a prolongation of bleeding time. The intact drug has nonsignificant in vitro activity at the concentrations attained in vivo; and, although analysis of urine and plasma indicates at least 20 metabolites, no metabolite which accounts for the activity of ticlopidine has been isolated. Ticlopidine was initially approved for the secondary prevention of stroke and was subsequently found to be beneficial for other types of vascular events [61]. It is typically administered twice daily with food. It is associated with a significant risk for severe neutropenia (approximately 1%), mainly in the first 2-3 months of treatment. A lesser risk of thrombotic thrombocytopenic purpura is also present. Because of these hematological adverse effects, complete blood counts are recommended every 2 weeks for the first 3

months that patients are on the drug [61]. Diarrhea occurs in more than 20% of patients as well. These side effects have significantly limited its use.

Effectiveness of ticlopidine. Three major trials involving patients with TIA and stroke evaluated its role in stroke prevention. The Canadian American Ticlopidine Study, which included 1072 patients with ischemic stroke, compared ticlopidine with placebo [62]. Patients in the ticlopidine group had a significant 23.3% reduction in the combined end point of stroke, MI, or vascular death compared with the placebo group (11.3% per year vs. 14.8% per year; p=0.02). The CATS trial compared ticlopidine vs.placebo in patients who had suffered a significant stroke. At a mean of 24 months follow-up, the primary composite end point of stroke, MI, and vascular death was significantly lower with ticlopidine compared with placebo (10.8% vs. 15.3%, relative risk reduction [RRR] 30%) [62]. Analysis by intention-to-treat gave a smaller estimate of RRR for stroke, MI, or vascular death (23%). The Ticlopidine ASA Stroke Study (TASS) trial compared ticlopidine (500 mg/day) to ASA (1300 mg/day) in 3,069 patients with a recent TIA or mild stroke [63]. There was a 12% reduction in the primary end point of nonfatal stroke or death in patients receiving ticlopidine compared with those receiving ASA (17% vs. 19%; p=0.048). Ticlopidine treatment was also associated with a significant reduction in the rate of fatal and nonfatal stroke compared with ASA (10% vs. 13%, respectively; RRR 21% [95% CI 4-38]). A TASS subgroup analysis showed a larger benefit for ticlopidine in African Americans prompting the African American Antiplatelet Stroke Prevention Study (AAASPS), in which ticlopidine was compared with ASA for secondary stroke prevention in African American stroke/TIA patients [64]. The AAASPS trial compared ticlopidine (500 mg/day) to ASA (650 mg/day) in 1809 black patients with noncardioembolic ischemic stroke [64]. At two-year follow-up, there was nonsignificant difference in the primary end point (stroke, MI, vascular death) between ticlopidine and ASA in African Americans. However, for the end point of fatal or non-fatal stroke, there was a trend favoring ASA over ticlopidine. The hematologic side effects and the availability of clopidogrel have significantly reduced the use of ticlopidine for recurrent stroke prevention in patients with ischemic stroke. Despite the evidence of benefit in the CATS and TASS trials, ticlopidine is not considered a first-line antiplatelet agent for stroke prevention because of side effects and relatively high cost.

Side effects of ticlopidine. Severe neutropenia, which occurs in approximately 1% of patients is the most serious complication of ticlopidine therapy. Thus, for the first three months of treatment, patients must undergo biweekly complete blood counts. This side effect limits the utility of ticlopidine. Other common side effects, which occur more frequently with ticlopidine than ASA, are rash and diarrhea.

Clopidogrel

Clopidogrel is a thienopyridine that inhibits ADP-dependent platelet aggregation (Table 64.4) [60]. Clopidogrel, an antiplatelet agent structurally and pharmacologically similar to ticlopidine, is used to reduce atherosclerotic events such as myocardial infarction, stroke, and vascular death in patients who have had a recent stroke, recent MI, or have established peripheral vascular disease. The active metabolite of clopidogrel prevents binding of adenosine diphosphate (ADP) to its platelet receptor, impairing the ADP-mediated activation of the glycoprotein GPIIb/IIIa complex. It is proposed that the inhibition involves a defect in the mobilization from the storage sites of the platelet granules to the outer membrane. No direct interference occurs with the GPIIb/IIIa receptor. As the glycoprotein GPIIb/IIIa complex is the major receptor for fibrinogen, its impaired activation prevents fibrinogen binding to platelets and inhibits platelet aggregation. By blocking the amplification of platelet activation by released ADP, platelet aggregation induced by agonists other than ADP is also inhibited by the active metabolite of clopidogrel.

Structure	 Chemical formula: $C_{16}H_{16}ClNO_2S$ SMILES: COC(=O)[C@@H](N1CCC2=C(C1)C=CS2)C1=CC=CC=C1Cl
Pharmacodynamics	Clopidogrel, an antiplatelet agent structurally and pharmacologically similar to ticlopidine, is used to reduce atherosclerotic events such as myocardial infarction, stroke, and vascular death in patients who have had a recent stroke, recent MI, or have established peripheral vascular disease
Mechanism of action	The active metabolite of clopidogrel prevents binding of adenosine diphosphate (ADP) to its platelet receptor, impairing the ADP-mediated activation of the glycoprotein GPIIb/IIIa complex. It is proposed that the inhibition involves a defect in the mobilization from the storage sites of the platelet granules to the outer membrane. he drug specifically and irreversibly inhibits the P2Y12 subtype of ADP receptor, which is important in aggregation of platelets and cross-linking by the protein fibrin. No direct interference occurs with the GPIIb/IIIa receptor. As the glycoprotein GPIIb/IIIa complex is the major receptor for fibrinogen, its impaired activation prevents fibrinogen binding to platelets and inhibits platelet aggregation. By blocking the amplification of platelet activation by released ADP, platelet aggregation induced by agonists other than ADP is also inhibited by the active metabolite of clopidogrel
Absorption	Absorption is at least 50% based on urinary excretion of clopidogrel-related metabolites. Bioavailability has not been found to be affected by food.
Volume of distribution	Not available
Protein binding	98%
Metabolism	Hepatic, extensive and rapid, by hydrolysis to the main circulating metabolite, a carboxylic acid derivative, which accounts for approximately 85% of the circulating drug-related compounds. A glucuronic acid derivative of the carboxylic acid derivative has also been found in plasma and urine. Neither the parent compound nor the carboxylic acid derivative has a platelet inhibiting effect
Route of elimination	Following an oral dose of 14C-labeled clopidogrel in humans, approximately 50% of total radioactivity was excreted in urine and approximately 46% in feces over the 5 days post-dosing
Half life	Carboxylic acid derivative: 8 hours (after single and multiple doses). Covalent binding to platelets has accounted for 2% of radiolabeled clopidogrel with a half-life of 11 days
Clearance	Not available
Toxicity	Symptoms of acute toxicity include vomiting (in baboons), prostration, difficult breathing, and gastrointestinal hemorrhage

Drug interactions	Drug	Interaction
	Bortezomib	Moderate CYP2C19 Inhibitors like bortezomib may decrease serum concentrations of the active metabolite(s) of Clopidogrel. Avoid concurrent use of moderate CYP2C19 inhibitors with clopidogrel whenever possible. If such a combination must be used, monitor closely for evidence of reduced clinical response to clopidogrel
	Drotrecogin alfa	Antiplatelet agents such as clopidogrel may enhance the adverse/toxic effect of Drotrecogin Alfa. Bleeding may occur. Increase monitoring for signs/symptoms of bleeding during concomitant therapy. If possible, avoid use of drotrecogin within 7 days of use of any IIb/IIIa antagonists, higher dose aspirin (more than 650 mg/day), or use of other antiplatelet agents
	Esomeprazole	Esomeprazole may decrease serum concentrations of the active metabolite(s) of clopidogrel. Due to the possible risk for impaired clopidogrel effectiveness with this combination, clinicians should carefully consider the need for concurrent esomeprazole therapy in patients receiving clopidogrel. Monitor response to clopidogrel closely when using clopidogrel with esomeprazole. Whether there are differences among individual proton pump inhibitors is unclear. Other acid-lowering therapies (e.g., H2-receptor antagonists, antacids, etc.) do not appear to share this interaction with clopidogrel
	Ginkgo biloba	Additive anticoagulant/antiplatelet effects may increase bleed risk. Concomitant therapy should be avoided
	Lansoprazole	Lansoprazole may decrease serum concentrations of the active metabolite(s) of clopidogrel. Due to the possible risk for impaired clopidogrel effectiveness with this combination, clinicians should carefully consider the need for concurrent lansoprazole therapy in patients receiving clopidogrel. Monitor response to clopidogrel closely when using clopidogrel with lansoprazole. Whether there are differences among individual proton pump inhibitors is unclear. Other acid-lowering therapies (e.g., H2-receptor antagonists, antacids, etc.) do not appear to share this interaction with clopidogrel
	Omeprazole	Omeprazole may decrease serum concentrations of the active metabolite(s) of clopidogrel. Clopidogrel prescribing information recommends avoiding concurrent use with omeprazole, due to the possibility that combined use may result in decreased clopidogrel effectiveness
	Pantoprazole	Pantoprazole may decrease serum concentrations of the active metabolite(s) of clopidogrel. Due to the possible risk for impaired clopidogrel effectiveness with this combination, clinicians should carefully consider the need for concurrent pantoprazole therapy in patients receiving clopidogrel. Monitor response to clopidogrel closely when using clopidogrel with pantoprazole. Whether there are differences among individual proton pump inhibitors is unclear. Other acid-lowering therapies (e.g., H2-receptor antagonists, antacids, etc.) do not appear to share this interaction with clopidogrel

	Rabeprazole	Rabeprazole may decrease serum concentrations of the active metabolite(s) of clopidogrel. Due to the possible risk for impaired clopidogrel effectiveness with this combination, clinicians should carefully consider the need for concurrent rabeprazole therapy in patients receiving clopidogrel. Monitor response to clopidogrel closely when using clopidogrel with rabeprazole. Whether there are differences among individual proton pump inhibitors is unclear. Other acid-lowering therapies (e.g., H_2-receptor antagonists, antacids, etc.) do not appear to share this interaction with clopidogrel
	Rivaroxaban	Antiplatelet agents such as clopidogrel may enhance the anticoagulant effect of rivaroxaban. Avoid concurrent use of clopidogrel with rivaroxaban unless the anticipated benefits outweigh the risks of bleeding. Canadian rivaroxaban labeling recommends avoiding concurrent use with any antiplatelet agent, while the U.S. rivaroxaban labeling recommends caution and increased monitoring if used with any other antiplatelet agent. Any combined use should only be undertaken with increased monitoring for evidence of bleeding
	Treprostinil	The prostacyclin analogue, Treprostinil, increases the risk of bleeding when combined with the antiplatelet agent, clopidogrel. Monitor for increased bleeding during concomitant thearpy
	Warfarin	Increased bleed risk may occur as a result of additive anticoagulant effects. Increase monitoring for signs and symptoms of bleeding during concomitant therapy.
Food interactions	Take without regard to meals	
Class effects	Thienopyridines may be slightly more effective than ASA for preventing serious vascular events in high-risk patients (Level 2 [mid-level] evidence) [35]	

Clopidogrel plus ASA	• Combination of ASA plus clopidogrel not usually recommended for secondary prevention of stroke or transient ischemic attack (TIA) in patients without atrial fibrillation:
	  ▪ Single-agent antiplatelet therapy recommended over combination of clopidogrel plus ASA for long-term antiplatelet therapy (ACCP Grade 1B) [15]
	  ▪ Addition of ASA to clopidogrel increases risk of hemorrhage and is not routinely recommended for secondary prevention of stroke (AHA/ASA Class III, Level A) [13]
	  ▪ Long term combination of ASA and clopidogrel is not recommended for secondary stroke prevention unless there is a compelling indication (CSN Grade B) [16]
	• For patients with cardioembolic stroke or TIA (that is, atrial fibrillation):
	  ▪ For patients unsuitable for or who choose not to take an oral anticoagulant (for reasons other than concerns about major bleeding), combination therapy with ASA plus clopidogrel recommended over ASA (ACCP Grade 1B) [15]
	  ▪ Clopidogrel with ASA not recommended for patients with hemorrhagic contraindication to warfarin (AHA/ASA Class III, Level B) [2]
	• Combination of ASA plus clopidogrel for secondary stroke prophylaxis increases risk of life-threatening or major bleeding (Level 1 [likely reliable] evidence) [31,66]	

Table 64.4. **Clopidogrel overview. SMILES indicates simplified molecular-input line-entry system.**

Clopidogrel is structurally similar to ticlopidine, differing by the addition of a carboxymethyl side group. The 2- to 3-day lag from initiation of clopidogrel to platelet inhibition can be overcome by oral clopidogrel loading (300-600 mg), which can result in platelet inhibition in 2 to 3 hours. Much of the evidence for a benefit with this drug comes from the cardiac literature, where it has been shown to reduce recurrent events in patients with an acute MI and lower reocclusion rates in patients undergoing coronary angioplasty and stenting. Safety profile is much better for clopidogrel than ticlopidine and carries a minimal risk for neutropenia. It has largely replaced ticlopidine in practice. Clopidogrel is significantly but marginally more effective than ASA: it reduced the long-term risk of stroke and other major vascular events by 8.7% (95% CI 0.3-16.5) compared with ASA among 19,185 patients at high vascular risk, and by 7.3% (−5.7-18.7%) among a subgroup of 6431 patients with ischemic stroke [26,35]. The Clopidogrel vs. ASA in Patients at Risk of Ischemic Events (CAPRIE) trial [26] compared clopidogrel (75 mg) to ASA (325 mg) in more than 19,000 patients with symptomatic vascular disease, defined by either recent ischemic stroke (within 1 week to 6 months), MI (within 35 days), or documented peripheral arterial disease. Among all patients, clopidogrel was associated with a significant 8.7% RRR compared with ASA for the primary end point of ischemic stroke, MI, or vascular death (5.32% vs. 5.83% per year; p=0.043). The benefit of clopidogrel over ASA was most pronounced for patients in the peripheral arterial disease subgroup (3.71% vs. 4.86% per year; p=0.0028) but ineffective for the 6,431 patients in the stroke subgroup (7.15% vs. 7.71% per year; p>0.2). However, the strength of these observations is limited, since they are based on subgroup analyses. Although the overall relative benefit of clopidogrel over ASA in the CAPRIE trial was modest (absolute risk reduction of 0.5% per year) and there was no statistically significant benefit over ASA for the stroke patients in this study, clopidogrel has become an important treatment option for patients with stroke. Hemorrhagic risk was similar between the groups.

Reccomendations

American College of Chest Physicians (ACCP) recommendations (Ninth Edition) [15]:

- Following noncardioembolic stroke or transient ischemic attack (TIA):
  - Clopidogrel 75 mg once daily recommended as an option for long-term antiplatelet therapy over: no antiplatelet therapy (ACCP Grade 1A), oral anticoagulants (ACCP Grade 1B), combination of clopidogrel plus ASA (ACCP Grade 1B), Triflusal (ACCP Grade 2B).
  - Among the recommended antiplatelet regimens, clopidogrel or combination of ASA plus extended-release DP suggested over ASA alone (ACCP Grade 2B) or triflusal (ACCP Grade 2C).
  - Benefit of clopidogrel over ASA for preventing major vascular events may be offset with long-term use (>5 years) by lower cancer-related mortality with ASA.
- Following cardioembolic stroke or TIA (that is, atrial fibrillation, including paroxysmal atrial fibrillation):
  - OAT recommended over:no antithrombotic therapy (ACCP Grade 1A), ASA (ACCP Grade 1B), combination therapy with ASA plus clopidogrel (ACCP Grade 1B).
  - For patients unsuitable for or who choose not to take an oral anticoagulant (for reasons other than concerns about major bleeding), combination therapy with ASA plus clopidogrel recommended over ASA (ACCP Grade 1B).

American Heart Association (AHA) recommendations [13]:

- For patients with noncardioembolic ischemic stroke or TIA, antiplatelet agents recommended rather than OAT (AHA/ASA Class I, Level A):
  - Acceptable options include: ASA 50-325 mg daily (AHA/ASA Class I, Level A), combination ASA 25 mg twice daily and extended-release DP 200 mg twice daily (AHA/ASA Class I, Level B), clopidogrel 75 mg daily (AHA/ASA Class IIa, Level B).

  - Selection of antiplatelet agent should be individualized based on patient risk factors, cost, tolerance and other clinical factors.
  - Addition of ASA to clopidogrel increases risk of hemorrhage and is not routinely recommended for secondary prevention of stroke (AHA/ASA Class III, Level A).
  - Clopidogrel reasonable for patients allergic to ASA (AHA/ASA Class IIa, Level C).
- For patients who have ischemic stroke while taking ASA (AHA/ASA Class IIb, Level C): no evidence for additional efficacy with increasing dose of ASA, alternative antiplatelet agents often considered, but no regimen specifically studied.
- For patients with ischemic stroke or TIA and paroxysmal or permanent atrial fibrillation:
  - If unable to take oral anticoagulants, ASA alone is recommended (AHA/ASA Class I, Level A).
  - Clopidogrel with ASA not recommended for patients with hemorrhagic contraindication to warfarin (AHA/ASA Class III, Level B).
  - Optimal medical therapy for patients with extracranial arterial disease (carotid or vertebrobasilar) and TIA or stroke should include antiplatelet therapy (AHA/ASA Class I, Level B).
- For patients with stroke or TIA due to 50%-99% stenosis of major intracranial artery, ASA 50-325 mg/day is recommended over warfarin (AHA/ASA Class I, Level B).
- For patients with cardiomyopathy:
  - Insufficient evidence for use of warfarin in patients with prior stroke or TIA, sinus rhythm, cardiomyopathy and ejection fraction ≤ 35% (AHA/ASA Class IIb, Level B)
  - Treatments to consider for patients with ischemic stroke or TIA and cardiomyopathy include (AHA/ASA Class IIb, Level B): Warfarin (INR 2-3), ASA 81 mg/day, clopidogrel 75 mg/day, combination of ASA 25 mg twice daily and extended-release DP 200 mg twice daily.
- For patients with native valvular heart disease:
  - Antiplatelet therapy may be considered for patients with ischemic stroke or TIA and: native aortic or nonrheumatic mitral valve disease and no atrial fibrillation (AHA/ASA Class IIb, Level C), mitral annular calcification (AHA/ASA Class IIb, Level C), mitral valve prolapse (AHA/ASA Class IIb, Level C).
- To avoid additional bleeding risk, antiplatelet agents should not be routinely added to warfarin (AHA/ASA Class III, Level C).

National Institute of Health and Clinical Excellence (NICE) guidance on clopidogrel and modified-release DP in prevention of occlusive vascular events [65]:

- Guidance applies to people with history of occlusive vascular event or with symptomatic peripheral arterial disease
- Clopidogrel alone (within licensed indications) recommended for people intolerant of low-dose ASA (proven hypersensitivity or history of severe dyspepsia) who have had occlusive vascular event or symptomatic peripheral arterial disease.

Canadian Stroke Network (CSN) recommendations [16]:

- All patients with ischemic stroke should be prescribed antiplatelet therapy for secondary prevention of recurrent stroke unless indication for anticoagulation (CSN Grade A).
- Medications include (CSN Grade A):
  - ASA 80-325 mg/day (1-5 mg/kg/day in children [CSN Grade B]).
  - Combined ASA (25 mg) and extended-release DP (200 mg) twice daily.
- Clopidogrel 75 mg/day.
- Clopidogrel may be considered an alternative in pediatric patients with contraindication to ASA (CSN Grade C)
- Long term combination of ASA and clopidogrel is not recommended for secondary stroke prevention unless there is a compelling indication (CSN Grade B).

Side effects of clopidogrel. The side effect profile of clopidogrel is favorable compared with ASA, with lower frequency of gastric upset or gastrointestinal bleeding but a slightly higher frequency of rash and diarrhea [20]. Severe neutropenia is not seen more frequently with clopidogrel than with ASA [26]. Clopidogrel causes less gastrointestinal bleeding than 325 mg ASA daily (RR 0.69 [95% CI 0.48-1.00]; absolute annual decrease 0.12% [0.00-0.28%]), but does not reduce the risk of other types of bleeding [26,35].

Platelets response to clopidogrel treatment varies, and may be due to clinical, cellular, or genetic factors [58,67-69]. Clopidogrel is an inactive prodrug that requires two-step oxidation by the hepatic cytochrome P450 (CYP) system to generate its active compound, the thiol metabolite, which targets and irreversibly inhibits the ADP P2Y purinoceptor 12 on circulating platelets. The hepatic CYP isoenzymes involved in this two-step metabolization process of clopidogrel include CYP2C19, CYP3A4/5, CYP1A2, CYP2B6, and CYP2C9. Several genetic polymorphisms have been described that may be associated with impaired pharmacokinetic and pharmacodynamic response to clopidogrel, with possible clinical consequences [58,67-69]. The first genome-wide association study of clopidogrel response has recently reported that the loss-of-function *CYP2C19*2* genotype was associated with diminished effect of clopidogrel inhibition of ADP-induced platelet aggregation and poorer cardiovascular outcomes [58]. Whether the *CYP2C19*2* polymorphism is associated with higher cardiovascular risks that are independent from the diminished conversion of the prodrug to the active form of clopidogrel remains to be determined. A genomic profile may identify patients at risk of ischemic events for whom an alternative antiplatelet approach may be more effective while taking clopidogrel. This hypothesis remains to be validated externally. At the moment, no convincing prospective data support routine testing for clopidogrel resistance with in vitro tests of platelet function or genotyping in patients with cardiovascular disease, particularly for those with a history of stroke or TIA. A 2010 clinical alert from the American College of Cardiology Foundation and the American Heart Association noted that adherence to existing guidelines for the use of antiplatelet therapy should remain the basis for therapy, and further that there is insufficient evidence to recommend routine platelet function testing or genetic testing for clopidogrel [70]. Concomitant administration of clopidogrel with a proton pump inhibitor, particularly omeprazole, to minimize the risk of gastrointestinal bleeding complications, also attenuates clopidogrel's antiplatelet action in about a third of patients [58,67-69]. The mechanism is thought to be a drug-drug interaction at the level of the hepatic CYP system, because hepatic metabolization of omeprazole is also CYP dependent. However, although treatment with a proton pump inhibitor attenuates the pharmacodynamic effects of clopidogrel, the effect is modest and apparently insufficient to affect the clinical outcome of patients on clopidogrel (or prasugrel – another thienopyridine) [71,72]. In the long-term use (18 months), ASA plus clopidogrel is no more effective than clopidogrel alone in prevention of ischemic stroke, MI, vascular death, and rehospitalization for acute ischemia (RR 0.94 [95% CI 0.84-1.05]) [31]; while it was associated with an increase in life threatening bleeding (2.6% on ASA and clopidogrel vs. 1.3% on ASA; absolute risk increase 1.3% [0.6-1.9]) [40].

ASA Plus Clopidogrel

The combined use of ASA plus clopidogrel does not offer greater benefit for stroke prevention than either agent alone but increases the risk of bleeding complications [28,31,73]. Combination therapy with clopidogrel plus ASA has been shown to be more effective than ASA monotherapy in patients with acute MI, unstable angina, or coronary interventions [74,75], and its use is common, especially in patients with coronary artery disease. The combination therapy in patients with stroke was tested in the Management of Atherothrombosis with Clopidogrel in High-risk Patients (MATCH) trial, in which clopidogrel plus ASA was compared with clopidogrel monotherapy [31]. This specific compari-

son was based on the assumption that clopidogrel monotherapy is the gold standard for antiplatelet secondary prevention [28]. This study enrolled 7,599 patients with stroke or TIA who also had some additional "high-risk" feature, defined as prior MI, prior stroke (in addition to the index event), diabetes, angina, or symptomatic peripheral artery disease (PAD). The primary end point was a composite of ischemic stroke, MI, vascular death, or rehospitalization for acute ischemia. Patients were randomly assigned to the combination of clopidogrel (75 mg daily) plus ASA (75 mg daily) vs. clopidogrel (75 mg daily) alone. Follow-up was 18 months. The main results of this trial were [31]: 1) ASA plus clopidogrel treatment did not reduce the risk of major vascular events compared with clopidogrel alone (RRR 6.4%, 95% CI -4.6-16.3); 2) ASA plus clopidogrel was associated with a significant increase in life-threatening bleeding complications, mainly intracranial and gastrointestinal, compared with clopidogrel alone with an absolute excess of 1.3% for life-threatening hemorrhage (95% CI 0.6-1.9) over the 18-month trial period and an additional 1.3% for major hemorrhage in patients assigned combination therapy. (3) Overall, the combination treatment with ASA and clopidogrel compared with clopidogrel alone might prevent 10 ischemic events per 1000 treated (not statistically significant) at the cost of 13 life-threatening hemorrhages per 1000 treated. However, MATCH trial has several limitations such as 54% of MATCH subjects qualified for trial entry because of a lacunar stroke, a stroke subtype that has the lowest recurrence risk [76], and data regarding interaction between treatment and stroke mechanism were not reported, raising the question of whether combination therapy might still play a role in particular stroke subtypes. In conclusions, the MATCH results do not support the use of combination therapy of clopidogrel plus ASA for patients with stroke. Future trials to evaluate the benefit and safety of the combination of ASA and clopidogrel when administered immediately after TIA and ischemic stroke (ie, within 12 to 24 hours rather than 15 days) with a loading dose of clopidogrel (300 mg or 600 mg) and for a short period of 3 months, when the benefits are likely to be greatest and the cumulative risks of bleeding avoided could be of interest and useful [77]. The combination of ASA and clopidogrel has been shown to have benefit over ASA alone in patients with acute coronary syndromes. However, there are important differences between patients with coronary and cerebrovascular disease [78], and between short-term therapy initiated in the acute setting, and longer term preventative therapy. On the contrary, the CHARISMA trial evaluated ASA plus clopidogrel vs. ASA alone in patients with symptomatic cardiovascular disease or asymptomatic multiple cardiovascular risk factors [28]. CHARISMA enrolled 15,603 patients with either documented cardiovascular disease (coronary, ischemic cerebrovascular, or peripheral arterial) or, in 21% of patients, multiple atherothrombotic risk factors (eg, diabetes, hypertension, primary hypercholesterolemia, current smoking, asymptomatic carotid stenosis ≥70%) and randomly assigned them to low-dose ASA (75 to 162 mg/day) plus either clopidogrel (75 mg/day) or placebo. The combination of ASA plus clopidogrel was not more effective than ASA alone for reducing the rate of MI, stroke, or death from cardiovascular causes [28]. Combined ASA plus clopidogrel treatment did not reduce the risk of the composite primary end point (MI, stroke of any cause, or death from cardiovascular causes) compared with ASA alone (6.8% vs. 7.3%, RR 0.93, 95% CI 0.83-1.05). Combination therapy compared with ASA alone was associated with a significant increase in moderate bleeding (2.1% vs. 1.3%) and a nonsignificant increase in severe bleeding (1.7% vs. 1.3%).

The use of dual antiplatelet therapy with ASA plus clopidogrel has also been studied in different subtypes of ischemic stroke, including small vessel disease and large artery atherosclerosis. In the randomized Secondary Prevention of Small Subcortical Strokes (SPS3) trial evaluating patients with subcortical (ie, lacunar) stroke confirmed by MRI, the arm testing the combination of ASA plus clopidogrel was terminated before completion because a preliminary review of trial data found a higher frequency of bleeding events (mostly sys-

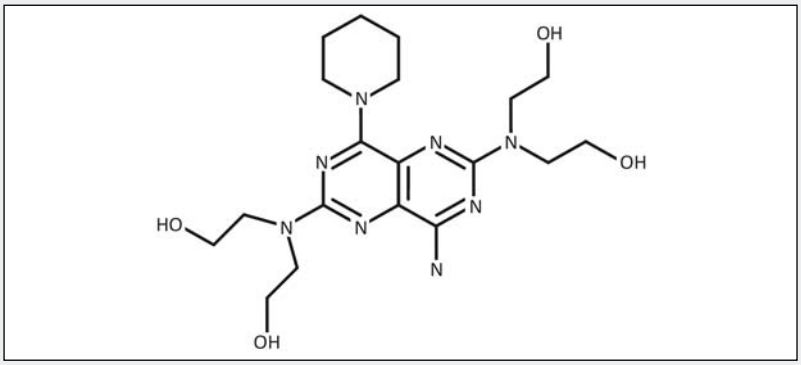
temic) in patients assigned to ASA and clopidogrel compared with those assigned to ASA alone (6.5% vs. 3.3%) [79]. The dual antiplatelet therapy group showed a higher mortality rate from all causes compared with the ASA alone group (5.8% vs. 4.1%; hazard ratio [HR], 1.5; p=0.005). This result was not confirmed in a meta-analysis of twelve trials included 90,934 participants. There was nonsignificant increase in mortality with the combination therapy either in 4 short-term (14 days-3 months; OR, 0.93, 95% CI 0.87- 0.99) or in 7 long-term (>3 months; HR 0.97, 95% CI 0.91-1.04) trials after the SPS3 trial was excluded because of heterogeneity. It was confirmed that addition of clopidogrel was associated with an increase in fatal hemorrhage (OR 1.35, 95% CI 0.97-1.90) and a reduction in MI (OR 0.82, 95% CI 0.74-0.91) [80]. These results, together with those of the MATCH trial, suggest that dual antiplatelet therapy with ASA and clopidogrel is harmful for patients with lacunar stroke. Two small trials (CARESS and CLAIR) of patients with recently symptomatic large artery stenosis found that, compared with ASA alone, early treatment with ASA plus clopidogrel reduced the number of microembolic signals detected on transcranial Doppler ultrasound [81,82]. However, whether this surrogate measure would translate into clinical benefit for patients with symptomatic large artery stenosis remains uncertain. In the SAMMPRIS trial, all subjects with recently symptomatic intracranial large artery stenosis, received combined ASA and clopidogrel for the first 90 days after enrollment to evaluate angioplasty and stenting plus intensive medical management vs. intensive medical management alone [83]. The results were notable for a reduced rate of recurrent stroke and death in the medical management arm compared with historical controls, suggesting that short-term dual antiplatelet therapy is beneficial in this scenario. Therefore, we suggest dual antiplatelet therapy with ASA plus clopidogrel for 90 days, followed by antiplatelet monotherapy, for patients with recently symptomatic intracranial large artery disease.

Dipyridamole

Dipyridamole (DP) likely inhibits both adenosine deaminase and phosphodiesterase, preventing the degradation of cAMP, an inhibitor of platelet function (Table 64.5). This elevation in cAMP blocks the release of arachidonic acid from membrane phospholipids and reduces thromboxane A2 activity. DP also directly stimulates the release of prostacyclin, which induces adenylate cyclase activity, thereby raising the intraplatelet concentration of cAMP and further inhibiting platelet aggregation [84].

Because of its short half-life, the regular form is taken every 8 hours and the ER form is taken twice per day. DP is currently available in two forms: an immediate-release form, usually given as 50 to 100 mg three times per day and a proprietary formulation containing both ER-DP 200 mg and 25 mg ASA, given two times per day.

Structure



Chemical formula: $C_{24}H_{40}N_8O_4$
SMILES: CCN(CCO)C1=NC2=C(N=C(N=C2N2CCCCC2)N(CCO)CCO)C(=N1)N1CCCCC1

Pharmacodynamics	DP, a non-nitrate coronary vasodilator that also inhibits platelet aggregation, is combined with other anticoagulant drugs, such as warfarin, to prevent thrombosis in patients with valvular or vascular disorders. DP is also used in myocardial perfusion imaging, as an antiplatelet agent, and in combination with aspirin for stroke prophylaxis	
Mechanism of action	DP likely inhibits both adenosine deaminase and phosphodiesterase, preventing the degradation of cAMP, an inhibitor of platelet function. This elevation in cAMP blocks the release of arachidonic acid from membrane phospholipids and reduces thromboxane A2 activity. DP also directly stimulates the release of prostacyclin, which induces adenylate cyclase activity, thereby raising the intraplatelet concentration of cAMP and further inhibiting platelet aggregation	
Absorption	70%	
Volume of distribution	1 to 2.5 l/kg	
Protein binding	99%	
Metabolism	Hepatic	
Route of elimination	DP is metabolized in the liver to the glucuronic acid conjugate and excreted with the bile	
Half life	40 minutes	
Clearance	2.3-3.5 ml/min/kg	
Toxicity	Hypotension, if it occurs, is likely to be of short duration, but a vasopressor drug may be used if necessary. The oral LD_{50} in rats is greater than 6,000 mg/kg while in the dogs, the oral LD_{50} is approximately 400 mg/kg. LD_{50}=8.4g/kg (orally in rat)	
Affected organisms	Humans and other mammals	
Interactions	**Drug**	**Interaction**
	Adenosine	DP may increase the effect/toxicity of adenosine
	Fludarabine	DP may decrease the effect of fludarabine
	Ginkgo biloba	Additive anticoagulant/antiplatelet effects may increase bleed risk. Concomitant therapy should be avoided
	Topotecan	The p-glycoprotein inhibitor, DP, may increase the bioavailability of oral topotecan. A clinically significant effect is also expected with IV topotecan. Concomitant therapy should be avoided
	Treprostinil	The prostacyclin analogue, Treprostinil, increases the risk of bleeding when combined with the antiplatelet agent, DP. Monitor for increased bleeding during concomitant thearpy. Additive hypotensive effect. Monitor antihypertensive therapy during concomitant use
Food interactions	Coffee and tea can decrease the effect of DP Take with food to reduce irritation	
Combination formulation with ASA	• Aggrenox FDA approved to reduce risk of stroke in patients who have had transient ischemia of brain or completed ischemic stroke due to thrombosis: ▪ Each capsule contains extended-release DP 200 mg plus immediate-release ASA 25 mg ▪ 1 capsule orally twice daily, swallow whole; do not crush, chew or open ▪ Cautions: peripheral vasodilation so caution if hypotension or severe coronary artery disease, amount of ASA may be inadequate for protection against myocardial infarction, Pregnancy Category D ▪ Adverse reactions: headache, dizziness, gastrointestinal upset, flushing, weakness, syncope, rash, pruritus, increased liver enzymes ▪ available in Europe as Asasantin/Aggrenox • Expensive, but generic substitutions with immediate-release DP may be less effective	

Efficacy	• Addition of DP to ASA reduces risk of vascular events after stroke or TIA (Level 1 [likely reliable] evidence) [33,66,85,86] • Extended-release DPis effective alone and more effective in combination with ASA in secondary prevention of stroke (Level 1 [likely reliable] evidence) [44,87] • Addition of DP to ASA may reduce risk of combined outcome of cardiovascular events (Level 2 [mid-level] evidence) [86] • Addition of DP to ASA might not reduce vascular events in patients after severe disabling stroke (level 2 [mid-level] evidence) [88] • Initiating DP plus ASA after 7 days of ASA therapy alone may be as effective as initiating within 24 hours of TIA or stroke (Level 2 [mid-level] evidence) [89] • Oatients>80 years old may still have reduced risk of stroke or death with ASA plus DP (level 2 [mid-level] evidence) [90]
Triple therapy	Antiplatelet therapy with combination ASA, clopidogrel, and DP associated with increased adverse events and bleeding complications (Level 2 [mid-level] evidence) [91]
Comparative efficacy	• ASA plus extended-release DP appears similar to clopidogrel for prevention of recurrent stroke but may have slightly more major hemorrhagic events (Level 2 [mid-level] evidence) [36,89] • ASA plus extended-release DP appears similar to clopidogrel in short-term functional outcome, recurrence and death (Level 2 [mid-level] evidence) [92] • DP plus ASA reported to be more effective than clopidogrel, ticlopidine or ASA for prevention of serious vascular events after TIA or stroke (Level 3 [lacking direct] evidence) [93]

Table 64.5. **Dipyridamole (DP) overview. SMILES indicates simplified molecular-input line-entry system [25].**

In the European Stroke Prevention Study 2 (ESPS-2) trial 6602 patients with a recent TIA or ischemic stroke were randomly assigned to four treatment groups: 25 mg ASA, 200 mg ER -DP, 25 mg ASA plus ER-DP, and placebo using a factorial design [44]. The three active treatments significantly reduced the incidence of stroke compared with placebo: (ASA vs. placebo: 12.5% vs. 15%, RRR 18.1%, p=0.01; ER-DP vs. placebo: 12.7% vs. 15%, RRR 16.3%, p=0.04; ASA combined with ER-DP: 9.5% vs. 15%, RRR 37.0%, p=0.001). The benefit of combination ER-DP plus ASA was significantly greater still than the two components alone and significantly greater than placebo (OR 0.59, 95% CI 0.48-0.73). A subsequent meta-analysis of individual patient data from all available randomized trials found that DP alone was effective for reducing recurrent stroke compared with control (OR 0.82, 95% CI 0.68-1.0) [85]. Since the ESPS-2 trial [44] provided 57% of the data in this meta-analysis, it is possible that ESPS-2 was the primary driver behind the results [85]. When ESPS-2 data were excluded, the effectiveness of DP alone compared with control did not achieve statistical significance. Whether this is related to the lower doses and immediate-release formulation used in trials other than ESPS-2 remains unclear.

Side Effects of DP

Headache is a well-known side effect of DP [85], and was the most frequent adverse event associated with ER-DP in two large clinical trials, ESPS-2 and ESPRIT [44,86]. DP causes headache in 24-70% of patients, in 39.7% after a single dose [94], which is sufficient to prompt discontinuation in about 10% of patients, usually within the first 3 months. Headache is more likely to occur in women, non-smokers, and patients with an absence of relevant ischemic lesions on brain imaging [95]. The headaches associated with ASA plus ER-DP treatment were mostly self-limited, and treatment with acetaminophen was not significantly better than with placebo, as measured by response at two hours (75.5% and 69.4%). The overall incidence of headache declined markedly over seven days to less than 20%. Gastric upset and/or diarrhea requiring drug cessation was

also more common with DP compared with ASA or placebo in ESPS-2. Notably, ASA use was associated with significantly greater overall bleeding and gastrointestinal bleeding compared with DP or placebo in ESPS-2 and a subsequent meta-analysis [44,85]. In fact, in ESPS-2, the frequency of bleeding complications with DP was comparable to placebo.

Cardiac Effects

Concern that DP use might lead to increased rates of myocardial ischemia has been largely laid to rest by data from two large clinical trials (ESPS-2 and ESPRIT) and a meta-analysis [85,86,96]. This concern is related to the potential for DP to cause vasodilation of coronary vessels [97], with the use of intravenous DP in cardiac stress testing [98]. The 2002 American College of Cardiology/American Heart Association guideline for the management of patients with chronic stable angina recommend avoidance of DP in patients with stable angina [99]. An analysis of data from ESPS-2 found that use of ER-DP was not associated with increased cardiac ischemia or mortality in patients with a history of coronary artery disease [96]. A meta-analysis found that oral DP had a neutral cardiac effect and did not alter the rate of MI in patients with previous stroke or TIA, either when compared with control, or when administered in combination with ASA and compared with ASA alone [85]. In ESPRIT, the use of combination therapy with ASA and DP, mainly ER-DP, was associated with a nonsignificant decrease in the outcome of first cardiac event, and a significant decrease in the primary composite outcome that included death from all vascular causes and nonfatal MI [86]. The cited observations suggest that ER-DP use for stroke prevention is NOT associated with an increased risk of myocardial ischemia or infarction.

ASA plus DP

Currently, the most commonly used preparation combines the ER form of DP (200 mg) with ASA (25 mg) into one pill. The combination of 25 mg ASA with 200 mg ER-DP costs substantially more than ASA but less than clopidogrel. In the USA, use of clopidogrel and the combination of ASA and ER-DP increased between 2001 and 2005, as their superior efficacy to ASA was recognized, despite the greater costs of the drugs [87]. In patients with previous TIA or ischemic stroke, the combination of ASA and ER-DP is significantly more effective than ASA alone in reducing the risk of stroke and other major vascular events (HR 0.82, 95% CI 0.72-0.92) without excessive bleeding or MI [33]. The combination of ASA and DP has been compared with ASA monotherapy for stroke prevention among patients with TIA or stroke in several clinical trials. Stroke risk was significantly reduced with ASA plus DP (including immediate and ER formulations) compared with ASA alone (RR 0.77, 95% CI 0.67-0.89) as reported in a meta-analysis of six randomized trials with 7,648 patients [86]. The beneficial effects of ASA and DP for secondary stroke prevention appear to be additive such that the combination of ASA plus ER-DP is significantly more effective than ASA alone for stroke prevention. In the ESPS-2 trial, the stroke rate at 24 months of follow-up was significantly reduced in the ASA plus ER-DP group compared with the ASA alone group (9.9% vs. 12.9%; RRR 23%, 95% CI 9.2-37.0) [44]. The risk of death and bleeding complications was not significantly different between the ASA plus ER-DP group and the ASA monotherapy group, whereas both groups experienced a greater frequency of bleeding complications than the placebo group. In the ESPRIT trial, the composite primary outcome (death from all vascular causes, nonfatal stroke, nonfatal MI, or major bleeding complication) was significantly less frequent in the ASA plus DP group than the ASA group (13% vs. 16%, HR 0.80, 95% CI 0.66-0.98, absolute risk reduction 1.0% per year) over a mean follow-up of 3.5 years [88]. In this trial, 2,739 patients within six months of a TIA or minor stroke of presumed arterial origin were randomly assigned to open-label treatment with ASA (30 to 325 mg/day) alone or ASA plus

DP (200 mg twice daily). The median ASA dose was 75 mg/day in both treatment groups, and the DP formulation used by most patients (83%) was ER rather than immediate release [88] ESPRIT included patients using ASA doses ranging from 30 to 325 mg daily, allaying concerns that the very low ASA dose (25 mg twice daily) used in ESPS-2 was in part responsible for the benefit of combined ASA plus ER-DP over ASA alone. The specific DP preparation may also be important because the combination of ASA and immediate-release DP was nonsignificantly better than ASA alone for secondary prevention of stroke (RR 0.83, 95% CI 0.59-1.15); on the contrary ASA plus ER-DP was associated with a significant reduction in stroke risk compared with ASA alone (RR 0.76, 95% CI 0.65-0.89) [86]. Extended release DP was used in all or the vast majority of patients in the much larger ESPS-2 and ESPRIT trials [47,88].

Recommendations for Use of DP for Secondary Prevention of Stroke

American College of Chest Physicians (ACCP) recommendations (Ninth Edition) [15]:

- Following noncardioembolic stroke or transient ischemic attack (TIA):
  - Combination of ASA 25 mg plus DP extended-release 200 mg twice daily recommended as an option for long-term antiplatelet therapy over: no antiplatelet therapy (ACCP Grade 1A), oral anticoagulants (ACCP Grade 1B), combination of clopidogrel plus ASA (ACCP Grade 1B), triflusal (ACCP Grade 2B).
  - Among the recommended antiplatelet regimens, clopidogrel or combination of ASA plus extended-release DP suggested over ASA alone (ACCP Grade 2B) or triflusal (ACCP Grade 2C).

American Heart Association (AHA) recommendations [13]:

- For patients with noncardioembolic ischemic stroke or TIA, antiplatelet agents recommended rather than OAT (AHA/ASA Class I, Level A):
  - Acceptable options include. ASA 50-325 mg daily (AHA/ASA Class I, Level A), combination ASA 25 mg twice daily and extended-release DP 200 mg twice daily (AHA/ASA Class I, Level B), clopidogrel 75 mg daily (AHA/ASA Class IIa, Level B).
  - Selection of antiplatelet agent should be individualized based on patient risk factors, cost, tolerance and other clinical factors.
  - Addition of ASA to clopidogrel increases risk of hemorrhage and is not routinely recommended for secondary prevention of stroke (AHA/ASA Class III, Level A).
  - Clopidogrel reasonable for patients allergic to ASA (AHA/ASA Class IIa, Level C).
  - For patients who have ischemic stroke while taking ASA (AHA/ASA Class IIb, Level C): no evidence for additional efficacy with increasing dose of ASA, alternative antiplatelet agents often considered, but no regimen specifically studied.
- For patients with ischemic stroke or TIA and paroxysmal or permanent atrial fibrillation:
  - If unable to take oral anticoagulants, ASA alone is recommended (AHA/ASA Class I, Level A).
  - Clopidogrel with ASA not recommended for patients with hemorrhagic contraindication to warfarin (AHA/ASA Class III, Level B).
- Optimal medical therapy for patients with extracranial arterial disease (carotid or vertebrobasilar) and TIA or stroke should include antiplatelet therapy (AHA/ASA Class I, Level B).
- For patients with stroke or TIA due to 50%-99% stenosis of major intracranial artery, ASA 50-325 mg/day is recommended over warfarin (AHA/ASA Class I, Level B).
- For patients with cardiomyopathy:
  - Insufficient evidence for use of warfarin in patients with prior stroke or TIA, sinus rhythm, cardiomyopathy and ejection fraction ≤ 35% (AHA/ASA Class IIb, Level B).
  - Treatments to consider for patients with ischemic stroke or TIA and cardiomyopathy include (AHA/ASA Class IIb, Level B): warfarin (INR 2-3), ASA 81 mg/day,

clopidogrel 75 mg/day, combination of ASA 25 mg twice daily and extended-release DP 200 mg twice daily.

- For patients with native valvular heart disease:
  - Antiplatelet therapy may be considered for patients with ischemic stroke or TIA and: native aortic or nonrheumatic mitral valve disease and no atrial fibrillation (AHA/ASA Class IIb, Level C), mitral annular calcification (AHA/ASA Class IIb, Level C), mitral valve prolapse (AHA/ASA Class IIb, Level C).

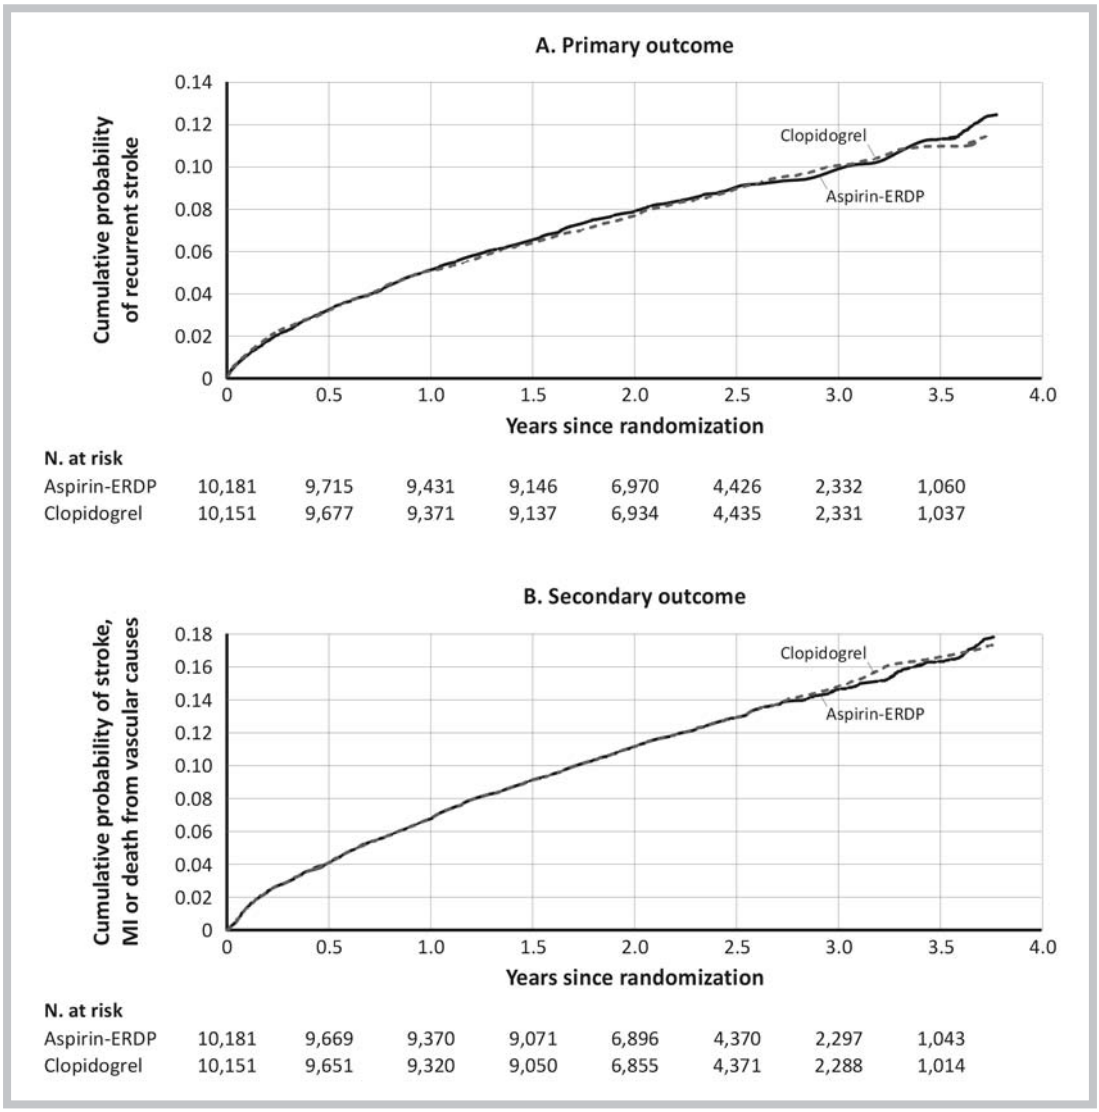


Figure 64.3. **Kaplan-Meier estimates of the cumulative probability of primary and secondary outcomes, according to treatment group. The primary outcome of first recurrence of stroke (Panel A) occurred in 916 of 10,181 patients (9.0%) treated with aspirin plus extended-release dipyridamole (ERDP) and in 898 of 10,151 patients (8.8%) treated with clopidogrel (hazard ratio for aspirin-ERDP, 1.01; 95% confidence interval [CI], 0.92 to 1.11). The main secondary outcome of stroke, myocardial infarction (MI), or death from vascular causes (Panel B) occurred in 1333 patients (13.1%) in each of the two groups (hazard ratio for aspirin-ERDP, 0.99; 95% CI, 0.92 to 1.07). The estimated hazard ratios are based on a Cox model with covariates of baseline values of age, use or nonuse of angiotensin-converting-enzyme inhibitors, diabetes status, and score on the modified Rankin scale. Adapted from [36].**

  - To avoid additional bleeding risk, antiplatelet agents should not be routinely added to warfarin (AHA/ASA Class III, Level C).
- For patients with ischemic stroke or TIA due to extracranial arterial dissection (carotid or vertebral):
  - Antithrombotic therapy for at least 3-6 months is reasonable (AHA/ASA Class IIa, Level B).
  - Relative efficacy of antiplatelet therapy vs. anticoagulation is unknown (AHA/ASA Class IIb, Level B).
- For patients with patent foramen ovale (PFO):
  - Antiplatelet therapy is reasonable for patients with ischemic stroke or TIA and PFO (AHA/ASA Class IIa, Level B).
  - Insufficient data to determine whether anticoagulation is as or more effective than ASA for secondary stroke prevention in patients with PFO (AHA/ASA Class IIb, Level B).

National Institute of Health and Clinical Excellence (NICE) guidance on clopidogrel and modified-release DP in prevention of occlusive vascular events [65]:

- Guidance applies to people with history of occlusive vascular event or with symptomatic peripheral arterial disease.
- Combination of modified-release DP and ASA recommended for people who had ischemic stroke or transient ischemic attack for 2 years from most recent event then continue with low-dose ASA.

Canadian Stroke Network (CSN) recommendations [16]:

- All patients with ischemic stroke should be prescribed antiplatelet therapy for secondary prevention of recurrent stroke unless indication for anticoagulation (CSN Grade A).
- Combined ASA (25 mg) and extended-release DP (200 mg) twice daily is an option for antiplatelet therapy.

ASA Plus Extended-release Dipyridamole vs. Clopidogrel

In the PRoFESS trial clopidogrel monotherapy and ASA plus ER-DP showed similar risks and benefits for secondary stroke prevention [36]. Using a 2x2 factorial design in which the patients were also randomly assigned to telmisartan or placebo, the trial enrolled 20,332 patients with noncardioembolic ischemic stroke and randomly assigned them to treatment with either ASA plus ER-DP (25/200 mg twice daily) or clopidogrel (75 mg once daily). At an average follow-up of 2.5 years, a direct comparison of 75 mg clopidogrel daily with the combination of 25 mg ASA and 200 mg ER-DP twice daily in 20,332 patients with ischemic stroke showed nonsignificant difference between either regimen in the prevention of recurrent stroke (9.0% on ASA plus ER-DP vs. 8.8% on clopidogrel; HR 1.01, 95% CI 0.92-1.11), MI (1.7% vs. 1.9%; HR 0.90, 0.73-1.10), and the composite secondary outcome of stroke, MI, and vascular death (13.1% vs. 13.1%; HR 0.99, 0.92-1.07; Figure 64.3). The trial failed to meet the prespecified noninferiority criteria for treatment with ASA plus ER-DP, the rate of recurrent ischemic stroke was slightly lower in those assigned to ASA plus ER-DP compared with clopidogrel (7.7% vs. 7.9%) among patients who had recurrent strokes, while ICH were slightly increased (0.9% vs. 0.5%). The benefit-risk ratio (the combination of recurrent stroke plus major hemorrhage) was not significantly different between ASA plus ER-DP and clopidogrel (11.7% vs. 11.4%; HR 1.03, 95% CI 0.95-1.11). Discontinuation due to headache was significantly more frequent in patients assigned to ASA plus ER-DP than in those assigned to clopidogrel (5.9% vs. 0.9%) while New or worsening heart failure was slightly less frequent in patients assigned to ASA plus ER-DP compared to those assigned to clopidogrel (1.4% vs. 1.8%, 95% CI 0.62-0.96).

64.2.1 Other Antithrombotic Regimens

Cilostazol

The antiplatelet agent cilostazol is a phosphodiesterase 3 inhibitor that is used in the alleviation of the symptom of intermittent claudication in individuals with peripheral vascular disease (Table 64.6). The mechanism of the effects of cilostazol on the symptoms of intermittent claudication and in the prevention of recurrent ischemic stroke is not fully understood. Cilostazol and several of its metabolites are cyclic AMP (cAMP) phosphodiesterase III inhibitors (PDE III inhibitors), inhibiting phosphodiesterase activity and suppressing cAMP degradation with a resultant increase in cAMP in platelets and blood vessels, leading to inhibition of platelet aggregation and vasodilation [84].

Structure	 Chemical formula: $C_{20}H_{27}N_5O_2$ SMILES: O=C1CCC2=C(N1)C=CC(OCCCCC1=NN=NN1C1CCCCC1)=C2
Indication	For the reduction of symptoms of intermittent claudication (pain in the legs that occurs with walking and disappears with rest)
Pharmacodynamics	Cilostazol is a quinolinone derivative indicated for the reduction of symptoms of intermittent claudication, as indicated by an increased walking distance. Intermittent claudication is pain in the legs that occurs with walking and disappears with rest. The pain occurs due to reduced blood flow to the legs
Mechanism of action	Cilostazol and several of its metabolites are cyclic AMP (cAMP) phosphodiesterase III inhibitors (PDE III inhibitors), inhibiting phosphodiesterase activity and suppressing cAMP degradation with a resultant increase in cAMP in platelets and blood vessels, leading to inhibition of platelet aggregation and vasodilation
Absorption	Cilostazol is absorbed after oral administration. A high fat meal increases absorption, with an approximately 90% increase in C_{max} and a 25% increase in AUC. Absolute bioavailability is not known
Volume of distribution	Not available
Protein binding	95-98%
Metabolism	Hepatic. Cilostazol is extensively metabolized by hepatic cytochrome P-450 enzymes, mainly 3A4, and, to a lesser extent, 2C19, with metabolites largely excreted in urine. Two metabolites are active, with one metabolite appearing to account for at least 50% of the pharmacologic (PDE III inhibition) activity after administration of cilostazol
Route of elimination	Cilostazol is extensively metabolized by hepatic cytochrome P-450 enzymes, mainly 3A4, and, to a lesser extent, 2C19, with metabolites largely excreted in urine. Cilostazol is eliminated predominately by metabolism and subsequent urinary excretion of metabolites. The primary route of elimination was via the urine (74%), with the remainder excreted in feces (20%). No measurable amount of unchanged cilostazol was excreted in the urine, and less than 2% of the dose was excreted as 3,4-dehydro-cilostazol. About 30% of the dose was excreted in urine as 4'-trans-hydroxy-cilostazol

Half life	11-13 hours	
Clearance	Not available	
Toxicity	Information on acute overdosage with cilostazol in humans is limited. The signs and symptoms of an acute overdose can be anticipated to be those of excessive pharmacologic effect: severe headache, diarrhea, hypotension, tachycardia, and possibly cardiac arrhythmias. The oral LD_{50} of cilostazol is >5.0 g/kg in mice and rats and >2.0 g/kg in dogs	
Drug interactions	**Drug**	**Interaction**
	Diltiazem	Diltiazem, a moderate CYP3A4 inhibitor, may increase the serum concentration of cilostazol by decreasing its metabolism. Monitor for changes in the therapeutic and adverse effects of cilostazol if diltiazem is initiated, discontinued or dose changed
	Erythromycin	Erythromycin increases the effect of cilostazol
	Fluconazole	Fluconazole may decrease the effect of cilostazol
	Fluoxetine	Fluoxetine, a moderate CYP2C19 inhibitor, may decrease the metabolism of cilostazol. Monitor for changes in the therapeutic and adverse effects of cilostazol if fluoxetine is initiated, discontinued or dose changed
	Fluvoxamine	Fluvoxamine increases the effect of cilostazol
	Ginkgo biloba	Additive anticoagulant/antiplatelet effects may increase bleed risk. Concomitant therapy should be avoided
	Itraconazole	Itraconazole may increase the effect of cilostazol
	Josamycin	Erythromycin increases the effect of cilostazol
	Ketoconazole	Ketoconazole may increase the effect of cilostazol
	Nefazodone	Nefazodone increases the effect of cilostazol
	Omeprazole	Omeprazole increases the effect of cilostazol
	Sertraline	Sertraline increases the effect of cilostazol
	Telithromycin	Telithromycin may reduce clearance of cilostazol. Consider alternate therapy or monitor for changes in the therapeutic/adverse effects of cilostazol if telithromycin is initiated, discontinued or dose changed
	Ticlopidine	Ticlopidine may decrease the metabolism and clearance of cilostazol. Consider alternate therapy or monitor for adverse/toxic effects of cilostazol if ticlopidine is initiated, discontinued or dose changed
	Treprostinil	The prostacyclin analogue, treprostinil, increases the risk of bleeding when combined with the antiplatelet agent, cilostazol. Monitor for increased bleeding during concomitant thearpy
	Voriconazole	Voriconzole may increase the serum concentration of cilostazol by decreasing its metabolism. Monitor for increased therapeutic/adverse effects of cilostazol and consider reducing the dose during concomitant therapy
Food interactions	• Grapefruit and grapefruit juice should be avoided throughout treatment, grapefruit can significantly increase serum levels of this product • Take on an empty stomach, a lipid rich meal will increase absorption	

Efficacy	• Cilostazol decreases risk of hemorrhagic stroke but increases risk of adverse events compared with ASA in patients with previous cerebral infarction (Level 1 [likely reliable] evidence) [89] • Cilostazol decreases stroke but increases minor adverse events compared to ASA in patients with previous cerebral infarction (Level 1 [likely reliable] evidence) [91] • Cilostazol is at least as effective as ASA for reducing risk of recurrent stroke (Level 1 [likely reliable] evidence) [92] • Cilostazol may reduce risk of pneumonia (Level 2 [mid-level] evidence) [93]

Table 64.6. **Cistazol overview. SMILES indicates simplified molecular-input line-entry system [60].**

Several controlled trials have found that cilostazol is effective for preventing cerebral infarction. For longer term secondary prevention, cilostazol (100 mg twice daily) reduced the risk of stroke (RRR 42%, 95% CI 9.2-62.5) compared with placebo among 1095 Japanese patients with ischemic stroke [94], and by about 38% (−26-70%) compared with ASA in a pilot trial involving 720 Chinese patients with ischemic stroke (3.3% vs. 5.6%, HR 0.62, 95% CI 0.30-1.26) but this result was not statistically significant [92]. In the non-inferiority CSPS II trial, 2757 Japanese patients with a recent noncardioembolic cerebral infarction were randomly assigned to cilostazol (100 mg twice daily) or ASA (81 mg daily) [91]. Cilostazol is non-inferior to ASA for stroke prevention, the yearly rates of recurrent stroke (infarction or hemorrhage) for cilostazol and ASA were 2.7% and 3.7% (HR 0.74, 95% CI 0.56-0.98) at a mean follow-up of 29 months. Annual rates of hemorrhagic events (ICH, subarachnoid hemorrhage, or other hemorrhage requiring hospitalization) were lower with cilostazol than with ASA (0.8% vs. 1.8%, HR 0.46, 95% CI 0.30-0.71).

However, side effects (headache, diarrhea, palpitation, dizziness, and tachycardia) were more frequent with cilostazol, and more patients discontinued cilostazol than ASA (20% vs. 12%). These data support the safety and efficacy of cilostazol for secondary stroke prevention in Asian populations. However, there are as yet no high-quality data regarding the use of cilostazol for secondary stroke prevention in non-Asian ethnic groups. Furthermore, drugs similar to cilostazol have increased the risk of death in patients with congestive heart failure, studies of significant size have not addressed people without the disease. Finally, the lower tolerability and higher cost of cilostazol compared with ASA may limit its more widespread use for stroke prevention.

Recommendations for Use of Cilostazol for Secondary Prevention of Stroke

American College of Chest Physicians (ACCP) recommendations (Ninth Edition) for secondary prevention of stroke [15]:

- Following noncardioembolic stroke or transient ischemic attack (TIA), cilostazol 100 mg twice daily recommended as an option for long-term antiplatelet therapy over:
  - No antiplatelet therapy (ACCP Grade 1A).
  - Oral anticoagulants (ACCP Grade 1B).
  - Combination of clopidogrel plus ASA (ACCP Grade 1B).
  - Triflusal (ACCP Grade 2B).

Triflusal

Triflusal is an antiplatelet agent that is structurally related to ASA (Table 64.7).

Structure	 Chemical formula: $C_{10}H_7F_3O_4$ SMILES: CC(=O)Oc1cc(C(F)(F)F)ccc1C(=O)O	
Pharmacodynamics	Triflusal is an antithrombotic anticoagulant. It irreversibly inhibits the production of thromboxane-B2 in platelets by acetylating cycloxygenase-1. Triflusal affects many other targets such as NF kappa B, which is a gene expression regulatory factor for cycloxygenase-a and cytokines. Numerous studies comparing the efficacy and safety profile (i.e. systemic hemorrhage) between triflusal and acetylsalsylic acid has shown either nonsignificant difference or a better effacy and safety profile for triflusal. Triflusal has been shown to protect cerebral tissue due to its inhibition of lipid peroxidation resulting from anoxia-reoxygenation	
Mechanism of action	Triflusal is chemically related to acetylsalicylic acid (ASA) and irreversibly inhibits cycloxygenase-1 (COX-1) in platelets. Acetylation of the active group of COX-1 prevents the formation of thromboxane-B2 in platelets. However, it is unique because it spares the arachidonic acid metabolic pathway in endothelial cells. In addition, it favors the production of nitric oxide, a vasodilator	
Absorption	Absorbed in the small intestine with a bioavailability range from 83% to 100%. There is nonsignificant difference between the absorption of the oral solution and capsule formulation	
Volume of distribution	34 l	
Protein binding	Binds to plasma proteins almost entirely (99%)	
Metabolism	In the liver, triflusal undergoes deacetylation, forming its main metabolite 2-OH-4-trifluoromethyl benzoic acid (HTB)	
Route of elimination	Primarily renal	
Half life	In healthy human, the half life is 0.5 ± 0.1h, while that of HTB is 34.3 ± 5.3 h	
Clearance	Renal clearance is 0.8 ± 0.2 l/h and 0.18 ± 0.04 l/h for triflusal and HTB, respectively	
Toxicity	Excessive bleeding. The risk of bleeding is less than that of acetylsalicylic acid	
Affected organisms	Not available	
Drug Interactions	**Drug**	**Interaction**
	Ibuprofen	The metabolite of triflusal, 2-hydroxy-4-trifluoro-methyl-benzoic acid (HTB), impairs the serum protein binding of ibuprofen to the same extent as acetylsalisylic acid. Thus, the free fraction of glisentide may be increased. A dosage reduction may be required if used in combination
	Naproxen	The metabolite of triflusal, 2-hydroxy-4-trifluoro-methyl-benzoic acid (HTB), impairs the serum protein binding of naproxen to the same extent as acetylsalisylic acid. Thus, the free fraction of glisentide may be increased. A dosage reduction may be required if used in combination

	Piroxicam	The metabolite of triflusal, 2-hydroxy-4-trifluoro-methyl-benzoic acid (HTB), impairs the serum protein binding of glisentide to the same extent as acetylsalisylic acid. Thus, the free fraction of glisentide may be increased. A dosage reduction may be required if used in combination
	Warfarin	The metabolite of triflusal, 2-hydroxy-4-trifluoro-methyl-benzoic acid (HTB), impairs the serum protein binding of warfarin to the same extent as acetylsalisylic acid. Thus, the free fraction of glisentide may be increased. A dosage reduction may be required if used in combination
Food interactions	Gingko bilboa Herbs with anticoagulant/antiplatelet activity such as alfalfa, feverfew, ginger, ginseng, grape seed, green tea, horseradish	
Efficacy	Triflusal appears as effective as ASA with less hemorrhagic complications for secondary prevention of vascular events (level 2 [mid-level] evidence) [29,95]	

Table 64.7. **Triflusal overview. SMILES indicates simplified molecular-input line-entry system [25].**

Approved by the European Stroke Organization, triflusal is recommended as lone therapy for the secondary prevention of atheroembotic stroke. Triflusal appears to be equally effective with a better safety profile than ASA plus DP and clopidogrel alone based on a double blind, randomized TACIP and TAPIRSS trials [95,96]. The effectiveness of triflusal was similar to ASA (325 mg/day) at preventing vascular events after stroke, but it did have a lower rate of hemorrhagic complications [95]. Similar findings were noted in a smaller randomized trial and a meta-analysis of four trials [29,96]. It is not clear whether triflusal would have had a lower rate of hemorrhagic complications than lower-dose ASA [98].

Recommendations for Use of Triflusal for Secondary Prevention of Stroke

American College of Chest Physicians (ACCP) recommendations (Ninth Edition) for secondary prevention of stroke [15]:

- For antiplatelet therapy for secondary prevention of stroke, triflusal is not suggested over clopidogrel or combination of ASA plus extended-release dipyridamole (ACCP Grade 2C).

Sarpogrelate

Sarpogrelate acts as an antagonist at the $5HT_{2A}$ and $5\text{-}HT_{2B}$ receptors and blocks serotonin-induced platelet aggregation. In S-ACCESS trial, sarpogrelate (100 mg 3 times daily plus placebo ASA) was not as effective as ASA (81 mg daily plus placebo sarpogrelate) for secondary prevention of cerebral infarction in 1510 Japanese patients with ischemic stroke in previous 1 week to 6 months randomized to sarpogrelate vs. ASA (level 2 [mid-level] evidence) [100].

Terutroban

Terutroban is selective TX-prostaglandin receptor antagonist. In PERFORM trial, terutroban (30 mg orally per day) was no more effective than ASA (100 mg orally per day) in 19,120 patients with ischemic stroke during prior 3 months or TIA within prior 8 days followed for mean 28.3 months for reducing vascular events (level 1 [likely reliable] evidence) [101]. The trial comparing terutroban with 100 mg ASA daily in 18,000 patients with a history of recent ischemic stroke or TIA has recently been halted because interim analyses suggested that continuation of the study would be futile [101].

64.2.2 Special Antithrombotic Regimens

In acute TIA and ischemic stroke, the combination of ASA plus clopidogrel may be more effective than ASA alone if administered immediately and for only the first few months, when the risk of recurrent stroke is highest [99]. This strategy reduces the long-term risks of bleeding associated with the combination of clopidogrel and ASA compared with ASA or clopidogrel alone [28,33].

The POINT (Platelet-Oriented Inhibition in New TIA) trial, are being planned to establish the relative safety and efficacy of the combination of clopidogrel and ASA compared with ASA in patients with acute TIA and mild ischemic stroke [102]. In the acute phase of ischemic stroke, short-term abciximab is not more effective than ASA (OR 0.97 [95% CI 0.70-1.36]) [34,103].

64.2.3 Antiplatelets vs. Anticoagulants

Warfarin has been shown in multiple trials to be superior to ASA for patients with AF, and is clearly indicated in patients with stroke caused by AF if they have no contraindications to therapy. Two recent trials have failed to show that OAT was better than ASA for other ischemic stroke subtypes [59,104].

The Warfarin ASA Recurrent Stroke Study (WARSS) was a superiority trial that compared ASA to warfarin for secondary stroke prevention in 2206 patients with recent noncardioembolic stroke. The goal INR in this study was 1.4 to 1.8. Event rates (17.8% for warfarin vs. 16.0% for ASA) as well as major hemorrhage rates (3.4% for warfarin vs. 2.7% for ASA) were nonsignificantly higher in the warfarin arm. In subgroup analyses, no patient subgroup clearly benefited from warfarin compared with ASA, including those with antiphospholipid antibodies, patent foramen ovale, and posterior circulation strokes [59]. In addition, patients who were taking ASA at the time of their initial stroke did not benefit from warfarin compared with ASA.

The Warfarin vs. ASA for Symptomatic Intracranial Disease (WASID) study compared high-dose ASA (1300 mg) to warfarin (INR goal 2-3) in patients with symptomatic atherosclerotic intracranial stenosis [104]. The study was stopped prematurely after enrollment of 569 of the planned 806 patients due to concerns about the safety of patients randomized to warfarin. Compared with ASA, warfarin was associated with a higher rate of death (9.7% vs. 4.3%, p=0.02), major hemorrhage (8.3% vs. 3.2%, p=0.01), and MI or sudden death (7.3% vs. 2.9% p=0.02). We recommend antiplatelet agents over OAT for most patients with noncardioembolic stroke. For the subset of patients with noncardioembolic stroke with well-documented prothrombotic disorders, we suggest OAT over antiplatelet agents.

64.2.4 National Guidelines and Consensus Statements Regarding Choice of Antiplatelet Agents

American Heart Association/American Stroke Association (AHA/ASA) and the American College of Chest Physicians (ACCP) current guidelines recommend that patients with a noncardioembolic (ie, atherothrombotic, lacunar, or cryptogenic) stroke or TIA and no contraindication receive an antiplatelet agent to reduce the risk of recurrent stroke [13,15].

These guidelines note that ASA, clopidogrel, and the combination of ASA plus ER-DP are all acceptable options for preventing recurrent noncardioembolic ischemic stroke

or TIA. The 2011 AHA/ASA guidelines recommend the use of the combination of ASA and ER-DP instead of ASA [13]. The 2012 ACCP guidelines include cilostazol in this group of recommended antiplatelet agents, and further suggest the use of the combination of ASA plus ER-DP or clopidogrel over aspirin or cilostazol. However, the publication of the PRoFESS trial provides high-quality evidence that clopidogrel monotherapy and ASA plus ER-DP are equivalent in terms of effectiveness and safety for secondary prevention of ischemic stroke [36]. The most important guidelines are summarized in Table 64.8.

American College of Chest Physicians (ACCP) guidelines (Ninth Edition) [15,117]	• Following noncardioembolic stroke or transient ischemic attack (TIA):
	  ▪ Long-term antiplatelet therapy recommended with 1 of: clopidogrel 75 mg once daily, combination of ASA 25 mg plus DP extended-release 200 mg twice daily, ASA 75-100 mg once daily, cilostazol 100 mg twice daily
	  ▪ Any of these antiplatelet agents recommended over, no antiplatelet therapy (ACCP Grade 1A), oral anticoagulants (ACCP Grade 1B), combination of clopidogrel plus ASA (ACCP Grade 1B), triflusal (ACCP Grade 2B)
	  ▪ Among the recommended antiplatelet regimens, clopidogrel or combination of ASA plus extended-release DP suggested over ASA alone (ACCP Grade 2B) or triflusal (ACCP Grade 2C)
	  ▪ Benefit of clopidogrel over ASA for preventing major vascular events may be offset with long-term use (>5 years) by lower cancer-related mortality with ASA
	• Following cardioembolic stroke or TIA (that is, atrial fibrillation, including paroxysmal atrial fibrillation):
	  ▪ OAT recommended over: no antithrombotic therapy (ACCP Grade 1A), ASA (ACCP Grade 1B), combination therapy with ASA plus clopidogrel (ACCP Grade 1B)
	  ▪ OAT with dabigatran 150 mg twice daily suggested over adjusted-dose vitamin K agonist therapy (target range 2-3) (ACCP Grade 2B); dabigatran contraindicated if creatinine clearance ≤ 30 ml/minute
	  ▪ For patients unsuitable for or who choose not to take an oral anticoagulant (for reasons other than concerns about major bleeding), combination therapy with ASA plus clopidogrel recommended over ASA (ACCP Grade 1B)
	  ▪ OAT should generally be started within 1-2 weeks after stroke onset, but timing may vary with risk for bleeding
	  ▪ Use of ASA as bridging therapy suggested until anticoagulation reaches therapeutic level
	• With history of symptomatic primary intracerebral hemorrhage, long-term use of antithrombotic therapy for prevention of ischemic stroke suggested against (ACCP Grade 2C)
	• If cerebral venous sinus thrombosis, anticoagulation during acute and chronic phases suggested over no anticoagulant therapy (ACCP Grade 2C)

National Institute for Health and Clinical Excellence (NICE) [65]	• NICE guidance on clopidogrel and modified-release DP in prevention of occlusive vascular events:
	  ▪ Guidance applies to people with history of occlusive vascular event or with symptomatic peripheral arterial disease
	  ▪ Combination of modified-release DP and ASA recommended for people who had ischemic stroke or transient ischemic attack for 2 years from most recent event then continue with low-dose ASA
	  ▪ Clopidogrel alone (within licensed indications) recommended for people intolerant of low-dose ASA (proven hypersensitivity or history of severe dyspepsia) who have had occlusive vascular event or symptomatic peripheral arterial disease

American Heart Association (AHA) guidelines [13]	• For patients with noncardioembolic ischemic stroke or TIA, antiplatelet agents recommended rather than OAT (AHA/ASA Class I, Level A):
	  ▪ Acceptable options include: ASA 50-325 mg daily (AHA/ASA Class I, Level A), combination ASA 25 mg twice daily and extended-release DP 200 mg twice daily (AHA/ASA Class I, Level B), clopidogrel 75 mg daily (AHA/ASA Class IIa, Level B)
	  ▪ Selection of antiplatelet agent should be individualized based on patient risk factors, cost, tolerance and other clinical factors
	  ▪ Addition of ASA to clopidogrel increases risk of hemorrhage and is not routinely recommended for secondary prevention of stroke (AHA/ASA Class III, Level A)
	  ▪ Clopidogrel reasonable for patients allergic to ASA (AHA/ASA Class IIa, Level C)
	  ▪ For patients who have ischemic stroke while taking ASA (AHA/ASA Class IIb, Level C): no evidence for additional efficacy with increasing dose of ASA, alternative antiplatelet agents often considered, but no regimen specifically studied
	• For patients with ischemic stroke or TIA and paroxysmal or permanent atrial fibrillation:
	  ▪ If unable to take oral anticoagulants, ASA alone is recommended (AHA/ASA Class I, Level A)
	  ▪ Clopidogrel with ASA not recommended for patients with hemorrhagic contraindication to warfarin (AHA/ASA Class III, Level B)
	• Optimal medical therapy for patients with extracranial arterial disease (carotid or vertebrobasilar) and TIA or stroke should include antiplatelet therapy (AHA/ASA Class I, Level B)
	• For patients with stroke or TIA due to 50%-99% stenosis of major intracranial artery, ASA 50-325 mg/day is recommended over warfarin (AHA/ASA Class I, Level B)
	• For patients with cardiomyopathy:
	  ▪ Insufficient evidence for use of warfarin in patients with prior stroke or TIA, sinus rhythm, cardiomyopathy and ejection fraction ≤ 35% (AHA/ASA Class IIb, Level B)
	  ▪ Treatments to consider for patients with ischemic stroke or TIA and cardiomyopathy include (AHA/ASA Class IIb, Level B): warfarin (INR 2-3), ASA 81 mg/day, clopidogrel 75 mg/day, combination of ASA 25 mg twice daily and extended-release DP 200 mg twice daily
	• For patients with native valvular heart disease:
	  ▪ Antiplatelet therapy may be considered for patients with ischemic stroke or TIA and: native aortic or nonrheumatic mitral valve disease and no atrial fibrillation (AHA/ASA Class IIb, Level C), mitral annular calcification (AHA/ASA Class IIb, Level C), mitral valve prolapse (AHA/ASA Class IIb, Level C)
	  ▪ To avoid additional bleeding risk, antiplatelet agents should not be routinely added to warfarin (AHA/ASA Class III, Level C)
	• For patients with ischemic stroke or TIA due to extracranial arterial dissection (carotid or vertebral):
	  ▪ Antithrombotic therapy for at least 3-6 months is reasonable (AHA/ASA Class IIa, Level B)
	  ▪ Relative efficacy of antiplatelet therapy vs. anticoagulation is unknown (AHA/ASA Class IIb, Level B)
	• For patients with patent foramen ovale (PFO)
	  ▪ Antiplatelet therapy is reasonable for patients with ischemic stroke or TIA and PFO (AHA/ASA Class IIa, Level B)
	• Insufficient data to determine whether anticoagulation is as or more effective than ASA for secondary stroke prevention in patients with PFO (AHA/ASA Class IIb, Level B)

Canadian Stroke Network/Heart and Stroke Foundation of Canada [16]	• All patients with ischemic stroke should be prescribed antiplatelet therapy for secondary prevention of recurrent stroke unless indication for anticoagulation (CSN Grade A) • Medications include (CSN Grade A): · ASA 80-325 mg/day · Combined ASA (25 mg) and extended-release DP (200 mg) · Clopidogrel • Long term combination of ASA and clopidogrel are not recommended for secondary stroke prevention (CSN Grade B)	
Other reviews	• Recommended initial antiplatelet therapy (Grade B recommendation [inconsistent or limited evidence]) [97], based on literature review: · ASA or clopidogrel is agent of choice for transient ischemic attack, stroke, chronic stable angina, and peripheral arterial disease · ASA plus DP is an alternative for first episode of TIA or stroke in absence of clinically apparent coronary artery disease • ASA or combination extended-release DP plus ASA appear cost-effective for prevention of second strokes [118]: · Clopidogrel not considered cost-effective • Age >80 years should not be deterrent to using antiplatelet drugs (grade B recommendation [inconsistent or limited evidence]) [90], based on subgroup analysis of randomized trial: · 1306 patients with TIA or stroke randomized to combination of ASA 330 mg plus DP 75 mg vs. placebo orally 3 times daily for 2 years · Statistically significant decreases in combined outcome of stroke or death occurred in subgroups with ages>60 years,>70 years and>80 years; 40 patients were>80 years old	
Recommendation grading systems used	American College of Chest Physicians (ACCP) grades	• Grade 1: strong recommendation based on clear risk/benefit balance • Grade 2: weak recommendation based on unclear or close risk/benefit balance • Grade A: high-quality evidence based on consistent evidence from randomized trials without important limitations or exceptionally strong evidence from observational studies • Grade B: moderate-quality evidence based on randomized trials with important limitations (inconsistent results, methodologic flaws, indirect or imprecise results) or very strong evidence from observational studies • Grade C: low- or very low-quality evidence based on observational studies, case series, or randomized trials with serious flaws or indirect evidence • Reference: ACCP Evidence-Based Clinical Practice Guidelines (Ninth Edition) Methodology for the Development of Antithrombotic Therapy and Prevention of Thrombosis Guidelines [119]
	Canadian Stroke Network (CSN)/Heart and Stroke Foundation of Canada definitions of strength of recommendations [16]	• Grade A: strong recommendation · Evidence from randomized controlled trials or meta-analyses of randomized controlled trials · Desirable effects clearly outweigh undesirable effects, or vice versa

		• Grade B: · Single randomized controlled trial or well-designed observational study with strong evidence, or · Well-designed cohort or case-control analytic study, or · Multiple time series or dramatic results of uncontrolled experiment · Desirable effects closely balanced with undesirable effects. • Grade C: · At least 1 well-designed, nonexperimental descriptive study (such as comparative studies, correlation studies, case studies), or · Expert committee reports, opinions and/or experience of respected authorities, including consensus from development and/or reviewer groups
	American Heart Association/American Stroke Society (AHA/ASA) grading system for recommendations [12]	• Classifications of recommendations: · Class I: procedure or treatment should be performed or administered · Class IIa: reasonable to perform procedure or administer treatment, but additional studies with focused objectives needed · Class IIb: procedure or treatment may be considered; additional studies with broad objectives needed, additional registry data would be useful · Class III: procedure or treatment should not be performed or administered because it is not helpful or may be harmful · Class III ratings may be subclassified as Class III No Benefit or Class III Harm • Levels of evidence: · Level A: data derived from multiple randomized clinical trials or meta-analyses · Level B: data derived from single randomized trial or nonrandomized studies · Level C: only consensus opinions of experts, case studies, or standard of care

Table 64.8. **Guidelines regarding the choice of antiplatelets agents.**

64.2.5 Implications for Clinicians: Choosing Initial Therapy

The most important priority in the management of patients with ischemic stroke and TIA of arterial origin is to ensure that they are prescribed, taking, and tolerating an effective antiplatelet drug. ASA is effective for secondary stroke prevention in patients with noncardioembolic TIA and ischemic stroke. However, clopidogrel treatment was better than ASA as measured by a composite outcome of stroke, MI, or vascular death in the CAPRIE study [26], and the combination of ASA and ER-DP had greater benefit for secondary stroke risk reduction than ASA alone in two clinical trials (ESPS-2 and ESPRIT) [44,88]. Immediate-release DP cannot be routinely recommended for secondary prevention of ischemic stroke, given the limited evidence supporting its effectiveness and

the significant pharmacokinetic differences between it and ER-DP. Ticlopidine is rarely used because of its side-effect profile and lack of clear superiority over the other available agents. ASA and clopidogrel should not be used in combination for stroke prevention, given the lack of greater efficacy compared with either agent alone, and given the substantially increased risk of bleeding complications.

Because ASA is widely available, affordable, and albeit modestly effective, it is arguably the first-line treatment of choice, noting that the alternative antiplatelet regimens (clopidogrel or combined ASA and ER-DP) have an apparent modest advantage in benefit that is offset by a severe disadvantage in cost. However, if patients are intolerant of or allergic to ASA, at high risk of a recurrent stroke (more than 15-20% per year) [3], or have experienced a recurrent ischemic event of arterial origin while taking ASA, then one of the two more effective, although more expensive, regimens is indicated. As with any medication choices, individual patient characteristics play a role in the decision to start clopidogrel or the combination of ASA and ER-DP. Factors to keep in mind include medication costs and patient comorbidities.

Costs

The costs of prescription medications can be important in medication decisions. Clopidogrel and the combined ER-DP plus ASA each costs approximately $115 per month. The potential benefits of these two alternatives to ASA, which has a monthly cost of only a few dollars, must be carefully considered.

Medical Comorddidities

Stroke patients with unstable coronary artery disease or recent MI will generally benefit from the use of clopidogrel. ASA plus ER-DP has not been proven to be effective for the treatment of patients with coronary artery disease, but was not associated with any excess MI as an outcome event in stroke patients [31,36]. Patients with gastric ulcers may best be served with low-dose ASA or one of the other antiplatelet choices (major bleeding in 4.1% of patients on ASA with ER-DP vs. 3.6% on clopidogrel). For patients with headaches (headache 6% of patients on ASA with ER DP vs. 1% on clopidogrel), the potential side effect of worsening headache with ER-DP should be discussed at the time treatment is started, or another antiplatelet agent could be chosen.

Recurrent events on treatment. No clinical trials have directly addressed the issue of subsequent therapy for patients who experience recurrent episodes of brain ischemia while taking ASA. The WARSS trial demonstrated that patients who had their baseline event while on ASA had higher recurrent-event rates then the overall study population, regardless of treatment with warfarin or ASA, suggesting that these patients constituted a population at higher risk [59]. Some physicians select an alternative antiplatelet drug for patients who have an event while taking ASA but no regimen specifically studied neither evidence for additional efficacy with increasing dose of ASA (AHA/ASA class IIb, level C) [13]. Measuring platelet aggregation may be useful for identifying patients who have incomplete platelet inhibition on ASA or clopidogrel. The effect of increasing antiplatelet dosages on subsequent stroke risk has not been studied.

64.2.6 Antiplatelet Use in Secondary Prevention After Intracerebral Hemorrhage

The use of antiplatelet agents, especially ASA, after an episode of ICH is based on the proven benefits of these agents for the prevention of coronary and cerebrovascular ischemic events. Because ischemic vascular disease and ICH share risk factors, it is not unusu-

al for a patient who has suffered an ICH to need antiplatelet treatment. This raises the concern about an increased risk of ICH recurrence in the setting of continuing or starting antiplatelet therapy after the index episode of ICH. The clinical decision making in this situation depends on the magnitude of the risk of recurrent ICH under antiplatelet treatment. No data from randomized trials to guide secondary prevention of stroke after intracranial hemorrhage. Few data are available to assist the clinician in this decision. In patients with history of symptomatic primary ICH, Flynn and colleagues assessed the risk of recurrent ICH in a hospital-based cohort of 417,417 ICH patients who survived to discharge [105]. Of these, 120 patients were prescribed subsequent antiplatelet medicines (28.8%). The median time from discharge to antiplatelet use was 14.8 months (range, 2 days-7.5 years). HRs associated with antiplatelet exposure were 1.07 (95% CI 0.24-4.84) for recurrent ICH, 0.23 (95% CI 0.03-1.68) for ischemic stroke, and 0.72 (95% CI 0.25-2.02) for ischemic strokes or MI. Similarly, Viswanathan and colleagues addressed this issue by prospectively assessing the risk of recurrent ICH in a hospital-based cohort of 207 survivors of ICH (127 lobar, 80 deep), 46 (22%) of whom were treated with antiplatelet agents [106]. In a median of 19.5 months of follow-up, they observed 39 instances of recurrent ICH, which corresponded to a 2-year recurrence rate of 22% for lobar ICH patients and 4% for deep ICH patients. Exposure to antiplatelet agents resulted in no increase in the risk of recurrent ICH in survivors of lobar and deep ICH (Figure 64.4) [106].

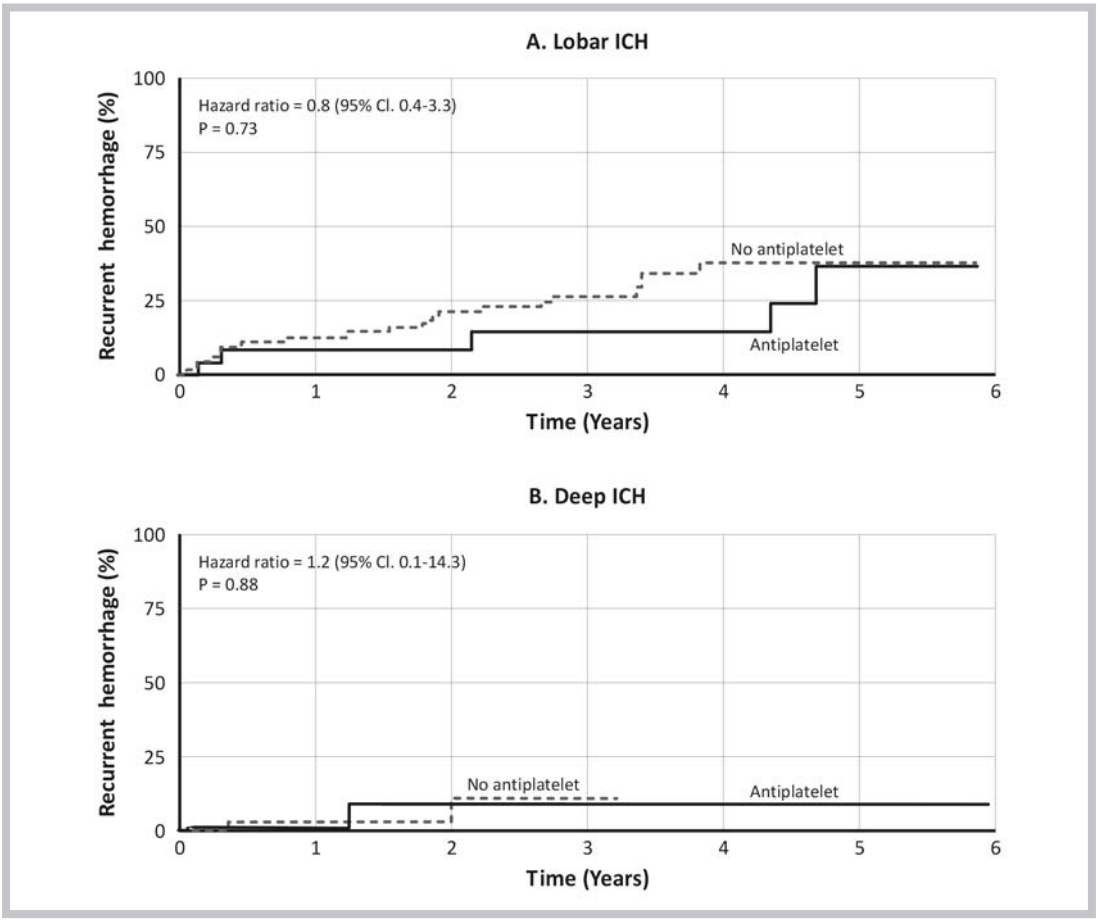

Figure 64.4. **Modified Kaplan-Meier plot of the effect of antiplatelet use on the rate of recurrent intracerebral hemorrhage (ICH) in survivors of lobar (A) and deep (B) ICH. Redrawn from [106].**

Factors to consider in restarting antiplatelet therapy include type of ICH, patient age, risk factors for recurrent ICH, risk factors for ischemic stroke, and indications for antithrombotic therapy. Risk factors for recurrent ICH include lobar hemorrhage, microbleeds on magnetic resonance imaging (MRI), advanced age, hypertension, dialysis, leukoaraiosis, and degree of anticoagulation [107]. These results suggest that there should be a compelling reason (such as active coronary artery disease or AF) for using antiplatelet agents after ICH (at a low dose [81 mg aspirin once daily]), especially if the ICH is deep in location. Furthermore, those with features suggestive of cerebral amyloid angiopathy as the underlying condition should require "the most compelling indication" because of their markedly increased risk of recurrent ICH [108]. For these reasons, the American College of Chest Physicians (ACCP Grade 2C) is against the long-term use of antithrombotic therapy for prevention of ischemic stroke in ICH patients [15]. The American Heart Association/American Stroke Association recommendations for use of antithrombotic therapy following ICH suggest [13] to restart antithrombotic therapy after ICH related to antithrombotic therapy depending on risk of subsequent arterial or venous thromboembolism, risk of recurrent ICH, and overall status of patient (AHA/ASA Class IIb, Level B). For patients with comparatively lower risk of cerebral infarction (such as AF without prior ischemic stroke) and higher risk of amyloid angiopathy (such as elderly patients with lobar ICH) or with very poor overall neurological function, an antiplatelet agent may be considered for prevention of ischemic stroke. For patients with very high risk of thromboembolism, it may be reasonable to restart warfarin therapy at 7-10 days after onset of ICH. For patients with hemorrhagic cerebral infarction, it may be reasonable to continue anticoagulation, depending on specific clinical scenario and underlying indication for anticoagulant therapy (AHA/ASA Class IIb, Level C).

On the basis of these limited data, it seems appropriate to limit the use of antiplatelet agents after ICH to those patients who are at high risk of coronary events and have sustained a deep ICH. Likewise, in those with suspected cerebral amyloid angiopathy (by virtue of having a history of lobar ICH preceding the lobar index event, a high load of microhemorrhages at baseline, and prominent white matter hypodensity on CT scan), antiplatelet treatment should be reserved for only those patients with the strongest indication.

64.2.7 Summary and Recommendations

ASA, clopidogrel, and the combination of ASA plus ER-DP are all acceptable options for preventing recurrent noncardioembolic ischemic stroke. For patients with a history of noncardioembolic stroke or TIA of atherothrombotic, lacunar (small vessel occlusive type), or cryptogenic type, we recommend treatment with an antiplatelet agent. Initial therapy with ASA is appropriate for patients who cannot afford or cannot obtain the more effective antiplatelet agents (clopidogrel or ASA plus extended-release DP). Although the optimal dose of ASA is uncertain, there is no compelling evidence that any specific dose is more effective than another, and fewer gastrointestinal side effects and bleeding occur with lower doses (≤325 mg a day). We recommend a dose of 50 to 100 mg daily when using ASA for the secondary prevention of ischemic stroke. In the absence of a substantial financial burden, initial antiplatelet therapy using either clopidogrel (75 mg daily) as monotherapy, or the combination of ASA plus ER-DP (25 mg/200 mg twice a day), rather than ASA should be preferred. The choice between clopidogrel and ASA plus ER-DP is dependent mainly on patient tolerance and contraindications. ER-DP contains ASA and should not be used in patients who cannot tolerate ASA. Clopidogrel (75 mg/day) is an obvious alternative for patients who cannot tol-

erate ASA. Ticlopidine should be reserved for patients intolerant of ASA and clopidogrel. For most patients with a noncardioembolic stroke or TIA, we recommend NOT using ASA and clopidogrel in combination for long-term stroke prevention, given the lack of greater efficacy compared with clopidogrel alone and the substantially increased risk of bleeding complications. However, selected patients with a recent acute MI, other acute coronary syndrome, or arterial stent placement are treated with clopidogrel plus ASA could be beneficed from a short (3-months) period.

64.3 Anticoagulation Regimens: Stroke Anticoagulation and Prophylaxis

64.3.1 Role of Anticoagulants

Drugs vitamin K antagonists (VKA) represent one of the major classes of drugs used in cardiovascular medicine; 1-1.5% of general population in Western countries is subject to VKA therapy, so-called oral anticoagulant therapy (OAT) [109], with a widespread use over the last two decades [110,111]. The controlled therapeutic inhibition of blood clotting by means of appropriate drugs (ie, anticoagulants) is defined anticoagulation. For many years, anticoagulation was used routinely in acute ischemic stroke. However, in the past 2 decades, randomized, controlled studies have helped to better define the role of anticoagulants in the acute treatment and prevention of stroke changing the actual role of anticoagulants in the treatment of cerebral ischemia. Furthermore in the last years, several new oral and parenteral anticoagulants are in different stages of clinical trials for use in the prophylaxis of ischemic thromboembolic stroke. Current data do not support the routine use of anticoagulation for acute ischemic stroke, limiting its use in secondary prevention. In fact, several randomized, controlled trials with IV heparinoids, subcutaneous low-molecular-weight heparin (LMWH), or subcutaneous unfractionated heparin (UFH) failed to show a significant overall benefit in their early use after ischemic stroke.

No difference in morbidity and mortality from stroke was shown between the group treated with aspirin and the group treated with UFH in the International Stroke Study

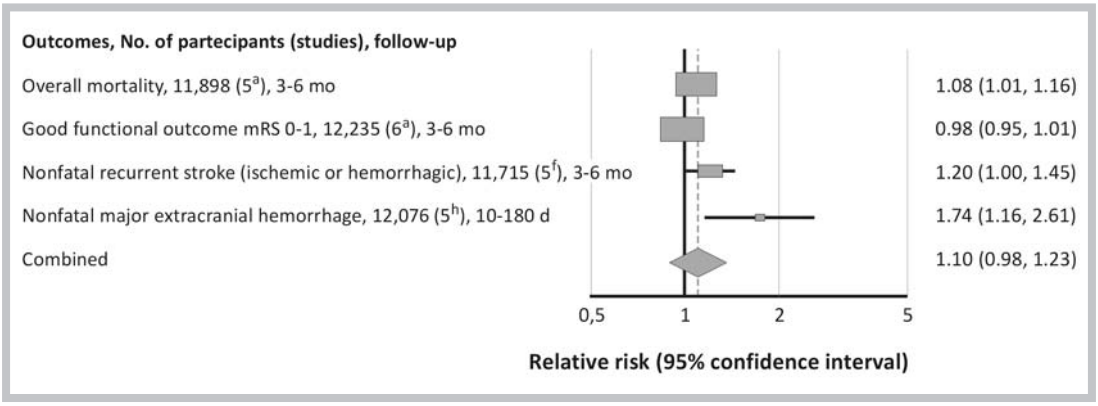

Figure 64.5. **Summary of findings: anticoagulants compared with antiplatelets in patients with acute ischemic stroke or TIA [113].**

[a]IST (1997), RAPID (2005), TAIST (2001), HAEST (2000), FISS-tris (2007). [f]IST (1997), RAPID (2005), HAEST (2000), TAIST (2001). [h]IST (1997), Pince (1981), TAIST (2001), HAEST (2000), FISS-tris (2007). Mo indicates months; d, days.

(IST) compared aspirin with subcutaneous UFH at 2 different doses (5000 units or 12,500 units bid). Although UFH seemed to decrease the risk of pulmonary embolism and deep venous thrombosis (DVT), it increased the risk of hemorrhagic complications [112]. The anticoagulation with UFH, LMWH, heparinoids, oral anticoagulants, or thrombin inhibitors did not decrease the odds of death or development of dependency from stroke in the last systematic review by the Cochrane collaboration [113]. It provides high-quality evidence that treatment with treatment-dose anticoagulation compared with aspirin results in more deaths, fewer patients with a favorable outcome, and more nonfatal major extracranial bleeding events [113]. Although anticoagulants prevent pulmonary embolism and determine a small decrease in recurrent ischemic strokes, they also increase the risk of hemorrhage, leading to the conclusion that anticoagulation cannot be recommended for the treatment of acute ischemic stroke [113]. Figure 64.5 summarizes the effect of parenteral anticoagulation compared with antiplatelet therapy according to data from updated Cochrane review [113]. If early anticoagulation after ischemic stroke is indicated but UFH is contraindicated because of large brain infarctions, hemorrhagic infarctions, or pronounced microangiopathic changes in the brain, LMWH (in a bodyweight-adapted dose) could be used because of lower bleeding risk, although this recommendation is not based on solid evidence. There is also not a net benefit of acute anticoagulant therapy over antiplatelet therapy in stroke patients with AF [114]. In patients with acute ischemic stroke and AF, a controlled, randomized study (Heparin in Acute Embolic Stroke Trial [HAEST]) failed to show the superiority of LMWH (dalteparin 100 IU/kg subcutaneously bid) to aspirin (160 mg/d) [115]. The risk for extracerebral hemorrhages was greater with anticoagulation than with antiplatelet therapy (5.8% vs. 1.8%, p=0.028). On the basis of this evidence, patients with acute ischemic stroke and AF should be treated with aspirin in the acute phase (and then placed on anticoagulation). When long-term anticoagulation is indicated, the use of UFH or LMWH has been advocated to serve as a bridge while a therapeutic international normalized ratio (INR) is achieved with warfarin. A small pilot study found that LMWH (enoxaparin 1 mg/kg subcutaneously bid) was safer than IV UFH for this purpose in patients with subacute cerebral ischemia [116]. However, further studies are needed to confirm this finding before this approach can be recommended generally. Despite evidence from the randomized clinical trials discussed above, anticoagulation continues to be recommended for some specific clinical situations. These recommendations are based on uncontrolled studies and expert opinion. Even among experts there is disagreement about the best level of anticoagulation, route of administration, timing and duration of treatment, use of a bolus dose, and safety of the therapy, given the severity of neurologic deficits, size of infarction on baseline CT, vascular distribution, or presumed cause of stroke. Some of the indications currently proposed by many experts for early full-dose IV heparin after stroke or TIA are summarized in Table 64.9.

Apparently, patients with acute ischemic stroke ipsilateral to a severe stenosis or occlusion of the internal carotid artery could be an exception to the lack of anticoagulation benefit. This group appeared to benefit from early IV administration of the LMWH danaparoid in the TOAST (Trial of Org 10172 in Acute Stroke Treatment) trial. Although the Trial of Org 10172 in Acute Stroke Treatment (TOAST) reported that a favorable functional outcome at 3 months occurred more frequently in the subgroup of patients with large artery atherosclerotic stroke who were treated with danaparoid (68.1% vs. 54.7%, p=0.04), the rates of recurrent stroke were similar between treatment regimens, and there was no benefit of danaparoid in the overall trial population. However, this was a post hoc analysis with a small number of individuals, so the effect of chance cannot be excluded [120]. A recent systematic review based on observational studies failed to demonstrate a significant difference between antiplatelet therapy and anticoagula-

- Symptomatic extracranial or intracranial arteriosclerotic stenosis with crescendo TIAs or early progressive stroke
- Basilar artery occlusion before or after intra-arterial pharmacological or mechanical thrombolysis.
- Conditions with potential high risk of early cardiogenic reembolization, such as atrial fibrillation with proven intracardial thrombus on echocardiography, artificial valves, left atrial or ventricular thrombi, or myocardial infarction during the last 4 weeks
- Symptomatic dissection of the arteries supplying the brain (after exclusion of subarachnoid hemorrhage on CT scan)
- Known hypercoagulable states (e.g., protein C and S deficiencies, activated protein C [APC] resistance, antithrombin deficiency, relevant titer of antiphospholipid antibodies)
- Cerebral venous sinus thrombosis

Table 64.9. **Early anticoagulation in subpopulations.**

tion for the acute treatment of patients with stroke secondary to cervical artery dissection [121]. No convincing evidence supports anticoagulation for patients with stroke due to large artery atherosclerosis. Conclusive data are also lacking about the management of anticoagulation in patients with hemorrhagic conversion of ischemic brain infarction or primary ICH who have an absolute indication for anticoagulation for the prevention of embolism (ie, AF or mechanical heart valves). Small retrospective case series of patients with urgent need for anticoagulation (eg, with artificial heart valves) showed a better outcome for those treated with full-dose IV heparin (only after normalization of INR values by administration of prothrombin complex and/or other warfarin antagonists) than for those treated with low-dose subcutaneous heparin; however, these studies lack concomitant control subjects, thus making any conclusions about true efficacy and safety difficult. The use of anticoagulation in cerebral venous sinus thrombosis is based on open case series with no controls. Anticoagulation has been used even in the presence of hemorrhagic infarctions typical of this condition. Obviously, at the present time, patients with acute ischemic stroke treated with intravenous recombinant tissue plasminogen activator (rtPA) clearly should not be treated with anticoagulation for at least 24 hours post thrombolysis. ASA therapy is therefore recommended for all patients with acute ischemic stroke based on high-quality evidence in favor of antiplatelet therapy and the lack of evidence to support anticoagulation over antiplatelet therapy for any subpopulation of ischemic stroke patients thus far investigated. In conclusion, early (within 48 h) ASA therapy with an initial dose of 160 to 325 mg over therapeutic parenteral anticoagulation (Grade 1A) in patients with acute ischemic stroke or TIA [15]. There are, however, some patients at particularly high risk for recurrent embolic events (eg, those with mechanical heart valves or intracardiac thrombi) who were either not included or underrepresented in the acute antithrombotic therapy stroke trials. Although long-term anticoagulation for secondary stroke prevention may be indicated for these patients, the optimal choice of acute antithrombotic therapy is uncertain. As a result, there is considerable variation in clinical practice. Acute anticoagulation could be considered in this setting when the risk of hemorrhagic complications is low (eg, small ischemic burden and no evidence of hemorrhage on imaging).

64.3.2 Prevention of Recurrent Ischemic Stroke of Cardiac Origin

Cardioembolic strokes account for one third of ischemic strokes and AF represents the main source of this stroke subtype [122]. The rate of stroke is 5%/year in patients with AF. Patients with AF have a 2-7 fold increased risk of stroke compared to patients without AF [10,122-124]. Cardioembolic strokes have poorer prognosis compared to other subtypes of ischemic strokes, such as atherotrombotic and lacunar forms, due to wider

ischemic damage and major risk of hemorrhagic transformation with the consequence of higher risk of in-hospital, 30-days and 12-months mortality and severe disability [125-127]. Stroke prevention in AF (SPAF) is therefore of utmost importance and represents a major point in the modern management of AF [10,123,124]. The risk of stroke is high in patients with AF associated to severe mitral stenosis, mechanical prosthetic valve, history of previous cerebrovascular ischemic event, moderate when AF is associated to age over than 75 years, systemic blood hypertension, diabetes mellitus, heart failure with depressed contractility and finally is low but consistent when AF is associated to female sex, vascular disease such as coronary artery disease or peripheral artery disease, age 65 to 74 years and thyrotoxicosis [10,123,124,128]. Practical prognostic scores, such as $CHADS_2$ [129] and the most recent CHA2DS2-VASC (see Appendix), help in predicting stroke risk in patients with AF [123]. For information on how to calculate the CHADS2 score, see You et al. [130]. CHA2DS2-VASC score seems to better predict the low risk of stroke or systemic embolism respect CHADS2 [123]. The most important function of these and similar schemes is to identify patients with AF who are likely to benefit from OAT, and thus accurately discriminate patients at high risk of stroke or systemic embolism (for whom OAT is indicated) from those at moderate risk (OAT or ASA) and low risk (ASA). Although the CHADS2 score might not be as accurate as the other schemes in predicting stroke risk, its discriminative capacity is sufficiently adequate to guide thromboprophylactic treatment decisions, and it can be calculated at the bedside or in the clinic from simple clinical features (without requiring access to echocardiography). The choice of drugs aimed to reduce the cardioembolic risk should take in account the risk of bleedings and carefully weighted. Several risk stratification models have been proposed to calculate bleeding risk in patients on antithrombotic treatment to reduce the thromboembolic risk in AF. Much recently, two practical scores named HAS-BLED [131] and ATRIA respectively (Appendix) [132], have been proposed. They identify categories of patients at different risk of bleeding assigning points to the considered risk factors. Unfortunately many risk factors are at the same time risks for thromboembolic and for bleeding events, making choice difficult.

Almost all patients with AF, including paroxysmal AF, who are at high risk of stroke ($CHADS_2 \geq 2$) should be treated with anticoagulation. This includes all patients with a history of stroke or TIA, as a history of stroke or TIA alone accounts for two points on the $CHADS_2$ score. For patients with TIA or ischemic stroke due to cardioembolism, particularly those with AF, the use of oral VKAs (i.e., warfarin) maintaining an international normalized ratio (INR) of 2.0-3.0, has been the cornerstone of antithrombotic therapy for more than 20 years [133,134]. Recommendations for patients with AF and a

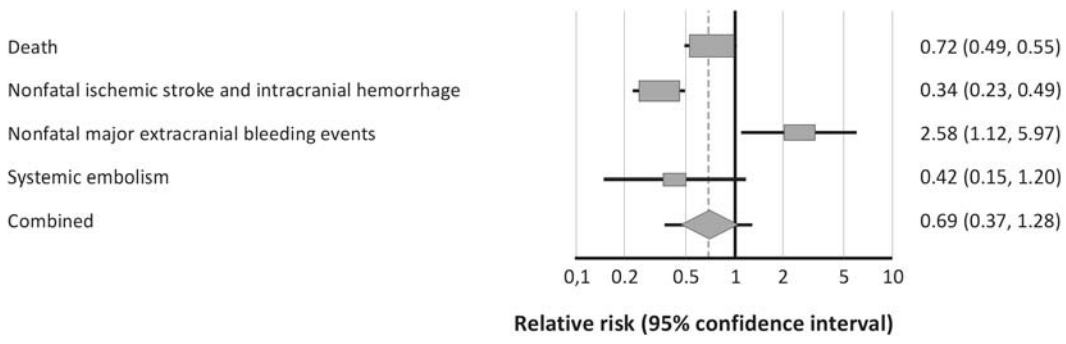

Figure 64.6. **Anticoagulation compared with no anticoagulation for secondary prevention in patients with AF and a history of ischemic stroke or TIA.**

history of stroke or TIA are based on the pooled effect of anticoagulation in primary and secondary prevention studies as the data exclusively on secondary prevention are limited to only two trials [135,136]. Pooled data from these anticoagulation trials are summarized in Figure 64.6. Recommendations for antithrombotic therapy in patients with AF with a history of stroke or TIA therefore follow the recommendations for patients with AF at high risk of stroke [130]. Patients with AF and with a history of stroke or TIA showed a much higher recurrence stroke rate in the two secondary prevention trials (8.0% per year) [135,136] compared with the nine mainly primary prevention trials (2.6% per year) [135,137-144]. In the two secondary-prevention trials, the benefit of anticoagulation was represented by a lower incidence of any (ischemic or hemorrhagic) recurrent stroke (52 fewer per 1000 over 1-2.3 years); although at a cost of more major extracranial bleeding events (12 more per 1000 over 1-2.3 years) [134]. Both primary and secondary prevention studies showed a neutral effect of anticoagulation therapy on mortality [134].

The optimal time to begin OAT following a cardioembolic stroke depends primarily on the balance of risks of early ischemic stroke recurrence and hemorrhagic transformation of the index stroke. Few studies can help guide the timing of anticoagulation after stroke secondary to AF. There is ≈5% risk of symptomatic hemorrhagic transformation between AF patients in the 2 weeks after presentation with an acute ischemic stroke and the risk is greater in patients with larger infarcts [145]. No increase in ICH was apparent in patients started early (<2 weeks) vs. later (2 weeks to 3 months) in the European Atrial Fibrillation Trial (EAFT) [136], where about half of the patients receiving anticoagulation were randomized within 2 weeks after symptom onset. In this trial patients with previous stroke or TIA who also were diagnosed with AF were randomized to oral anticoagulation, 300 mg aspirin daily, or placebo. Similar results were found in the Heparin in Acute Embolic Stroke Trial (HAEST) study where patients with AF presenting with acute ischemic stroke were randomized to early treatment (within 30 h of stroke onset) with LMWH or ASA. It did not find evidence of a statistically significant difference in recurrent ischemic stroke (the primary outcome) or ICH [115]. A subgroup analysis of 3,169 patients with AF enrolled in the IST showed no net advantage to early treatment with UFH compared with no heparin; patients who received heparin experienced reductions in ischemic stroke that were offset by an increase in ICH within the first 14 days [146]. In summary, there is no net benefit or harm associated with the early initiation of anticoagulation, but that the risk of symptomatic hemorrhagic transformation is greater with large infarcts. From this low-quality evidences, it is therefore recommended initiation of OAT within 2 weeks of a cardioembolic stroke; however, for patients with large infarcts or other risk factors for hemorrhage, additional delays are appropriate. Before anticoagulation is initiated and during the time that anticoagulation is started but has not yet reached therapeutic levels (ie, INR<2.0), treatment with ASA is recommended. ASA is beneficial in the early treatment of acute stroke and indirect data from randomized trials of ASA in patients with AF who have not yet had a stroke that suggest a RRR of recurrent stroke of approximately 20% [130]. The benefit of ASA over placebo is also suggested by EAFT subanalyses [136]. Long-term ASA use was associated with a 14% reduction in the annual rate of stroke (HR 0.86; 95% CI 0.64-1.15) between ASA (300 mg/d) arm when compared to placebo in patients with AF who had suffered a stroke or TIA; although this difference was not statistically significant.

Vitamin K Antagonists (VKA)

VKA drugs available are represented by warfarin, acenocoumarol and phenprocoumon, which differ for the different plasma half-life. Up to now, VKA drugs have demonstrated to be the most effective choice in SPAF and clinical guidelines have suggested to consid-

er these as the first choice [10,123]. Between VKA, warfarin is the most frequent used. Warfarin inhibits vitamin K reductase, resulting in depletion of the reduced form of vitamin K (vitamin KH2) (Table 64.10) [147,148]. As vitamin K is a cofactor for the carboxylation of glutamate residues on the N-terminal regions of vitamin K-dependent proteins, this limits the gamma-carboxylation and subsequent activation of the vitamin K-dependent coagulant proteins. The synthesis of vitamin K-dependent coagulation factors II, VII, IX, and X and anticoagulant proteins C and S is inhibited. Depression of three of the four vitamin K-dependent coagulation factors (factors II, VII, and X) results in decreased prothrombin levels and a decrease in the amount of thrombin generated and bound to fibrin.

Structure	 Chemical formula: $C_{19}H_{16}O_4$ SMILES: CC(=O)CC(C1=CC=CC=C1)C1=C(O)C2=C(OC1=O)C=CC=C2
Pharmacodynamics	Warfarin, a coumarin anticoagulant, is a racemic mixture of two active isomers. It is used in the prevention and treatment of thromboembolic disease including venous thrombosis, thromboembolism, and pulmonary embolism as well as for the prevention of ischemic stroke in patients with atrial fibrillation (AF)
Mechanism of action	Warfarin inhibits vitamin K reductase, resulting in depletion of the reduced form of vitamin K (vitamin KH2). As vitamin K is a cofactor for the carboxylation of glutamate residues on the N-terminal regions of vitamin K-dependent proteins, this limits the gamma-carboxylation and subsequent activation of the vitamin K-dependent coagulant proteins. The synthesis of vitamin K-dependent coagulation factors II, VII, IX, and X and anticoagulant proteins C and S is inhibited. Depression of three of the four vitamin K-dependent coagulation factors (factors II, VII, and X) results in decreased prothrombin levels and a decrease in the amount of thrombin generated and bound to fibrin. This reduces the thrombogenicity of clots
Absorption	Rapidly absorbed following oral administration with considerable interindividual variations. Also absorbed percutaneously
Volume of distribution	0.14 l/kg
Protein binding	99% bound primarily to albumin
Metabolism	Metabolized stereo- and regio-selectively by hepatic microsomal enzymes. S-warfarin is predominantly metabolized by cytochrome P450 (CYP) 2C9 to yield the 6- and 7-hydroxylated metabolites. R-warfarin is metabolized by CYP1A1, 1A2, and 3A4 to yield 6-, 8-, and 10-hydroxylated metabolites. Hydroxylated metabolites may be further conjugated prior to excretion into bile and urine. UGT1A1 appears to be responsible for producing the 6-O-glucuronide of warfarin, with a possibly contribution from UGT1A10. Five UGT1As may be involved in the formation of 7-O-glucuronide warfarin. S-warfarin has higher potency than R-warfarin and genetic polymorphisms in CYP2C9 may dramatically decrease clearance of and increase toxicity of the medication

Route of elimination	The elimination of warfarin is almost entirely by metabolism. Very little warfarin is excreted unchanged in urine. The metabolites are principally excreted into the urine; and to a lesser extent into the bile	
Half life	R-warfarin $t_{1/2}$=37-89 hours; S-warfarin $t_{1/2}$=21-43 hours	
Clearance	0.065 ± 0.025 ml/min/kg [CYP2C9 Genotype 1/1] 0.041 ± 0.021 [CYP2C9 Genotype 1/2 or 1/3] 0.020 ± 0.011 [CYP2C9 Genotype 2/2, 2/3, or 3/3]	
Toxicity	LD_{50}=374 (orally in mice)	
Drug interactions	**Drug**	**Interaction**
	Acetaminophen	Acetaminophen increases the anticoagulant effect of warfarin. Monitor for changes in the therapeutic and adverse effects of warfarin if acetaminophen is initiated, discontinued or dose changed
	Acetylsalicylic acid	The antiplatelet effects of acetylsalicylic acid may increase the bleed risk associated with warfarin
	Allopurinol	Allopurinol may increase the anticoagulant effect of warfarin. Monitor for changes in prothrombin times and therapeutic effects of warfarin if allopurinol is initiated, discontinued or dose changed
	Aminoglutethimide	Aminoglutethimide may decrease the anticoagulant effect of warfarin by increasing its metabolism. Monitor for changes in prothrombin time and therapeutic effects of warfarin if aminoglutethimide is initiated, discontinued or dose changed
	Aminosalicylic Acid	The antiplatelet effects of aminosalicylic acid may increase the bleed risk associated with warfarin
	Amiodarone	Amiodarone may increase the anticoagulant effect of warfarin. Monitor for changes in prothrombin time and therapeutic effects of warfarin if amiodarone is initiated, discontinued or dose changed
	Amobarbital	Amobarbital may decrease the serum concentration of warfarin by increasing its metabolism. Monitor for changes in the therapeutic and adverse effects of warfarin if amobarbital is initiated, discontinued or dose changed
	Amprenavir	Amprenavir may increase the anticoagulant effect of warfarin by increasing its serum concentration
	Aprepitant	Aprepitant may decrease the anticoagulant effect of warfarin by decreasing its serum concentration
	Atazanavir	The protease inhibitor, atazanavir, may increase the anticoagulant effect of warfarin
	Azathioprine	Azathioprine may decrease the anticoagulant effect of warfarin
	Azithromycin	Azithromycin may increase the anticoagulant effect of warfarin by increasing its serum concentration
	Betamethasone	The corticosteroid, betamethasone, alters the anticoagulant effect of warfarin
	Bezafibrate	Bezafibrate may increase the anticoagulant effect of warfarin. Monitor prothrombin time and therapeutic and adverse effects of warfarin if bezafibrate is initiated, discontinued or dose changed

	Bosentan	Bosentan may decrease the anticoagulant effect of warfarin by increasing its metabolism
	Butabarbital	Butabarbital may decrease the serum concentration of warfarin by increasing its metabolism. Monitor for changes in the therapeutic and adverse effects of warfarin if butabarbital is initiated, discontinued or dose changed
	Butalbital	Butalbital may decrease the serum concentration of warfarin by increasing its metabolism. Monitor for changes in the therapeutic and adverse effects of warfarin if butalbital is initiated, discontinued or dose changed
	Capecitabine	Capecitabine may increase the serum concentration of warfarin by decreasing its metabolism. Monitor for changes in prothrombin time and therapeutic effects of warfarin if capecitabine is initiated or discontinued. Subsequent cycles of capecitabine may increase this effect
	Carbamazepine	Carbamazepine may decrease the anticoagulant effect of warfarin. Monitor for changes in prothrombin time and therapeutic and adverse effects of warfarin if carbamazepine is initiated, discontinued or dose changed
	Cefotetan	The cephalosporin, cefotetan, may increase the anticoagulant effect of warfarin
	Cefoxitin	The cephalosporin, cefoxitin, may increase the anticoagulant effect of warfarin
	Ceftriaxone	The cephalosporin, ceftriaxone, may increase the anticoagulant effect of warfarin
	Celecoxib	Celecoxib may increase the anticoagulant effect of warfarin
	Cholestyramine	The bile acid sequestrant, cholestyramine, may decrease the anticoagulant effect of warfarin by decreasing its absorption
	Cimetidine	Cimetidine may increase the serum concentration of warfarin. Monitor for changes in prothrombin time and therapeutic and adverse effects of warfarin if cimetidine is initiated, discontinued or dose changed
	Ciprofloxacin	The quinolone antibiotic, ciprofloxacin, may increase the anticoagulant effect of warfarin
	Cisapride	Cisapride may increase the anticoagulant effect of warfarin
	Citalopram	The SSRI, citalopram, increases the effect of anticoagulant, warfarin
	Clarithromycin	The macrolide, clarithromycin, may increase the anticoagulant effect of warfarin
	Clofibrate	The fibrate increases the anticoagulant effect
	Clopidogrel	Increased bleed risk may occur as a result of additive anticoagulant effects. Increase monitoring for signs and symptoms of bleeding during concomitant therapy

	Colestipol	The bile acid sequestrant, colestipol, may decrease the anticoagulant effect of warfarin by decreasing its absorption
	Cyclophosphamide	The antineoplastic agent, cyclophosphamide may alter the anticoagulant effect of warfarin
	Danazol	Danazol may increase the serum concentration and anticoagulant effect of warfarin. Monitor for changes in prothrombin time and therapeutic effects of warfarin if danazol is initiated, discontinued or dose changed
	Delavirdine	Delavirdine, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if delavirdine is initiated, discontinued or dose changed
	Demeclocycline	The tetracycline, demeclocycline, may increase the anticoagulant effect of warfarin
	Desogestrel	Desogestrol may alter the anticoagulant effect of warfarin. Concomitant therapy should be avoided. Monitor for changes in coagulation status if desogestrol is initiated, discontinued or dose changed
	Dexamethasone	The corticosteroid, dexamethasone, alters the anticoagulant effect of warfarin
	Dextrothyroxine	The thyroid hormone, dextrothyroxine, increase the anticoagulant effect of warfarin
	Diclofenac	The antiplatelet effects of oral diclofenac may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Dicloxacillin	Dicloxacillin may decrease the anticoagulant effect of warfarin
	Diflunisal	The antiplatelet effects of diflunisal may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Disulfiram	Disulfiram may increase the anticoagulant effect of warfarin
	Doxycycline	The tetracycline, doxycycline, may increase the anticoagulant effect of warfarin
	Drospirenone	Drospirenone may alter the anticoagulant effect of warfarin. Concomitant therapy should be avoided. Monitor for changes in coagulation status if drospirenone is initiated, discontinued or dose changed
	Drotrecogin alfa	Increased risk of bleeding
	Erythromycin	The macrolide, erythromycin, may increase the anticoagulant effect of warfarin
	Ethchlorvynol	Ethchlorvynol may decrease the anticoagulant effect of warfarin
	Ethinyl estradiol	Ethinyl estradiol may alter the anticoagulant effect of warfarin. Concomitant therapy should be avoided. Monitor for changes in coagulation status if ethinyl estradiol is initiated, discontinued or dose changed

	Ethynodiol diacetate	Ethynodiol diacetate may alter the anticoagulant effect of warfarin. Concomitant therapy should be avoided. Monitor for changes in coagulation status if ethynodiol diacetate is initiated, discontinued or dos
	Etodolac	The antiplatelet effects of etodolac may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Etonogestrel	Etonogestrel may alter the anticoagulant effect of warfarin. Concomitant therapy should be avoided. Monitor for changes in coagulation status if etonogestrel is initiated, discontinued or dose changed.
	Etoricoxib	Etoricoxib may increase the anticoagulant effect of warfarin
	Fenofibrate	Fenofibrate may increase the anticoagulant effect of warfarin. Monitor prothrombin time and therapeutic and adverse effects of warfarin if fenofibrate is initiated, discontinued or dose changed
	Fenoprofen	The antiplatelet effects of fenoprofen may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Floxuridine	Floxuridine, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if floxuridine is initiated, discontinued or dose changed
	Fluconazole	Fluconazole, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if fluconazole is initiated, discontinued or dose changed
	Fludrocortisone	The corticosteroid, fludrocortisone, alters the anticoagulant effect of warfarin
	Fluorouracil	Fluorouracil, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if fluorouracil is initiated, discontinued or dose changed
	Fluoxetine	The SSRI, fluoxetine, increases the effect of anticoagulant, warfarin
	Fluoxymesterone	Fluoxymesterone may increase the serum concentration and anticoagulant effect of warfarin. Monitor for changes in prothrombin time and therapeutic effects of warfarin if fluoxymesterone is initiated, discontinued or dose changed
	Flurbiprofen	Flurbiprofen, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. The antiplatelet effect of flurbiprofen may also increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if flurbiprofen is initiated, discontinued or dose changed

	Fluvastatin	Fluvastatin may increase the anticoagulant effect of warfarin. Monitor for changes in the therapeutic and adverse effects of warfarin if fluvastatin is initiated, discontinued or dose changed
	Fluvoxamine	Fluvoxamine may increase the anticoagulant effect of warfarin by increasing its serum concentration
	Fosamprenavir	The protease inhibitor, fosamprenavir, may increase the anticoagulant effect of warfarin
	Fosphenytoin	Increased hydantoin levels and risk of bleeding
	Gefitinib	Gefitinib may increase the anticoagulant effect of warfarin
	Gemcitabine	Gemcitabine may increase the anticoagulant effect of warfarin
	Gemfibrozil	Gemfibrozil, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if gemfibrozil is initiated, discontinued or dose changed
	Ginkgo biloba	Additive anticoagulant/antiplatelet effects may increase bleed risk. Concomitant therapy should be avoided
	Ginseng	Additive anticoagulant effects increase the risk of bleeding. Concomitant therapy should be avoided
	Glutethimide	Glutethimide may decrease the serum concentration of warfarin by increasing its metabolism. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if glutethimide is initiated, discontinued or dose changed.
	Griseofulvin	Griseofulvin may decrease the anticoagulant effect of warfarin
	Hydrocortisone	The corticosteroid, hydrocortisone, alters the anticoagulant effect of warfarin
	Ibuprofen	Ibuprofen, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. The antiplatelet effect of ibuprofen may also increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if ibuprofen is initiated, discontinued or dose changed
	Imatinib	Imatinib may increase the anticoagulant effect of warfarin increasing the risk of bleeding. Monitor for changes in prothrombin time and therapeutic and adverse effects of warfarin if imatinib is initiated, discontinued or dose changed
	Indinavir	The protease inhibitor, indinavir, may increase the anticoagulant effect of warfarin
	Indomethacin	Indomethacin, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. The antiplatelet effect of indomethacin may also increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if indomethacin is initiated, discontinued or dose changed

	Isoniazid	Isoniazid may increase the anticoagulant effect of warfarin
	Itraconazole	Itraconazole may increase the anticoagulant effect of warfarin by decreasing its metabolism
	Ketoconazole	Ketoconazole, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if ketoconazole is initiated, discontinued or dose changed
	Ketoprofen	The antiplatelet effects of ketoprofen may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Ketorolac	The antiplatelet effects of ketorolac may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Leflunomide	Leflunomide may increase the anticoagulant effect of warfarin
	Levamisole	Levamisole may increase the anticoagulant effect of warfarin.
	Levofloxacin	The quinolone antibiotic, levofloxacin, may increase the anticoagulant effect of warfarin
	Levonorgestrel	Levonorgestrel may alter the anticoagulant effect of warfarin. Concomitant therapy should be avoided. Monitor for changes in coagulation status if levonorgestrel is initiated, discontinued or dose changed
	Levothyroxine	Levothyroxine may contribute to the anticoagulant effect of warfarin by increasing the metabolism of vitamin K-dependent clotting factors. Monitor for changes in prothrombin time and anticoagulant effects if levothyroxine is initiated, discontinued or dose changed
	Liothyronine	Liothyronine may contribute to the anticoagulant effect of warfarin by increasing the metabolism of vitamin K-dependent clotting factors. Monitor for changes in prothrombin time and anticoagulant effects if liothyronine is initiated, discontinued or dose changed
	Liotrix	Liotrix may contribute to the anticoagulant effect of warfarin by increasing the metabolism of vitamin K-dependent clotting factors. Monitor for changes in prothrombin time and anticoagulant effects if liotrix is initiated, discontinued or dose changed
	Lovastatin	Lovastatin may increase the anticoagulant effect warfarin. Monitor for changes in the therapeutic and adverse effects of warfarin if lovastatin is initiated, discontinued or dose changed
	Lumiracoxib	Lumiracoxib may increase the anticoagulant effect of warfarin

	Meclofenamic acid	The antiplatelet effects of meclofenamic acid may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Medroxyprogesterone	Medroxyprogesterone may alter the anticoagulant effect of warfarin. Concomitant therapy should be avoided. Monitor for changes in coagulation status if medroxyprogesterone is initiated, discontinued or dose changed
	Mefenamic acid	Mefenamic acid, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. The antiplatelet effect of mefenamic acid may also increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if mefenamic acid is initiated, discontinued or dose changed
	Mefloquine	Mefloquine may increase the anticoagulant effect of warfarin
	Meloxicam	The antiplatelet effects of meloxicam may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Mercaptopurine	Mercaptopurine may decrease the anticoagulant effect of warfarin
	Mestranol	Mestranol may alter the anticoagulant effect of warfarin. Concomitant therapy should be avoided. Monitor for changes in coagulation status if mestranol is initiated, discontinued or dose changed
	Methimazole	Methimazole may decrease the anticoagulant effect of warfarin. Monitor for changes in the therapeutic and adverse effects of warfarin if methimazole is initiated, discontinued or dose changed
	Methohexital	Methohexital may decrease the serum concentration of warfarin by increasing its metabolism. Monitor for changes in the therapeutic and adverse effects of warfarin if methohexital is initiated, discontinued or dose changed
	Metronidazole	Metronidazole may increase the serum concentration of warfarin by decreasing its metabolism. Consider alternate therapy or a dose reduction in warfarin. Monitor for changes in prothrombin time and therapeutic and adverse effects of warfarin if metronidazole is initiated, discontinued or dose changed
	Miconazole	Miconazole, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if miconazole is initiated, discontinued or dose changed
	Minocycline	The tetracycline, minocycline, may increase the anticoagulant effect of warfarin

	Mitotane	Mitotane may decrease the anticoagulant effect of warfarin
	Moxifloxacin	The quinolone antibiotic, moxifloxacin, may increase the anticoagulant effect of warfarin
	Nabumetone	The antiplatelet effects of nabumetone may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Nafcillin	Nafcillin may increase the anticoagulant effect of warfarin increasing the risk of bleeding. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if nafcillin is initiated, discontinued or dose changed
	Nalidixic acid	The quinolone antibiotic, nalidixic acid, may increase the anticoagulant effect of warfarin
	Nandrolone decanoate	Nandrolone may increase the serum concentration and anticoagulant effect of warfarin. Monitor for changes in prothrombin time and therapeutic effects of warfarin if nandrolone is initiated, discontinued or dose changed
	Nandrolone phenpropionate	Nandrolone may increase the serum concentration and anticoagulant effect of warfarin. Monitor for changes in prothrombin time and therapeutic effects of warfarin if nandrolone is initiated, discontinued or dose changed
	Naproxen	The antiplatelet effects of naproxen may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Nelfinavir	The protease inhibitor, nelfinavir, may increase the anticoagulant effect of warfarin
	Nevirapine	Nevirapine may decrease the anticoagulant effect of warfarin by increasing metabolism of R-warfarin via CYP3A4
	Nicardipine	Nicardipine, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if nicardipine is initiated, discontinued or dose changed
	Norethindrone	Norethindrone may alter the anticoagulant effect of warfarin. Concomitant therapy should be avoided. Monitor for changes in coagulation status if norethindrone is initiated, discontinued or dose changed
	Norfloxacin	The quinolone antibiotic, norfloxacin, may increase the anticoagulant effect of warfarin
	Norgestimate	Norgestimate may alter the anticoagulant effect of warfarin. Concomitant therapy should be avoided. Monitor for changes in coagulation status if norgestimate is initiated, discontinued or dose changed
	Ofloxacin	The quinolone antibiotic, ofloxacin, may increase the anticoagulant effect of warfarin
	Orlistat	Orlistat may increase the anticoagulant effect of warfarin

	Oxandrolone	Oxandrolone may increase the serum concentration and anticoagulant effect of warfarin. Monitor for changes in prothrombin time and therapeutic effects of warfarin if oxandrolone is initiated, discontinued or dose changed
	Oxaprozin	The antiplatelet effects of oxaprozin may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Oxymetholone	Oxymetholone may increase the serum concentration and anticoagulant effect of warfarin. Monitor for changes in prothrombin time and therapeutic effects of warfarin if oxymetholone is initiated, discontinued or dose changed
	Oxyphenbutazone	The NSAID, oxyphenbutazone, may increase the anticoagulant effect of warfarin
	Paroxetine	The SSRI, paroxetine, increases the effect of the anticoagulant warfarin
	Pentobarbital	Pentobarbital may decrease the serum concentration of warfarin by increasing its metabolism. Monitor for changes in the therapeutic and adverse effects of warfarin if pentobarbital is initiated, discontinued or dose changed
	Pentoxifylline	Pentoxifylline may increase the anticoagulant effect of warfarin
	Phenobarbital	Phenobarbital may decrease the serum concentration of warfarin by increasing its metabolism. Monitor for changes in the therapeutic and adverse effects of warfarin if phenobarbital is initiated, discontinued or dose changed
	Phenylbutazone	The NSAID, phenylbutazone, may increase the anticoagulant effect of warfarin
	Phenytoin	Warfarin may increase the serum concentration of phenytoin possibly by competing for CYP2C9 metabolism. Phenytoin may increase the anticoagulant effect of warfarin. Monitor phenytoin levels, prothrombin time, and therapeutic and adverse effects of both agents during concomitant therapy
	Phytonadione	Phytonadione (vitamin K) may antagonize the anticoagulant effects of warfarin. Monitor for changes in prothrombin time if phytonadione intake (either via supplements or vitamin K-rich foods) is increased or decreased
	Piroxicam	Piroxicam, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. The antiplatelet effect of piroxicam may also increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if piroxicam is initiated, discontinued or dose changed
	Prednisolone	The corticosteroid, prednisolone, alters the anticoagulant effect of warfarin

	Prednisone	The corticosteroid, prednisone, alters the anticoagulant effect of warfarin
	Primidone	The barbiturate, primidone, decreases the anticoagulant effect of warfarin
	Propafenone	Propafenone may increase the anticoagulant effect of warfarin
	Propoxyphene	Propoxyphene may increase the anticoagulant effect of warfarin
	Propylthiouracil	Propylthiouracil may decrease the anticoagulant effect of warfarin. Monitor for changes in the therapeutic and adverse effects of warfarin if propylthiouracil is initiated, discontinued or dose changed
	Quinidine	Quinidine may increase the anticoagulant effect of warfarin
	Quinine	Quinine, a moderate CYP2C9 inhibitor, may increase the serum concentration of S-warfarin by decreasing its metabolism via CYP2C9
	Ranitidine	Ranitidine may increase the anticoagulant effect of warfarin (conflicting evidence)
	Rifabutin	Rifabutin may decrease the anticoagulant effect of warfarin by increasing its metabolism.
	Rifampin	Rifampin may decrease the anticoagulant effect of warfarin by increasing its metabolism
	S-adenosylmethionine	Additive anticoagulant effects increase the risk of bleeding. Concomitant therapy should be avoided
	Salicylate-sodium	The antiplatelet effects of sodium salicylate may increase the bleed risk associated with warfarin
	Secobarbital	Secobarbital may decrease the serum concentration of warfarin by increasing its metabolism. Monitor for changes in the therapeutic and adverse effects of warfarin if secobarbital is initiated, discontinued or dose changed
	Sitaxentan	Sitaxentan, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Warfarin doses should be decreased by 80% upon initiated of concomitant therapy. Monitor for changes in the therapeutic and adverse effects of warfarin if sitaxentan is initiated, discontinued or dose changed
	St. John's Wort	St. John's Wort may decrease the serum concentration of warfarin by increasing its metabolism. Concomitant therapy should be avoided. Monitor for changes in the therapeutic and adverse effects of warfarin if St. John's Wort is initiated, discontinued or dose changed
	Sucralfate	Sucralfate may reduce the absorption of warfarin. Warfarin should be administered at least 2 hours before or 6 hours after sucralfate administration. Monitor for changes in prothrombin time if sucralfate is initiated, discontinued or dose changed

	Sulfadiazine	Sulfadiazine, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if sulfadiazine is initiated, discontinued or dose changed
	Sulfamethoxazole	Sulfamethoxazole may increase the anticoagulant effect of warfarin by decreasing its metabolism. Consider alternate therapy or monitor for changes in prothrombin time if sulfamethoxazole is initiated, discontinued or dose changed
	Sulfinpyrazone	Sulfinpyrazone may increase the anticoagulant effect of warfarin by decreasing its metabolism and protein binding
	Sulfisoxazole	Sulfisoxazole, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if sulfisoxazole is initiated, discontinued or dose changed
	Sulindac	The antiplatelet effects of sulindac may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Tamoxifen	Tamoxifen, a CYP2C9 inhibitor, may increase the serum concentration of warfarin by decreasing its metabolism. Concomitant therapy is contraindicated due to significant increase in bleed risk
	Telithromycin	Telithromycin may increase the anticoagulant effect of warfarin. INR should be monitored and warfarin dose adjusted accordingly during concomitant therapy
	Tenoxicam	The NSAID, tenoxicam, may increase the anticoagulant effect of warfarin
	Testolactone	Testolactone may increase the serum concentration and anticoagulant effect of warfarin. Monitor for changes in prothrombin time and therapeutic effects of warfarin if testolactone is initiated, discontinued or dose changed
	Testosterone	Testosterone may increase the serum concentration and anticoagulant effect of warfarin. Monitor for changes in prothrombin time and therapeutic effects of warfarin if testosterone is initiated, discontinued or dose changed
	Testosterone Propionate	The androgen, testosterone, may incrase the anticoagulant effect of the Vitamin K antagonist, warfarin. Monitor for changes in the therapeutic effect of warfarin if testosterone is initiated, discontinued or dose changed
	Tetracycline	Tetracycline may increase the anticoagulant effect of warfarin
	Thiopental	Thiopental may decrease the serum concentration of warfarin by increasing its metabolism. Monitor for changes in the therapeutic and adverse effects of warfarin if thiopental is initiated, discontinued or dose changed

	Tiaprofenic acid	The antiplatelet effects of tiaprofenic acid may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	Ticlopidine	Increased bleeding risk. Monitor INR
	Tigecycline	Tigecycline may increase the serum concentration of warfarin
	Tolbutamide	Tolbutamide, a strong CYP2C9 inhibitor, may decrease the metabolism of warfarin. Consider alternate therapy or monitor for changes in the therapeutic and adverse effects of warfarin if tolbutamide is initiated, discontinued or dose changed
	Tolmetin	The antiplatelet effects of tolmetin may increase the bleed risk associated with warfarin. Consider alternate therapy or monitor for signs and symptoms of bleeding during concomitant therapy
	transdermal testosterone gel	The androgen, Testosterone, may incrase the anticoagulant effect of the vitamin K antagonist, and warfarin. Monitor for changes in the therapeutic effect of warfarin if testosterone is initiated, discontinued or dose changed
	Treprostinil	The prostacyclin analogue, treprostinil, increases the risk of bleeding when combined with the anticoagulant, Warfarin. Monitor for increased bleeding during concomitant thearpy
	Triamcinolone	The corticosteroid, triamcinolone, alters the anticoagulant effect of warfarin
	Triflusal	The metabolite of triflusal, 2-hydroxy-4-trifluoro-methyl-benzoic acid (HTB), impairs the serum protein binding of warfarin to the same extent as acetylsalisylic acid. Thus, the free fraction of glisentide may be increased. A dosage reduction may be required if used in combination
	Trimetrexate	The anticoagulant effect of Warfarin, a Vitamin K antagonist, may be altered by antineoplastics such as Trimetrexate. Monitor for changes in the anticoagulant effects of warfarin and other coumarin derivatives during concomitant use
	Trisalicylate-choline	The antiplatelet effects of trisalicylate-choline may increase the bleed risk associated with warfarin
	Vilazodone	Increased risk of bleeding with concomitant use of warfarin and vilazodone
Food interactions	• Avoid alcohol • Avoid drastic changes in dietary habit • Avoid St. John's Wort • Consult your doctor before ingesting large amounts of dietary Vitamin K (e.g. from green leafy vegetables) • Limit garlic, ginger, gingko, and horse chestnut	

Efficacy (vs. no anticoagulant)	• Warfarin with INR target≥2 associated with decreased risk of systemic embolism compared to antiplatelet agents and placebo, but higher rate of major bleeding compared to placebo and low-dose warfarin (Level 2 [mid-level] evidence) [159] • For patients with nonvalvular atrial fibrillation and with no history of stroke or transient ischemic attack (TIA), warfarin with target INR 2-3 reduces risk of stroke (Level 1 [likely reliable] evidence) [160] • For patients with nonrheumatic atrial fibrillation and recent TIA or minor ischemic stroke, anticoagulants reduce risk of stroke (Level 1 [likely reliable] evidence) [133] • Risks and benefits of warfarin treatment for atrial fibrillation vary by age, gender, and medical history (Level 2 [mid-level] evidence) [161]
Clinical outcome rates on warfarin (noncomparative data)	• Warfarin use associated with low annual rate of stroke or systemic embolism in patients with nonvalvular atrial fibrillation (Level 2 [mid-level] evidence) [162] • Warfarin use in clinical practice associated with outcomes similar to those in randomized trials except increased risk for minor bleeding [163] • Rates of stroke and bleeding complications in actual practice were similar to rates reported in randomized trials [164] • Long-term warfarin did not worsen self-reported perceptions of health except in patients who bled (even minor bleeding) [165]

Target INR	• INR 2.5-3.5 if rheumatic mitral stenosis or prosthetic heart valve
	• INR 2-3 if heart failure within 3 months, history of hypertension, echocardiography shows left ventricular systolic dysfunction, left atrial enlargement by echocardiography, left ventricular hypertrophy (LVH) by echocardiography, prior myocardial infarction, diabetes mellitus, significant mitral annular calcium, age>65 years, history of stroke or transient ischemic attack, clinical coronary artery disease, mitral stenosis, thyrotoxicosis
	• INR<2 or>3 associated with adverse outcomes (Level 2 [mid-level] evidence) [166]
	  ▪ optimum INR range is 2.0-3.9, INR<2 not protective against stroke, INR>5 associated with major bleeding [167]
	  ▪ INR<2 much less protective in reducing risk for stroke [168]
	• INR target of 1.8 does not appear to decrease risk of thromboembolic events and major bleeding compared with standard target INR among elderly patients with nonvalvular atrial fibrillation (Level 2 [mid-level] evidence) [169]

Table 64.10. **Warfarin overview. SMILES indicates simplified molecular-input line-entry system [25].**

This reduces the thrombogenicity of clots. Meta-analyses of the RCTs aimed to evaluate the antithrombotic efficacy of VKA in SPAF, in fact, have previously demonstrated that these drugs produce a RRR of stroke and systemic embolism of 64% (95% CI 49-74%) when compared to placebo and 39% (95% CI 19-53%) when compared to ASA [134]. Specifically, warfarin reduces the risk of recurrent stroke or systemic embolism by about 61% (95% CI 37-75%) compared with control in AF patients with recent TIA or ischemic stroke [133,134]. This proportional risk reduction is consistent with that observed for the prevention of first-ever stroke among individuals with AF, including the elderly [134,142]. Warfarin also increases the odds of major extracranial hemorrhage (OR 4.3 [95% CI 1.5-12.1]) [133]. Much recently the BAFTA trial (Birmingham Atrial Fibrillation Treatment of the Aged Study) has confirmed the superiority of VKA drugs on ASA in SPAF [149]. The superiority of VKA is clear only when the time spent in therapeutic range (TTR) measured by INR 2.0-3.0 is over than 40% [150].

Once the decision has been made to start OAT with VKA in patients with AF who are at medium or high risk of stroke, a clinical algorithm or fixed-dose approach is common-

ly used. However, adverse effects can arise while finding the appropriate maintenance dose, which can vary by a factor of ten among patients. VKA have a narrow therapeutic window; the risk of stroke and systemic embolism is increased at lower levels of anticoagulation (INR<2.0) and the bleeding risk is higher when INR is over 3.0 [151]. VKA have a slower onset and offset of action requiring a bridging therapy with parenteral antithrombotic drugs such as intravenous or subcutaneous heparins. Moreover VKA have an unpredictable pharmacologic profile in different patients, based on genetic polimorphisms in *CYP2C9* and vitamin K epoxide reductase complex subunit 1 (*VKORC1*) genes and multiple food and drug interactions. VKA require close laboratory monitoring of INR with frequent dose adjustments and patients' discomfort. Due to these limitations TTR is often sub-optimal in the real practice, being less than 60% [152]. An algorithm for estimating the appropriate warfarin dose that is based on clinical and genetic data has been developed and validated, and provided significantly better predictions of appropriate dose of warfarin than either the clinical algorithm or a fixed-dose approach [153]. This suggests that testing for variants in genes involved in warfarin metabolism and sensitivity (*CYP2C9*2*, *CYP2C9*3*, and/ or *VKORC1*) might allow more personalized dosing of warfarin during the induction phase than would standard warfarin induction [153]. However, any clinical benefits of genotyping are unproven in terms of fewer future strokes or bleeds, and the additional cost of genotype testing is unlikely to be cost-effective for typical patients with non-valvular AF. Actually, the best way to determine the genotype of a patient is to measure their INR when starting OAT [153]. Despite strong literature evidence, VKA are underused in real clinical practice. A much recent meta-analysis shows that only 60% of patients suitable for treatment with VKA receives these drugs [154]. The reasons for this underuse must be researched in their many limitations. VKA limitations have lead to development and clinical experimental use of new anticoagulant molecules aimed to overcome these limits. In the last years new oral anticoagulants have reached phase III of clinical experimentation. Their targets on coagulation cascade are the direct inhibition of thrombin (actived factor II) and actived factor X.

Recommendations for Use of Warfarin for Secondary Prevention of Stroke

Recommendations apply to patients with permanent, persistent, or paroxysmal atrial fibrillation, atrial flutter, and patients managed with rhythm control strategy:

- For risk stratification consider CHADS2 score (CCS Strong recommendation, High-quality evidence):
  - 1 point for each of congestive heart failure, hypertension, age≥75 years, diabetes mellitus; 2 points for prior stroke or transient ischemic attack.
  - various risk scores predict risk for stroke; CHADS2 risk score may be simplest and most accurate (Level 2 [mid-level] evidence).
  - HAS-BLED score predicts risk of bleeding in patients with atrial fibrillation taking warfarin (Level 1 [likely reliable] evidence).
- Most patients with atrial fibrillation or atrial flutter should receive either oral anticoagulant or aspirin (ACC/AHA Class I, Level A, CCS Strong recommendation, High-quality evidence):
  - Warfarin with INR target ≥2 associated with decreased risk of systemic embolism compared to antiplatelet agents and placebo, but higher rate of major bleeding compared to placebo and low-dose warfarin (Level 2 [mid-level] evidence)-
  - OAT recommended for patients.
- Non-vitamin K antagonist (VKA) anticoagulantswith intermediate risk for stroke (for example, CHADS2 score=1) (CCS Strong recommendation, High-quality evidence, ACCP Grade 1B compared to no therapy, ACCP Grade 2B compared to antiplatelet therapy); high risk for stroke (for example, CHADS2 score≥2) (CCS Strong recom-

mendation, High-quality evidence, ACCP Grade 1A compared to no therapy, ACCP Grade 1B compared to antiplatelet therapy); mitral stenosis (considered high risk for stroke) (ACC/AHA Class I, Level A, ACCP Grade 1B compared to no therapy or antiplatelet therapy); history of cardioembolic stroke or transient ischemic attack (TIA) (ACC/AHA Class I, Level A, ACCP Grade 1A compared to no therapy, ACCP Grade 1B compared to antiplatelet therapy); for patients with nonrheumatic atrial fibrillation and history of stroke or TIA, anticoagulants reduce risk of stroke compared to placebo (Level 1 [likely reliable] evidence) or antiplatelet therapy (Level 2 [mid-level] evidence); if low risk for stroke (for example, CHADS2 score=0); no therapy suggested rather than antithrombotic therapy (ACCP Grade 2B), especially if male<65 years old without vascular disease (CCS Conditional recommendation, Low-quality evidence); aspirin 75-325 mg once daily suggested if antithrombotic therapy used (ACCP Grade 2B) and suggested for patients<65 years old if female or if vascular disease (CCS Conditional recommendation, Low-quality evidence); oral anticoagulant suggested if patient>65 years old, or female with vascular disease (CCS Conditional recommendation, Low-quality evidence); for patients with nonvalvular atrial fibrillation and with no history of stroke or TIA; warfarin with target INR 2-3 reduces risk of stroke (Level 1 [likely reliable] evidence); aspirin may reduce risk of stroke and major vascular events (Level 2 [mid-level] evidence).

- For patients using oral anticoagulation:
  - New anticoagulant (dabigatran, rivaroxaban, or apixaban) preferred over warfarin (CCS Conditional recommendation, High-quality evidence).
  - Dabigatran 150 mg twice daily suggested rather than adjusted-dose VKA therapy (target INR range 2-3) (ACCP Grade 2B, ACC/AHA Class I, Level B).
  - Compared to warfarin, dabigatran (Pradaxa) 150 mg twice daily further reduces risk for stroke with similar bleeding risk (Level 1 [likely reliable] evidence) and possibly higher incidence of myocardial infarction (Level 2 [mid-level] evidence).
  - Rivaroxaban (Xarelto) may be as effective as warfarin for preventing stroke or systemic embolism in patients with nonvalvular atrial fibrillation (Level 2 [mid-level] evidence).
  - Apixaban (Eliquis) associated with reduced risk of stroke and major bleeding and might reduce risk of mortality compared to warfarin (Level 2 [mid-level] evidence).
- If patient is unsuitable for or chooses not to take oral anticoagulant (for reasons other than concerns about major bleeding):
  - Combination therapy with aspirin and clopidogrel suggested rather than aspirin alone (ACC/AHA Class IIb, Level B, ACCP Grade 2B for intermediate-risk patients, ACCP Grade 1B for high-risk patients).
  - Addition of clopidogrel to aspirin associated with reduced risk for major vascular events and increased risk for major hemorrhage in patients with atrial fibrillation for whom VKA therapy is unsuitable (Level 2 [mid-level] evidence).
  - Apixaban reduces risk of stroke without increased risk of major bleeding or intracranial hemorrhage compared to aspirin in patients with atrial fibrillation for whom VKAs are unsuitable (Level 1 [likely reliable] evidence).

American College of Chest Physicians (ACCP) guidelines (Ninth Edition) on antithrombotic therapy in atrial fibrillation [130]:

- All antithrombotic therapy recommendations for atrial fibrillation (AF) apply to patients with:
  - Permanent, persistent, or paroxysmal AF (recommendations do not apply to patients with single, transient, self-limited AF associated with acute illness).
  - Atrial flutter.

  - Patients with AF being managed with a rhythm control strategy (pharmacologic or catheter ablation), regardless of apparent persistence of normal sinus rhythm (ACCP Grade 2C).
- OAT refers to use of dabigatran or adjusted-dose vitamin K antagonist (VKA) therapy; cautions with dabigatran include:
  - Dabigatran contraindicated if creatinine clearance ≤30 ml/minute.
  - There is no antidote for dabigatran.
- For risk stratification, consider CHADS2 score:
  - Congestive heart failure=1 point.
  - Hypertension=1 point.
  - Age ≥75 years=1 point.
  - Diabetes mellitus=1 point.
  - Prior Stroke or transient ischemic attack=2 points.
- For patients with nonrheumatic AF:
  - If low risk for stroke (for example, CHADS2 score=0): no therapy suggested rather than antithrombotic therapy (ACCP Grade 2B); for patients who choose antithrombotic therapy, aspirin (75-325 mg once daily) suggested rather than either OAT (ACCP Grade 2B) or combination therapy with aspirin and clopidogrel (ACCP Grade 2B).
  - If intermediate risk for stroke (for example, CHADS2 score=1): OAT recommended rather than no therapy (ACCP Grade 1B); OAT with dabigatran 150 mg twice daily suggested rather than adjusted-dose vitamin K antagonist (VKA) therapy (target INR range 2-3) (ACCP Grade 2B); OAT suggested rather than either aspirin (75-325 mg once daily) (ACCP Grade 2B) or combination therapy with aspirin and clopidogrel (ACCP Grade 2B);
  - If patient is unsuitable for or chooses not to take oral anticoagulant (for reasons other than concerns about major bleeding), combination therapy with aspirin and clopidogrel suggested rather than aspirin (75-325 mg once daily) (ACCP Grade 2B).
  - If high risk for stroke (for example, CHADS2 score≥2): OAT recommended rather than any of: no therapy (ACCP Grade 1A); aspirin (75-325 mg once daily) (ACCP Grade 1B); combination therapy with aspirin and clopidogrel (ACCP Grade 1B); OAT with dabigatran 150 mg twice daily suggested rather than adjusted-dose VKA therapy (target INR range, 2-3) (ACCP Grade 2B); if patient is unsuitable for or chooses not to take an oral anticoagulant (for reasons other than concerns about major bleeding), combination therapy with aspirin and clopidogrel recommended rather than aspirin (75-325 mg once daily) (ACCP Grade 1B).
- For patients with AF and mitral stenosis:
  - Adjusted-dose VKA therapy (target INR range 2-3) recommended rather than no therapy, aspirin (75-325 mg once daily), or combination therapy with aspirin and clopidogrel (all ACCP Grade 1B)
  - If patient is unsuitable for or chooses not to take adjusted-dose VKA therapy (for reasons other than concerns about major bleeding), combination therapy with aspirin and clopidogrel recommended rather than aspirin (75-325 mg once daily) alone (ACCP Grade 1B).
- For patients with AF and stable coronary artery disease (for example, no acute coronary syndrome [ACS] within the previous year):
  - If patient chooses oral anticoagulation, adjusted-dose VKA therapy alone (target INR range 2-3) suggested rather than combination of adjusted-dose VKA therapy and aspirin (ACCP Grade 2C).

- For patients with AF and intracoronary stent placement (with or without recent ACS):
  - If high risk of stroke (for example, CHADS2 score ≥2): during first month after placement of bare-metal stent or first 3-6 months after placement of drug-eluting stent, triple therapy (with VKA therapy, aspirin, and clopidogrel) suggested rather than dual antiplatelet therapy (with aspirin and clopidogrel) (ACCP Grade 2C); after initial period of triple therapy, VKA therapy (target INR 2-3) plus single antiplatelet drug suggested rather than VKA alone (ACCP Grade 2C); at 12 months after intracoronary stent placement, if patient chooses oral anticoagulation, adjusted-dose VKA therapy alone (target INR range 2-3) suggested rather than combination of adjusted-dose VKA therapy and aspirin (ACCP Grade 2C).
  - If low to intermediate risk for stroke (for example, CHADS2 score 0 or 1): during first 12 months after placement of intracoronary stent (bare metal or drug-eluting), dual antiplatelet therapy suggested rather than triple therapy (ACCP Grade 2C); at 12 months after intracoronary stent placement, if patient chooses oral anticoagulation, adjusted-dose VKA therapy alone (target INR range 2-3) suggested rather than combination of adjusted-dose VKA therapy and aspirin (ACCP Grade 2C).
- For patients with AF and ACS and no intracoronary stent placement:
  - If intermediate to high risk of stroke (for example, CHADS2 score≥1): for first 12 months, adjusted-dose VKA therapy (target INR 2-3) plus single antiplatelet therapy suggested rather than dual antiplatelet therapy (for example, aspirin and clopidogrel) or triple therapy (for example, warfarin, aspirin, and clopidogrel) (ACCP Grade 2C); after 12 months, if patient chooses oral anticoagulation, adjusted-dose VKA therapy alone (target INR range 2-3) suggested rather than combination of adjusted-dose VKA therapy and aspirin (ACCP Grade 2C)
  - If low risk for stroke (for example, CHADS2 score=0): dual antiplatelet therapy (for example, aspirin and clopidogrel) suggested rather than adjusted-dose VKA therapy (target INR 2-3) plus single antiplatelet therapy or triple therapy (for example, warfarin, aspirin, and clopidogrel) (ACCP Grade 2C); after 12 months, if patient chooses oral anticoagulation, adjusted-dose VKA therapy alone (target INR range 2-3) suggested rather than combination of adjusted-dose VKA therapy and aspirin (ACCP Grade 2C).
- For patients having cardioversion:
  - Same approach suggested for both atrial fibrillation and atrial flutter.
  - For patients having elective cardioversion (pharmacologic or electrical): for atrial fibrillation of≥48 hours or of unknown duration; therapeutic anticoagulation recommended rather than no anticoagulation (ACCP Grade 1B); pre-cardioversion treatment options are: therapeutic anticoagulation for at least 3 weeks before cardioversion, using any of: adjusted-dose vitamin K antagonist (VKA) therapy (target INR range 2-3); low-molecular-weight heparin (LMWH) at full venous thromboembolism (VTE) treatment doses; dabigatran; transesophageal echocardiography (TEE)-guided approach with abbreviated anticoagulation before cardioversion; start LMWH at full venous thromboembolism treatment doses or IV unfractionated heparin (UFH) (to maintain activated partial thromboplastin time [aPTT] prolongation equal to plasma heparin levels of 0.3-0.7 units/ml antifactor Xa activity); TEE screening for thrombus in either atrial appendage or atrium. If no thrombus seen, cardioversion within 24 hours: therapeutic anticoagulation recommended for at least 4 weeks after successful cardioversion to sinus rhythm rather than no anticoagulation, regardless of baseline risk of stroke (ACCP Grade 1B); anticoagulation decisions beyond 4 weeks should be made in accordance with risk-based recommendations for long-term antithrombotic therapy. For atri-

al fibrillation of known duration<48 hours: starting anticoagulation (with LMWH or IV UFH at full VTE treatment doses) at presentation and proceeding to cardioversion suggested rather than delaying cardioversion (for 3 weeks of therapeutic anticoagulation or for TEE-guided approach) (ACCP Grade 2C). After successful cardioversion to sinus rhythm, therapeutic anticoagulation recommended for at least 4 weeks rather than no anticoagulation, regardless of baseline stroke risk (ACCP Grade 2C): anticoagulation decisions beyond 4 weeks should be made in accordance with risk-based recommendations for long-term antithrombotic therapy.
    - For urgent cardioversion in hemodynamically unstable patient: initiation of therapeutic-dose parenteral anticoagulation suggested before cardioversion, if possible (ACCP Grade 2C); initiation of anticoagulation should not delay any emergency intervention (ACCP Grade 2C); therapeutic anticoagulation for at least 4 weeks after successful cardioversion to sinus rhythm suggested rather than no anticoagulation, regardless of baseline stroke risk (ACCP Grade 2C); anticoagulation decisions beyond 4 weeks should be made in accordance with risk-based recommendations for long-term antithrombotic therapy.
- For secondary stroke prevention after cardioembolic stroke or transient ischemic attack (TIA) (that is, in patients with atrial fibrillation, including paroxysmal atrial fibrillation) [15]:
    - OAT recommended over: no antithrombotic therapy (ACCP Grade 1A); aspirin (ACCP Grade 1B); combination therapy with aspirin plus clopidogrel (ACCP Grade 1B); OAT with dabigatran 150 mg twice daily suggested over adjusted-dose vitamin K antagonist therapy (target range 2-3) (ACCP Grade 2B); dabigatran contraindicated if creatinine clearance ≤30 ml/minute.
    - For patients unsuitable for or who choose not to take an oral anticoagulant (for reasons other than concerns about major bleeding), combination therapy with aspirin plus clopidogrel recommended over aspirin (ACCP Grade 1B)
    - OAT should generally be started within 1-2 weeks after stroke onset, but timing may vary with risk for bleeding.
    - Use of aspirin as bridging therapy suggested until anticoagulation reaches therapeutic level.

American College of Cardiology/American Heart Association (ACC/AHA) guidelines:

- Antithrombotic therapy to prevent thromboembolism is recommended for all patients with atrial fibrillation, except patients with lone atrial fibrillation (age<60 years old without heart disease or risk factors for thromboembolism) or contraindications (ACC/AHA Class I, Level A) [155].
- Antithrombotic therapy is recommended for patients with atrial flutter (ACC/AHA Class I, Level C) [155].
- Long-term anticoagulation with vitamin K antagonist (VKA) not recommended for primary prevention of stroke in patients<60 years old without heart disease (lone atrial fibrillation) or any risk factors for thromboembolism (ACC/AHA Class III, Level C) [155].
- Selection of antithrombotic agent:
    - Should be based upon absolute risks of stroke and bleeding and relative risk and benefit for a given patient (ACC/AHA Class I, Level A) irrespective of pattern of atrial fibrillation (paroxysmal, persistent, or permanent) (ACC/AHA Class IIa, Level B) [155].
    - VKA recommended for [155]: patients at high risk of stroke due to prior thromboembolism (stroke, transient ischemic attack, or systemic embolism) or rheumatic mitral stenosis (ACC/AHA Class I, Level A); patients with>1 moderate risk factor

such as age≥75 years, hypertension, heart failure, impaired left ventricular systolic function (ejection fraction ≤ 35% or fractional shortening<25%) and diabetes mellitus (ACC/AHA Class I, Level A).
  - Either aspirin or VKA is reasonable for primary prevention of thromboembolism in patients with only 1 moderate risk factor such as age≥75 years, hypertension, heart failure, impaired left ventricular systolic function (ejection fraction ≤ 35% or fractional shortening<25%) and diabetes mellitus (ACC/AHA Class IIa, Level A) [155].
  - Either aspirin or VKA is reasonable for patients with less well-validated risk factors such as age 65-74 years, female gender or coronary artery disease (ACC/AHA Class IIa, Level B) [155].
  - Dabigatran is useful as an alternative to warfarin for prevention of stroke and thromboembolism in patients with paroxysmal, persistent, or permanent atrial fibrillation and risk factors for stroke or systemic embolization who do not have any of (ACC/AHA Class I, Level B) [156]: prosthetic heart valve; hemodynamically significant valve disease; severe renal failure (creatinine clearance<15 ml/minute); advanced liver disease (impaired baseline clotting function).
  - Aspirin 81-325 mg daily is recommended as an alternative to VKAs in low-risk patients or in patients with contraindications to OAT (ACC/AHA Class I, Level A) [155].
  - Addition of clopidogrel to aspirin might be considered in patients for whom warfarin is considered unsuitable due to patient preference or concern for ability to safely sustain anticoagulation (ACC/AHA Class IIb, Level B) [157].
- For patients on VKA [155]:
  - INR should be determined at least weekly during initiation of therapy and monthly when anticoagulation is stable (ACC/AHA Class I, Level A).
  - Target INR 2-3 in patients without mechanical heart valves (ACC/AHA Class I, Level A).
  - For patients with mechanical heart valves, target INR should be based on type of prosthesis, maintaining INR≥2.5 (ACC/AHA Class I, Level B).
  - Lower target INR of 2 (range 1.6-2.5) may be considered for patients≥75 years old or other patients at increased risk of bleeding but without contraindications to oral anticoagulant therapy (ACC/AHA Class IIb, Level C).
  - If ischemic stroke or systemic embolism on anticoagulation within INR 2-3, increasing target INR to 3-3.5 may be reasonable instead of adding antiplatelet agent (ACC/AHA Class IIb, Level C).
  - For surgical or diagnostic procedures with bleeding risk: for patients without mechanical heart valves, interruption of OAT for up to 1 week without substituting heparin is reasonable (ACC/AHA Class IIa, Level C); for high-risk patients requiring interruption of OAT for>1 week, subcutaneous unfractionated heparin or low-molecular-weight heparin may be given (ACC/AHA Class IIb, Level C)
  - Following percutaneous coronary intervention or revascularization surgery, low-dose aspirin<100 mg/day and/or clopidogrel 75 mg/day may be given with anticoagulation (ACC/AHA Class IIb, Level C).
  - Reasonable to reevaluate need for anticoagulation at regular intervals (ACC/AHA Class IIa, Level C).

American Heart Association/American Stroke Association (AHA/ASA) guidelines for secondary prevention of stroke in patients with paroxysmal or permanent atrial fibrillation [13]:

- Use vitamin K antagonist for anticoagulation (AHA/ASA Class I, Level A).
- Use aspirin if patient unable to take OAT medications (AHA/ASA Class I, Level A).

- Clopidogrel with aspirin not recommended for patients with hemorrhagic contraindication to warfarin (AHA/ASA Class III, Level B).
- Use bridging therapy with subcutaneous low-molecular-weight heparin if temporary interruption of OAT in patient at high risk (such as TIA within 3 months, mechanical valve disease) (AHA/ASA Class IIa, Level C).

Canadian Cardiovascular Society (CCS) guidelines:

- Use predictive index for stroke risk (such as CHADS2) and for risk of bleeding (such as HAS-BLED) to assess all patients with atrial fibrillation or atrial flutter (paroxysmal, persistent, or permanent) (CCS Strong recommendation, High-quality evidence) [158].
- Most patients with atrial fibrillation or atrial flutter should receive either oral anticoagulant or aspirin (CCS Strong recommendation, High-quality evidence) [158].
- When oral anticoagulant is indicated [158]:
  - New anticoagulant (dabigatran, rivaroxaban, or apixaban) preferred over warfarin (CCS Conditional recommendation, High-quality evidence).
  - Consider dose reduction of new anticoagulant, especially dabigatran, in patients>75 years old.
- Risk-based selection of antithrombotic therapy for stroke prevention [158]:
  - If CHADS2 score ≥2, give oral anticoagulant (CCS Strong recommendation, High-quality evidence).
  - If CHADS2 score=1: give most patients oral anticoagulant (CCS Strong recommendation, High-quality evidence); consider aspirin as reasonable alternative based on individual risk/benefit considerations (CCS Conditional recommendation, Moderate-quality evidence).
  - If CHADS2 score=0: consider additional risk factors for stroke (age 65-74 years, female gender, vascular disease) (CCS Conditional recommendation, Moderate-quality evidence); oral anticoagulant suggested if patient >65 years old, or female with vascular disease (CCS Conditional recommendation, Low-quality evidence); aspirin 75-325 mg/day suggested if patient is male with vascular disease or female without vascular disease (CCS Conditional recommendation, Low-quality evidence); consider no antithrombotic therapy for patients with no additional risk factors for stroke (CCS Conditional recommendation, Low-quality evidence)-
  - For patients with coronary artery disease and atrial fibrillation/atrial flutter. For patients with stable coronary artery disease, select antithrombotic therapy based on risk of stroke (CCS Conditional recommendation, Moderate-quality evidence): consider oral anticoagulant for most patients with CHADS2 score ≥1; consider aspirin for most patients with CHADS2 score=0. For patients with recent acute coronary syndrome or percutaneous coronary intervention, select antithrombotic therapy based on assessment of risks of stroke, recurrent coronary artery events, and hemorrhage (CCS Conditional recommendation, Low-quality evidence): consider aspirin plus clopidogrel plus oral anticoagulant in patients with CHADS2 score ≥2; consider aspirin plus clopidogrel in patients with CHADS2 score ≤1.
- Renal function considerations in patients with atrial fibrillation receiving oral anticoagulant [158]:
  - Assess renal function at least annually by measuring serum creatinine and calculating estimated glomerular filtration rate (egfr) (CCS Strong recommendation, Moderate-quality evidence)
  - Regularly consider alteration of OAT drug or dose based on egfr (CCS Strong recommendation, Moderate-quality evidence).
  - If EGFR>30 ml/minute: give antithrombotic therapy according to CHADS2 score as recommended for patients with normal renal function (CCS Strong recommen-

dation, High-quality evidence); if EGFR 30-50 ml/minute, consider more frequent egfr measurements and oral anticoagulant dose reductions with conditions that may transiently reduce egfr, especially if patient >75 years old.

- If EGFR 15-30 ml/minute and patient not on dialysis, give antithrombotic therapy according to CHADS2 score as recommended for patients with normal renal function but warfarin suggested as preferred agent for OAT (CCS Conditional recommendation, Low-quality evidence).
- If EGFR <15 ml/minute and patient on dialysis, oral anticoagulant or aspirin suggested not to be used routinely (CCS Conditional recommendation, Low-quality evidence).

64.3.3 Oral Direct Thrombin Inhibitors

Dabigatran Etexilate

Dabigatran is a selective and reversible inhibitor of thrombin. It derives from a binding between a N-α-naphthylsulphonylglycyl-4-amidino-phenylalanine-piperidine compound to a benzamidine which leads to antithrombotic activity (Table 64.11) [170-172]. Dabigatran reversibly binds to active site of thrombin both when free and when clot-bound.

Dabigatran is administered as pro-drug (dabigatran etexilate); non specific enzymes convert the pro-drug to the active molecule (dabigatran). This is of utmost importance because high polarity of dabigatran proves the impossibility of gastro-intestinal absorption [170-172]. Dabigatran has a quick onset of action when orally administrated and a predictable anticoagulant effect. Therapeutic dose does not lead to interactions with coagulation parameters such as prothombin time (PT) and actived partial thromboplastin (aPTT). Sovra-therapeutic dose could be detected by aPTT. The coagulation parameters thrombin time (TT) and echarin clotting (ECT) time are both altered by dabigatran, but, unfortunately, these assays are not widely diffuse in laboratories. After administration bioavailability is near 6.5%. Time to reach maximum plasma concentration is 90-270 minutes. Volume of distribution is around 60-70 liters. Metabolism starts in gastro-intestinal tract and end in liver, but it is not mediated by cytochrome P450. Dabigatran have not interactions with food. Contemporary adiministration of protonic pump inhibitors reduces the max concentration of 20-25% whereas food decreases the plasma peak of two hours. Halflife of dabigatran is near 8 hours after the first dose and 6 hours after multiple doses; after 4-6 hours max concentration is reduced for 30%. Therefore dabigatran needs of two administrations in a day. Steady-state is reached in 3 days. Dabigatran is excreted for 80% from kidneys, therefore renal failure could prove a reduced excrection. Dabigatran is contraindicated in patients with severe renal failure (creatinine clearance, ClCr, <30 ml/min). Hepatotoxicity with dabigatran has not been demonstrated [170-172]. Dabigatran has not a specific antidote for urgent reversal. Up to now fresh frozen plasma (FFP), FEIBA, recombinant actived Factor VII (raFVII) and dyalisis seem to be possible choices in this context [173]. Two doses of dabigatran, 110 mg twice daily and 150 mg twice daily, administered in blinded fashion, have been compared with adjusted doses to INR 2.0-3.0 of warfarin administered in un-blinded fashion, in patients with AF in the RE-LY study, a randomized clinical trial (RCT) of phase III aimed to demonstrate the non-inferiority of dabigatran in terms of cardioembolic risk (effectiveness) and bleeding risk (safety) [174]. The RE-LY trial has demonstrated that lower dosage of dabigatran, 110 mg twice daily, is not inferior to warfarin in preventing combined ischemic and hemorrhagic strokes and systemic embolism (RR 0.90, 95% CI 0.74-1.10, p<0.001 for non-inferiori-

ty, p=0.29 for superiority), while it is superior to warfarin in reduce total (RR 0.78, 95% CI 0.73-0.83, p<0.001) and major bleeding risk (RR 0.80, 95% CI 0.70-0.93, p=0.003) [174,175]. Higher dosage of dabigatran, 150 mg twice daily, results superior to warfarin in reducing the above mentioned combined endpoint (RR 0.65, 95% CI 0.52-0.81, p<0.001 both for non-inferiority and superiority) and non inferior to warfarin in major bleedings (RR 0.93, 95% CI 0.81-1.07, p<0.31), with the exception of gastrointestinal bleedings, significantly higher for dabigatran (RR 1.48, 95% CI 0.18-1.85, p=0.001 for warfarin superiority) [174,175]. Lower doses of dabigatran reduce the risk of intracranial bleeding of 70% compared to warfarin, whereas higher doses prove a RRR of 59% [174,175]. Based on the results of RE-LY, dabigatran is now recommended by ACCF/AHA/HRS as an alternative to VKA in high risk patients (IB) [156]. A specific question is whether the overall results of RE-LY can be generalised to patients with AF and a history of stroke or TIA. Among the 3,623 (20%) patients with a previous stroke or TIA who were enrolled, the results were consistent with the overall trial results (annual rate of the primary outcome event: warfarin, 2.75%; 110 mg dabigatran, 2.32%; 150 mg dabigatran, 2.07%), without significant differences between the HRs for patients with or without a history of cerebral ischemia (p=0.34 for interaction). However, the 95% CIs for patients with a history of cerebral ischemia were wide, indicating that evidence for the efficacy of dabigatran compared with warfarin in patients with a history of cerebral ischemia is still limited.

Dabigatran has been approved for this indication in many countries of the world. However, the potential benefits of dabigatran compared with warfarin may be reduced in poorly compliant patients (because the longer half-life of warfarin could provide them with a more consistent anticoagulant effect) and in patients taking potent P-glycoprotein inhibitors, which can increase serum concentrations of dabigatran (Table 64.11).

Structure	 Chemical structure: $C_{34}H_{41}N_7O_5$ SMILES: CCCCCCOC(=O)N=C(N)C1=CC=C(NCC2=NC3=C(C=CC(=C3)C(=O)N(CCC(=O)OCC)C3=CC=CC=N3)N2C)C=C1
Pharmacodynamics	Dabigatran etexilate is an inactive pro-drug that gets converted to dabigatran, the active form, by esterase-catalyzed hydrolysis in the plasma and liver. Dabigatran, the main active principle in plasma, is a rapid-acting competitive and reversible direct inhibitor of thrombin. Thrombin, a serine protease, is responsible for the conversion of fibrinogen to fibrin during the coagulation cascade. Inhibition of thrombin consequently prevents thrombus development. Dabigatran inhibits free thrombin, fibrin-bound thrombin and thrombin-induced platelet aggregation.
Mechanism of action	Esterase-catalysed hydrolysis of dabigatran etexilate in the plasma and liver yields the active form, dabigatran. Dabigatran competitively and reversibly binds to thrombin thereby inhibiting its ability to convert fibrinogen to fibrin during the coagulation cascade

Absorption	Peak plasma concentrations were achieved in 6 hours in post surgical patients. In healthy patients, maximum concentrations were achieved in 0.5 to 2 hours. The absolute bioavailability of dabigatran in the body after administration of dabigatran etexilate was 6.5%. Food does not affect the bioavailability of dabigatran etexilate, but it delays the time to peak plasma concentrations by 2 hours. Oral bioavailability may increase by up to 75% when pellets are taken out of the hydroxypropylmethylcellulose (HPMC) capsule. Therefore, capsules should not be opened and pellets taken alone	
Volume of distribution	Moderate tissue distribution with V_d of 60-70 l	
Protein binding	Relatively low binding (34-35%) to plasma proteins	
Metabolism	Dabigatran is typically metabolised by esterases and microsomal carboxylesterases. CYP450 enzymes do not seem to be involved. Pharmacologically active acylglucoronides are formed via conjugation. Four positional isomers, 1-O, 2-O, 3-O, and 4-O, acylglucuronides exist, each accounting for less than 10% of total plasma dabagatran	
Route of elimination	Mainly excreted in urine (85%). Fecal excretion accounts for 6% of the orally administered dose. Dabigatran is primarily eliminated unchanged via the kidneys at a rate of 100 ml/min corresponding to the glomerular filtration rate	
Half life	12-14 hours in healthy volunteers. 14-17 hours in patients treated for prevention of venous thromboembolism following hip- or knee-replacement surgery.	
Clearance	Not available	
Toxicity	The most common adverse reactions include dyspepsia or gastritis-like symptoms. The approximate lethal dose in rats and mice was observed at single oral doses of>2000 mg/kg. Oral doses of 600 mg/kg did not induce any toxicologically meaningful changes in dogs and Rhesus monkeys. Dabigatran was well-tolerated in rats and Rhesus monkeys during repeat-dose toxicity studies. No evidence of mutagenic potential	
Drug interactions	**Drug**	**Interaction**
	Amiodarone	Amiodarone may increase the serum concentration of dabigatran etexilate, resulting in increased risk of bleeding. Consider modifying therapy.
	Carbamazepine	P-Glycoprotein inducers such as carbamazepine may decrease the serum concentration of dabigatran etexilate. This combination should be avoided.
	Dexamethasone	P-Glycoprotein inducers such as dexamethasone may decrease the serum concentration of dabigatran etexilate. This combination should be avoided.
	Doxorubicin	P-Glycoprotein inducers such as doxorubicin may decrease the serum concentration of dabigatran etexilate. This combination should be avoided.
	Ginkgo biloba	Additive anticoagulant/antiplatelet effects of gingko may increase bleed risk for patients on dabigatran. Concomitant therapy should be avoided.
	Nefazodone	P-Glycoprotein inducers such as nefazodone may decrease the serum concentration of dabigatran etexilate. This combination should be avoided.
	Prazosin	P-Glycoprotein inducers such as prazosin may decrease the serum concentration of dabigatran etexilate. This combination should be avoided.
	Quinidine	Quinidine may increase the serum concentration of dabigatran etexilate, resulting in increased bleeding. Consider modification of therapy.
	Rifampin	P-Glycoprotein inducers such as rifampin may decrease the serum concentration of dabigatran etexilate. This combination should be avoided

	Rivaroxaban	Using additional anticoagulants such as dabigatran can increase the anticoagulant effect of rivaroxaban. Avoid concurrent use of rivaroxaban with other anticoagulants whenever possible, other than during transition periods, due to the possible increased for bleeding
	Tipranavir	P-Glycoprotein inducers such as tipranavir may decrease the serum concentration of dabigatran etexilate. This combination should be avoided
	Trazodone	P-Glycoprotein inducers such as trazodone may decrease the serum concentration of dabigatran etexilate. This combination should be avoided
	Verapamil	Verapamil may increase serum concentrations of the active metabolite(s) of dabigatran etexilate, resulting in an increased risk of bleeding. Therapy modification should be considered
	Vinblastine	P-Glycoprotein inducers such as vinblastine may decrease the serum concentration of dabigatran etexilate. This combination should be avoided
Food interactions	St. John's Wort	
Efficacy	• Compared to warfarin, dabigatran 150 mg twice daily further reduces risk for stroke with similar bleeding risk, while dabigatran 110 mg twice daily has similar efficacy to warfarin and lower bleeding risk (Level 1 [likely reliable] evidence); dabigatran associated with nonsignificant increase in incidence of myocardial infarction (Level 2 [mid-level] evidence) [174,177,178] · dabigatran may reduce major bleeding in patients<75 years old but not in patients≥75 years old [179] · prior vitamin K antagonist (VKA) exposure does not appear to influence efficacy of dabigatran or warfarin (Level 2 [mid-level] evidence) [180] · dabigatran 110 mg or 150 mg twice daily has similar efficacy as warfarin in reducing stroke or systemic embolism, while dabigatran 110 mg dose reduces bleeding risk in patients with previous stroke or TIA (Level 1 [likely reliable] evidence) [181] · dabigatran 110 mg or 150 mg appears as effective as warfarin for prevention of stroke or systemic embolism within 30 days of cardioversion (Level 2 [mid-level] evidence) [182] • Dabigatran associated with decreased risk of stroke compared with placebo, ASA monotherapy, or ASA plus clopidogrel (Level 2 [mid-level] evidence) [183] • Dabigatran associated with small increase in risk of myocardial infarction (MI) and acute coronary syndrome (ACS) compared with other anticoagulants or placebo (Level 2 [mid-level] evidence) [184]	

Table 64.11. **Dabigatran overview. SMILES indicates simplified molecular-input line-entry system [25].**

Several general concerns remain about its safety in ederly with moderate renal impairment, its long-term safety and efficacy (ie,>2 years mean follow-up), which is currently being assessed in an follow-up study of RE-LY patients, and the absence of an antidote to dabigatran, although dabigatran can be eliminated by means of dialysis. Dabigatran might be a safe and effective alternative to warfarin for patients with AF at risk of stroke. If, and once, the drug is approved, clinicians are likely to have a choice of doses, which they can tailor to the patient's risks of stroke and bleeding; the more efficacious 150 mg dose is likely to be appropriate for patients at high risk of stroke, and the safer 110 mg dose for those at high risk of bleeding or drug interactions, such as those taking potent P-glycoprotein inhibitors [176]. However, patients who are already taking and tolerating once-daily warfarin with good INR control may prefer to stay on warfarin and not switch to dabigatran. Despite the potential benefits of dabigatran in lowering rates of stroke and ICH and not requiring coagulation monitoring, these patients may be discour-

aged from a switch because dabigatran will need to be administered twice daily and has a greater risk of non-hemorrhagic side-effects (ie, dyspepsia), which may increase the likelihood of drug discontinuation [176].

Recommendations for Use of Dagibatran for Secondary Prevention of Stroke

Dabigatran may be preferred over warfarin for oral anticoagulation:

- For oral anticoagulation, dabigatran 150 mg twice daily suggested rather than adjusted-dose vitamin K antagonist (VKA) therapy (target INR range 2-3) (ACCP Grade 2B) [15].
- New anticoagulant (such as dabigatran) preferred over warfarin when oral anticoagulant therapy used (CCS Conditional recommendation, High-quality evidence) [158]
- Dabigatran is a direct thrombin inhibitor and alternative oral anticoagulant to warfarin for prevention of stroke and thromboembolism in patients with paroxysmal, persistent, or permanent atrial fibrillation and risk factors for stroke or systemic embolization who do not have any of (ACC/AHA Class I, Level B) [156]:
  - Prosthetic heart valve.
  - Hemodynamically significant valve disease.
  - Severe renal failure (creatinine clearance <15 ml/minute).
  - Advanced liver disease (impaired baseline clotting function).

Ximelagatran

Ximelagatran was the first oral direct thrombin inhibitors to be studied in phase III clinical trials for stroke and systemic embolism prevention in AF. In the SPORTIF III and SPORTIF V trials [185], ximelagatran showed promise in terms of being non-inferior to warfarin with a better bleeding profile. Among 7329 patients with AF who were randomly assigned to warfarin (INR 20-3.0) or ximelagatran (36 mg twice daily) and followed for 11,346 patient-years (mean 18.5 months per patient), ximelagatran was considered not inferior to warfarin in prevention of stroke and systemic embolism (1.62% vs. 1.65% per year; p=0·94) or in causing major bleeding (1.88% vs. 2.46% per year; p=0.054) [185,186]. However, after marketing, clinical practice revealed increased hepatotoxicity and adverse cardiovascular events with the drug and hence, ximelagatran was withdrawn from the market and further developments of ximelagatran in AF were precluded [187].

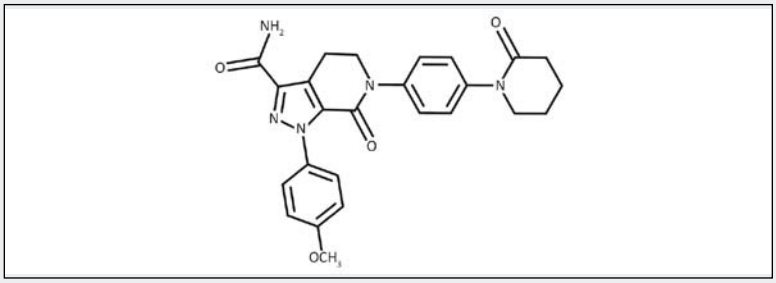
64.3.4 Factor Xa Inhibitors

Several oral and subcutaneous factor Xa inhibitors are currently undergoing clinical evaluation. These include apixaban, rivaroxaban, and edoxaban, which are currently being compared with warfarin.

Apixaban

Apixaban has been compared both with warfarin and with ASA in antithrombotic prevention of patients with AF (Table 64.12) [188,189].

Apixaban is a factor Xa inhibitor



New anticoagulant (such as apixaban, once approved by Health Canada) preferred over warfarin when oral anticoagulant therapy used (CCS Conditional recommendation, High-quality evidence) [158]	

Apixaban associated with reduced risk of stroke and major bleeding and might reduce risk of mortality compared to warfarin (Level 2 [mid-level] evidence) [188]	• Based on randomized trial with high dropout rate
	• 18,201 patients (median age 70 years) with atrial fibrillation and≥1 additional risk factor for stroke randomized to apixaban 5 mg twice daily vs. Warfarin (target inr 2-3)
	• Discontinuation of study drug before end of trial in
	  · 25.3% with apixaban (3.6% of discontinuations due to death)
	  · 27.5% with warfarin (3.8% of discontinuations due to death)
	• Comparing apixaban vs. Warfarin at median 1.8-year follow-up
	  · Any stroke or systemic embolism in 1.27% per year vs. 1.6% per year (p=0.01, nnt 303 per year)
	  · Hemorrhagic stroke in 0.24% per year vs. 0.47% per year (p<0.001, nnt 435 per year)
	  · Jo ischemic or uncertain type of stroke in 0.97% per year vs. 1.05% per year (not significant)
	  · Systemic embolism in 0.09% per year vs. 0.1% per year (not significant)
	  · Major bleeding in 2.13% per year vs. 3.09% per year (p<0.001, NNT 105 per year)
	  · All-cause mortality 3.52% vs. 3.94% (p=0.047, NNT 238)
	• Rates of stroke or systemic embolism comparing apixaban vs. Warfarin in subgroup analysis by previous stroke or transient ischemic attack [190]
	  · 2.46% per year vs. 3.24% per year in subgroup of 3,436 (19%) patients with previous stroke or transient ischemic attack (hazard ratio 0.76, 95% ci 0.56-1.03)
	• 1.01% per year vs. 1.23% per year in subgroup without prior stroke or transient ischemic attack (hazard ratio 0.82, 95% ci 0.65-1.03)

Apixaban reduces risk of stroke without increased risk of major bleeding or intracranial hemorrhage compared to ASA in patients with atrial fibrillation for whom vitamin K antagonists are unsuitable (Level 1 [likely reliable] evidence) [189]	• Based on randomized trial
	• 5,599 patients with atrial fibrillation at increased risk for stroke and for whom vitamin K antagonist therapy was unsuitable were randomized to apixaban (factor Xa inhibitor) 5 mg twice daily vs. ASA 81-324 mg/day and followed for mean 1.1 years
	  · Increased risk for stroke based on≥1 $CHADS_2$ criteria or documented peripheral artery disease
	• Patients unsuitable for vitamin K therapy included those proven to have problems with INR control, unlikely to comply with monitoring, refusing
	• Comparing apixaban vs. ASA
	  · Any stroke in 1.7% vs. 3.8% (p<0.001, nnt 48): ischemic stroke in 1.3% vs. 3.3% (p<0.001, nnt 50), disabling or fatal stroke in 1.1% vs. 2.6% (p<0.001, nnt 67)
	  · Systemic embolism in 0.007% vs. 0.5% (p=0.01, nnt 203)
	  · All-cause death in 4% vs. 5% (p=0.07)
	  · Major bleeding in 1.6% vs. 1.4% (not significant)
	  · Intracranial bleeding in 0.4% vs. 0.5% (not significant)
	  · First hospitalization for cardiovascular causes in 13.1% per year vs. 16.3% per year (p<0.001, nnt 31)
	• Similar findings in patients with or without prior vitamin K antagonist exposure, and according to $CHADS_2$ score

Table 64.12. **Apixaban: Summary of clinical data.**

The ARISTOTLE study, a double blind, double dummy, randomized clinical trial of phase III which has compared apixaban 5 mg (2.5 in patients with at least two of age>80 years, weight<60 Kg, creatinine levels>1.5 mg/dl) twice daily with adjusted doses of warfarin (range INR 2.0-3.0) with the aim of demonstrating non-inferiority and superiority [188]. The ARISTOTLE trial has demonstrated the superiority of apixaban on warfarin in reducing the combined endpoint ischemic and hemorrhagic stroke and systemic embolism (HR 0.79, 95% CI 0.66-0.95, p=0.01, RRR -21%), deaths from any cause (HR 0.89, 95% CI 0.80-0.99, p=0.047, RRR -11%) and major and clinically relevant nonmajor bleedings events (HR 0.68, 95% CI 0.61-0.75, p<0.001, RRR -32%) [188]. Apixaban reduces the risk of intracranial bleeding of 58% [188]. In subgroup analysis of patients with previous stroke or TIA, apixaban group showed lower rates of stroke and systemic embolism (2.46% per year vs. 3.24% per year (HR 0.76, 95% CI 0.56-1.03) [190].
The AVERROES study is a double-blind randomized clinical trial of phase III which has compared apixaban 5 mg twice daily (2.5 in patients with at least two of age>80 years, weight<60 Kg, creatinine levels>1.5 mg/dl) with ASA 81-324 mg in prevention of thromboembolic events in patients with AF [189]. This trial has clearly demonstrated the superiority of apixaban on ASA in terms of effectiveness and non inferiority of apixaban on ASA in terms of safety. Apixaban was associated to 55% of RRR of combined endpoint stroke and systemic embolism (HR 0.45, 95% CI 0.32-0.62, p<0.001) and 36% when death was added to the above mentioned endpoint (HR 0.64, 95% CI 0.51-0.78, p<0.001). Major and clinically relevant non major bleedings rate was similar in apixaban and ASA groups (1.4 vs. 1.2%/yr, HR 1.13, 95% CI 0.74-1.75, p=0.57 and 3.1 vs. 2.7%/yr, HR 1.15, 95% CI 0.86-1.54, p=0.35), whereas the rate of intracranial bleedings was the same (0.4 vs. 0.4%/yr, p=0.69) [189]. The substantial net clinical benefit of apixaban on ASA proved the early termination of this study [189].

Rivaroxaban

Rivaroxaban is an oxazolidinone derivate which acts making a strong inhibition of FXa binding to its active site both when free and prothrombin (factor II)-bound (Table 64.13) [170,191]. Rivaroxaban has not a pro-drug; it has an optimal adsorbent profile by gastrointestinal tract when orally administered. Bio-availability is very high (80%). Plasma peak is reached in 180 minutes. Halflife ranges from 6-8 hours in adults to 12 hours in the elderly. Rivaroxaban is metabolized from liver with a mechanism which is independent from cytochrome P450. Excretion is guaranteed from kidneys for 65%, whereas 65% is due to biliary system with the interaction of P-glyco-protein. The anticoagulant effect of rivaroxaban is viewable by interaction with PT and aPTT, but its effect on these parameters is very short and detectable only at concentration peak, therefore close laboratory monitoring is not routinariely recommended. Rivaroxaban does not interact with food, whereas it could have interactions with drugs with action on cytochromo P 3A4 and on P-glyco-protein, such as ketokonazol and ritonavir. Rivaroxaban is contraindicated in patients with sever liver or kidney disease (ClCr<20 ml/min). Rivaroxaban is administered once daily [170,191]. Rivaroxaban has not a specific antidote for urgent reversal. Up to prothrombin complex concentrates (PCC), FFP, FEIBA and raFVII [173,192].
The ROCKET-AF study, a randomized double blind, double dummy, controlled clinical trial of phase III which has compared rivaroxaban 20 mg once daily (15 mg in patients with moderate renal failure which means ClCr 30-50 ml/min) with adjusted doses of warfarin at therapeutic range 2.0-3.0 with the aim to demonstrate the non-inferiority of rivaroxaban in terms of effectiveness and safety; superiority of rivaroxaban was tested in the safety profile [193]. ROCKET-AF has demonstrated that rivaroxaban is not inferior to warfarin in combined endpoint ischemic and hemorrhagic strokes and systemic embolism (HR 0.79, 95% CI 0.66-0.96, p<0.001 for non-inferiority in per-protocol population

and HR 0.88, 95% CI 0.75-1.13, p<0.001 for non-inferiority in intention to treat population) [193]. Moreover ROCKET-AF has demonstrated that rivaroxaban is not-inferior to warfarin in terms of safety (major and clinically relevant non-major bleedings HR 1.03, 95% CI 0.96-1.11, p=0.44 for superiority), with exception of gastrointestinal bleedings (3.2% vs. 2.2%/yr, p<0.001 for warfarin superiority). Total and major bleedings rate is statistically not significant higher for rivaroxaban (14.9% vs. 14.5%/yr and 3.6% vs. 3.4%/yr respectively), while rivaroxaban is significantly superior to warfarin for reduction of intracranial bleeding rate (RRR -33%) [193].

Rivaroxaban is a direct factor Xa inhibitor FDA approved for reducing risk of stroke in patients with abnormal heart rhythm (nonvalvular atrial fibrillation)	New anticoagulant (such as rivaroxaban) preferred over warfarin when oral anticoagulant therapy used (CCS Conditional recommendation, High-quality evidence) [158]	

Rivaroxaban may be as effective as warfarin for preventing stroke or systemic embolism in patients with nonvalvular atrial fibrillation (level 2 [mid-level] evidence) [193]	• Based on randomized noninferiority trial with high dropout rate
	• 14,264 patients with nonvalvular atrial fibrillation and at increased risk for stroke randomized to rivaroxaban 20 mg once daily (or 15 mg once daily if creatinine clearance 30-49 ml/minute) vs. Dose-adjusted warfarin
	• Patients followed for median 707 days
	• Patients stopping treatment before endpoint event and before trial termination 23.7% with rivaroxaban vs. 22.2% with warfarin
	• Noninferiority based on 1-sided significance level of 0.025 and superiority based on 2-sided significance level of 0.05
	• Comparing rivaroxaban vs. Warfarin
	  - Stroke or systemic embolism in 2.1% per year vs. 2.4% per year in intention-to-treat population (p<0.001 for noninferiority, not significant for superiority)
	  - Stroke or systemic embolism in 1.7% per year vs. 2.2% per year in per-protocol population (p<0.001 for noninferiority)
	  - Major and nonmajor clinically relevant bleeding in 14.9% per year vs. 14.5% per year (not significant for superiority)
	  - Intracranial hemorrhage in 0.5% vs. 0.7% (p=0.02 for superiority)
	• Fatal bleeding in 0.2% vs. 0.5% (p=0.003 for superiority)

Rivaroxaban may be as effective as warfarin for preventing stroke or systemic embolism in patients with nonvalvular atrial fibrillation and moderate renal impairment (level 2 [mid-level] evidence) [194]	• Based on subgroup analysis of ROCKET AF trial
	• 2,950 patients (mean age 79 years) with moderate renal impairment (creatinine clearance 30-49 ml/minute) who were randomized to rivaroxaban 15 mg once daily vs. Dose-adjusted warfarin in ROCKET AF trial were analyzed
	• Comparing rivaroxaban vs. warfarin
	  - Stroke or systemic embolism in 2.32% per year vs. 2.77% per year in intention-to-treat population (not significant)
	  - Major and nonmajor clinically relevant bleeding in 17.8% per year vs. 18.3% per year (not significant)

Table 64.13. **Rivaroxaban: summary of clinical data.**

Overall, phase III clinical trials on new oral anticoagulants for SPAF reveal good profile of effectiveness and safety of new molecules. With exception of dabigatran at higher doses and rivaroxaban in terms of gastrointestinal bleedings, new drugs seem to be at least not inferior to VKA, taking in account that for many endpoints they could be significantly superior. Furthermore pharmacoeconomic studies seem to demonstrate advantage of the new oral anticoagulants on VKA from a cost/benefit point of view [195-198].

64.3.5 Special Treatment Regimens in Secondary Prevention of Atrial Fibrillation Patients

ASA

ASA is considered as alternative to VKA in high risk patients when VKA are contraindicated or unsuitable and in moderate risk patients; when compared to placebo ASA produces a RRR of stroke and systemic embolism of 19% (95% CI 1-35%) [134], while reduces the risk of recurrent stroke and other major vascular event in patients with AF by about 17% (HR 0.83, 95% CI 0.65-1.05) compared with control [136]. Adjusted-dose warfarin is significantly more effective than antiplatelet therapy for preventing recurrent stroke (OR 0.49, 95% CI 0.33-0.72) in patients with AF, similarly to the effect of adjusted-dose warfarin compared with antiplatelet therapy in primary prevention (RR 0.61, 95% CI 0.48-0.78) [133,134]. The absolute benefit of OAT (vs. antiplatelet therapy) increases with older age because stroke risk increases with age and the relative efficacy of OAT to prevent ischemic stroke does not change while the relative efficacy of antiplatelet therapy to prevent ischemic stroke seems to decrease as patients with AF get older [199].

ASA Plus Clopidogrel vs. Warfarin and ASA Plus Clopidogrel vs. ASA Alone

The efficacy and safety of the association between ASA and clopidogrel in SPAF has been recently verified. The ACTIVE-W trial (Atrial Fibrillation Clopidogrel Trial With Irbesartan for Prevention of Vascular Events-Warfarin) [200] was aimed to compare ASA plus clopidogrel vs. VKA while the ACTIVE-A (Atrial Fibrillation Clopidogrel Trial With Irbesartan for Prevention of Vascular Events-Aspirin) [200] compared ASA plus clopidogrel vs. ASA. Clopidogrel (75 mg once daily) plus ASA (75-100 mg daily) treatment was associated with a significant increase in the primary outcome of stroke, myocardial infarction, non-CNS systemic embolism, or death from vascular causes, after a median follow-up of 1.3 years, compared with assignment to warfarin (target INR 2.0-3.0; 5.6% per year for those on clopidogrel plus ASA vs. 3.9% per year on warfarin; RR 1.44, 95% CI 1.18-1.76). Random assignment to 75 mg clopidogrel once daily plus ASA was associated with a reduction in the primary outcome of stroke, myocardial infarction, non-CNS systemic embolism, or death from vascular causes, after a median of 3·6 years of follow-up, compared with placebo plus ASA (6.8% vs. 7.6% per year; RR 0.89, 95% CI 0.81-0.98) [200]. However, major bleeding was greater among patients assigned clopidogrel plus ASA vs. those on ASA alone (2.0% vs. 1.3% per year; RR 1.57, 95% CI 1.29-1.92). These RCTs have found that the association ASA/clopidogrel does not reduce the risk of cardioembolic stroke when compared with VKA, at least when TTR is≥65% [201], but it is more effective when compared to ASA alone. The combination of ASA and clopidogrel is not as effective as warfarin, particularly for patients who are taking warfarin without complication [200]. However in these RCTs the bleeding risk associated to the ASA/clopidogrel use is higher both when compared to VKA and when it is compared with ASA alone [200]. Moreover the association of ASA/clopidogrel seems to be not superior to ASA alone when the con-

sidered endpoints are mortality and mortality plus disability after ischemic and hemorrhagic strokes [202]. However the association of ASA/clopidogrel for SPAF is now considered as potential alternative to VKA in patients with low risk of bleeding in ACCF/AHA/HRS guidelines but with a low grade of recommendation (IIb) [157].

ASA and Warfarin

Both warfarin and ASA are thought to be needed to prevent thrombus formation in the left atrium and arteries in patients with AF who have coexisting atherosclerotic vascular disease (such as ischemic heart disease). This principle appears valid in patients with AF with unstable vascular disease such as an acute coronary syndrome, or subjects with recent percutaneous coronary or carotid intervention or stenting. Warfarin prevents the formation of fibrin-rich thrombus (so-called "red clot") associated with AF, whereas antiplatelet treatment prevents the formation of the platelet-rich thrombus (so-called "white clot") associated with arterial vascular disease. For such AF patients, the long-term benefit-to-harm ratio of combination therapy is not known and should be left to the clinician's discretion. However, for AF patients with stable vascular disease, there is no reliable evidence to indicate that adding ASA (or clopidogrel) to warfarin is safe and effective compared with warfarin alone. Indeed, warfarin can be an effective drug for stable coronary and cerebrovascular disease, and the hemorrhage rate seems to be greater with the combination of ASA and warfarin [203-205].

64.3.6 Other Cardioembolic Sources

These special populations include patients with recent MI, left ventricular (LV) thrombus, and low ejection fraction mechanical heart valves, nonbacterial thrombotic endocarditis, infective endocarditis, mitral valve prolapse, mitral valve strands, and aortic arch atheroma [117,206]. Although the recommendations in these patients are focus on long-term antithrombotic therapy for primary stroke prevention, they also apply to patients who have suffered a stroke in the setting of one of these conditions (ie, secondary stroke prevention) [130,206]. Absolute indications for OAT (primary and secondary stroke prevention) are summarized in Table 64.14.

Although ASA and clopidogrel are superior to warfarin for the prevention of acute stent thrombosis, their relative effect on the prevention of systemic embolization in patients with LV thrombus is largely unknown. Physicians must attempt to weigh the potential benefits and risks of adding warfarin to dual antiplatelet therapy (low-dose ASA plus clopidogrel 75 mg daily) in these patients. Given the increased risk of major bleeding, the duration of triple therapy (warfarin [INR 2.0-3.0], low-dose ASA, clopidogrel 75 mg daily), if chosen, should be minimized. Although the formation of LV thrombus was observed in most patients in the first few weeks, additional clots developed up to 3 months after anterior MI. For patients at risk for LV thrombus (but no thrombus identified on initial echocardiogram) in whom warfarin therapy is withheld, repeat echocardiogram in 1 to 2 weeks to rule out subsequent development of thrombus may be advisable. The minimal duration of dual antiplatelet therapy should be 1 month following BMS and 3 to 6 months following DES.

For patients with anterior MI and LV thrombus or at high risk for LV thrombus (ejection fraction<40%, anteroapical wall motion abnormality) who do not undergo stenting warfarin (INR 2.0-3.0) plus low-dose aspirin 75 to 100 mg daily is the recommend therapy over single antiplatelet therapy or dual antiplatelet therapy for the first 3 months (Grade 1B) [165]. Triple therapy (warfarin [INR 2.0-3.0], low-dose aspirin, clopidogrel 75 mg daily) for 1 month over dual antiplatelet therapy (Grade 2C) is suggested for patients with

Cardiac	• Mechanical heart valve (target INR depending on type and location of valve, mostly 3.0, range 2.5-3.5) • Mitral valve stenosis with any prior embolic event (target INR 2.5, range 2-3) • Left atrial myxoma (target INR 2.5, range 2-3) • Intraventricular thrombus (target INR 2.5, range 2-3) • Ventricular aneurysm with thrombus (target INR 2.5, range 2-3) • Mobile thrombus in the ascending aorta (target INR 2.5, range 2-3) • Dilated cardiomyopathy (target INR 2.5, range 2-3) • Mitral valve prolapse with myxomatous leaflets (target INR 2.5, range 2-3; not evidence based) • Rupture of chordae tendineae (target INR 2.5, range 2-3) • Dyskinetic ventricular wall segment (target INR 2.5, range 2-3) • Mitral ring calcifications (target INR 2.5, range 2-3) • Persistent or paroxysmal atrial fibrillation (target INR 2.5, range 2-3) • Left ventricular thrombus (target INR 2.5, range 2-3) • Left ventricular aneurysm (target INR 2.5, range 2-3) • Extensive wall motion abnormalities resulting in a left ventricular ejection fraction (LVEF)<25% (target INR 2.5, range 2-3)
Thrombophilia and hypercoagulable states	• Antithrombin III deficiency (target INR 2.5, range 2-3) • Protein C deficiency (target INR 3, range 3-3.5) • Protein S deficiency (target INR 2.5, range 2-3) • Activated protein C (APC) resistance (factor V Leiden; target INR 2.5, range 2-3) • Plasminogen deficiency/inhibition (target INR 2.5, range 2-3) • Dysfibrinogenemia (target INR 2.5, range 2-3)

Table 64.14. **Absolute indications for OAT (primary and secondary stroke prevention).**

anterior MI and LV thrombus, or at high risk for LV thrombus (ejection fraction<40%, anteroapical wall motion abnormality) [165], who undergo BMS placement, while a longer triple therapy (3 to 6 months) is suggested for patients with anterior MI and LV thrombus or at high risk for LV thrombus (ejection fraction<40%, anteroapical wall motion abnormality) who undergo DES placement [165]. Thereafter, discontinuation of warfarin and continuation of dual antiplatelet therapy for up to 12 months as per the ACS recommendations. After 12 months, single antiplatelet therapy is recommended as per the established CAD recommendations [165].

VKA are recommended in rheumatic mitral disease, when the left atrial diameter is>55 mm (Grade 2C) or when complicated by left atrial thrombus (Grade 1A) [206], in candidates for percutaneous mitral valvotomy with left atrial thrombus until thrombus resolution (Grade 1A) [206]. Long-term VKA therapy is We recommended for all mechanical valves (Grade 1B): target INR 2.5 for aortic (Grade 1B) and 3.0 for mitral or double valve (Grade 2C). In patients with mechanical valves at low bleeding risk, addition of low-dose aspirin (50-100 mg/d) can be also used (Grade 1B) [206].

In patients with aortic atheromas identified on echocardiography, the ideal strategy for stroke prevention remains uncertain. Mixed outcomes have been reported for anticoagulation therapy; plaque stabilization with statins appears promising. Neither approach has been tested in randomized, controlled trials [207].

64.3.7 Patent Foramen Ovale (PFO)

The risk of stroke recurrence is estimated to be only 1% to 2% per year among stroke patients with a PFO [208,209]. The PICSS (PFO in Cryptogenic Stroke Study) trial did not show any significantly increased 2-year risk of recurrent stroke or death compared with those without a PFO, neither any significant difference in the 2-year event rates among

those treated with warfarin vs. aspirin [210]. Given the known increased risk of bleeding complications with anticoagulation and the lack of data to demonstrate a benefit in terms of reduction of recurrent ischemic cardiovascular events, the American College of Chest Physicians (ACCP) suggests the use of ASA (50-100 mg/day) over no ASA (ACCP Grade 1A) and the use of VKA (target INR 2.5, range 2-3) if recurrent events occur despite ASA therapy (ACCP Grade 2C) and in the presence of evidence of deep vein thrombosis (target INR 2.5, range 2-3, for 3 months) (ACCP Grade 1B) [15]. OAT is also indicated for patients with a large PFO and co-occurrence with atrial septal aneurysm. The target INR in such cases is 2.5 (range 2-3). The duration of anticoagulation is usually 2 years or longer. As an alternative to anticoagulation, operative or transcatheter occlusion of the PFO may be considered. However, although systematic reviews of observational studies showed that percutaneous and transcather closure of PFO is associated with reduced incidence of recurrent stroke compared to anticoagulant or antiplatelet therapy [211,212]; these results were not confirmed by the CLOSURE I trial where 909 patients aged 18-60 years with cryptogenic stroke or TIA and PFO were randomized to closure device plus antiplatelet therapy (clopidogrel 75 mg daily for 6 months and aspirin 81 mg or 325 mg daily for 2 years) vs. medical therapy alone (warfarin [target INR of 2-3], aspirin 325 mg daily, or both at discretion of principal investigator at each site). The addition of closure of PFO with STARFlex percutaneous transcatheter to antiplatelet therapy did not reduce the risk of recurrent stroke (2.9% vs. 3.1% p=0.79) or TIA (at 2 years in 3.1% vs. 4.1% p=0.44) but increased the risk of developing AF (5.7% vs. 0.7%; p<0.001) [213].

64.3.8 Venous Sinus Thrombosis

Several smaller studies demonstrated that of patients with venous sinus thrombosis, those treated with full-dose heparin had better outcomes than those treated with placebo. A Cochrane systematic review summarized two randomized trials of anticoagulation for patients with symptomatic cerebral sinus thrombosis [214]. This includes patients who present with headache, focal neurologic deficits, seizures, alterations of consciousness, and/or papilledema [215]. The overall quality of evidence is low for venous sinus thrombosis and the suggestion to treat patients with symptomatic cerebral sinus thrombosis with anticoagulation therefore reflects the expert's judgment based on the best available, albeit low-quality, evidence. After improvement under heparin therapy, patients usually are switched to OAT (target INR 2.5, range 2-3). Although the optimal duration has not been determined in randomized studies, OAT is recommended for at least 6 months. It is unclear whether the decision to stop anticoagulation should be based on the result of venography (magnetic resonance or conventional venography) after 6 months. In a recent study of 39 patients placed on anticoagulation, recanalization occurred only within the first 4 months, but not thereafter [216]. The two trials included in the meta-analysis had a relatively high percentage of patients who had some degree of ICH prior to anticoagulation therapy (three of 10 in one trial and 15 of 30 in the second trial) [217]. Despite this, no occurrences of new symptomatic ICH were observed in patients treated with anticoagulation. Anticoagulation is therefore recommended even in the presence of hemorrhage within a venous infarction. However, for patients with venous infarcts and large parenchymal hematomas the risk of hemorrhage extension is likely high. The uncertain benefits of anticoagulation do not outweigh the potential for harm. Either dose-adjusted heparin or LMWH can be used for the initial treatment of patients with cerebral venous sinus thrombosis. Heparin should be continued until the patient has stabilized clinically. For patients who demonstrate progressive neurologic deterioration despite adequate anticoagulation, other options, such as endovascular thrombec-

tomy [218] or local intrathrombus infusion of a thrombolytic agent [217], together with IV heparin, can be considered [219,220]. Patients who have stabilized can be switched from heparin to oral anticoagulation. OAT is generally recommended for a period of 3 to 6 months [221]. Lifelong anticoagulation could be considered in the presence of permanent risk factors for recurrent events [221].

64.3.9 Dissections of Internal Carotid and Vertebral Arteries

The majority (85-95%) of ischemic symptoms after dissection of brain-supplying arteries are caused by emboli from the site of the dissection, while the remainder are due to vessel narrowing with hemodynamic insufficiency. Many experts recommend anticoagulation with IV heparin in the acute phase and subsequent OAT for 3-24 months (target INR 2.5, range 2-3) followed by antiplatelet agents for at least 2 years. To present the results of the nonrandomized arm of the Cervical Artery Dissection in Stroke Study (CADISS-NR) trial [222], comparing anticoagulation and antiplatelets for prevention of recurrent stroke after carotid and vertebral dissection, shows no evidence for superiority of anticoagulation or antiplatelet therapy in prevention of stoke after carotid and vertebral artery dissection. A systematic meta-analysis confirms these results showing that there was nonsignificant difference between the 2 treatments in recurrent stroke risk [222]. The practice of anticoagulation is supported only by several published case series demonstrating good outcome with low complication rates in patients undergoing anticoagulation. However, these studies do not have a control or comparative group to establish efficacy. Only in rare cases (eg, with persistent high-grade proximal stenosis of the internal carotid artery or with severe hemodynamic impairment) should an operation or stenting be considered. No evidence of a higher embolic activity of pseudoaneurysms due to dissection exists; after OAT for 3-6 months, a platelet antiaggregant is sufficient in most cases. Only in selected cases, continuation of anticoagulation or interventional therapy may be preferable, but this practice is not supported by randomized, controlled studies. Anticoagulation is contraindicated in intracranial dissections complicated by subarachnoid hemorrhage.

64.3.10 Thrombophilia and hypercoagulable states

In patients with cerebral ischemia of unknown origin who are younger than 40 years, a search for hereditary thrombophilia is generally recommended [223]. The yield of hypercoagulable testing in patients with stroke is low overall, but somewhat higher in patients with stroke of undetermined cause [224,225]. Data associating stroke with the factor V Leiden and prothrombin G20210A mutations, and protein C, protein S, and antithrombin III deficiencies are limited and conflicting, but on the whole do not demonstrate any clear association. In the case of homocysteine, the association with stroke risk is stronger, but evidence for a stroke preventative effect of homocysteine lowering is inconclusive [226]. OAT after cerebral ischemia is usually recommended for patients with hypercoagulable states such as activated protein C (APC) resistance; protein C, protein S, or antithrombin III (ATIII) deficiencies; or antiphospholipid syndrome (APS) are treated with anticoagulants for stroke prophylaxis, especially if deep vein thrombosis (DVT) is present or recurrent thrombotic events have occurred (Table 64.15) [223,227].
The anticoagulation regimen usually is started with intravenous (IV) heparin, maintaining the aPTT at 2-3 times normal, until an oral anticoagulant (ie, warfarin) is able to achieve a therapeutic PT (INR). As an alternative to oral anticoagulants, patients with thrombophilia may be treated with fixed, low-dose subcutaneous UFH or LMWH. Patients with

ATIII deficiency can receive ATIII concentrates for acute intervention or LMWH. After a single event of thrombosis or thromboembolism, anticoagulation should be continued for at least 6 months. After recurrent or life-threatening thrombosis or in the case of a combination of different thrombophilias, lifelong anticoagulation is usually recommended. Starting heparin before warfarin is imperative to avoid warfarin-induced skin necrosis in protein C and S deficiencies. The level of anticoagulation in terms of PT (INR) required for stroke prophylaxis is uncertain.

Several studies have addressed secondary prevention of stroke in patients with antiphospholipid antibodies (APLA). This group includes patients with medium or high-titer APLA or the presence of lupus anticoagulants. The Antiphospholipid Antibodies and Stroke Study (APASS) found no difference in recurrent thrombotic events between those with and without Antiphospholipid Antibodies (APLA), and no benefit to warfarin compared with aspirin in patients with APLA [228]. However, in the APASS study, APLA were measured only one time (and were present in 41% of the 1770 patients enrolled) and the population enrolled was older (mean age 62) with a high prevalence of typical vascular risk factors. Extrapolation from this data to younger patients meeting diagnostic criteria for APLA syndrome is probably unwise. Based on the APASS data, patients with first ischemic stroke and a single positive APLA test result who do not have another indication for anticoagulation may be treated with aspirin (325 mg/day) or warfarin (INR 1.4-2.8). Aspirin is likely to be preferred because of its ease of use and lack of need for laboratory monitoring. Patients with ischemic stroke due to cerebral arterial thrombosis and a positive APLA test who have a history of venous thrombosis but were not receiving anticoagulant drugs when suffering the stroke should be treated with moderate-intensity warfarin (target INR 2.5, range 2-3). In the treatment of APS, high-intensity warfarin (target INR 3.5, range 3-4) was not superior to moderate-intensity warfarin (target INR 2.5, range 2-3) in preventing recurrent thrombosis and was associated with an increased rate of minor hemorrhagic complications [228,229].

In stroke patients with cancer, marantic endocarditis is found in up to 20%, and an additional 10% have other definite embolic sources consistent with a hypercoagulable state on transesophageal echocardiography (TEE) [230]. LMWH is the preferred treatment strategy for patients with venous thrombosis associated with cancer, and this may also be applicable to patients with cancer-associated stroke, particularly if mediated by marantic endocarditis [231].

64.3.11 Recurrent Thrombosis

Patients with recurrent thrombotic events despite warfarin pose a challenge for clinicians. The INR at the time of recurrence is important. An INR below the target therapeutic range represents inadequate anticoagulation as opposed to warfarin failure. These patients may be treated in the same manner as a patient presenting with new thrombosis without warfarin. Possible treatment options for recurrent thrombosis despite an INR in the target range include increasing the intensity of warfarin anticoagulation to achieve a higher target INR (target INR, 2.5-3.5 or 3.0-4.0), switching from warfarin to therapeutic doses of UFH or LMWH, or adding an antiplatelet agent to warfarin [232].

64.3.12 Summary and Recommendations

OAT is clearly superior to single or double antiplatelet therapy in patients with cardioembolic stroke, mainly caused by AF. National Guidelines and Consensus Statements regarding thromboembolic prophylaxis in AF are given in (Table 64.15).

American College of Chest Physicians (ACCP) guidelines (Ninth Edition) on antithrombotic therapy in atrial fibrillation [130,206]	• For secondary stroke prevention after cardioembolic stroke or transient ischemic attack (TIA) (that is, in patients with atrial fibrillation, including paroxysmal atrial fibrillation): ▪ OAT recommended over: no antithrombotic therapy (ACCP Grade 1A), ASA (ACCP Grade 1B), combination therapy with ASA plus clopidogrel (ACCP Grade 1B) ▪ OAT with dabigatran 150 mg twice daily suggested over adjusted-dose vitamin K antagonist therapy (target range 2-3) (ACCP Grade 2B); dabigatran contraindicated if creatinine clearance ≤ 30 ml/minute ▪ Ffor patients unsuitable for or who choose not to take an oral anticoagulant (for reasons other than concerns about major bleeding), combination therapy with ASA plus clopidogrel recommended over ASA (ACCP Grade 1B) ▪ OAT should generally be started within 1-2 weeks after stroke onset, but timing may vary with risk for bleeding • Use of ASA as bridging therapy suggested until anticoagulation reaches therapeutic level
American College of Cardiology/ American Heart Association (ACC/ AHA) guidelines [13]	• American Heart Association/American Stroke Association (AHA/ASA) guidelines for secondary prevention of stroke in patients with paroxysmal or permanent atrial fibrillation ▪ use vitamin K antagonist for anticoagulation (AHA/ASA Class I, Level A) ▪ use ASA if patient unable to take OAT medications (AHA/ASA Class I, Level A) ▪ clopidogrel with ASA not recommended for patients with hemorrhagic contraindication to warfarin (AHA/ASA Class III, Level B) • Use bridging therapy with subcutaneous low-molecular-weight heparin if temporary interruption of OAT in patient at high risk (such as TIA within 3 months, mechanical valve disease) (AHA/ASA class IIa, level C)
Canadian Cardiovascular Society (CCS) guideline:	• For patients with recent TIA or minor ischemic stroke, ASA is safe and probably effective for secondary prevention of cerebral ischemia in patients with nonrheumatic atrial fibrillation (level 2 [mid-level] evidence) [233] • antiplatelet therapy appears effective for preventing stroke in patients with nonvalvular atrial fibrillation (level 2 [mid-level] evidence) [234]
Comparative efficacy vs. anticoagulation	For patients with atrial fibrillation and recent transient ischemic attack (TIA) or minor ischemic stroke, anticoagulation appears superior to antiplatelet therapy for secondary prevention of stroke (level 2 [mid-level] evidence) [235]
Anticoagulant plus antiplatelet	Combination of antiplatelet and low-intensity anticoagulant therapy may further reduce risk of vascular death (level 2 [mid-level] evidence) [140]

Table 64.15. **National Guidelines and Consensus Statements regarding thromboembolic prophylaxis in atrial fibrillation.**

Dose-adjusted warfarin has been the mainstay of therapy. Warfarin has also been shown to be more effective than ASA or the combination of ASA plus clopidogrel for secondary prevention of stroke in patients with AF. Warfarin therapy aimed at a target INR of 2.5 (range 2.0-3.0) is recommended for stroke prevention in patients with paroxysmal or permanent AF. ASA alone is recommended in patients with AF who are unable to take oral anticoagulants.

Bridging anticoagulation with LMWH is recommended for patients at the highest risk for stroke (defined as having a stroke or TIA within 3 months, a CHADS2 score of at least 5, a mechanical cardiac valve, and rheumatic valve disease) in circumstances in which OAT must be temporarily interrupted.

Patients with TIA or ischemic stroke and acute MI complicated by left ventricular mural thrombus should be anticoagulated to a target INR of 2.5 for a minimum of 3 months. However, warfarin has no demonstrated benefit for secondary stroke prevention in the presence of systolic cardiac dysfunction alone.

Long-term warfarin therapy with a target INR of 2.5 is reasonable for secondary stroke prevention in patients with rheumatic mitral valve disease. Antiplatelet agents should not be combined with warfarin due to additional bleeding risk.
Antiplatelet agents are reasonable for secondary stroke prevention in patients with non-rheumatic native valve disease, mitral annular calcification, and mitral valve prolapse in the absence of AF. Warfarin with a target INR of 3.0 is recommended for prevention of stroke in patients with mechanical heart valves. The addition of ASA at 75-100 mg/day is reasonable in those who have had TIA or stroke despite adequate OAT and in whom the bleeding risk is not excessive. New oral anticoagulants seem promising a new era in antithrombotic prophylaxis of patients with AF. Up to now, all the published phase III trials have demonstrated at least the non-inferiority of direct thrombin inhibitor dabigatran and direct FXa inhibitors rivaroxaban and apixaban when compared with warfarin. For many endpoints, such as intracranial bleedings, new oral anticoagulants result superior to warfarin. New oral anticoagulants could become an effective and safe choice in this context.

65 The Consciousness Disorders, Definitions and Clinical Assessment

Didier Ledoux [1], **Steven Laureys** [1]

[1] Coma Science Group, Cyclotron Research Centre, University of Liege, Liège, Belgium

65.1 Alterated States of Consciousness

An accurate and reliable evaluation of the level and content of consciousness in severely brain-damaged patients is of paramount importance for their appropriate management. Progress in medicine has increased the number of patients who survive severe acute brain damage. Although the majority of these patients recover from coma within the first days after the insult, some permanently lose all brainstem functions (brain death), while others evolve to a state of "wakeful unawareness" (vegetative state; VS). Those who recover, typically progress through different stages before fully or partially recovering consciousness (minimally conscious state; MCS) (Figure 65.1).

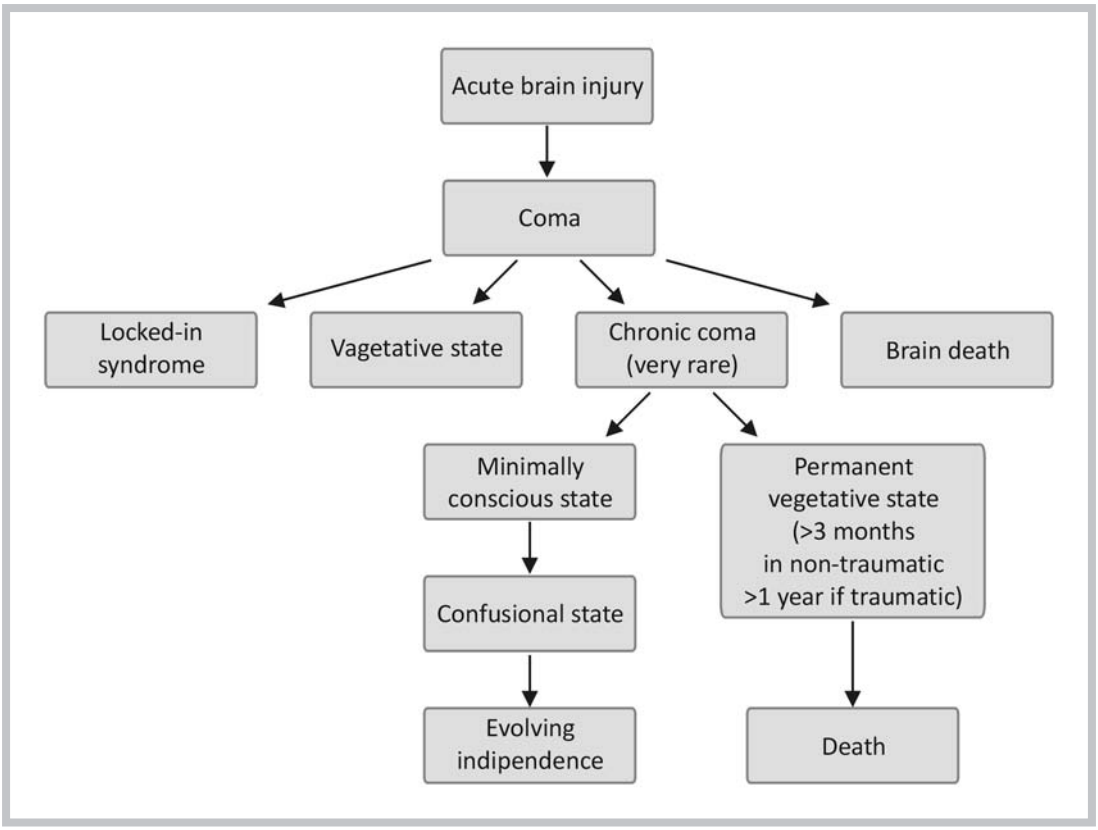

Figure 65.1. **Flow chart of the different conditions that follow a cerebral insult. Classically vegetative state follows a coma; after 1 month the term "persistent vegetative state" is used; after 3 months (non-traumatic insult) or 1 year (traumatic insult) some authors use the term "permanent vegetative state" which implies no chance of recovery. Adapted from [Laureys et al.,** *Lancet Neurology* **2005].**

Clinical practice shows that recognizing unambiguous signs of conscious perception of the environment and of the self in such patients with disorders of consciousness can be very challenging. This difficulty is reflected in the frequent misdiagnoses of VS, MCS and locked-in syndrome (LIS) [1-7]. Bedside evaluation of residual brain function in severely brain-damaged patients is difficult because motor responses may be very limited or inconsistent. In addition, consciousness is not an all-or-none phenomenon [8] and its clinical assessment relies on inferences made from observed responses to external stimuli at the time of the examination [7].

After briefly defining consciousness as it can be assessed at the patient's bedside and reviewing the major clinical entities of altered states of consciousness following severe brain damage, we will here review evaluation scales available for the assessment of patients suffering from disorder of consciousness.

65.1.1 Consciousness, Awareness and Arousal

Consciousness is a multifaceted concept that has two major components: awareness of environment and of self (i.e., content of consciousness) and wakefulness (i.e., level of consciousness). One needs to be awake in order to be aware (REM-sleep being a notorious exception). Figure 65.2 shows that in normal physiological states (green); level and content are positively correlated (with the exception of the oneiric activity during REM-sleep). Patients in pathological or pharmacological coma (that is, general anesthesia) are unconscious because they cannot be awakened (red). The vegetative state (blue) is a unique persistent dissociated state of consciousness (i.e., patients being seemingly awake but lacking any behavioral evidence of "voluntary" or "willed" behavior).

Arousal is supported by several brainstem neuronal populations that directly project to both thalamic and cortical neurons [9]. Therefore depression of either brainstem or both cerebral hemispheres may cause reduced wakefulness. Brainstem reflexes are a key to the assessment of the functional integrity of the brainstem (Figure 65.3). However, profound impairment of brainstem reflexes can sometimes coexist with intact function of the reticular activating system if the tegmentum of the rostral pons and mesen-

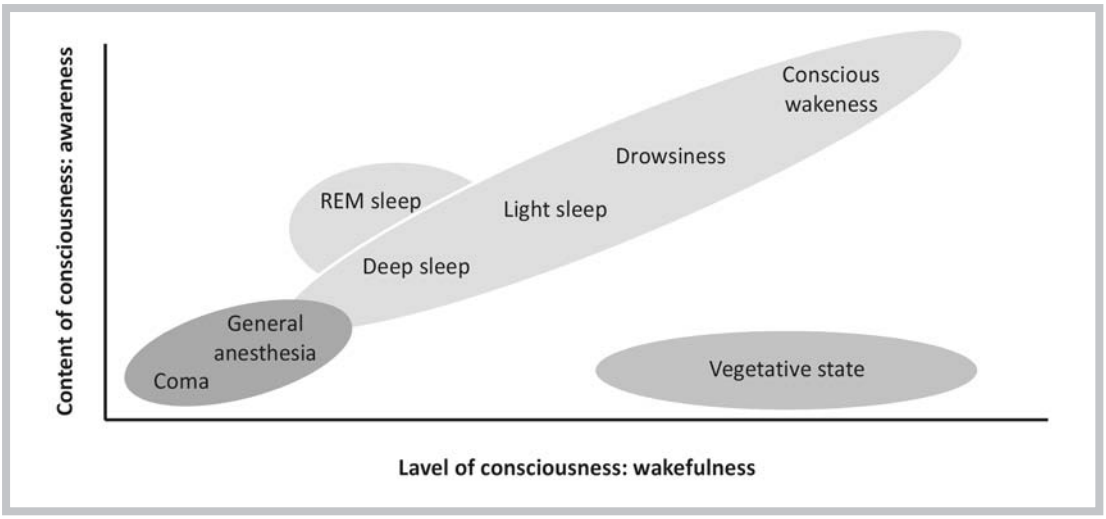

Figure 65.2. **Oversimplified illustration of consciousness' two major components: the level of consciousness (i.e., wakefulness or arousal) and the content of consciousness (i.e., awareness or experience). Adapted from [Laureys,** *Trends in Cognitive Sciences* **2005].**

cephalon are preserved. Awareness is thought to be dependent upon the functional integrity of the cerebral cortex and its reciprocal subcortical connections; each of its many aspects resides to some extent in anatomically defined regions of the brain [10-12]. Unfortunately, for the time being, consciousness cannot be measured objectively by any machine. Its estimation requires the interpretation of several clinical signs. Many scoring systems have been developed for a standardized assessment of consciousness in severely brain damaged patients (For review see [13]).

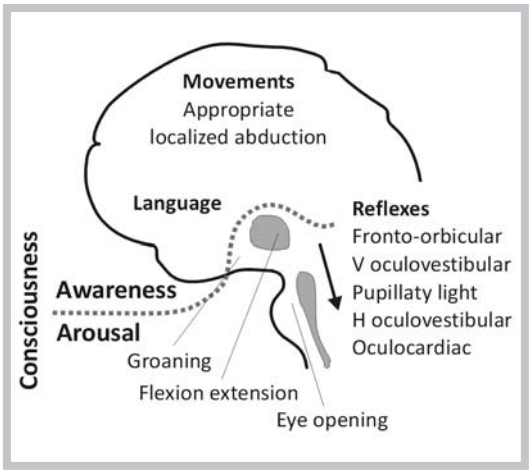

Figure 65.3. **A simplified scheme of consciousness and its two major components: arousal and awareness. Note: the gray area represents the reticular activating system encompassing the brainstem and thalamus; the arrow near the brainstem denotes the progressive disappearance of brainstem reflexes during rostral-caudal deterioration (i.e., evolution from coma to brain death). Adapted from [13].**

V = vertical

65.1.2 Clinical Definitions

Survivors of severe traumatic or hypoxic-ischemic brain damage classically go through different clinical entities before partially or fully recovering consciousness. Coma is defined as "unarousable unresponsiveness". Irreversible coma may in some conditions equal brain death. After some days to weeks, comatose patients who recover will eventually open their eyes. When this return of "wakefulness" is accompanied by reflexive motor activity only, devoid of any voluntary interaction with the environment, the condition is called a vegetative state. The vegetative state may be a transition to further recovery, or not. Signs of voluntary motor activity should be actively searched for in vegetative state patients, as they herald the minimally conscious state (MCS). Functional communication indicates the next boundary – emergence from MCS – in the course of recovery. We will here briefly define brain death, coma, VS, MCS and LIS.

Brain Death

The concept of brain death as defining the death of the individual is largely accepted [14]. Most countries have published recommendations for the diagnosis of brain death but the diagnostic criteria differ from country to country [15]. Some rely on the death of the brainstem only [16] others require death of the whole brain including the brain stem [17]. However, the clinical assessments for brain death are very uniform and based on the loss of all brainstem reflexes and the demonstration of continuing cessation of respiration in a persistently comatose patient [procedures of a standardized apnea test can be found in 18]. There should be an evident cause of coma and confounding factors (including hypothermia, drugs, electrolyte, and endocrine disturbances) should be excluded. A repeat evaluation in 6h is advised, but the time period is considered arbitrary [19]. Confirmatory neurophysiological tests such as EEG, ERP, angiography, Doppler sonography, or scintigraphy or are only required when specific components of the clinical testing cannot be reliably evaluated and are recommended by a number of national professional societies to confirm the clinical diagnosis of brain death [20].

Coma

Coma is characterized by the absence of arousal and thus also of consciousness. It is a state of unarousable unresponsiveness in which the patient lies with the eyes closed and has no awareness of self and surroundings. The patient lacks the spontaneous periods of wakefulness and **eye-opening induced by stimulation** that can be observed in the VS [21]. To be clearly distinguished from syncope, concussion, or other states of transient unconsciousness, coma must persist for at least one hour. In general, comatose patients who survive begin to awaken and recover gradually within 2 to 4 weeks. This recovery may go no further than VS or MCS, or these may be stages (brief or prolonged) on the way to more complete recovery of consciousness.

Vegetative state

Patients in a VS are awake but are unaware of self or of the environment [22, 23]. Jennett and Plum cited the Oxford English Dictionary to clarify their choice of the term "vegetative": to vegetate is to "live merely a physical life devoid of intellectual activity or social intercourse" and vegetative describes "an organic body capable of growth and development but devoid of sensation and thought". "**Persistent VS**" has been arbitrarily defined as a vegetative state still present one month after acute traumatic or non-traumatic brain damage but does not imply irreversibility [24]. "**Permanent VS**" denotes irreversibility. The Multi-Society Task Force on PVS concluded that three months following a non-traumatic brain damage and 12 months after traumatic injury, the condition of VS patients may be regarded as 'permanent' and therefore irreversible. However, these guidelines are best applied to patients who have suffered diffuse traumatic brain injuries and post anoxic events; other non-traumatic etiologies may be less well predicted (see for example [25,26]) and require further considerations of etiology and mechanism in evaluating prognosis. Even after these long and arbitrary delays, some exceptional patients may show some limited recovery. This is more likely in patients with non-traumatic coma without cardiac arrest, who survive in VS for more than 3 months. The diagnosis of VS should be questioned when there is any degree of sustained visual pursuit, consistent and reproducible visual fixation, or response to threatening gestures [24] but these responses are observed in some patients who remain in VS for years. It is essential to establish repetitively the formal absence of any sign of conscious perception or deliberate action before making the diagnosis.

It is very important to stress the difference between persistent and permanent vegetative state which are, unfortunately, too often abbreviated identically as PVS, causing unnecessary confusion [27]. When the term "persistent vegetative state" was first described [22], it was emphasized that persistent didn't mean permanent and it is now recommended to **omit "persistent"** and to describe a patient as having been vegetative for a certain time. When there is no recovery after a specified period (depending on etiology three to twelve months) the state can be declared permanent and only then do the ethical and legal issues around withdrawal of treatment arise [28,29]. The vegetative state can also be observed in the end-stages of some chronic neurodegenerative diseases, such as Alzheimer's, and in anencephalic infants.

65.2 Clinical Evaluation of the Neurocritical Care Patient: The Coma Scales

The adequate evaluation of consciousness in patients suffering from severe brain damage is of a major importance for their optimal management over from the emergency

department throughout their acute hospital stay and their rehabilitation. On this evaluation will indeed depend, not only the therapeutic surgical or medical decisions, but also often cares limitation. Before the development and the diffusion of the scales of coma and in particular of the scale of Glasgow [30], the evaluation of the patient presenting with altered consciousness was based on a rather vague nomenclature. The description of the depth of coma was made by means of terms often vague such as: drowsy, **comatose**, somnolent, obtunded, obnubilated, obstreperous or combative.

During the World War II and later, during the Korean and Vietnam campaigns, it appeared important to physician to set up methods making it possible to evaluate patients after a traumatic brain injury so as to facilitate the transmission of information on the clinical state of wounded between the doctors of ground and the doctors ensuring the continuation of the treatment [31]. From these efforts were born the first classifications for altered consciousnesses states [32]. The neurosurgical literature on head injuries sustained in the Vietnam conflict classified their initial state in three grades, variously defined [33,34]. These classification suffered from their lack of precision and from the hence ambiguity of the terms employed. This type of classification should be abandoned for the assessment of altered consciousnesses.

65.2.1 The Glasgow Coma Scale

The publication of the Glasgow coma scale (GCS) in 1974 by Teasdale and Jennet [30] brought a major change in the clinical assessment of patients presenting with post-traumatic altered consciousness. These authors took special care to the construction of their scale to overcome the ambiguities that arose when information about comatose patients was presented and groups of patients compared. Among the objectives of its originators, there was the desire to establish an evaluation tool based on simple, clear, unambiguous items that could be easily translated in various languages. Moreover, the scale had to be utilizable in a reliable way not only by any doctor but also by nurses and paramedics. Considering that the deterioration of consciousness varies according to a continuum and thus does not lend to a categorization, these authors preferred to create an instrument based on the distinct clinical evaluation from three aspects of the behavioral response to the stimulation of the patient with altered consciousness (Figure 65.4): eye opening (E, 4 levels), verbal activity (V, 5 levels) and motor response (M, 5 then 6 levels [35]).

Eye Opening

Eye opening in response to pain should be tested by stimulation at the level of the limbs, because the grimacing associated with supra-orbital or jaw-angle pressure may cause eye closure. The eye opening either spontaneously or on stimulation defines the transition from coma to vegetative state.

Verbal Activity

The presence of verbal responses indicates the restoration of a high degree of interaction with the environment (i.e., awareness). An oriented conversation implies awareness of the self and environment. Confused speech is recorded when the patient is capable of producing language, for instance phrases and sentences, but is unable to answer the questions about orientation. When the patient presents intelligible articulation but exclaims only isolated words in a random way (often swear words, obtained by physical stimulation rather than by a verbal approach), this is scored as ‘‘inappropriate speech’’. Incomprehensible sounds refer to moaning and groaning without any recognizable words. This rudimentary vocalization does not necessitate awareness and is

thought to depend upon sub cortical functioning as it can be observed in anencephalic children and vegetative patients.

Motor Response

The motor response first assesses whether the patient obeys simple commands, given in verbal, gestural or written form. A non-specific sound stimulus may induce a reflex

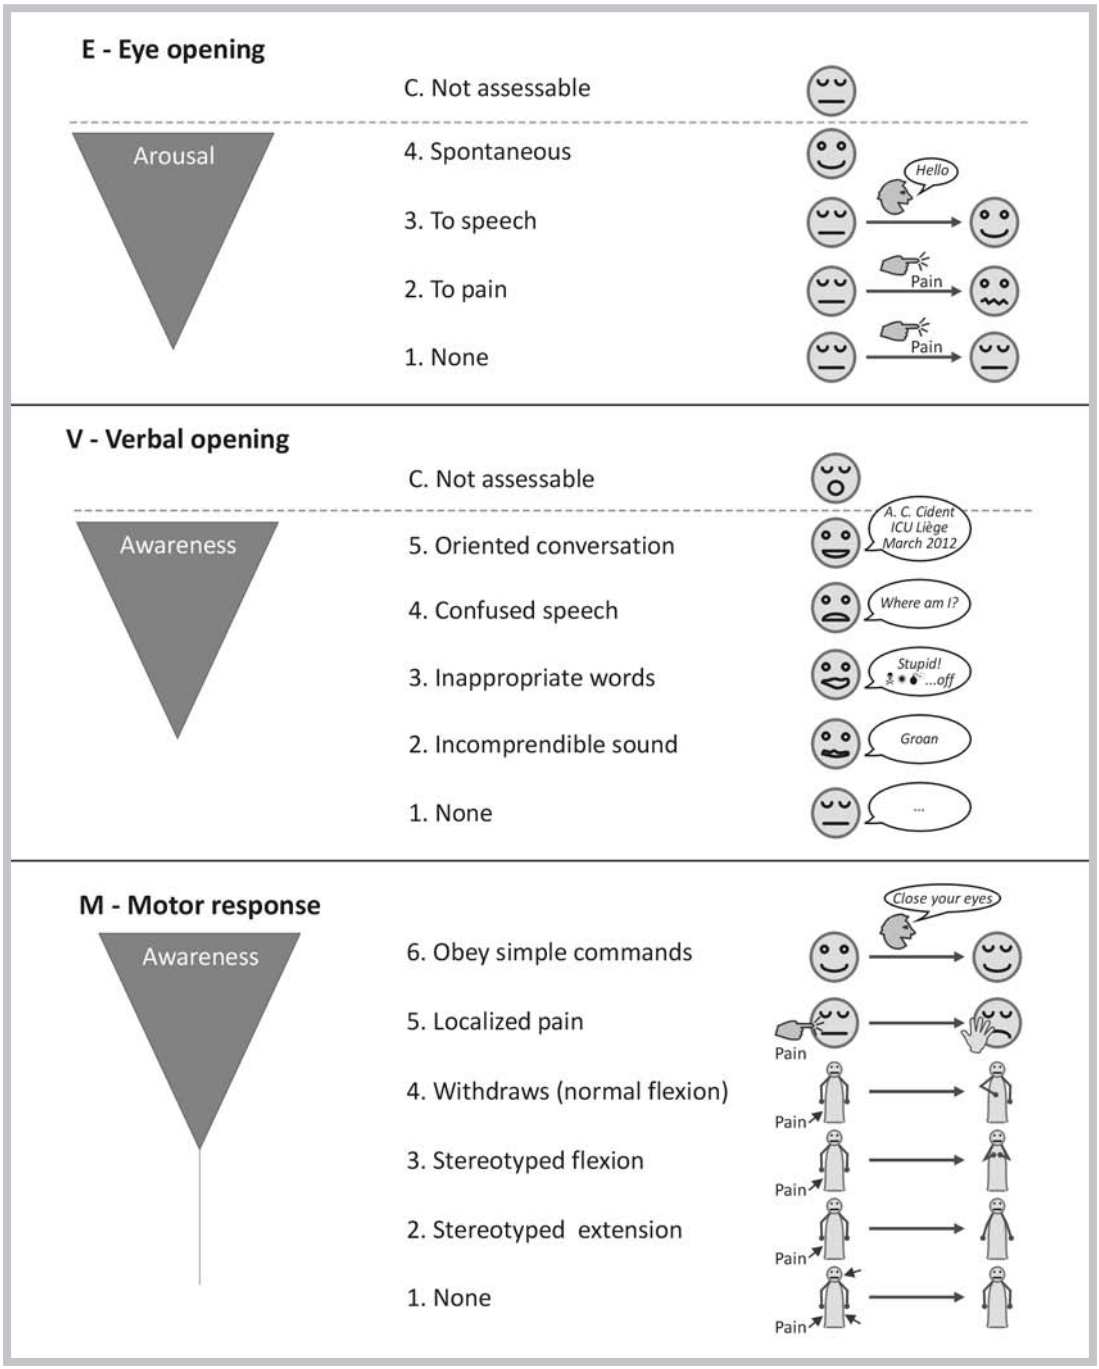

Figure 65.4. **Pictographic representation of the Glasgow coma scale. Adapted from [13].**

contraction of the patient's fingers or alternatively such a reflex response can result from the physical presence of the examiner's fingers against the palm of the patient (i.e., grasping reflex). Before accepting that the patient is truly obeying commands, it is advised to test that the patient will also release and squeeze again to repeated commands. If there is no response on command a painful stimulus is applied. First, pressure is applied to the fingernail bed. If flexion is observed, stimulation is then applied to other sites (applying pressure to the supra-orbital ridge, pinching the trapezium or rubbing the sternum) to differentiate between localization (i.e., attempt to remove a noxious stimulus by crossing the midline), withdrawal flexion (i.e., flexion of the elbow associated with abduction of the shoulder) or stereotyped flexion (i.e., stereotyped flexion of the elbow with adduction of the shoulder that can be achieved when stimulated at other sites). Extensor posturing is more easily distinguished and is usually associated with adduction, internal rotation of the shoulder and pronation of the forearm. Abnormal flexion and extension motor responses often coexist [36].

In a paper published the year following the original publication, numbers were ascribed to each level of response so that the responsiveness could be easily expressed, for example as E4, V3, M5, making communication more easy [37]. The use of these scores allowed, by summation the three component of the scale, to obtain a single total score [35]. This led to a score that ranged from 3 for deepest coma to 15 points for fully alert and oriented. The total score allows assessing the link between the gravity of altered consciousnesses and patients' outcome. However, in spite of its interest, the use of the total score induces a loss of information during the individual evaluation [38,39]. Moreover, the sum of the components causes a mathematical problem since weighting is in favor of motor response (6 points) as compared to eye opening (4 points) and verbal activity (5 points). The total score is consequently more influenced by the motor response than by the other two components [40]. It therefore appears essential, on the clinical level, to communicate the Glasgow coma scale by giving its three components (E, V, M) rather than their sum alone [41]. Although the Glasgows coma scale was initially built for post-traumatic brain injury evaluation, it was later also validated for the assessment of patients suffering from nontraumatic consciousness disorders [42,43].

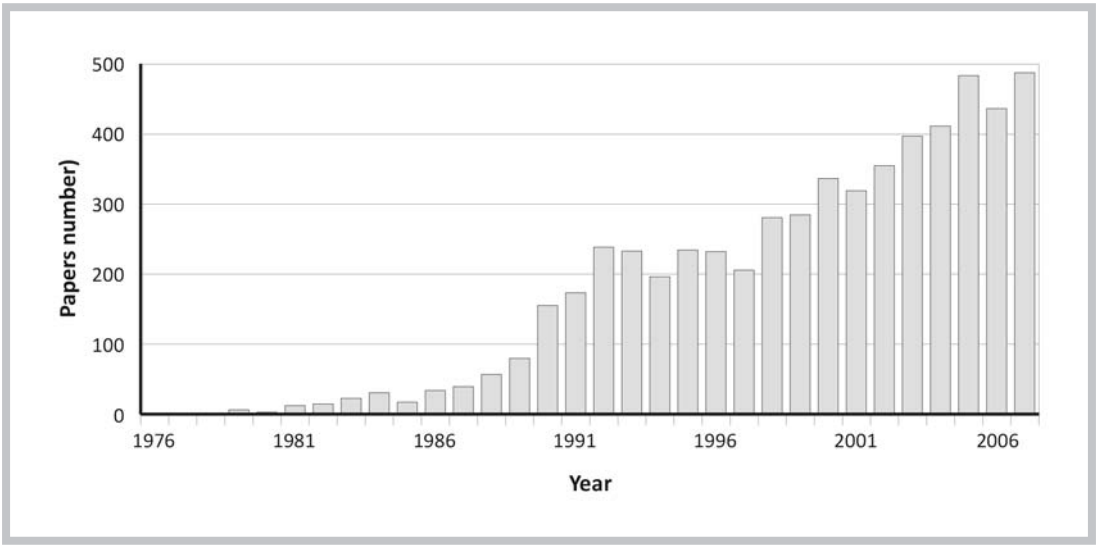

Figure 65.5. **Number of publication making reference to the Glasgow coma scale (Medline research from July 1974 to June 2008).**

The Glasgow coma scale was also studied in General Intensive Care [44] and, in addition, it is integrated in several general scores of gravity such as APACHE II [45], SAPS II [46] and SAPS 3 [47] where it has an important weight in the hospital risk of death prediction. The Glasgow coma scale remains to date the most internationally used coma scale with, since its publication, more than 5900 citations (Medline research from July 1974 to June 2008) (Figure 65.5). Apart from the Apgar score [48] with nearly 6500 quotations over the same period of time, there is probably no patients other severity of illness score which is quoted as much in the literature nor which has such an extended clinical application.

In spite of its undeniable qualities, the scale of Glasgow suffers from a certain number of imperfections. Its use causes problem in mechanically ventilated patients which a very common situation for patients with severe consciousness disorders. Indeed, in this circumstance, it is not possible to evaluate the verbal component of the scale and consequently the provided information is somewhat truncated in a substantial proportion of patients. Murray et al. indeed showed, in a study including 1000 head injured patients, that 40% of these patients could not be assessed by the Glasgow coma scale on the prior their hospital admission; this rate of unevaluable patients raised up to 50% when patients were assessed in the intensive care [49]. Another shortcoming of the Glasgow coma scale is that eye opening is insufficient to properly assess activity in the brainstem arousal system. This limitation induces a considerable loss of information for the prognosis assessment of brain injured patients. The **Glasgow-Liege scale** (Figure 65.6) is an adaptation of the scale of Glasgow; it combines the Glasgow coma scale with five brainstem reflexes [50]. This allows an approach of the brain as a whole and consequently

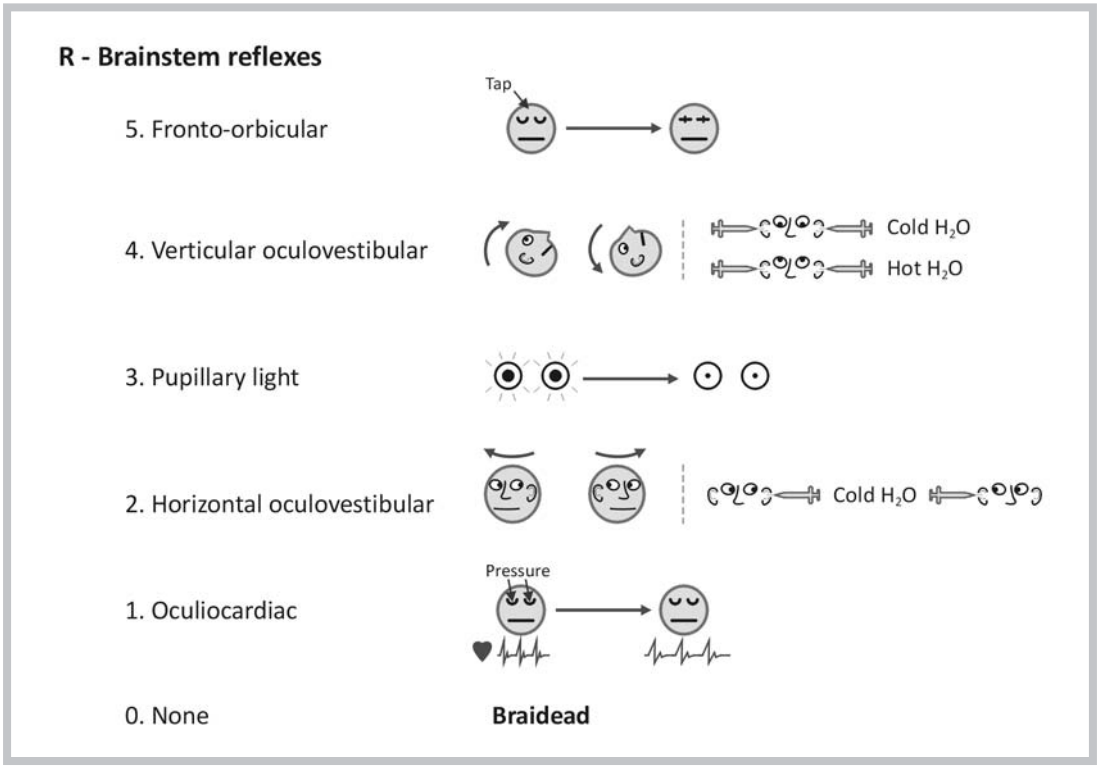

Figure 65.6. **Pictographic representation of the Glasgow-Liège scale (Born et al. 1982). Note: when oculocephalic reflexes (doll's eyes) cannot be tested or are absent, the (vertical and horizontal) oculovestibular reflexes (ice water testing) should be evaluated. Adapted from [13].**

provides more elements to evoke the diagnosis of brain death. Finally the Glasgow coma scale lacks reliability when assessing patients progressively recovering from their coma and entering a vegetative or minimally conscious state [51]. It also fails to detect more subtle the state of consciousness such as Locked-in Syndrome (LIS). For these patients, more sensitive scales are the coma recovery scale-revised, sensory modality assessment and rehabilitation technique, or Wessex head injury matrix [52-54]. These scales, however, are not adapted for use in acute settings.

65.2.2 Other Scales for Acute Consciousness Disorders Assessment

Since the publication of the Glasgow coma scale, several other scales have been proposed. In 1981, Salcman et al. published the **Scale of coma of Maryland** [55], as compared to the Glasgow coma scale this scale had the advantage to include indicators for the brainstem assessment; it however never convinced the medical community. The **Edinburgh-2 coma scale** [56] proposed by Sugiura et al. (1983) is a one-dimensional scale (Table 65.1) varying from zero to nine in a way inversely proportional to deterioration of the state conscience. This scale is simpler than the scale of Glasgow yet it never took a real rise.

Among the imperfections of this scale, one could mention the fact that it cannot be validly applied to individuals that are unable to give a verbal answer – such as intubated patients – and the fact that, in this single dimension scale is based on various neurological characteristics take place. The **Clinical Neurologic Assessment** scale (CNA), published in 1989 by Crosby et al. [57], is a 21 items instrument evaluating not only the verbal answer and the capacity to answer simple orders but also neurological aspects such as the muscular tone, the position of the body, movements, chewing or yawn. Although it offers subtle assessment possibilities than the Glasgow coma scale, this tool remained unexploited. In 1991, Benzer et al. published the **Innsbruck coma scale** [58]. In its principle, this scale is rather similar to the Glasgow coma scale; with various components scored separately then aggregated into a total score varying from 0 to 23 points. The Innsbruck coma scale however differs from the Glasgow coma scale by its number of components – eight instead of three – and by their nature: if eye opening and motor response are similar components, there is not in this scale an assessment of verbal activity but instead items assessing reaction to acoustic stimuli, body posture, pupils size and response to light, position and movement of the eyeballs and oral automatisms. Although this scale has potential advantages as compared to the Glasgow coma scale, it is cited in very few

Stimulation (maximal)	Response (best)	Score
Two sets of questions :	Answers correctly to both	0
1. Month?	Answers correctly to either	1
2. Age?	Incorrect for both	2
Two sets of commands:	Obeys correctly to both	3
1. Close and open hands	Obeys correctly to either	4
2. Close and open eyes	Neither correct	5
Strong pain	Localizing	6
	Flexion	7
	Extension	8
	None	9

Table 65.1. Edinburgh-2 coma scale [56].

Clinical descriptor	Responsiveness	Score
Alert	No delay in response, responsive without simulation	1
Drowsy or confused	Responsive to light stimulation	2
Very drowsy or confused	Responsive to strong stimulation	3
Unconscious	Localizes but does not ward of pain	4
Unconscious	Withdrawing movements on pain stimulation	5
Unconscious	Stereotyped flexion movements on pain stimulation	6
Unconscious	Stereotyped extension movements on pain stimulation	7
Unconscious	No response on pain stimulation	8

Table 65.2. The Reaction Level Scale (RLS85).

publications and its clinical use is limited. A Swedish scale, the **Reaction Level Scale** (RLS85), was proposed by Starmark et al. [59]. This tool is a simple ordinal scale varying from 1 to 8 combining verbal and motor responses (Table 65.2). This scale correlates with the scale of Glasgow, moreover it has a better inter-observers agreement than the latter [60]. However the use of this instrument remains primarily limited to Sweden.

65.2.3 The Full Outline off UnResponsiveness Score (FOUR score)

The **Full Outline off UnResponsiveness score** (FOUR) published by Wijdicks et al. in 2005 [61] is certainly a very interesting alternative on a Glasgow scale represents. This acronym reflects the number of components tested (eye response, motor response, brainstem reflexes and respiratory function) and the maximum score assigned to each of these (E4, M4, B4 and R4) (Table 65.3). The sum of the points attributed to each component can thus vary from 0 to 16. With all FOUR categories graded zero, the scale alerts to consider brain death or standard apnoea (oxygen-diffusion) testing. The main characteristic of the FOUR score are described below.

Eye Response

The FOUR score specifically evaluates ocular movements or the eye blinking on command, this implies to open the eyes manually if the patient does not open them spontaneously. This assessment facilitates the early diagnosis of locked-in syndrome which represents a considerable improvement since recent studies show that, at the initial phase, the clinicians miss this diagnosis in up to 50% of the cases [62].The FOUR score also evaluates eye tracking which is known as being this is the first sign heralding the transition from a vegetative to a minimally conscious state [63]. This distinction is not only a matter of semantics since patients in minimal state of consciousness have a more favorable outcome than patients in vegetative state [51]. The others items of the FOUR's eye score are similar to those of the scale of Glasgow.

Motor Response

With regard to the motor response, the most innovative item of the FOUR score is the hand position test, in which patients are asked to make thumbs-up, fist, or peace signs. This is a smart alternative to the V-score of the Glasgow coma scale and remains testable in intubated patients. The rest of the M-score is taken from the Glasgow coma scale, with the exception that no difference is made between abnormal stereotyped flexion and normal flexion to pain (similar to the early version of the Glasgow coma scale [30]). This difference may be difficult for inexperienced observers to appreciate but might lead

to lower prognostic power of the FOUR scale. Generalized myoclonic status epilepticus, which is a sign of poor prognosis in anoxic coma, is scored the same as absent motor response to pain.

Brainstem Reflexes

Amending the Glasgow coma scale's lack of brainstem-reflexes assessment, FOUR tests pupil, cornea, and cough reflexes and separately scores respiration. For untrained users, evaluation of the brainstem component is probably the most complex because it proposes different combinations of the presence or absence of each of its three reflexes. Unilateral fixed midriasis, alerting uncal herniation, has a separate score. To avoid corneal trauma by repeated testing, it is cleverly proposed to instil some drops of saline on the cornea.

Respiration

The last category of FOUR scores respiration as spontaneous regular, irregular, Cheyne-Stokes, ventilator-assessed patient-generated breaths, or absent. Whether pulmonary disease and respiratory settings will bias the assessment and how reliably inexperienced users can separate Cheyne-Stokes from irregular respiration are unknown.

In the past 30 years, many coma scales have been proposed as an alternative to the Glasgow coma scale, but none with success. The FOUR score has not been widely validated yet. To date only one study validated the score and assessed the inter-rater agreement [64]. The validity of this new scale needs to be corroborated when used in a general ICU setting by examiners other than neuroscience professionals. By virtue of its simplicity, and despite its drawbacks, the Glasgow coma scale became the most universally used and validated consciousness scale worldwide. Albeit convinced of the valuable improvement of the FOUR score, the Glasgow coma scale will not be dethroned effortlessly.

E	Eye response
4	Eye tracking (at least 3 times), or eyelids blinking to command (at least 2 of 3). Open eyes and assess tracking (horizontally and vertically) if necessary
3	Eyelids open but not tracking
2	Eyelids closed but open to loud voice
1	Eyelids closed but open to pain*
0	Eyelids remain closed with pain*
M	**Motor response**
4	Thumbs-up, fist, or peace sign (at least one of these)
3	Localizing to pain*
2	Flexion response (normal or stereotyped) to pain*
1	Extension response to pain*
0	No response to pain or generalized myoclonus status
B	**Brainstem reflexes**
4	Pupil and corneal reflexes present°
3	One pupil wide and fixed
2	Pupil OR corneal reflexes absent
1	Pupil AND corneal reflexes absent
0	Absent pupil AND corneal, AND cough reflex**
R	**Respiration**
4	Not intubated, regular breathing pattern
3	Not intubated, Cheyne-Stokes breathing pattern
2	Not intubated, irregular breathing
1	Breathes above ventilator rate^
0	Breathes at ventilator rate OR apnea§

Table 65.3. **The Full Outline UnResponsiveness (FOUR) score Adapted from [Wijdicks, 2005]. Instructions for the assessment of the individual categories of the FOUR score: Grade the best possible response.**

* Temporo-mandibular joint or supra-orbital nerve nociceptive stimulation

° Corneal reflexes are tested by instilling two to three drops sterile saline on the cornea from a distance of 10-15 cm (this minimizes corneal trauma from repeated examinations)

** The cough reflex to tracheal suctioning is tested only when both pupil and corneal reflexes are absent

^ No adjustments are made to the ventilator while the patient is graded, but grading is done preferably with $PaCO_2$ within normal limits

§ A standard apnea (oxygen-diffusion) test may be needed when patient breathes at ventilator rate (R0)

66 Glycemic Control During Acute Cerebral Injury

Daniel Agustín Godoy [1], Mario Di Napoli [2], Alejandro A. Rabinstein [3]

66.1 Introduction

The French physiologist Claude Bernard was the first to describe an association between high blood glucose levels and brain damage in 1849 [1]. Since then, hyperglycemia has been frequently recognized and associated with increased morbidity and mortality in neuroinjury scenarios including ischemic stroke [2-10], subarachnoid hemorrhage [11,12], severe traumatic brain injury [13-17], and spontaneous intracerebral hemorrhage [18-21], with or without diabetes mellitus.

There are multiple mechanisms involved in the exacerbation and/or production of hyperglycemia-induced brain injury, however, there is no consensus on whether hyperglycemia *per se* is a causal mechanism or merely an epiphenomenon accompanying cerebral damage [2,5,8,10]. Moreover, experimental animal studies have shown that besides reducing serum glucose concentrations, insulin has other beneficial pleiotropic neuroprotective effects [10]. In this context, recent studies have shown very positive results obtained with intensive insulin therapy (IIT), particularly in critically ill surgical patients [22,23]. The reason for the improved outcomes remains unknown, although the therapy's effectiveness could be largely due to the reduction of sepsis and multiorgan dysfunction by preventing mitochondrial and cell overloading and glucose toxicity [22-24].

The brain uses glucose in an insulin-independent way, ensuring an adequate amount of substrate (if available) especially during injuries, yet it is highly susceptible to damage caused by hypoglycemia, a potential complication during an IIT regimen [25-27]. Moreover, microdialysis studies have shown that in several conditions of acute brain injury an IIT regimen is often associated with overt brain extracellular glucopenia, which is potentially dangerous because it compromises glucose metabolism, triggering the so called "energy crisis" and further cell damage [28-31]. What remains to be determined is whether the positive effect of IIT observed in other populations of critically ill patients can be extrapolated to acute brain injury victims.

In this chapter, we will review the aspects related to the detrimental role of Hyperglycemia on the injured brain, and we will analyze the available evidence on glycemic control in neurocritically ill patients.

66.2 Cerebral Glucose Metabolism

The brain is unique in its high energy demand; together with spinal cord and retina, it needs a continuous and adequate supply of oxygen and glucose [25-27,32]. Although it weighs about 1500 g, accounting for only 2% of body weight, it receives 15% of cardiac output, 20% of the oxygen and 25% of the total glucose consumed by the entire organ-

ism. The brain has a high metabolic cost. The obligatory energy substrate for the brain is glucose, which is almost entirely oxidized to carbon dioxide (CO_2) and H_2O. The energy sources are supplied by the blood.

Cerebral blood flow averages 50 ml/100 g of tissue/min. As one might expect of an organ with highly specialized functions, the brain has a significant spare capacity because it only removes slightly over one third (33%) of the available oxygen and only 10% of the glucose. Cerebral oxygen consumption averages about 50 ml/min and CO_2 production is almost identical; hence, the cerebral respiratory quotient (RQ) is close to 1, indicating that carbohydrates are the main substrate for oxidative metabolism. Given a theoretical stoichiometry of 6 µmol of oxygen consumed for each µmole of glucose, glucose utilization by the brain should in theory be 26.6 µmol/100 g/min. However, the measured glucose utilization is 31 µmol/100 g/min, indicating that an excess of 4.4 µmol/100 g/min of glucose follows other metabolic fates.

Glucose can produce metabolic intermediates, such as lactate and pyruvate, which do not necessarily enter the tricarboxylic acid cycle but rather can be released and removed by the circulation. Furthermore, glucose can be incorporated into lipids, proteins, and glycogen, and it is also the precursor of certain neurotransmitters such as γ-aminobutyric acid (GABA), glutamate, and acetylcholine [33]. The cerebral metabolic consumption of glucose is 5 mg/100 g of brain parenchyma/min, which is equivalent to 140 grams per day. The amount of cerebral glucose linearly depends on blood glucose levels; it is typically 30% of the latter, being subject to variations according to blood levels (Figure 66.1). The range of brain glucose fluctuation is much smaller than that of blood glucose during euglycemia [34]. In rats, an increase of 50 mg/dl in blood glucose level from baseline only caused a 10 mg/dl increase in brain glucose level [35]. The brain microenvironment is isolated from the plasma by the blood brain barrier formed by tight junctions between vascular endothelial cells, where tightness excludes free diffusion of polar, hydrophilic molecules such as glucose resulting in a constant and significant glucose concentration gradient from blood to brain (Barros et al. 2007).

Because glucose cannot freely enter the brain, it requires a transport system to cross the endothelial cells of the blood-brain barrier and the membranes of neurons and astrocytes. There are several glucose carrier isoforms present in the brain (Figure 66.2). The predominant glucose transporter (GLUT) proteins involved in cerebral glucose utilization are GLUT-1 and GLUT-3, with GLUT-1 present in all brain cells including the endothelial cells of the capillaries (with very low neuronal expression in vivo), and GLUT-3 which is almost completely restricted to neurons (reviewed in [36]).

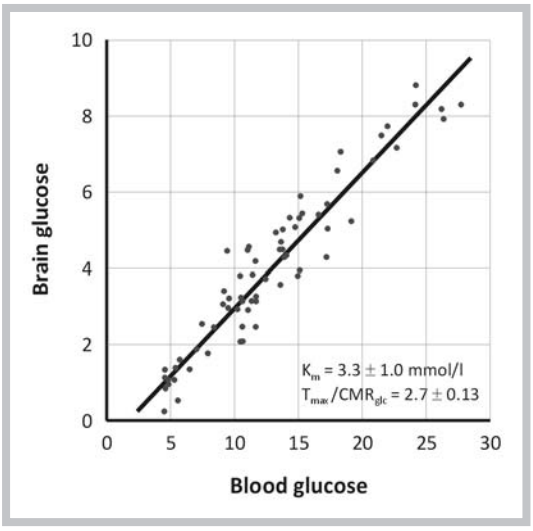

Figure 66.1. **Direct relationship between brain and blood glucose levels.**

Both carrier proteins are facilitative glucose transporters that allow glucose to enter cells independently of insulin and are activated by cytokines released via inflammatory responses. They are also upregulated during periods of increased brain activity in order to optimize glucose transport according to demand.

Repressive adaptation of GLUT across the blood-brain barrier occurs in response to chronic hyperglycemia to prevent a rise in brain glucose content [37]. This glucose

accumulation is avoided by bi-directional flux, which is influenced by the glucose concentration gradient (Figure 66.2) [36]. The different uptake kinetics according to the Michaelis-Menten equation (K_M) guarantees glucose uptake even at low blood glucose levels, which is essential for neurons especially during hypoglycemia (GLUT3: 2.8 mM, GLUT1: 8 mM) [36]. Cerebral glucose consumption depends directly on metabolic activity and on a continuous systemic supply because the brain has no glucose reserves: the low glycogen stores available mainly in astrocytes are rapidly depleted within 2 minutes.

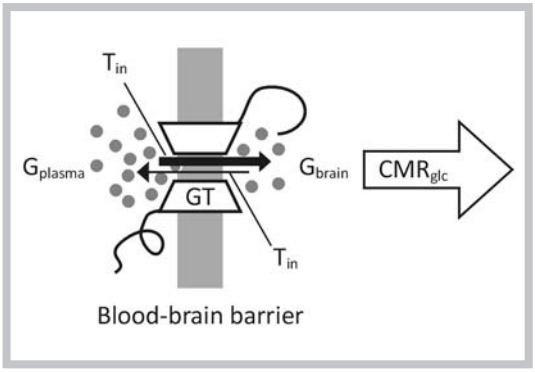

Figure 66.2. **Unidirectional model of glucose transport.**

The central nervous system cells need a sufficient availability of substrate so they can generate energy to develop and maintain their functions. This is achieved at the expense of consuming glucose to generate ATP as well as CO_2 and H_2O.

The pathway that glucose must follow in order to produce energy is a multisequential and finely regulated process. It starts with glycolysis, a metabolic pathway by which glucose is converted into pyruvate or lactate, with the net production of 2 moles of ATP per mole of glucose. The generated pyruvate can then enter the tricarboxylic acid cycle or Krebs cycle: through this cycle and another process known as oxidative phosphorylation,

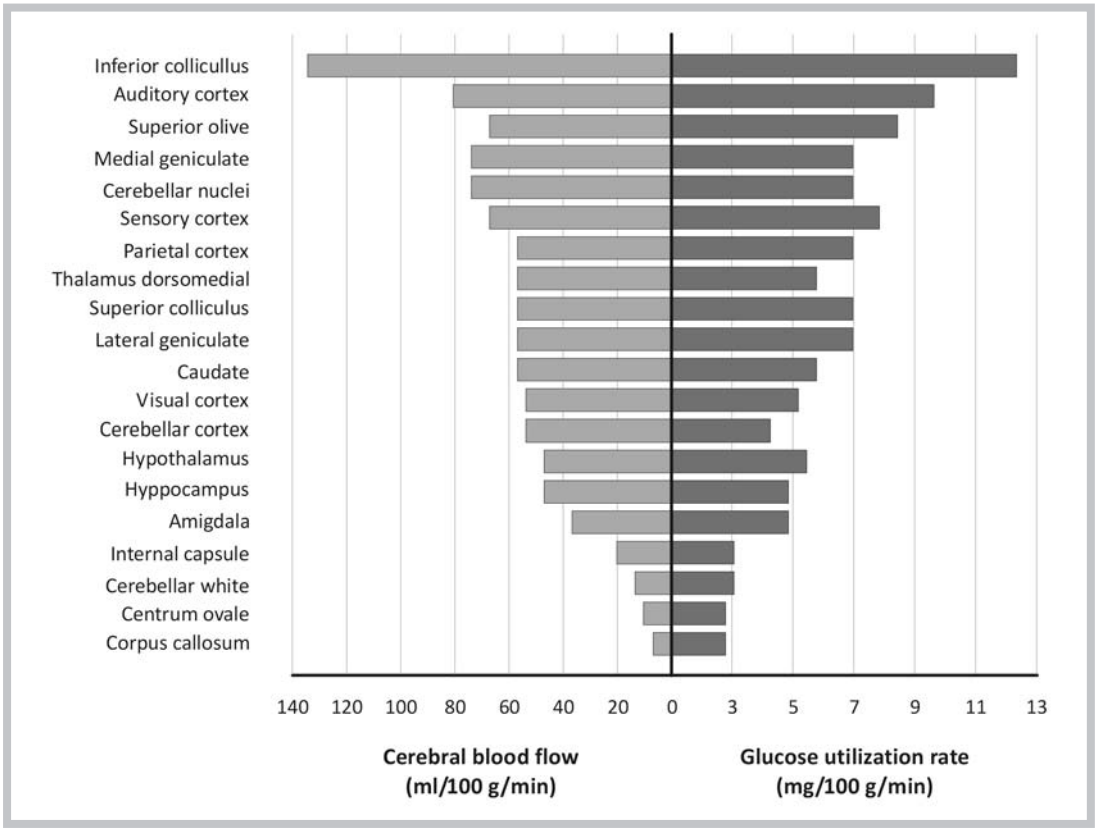

Figure 66.3. **Regional differences in cerebral and glucose consumption.**

30 moles of ATP are produced per mole of glucose metabolized, making this metabolic pathway the most efficient one for producing energy.

The control of brain glucose concentration is very important for humans. Very low glucose concentrations can immediately induce seizures, loss of consciousness, and death, while chronic hyperglycemia induces changes in hippocampal gene expression and function [38].

As mentioned, glucose can originate intermediates such as lactate and pyruvate, metabolites which in certain circumstances can maintain neuronal activity. However, neither molecule crosses the blood-brain barrier freely, and because neither of the two have specific carriers they cannot replace glucose as a cerebral energy substrate in physiological conditions. Numerous studies have investigated molecules that could substitute glucose as an alternative substrate for brain energy metabolism. Among the vast array of molecules tested, mannose is the only one that can sustain normal brain function in the absence of glucose. Mannose crosses the blood-brain barrier and is converted to fructose-6-phosphate, a physiological intermediate of the glycolytic pathway, via enzymatic steps.

However, mannose is not normally present in the blood and therefore cannot be considered a physiological substrate for brain energy metabolism. Lactate and pyruvate can sustain synaptic activity in vitro [39,40]. Because of their limited permeability across the blood–brain barrier, they cannot substitute for plasma glucose to maintain brain function [41,42]. When formed inside the brain parenchyma, however, they are useful metabolic substrates for neural cells [41,42].

In certain pathological conditions such as fasting, malnutrition, diabetes, and ketonic states, acetoacetate and D-3-hydroxybutyrate are markedly elevated because they may be used by the brain as metabolic substrates. As a corollary to these studies, steady-state arterial-venous (A-V) differences provide indirect evidence that a substance can either be used as a substrate by the brain (a positive A-V difference) or produced by the brain (a negative A-V difference) from a particular substrate such as glucose. Thus, in ketotic states, positive A-V differences have been measured for acetoacetate and D-3-hydroxybutyrate, indicating net utilization under these particular conditions. A net release of lactate and pyruvate (a negative A-V difference) is occasionally found in normal individuals and more frequently in aged subjects or during convulsions.

This makes it clear that glucose is the brain energy plant and that it participates in various processes fundamental to brain cell activity. Glucose allows the proper functioning of ion channels, which are essential to maintain transmembrane transport; it enters the production of nucleic acids, amino acids and lipid and the synthesis of hormones and neurotransmitters such as glutamate, acetylcholine and GABA.

Brain energy metabolism can be measured by two techniques: the method of 2-deoxyglucose (2-DG) and positron emission tomography (PET). The 2-DG method developed by Sokoloff and colleagues afforded a sensitive means to measure local rates of glucose utilization (LCMRglu) with a spatial resolution of approximately 50 to 100 μm [43]. With this method, LCRMglu has been determined in virtually all structurally and functionally defined brain structures in various physiological and pathological states, including sleep, seizures, and dehydration, and following a variety of pharmacological treatments [43]. Furthermore, an increase in glucose utilization following the activation of pathways subserving specific modalities, such as visual, auditory, olfactory, or somatosensory stimulation, as well as during motor activity, has been found in the pertinent brain structures [43]. Similarly, local oxygen consumption and changes in blood flow can be studied in humans by means of PET using $^{15}O_2$ and $H_2{}^{15}O$ and by means of local glucose utilization with 2-(^{18}F)fluoro-2-deoxyglucose [44]. Both have revealed the characteristic features of glucose metabolism: regional heterogeneity and relationship with the developed activity

(Figure 66.3). Glucose utilization by the gray matter varies between 5 and 15 mg per 100 g of tissue per minute. This variation depends on the brain region analyzed and that area's specific function. The average rate of glucose consumed by the white matter is 1.5-2 mg/100 g/min. Physiological activation of specific pathways results in a 1.5 to 3-fold increase in LCMRglc, as determined by the 2-DG technique.

Another interesting aspect of the two techniques is the simultaneous study of cerebral consumption of glucose and oxygen, together with blood flow, which has enabled and enhanced our understanding of phenomena occurring not only during functional activation but perhaps more importantly during situations of injury, clearly establishing a relationship between functional activity and energy metabolism.

Most current information on brain energy metabolism comes from studies of purified cell cultures enriched with astrocytes, neurons and endothelial cells. However, caution is warranted when extrapolating results obtained in vitro to in vivo situations. It is generally accepted, however, that insights may be gained from these cellularly homogeneous preparations. The results have allowed to review classic assumptions which considered neurons as the only metabolically active cell group and to properly reflect on what happens in the whole brain.

Although there are anatomical and structural differences between species, the neuronal population contributes up to 50% of the cerebral cortical volume. In addition, there are strong arguments for attributing astrocytes a key role in brain energy metabolism. Structurally speaking, there are 10 astrocytes per neuron, a relationship found in all brain regions studied.

Astrocytes are star-shaped cells strategically located around synapses; they possess receptors for a variety of neurotransmitters and reuptake sites mainly for glutamate. They differ from other cell types by having multiple extensions called "end-feet" in close contact with the wall of the capillaries where glucose transporters such as GLUT1 are expressed (Figure 66.2). Glutamate, the major excitatory amino acid, after exercising its function is taken up by astrocytes in the postsynaptic terminals and converted to glutamine, which is then released and taken up by neurons to maintain the neurotransmitter pool. This process results in the stimulation of aerobic glycolysis (requiring a sufficient amount of oxygen) and lactate production through a mechanism that involves activation of the sodium/potassium pump ATPase. Recent magnetic resonance spectroscopy studies in humans have shown that for every molecule of glutamate released from active synaptic terminals and captured by astrocytes one glucose molecule can be metabolized to lactate.

As noted earlier, in circumstances such as stimulation or vigorous activity, lactate can be used as an energy source by neurons although it doesn't cross the blood-brain barrier: the situation is different when it is generated within the brain parenchyma. In summary, during neuronal activation lactate is released into the perisynaptic space, the astrocyte detects it and stimulates glucose uptake from the bloodstream. Glucose is metabolized to lactate, which is released and taken up by neurons to produce ATP via the Krebs cycle and oxidative phosphorylation.

Astrocytes have two well-established functions: 1) to maintain extracellular potassium homeostasis; and 2) to ensure neurotransmitter reuptake (mainly glutamate). They can also be involved in water regulation and exchange by activating aquaporins (AQP4), which are densely grouped on the extensions around the capillaries. Their shape and location suggest they play a key role in the transit of glucose from the bloodstream and in the coupling of energy metabolism to synaptic activity.

Earlier we mentioned that when the cells of the nervous system are active and energy-hungry, their main mechanism of energy supply is the increase in cerebral blood flow (CBF) to provide sufficient amounts of oxygen and glucose. This is accomplished by dif-

ferent types of signals: either metabolites such as lactate, adenosine, K^+, H^+, or neurotransmitters (vasoactive intestinal peptide, noradrenalin, acetylcholine) or nitric oxide. In this way, there is a "physiological coupling between CBF and energy metabolism" which is not always maintained, especially during injury.

66.3 Glucose Metabolism and Acute Brain Injury

During brain injury, whether of traumatic, hemorrhagic or ischemic origin, profound changes in brain energy metabolism occur [45-52]. The brain enters a state of energy dysfunction, called a "metabolic crisis" by some authors. Studies using microdialysis and PET techniques have discovered that this state of crisis may take several days to resolve and that it differs from cerebral ischemia. Energy dysfunction is characterized by its heterogeneity (not all brain areas are affected in the same way), and a marked decrease in oxidative metabolism and alterations in glucose metabolism. Immediately after primary brain damage, glucose use dramatically increases to ensure the supply of enough energy to meet the increased metabolic demands, thereby maintaining ion gradients and cell membrane function intact. This defence mechanism against injury has been called hyperglycolysis. It is short-lasting and followed by a period of decline in glucose utilization. During this phase, secondary events such as seizures, intracranial hypertension, and hypoglycemia increase the demands on a tissue already working at diminished capacity, further compromising the limited energy reserves available to mitigate catastrophe.
Importantly, in pathological situations where the energy production is reduced and the cells cannot metabolize lactate aerobically, utilizing glucose acquires enormous significance. The main source of glucose derives from the extracellular space which, in turn, depends on an adequate supply and transport of glucose from the bloodstream. In these conditions, adequate glucose supplies to the brain might only be sustained when the concentration of systemic glucose is sufficient. Glucose can produce metabolic intermediates, such as lactate and pyruvate, which do not necessarily enter the tricarboxylic acid cycle but rather can be released and removed by the circulation. In this context, astrocytes play a role in glucose uptake by neurons by processing glucose through a glycolytic pathway and subsequently releasing lactate as a metabolic neuronal substrate [53]. Glucose metabolism in neurons is directed mainly to the pentose phosphate pathway, leading to the regeneration of reduced glutathione. Neurons die rapidly following the inhibition of mitochondrial respiration, whereas astrocytes utilize glycolytically generated ATP to increase their mitochondrial membrane potential, thus becoming more resistant to pro-apoptotic stimuli [53].
The increase in glucose utilization, together with a higher cerebral metabolic rate in the immediate hours following acute brain injury, lead to an increase in the capillary density of GLUT1, facilitating the transport of glucose from the blood to the brain interstitium [54]. The significant increase in GLUT3 and significant decrease of GLUT1 in neurons [55] suggest a mechanism of autoprotection against hypoglycemia due to the increased expression of high-affinity GLUT3 transporters (Km 2.8 mM) [55]. However, the lack of activity of the 6-phosphofructo-2-kinase/fructose 2,6-bisphosphatase, isoform 3 (PFKFB3), leads to a state of sustained brain energy dysfunction in both animals and humans and may eventually contribute to poor outcome [56,57]. Furthermore, transport of glucose at the blood-brain barrier and the neuronal plasma membrane may become inadequate to satisfy brain cellular metabolism.
The initial phase characterized by compensatory hyperglycemic glycolysis is typically followed by a regionally heterogeneous reduction in energy consumption, with a reduction

in cerebral metabolic oxidative metabolism and alterations in glucose metabolism [58]. Rapid-sampling microdialysis studies in patients with acute brain injury including ischemic stroke, subarachnoid hemorrhage (SAH), traumatic brain injury (TBI), and intracerebral hemorrhage [59] showed an inverse relationship between the rate of depolarization and the changes in tissue glucose, the highest rate being found in patients with the greatest falls in brain glucose levels. These results indicate a potential for a deficiency in the availability of extracellular glucose after severe brain injury which, in turn, is associated with worse neurological outcome.

Due to their expression of NMDA and non-NMDA receptors, neurons and oligodendrocytes are exquisitely sensitive to excitotoxicity by glutamate, which reaches high extracellular concentrations in brain injury for several reasons, including failing astrocyte uptake [53]. Excitotoxicity kills brain cells by energetic exhaustion (due to Na^+ extrusion after channel-mediated entry) combined with mitochondrial Ca^{2+}-mediated injury and the formation of reactive oxygen species.

Many but not all astrocytes survive energy deprivation for extended periods, but after returning to aerated conditions they are vulnerable to mitochondrial damage by cytoplasmic/mitochondrial Ca^{2+} overload and to nicotinamide adenine dinucleotide (NAD^+) deficiency. Ca^{2+} overload is established by reversal of Na^+/Ca^{2+} exchangers following Na^+ accumulation during Na^+-K^+-Cl^- co-transporter stimulation or pH regulation, compensating for excessive acid production [53]. NAD^+ deficiency inhibits glycolysis and eventually oxidative metabolism secondary to poly(ADP-ribose)polymerase (PARP) activity following DNA damage. This results in reduced pyruvate levels due to insufficiently replenished NAD+ and increased lactate levels due to metabolic short-cutting because pyruvate is metabolized to lactate by lactate dehydrogenase and cannot enter the citric acid cycle. Maintaining adequate intracerebral glucose levels can be beneficial for neurons, whereas excessive hyperglycemia increases astrocyte death due to enhanced acidosis.

66.4 Hypoglycemia-induced Brain Damage

Although there is no unanimous agreement, hypoglycemia in adults is defined as a decrease in serum glucose levels <50 mg/ dl (<2.8 millimol/l), regardless of the presence or absence of symptoms. The severity of a hypoglycemic episode is determined by the plasma glucose concentration together with the appearance of symptoms and changes in brain electrical activity [32,60-72]. The changes evidenced on the electroencephalogram (EEG) cover a wide spectrum from cortical slowing with predominantly theta and delta waves to silence or flat EEG through the suppression of wave patterns (“burst suppression”) and/or seizure activity. Glycemic thresholds that trigger symptoms or EEG impairment vary widely from individual to individual, even among non-diabetics and diabetics; indeed, fluctuations are noted among the latter regardless of whether glucose levels are under control or not.

However, several authors have underscored a key concept to bear in mind: hypoglycemia-induced brain injury occurs most often in patients in whom a strict control of blood glucose with insulin is attempted.

Hypoglycemia-induced brain damage is characterized by its depth or severity and duration. Brain energy metabolism is altered when one or both characteristics are present. This concept is important to emphasize because cerebral oxygen consumption remains unchanged during episodes of hypoglycemia, thus suggesting that alternative metabolic substrates are being utilized to ensure the production of ATP needed to maintain cellular functions.

From the physiological concepts described above it is clear that the work and survival of cells that make up the CNS is highly dependent on a continuous supply of glucose. The brain has a limited ability to adapt to situations of marked decrease in glucose intake. There are three compensatory mechanisms that counteract brain glucopenia: response to stress; increase in CBF; use of alternative reservoirs and substrates.

The systemic response to hypoglycemia is predominately via the release of counterregulatory hormones. Numbering among these hormones are catecholamines, glucagon, cortisol, and others. All favour the release of glucose into the bloodstream (hyperglycemia) in the attempt to preserve CNS cell function. Although several working groups have shown a marked increase in CBF during episodes of hypoglycemia, its pathophysiological mechanisms are not entirely clear. The extent of the increase in CBF depends on the severity of hypoglycemia. In addition, the cerebral blood vessels lose their ability to regulate their diameter in response to changes in perfusion pressure, i.e., the ability to self-regulate CBF. The astrocyte glycogen stores are depleted within 5 minutes. However, recent studies suggest that glycogen can be used longer, particularly when the supply of glucose to the brain is insufficient or when hypoglycemia is repeated.

Other endogenous substrates of energy utilized by the CNS cells both in vivo and in vitro are amino acids and fatty acids such as arachidonic acid, both of which are insufficient, inefficient and dangerous, since they induce the accumulation of products (e.g., oxygen free radicals, calcium) which are potentially toxic and lethal for neurons. Profound metabolic disorders ensue when the ability to cope with hypoglycemic insult fails or is depleted. Since glucose, besides being the brain's ultimate energy source, is involved in other vital processes, its lack or absence prevents amino acid metabolism, protein synthesis, neurotransmitter release, alters the local pH, and damages the cell membranes when ion channels don't work correctly.

As mentioned, the more profound and prolonged the hypoglycemia, the greater the likelihood of severe and irreversible damage. Multiple mechanisms are involved in neuronal death, including glutamate and adenosine toxicity, apoptosis, oxidative damage by oxygen free radicals, zinc and nitric oxide, and the accumulation of intracellular calcium. Not all brain regions show the same susceptibility to damage induced by hypoglycemia. The cerebral cortex, striatum and hippocampus are among the most vulnerable areas, while the hypothalamus, cerebellum and brain stem are highly resistant to hypoglycemic injury. Autopsy studies in humans have revealed scattered petechiae, congestion and edema of nerve cells, mainly located in axons and dendrites, which undergo a series of degenerative changes and subsequently disappear. Many areas of glial reaction, demyelination, and encephalomalacia can be found.

66.5 Hyperglycemia as a Prognostic Factor

When defining hyperglycemia in the context of serious illness in general and in patients with neurological/neurosurgical emergency in particular, the lack of a uniform definition in different series studied should be taken into account.

The values used to define it widely vary and were taken arbitrarily [1-21]. Nevertheless, it is estimated that the incidence of hyperglycemia in the neurocritical patient ranges between 28 and 68% [7,10,73]. Hyperglycemia is also an independent risk factor of mortality and poor functional outcomes in several situations of neurological injury such as ischemic stroke treated or not treated with thrombolysis [2-10,73-81], spontaneous intracerebral [18-21,82,83] and subarachnoid [11,12,84-87] hemorrhage, malignant brain tumors [88], severe head injury [13-17], and spinal cord injury [89-93].

Multiple studies have demonstrated the negative impact of hyperglycemia in the ischemic brain. Williams [6] showed a close association between hyperglycemia and mortality at 30 days, 1 year and 6 years after ischemic stroke. Capes et al. [5] in their meta-analysis showed that the risk of death after ischemic stroke was 3 times higher if blood glucose levels at hospital admission were between 110 and 126 mg/dl.

In a recent study, Stead et al. reported results similar to those above, because patients with cerebrovascular disease and hyperglycemia are 2.3 times more likely to die at 90 days compared to patients with normoglycemia [84]. The multicenter, prospective observational GLIAS study [81] established as its main objective to detect the glucose threshold with the greatest predictive power of poor outcome in the acute phase of ischemic stroke. The optimal cut-off point that most accuracy predicted poor outcome 3 months after the event is 155 mg/dl. This value is correlated with a 2.7-fold increase in the probability of poor outcomes after adjusting for variables such as age, presence of diabetes, glucose level at admission, infarct volume and stroke severity, while the risk of death is 3 times greater (hazard ratio [HR] 3.80, 95% confidence interval [CI], 1.79-8.10) [81].

Hyperglycemia is a common finding in patients with spontaneous intracerebral hemorrhage [18-21,82-83] and has a detrimental prognostic effect in the short term according to some studies (odds ratio [OR], 1.52; 95% CI 1.28-1.82; p <0.0001) [21].

Our working group investigated the relationship between early mortality, i.e., within 30 days after intracerebral hemorrhage, and elevated levels of blood glucose [21]. Patients who died had high blood glucose levels for 72 hours after the stroke (p <0.001). It is noteworthy that for each 18 mg/dl increase in glucose levels >90 mg/dl, the probability of experiencing a fatal event increases by 33%. The cut-off point in which the greatest predictive power is obtained is >164 mg/dl. All the above findings apply equally to diabetic and non diabetics patients [21].

Elevated glucose levels have been identified as independent predictors of final outcome after SAH [12,85-87]. A study by Frontera demonstrated a close association between hyperglycemia and the onset of complications such as heart and respiratory failure, pneumonia and brain herniation (p <0.05). Also, a close link was demonstrated between hyperglycemia and poor outcomes defined as either severe disability or death (OR 1.17; 95% CI 1.07-1.28; p <0.001) [12].

The Dutch group led by Kruyt [85] evidenced, after multivariate adjustment of baseline characteristics of non-diabetic patients with aneurysmal SAH, that the average levels of fasting glucose during the first week following initial bleeding predicts poor outcomes (OR 2.5; 95% CI 1.4-4.6) better than blood glucose at admission (OR 6.1; 95% CI 0.9-2.7) [85].

The deleterious effects of hyperglycemia on the injured brain in neurotrauma are well known. It is a factor of secondary damage to be avoided. However, currently available evidence is scarce and controversial at best, so we cannot definitively say whether high blood glucose levels are an independent risk factor of poor outcome after severe head trauma.

The few available studies show that patients with blood glucose >170 mg/dl have worse long-term results compared to subjects with normal blood glucose levels [13,16,17,89].

Salim et al. retrospectively analyzed a series of patients with severe TBI. Persistent hyperglycemia was defined as ≥150 mg/dl during the first week post-trauma was prevalent in older patients with a greater severity of head and systemic trauma, and on multivariate analysis independently predicted mortality (OR 4.91; 95% CI 2.88-8.56; p <0.0001) [90].

The degree of hyperglycemia seems to be important in prognosis [16]. Some predictive models have included hyperglycemia as a prognostic factor thus improving the prediction of outcomes [91-93].

Experimental models of spinal cord ischemic injury have shown that high blood glucose levels adversely affect neurological function [94-96]. In Only one retrospective study

concluded that after traumatic spinal cord injury hyperglycemia accompanies the most severe contusions, while hyperglycemia induced after spinal cord ischemia does not affect the final outcome [97].

66.6 Pathophysiology of Hyperglycemia in the Acute Phase of Brain Injury

The genesis of hyperglycemia after brain damage is not due to a single cause; instead, various multifactorial [10] mechanisms are involved [73] (Table 66.1). One hypothesis is that hyperglycemia is nothing more than an indicator of pre-existing and/or undiagnosed diabetes (intolerance to glucose); however, this hypothesis has not garnered much acceptance as many studies have shown that hyperglycemia in the absence of diabetes is by itself a risk factor of poor outcome in several neuroinjury scenarios [5-10,12-17,19-21,98,99].

Perhaps the most widely accepted explanation is that hyperglycemia during the early phase of neuroinjury is due to a non-specific reaction or response to "stress" situations [2,10,100-103]. This programmed, coordinated and adaptive response is of paramount importance for survival.

It has 3 main components: 1) Activation of the immune-neuroendocrine hypothalamus-pituitary-adrenal axis, with the subsequent release of counterregulatory and hyperglycemic hormones, such as catecholamines, cortisol, etc.; 2) Autonomic nervous system stimulation; 3) Modification of individual behaviour.

Each component to a different degree and in a different way contributes to the development of hyperglycemia, so that the greater the damage, the greater the response. Thus, hyperglycemia may be a marker of injury severity rather than a phenomenon that can worsen or trigger it. As mentioned, however, the prevalence of hyperglycemia is high, and independent of the type and severity of the neuroinjury [7,10,73,103]. Furthermore, studies which have reported a causal and unequivocal relationship between stress hormones and stroke are inconsistent [104].

Neuroendocrine dysregulation secondary to anatomic lesion of the insular cortex is one of the mechanisms thought to explain hyperglycemia [105,106] but evidence has not been sufficiently confirmed by other authors [107].

Inflammation triggered by CNS injury is another potential cause of hyperglycemia [100,108-116]. When brain damage of whatever origin occurs, a wide range of mediators including cytokines is immediately released mainly by astrocytes and microglia. Cytokines can, in turn, trigger hyperglycemia through the induction of insulin resistance in the liver and muscle.

The resulting hyperglycemia, coupled with the increased generation of glucose by the liver secondary to the above-mentioned metabolic response to stress, leads to glucose overload that perpetuates the inflammation and triggers the injury of endothelial cells [100,108-116]. In practical terms, we must take iatrogenic causes into account, since many drugs in routine neurointensive care (e.g., dopamine,

- Nonspecific response to tissue injury (autonomic, hormonal and metabolic alterations)
- Insulin resistance
- Drugs (catecholamines, steroids, tiazides, etc.)
- Hypothalamic dysfunction
- Irritation of central glucose regulation centers (hypothalamus, brainstem)
- Excessive glucose administration
- Unknown diabetes
- Latent diabetes

Table 66.1. **Pathophysiology of hyperglycemia in acute brain injury.**

norepinephrine, steroids, thiazides, dextrose-containing solutions, among others) can potentially trigger hyperglycemia [106,117-119]. In this context, adequate nutritional support is essential, given the multiple physiological changes triggering the injury. Among the less convincing hypotheses, or rather those not sufficiently backed in the literature, are those that seek to explain direct hypothalamic damage or irritation of the centres regulating blood glucose after neuroinjury [10].

66.7 Temporal Profile

Technological advances and the development of new monitoring techniques have greatly improved our understanding of the various phenomena occurring after brain damage, many of which can establish, perpetuate and worsen the initial injury. Hyperglycemia is one such factor. Although there is no a uniform and unanimous definition of hyperglycemia in the context of neuroinjury, cut-offs used to define it vary from study to study and most were obtained in an arbitrary manner from the analysis of retrospective series [2-21,70-87]. There are several forms of monitoring and all of them determine glucose levels by an enzymatic or electrochemical method based on the reaction of glucose oxidase. Blood glucose values can be obtained in the following ways: intravenous or arterial; capillary, "pricking" the fingertips; subcutaneous using a sensor inserted into the abdominal wall to record interstitial glucose values [76,120].

The units of expression of blood glucose values are standardized: 1) milligrams per decilitre (mg/dl) or 2) millimoles per litre (mmol/l), as expressed by most European studies. Hospital admission is the moment most authors select when analyzing the prognostic role of elevated blood glucose values during CNS injury [2-21,73-84].

Like other biological variables, however, blood glucose is characterized by its dynamic fluctuating nature because it is subject to variations induced by: nutrition, stress situations (pain, trauma, surgery), drugs, and other factors. Therefore, it is logical to think that the deleterious effects of hyperglycemia persist beyond the first few hours after injury, making serial monitoring of blood glucose levels during brain damage of paramount importance.

Few studies have elucidated the behaviour over time of blood glucose values. Baird [76] in a small series of patients reported that 35% had hyperglycemia at admission, in 43% of which high levels persisted over the study period (72 h post-ischemic stroke), whereas 46% with normal values at the admission in hospital developed hyperglycemia.

Hyperglycemia is strongly associated with infarct expansion ($r \geq 0.60$, $p < 0.01$) and poor functional outcome on the National Institutes of Health Stroke Scale ([NIHSS] $r \geq 0.53$, $p < 0.02$) or the modified Rankin scale ([mRS] $r \geq 0.53$, $p = 0.02$) [76].

Allport et al. [120] described two phases of occurrence of hyperglycemia in a series of 59 patients suffering from ischemic stroke: an early stage occurring in all diabetic patients and 50% of non-diabetic patients within 8 hours after the stroke, and a late phase (48-88 hours post-stroke) in 27% of non-diabetic and 78% of diabetic patients.

The recently published GLIAS study [81] highlights that hyperglycemia occurring within the initial 48 hours post-ischemic stroke is most important factor in determining the final results, regardless of the presence of known and widely validated predictors such as age, presence of diabetes mellitus, infarct volume and stroke severity.

In turn, Godoy et al. [21] identified four evolutionary patterns in a series of nearly 300 patients with spontaneous intracerebral hemorrhage; but perhaps most important was the relationship between different groups and mortality: the mortality was 8.6% among patients with normal blood glucose values and 79.5% for those with persistent hyperglycemia during the study period ($p < 0.0001$).

The main conclusions highlight that hyperglycemia is common, of long duration and with different evolutionary profiles in neurocritical patients. Additionally, it is strongly associated with death and poor functional outcomes.

66.8 Mechanisms of Hyperglycemia-induced Brain Injury

The body's cells naturally protect themselves against the potential toxicity of hyperglycemia by regulating glucose transporters [24,121]. Some cell groups, including neurons, astrocytes, hepatocytes, epithelial and endothelial cells, and the cells of the immune system, receive glucose (without using insulin) from transporter proteins GLUT 1, 2 and 3, which are responsible for facilitating the entry of this energy source into the cell [24,121].

During injury, local hypoxia and the release of mediators (e.g., cytokines, angiotensin II, endothelins) stimulate GLUT expression and localization on the cell membranes, thus deranging the cell's the defence system, ensuing in a glucose overload in the cellular microenvironment [24,122-126].

Although the precise mechanism of hyperglycemia-induced neuronal damage is not known, multiple factors, either together or isolated, interact to trigger, perpetuate or exacerbate the injury. In two elegant papers, Garg [10] and Tomlinson [127] reviewed the potential mechanisms involved. Briefly:

66.8.1 Reduced Cerebral Blood Flow (CBF)

A decrease of up to 25% has been shown in experimental animals [128,129]. Nitric oxide seems to play a key role: neutralizing it or inhibiting its production by the vascular endothelium produces an imbalance in cerebral vascular tone where vasoconstriction predominates. The trend towards microthrombosis of cerebral capillaries triggered by inflammatory mediators such as tissue factor is associated with this mechanism. In occlusion-ischemia models it has been observed that the decrease in flow also involves the penumbra area, showing that the initial area of infarction can be increased when hyperglycemia is present.

66.8.2 Metabolic Dysfunction

Kushner's study with PET and 2-deoxyglucose technique described a profound metabolic depression in the ischemic brain in patients with an average blood glucose level >155 mg/dl [130]. The hypometabolism may be due to impaired mitochondrial function secondary to the toxic effects of glucose overload or to the local lactic acidosis generated during hyperglycemia [10,130].

66.8.3 Toxicity Due to Excitatory Amino Acids and Calcium

Hyperglycemic states increase the availability of extracellular glutamate which activates postsynaptic NMDA receptors to open ion channels, thus allowing the massive entry of calcium into the cells, with consequent mitochondrial dysfunction and neuronal death [10,131]. Hyperglycemia also prevents the reuptake of calcium into the cell after reperfusion in cerebral ischemia models; therefore, it becomes a threat or impediment to the recovery of damaged tissue in such situations [132].

66.8.4 Inflammation

The injury-induced hyperglycemia and tissue damage trigger a complex series of events, among which inflammation and oxidative stress, resulting in the released of mediators such as cytokines, chemokines, oxygen free radicals which, in turn, aggravate the injury through several and varied mechanisms [10,119]. It is well known that the oxygen free radicals cause peroxidation of cell membrane lipids, carboxylation of proteins vital to cell function, and denaturation of DNA. Moreover, they also inhibit the endothelial production of nitric oxide or block its action [10,119,133].

Cytokines perpetuate the inflammatory activity [134] and induce the production and/or transcription of extracellular matrix metalloproteinases (MMPs) which will play a major role in damaging the blood-brain barrier and causing cerebral edema [135,136]. Also, hyperglycemia compromises cerebral microcirculation by altering the balance between thrombotic and fibrinolytic factors [10].

As a corollary, we can deduce that the mechanism of injury analyzed in isolation or together with other phenomena clearly explains the development of certain compli-

cations in neurocritical diseases: hemorrhagic transformation [4,77,79] and/or expansion of cerebral infarction [76] or spontaneous enlargement of intracerebral hematoma [136], and vasospasm after subarachnoid hemorrhage [11,12,137].

66.9 Insulin: Neuroprotector?

Insulin, a key hormone in the control of intermediate metabolism, was isolated from the pancreas by Benting and Best in 1922 [138]. It has a profound effect on the metabolism of carbohydrates, lipids and a significant influence on protein metabolism. It plays a major role in mineral metabolism and energy storage.

Unlike other body tissues, the cells of the human CNS are highly permeable to glucose: they capture and utilize without requiring the action of insulin, i.e., cerebral glucose consumption and metabolism depends almost exclusively on the contribution and availability of glucose in the blood, its main vehicle of transport [24,121,139-141].

Evidence from experimental cerebral ischemia models has shown that, besides its physiological actions on blood glucose levels, insulin possesses certain neuroprotective properties by significantly reducing neuronal necrosis [10,73,142-145].

Insulin has recently been shown to exert a potent anti-inflammatory action in vivo and *in vitro* by blocking the production of pro-inflammatory agents, the generation of oxygen free radicals and the synthesis of MMPs [146-152]. As a result, this action of insulin increases the release of nitric oxide from endothelial cells, astrocytes and neurons, which would favour the maintenance of adequate blood flow [153-156].

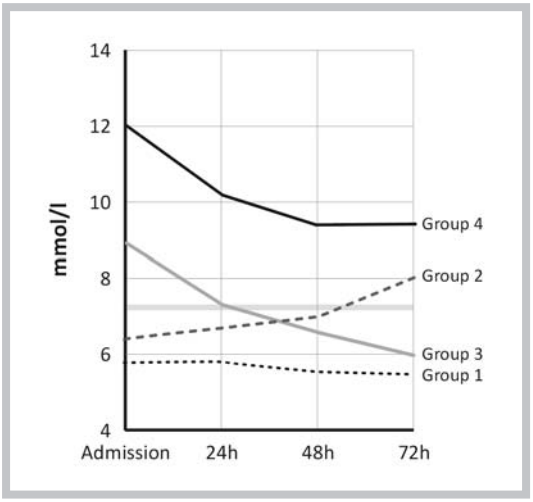

Figure 66.5. **Changes in blood glucose levels during initial 72 hours after spontaneous intracerebral hemorrhage in 295 patients. Different patterns were observed: persistently normal (group 1), increasing (group 2), decreasing (group 3), and persistent elevation (group 4).**

Insulin decreases the expression, transcription and synthesis of MMPs, so that tissue damage is limited by keeping the blood-brain barrier intact [152]. Additionally, insulin has antiplatelet, anticoagulant and profibrinolytic effects [10,73,156-159]. These mechanisms enhance insulin's anti-inflammatory action and hypothetically may improve cerebral microcirculation.

Other benefits of insulin derive from its physiological action. Since it is an anabolic hormone, it promotes protein synthesis, thereby stimulating neuronal repair and regeneration [10,73,156].

66.10 Management of Glycemia in the Neurocritical Patient According to Clinical Practice Guidelines

The term "evidence-based medicine" (EBM) was first used in the 1980s to describe a new learning strategy used at McMaster Medical School, Canada, which stressed the

Organization	Year	Cutoff to start treatment (mg/dl)	Evidence level

importance of reviewing evidence from investigation, and cautious interpretation of the clinical information derived from non-systematic observations [160].
According to the definition by Sackett in 1996 [161], "Evidence-based medicine is the conscientious, explicit, and judicious use of current best evidence in making decisions about the care of individual patients".
Next, we will review past and present guidelines for the management of glycemia in different situations of acute brain injury.

66.10.1 Ischemic Stroke (IS)

All current recommendations have a common denominator when dealing with early detection, prevention and rapid correction of hypoglycemia since its deleterious role is well known in situations of acute brain injury (Class I, Level of Evidence Grade C) [162-167].
In the management of elevated blood glucose levels, according to then available evidence, the expert committee of the Stroke Council of the American Heart Association (AHA) stated in 1994 that the association between hyperglycemia and poor outcomes is uncertain and controversial. Nevertheless, it suggested treating hyperglycemia, without specifying guidelines or thresholds (Level of Evidence III-IV, Grade C) [162].
Later, in 1996, the AMA issued guidelines for thrombolytic therapy in ischemic stroke which advised keeping blood glucose values between 50 and 400 mg/dl [163]. A decade later, the AHA recognized the harm of hyperglycemia in the context of ischemic stroke, suggesting a cautious approach to hyperglycemia control, i.e., to keep levels <300 mg/dl (Level of Evidence Grade C) [164-165].

At the same time, the working group of cerebrovascular diseases in the European Stroke Initiative (EUSI) emphasized how frequent and dangerous hyperglycemia is during the acute phase of ischemic stroke, recommending the control of blood glucose values >180 mg/dl (Level of Evidence IV) [166].
Recently, the AHA and EUSI updated their guidelines in which hyperglycemia is recognized as a common phenomenon accompanying ischemic stroke in both diabetic and non-diabetic patients, highlighting its role in triggering and/or maintaining secondary injury, associated with such complications as expansion or hemorrhagic transformation of infarcts and poor outcome.
The AHA now recommends keeping blood glucose levels <185 mg/dl, suggesting also a possible, hypothetical additional benefit obtained by treating values >140 mg/dl (Class IIa, Level C) [167]. In contrast, the 2003 EUSI guidelines (Level of Evidence IV, GCP, remain unchanged [168].

66.10.2 Severe Traumatic Brain Injury (sTBI)

In 1995 and 1997, respectively, the Brain Trauma Foundation [169] and the European Brain Injury Consortium (EBIC) [170], presented the first recommendations for the management of TBI patients. The recommendations were updated in 2000 [171] and again in 2007 [172].
In the section on nutrition, all versions of the document stress that hyperglycemia is a contributing factor to secondary injury and that its presence worsens the prognosis. But there is no mention of cut-off points up- or downwards at which treatment for altered glucose levels should be initiated.

66.10.3 Aneurysmal Subarachnoid Hemorrhage (SAH)

The Stroke Council of the American Heart Association in 1994 [173], and again in 2009 [174], published clinical practice guidelines for the management of SAH following the rupture of a cerebral aneurysm. Similarly to the recommendations for the management of TBI, they only highlight that hyperglycemia should be avoided owing to its detrimental role in the pathophysiology of brain damage but without specifying how or when this should be done.

66.10.4 Spontaneous Intracerebral Hemorrhage (sICH)

In 2007, the AHA updated their guidelines for the treatment of acute phase of sICH. In contrast to the first edition [175], hyperglycemia is recognized as a component of the body's response to brain injury, its presence is identified as a marker of the severity of damage, and is associated with poor outcomes in the short and long term. Additionally and more importantly, they establish (Level of Evidence IIa, level C),

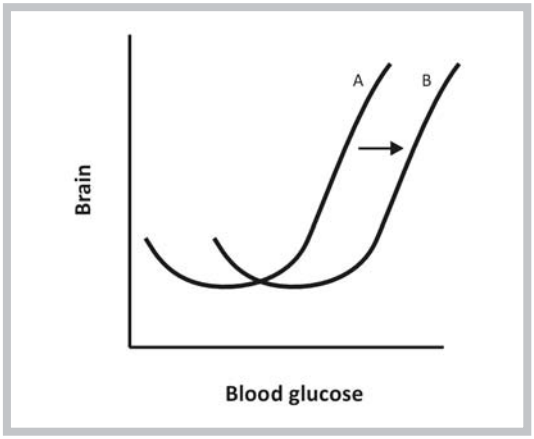

Figure 66.6. Hypo- or hyperglycemia increases the possibility of brain damage (A). During injury there is a shift of the curve towards B, showing an increased need for glucose by the brain, as well as increased susceptibility to glycogenesis in such situations.

the threshold for initiation of insulin therapy [176] starting at 185 mg/dl (possibly >140 mg/dl). In turn, the European Initiative (low level of evidence), suggested keeping blood glucose levels <300 mg/dl [177].

66.11 Intensive Insulin Therapy

There are two treatment options to decrease blood glucose levels in diabetic patients: insulin and oral hypoglycemic agents (OHAs). The latter have no place in the treatment of hyperglycemia in critical illnesses owing to circumstances that can alter their pharmacokinetics and pharmacodynamics.

The effects of many drugs commonly used in intensive care are enhanced or antagonized by OHAs. In addition, in critically ill patients a drug's bioavailability, volume of distribution and metabolism are all altered due to increased capillary permeability, hepatic and renal dysfunction [178].

Another important aspect to consider is the mechanism of action of OHAs. These drugs act by promoting insulin secretion and action by augmenting its receptor function. In contrast, in the critically ill patient, due to the metabolic response to stress-induced injury, the ability to release insulin is reduced and insulin resistance is increased [100,108-116].

Finally, one of the most feared side effects of OHAs is hypoglycemia, which is often very severe, prolonged and life-threatening, especially in neurocritical patients [60-72,178].

There are several routes and forms to administer insulin. The intravenous (IV) route is the one most frequently used in critically ill patients. Administration regimens vary. Some working groups prefer to correct the blood glucose levels in a phased manner and according to monitoring: this scheme is called "reactive". Instead, others estimate the requirements, trying to keep blood glucose levels within a preset range, and this regimen is known as "proactive". Both regimens have their pros and cons, but none has shown superiority or advantage over the other [73].

On the basis of the available evidence for the detrimental role of hyperglycemia, in 2001 van den Berghe published the results of a new therapeutic modality called intensive insulin therapy which aimed at maintaining blood glucose levels within a narrow range, i.e., between 80 and 110 mg/dl [22].

This prospective, randomized single-centre study included postoperative patients on mechanical ventilation, two thirds of which had undergone cardiac surgery. When compared with the group in which blood glucose levels were maintained between 180 and 200 mg/dl, a significant decrease in mortality is observed (8% vs. 4.6%; $p < 0.04$) especially in the patients who remained in critical care for more than 5 days, had proven septic focus, and developed multiple organ dysfunction (20.2% vs. 10.6% for those treated with conventional and intensive regimen, respectively; $p < 0.006$).

Additional benefits obtained from IIT were a lower incidence of infection, days on mechanical ventilation, hospital mortality, development of polyneuropathy of critical ill patients, and need for blood transfusions or dialysis in patients with acute renal failure.

The authors could not replicate the previous data in a series of patients with non-surgical pathology, except in a small subpopulation requiring critical care stay for more than 3 days [179].

Years later, the results of other multicenter studies that questioned the findings of the Belgian group were disclosed [180-184]. Brunkhorst in Germany applied prospectively and randomly IIT to septic patients. Not only was there no difference in mortality between the study groups but also the trial had to be aborted, upon the suggestion of the safety committee, because of the high rate of severe hypoglycemia [180].

Similar data were reported in diabetic and non diabetic patients, victims of acute myocardial infarction [182,183], and in a heterogeneous population of critically ill patients [184].
The prospective, randomized multicenter NICE-SUGAR study involving critically ill patients with different medical and surgical pathologies compared two goals in glycemic control. In one group, IIT was aimed at maintaining blood glucose between 81 and 108 mg/dl (intensive), while in the other one the objective to achieve slightly higher levels between 144 and 180 mg/dl (conventional).
At 90 days after admission to the ICU, the mortality in the intensive group was significantly higher (27.5% vs. 24.9%; OR 1.14; p=0.02), as was the incidence of severe hypoglycemia (6.8% vs. 0.5%; p <0.001), whereas there were no differences between the two therapeutic arms when comparing number of days on mechanical ventilation, length of ICU or hospital stay, or need for dialysis [185].
Therefore, to date, no accurate conclusions can be drawn as even the available meta-analysis of IIT come to different conclusions [186,187].

66.12 Can or Should the Data Obtained in Critically Ill Patients in General Be Extrapolated to Patients With Acute Brain Injury?

This patient subpopulation deserves special consideration. Some authors have approached the subject partially and from different perspectives [73,80,188,189]. While there is unanimous agreement that elevated serum glucose levels or hypoglycemia contribute to secondary damage and worsen the prognosis of these patients, there is no consensus on delineating the levels at which glucose should be maintained.
Although there are no studies specifically addressed to hypoglycemia, the body of available evidence says that there is no doubt that it must be avoided and/or treated in an urgent and aggressive way [60-71,162-177,190].
The debate about hyperglycemia is more complex and focuses on two unsolved questions:

- When or at what level should therapy be initiated?
- In what range or interval should it be maintained?

66.13 Effects of Intensive Insulin Therapy on Cerebral Metabolism

Under physiological conditions, glucose is the major metabolic substrate for the brain, so the possibility to measure or objectify interstitial concentrations of glucose in the brain parenchyma is interesting and fascinating [25-27,32,138] One technique that has furthered our understanding of the brain's energy metabolism is microdialysis [191-193]. This monitoring mode provides us with direct metabolic data, though local, on the fundamental brain energy substrate, glucose, and the production of metabolites and neurotransmitters.
Some of the metabolites usually analyzed in the clinical setting inform us about energy metabolism (glucose, lactate, pyruvate), while others indicate tissue damage (glutamate, glycerol) [191-193].

Another possibility offered by microdialysis is the evaluation of IIT on cerebral metabolism. The brain does not produce insulin or does so only in an insignificant way. Insulin enters the CNS by receptor-mediated transport [194-195]. There are insulin receptors distributed throughout the whole brain, with functions appreciably different from peripheral receptors [139-141,196,197].

Experimental studies suggest that insulin has other physiological functions to stimulate and maintain neuronal survival, without participating in the cerebral metabolic pathways for glucose utilization [25-27,32,139-141,192,194-197].

Therefore, brain interstitial glucose represents the balance between available and consumed glucose [192,193]. There are multiple mechanisms that can lead to neuroglycopenia, including:

- Decreased availability in the blood (hypoglycemia, insulin therapy).
- Impaired cerebral blood flow (severe hypotension, intracranial hypertension).
- Altered transport across the blood-brain barrier (inflammation).
- Increased glucose consumption (seizures, fever).

Two studies showed that low brain extracellular glucose levels are closely associated with poor outcome after SAH [198] or severe head trauma [33].

Vespa [30] conducted pioneer work in determining the effects of IIT on metabolism and the interstitial concentration of cerebral glucose in severe traumatic injury. Patients with severe TBI (GCS ≤8) or moderate (GCS ≤12) with space-occupying lesions on computed tomography (CT) were monitored by mean of microdialysis, xenon 133 and PET for commonly used variables (intracerebral pressure, jugular oxygen saturation) and cerebral blood flow, oxygen consumption rate, glucose, metabolic markers.

Continuous insulin infusion was used to maintain plasma glucose levels between 90-120 mg/dl (intensive) in one group and compared with another in which blood glucose was maintained in the range 120-150 mg/dl (conventional) but with a regimen of subcutaneous administration of insulin adjusted according to monitoring values.

In the whole population, enteral feeding was initiated within 12 hours postinjury. While IIT did not alter overall glucose metabolism, there was a significant decrease in the extracellular concentration of glucose in the brain parenchyma, associated with increases in oxygen and glutamate extraction, and in the lactate/pyruvate ratio, markers of cellular energy dysfunction. Although not designed for this purpose, the study showed no additional benefits in terms of mortality or functional outcomes [30].

Similar results were reported by Oddo [31] and Schlenk [199] in individuals after severe head trauma or SAH, respectively. Both reached the same conclusion, agreeing that IIT generates a decrease in interstitial glucose accompanied by an increase in markers of cellular distress despite the achievement and maintenance of normal glycemia.

In Switzerland, Holbein et al. retrospectively analyzed the effect that four intervals of different glycemic controls in severe head trauma victims have on cerebral metabolism. Glucose ranges varied widely from 72 to 163 mg/dl. Metabolic parameters were obtained indirectly through formulas derived from arteriojugular differences of the variable to be measured. Despite the limitations of the study, the authors concluded that brain metabolism is more “stable” when blood glucose levels are kept between 109 and 145 mg/dl [200].

66.14 Clinical Trials

Building on original work [22], van der Berghe discussed the effects of IIT on the central and peripheral nervous system [190] in a subpopulation with prolonged ICU stay

(≥7 days). In all, 405 patients took part in the follow-up assessment with weekly electromyograms (EMG) for detecting polyneuropathy (PNP). In the patients treated with IIT to maintain a strict control of blood glucose levels (range, 80 to 110 mg/dl), the risk of developing polyneuropathy was reduced by 49% (p <0.0001), with a lower risk of prolonged mechanical ventilation (OR 3.75; 95% CI 1.49-9.39; p=0.005).
It should be noted here that the number of patients so diagnosed varied greatly because only one or two EMGs were performed, which may question the criteria used to define polyneuropathy. No conclusions can be drawn regarding the 63 patients included in the "isolated brain injury" subset because of the small, heterogeneous and not well characterized sample [190].
We will next consider the available evidence for IIT in various neurocritical diseases.

66.14.1 Ischemic Stroke

As discussed above, there is a close association between hyperglycemia and poor outcomes in ischemic stroke [2-10,73-81,84,191]; however, the available evidence for the effects of increased blood glucose control in this group of patients is very limited. In ischemic thromboembolic stroke, Gentile et al. [201] in their retrospective study involving 960 patients once again reaffirmed the prognostic value of hyperglycemia at admission. Hyperglycemia was defined as ≥130 mg/dl. No defined treatment protocol was designed to control high blood glucose levels. Insulin, OHAs or a combination thereof were used interchangeably. The authors concluded that patients whose initial values had fallen within 48 hours post-stroke showed a mortality similar to those who had euglycemia during the same period of time, opening a research path aimed at controlling hyperglycemia in the acute phase of stroke [201].
In two subsequent pilot studies the primary endpoint was to determine the possibility of intensively controlling blood glucose levels with IV insulin infusion. Although the goals and treatment protocols differed, both arrived at similar conclusions: IIT is possible, well tolerated and has an acceptable safety profile [202-203].
In the United Kingdom, a prospective, randomized controlled phase 3 study was conducted to determine in patients with acute ischemic stroke whether the IIT designed to keep blood sugar levels in the range 72 to 127 mg/dl reduced mortality at 3 months from the event [204]. The intensive treatment regimen included continuous infusion of dextrose 10% together with potassium and human recombinant insulin (GKI) during the initial 24 hours. The study was terminated prematurely because of slow recruitment, however, the material from 933 patients was employed in the analysis.
Although GKI infusion significantly reduced and controlled serum levels of glucose, it also decreased blood pressure (average decrease, 9 mmHg; p <0.0001), and no difference was observed in mortality or in the secondary endpoints in outcomes such as prevalence of severe disabling sequelae [204].
Currently, the University of Virginia in collaboration with the National Institute of Neurological Disorders and Stroke (NINDS) is conducting a prospective, multicenter randomized open-label study to determine whether strict glycemic control provides benefits in the acute phase of ischemic stroke.
Within 24 hours from the onset of symptoms, patients are randomized to one of three treatment arms:

- Control group where blood glucose levels are kept <300 mg/dl and a>70 mg/dl.
- Intensive treatment group with levels maintained between 70 and 110 mg/dl.
- More elastic control group which allows values between 70 and 200 mg/dl.

Insulin is administered by IV infusion in combination with dextrose and potassium and feeding is allowed. Outcome measures are mainly intended to obtain a safety profile of

treatment by analyzing the hypoglycemia event rate. The trial called GRASP (Glucose Regulation in Acute Stroke Patients) completed the enrolment, but the data have not yet been released [205].

66.14.2 Neurosurgical Patients

Two small retrospective studies conducted in Brasil [206] and Australia [207], two completely dissimilar countries in economic, social and cultural context, even with methodological problems such as use of historical controls at the time of comparing heterogeneous populations and different therapeutic ranges among others, drew a similar conclusion: IIT is associated with an increased probability of hypoglycemia without altering mortality or functional neurological status [206,207].
In turn, Bilotta et al. [208], in a randomized, prospective controlled trial, analyzed the safety profile and effectiveness of a protocol of aggressive blood glucose control with continuous infusion of insulin for achieving values between 80-110 mg/dl, versus conventional management aimed at maintaining blood glucose levels >180 and <216 mg/dl, in a series of individuals undergoing neurosurgery. Enteral or parenteral feeding was initiated early with standardized regimens.
The treatment protocol was maintained until discharge from the ICU and/or to the second week after surgery. While the length of intensive care stay and the rate of infection were lower in the intensive treatment group, the risk of hypoglycemia was higher, with no observed difference in mortality or functional outcomes at 6 months postoperatively [209].

66.14.3 Aneurysmal Subarachnoid Hemorrhage

The effects of intensive insulin therapy on patients with aneurysmal SAH secondary to rupture of a cerebral aneurysm were evaluated prospectively by an Italian working group [209]. The analysis included 78 patients who underwent clipping for exclusion of the aneurysm. After the patients were stratified according to their neurological status, they were randomized to receive insulin infusion to maintain blood glucose between 80 and 220 mg/dl or intensive treatment to maintain plasma glucose levels in the range of 80-120 mg/dl. Enteral and/or parenteral feeding was initiated after the first 24 hours. The protocol was extended until discharge from the ICU or until the second week after surgery.
The group that received IIT developed significantly fewer infections than the conventionally treated group (27% vs. 42%; $p < 0.001$), but no benefit was obtained in the prevalence of postoperative vasospasm, mortality and functional outcomes [209]. Latorre recently released the results of a retrospective series in two different time periods [210]. For patients admitted before 2003, the blood glucose values were corrected without a specific protocol only if the levels were >200 mg/dl, while after 2003 glycemia was treated more aggressively with a protocol designed to maintain blood glucose between 80 and 140 mg/dl. There were no differences in the final results between the two groups, showing only a trend for improvement in those patients treated intensively in whom the therapeutic goal or good glycemic control was achieved.

66.14.4 Severe Head Trauma

A very recent study involved 97 patients with severe head trauma (Glasgow Coma Scale [GCS] score ≤8), 60% of whom had space-occupying lesions. The management

of blood glucose was consecutively randomized. Continuous intravenous insulin infusion was regulated with the target set on achieving blood glucose levels 80-220 g/dl (conventional management) versus intensive therapy aimed at maintaining blood glucose 80-120 mg/dl.

The patients undergoing IIT obtained as the only benefit a shorter ICU stay (7.3 vs. 10 days; $p < 0.05$) and double the number of episodes of hypoglycemia recorded for the conventional group in ($p < 0.0001$). Moreover, the infection and mortality rates and functional results during the 6 months follow-up after the event were similar in both treatment arms [211].

Meier et al. [212] retrospectively analyzed 228 severe head-injured patients over two different periods. The effects of IIT were compared in two groups with different goals in terms of blood glucose levels to achieve: the strict control group (63-118 mg/dl) vs. the permissive one (90-145 g/dl). They studied the impact that both treatment modalities had on the number of episodes of hypoglycemia, and the incidence of infections and mortality. Additionally, they analyzed the effect of IIT on intracranial pressure (ICP), ICU stay, and presence of inflammatory markers.

Extensive data are reported that make their interpretation complex. In establishing a cut-off point in the first week post-trauma, during the week itself, the incidence of hypoglycemia, increased ICP and infection rates were higher in the group under strict glycemic control, while during the second week there was a trend to a more efficient management of ICP values. Moreover, there was a trend towards increased mortality during the first 2 weeks in patients undergoing aggressive blood glucose control. The authors concluded that in general IIT with strict goals yields no benefits in this patient population [212].

66.15 Conclusions

Glucose is essential for brain activity as it is the ultimate energy substrate. Because the brain has no energy reservoirs, brain interstitial glucose available for metabolism comes almost entirely from the bloodstream. There is a close relationship between blood and extracellular glucose.

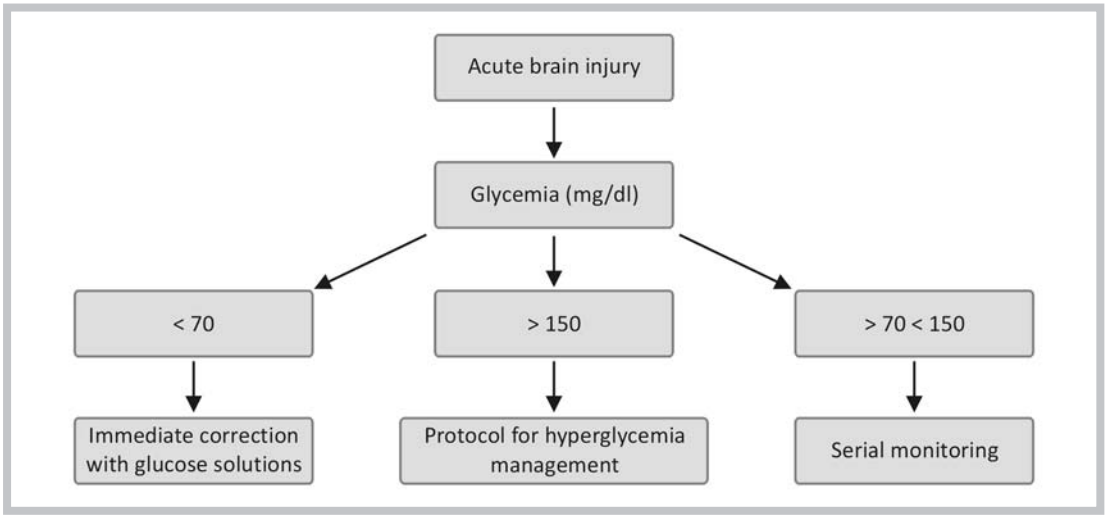

Figure 66.7. Management of acute brain injury.

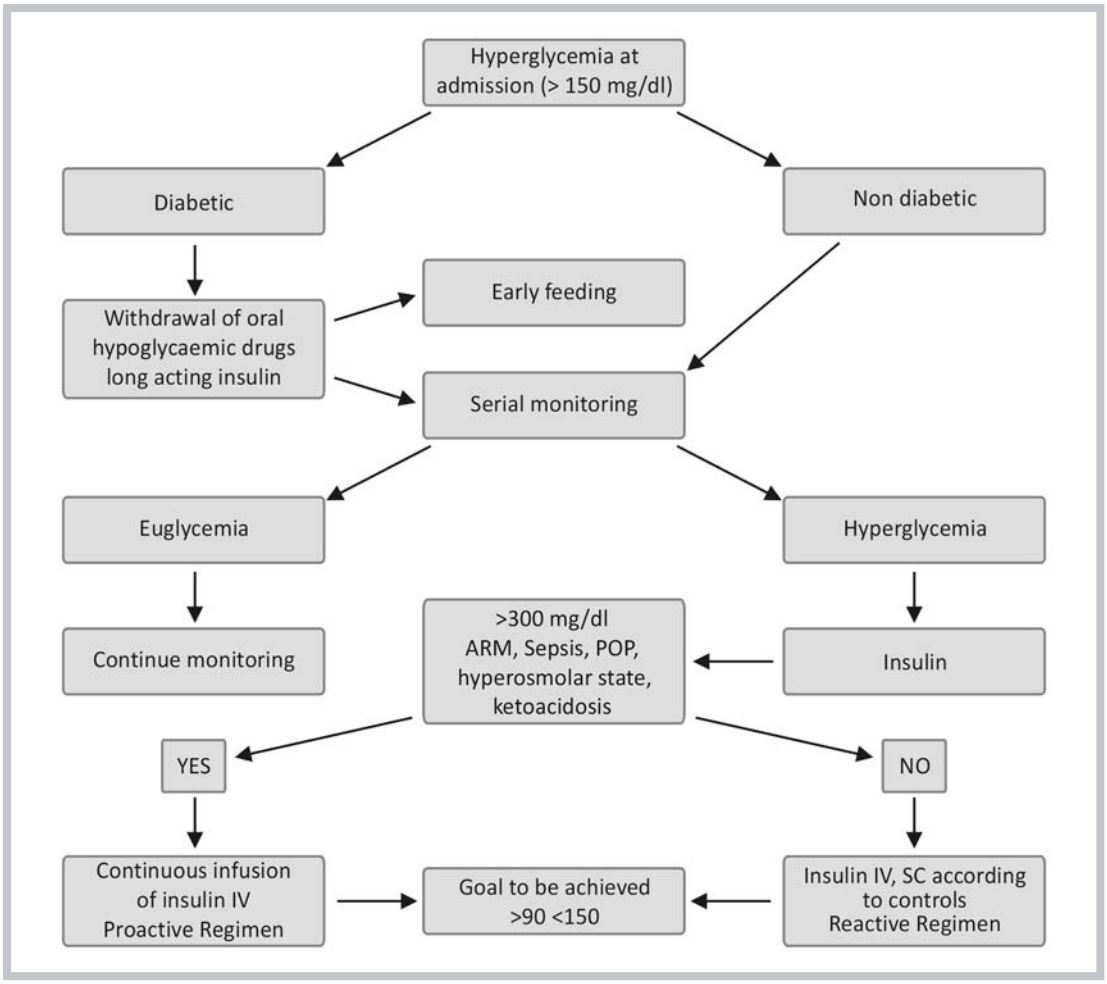

Figure 66.8. **Management of patients with hyperglycemia at admission.**

Physiologically, the brain has the ability to protect and adapt to extreme fluctuations in blood glucose levels. The glucose in the brain parenchyma depends on the balance between the supply and consumption by the cells. By contrast, glucose metabolism and need both increase after injury. The brain becomes more vulnerable to insufficient glucose supply; hence, the decrease in glucose intake is potentially dangerous.

Although available evidence suggests that elevated serum glucose levels or hypoglycemia contribute to secondary damage and worsen prognosis, there is no consensus on delineating the maximum and minimum levels at which blood glucose should be maintained. Treatment to intensively monitor serum glucose levels offers no advantage because it increases the likelihood of hypoglycemia and significantly decreased the concentration of glucose in the extracellular space despite euglycemia, increasing markers of energetic-metabolic dysfunction.

What the available data do suggest is that 150 mg/dl is the threshold at which hyperglycemia must begin to be treated [21,30,81]. In contrast, the lowest safe range has not been clearly defined. Perhaps, it might be broadly set, according to Vespa, as the serum glucose value that does not elicit metabolic disturbances in the brain [213].

Having determined this point, efforts should be directed to determine which method is most appropriate to keep blood glucose within the desired range and whether this is

better than moderate hyperglycemia. Pending the results of specific trials, we cannot recommend aggressive control of blood glucose levels in neurocritically ill patients regardless of the nature of the injury. Figures 66.7 and 66.8 summarize the management.

67 Practical Guidelines for Analgesia, Sedation, Muscular Relaxation, and Delirium Management in Neurocritical Patient

Alejandro Tellería Díaz [1], Ernesto Tellería Díaz [2]

[1] Department for Anesthesiology, Intensive Care Unit, Friedrich Schiller University, Jena, Germany
[2] Intensive Care Unit, Hospital Ortopédico Docente Fructuoso Rodríguez, Habana, Cuba

67.1 Analgesia, Sedation, Muscular Relaxation

Dosis sola venenum facit
[The dose alone makes the poison]
Paracelsus (Swiss alchemist and physician, 1493-1541)

The rapid broad-based development of intensive care medicine now allows the treatment and recovery of patients who some decades ago would have been considered hopeless. At the basis of this achievement lies not only a better understanding of pathophysiological mechanisms or the introduction of new drugs but also the implementation of invasive diagnostic, therapeutic and monitoring techniques. The critically ill patient often faces several potential sources of pain as well as physical and psychological stressors. The relief of pain and suffering is one of our priorities within this setting. The establishment of adequate analgosedation contributes to this goal and influences the prognosis and stay of patients in the the intensive care unit (ICU). Hence, health care professionals need to be familiar with the use of specific groups of drugs and have a proper knowledge of their various pharmacological aspects.

67.1.1 Terminology

Analgesia. A deadening or absence of the sense of pain without loss of consciousness.
Sedation. A drug-induced depression of central nervous system (CNS) activity; its intensity may be minimal (anxiolysis), moderate or deep (Table 67.1). In practical terms, sedation is the process of establishing a state of calm.
"Sedation", analgosedation or sedoanalgesia. Terms used indistinctly in anesthesiology and intensive care medicine to define therapeutic interventions performed to relief pain or provide sedation to reduce the signs and symptoms of pain, anxiety/stress, agitation, and delirium. Additionally, these procedures may include the use of amnesic drugs to prevent the "memory" and subsequent recall of unpleasant experiences or particularly stressful episodes.
General anesthesia refers to a pharmacologically induced and reversible state of unconsciousness (hypnosis) and lack of sensation, with the eventual addition or coexistence of analgesia, muscle relaxation, depression of the autonomic nervous system activity (decreased stress response) and amnesia.

Few seconds following the intravenous (IV) administration of a hypnotic dose of a general anesthetic, the patient loses consciousness and stops breathing. At the same time, airway reflexes are suppressed or impaired (risk of aspiration). Under such circumstances, positive pressure ventilation should be established (i.e., with a face mask, laryngeal mask or tracheal intubation). A properly anesthetized patient cannot be aroused even by means of intense painful stimulation.

Artificial coma, **pharmacological or barbiturate coma** refer to deep sedation or general anesthesia established to help patients recover from injury, serious life-threatening conditions in the ICU, or to protect the brain during or after certain major neurosurgical procedures. Pharmacological coma can be induced by means of different general anesthetic agents; barbiturate coma, for instance, may be used to lower elevated intracranial pressure (ICP) in patients with severe traumatic brain injury (TBI). Other uses include the treatment of refractory status epilepticus, cerebral vasospasm after subarachnoid hemorrhage (SAH), comatose survivors of cardiac arrest, and patients with cerebral edema and elevated ICP of any etiology other than TBI.

Anesthetics. Like narcotics (from the Greek word *narcosis* meaning stupor), anesthetics is a broad term under which the most commonly used drugs in anesthesia are grouped, i.e., opioids, hypnotics and muscle relaxants. Many anesthesiologists prefer to reserve this term for hypnotic or inducing agents, which can be subdivided into two categories: those given intravenously (propofol, midazolam, thiopental, ketamine, etomidate, etc.) and those inhaled (sevoflurane, desflurane, etc.).

Opiates and opioids are two other terms used interchangeably. Opiates are naturally occurring substances derived from opium obtained from the poppy plant (morphine, codeine, thebaine, papaverine, noscapine). The term opioids refers strictly to endogenous (endorphins, encephalin, dynorphins) or exogenous (synthetic agents distantly related chemically to opium's alkaloids) compounds with an intrinsic activity, either agonist or antagonist. Exogenous opioids are subdivided into semi-synthetic (heroin, oxycodone, tramadol, etc.) or synthetic (methadone, fentanyl, sufentanil, remifentanil, meperidine, etc.).

Minimal sedation	• Normal response to verbal stimuli • Cognitive function and coordination may be impaired. • Airway protective reflexes (±) and patency are preserved • Ventilatory and cardiovascular functions are unaffected
Moderate sedation/analgesia (conscious sedation)	• A drug-induced depression of consciousness during which the patient responds purposefully* to verbal command either alone or accompanied by light tactile stimulation • No interventions are necessary to maintain a patent airway** • Spontaneous ventilation is adequate** • Cardiovascular function is usually maintained
Deep sedation	• A drug-induced depression of consciousness during which the patient cannot be easily aroused, but responds purposefully* following repeated or painful stimulation • Independent ventilatory function may be impaired • Patient may require assistance to maintain a patent airway • Spontaneous ventilation may be inadequate • Cardiovascular function is usually maintained

Table 67.1. **Sedation levels according to the American Society of Anesthesiologists (ASA).**
(±) Swallow and gag
* Reflex withdrawal from a painful stimulus is NOT considered a purposeful response
** Patients with restrictive or chronic obstructive pulmonary disease, sleep apnoea, pregnant women, elderly or obese individuals may develop respiratory failure and arterial oxygen desaturation during moderate sedation

In the United States, the term **narcotics** are generally associated with opioids or opiates. The concept of narcotics includes any psychoactive compound with sleep-inducing properties which can also hinder the transmission of pain signals. Unfortunately, there is no anesthetic that fulfils these two requirements. It is true that the isolated administration of high doses of certain opioids can produce unconsciousness in humans. However, their effects are unpredictable and inconsistent. Furthermore, most currently available anesthetics (except ketamine) are simply hypnotics without an analgesic effect. Therefore, from a pharmacological standpoint, "narcotics" it is not an accurate term.
Muscle relaxation or neuromuscular blockade is the reversible paralysis of somatic striated muscle induced by the administration of pharmacological agents that interrupt the transmission of nerve impulses at the level of neuromuscular junction.

67.1.2 Analgesia in the Neurological ICU

Indications: to manage postoperative pain, traumatic injury, subacute or chronic pain, to facilitate tolerance to invasive diagnostic and therapeutic procedures, and to provide care and mobilization of patient by nursing and rehabilitation staff.

Monitoring of Pain

Pain intensity can be recorded on a variety of scales. Rating pain intensity allows the evaluation of the effect of analgesic regimens in individual patients. The numerical rating scale (NRS) is a good option when a patient preserves verbal communication. With this numerical scale, the user has the option to verbally rate the pain on a scale from 0 to 10 (where 0 indicates the absence of pain and 10 the worst pain possible). If verbal communication is not possible (i.e., due to tracheal intubation, speech or language disturbances), a 10 cm line with two end points (representing "no pain" and "worst pain imaginable", respectively), can be drawn on paper (visual analogue scale [VAS]). Patients are asked to rate their pain by indicating or placing a mark on the line corresponding to their current level of pain. The VAS score is determined by measuring in centimetres from the left end of the line ("no pain") to the point that the patient marks. A numerical score ≤3 on the NRS or VAS can be used as evidence of effective analgesia. The use of surrogate signs of pain such as physiological parameters (e.g., blood pressure or heart rate) or elicited behaviors (e.g., facial expression, lacrimation) is an unproven and probably inappropriate practice.

Opiates	• Morphine
Opioids	• Fentanyl • Sufentanil • Remifentanil • Piritramide • Oxycodone • Meperidine • Tramadol • Tilidine

Nonsteroidal anti-inflammatory drugs (NSAIDs)	• Nonselective COX inhibitors:
	  ▪ Metamizol
	  ▪ Ketorolac
	  ▪ Ibuprofen
	  ▪ Dexketropofen
	• Selective cyclo-oxygenase (COX-2) inhibitors:
	  ▪ Parecoxib

General anesthetics	Ketamine
Other drugs	α-2 agonists: • Clonidine • Dexmedetomidine • Radolmidine
Steroids	
Antidepressants	
Anticonvulsants	

Table 67.2. **Pharmacologic options options for analgesia in the neurological ICU.**

In unconscious or paralyzed patients, such signs may include: a transient increase in blood pressure or heart rate; grimaces or running tears; tachypnea when spontaneous respiration is preserved; pupil size changes; or increased muscle tone when the patient is not paralyzed. Practitioners should have a high level of suspicion in front of severe critically ill patients. Routine administration of analgesics is not always a synonym of an effective analgesia. In fact, about 50% of patients discharged from the ICU remember pain as their worst experience while in the ICU.

Pharmacological and Nonpharmacological Options

Pharmacological options are summarized in Table 67.2.

On the other hand, regional anaesthesia techniques encompass: continuous epidural anaesthesia (epidural catheter), plexus block, and peripheral nerve blocks. Other methods such: transcutaneous nerve stimulation, neuromodulation or neurostimulation, intrathecal pump implantation and other surgical procedures (i.e., rhizotomy) may eventually be considered.

Considerations and Precautions

The list of drugs included in the section on pharmacological options is partial. There are many others which for practical reasons will not be covered in this chapter. The availability and preferences for some of these drugs varies according to the country, institution, or personal experience. Similarly, the primary morbid nature of the disorder or the presence of certain accompanying conditions (renal failure, peptic ulcer, etc.) determine their selection and dosage.

- With few exceptions, opiates/opioids administration in hospitalized patients do not cause drug addiction. However, their withdrawal after prolonged administration may trigger rebound hyperalgesia.
- The effective dose of an opioid should be determined by patient response and not by a predetermined notion of what an effective dose should be (Table 67.3).
- Potent opioids induce severe respiratory and cardiovascular depression (Table 67.4).
- Chest wall rigidity, although rare, is another adverse reaction which can be triggered upon opioid administration.
- Potent opioids should administered by personnel familiar with these drugs and in an environment where all conditions for securing the airway and mechanically ventilate be readily available. .

Drug	Initial dose*	Peak effect upon IV administration**	Duration of operative analgesia [$]	Total analgesic effect [#]
Morphine	5-10 mg	15-30 min	(–)	3-5 h
Fentanyl	1-4 μg/kg	4-5 min	20-30 min	1-2 h
Sufentanil	0.1-0.2 μg/kg	2-3 min	30 min	Approx. 2 h
Remifentanil	0.5-0.75 μg/kg	1-1.5 min	5-10 min	Approx. 20 min
Piritramide	0 1 mg/kg	5-15 min	(–)	4-6 h
Meperidine	25 mg	15 min	(–)	2-3 h

Table 67.3. **Initial dose and duration of analgesic effect of some opioids used in anesthesia and intensive care medicine.**

* Required dose (in association with an hypnotic) to blunt the responses to airway stimulation (laryngoskopy, tracheal intubation)

** Time required to exert maximum effect

[$] Duration of maximal analgesia

[#] SIncludes time of maximal analgesia plus residual effect

(–) Not currently used during perioperative analgesia (anesthesia)

Drug	Comparative potency	Administration route	Half-life	Respiratory depression	Peculiarities
Morphine	1	IV, IM, SC, PO, epidural, intrathecal, rectal	114 min	+/++	Gold standard opiate in paliative care. Increases ICP. Its metabolite (morphine-3-glucoronide) may cause myoclonus and seizures
Fentanyl	100-300	IV, epidural, transdermal, intranasal	185-219 min	++++	Increases ICP. High doses rarely cause seizure activity; it is prone to accumulate. It does not cause histamine release
Sufentanil	1000	IV, epidural	148-164 min	+++	Most powerful opioid for use in humans. Chest wall rigidity after IV administration is rare
Remifentanil	200	IV	4-14 min	+++	Higher risk of chest wall rigidity than fentanyl when given by bolus; ultra-short half-life, it does not accumulate
Piritramide	0.7	IV, IM, SC	3-12 h	+/++	Does not induce histamine release; may be administered by bolus every 5-10 min. Good choice for PCA
Meperidine	0.1-0.2	IV, IM, PO, rectal	3.2-4.4 h	−/+	Is the first choice therapy for the treatment of post-anesthetic shivering. Its active metabolite (normeperidine) can accumulate and may trigger seizures, agitation, delirium, myoclonus and tremor
Oxycodone	1.5-2 (oral)	IV, IM, SC, PO, rectal; transdermal, intranasal	4-6 h	−/+	Second-line alternative to oral morphine for palliative cares; risk of addiction. Can trigger migraine. It has a cough suppressant effect. May accumulate in patients with renal or hepatic failure. May be effective in treating neuropathic pain
Tramadol	0.1	IV, IM, PO, rectal	6 h	−/+	Very weak opioid, wich induces serotonin release, and inhibits the reuptake of norepinephrine (eventual antidepressand and sedative effect). May be useful in treating restless legs syndrome. Not recommended in patients with history of seizures. Risk of addiction
Tilidine	0-0.2	IV, IM, SC, PO, rectal	4-6 h	−/+	Weak opioid, which may produce welfare state or euphoria (risk of addiction). Can be used to treat restless legs syndrome

Table 67.4. **Summary of pharmacological aspects of various opioid analgesics.**

- Use of background opioid infusion increases the risk of respiratory depression, especially when combined with sedative drugs.
- While pain antagonizes opioid-induced respiratory depression, sleep can intensify the depressant effects of opioids.
- Respiratory depression secondary to opioid use promotes the retention of carbon dioxide (CO_2).
- Hypercarbia related to respiratory depression may lead to cerebral vasodilatation increasing intracranial pressure (ICP) and thus impairing the condition in patients with poor intracranial compliance, or an acute brain catastrophe.
- When opioids are given intravenously, patients should be closely monitored (respiratory rate, pulse oximetry [SpO_2], ECG, blood pressure). Patients with severe hypercapnia may become somnolent (risk of CO_2 narcosis with respiratory acidosis and possible silent death consecutive to cardiac arrest).
- Caution: patients with respiratory depression and severe hypercarbia may show normal SpO_2 values!
- Fear of respiratory depression, however realistic or exaggerated, represents a major barrier to the most effective use of opioids in management of pain. Although serious complications or deaths from opioid-induced respiratory depression are rare, the risk is not zero, and a death or neurologic injury for a patient with an otherwise treatable illness is a great tragedy.
- Miosis is another side effect associated with opioids and an important sign to be taken into account during neurological examination.
- The anticholinergic effect of opioids, as well as several general anaesthetics, may cause delirium in some patients (see section on agitation and delirium).
- Opioid analgesics may disturb gastrointestinal motility; paralytic ileus can result when these agents are given continuously and in high doses.
- The appearance of tolerance (e.g. tachyphylaxis) is another problem associated with prolonged administration of some of these drugs, in such cases higher doses are needed to achieve the desired therapeutic effect. Dose increments may interfere at the time to perform the neurological examination, and ultimately trigger toxicity phenomena.
- The long-term administration of NSAIDs (mainly non-selective COX inhibitors) is often associated with a risk of bleeding dyscrasias or gastrointestinal bleeding (a relative contraindication in critically ill patients). Platelet aggregation disorders secondary to NSAIDs administration are an unwanted effect in patients with Intracranial bleeding.
- The use of selective COX-2 inhibitors occasionally provides significant pain relief in situations where other NSAIDs and even low-potency opioids are ineffective. This "superior" effect may be related to the particular mechanism of action inherent only to these specific drugs (see section on main drugs).
- Usually, NSAIDs provide good analgesia in neurosurgical patients; the rational use of these compounds can reduce opioid requirements or obviate the need for opioids altogether.
- An effective analgesia contributes to the maintenance of the sleep-wake cycle; pain and sleep deprivation are precipitating of delirium (see section on agitation and delirium).
- Analgesia is not only the act of blunting pain with drugs, but also through proper positioning of the patient, stabilising fractures and minimising harmful physical stimulation. For instance, proper patient positioning and frequent position changes help to prevent or decrease pain in the extremities or in support areas (i.e. back, sacrum, heels). Conscious patients, while intubated and paralyzed (i.e., Guillain-

Barré syndrome), may be experiencing unbearable pains undetected by medical personnel.

- Although regional anaesthetic techniques are an important complement to the analgesia regimen in some critically ill patients, they may be not taken into consideration if the medical staff are not familiar with them.
- The quality and duration of analgesia provided by regional anaesthesia techniques is superior to that offered by opioids or NSAIDs. Epidural analgesia allows the earlier return of bowel function. In addition, regional anesthesia may facilitate mobilization and physiotherapy and often it does not require complementary sedation. Under the effects of regional anaesthesia (i.e., thoracic epidural anaesthesia) both early mobilization of patient and normal thoracic excursions are guaranteed. Facilitating early mobilization and normal respiratory function allows early rehabilitation treatments and helps to reduce the incidence of complications such as atelectasis, pneumonia and thromboembolic events consecutive to deep vein thrombosis.

67.1.3 Sedation in the Neurological ICU

Anxiety, agitation and delirium represent diagnostic and therapeutic problems (see section on agitation and delirium). Increased physical activity during episodes of agitation increases oxygen consumption (VO_2) and the risk of self-harm (extubation, catheter dislocation, etc.). Moreover, sedation can interfere with the neurological examination. Talking to patients and making adjustments in the ICU environment should be the first steps to calm an anxious patient. However, in this setting drugs are often needed to calm patients. Anxiety and pain may be interrelated: pain is a major source of anxiety, and anxiety may lower the threshold for pain per¬ception. Sedation should only be performed by a qualified medical professional experienced in working with sedatives and who understands their potential side effects.

Chronic obstructive pulmonary disease patients or patient with obstructive sleep apnea are particularly prone to hypoxia during sedation treatments.

Patients with intracranial haemorrhage who preserve consciousness and may still rebleed need to be sedated. Sedation in these cases is aimed to ensure patient comfort but also to attenuate sympathetic activity. This simple measure can help to prevent unwanted events like tachycardia, sustained hypertension or systolic peaks. Similarly, patients at risk for secondary brain injury from cerebral edema and intracranial hypertension may benefit from sedation

Sedation in the neuro-ICU or general ICU as premedication is also an important

- Anxiety
- To induce amnesia
- To manage experiences after adverse life events (serious injury, mutilation, loss of loved ones, etc.)
- Mechanical ventilation
- Agitation with:
  - Risk of self-harm or harm to others
  - Risk of self-extubation, removal of catheters, venous lines, invasive monitoring devices, etc.
- Intracranial hemorrhage with risk of rebleeding
- Withdrawal syndrome (illicit drugs abuse, alcohol, etc.)
- Intracranial hypertension
- Refractory hypertension or sympathetic hyperactivity
- Recurrent seizures or status epilepticus
- Premedication before surgery
- Deep sedation during the immediate postoperative period in some patients with the aim to:
  - Reduce cerebral oxygen consumption to prevent the extension of injury or to ensure a faster recovery of central nervous system (CNS) function
  - Prevent certain complications such as rebleeding, sudden increases in ICP or blood pressure, seizures, etc.

Table 67.5. **Indications for sedation in the neurological ICU.**

component of the preoperative management for patients undergoing surgical procedures. Premedication should be reduced or withheld in the elderly, chronic obstructive pulmonary disease patients, or patients with obstructive sleep apnea, severe neurologic deterioration, or those candidates for awake or fiberoptic-assisted tracheal intubation e.g., cervical trauma, narrowed oral aperture (dermatomyositis, scleroderma, etc.). Indications for sedation are summarized in Table 67.5.

Monitoring

There is a wide variety of scoring systems to monitor sedation (Tables 67.7 and 67.8). These scores provide information about the grade of sedation but not about its quality, in addition, scoring indexes carry the potential for variability in measurements. Sedation scores are not intended for patients who are unconscious or receiving neuromuscular blocking agents.

In principle, most of these scores (see section on agitation and delirium) were created to evaluate patients admitted into general ICU, therefore, the inclusion of several important aspects of neurological evaluation were not included during their designs. These limitations should not be ignored considering how crucial neurological examination is to assess the effectiveness of treatment and the outcome of patients admitted to the neuro-ICU.

The bispectral index (BIS) is another alternative to monitor the depth of sedation. BIS monitors are noninvasive devices that reflect -into a single number- a signal-processed electroencephalogram (EEG). This technology was first developed as an adjunctive method of monitoring anesthesia states during surgery. Basically, it compares the patient's frontal EEG to processed data set from over 5000 volunteer EEG samples to scale the output of the measured EEG to between 0 and 100. A "fully awake state" is scored 100, whereas 0 is an isoelectric EEG reading; a score < 60 rates a high probability of unconsciousness. The aim during intraoperative monitoring is to achieve a score between 40 and 60, while sedation targets are typified by ranges of 60-75. Whether the use of BIS reduces drug doses, costs, length of mechanical ventilation or the length of ICU stay is controversial. Its main disadvantage is that it is best used when administering a short acting anesthetic (i.e., thiopental, propofol) on which the processed EEG algorithm is based. Agents such benzodiazepines, opioids or other classes of sedatives differentially influence the EEG and BIS is not programmed to interpret such changes. The Narcotrend index is other monitoring tool based on EEG pattern recognition during anesthesia or sedation. This technology has been developed in Germany and at present it is being use to assess the depth of sedation in several ICUs.

67.1.4 Pharmacological and Non-pharmacological Options

Pharmacological options are summarized in Table 67.6.

Non pharmacological options include: psychotherapy, background music, establishing effective communication with patients, and allowing flexible visiting hours, etc.

Considerations and Precautions

- When possible, sedation treatments that may interfere with neurological examination should be avoided. The goal of sedation in the ICU is a patient who is calm but easily arousable. Non-pharmacological options decrease sedative and analgesic requirements.
- A prolonged amnesia is not desirable, since it may interfere with long-term neuropsychological recovery.

- With few exceptions (e.g. morphine, tramadol) , opioids are not first-line sedation drugs because their sedative effect is usually achieved at higher doses than those required to produce analgesia. Agitation secondary to pain justifies the use of these drugs as sedatives (caution: consider side effects).
- Unlike opioids, therapeutic doses of benzodiazepines do not cause respiratory depression in healthy subjects, but this effect can occur in select ICU patients (Table 67.1).
- Airway protection often becomes insufficient after deep sedation.
- Paradoxical effects may occur upon administration of benzodiazepines (see chapter on agitation and delirium).
- Consider that all major antidepressant drugs, except trimipramine, mirtazapine and nefazodone suppress rapid eye movement (REM) sleep.

Benzodiazepines	• Midazolam • Lorazepam • Diazepam
Non-benzodiazepine GABA-A agonists	• Zopiclone • Zolpidem
Neuroleptics	• Haloperidol • Droperidol • Levomepromazine
Anesthetics	• Propofol • Thiopental
Barbiturates	• Thiopental • Pentobarbital • Phenobarbital
α_2 agonists	• Clonidine • Dexmedetomidine
Opiates or opioids	• Morphine • Fentanyl • Sufentanil • Remifentanil • Piritramide • Tramadol
Antidepressants	
Antihistamines	• Diphenhydramine • Hydroxyzine

Table 67.6. **Sedation: pharmacological options.**

67.1.5 Analgosedation

Pain and anxiety are frequently concurrent in critically ill patients. Analgosedation (or "sedation") is an essential therapy in the ICU where patients may be sedated for many hours and even days, largely because of their dependence on mechanical ventilation but also because of their poor general condition, post surgical or traumatic injuries, high treatment and monitoring invasiveness, nursing maneuvers, sleep deprivation, etc. The relief of pain and anxiety is not only a humanitarian gesture but also serves to attenuate the stress response (tachycardia, hypertension, increase of VO_2), which may be poorly tolerated by some patients. Increased VO_2 can have deleterious effects on patients with ischemic stroke, ischemic heart disease, anaemia, or acute respiratory distress syndrome (ARDS). Furthermore, there is some evidence that optimising analgesia may prevent wound infection, by improving the subcutaneous oxygenation.

However, sedation poses many problems since it is difficult to titrate. Inadequate, light sedation may lead to hypertension, tachycardia, and poor ventilator synchrony, producing stressful experiences, which sometimes are responsible for long-term psychological effects and the so called "post-traumatic stress disorder".

On the other hand, providing adequate and appropriate sedation for patients in prolonged or long-term mechanical ventilation is often a difficult task . Over-sedation, side effects, tolerance, ceiling effect and withdrawal symptoms are among the problems to be faced in this setting. Therefore, the medical personnel involved in this task should be aware to detect and treat such unwanted effects early.

When weaning neurological ICU patients from the ventilator and approaching extubation it has to be acknowledged that conventional ICU criteria for weaning and extubation can only have an orienting character and that dysphagia is much more frequent in these patients.

67.1.6 Peculiarities in Neurocritically Ill Patients

- In the setting of sedation, serious neurological events may be occurring and go undetected and untreated. For instance, in a neuro-ICU setting, the rates of nonconvulsive status epilepticus are as high as 35%.
- Certain specific aspects of brain-injured patients should be taken into account. These include interactions of drugs with intracranial pressure, disturbed autoregulation, a higher frequency of seizures and an increased risk of delirium.
- Patients with acute brain insult are mostly intubated, ventilated and sedated; neurological examination may be difficult, and the insult severity can be over-estimated.
- The lesions responsible for brain damage can evolve during the initial hours and, unfortunately, continuous sedation can mask important changes that can only be identified by clinical examination. For these reasons, the strategy of repeated wake up tests (WUt) is often used for reliable assessment.
- Patients with preexistent neurologic impairment are more sensitive to the sedative effects of multiple medications and may take a prolonged time to awaken from sedation or general anesthesia.
- When weaning neurological ICU patients from the ventilator and approaching extubation it has to be acknowledged that conventional ICU criteria for weaning and extubation can only have an orienting character and that dysphagia is much more frequent in these patients.

67.1.7 Key Points of Analgosedation

- Analgosedation is a combination therapy: a strong opioid analgesic plus a sedative, with the eventual addition of supportive drugs (e.g. clonidine). Drug combinations provide analgesia and anxyolisis, and reduce hypnotic dose requirements.
- Combine drugs according to patient's disease and expected sedoanalgesia duration (see SeSAM).
- The administration of drugs must be individualized based on the patient's response.
- Consider periodic dose adjustments: administer as much as is necessary, and as little as possible.
- Total pain suppression is not always desirable, since changes in pain intensity may be an indicator of illness course. A numerical score of 3 or less on the NRS or VAS can be considered as effective analgesia.
- Inadequate sedation complicates daily ICU tasks and management of ventilation; excessive sedation promotes difficulties in weaning and may delay enteral feeding.
- Whenever possible, etiological diagnosis should be addressed in case of pain and agitation. Does pain led to agitation, or does agitation obey to another disorder?
- Ideally, drug doses should be titrated to the minimum required to maintain patient comfort, and to allow a normal sleep pattern; promoting daily interruption of sedatives significantly improve clinical outcomes and reduce ICU stay. Nevertheless, it should be considered that, daily sedation holds (i.e., WUt) are not possible or appropriate in all patients.
- Avoid neuromuscular blocking agents whenever possible. However, neuromuscular relaxants may be required to treat certain conditions (e.g., refractory intracranial hypertension), or when IV sedatives and analgesics have proven ineffective in facilitating mechanical ventilation.
- Neuromuscular blocking agents do not produce analgesia or sedation and, because paralysis is an extremely frightening and even painful experience, it is imperative to establish the desired levels of sedation and analgesia before initiating drug-induced paralysis.

- Consider, some patients may require higher doses of sedatives and analgesics (e.g., alcoholics, drug addicts, smokers, patients undergoing hemofiltration). Conversely, opioid analgesic and sedative requirements can be less in elderly, renal failure or due to the synergism with other drugs.
- The potential for opioid, benzodiazepine, and propofol withdrawal should considered after high doses or more than seven days of continuous therapy. Doses should be tapered systematically to prevent withdrawal symptoms, e.g., 10-15% medication reduction every 6-8 h when sedation treatment lasted less than seven days, or 10-15% dose reduction per day by long-term sedation treatments (>10days).
- Consider, antidepressants may be required at the weaning time.
- According to a recent study, previous antidepressant use is associated with higher mortality in critically ill patients; however, the findings do not suggest the drugs cause deaths.

Sequential Analgosedation Management (SeSAM)

Category I (SeSAM I)

Sedation up to 24 h: e.g., short-term intubated patients including: drug overdose patients, short-term postoperative ventilation, etc. Drugs: 2% propofol (or midazolam IV by bolus), with a low potency opioid (i.e., piritramide 7.5 mg every 4-6 h), and the eventual addition of NSAIDs.

Category II (SeSAM II)

Sedation for 24-72 h (original concept), currently up to 7 days: e.g., patients who have not totally recovered within the first 24 hours; patients with multiple or serious underlying disease undergoing major surgery; patients in whom immediate weaning is unlikely (e.g., patients with extensive lung damage, patients undergoing brainstem surgery, etc.). Drugs: 2% propofol with sufentanil (separated infusion pumps). Regional anaesthetic techniques or clonidine may be added.

Category III (SeSAM III, stage 1 and 2)

Sedation for a period longer than 7 days.

Stage 1: e.g., for critically ill patients (severe TBI or polytrauma , sepsis, ARDS, etc.) in whom ventilation and sedation are essential components of treatment. During stage 1, patients undergo deep sedation (Ramsay Score 4-5). Drugs: midazolam and sufentanil IV (separated infusion pumps); ketamine/ketamine-S and sufentanil is an¬other alternative.
Stage 2: After stabilizing the patient, and when weaning is intended (Ramsay Score 2 during the day). Use drugs recommended for SeSAM II (propofol/sufentanil/clonidine).

Category IV (SeSAM IV)

Brief sedation (2-5 h): deep sedation (Ramsay Score 4-5) for few hours, striving to early spontaneous breathing. Drugs: e.g., propofol and remifentanil IV (separated infusion pumps).

Score	Clinical description	Assessment of sedation
0	Awake and fully oriented	Awake
1	Anxious and agitated or restless, or both	Insufficient
2	Cooperative, oriented and tranquil; e.g., tolerates mechanical ventilation	Optimal
3	Sedated, responds to commands	Suitable
4	Asleep, but with brisk response to light glabellar tap or loud auditory stimulus	Suitable
5	Asleep, exhibits a sluggish response to light glabellar tap or loud auditory stimulus	Deep
6	Asleep, exhibits no response	Too deep

Table 67.7. **Ramsay Scale (1974) with sedation assessment (modified).**

Agitation	1. Unresponsive to command or physical stimulation 2. Appropriate response to physical stimuli, state of calm 3. Mild anxiety, delirium, agitation (patient calms down easily) 4. Moderate anxiety, delirium, agitation 5. Severe anxiety, delirium, agitation
Alertness	1. Difficult to arouse, eyes remain closed 2. Mostly sleeping, eyes closed 3. Dozing intermittently, arouses easily 4. Awake, calm 5. Wide awake, hyper-alert
Respiration	1. Intubated, no spontaneous effort 2. Respirations even, synchronized with ventilator 3. Mild dyspnea/tachypnea, occasional asynchrony 4. Frequent dyspnea/tachypnea, ventilator asynchrony 5. Sustained, severe dyspnea/tachypnea
Patient classification (sedation goal)	Acutely ill (weaning not a goal) (5-9)
	Ventilated patient being weaned (7-10)
	Chronic ventilated patient (weaning not a goal) (6-9)
	Nonventilated patient (7-9)

Table 67.8. **AVRIPAS Scale (2001). Modified from [Avripas, 2001].**

Sedation Using Inhalational Anesthetics

The ideal IV sedative does not exist. Inhalational anesthetics are a feasible alternative, which have often shown better performance when compared to IV drugs. Unfortunately, most ICU-settings do not have the proper devices or facilities to administer inhalational anesthetics, and in many cases, the ICU staff is not familiar with the pharmacology, physiologic effects, and handling of volatile anesthetics.

Volatile anesthetics, for instance, have usually a quick onset of action, and their emergence time are shorter and more predictable than IV sedation. Inhalational anesthetics accumulate very little, and elimination via the lungs is independent of liver and kidney function. Volatile anesthetics act primarily on the cerebral cortex, and even at low concentrations may completely depress consciousness while leaving many autonomic functions undisturbed (e.g., breathing, temperature control, and blood pressure regulation). These characteristics, and others like a cardiovascular protective effect, make inhalational anesthetics an almost ideal sedative in general ICU-settings. However, regarding neurocritically ill patients, it has to be taken into account that volatile anesthetics increase ICP, and may trigger malignant hyperthermia in the setting of myopathy. Therefore, studies have to be performed in order to evaluate the impact of this attractive sedation modality in neuro-ICU settings.

67.1.8 Muscular Relaxation in the Neuro-ICU

Optimal administration of analgesics and sedatives, as well as the application of certain modalities of mechanical ventilation (i.e., biphasic positive airway pressure [BiPAP]) have led to a substantial reduction in the use of muscle relaxants in the ICU settings. Currently, less than 10% of ICU patients receive neuromuscular blocking agents. These drugs are not devoid of side effects. Their long-term administration has been associated with the development of a group of neuromuscular disorders (i.e. critical illness myopathy, cachectic myopathy, or necrotizing myopathy, among others). The relationship between these my¬opathies and the administration of muscle relaxants and high-dose cor-

ticoesteroids remains controversial. At present, certain metabolic derangements like hyperglycemia are being considered as a major risk factor for ICU-acquired neuromuscular disorders. Indications are summarized in Table 67.9.

- Facilitation of tracheal intubation
- Brief bedside invasive or surgical procedures
- Severe refractory intracranial hypertension
- Transport, facilitation of diagnostic procedures
- Eventually in the management of refractory status epilepticus
- Severe pulmonary disease with inability to mechanically ventilate
- Reversion or reduction of lung hyperinflation (air trapping, auto-PEEP, etc.)
- Nonconventional ventilation modes: high frequency ventilation, prone positioning, etc.
- Treatment of muscle spasms related to drug overdose or tetanus
- Eventually in the treatment of shivering, therapeutic hypothermia
- Extreme agitation in sedated and ventilated patients
- Management of chest wall rigidity secondary to opioid administration
- Preservation of delicate reconstructive surgery

Table 67.9. **Indications for muscular relaxation in the neurological ICU.**

Monitoring

Monitoring of neuromuscular function after the administration of neuromuscular blocking agents is extremely important for appropriately dosing these agents and to better guarantee patient safety. The depth of neuromuscular blockade, as well as residual neuromuscular blockade may be monitored by performing clinical manoeuvres or by using peripheral nerve stimulators.

Clinical manoeuvres include the head lift (at least 5 seconds with patient supine at 180°), the handgrip, or the assessment of inspiratory force (at least 40 cmH2O), among others. Examination of these signs usually takes place before extubation.

On the other hand, the peripheral nerve stimulator allows another group of tests, which encompass the single twitch, the train of four (TOF), the double burst stimulation, and the tetany. These monitoring techniques are simple and can be performed at the bedside. TOF is very likely the standard method of monitoring drug-induced neuromuscular blockade (Figure 67.1).

Figure 67.1. **Peripheral nerve stimulation. TOF test in the forearm. The electrodes are placed on the ulnar nerve and the thumb is extended for better test execution; an intensity of 40 mA is sufficient for correct stimulation. Other site options for electrode placement include posterior tibial, and facial.**

It denotes four successive stimuli in 2 seconds (2Hz). The twitches in a TOF pattern progressively fade as relaxation increases. Disappearance of the fourth twitch represents a 75% block; the third and the fourth twitches an 80% block; and the second, the third and the fourth twitches a 90% block. Clinical relaxation usually requires 75-95% neuromuscular blockade, in other words: the desired goal is 1 or 2 perceptible twitches, and the drug administration is adjusted to achieve that end-point; total absence of thumb adduction is evidence of excessive block (overdose), peripheral nerve stimulator malfunction, or improper electrodes positioning. Cautions: microshock from nerve stimulators may pose a risk to patients with implanted cardiac defibrillators (ICDs); electrical stimulation of these tests can be very uncomfortable in the awake patient; severe edema may prevent proper nerve stimulation.

At the time of extubation it should be taken into consideration that clinical observations and the use of peripheral nerve stimulator provide useful but not necessarily infallible information: an individual can lift his head for 5 seconds or longer, even when 50% of their muscle fibbers are relaxed. Similarly, the four twitches of TOF may manifest even with 70% block. Pharmacologic options for muscular paralysis are shown in Table 67.10.

Depolarizing muscle relaxants	• Succinylcholine
Nondepolarizing muscle relaxants	• Rocuronium • Cisatracurium • Mivacurium • Pancuronium

Table 67.10. **Pharmacological options for muscular relaxation.**

Considerations and Precautions

- Use neuromuscular blocking agents only when indicated. Administer the lowest effective dose, and for the shortest time necessary.
- Neuromuscular blocking agents can be avoided in most critically ill patients, when analgosedation regimens are sufficient. Airway maintenance is mandatory in patients under pharmacologic paralysis.
- The selection of neuromuscular blocking agents is based on certain criteria, i.e., reasons for its use, expected duration of paralysis, characteristics of primary disorder, personal medical history (underlying conditions e.g., renal failure, myopathies, etc.).
- The absence of coughing during paralysis impairs the clearance of respiratory secretions; pooling of secretions can lead to atelectasis and ventilator associated pneumonia.
- Succinylcholine increases ICP and intraocular pressure (unwanted effects in TBI, brain tumor, intracranial hemorrhage, glaucoma and open eye trauma).
- Loss of the milking action of muscle contraction on the venous return from the legs predisposes to venous thrombosis during neuromuscular paralysis; prophylaxis for venous thrombosis is mandatory under these circumstances.
- Other complications of continuous muscle relaxant use include increased incidence of skin pressure ulceration, and the possibility that a patient may be aware and/or in pain, but unable to express discomfort because of the paralysis.
- Neuromuscular paralysis makes neurological examination unreliable.
- Following situations should be avoided in paralyzed and ventilated patients: malfunction or accidental disconnection from ventilator; paralysis without sedation; accumulation of tracheobronchial secretions; corneal injury; overdose or unnecessary long lasting muscle relaxant administration with accumulation; adverse drug interactions (e.g., with aminoglycosides, steroids, furosemide, etc.).
- Tolerance can develop with prolonged administration.
- The effect of non-depolarizing muscle relaxants can be antagonized (i.e., neostigmine + atropine), the reversal should be attempted when at least 2 twitches of the TOF are present.
- Prolonged paralysis may be observed after a single dose of succinylcholine or mivacurium. This phenomenon is mostly related to a congenital enzyme (pseudocholinesterase) deficiency.
- Neuromuscular blocking drugs can be associated with prolonged periods of muscle weakness after the drugs are discontinued. Consider residual drug effect, or underlying conditions that may predispose to neuromuscular weakness (e.g., critical illness polyneuropathy).

Main Drugs for Analgesia, Sedation, and Muscular Relaxation

Morphine (Analgosedation in Ventilated Patients)

Dose: 1-3-5 mg IV bolus; e.g. 3-10 mg/h

Morphine is the "gold standard" opiate analgesic in palliative care. However, its use for long-term analgosedation in ICU settings in Germany is uncommon.

Tips for infusion pump preparation (50 ml syringe): 1st option, morphine ampoule 10 mg/1 ml; 50 mg morphine (5 ampoules) plus 20 ml NaCl, infusion rate 2-3 ml/h. 2nd option, morphine ampoule 10 mg/1 ml; 100 mg morphine (10 ampoules) plus 40 ml NaCl, Infusion rate 2-3 ml/h. 3rd option, morphine ampoule 100 mg/10 ml; 100 mg morphine (1 ampoule) plus 40 ml NaCl, Infusion rate 2-3 ml/h.

Cautions: do not use in patients with head trauma, since it moderately increases ICP (unknown mechanism, not related to hypercapnia). Risk of hypotension (not recommended in patients with hemodynamic instability) and bronchospasm due to histamine release. Its use in the ICU has been associated with a high incidence of delirium. One metabolite (morphine-3-glucoronide) can produce myoclonus and seizures. Risk of accumulation in patients with renal failure. Immunosuppressive effect.

Fentanyl (Analgosedation in Ventilated Patients)

Tips for infusion pump preparation (50 ml syringe): fentanyl ampoule 0.5 mg/10 ml; 1.5 mg fentanyl (3 ampoules) plus 20 ml NaCl 0.9% (= 30 μg/ml). Dosage: 1-3.5 μg/kg/h = 2-12 ml/h = 60-360 μg/h.

Dose adjustments are not need in renal failure. Fentanyl is preferred to other opioids for patients with hemodynamic compromise; it does not cause direct histamine release.

Cautions: like morphine, fentanyl also moderately increases ICP. Fentanyl is not easily controllable since it causes prolonged drug effects as a result of drug accumulation in fatty tissue when using continuous infusion; it may also trigger chest wall rigidity or skeletal muscular rigidity when given by bolus. High doses of fentanyl rarely cause seizure activity. Fentanyl exert a powerful respiratory depressant effect (Table 67.4).

Sufentanil (Analgosedation in Ventilated Patients)

Sufentanil is very likely at present, the most common used opioid for analgosedation in ICU settings.

Tips for infusion pump preparation (50 ml syringe): 1st option, sufentanil ampoule 0.25 mg/5 ml; 0.5 mg sufentanil (2 ampoules) plus 40 ml 0.9% NaCl (= 10 μg/ml). Dose: 0.5 to 1.5 μg/kg/h = 2-10 ml/h = 20-100 μg/h.

2nd option, sufentanil ampoule 1 mg/20 ml; 1 mg sufentanil plus 20 ml 0.9% NaCl (=25μg/ml). Dosage 0.5 to 1.5 μg/kg/h = 0.8-4 ml/h = 20-100 μg/h.

Sufentanil is the most powerful opioid currently available for use in humans (about 1000 times the efficacy of morphine) (Table 67.4). **Carfentanil**, another analogue of fentanyl with a potency 10,000 times greater than morphine, is intended for large animal use only (e.g. bears) as its extreme potency make it inappropriate for use in humans.

Remifentanil (Short-term Analgosedation in Ventilated Patients)

Tips for infusion pump preparation (50 ml syringe): remifentanil 1 mg lyophilized vial, 1 mg of remifentanil in 50 ml NaCl 0.9% (= 20 μg/ml). Remifentanil is also supplied as 2 mg and 5 mg lyophilized powder vials.

Dosage: 0.04 -0.1 μg/kg/min = 2.5 to 6 μg/kg/h = 0.1-0.3 ml/kg/h.

Remifentanil is an ultra-short acting opioid (Table 67.4). Interruption of its infusion lead to rapid offset of effect. Rapid clearance and lack of drug accumulation result in rapid dissipation of analgesic effect, therefore, an alternative analgesic therapy should be anticipated and administered in a timely fashion prior to discontinuation of remifentanil (e.g. piritramide).

Caution: rapid bolus doses of remifentanil should not be given, specially in awake patients, since they may trigger unpleasant and unwanted side effects like respiratory depression and chest wall or skeletal muscle rigidity (a neuromuscular blocking agent or a μ-opioid antagonist may be required to facilitate assisted or controlled respiration).

Piritramide

It's a synthetic opioid mostly used for post-surgery pain in several European countries. Its potency is about 0.7 times that of morphine (Table 67.4). Piritramide is a long-lasting drug, what allows intermittent bolus administration. After a single IV or IM injection of 15 mg, pain can be relieved for 4-6 h. Its effect is similar to morphine, although with greater sedative effect and lower likelihood of hypotension; nausea and vomiting are among the side effects observed in some patients.

Figure 67.2. **Patient-controlled analgesia (PCA) system. The dose by bolus, the dose intervals, and the maximum total dose are preset before allowing the patient to self-regulate analgesia; in this way, accidental overdosing or abuse of the medication by the patient is prevented.**

In our environment, 3 mg IV bolus doses are given to adults every 15 minutes up to a maximum of 30 mg in 4 hours; in some cases the first bolus may consist in a loading dose of 7.5 mg of piritramide or higher. Piritramide is also a good choice for "patient-controlled analgesia" (PCA). This method is only suitable for patients who are awake and capable of drug self-administration (Figure 67.2).

Meperidine

Was the first synthetic opioid synthesized in 1932. At present, this drug is no more effective in managing pain than other opioid analgesics (Table 67.4), and its use is associated with a variety of severe side effects (i.e. neurotoxics e.g., seizures, delirium, dysphoria, tremor). These features led to decline in the use of this opioid as analgesic. Although not advised as an analgesic in the ICU, meperidine is still the first choice therapy for the treatment of post-anaesthetic shivering (PAS). Dosage: 25 mg meperidine IV every 4-6 h. Caution: meperidine may trigger tachycardia; one of its metabolites (normeperidine/norpethidine) can accumulate with repeated doses, and this accumulation is more pronounced when renal function is impaired. Normeperidine is toxic and has convulsant and hallucinogenic effects. These toxic effects cannot be countered with opioid receptor antagonists (e.g. naloxone); meperidine should not be administered to patients under concurrent antidepressant therapy with selective serotonin reuptake inhibitors or monoamine oxidase inhibitors.

Parecoxib

Is a selective cyclooxygenase-2 (COX-2) inhibitor for parenteral administration, approved in the European Union for the short-term treatment of post-operative pain in adults. This NSAID is an attractive alternative in the treatment of postoperative pain because of the potential for fewer gastrointestinal events. Parecoxib is supplied in 20 mg or 40 mg powder vial and solvent for solution for injection.

Dosage and administration: 40 mg by IM or IV injection, followed every 6 to 12 hours by 20 mg or 40 mg as required to a maximun of 80 mg per day.

Some years ago, certain selective COX-2 inhibitors (i.e., Rofecoxib® or Vioxx®) were taken off the market because of concerns about increased risk of heart attack and stroke

associated with long-term high-dosage use. However, further studies have also shown that some nonselective COX inhibitors are not entirely devoid of similar adverse effects. Selective COX-2 inhibitors (or "coxibs") may be regaining interest since it recently has been shown, they exert an analgesic effect not only by inhibiting prostaglandin synthesis, but also by increasing the availability of endocannabinoids in the CNS (i.e. spinal cord) and thus hampering the central sensitization process . The latter mechanism could explain the eventual superiority of coxibs over nonselective NSAIDs and low potency opioids. However, these observations have yet to be tested.

Ketamine (Analgosedation in Ventilated Patients)

Tips for infusion pump preparation (50 ml syringe): ketamine ampoule 500 mg/10 ml; 1.5 g ketamine (3 ampoules) plus 20 ml NaCl 0.9% (= 30 mg/ml)

Dosage: 0.5-4.5 mg/kg/h = 2-10 ml/h = 60-300 mg/h

Ketamine is different from most other anesthetics in that it has significant analgesic effect. It does not usually depress the cardiovascular and respiratory system. However, with the use of adjuvant sedatives or anesthetic drugs, respiratory depression can develop. Ketamine is also bronchial smooth muscle relaxant (good choice for acute asthma exacerbations), but it does possess some worrisome adverse effects. For instance, ketamine has a propensity to cause hypertension and tachycardia (increasing myocardial oxygen consumption) specially when given by bolus. Thus, ketamine is contraindicated in patients with ischemic heart disease. Likewise, it is unwise to give ketamine to patients with vascular aneurysms because of the possible sudden change in arterial pressure. The potential of ketamine to induce delirium has also to be taken into account, although this can be prevented by the concomitant administration of low doses of benzodiazepines. Other sides effects include hypersalivation, increased production of tracheal secretions, nystagmus, laryngospasm and increase in pulmonary resistance.

Ketamine has been suggested as an adjunctive treatment for refractory status epilepticus. In addition, to antiepileptic effects ketamine may induce neuroprotection.

Traditionally, ketamine has been avoided in the management of patients with TBI owing to concerns that it may increase intracranial pressure. However, several recent studies have refuted the original findings and showed no statistically significant rise in ICP in brain injured patients who are sedated with ketamine. Thus, ketamine is a safe and effective sedative agent to use in patients with TBI. Unlike opioids, ketamine does not alter gastrointestinal motility, which is of great benefit in critically ill patients.

Synergy between ketamine and opioids reduces dose requirements. Additionally, ketamine as an NMDA antagonist prevents the risk of developing secondary opioid withdrawal hyperalgesia during weaning; the addition of magnesium (0.08 g/kg/day adjusted according to renal function) makes ketamine more efficient in synergy.

Caution: ketamine produces undesirable psychological reactions (e.g. illusions, disturbing dreams, extracorporeal experiences, etc.). Therefore, it should not be given as monotherapy for analgosedation; its combination with other drugs (e.g. benzodiazepines) is recommended.

Propofol (Sedation in Ventilated Patients)

Propofol is an ultra short acting anesthetic with no analgesic activity. Due to its short duration of action, propofol should be given as continuous infusion for sedation.

Caveat: propofol for ICU sedation should be restricted to patients over 16 years of age, for up to 7 days, and to a maximum dose of 4 to 5 mg/kg/h (see bellow).

Tips for infusion pump preparation (50 ml syringe): 2% propofol vial (20 mg/ml); pure.

Dosage: 0.8 to 3 mg/kg/h (0.01-0.05 mg/kg/min) ≈3-10 ml/h = 60-200 mg/h

Propofol is dosed based on ideal rather than actual body weight, and no dose adjustment is required for moderate hepatic insufficiency; propofol's metabolites may accu-

mulate during acute renal failure. In elderly patients and sicker patients, the infusion rates that are necessary are markedly reduced. Since propofol provides no analgesia, concurrent analgesics are needed for pain. Propofol may cause hypotension, especially when given by bolus; a fall in mean arterial blood pressure (MAP) may reduce the cerebral perfusion pressure (CPP) if this is not mitigated with adequate fluid resuscitation and vasopressors. Hemorrhagic shock greatly enhances the hypotensive effects of propofol, even after resuscitation with IV fluids. Other side effects include hypertriglyceridemia (usually after 3 days continuous infusion), immunosuppressive effects, and life-threatening brady-arrhythmias, especially in the patient with intracranial hypertension. Propofol-related lipid loads must be considered when calculating calorie intake and prescribing tube feeds. The lipid emulsion of propofol promotes bacterial growth, good sterile technique must be observed in preparation and handling.

On the other hand, propofol decreases ICP in patients with either normal or increased ICP. Propofol also reduce the cerebral metabolic rate (CMR), and the consequent decrease cerebral oxygen uptake might prevent ischemic damage in regions with low perfusion. Propofol appears to have predominately anticonvulsant properties (i.e. burst suppression), it has been successfully used to terminate status epilepticus, and may be safely administered to epileptic patients. Propofol has been shown to be useful as therapy for delirium tremens, not only as adjuvant therapy, but also in treating delirium tremens refractory to benzodiazepines.

There is increasing awareness in the literature of the central role of mitochondrial dysfunction and cerebral cell death in areas of the brain with high oxidative stress. Propofol may act as a neuroprotective agent through limitation of oxidative stress.

When compared with midazolam for maintenance of sedation, propofol provides equal or better control and more rapid recovery. Propofol does not trigger malignant hyperthermia, and can safely be used in patients with porphyria. Tachyphylaxis may occur after prolonged administration.

Caution: a rare but potentially life-threatening complication associated with excessively high doses of propofol is known at the “Propofol Infusion Syndrome”. This syndrome is characterized by metabolic acidosis, bradycardia, hyperlipidemia, dysrhythmias, rhabdomyolysis, renal failure and cardiac arrest. The triad of bradycardia, hyperlipidemia, and rhabdomyolysis are unique features that help to distinguish this syndrome from septic shock. While originally reported in pediatric patients, it has subsequently been reported in adult as well. Treatment involves prompt discontinuation of the drug, supportive care, and cardiac pacing when needed. The mortality is high (>80%) despite therapeutic efforts. Maintaining propofol infusions below a rate of 4 mg/kg/h may reduce the risk of this deadly condition.

Midazolam (Sedation in Ventilated Patients and Procedural Sedation)

Tips for infusion pump preparation (50 ml syringe): 1st option, midazolam ampoule 15 mg/3 ml; 90 mg midazolam (6 ampoules = 18 ml) plus 32 ml of NaCl 0.9% (= 1.8 mg/ml).

Adult Dosage: 2-5 µg/kg/min → 0.1-0.3 mg/kg/h = 4 -12 ml/h = 7-22 mg/h.

2nd option, dosage 0.05-0.2 mg/kg/h: midazolam ampoule 50 mg/10 ml; 240 mg/48 ml → 5 mg/ml, infusion rate 1-3 ml/h = 5-15 mg/h.

To reduce the risk for oversedation, the infusion rate of midazolam should be determined using ideal body weight rather than total body weight. Analgosedation regimens with midazolam in neurocritically ill patients can be started at an infusion rate of 0.02 mg/kg/h after a loading dose of 0.2 mg/kg.

Midazolam is a short-acting benzodiazepine, which possesses profoundly potent anxiolytic, sedative, amnestic, hypnotic, anticonvulsant, and “centrally acting” skeletal muscle relaxant properties. Midazolam is more lipid soluble than lorazepam; thus it has a more

brisk onset and offset, making it the benzodiazepine of choice for rapid or temporary sedation. Its elimination half-life (1.8-6.4 hours, mean approx. 3 hours) is the shortest of all benzodiazepines, but it can be prolonged in obesity, elderly, congestive heart failure, alcoholic patients, and in renal failure.

Because of its short duration of action, midazolam is commonly given by continuous infusion. However, midazolam can also be given by bolus (adult: 1-2 mg q 5-10 min., as required) for procedural sedation (e.g., bronchoscopy, cardioversion). Infusions of midazolam lasting more than a few hours can produce prolonged sedation after the drug infusion is stopped. This effect is the result of multiple factors (e.g., drug accumulation in the CNS, accumulation of a active metabolite, especially in renal failure, decreased metabolism, etc.). Tachyphylaxis can occur with prolonged use, particularly after 3 or more days; ceiling effect is also observed with midazolam.

Cautions: abrupt discontinuation following prolonged benzodiazepine administration can produce a withdrawal syndrome consisting of anxiety, agitation, disorientation, hypertension, tachycardia, hallucinations, and seizures. Midazolam, like other benzodiazepines, requires special precaution when used in the elderly (risk of oversedation, respiratory depression, and paradoxical reactions). α-hydroxymidazolam, an active metabolite, may accumulate in renal failure. The overdose of midazolam can be treated with flumazenil. However, flumazenil can trigger seizures in mixed overdoses and in benzodiazepine-dependent individuals. Flumazenil is contraindicated in patients with tricyclic antidepressant overdose and patients receiving benzodiazepines for control seizures or elevated ICP. Like other benzodiazepines, midazolam should not be administered to patients with myasthenia gravis. Other relative contraindications include, sleep apnoea, chronic obstructive lung disease, and glaucoma.

Lorazepam

Unlike midazolam and diazepam, lorazepam has poor lipid solubility. Thus, it crosses the blood-brain barrier more slowly, which results in a delayed onset of action. In addition, its high degree of protein binding (85-90%) means its volume of distribution is mainly the vascular compartment, causing relatively prolonged peak effects. After single IV dose administration, the duration of action of lorazepam is 4 to 6 hours compared with 5-20 min of midazolam or diazepam (depending on the dose). Therefore, lorazepam is preferred for long-term sedation. Lorazepam has a high relative potency (1-2 mg of lorazepam is equal in effect to 10 to 20 mg of diazepam), and its elimination half-life is 10-20 h. Its metabolism does not led to the formation of active metabolites.

Lorazepam is usually given by bolus, although it can also be given by continuous infusion (caveat: risk of toxicity). As pointed out above, lorazepam is preferred for prolonged sedation due to its pharmacokinetics and because of lower cost, more consistent efficacy, fewer drug interactions, and less dependence on hepatic metabolism. However, lorazepam is not a suitable drug when rapid awakening is required (e.g., for neurological assessment). Lorazepam has strong sedative/hypnotic effects, and the duration of clinical effects from a single dose makes it an appropriate choice for the short-term treatment of insomnia, in particular in the presence of severe anxiety. The dose of lorazepam should be tailored according to the patient's needs. Withdrawal symptoms, including rebound insomnia and rebound anxiety, may occur after only seven days' administration of lorazepam. Lorazepam's anticonvulsant and CNS depressant properties are useful for the treatment and prevention of alcohol withdrawal syndrome. In this setting, impaired liver function is not a hazard with lorazepam, since lorazepam does not require oxidation, hepatic or otherwise, for its metabolism.

Dose-adult: 1-4 mg (0.02-0.06 mg/kg) IV bolus every 4 to 8 h. Patients with withdrawal syndrome may require higher doses.

Cautions: accidental intra-arterial injection can cause severe vasoconstriction with gangrene. Propylene glycol is the solvent vehicle used to deliver lorazepam and diazepam IV; large-dose lorazepam infusion may led to propylene glycol toxicity (metabolic acidosis, hyperosmolality, renal dysfunction, seizures, etc.). Lorazepam impairs body balance and standing steadiness and is associated with falls and hip fractures in the elderly.

Diazepam

It's a highly lipophilic benzodiazepine drug, which results in rapid distribution into the brain as well a relatively short duration of action upon redistribution into peripheral tissues. The use of diazepam for sedation in ICU-setting is rather limited because of its short duration of action, and the risk for oversedation due to accumulation. Like midazolam, diazepam can be given for procedural sedation. Diazepam is metabolised in the liver, and it has several pharmacologically active metabolites. Because of these active metabolites, the serum values of diazepam alone are not useful in predicting the effects of the drug. Diazepam has a biphasic half-life of 22 to 50 hours, and two to seven days for the active metabolite desmethyldiazepam. The elimination half-life of diazepam and also the active metabolite desmethyldiazepam increases significantly in the elderly, which may result in prolonged action, as well as accumulation of the drug during repeated administration.

Dose-adult: 0.03-0.2 mg/kg bolus IV every 2-4 h as required.

Clonidine (Analgosedation in Ventilated Patients)

Tips for infusion pump preparation (50 ml syringe): clonidine ampoule 0.15 mg/1 ml; 2.25 mg of clonidine (15 ampoules) plus 35 ml 0.9% NaCl (= 45 µg/ml).

Dosage: 0.3-1.2 µg/kg/h = 0.5-4 ml/h → 22-(90)-180 µg/h; eventually with a loading dose of 150-450 µg over 10-15 minutes; rapid administration of the loading dose is not recommended, since it may cause transient hypertension due to α-1 receptors stimulation.

Clonidine has been prescribed as an antihypertensive drug since the 1950s; however, some of its side effects led to a gradual decrease in clinicians enthusiasm for this drug. Interestingly, few of these side effects like sedation, dry mouth, and eventually bradycardia are welcome during anesthesia. Thus, clonidine has become one of the most important adjuvant or supportive drugs in anesthesia.

Clonidine is a central α-2 adrenoreceptor agonist that stimulate post-synaptic α-2 adrenergic receptors in the vasomotor center in the brainstem, leading to enhanced activity of inhibitory neurons and subsequent decreased sympathetic outflow. It also acts peripherally on α-1 receptors to cause a pressor response that is usually overshadowed by its central effect. Clonidine also binds to specific I-1 imidazoline receptors in the rostral ventrolateral medulla, leading to hypotension. Its sedative effect is mediated by the activation of α-2 adrenergic receptor at the locus coeruleus in the brainstem, while its analgesic effect (spinal and supraspinal) is attributed to the inhibition on the release of nociceptive neurotransmitters like substance P, and the enhancement of the analgesic effect of opioids through the stimulation of α-2 receptors.

The respiratory depression produced by clonidine is clinically irrelevant. Unlike benzodiazepines, clonidine does not increase the respiratory depression associated with opioids use.

Clonidine is useful as premedication for alcoholic patients undergoing surgery, and as alternative therapy for the treatment of PAS. In the ICU-setting, clonidine may be used to ease withdrawal symptoms associated with the long-term use of opioids, alcohol and nicotine.

Dexmedetomidine (Analgosedation in Ventilated Patients)

The broad spectrum of action of clonidine aroused interest in synthesizing more selective drugs, leading to the introduction of dexmedetomidine in 1999. Dexmedetomidine

is a drug with 8 times higher affinity for the α2-adrenoreceptor than clonidine, which causes it to be a much more effective sedative and analgesic agent than clonidine. In addition, dexmedetomidine has less cardiovascular effects than clonidine and causes minimal or none respiratory depression. The absence of respiratory depression makes dexmedetomidine an appealing sedative for patients who are prone to drug-induced respiratory depression (e.g., patients with sleep apnea or chronic obstructive lung disease), especially when these patients are weaning from mechanical ventilation.

Patients who receive dexmedetomidine in the ICU remain sedated when undisturbed but arouse readily with stimulation. Dexmedetomidine has been continuously infused in mechanically ventilated patients prior to extubation, during extubation, and postextubation.

Dosage and administration: the doses should be titrated to the desired clinical effect. Dexmedetomidine must be diluted in 0.9% saline for solution. For adult patients, dexmedetomidine is usually initiated with a loading infusion of 1μg/kg over 10 minutes, followed by a maintenance infusion of 0.2-1.0 μg/kg/h. The bolus doses is not used as it can cause paradoxical increases in blood pressure.

Cautions: mild hypertension in response to the loading dose is observed in 15% of patients, this effect is usually transient, and it can minimized by giving the loading dose over 20 minutes. Drug infusions were initially recommended for not longer than 24 hours; however, recent studies have shown that the safety and efficacy of dexmedetomidine persist beyond 24 hours, without the emergence of rebound effects after discontinuation. Hypotension and bradycardia may occur during ongoing therapy. Dexmedetomidine should be used cautiously in patients with pre-existent severe bradycardia and conduction problems, in patients with reduced ventricular functions (ejection fraction <30%), and in patients who are hypovolemic or hypotensive. Dexmedetomidine dose should be reduced in patients with severe liver dysfunction. All effects of dexmedetomidine can be antagonized by administering atipamezole (Antisedan®).

Zopiclone and Zolpidem

Are nonbenzodiazepine hypnotics ("Z-drugs") used for the short-term treatment of insomnia. Long-term use of Z-drugs is not recommended as tolerance, dependence, addiction may eventually occur with prolonged use.

Nonbenzodiazepine hypnotics appears to offer significant advantages over benzodiazepines due to its lower incidence of adverse side effects.

Zolpidem (2.5 h half-life time) has not proven effective in maintaining sleep and is more used for sleep initiation problems. This drug has less residual effect on sleepiness and psychomotor function the next morning, although morning-after anterograde amnesia may occur. Zopiclone has longer duration of effects (3.5-6.5 h half-life time) and it is indicated for the treatment of insomnia where sleep initiation or sleep maintenance are prominent symptoms (dosage: 5 to 7.5 mg at bedtime). Zolpidem does not significantly alter sleep architecture at recommended doses (10 mg immediately before bedtime, 5 mg in the elderly); however, zopiclone reduces the total amount of time spent in REM sleep as well as delaying its onset. Zolpidem showed no significant incidence of respiratory depression in healthy adults although reductions in lowest oxygen saturations were reported in one study of mild to moderate sleep apnea patients given 10 milligrams of zolpidem.

At present, it is unknown whether non-benzodiazepine agents will help prevent the development of post-traumatic stress disorder in ICU patients.

Cautions: combinations of zolpidem with antidepressants have resulted in increased incidences of hallucinations in patients. Zopiclone may cause delirium. Nonbenzodiazepine hypnotics causes impairments in body balance and standing steadiness in individ-

uals who wake up at night or the next morning, geriatric patients may be more likely to experience accidental events, or falls with hip fractures while taking these drugs (i.e. zopiclone).

Caveat: critically ill patients do not suffer from reduced total sleep time, but have increased sleep fragmentation and reduced restful sleep. Pharmacological treatment of sleep disorders in the ICU should first involve a review of all current medication, as well as the detection of delirium or other trigger factors for insomnia. Any drug prescription for acute sleep disturbances in the ICU should be only a short course of therapy.

Succinylcholine

It's the only approved depolarizing neuromuscular blocker. This ultra-short-acting agent (6-8 min) with a rapid onset time (30-60 sec) is mostly used to induce muscle relaxation and short-term paralysis, usually to facilitate tracheal intubation.

Succinylcholine is often considered as the most dangerous drug used in anaesthesia and intensive care medicine since it can trigger life-threatening reactions. In fact, succinylcholine is a relatively safe drug when its contraindications are known, and assuming that its many potential complications are understood and avoided. Succinylcholine is contraindicated in the routine management of children and adolescents because of the risk of rhabdomyolysis, hyperkalemia, and cardiac arrest in children with undiagnosed myopathies. In certain high-risk patients, succinylcholine should be also avoided due to the potential for exaggerated K+ release and subsequent hyperkalemia-induced cardiac arrest. Therefore, do not use succinylcholine in patients with severe burns, massive trauma (crush injuries), personal or family history of muscle disease or malignant hyperthermia, acidosis, severe intra-abdominal infection, renal failure with pre-existing hyperkalemia, stroke, Guillain-Barré syndrome, tetanus, closed TBI or spinal cord injury with muscle weakness and atrophy.

Despite the potential complications mentioned above, succinylcholine remains the muscle relaxant of choice for rapid sequence induction or intubation (RSI) in adults (i.e., emergency intubation in patients with suspected or confirmed "full stomach", ileus, acute abdomen, etc.). Endotracheal intubation in critically ill patients is a high risk procedure containing the danger of hypoxia and cardiovascular collapse; therefore, RSI is also the method of choice for emergency intubation in the ICU setting.

Caution: succinylcholine is also contraindicated in patients with increased ICP, penetrating eye trauma, and Glaucoma. The duration of action of succinylcholine may be prolonged in case of pseudocholinesterase deficiency.

Dose: 1-1.5 mg/kg.

Rocuronium

Introduced in 1994, rocuronium is a non-depolarizing neuromuscular blocking agent with a rapid to intermediate onset of action (1.5-2-[3] min), depending on dose, and with an intermediate duration of action (30-40 min). Usually, it is administered by IV bolus and is devoid of significant cardiovascular side effects. Due to its rapid onset of block, rocuronium has become the second-line choice agent for RSI when succinylcholine is contraindicated or not desired. Rocuronium undergoes no metabolism and is eliminated mostly by the liver (~70%) and slightly by the kidneys (~30%).

Caution: Rocuronium can produce a prolonged duration of action in elderly patients; the maintenance dosage must be reduced in liver failure.

Initial dose: 0.5 to 0.6 mg/kg; use higher dose (twice the normal dose) for RSI (0.9-1.2 mg/kg). Maintenance dose: 0.1 mg/kg. Continuous infusion: ≈ 0.5 to 0.7 mg/kg/h (9-12 µg/kg/min).

Cisatracurium

Is a muscle relaxant with an intermediate duration of action (40-50 min) and with an onset time of 2-3 min. It can be administered by IV bolus, however, for sustained muscu-

lar relaxation it is better to consider a continuous infusion since it is rapidly degraded in the plasma. Like atracurium, cisatracurium spontaneously degrades at physiological pH via Hofmann elimination (a temperature and plasma pH dependant process), this feature favors the use of this neuromuscular blocking agent as suitable choice for patients with renal failure. Cisatracurium does not cause histamine release, does not cause cardiac depression, and it generates less laudanosine (a metabolite that may cause neuroexcitation) than atracurium.
Initial dose: 0.1 mg/kg. Maintenance: 0.02 mg/kg.
Continuous infusion: ≈ 0.05-0.1 mg/kg/h (1-2 µg/kg/min).

Pancuronium

Is a long acting (90-120 min) non-depolarizing neuromuscular blocking agent with an onset time of 45 to 90 seconds and a maximum block effect reached within 2 to 5 minutes. Muscle relaxation suitable for intubation sets in about 90–120 seconds after administration of the drug. Although pancuronium can be given by continuous infusion, it is usually given as intermittent IV bolus doses to decrease the risk of drug accumulation. About 80% of pancuronium is excreted through the kidneys and the remainder is metabolised in the liver and excreted in the bile. When hepatic and renal function are intact, pancuronium is the preferred neuromuscular blocking agent in the ICU.
Caution: tendency to accumulate with prolonged use. Pancuronium should be given carefully to patients in whom an increased heart rate would be detrimental, since it usually produce tachycardia and hypertension (vagolytic effect). In patients who are known to have myasthenia gravis or the myasthenic (Eaton-Lambert) syndrome, small doses of pancuronium bromide may have profound effects.
Initial dose: 0.07 to 0.1 mg/kg, maintenance: 0.015 to 0.02 mg/kg.

67.2 Agitation and Delirium in the Intensive Care Unit

When in a continued fever occur difficulty of breathing
and paraphrosyne (delirium), it is a fatal sign
Hippocrates (460-377)

The set of symptoms and signs that characterize the syndrome which we now call delirium, was described at least three millennia ago. However, the definition, study, and diagnosis of this disorder is still difficult due to its nature, fluctuating course, and presentation. The terms agitation and delirium are often indistinctly used in clinical practice. Even when these conditions might be related, not all delirium is manifest with agitation, nor do all agitated patients have delirium.
Delirium is the most common mental dysfunction in critically ill patients, occurring in up to 87% of the sickest intensive care unit (ICU) populations (i.e. ventilated patients). The disorder is reported to be also present in 10 to 30 % of all hospital admissions, representing a frequent mental disorder among elderly patients, and the most frequent postoperative complication in this group. Critically ill patients suffering delirium have a three times increased risk of death. Delayed treatment of delirium, longer periods of mechanical ventilation, and increased complications among other factors, contribute to a bad outcome. The occurrence of this disorder in the ICU increases length of stay, hospital costs, and at the same time represents a challenge for the medical staff. Attempts to deliver high quality care to patients with disruptive or combative behaviours compromise more time and effort, and may cause the interruption or shortening of care tasks required for other patients.

67.2.1 Terminology

The word "delirium" was first used in medical writing by Celsus in the first century AD, it derives from the Latin *deliro-delirare*: *de-lira*, to go out of the furrow, hence, to deviate from a straight line. Even though Celsus used this term to describe (either as a symptom or as a syndrome) mental disorders during fever or head trauma, it should be pointed out that it was Hippocrates in 500 B.C., who previously coined the terms *phrenitis*, *paraphrosyne*, *leros* (incoherent language) and *mania* among others, to encompass mental abnormalities caused by fever, poisoning or head trauma.

Synonyms: acute confusional state, acute cerebral failure (or dysfunction), ICU's psychosis, postoperative psychosis, ICU's syndrome, organic brain syndrome, acute brain syndrome, pseudodementia, etc.

Definition of delirium according to the Diagnostic and Statistical Manual of Mental Disorders (DSM) IV: disturbance of consciousness and attention; change in cognition (including memory deficit, disorientation or language disturbance); development of perceptual disturbance that is not better accounted for by a pre-existing or evolving dementia. The disorder develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition, substance intoxication or substance withdrawal.

Diagnosis of delirium according to the International Classification of Diseases-10th edition (ICD 10): impairment of consciousness and attention; global disturbance of cognition (including illusions, hallucinations, delusions and disorientation); psychomotor disturbances; disturbance of the sleep-wake cycle; emotional disturbances.

Other definitions of delirium: acute disturbance of mental status in the context of illness, stress, or drug intoxication (Meagher et al. 2008); Delirium is a symptom which indicates the transition of a purely somatic disease into a mental disorder (von Feuchtersleben 1845); "Delirium are the Dreams of waking Persons" (Quincy 1719); Delirium is an acute, fluctuating, transient and reversible condition caused by physical illness. Once the acute episode has remitted, the premorbid level of functioning is reached again, with personality reappearing intact (Adamis 2007).

Regarding this last definition, Adamis clarifies that experience and research shows that, not all cases survive this condition nor experience a full recovery of mental function. Delirium is often irreversible, especially in the elderly and those with pre-existing dementia, only 15% of patients with delirium return to their baseline level of functioning at the time of discharge, and less than 45% of the cases show a complete recovery at 6 months of leaving the hospital. Neither the existing DSM-IV and ICD-10 definitions of delirium describe this disorder in terms of evolution. In addition, it is considered that the ICD-10 criteria lack sensitivity and exclude many patients that would be classified as delirious by DSM systems and which have similar clinical profiles and prognosis as delirium. On the other hand, the DSM-IV definition does not cover characteristic features such as disturbances of sleep-wake cycle and motor activity. It is clear that a fully satisfactory definition of this disorder has not been yet achieved, however, the publication of ICD-11 may offer the possibility for an improved definition of delirium.

Central anticholinergic syndrome (CAS): this disorder, described by Longo in 1966, encompass the symptomatic complex of a psychosis induced by substances or medications with a central anticholinergic effect. In anesthetic practice, this syndrome arises during or immediately upon the emergence from general anesthesia. The definition of this disorder also includes the paradoxical reaction to certain psychotropic drugs (ie. benzodiazepines), or psychosis triggered by the consumption of psychoactive substances. The inci-

dence of SAC in anesthetic practice can be up to 10%. In the ICU however, its incidence is much lower (4.2%). Two variants of this syndrome are described: one with agitation and another comatose. The symptoms of both clinical forms respond well to intravenous administration of physostigmine. *Caveat*: clinical manifestations may recur several minutes after a first treatment with physostigmine. Seldom, as part of the symptomatic components of the syndrome, some patients manifest transitory respiratory depression or even breathing suppression after awakening.

Postoperative Cognitive Dysfunction (POCD): This term includes a wide spectrum of abnormalities of mental function, ranging from inconspicuous changes in memory and personality, to a complete loss of the skills needed for independent living.

The incidence of POCD increases with age, affecting up to 25% of subjects over the age of 90. Open heart surgery (e.g., cardiopulmonary bypass) and orthopedic surgery increase the frequency of occurrence of this disorder. Its manifestations are usually transient in young adults, disappearing at 3 months in the 40 to 59 years of age group. In elderly patients, symptoms can persist for long periods of time, or even be irreversible. It remains unclear whether this disorder is the result of the use of anesthetic drugs, or if it is an effect of surgery itself, or just the combination of both. According to a recent study, individuals carrying the apolipoprotein E-epsilon 4 (APOE4) are at high risk of developing POCD. Cerebrovascular disease or pre-existing dementia may also be contributing factors. In cases of cardiac surgery other pathophysiological mechanisms have been proposed, such as loss of pulsatile perfusion (cardiopulmonary bypass), altered cerebral autoregulation, and microembolisms. The use of neuraxial anesthesia procedures (spinal, epidural) does not reduce the incidence of POCD.

The availability of new anesthetics has substantially reduced the recovery time after general anesthesia. Today anesthetic recovery is usually reached in a period of time ranging from 30 to 240 minutes maximum. The diagnosis of POCD is usually considered when mental function abnormalities persist for more than 4 hours. Clinical manifestations can be subtle and only detected by the family. Often it tends to take from several days to up to 2 weeks until a deficiency is detected, whereas in another group of patients, the cognitive deficit is frankly obvious from the immediate postoperative period.

Postoperative delirium: this condition is independent from POCD and it affects between 10 and 60% of surgical patients 65 years of age or older. Postoperative delirium and POCD may coexist. As with POCD, the incidence of postoperative delirium is especially high in patients undergoing orthopedic surgery (e.g., hip fracture, knee replacement recipients, etc.) and open heart surgery. Currently it is doubtful that this variant of delirium is associated with hypoxia and hypotension intra-and/or postoperative, as previously accepted. Unlike the CAS, postoperative delirium may take several minutes or hours to develop after anesthesia recovery.

Abstinence syndrome: This disorder, also known as withdrawal syndrome, includes a set of signs and symptoms that occur upon the abrupt discontinuation/separation or a decrease in dosage of the intake of medications, recreational drugs, and alcohol. The group of symptoms of a withdrawal syndrome varies in intensity and form according to the type and amount of drug or substance used; the deprivation of certain substances such as alcohol, MAO inhibitors, hypnotics, amphetamines, etc., can lead to the development of genuine delirium if deprivation evolves for longer time..

Delirium tremens: is the most severe manifestation of alcohol withdrawal in individuals with a history of heavy alcohol use. While the symptoms of alcohol withdrawal usually appear between 4 to 12 h after the last drink, delirium usually occurs 3-10 days following the last alcohol consumption.

Psychomotor agitation: is a kind of restlessness or increased muscular activity associated with emotional distress. Agitation may vary in intensity, i.e., from slight restless-

↑ Cephalic Caudal ↓	Intracranial lesions	• Head trauma • Subdural or epidural hematoma • Traumatic subarachnoid hemorrhage • Intracerebral hemorrhage (i.e. non dominant temporal lobe) • Encephalitis/limbic encephalitis (paraneoplastic syndromes) • Meningitis/cerebral abscess • Neoplasms • Cerebral vasculitis (i.e. granulomatous, lupus)
	Encephalopathies	• Septic encephalopathy • Anoxic or ischemic-hypoxic encephalopathy (i.e. post cardiac arrest) • Hypertensive encephalopathy • Hepatic encephalopathy • Uremic encephalopathy • Wernicke encephalopathy • Pancreatic encephalopathy
	Endocrinopathies	• Pituitary dysfunction • Thyroid dysfunction • Parathyroid tumors • Adrenal dysfunction
	Intoxications	• Inhalant: ether gasoline, glue • Others: illicit drugs, CO, insecticides organophosphates, metals, etc. • Vitamins: A and D
	Drugs (medication)	• With direct anticholinergic effect: atropine, scopolamine, ipratropium bromide, disopyramide, neuroleptics, tri-cyclic antidepressants, antiparkinson drugs, H2-receptor blockers, other antihistaminics, etc. • With indirect anticholinergic effect: opiates/opioids, NSAIDs, benzodiazepines, inhaled anesthetics, propofol, ketamine, alcohol, local anesthetics • Others: theophylline, some antibiotics and antiarrhythmic agents, methyldopa, corticoesteroids, etc.
	Miscellaneous	• Sepsis • Postconvulsive delirium • Postoperative and postconcussive states • Sleep deprivation • Withdrawal syndromes (alcohol, sedatives, anti-psychotics, etc.) • Dehydration or hydric intoxication • Heat stroke • Hyper or hypothermia • Electrocution • Radiation • Extensive burns • Poisoning
	Respiratory disorders	• Hypoxemia/hypercapnia • Pneumonia • Pulmonary embolism • Acute respiratory distress syndrome
	Cardiovascular disorders	• Heart failure • Subacute endocarditis • Hypertension or hypotension
	Hepatic disorders	• Biliary sepsis • Hepatic insufficiency
	Metabolic and nutritional disorders	• Hyperglycemia/hypoglycemia • Electrolytes and acid-base disturbances • Porphyrias • Vitamin deficiencies: vitamin B1, B12, niacin, folic acid • Renal disorders • Urinary tract infections • Renal failure • Long bones, soft tissue trauma and burns • Fat embolism

Table 67.11. Some causes of delirium.

ness to vigorous uncoordinated movements. Motor activity tend to be purposeless, repetitive, and may also be accompanied by a sympathetic overdrive (autonomic hyperactivity). Agitated patients in the ICU exhibit continual motions like constant fidgeting, moving from side to side; pulling at dressings, bed sheets, and restraints; attempting to remove catheters or other tubes; overbreathing the ventilator; and evincing asynchrony with the current ventilator settings. In more severe cases, the motions may become harmful to the individual or to others. The agitated patient remains disoriented in one of several spheres. Depending on the degree of agitation and the ability of the patient to listen or communicate, commands may or may not be successfully followed.

67.2.2 Risk Factors and Causes of Delirium

Delirium is a multi-etiological disorder (Table 67.11), whose exact pathophysiologic mechanisms are still unknown. In addition, the pathophysiology of different subtypes of delirium may be different. Delirium is theorized to be a neurobehavioral manifestation of imbalances in the synthesis, release, and inactivation of neurotransmitters (acetylcholine, dopamine, GABA, serotonin, endorphins, and glutamate) that normally control cognitive function, behaviour, and mood.

Other hypotheses suggest: 1) an impairment of cerebral oxidative metabolism; 2) an excess of availability of some amino acids (i.e. tryptophan, phenylalanine) into the brain; and 3) the cerebral effect of certain mediators (for example IL-1, IL-6, tumor necrosis factor α, and other cytokines) released during an acute inflammatory response (i.e. sepsis, head trauma).

More useful in understanding delirium is the stress-diathesis model, which posits an interaction between the underlying constitutional or pre-existing factors (degree of susceptibility or diathesis) and the stressful nature of the insult (precipitating factors). For example, in an already vulnerable individual such as someone with established dementia, a minor factor, such as the prescription of a hypnotic, could trigger delirium, while in a healthy individual it would need a massive insult such as a major surgery to do so.

Risk factors for delirium can be categorized into two main groups: predisposing factors and precipitating factors (Table 67.12).

Predisposing factors	Precipitating factors (critical illness)	Precipitating factors (iatrogenic)
• Age (>65 years) • Male sex • Alcoholism • Smoking • Illicit drug use • APOE 4 polymorphism • Previous history of delirium • Cognitive impairment/dementia • Depression • Transfer from nursing home • Hypertension • Vision/hearing impairment • History of stroke • History of congestive heart failure	• Acidosis • Anemia • Fever/infection/sepsis • Hypotension • Metabolic disturbances • Respiratory disease • High severity of illness	• Immobilization (catheters, restraints) • Medications (for example, anesthetics, opioids, benzodiazepines) • Abrupt discontinuation of long-term treatments • Sleep disturbances

Table 67.12. **Risk factors for delirium in ICU patients.**

Predisposing risk factors encompass features existing before hospital or ICU admission, which can signify a patient's baseline vulnerability. Precipitating factors arise as a consequence of noxious insults or hospital-related issues.

67.2.3 Diagnosis of Delirium in the ICU

The Society of Critical Care Medicine (SCCM) recommends the systematic and simultaneous monitoring of the level of sedation and the possible presence of delirium for all critically ill patients. This has led to the development and validation of a number of delirium assessment tools in an effort to endorse and facilitate systematic screening for delirium. The Intensive Care Delirium Screening Checklist (ICDSC) and the Confusion Assessment Method for the ICU (CAM-ICU) allow nonpsychiatric physicians and other ICU personnel to diagnose delirium in ICU patients rapidly and reliably, even when the patient cannot speak because of endotracheal intubation

Using the ICSDC, or Bergeron's scale (Table 67.13), the patient is assigned a score from 0 to 8; a cut-off score of 4 has a sensitivity of 99% and specificity of 64% for identifying delirium.

The CAM-ICU, adapted from the conventional Confusion Assessment Method (Table 67.14), was designed for use in intubated patients. It has a high sensitivity (93% to 100%) and specificity (89% to 100%), but its main problem lies in its inability to distinguish between alterations of consciousness due to delirium from those caused by the effect of sedative medication. Using the CAM-ICU, delirium is diagnosed in two steps (Figure 67.3).

Level of consciousness is first assessed using a standardized sedation scale, while the content of consciousness is assessed using the CAM-ICU. One example, the Richmond Agitation-Sedation Scale (RASS), is a 10-point scale ranging from +4 to -5, with a RASS score of 0 denoting a calm and alert patient. By convention, RASS scores of -4 or -5 identify coma; a comatose patient cannot be assessed for delirium. All other patients, whether moderately sedated (RASS score -3) or more alert, should be evaluated for

Checklist item		Description
Altered level of consciousness*	A	No response
	B	Response to intense and repeated stimulation
	C	Response to mild or moderate stimulation
	D	Normal wakefulness
	E	Exaggerated response to normal stimulation
Inattentiveness		Difficulty following instructions or easily distracted
Disorientation		To time, place, or person
Hallucination-delusion-psychosis		Clinical manifestation or suggestive behavior
Psychomotor agitation or retardation		Agitation requiring use of drugs or restraints, or slowing
Inappropriate speech or mood		Related to events or situation, or incoherent speech
Sleep/wake cycle disturbance		Sleeping <4 hours/day, waking at night, sleeping all day
Symptom fluctuation		Symptoms above occurring intermittently
Total score		**0 to 8**

Table 67.13. **The Intensive Care Delirium Screening Checklist (ICSDC)**
* If A or B, then no other items are assessed that day. The ICDSC consists of eight items (rated present=1, or absent=0), and each patient is given a score from 0 to 8; 4 or greater is considered diagnostic of delirium.

delirium. The CAM-ICU assesses patients for four features of delirium (acute changes or fluctuations in mental status, inattention, disorganized thinking, and altered level of consciousness); three out of four features are required for a diagnosis of delirium (Figure 67.3).

Feature		Score	Check here if present
1. Acute onset or fluctuating course	Is the patient different than his/her baseline mental status? OR Has the patient had any fluctuation in mental status in the past 24 hours as evidenced by fluctuation on a sedation scale (i.e., RASS), GCS, or previous delirium assessment?	Either question yes	☐
2. Inattention	**Letters Attention Test** Directions: Say to the patient, "I am going to read you a series of 10 letters. Whenever you hear the letter 'A,' indicate by squeezing my hand." Read letters from the following letter list in a normal tone 3 seconds apart. S A V E A H A A R T Errors are counted when patient fails to squeeze on the letter "A" and when the patient squeezes on any letter other than "A."	Number of errors >2	☐
3. Altered level of consciousness	Present if the actual RASS score is anything other than alert and calm (zero)	RASS anything other than zero	☐
4. Disorganized thinking	**Yes/No Questions** 1. Will a stone float on water? 2. Are there fish in the sea? 3. Does one pound weigh more than two pounds? 4. Can you use a hammer to pound a nail? Errors are counted when the patient incorrectly answers a question.	Combined number of errors >1	☐
	Command Say to patient: "Hold up this many fingers" (Hold 2 fingers in front of patient) "Now do the same thing with the other hand" (Do not repeat number of fingers) *If pt is unable to move both arms, for 2nd part of command ask patient to "Add one more finger". An error is counted if patient is unable to complete the entire command.		
Overall CAM-ICU Feature 1 plus 2 and either 3 or 4 present=CAM-ICU positive		Criteria met	☐ CAM-ICU Positive (Delirium Present)
		Criteria not met	☐ CAM-ICU Negative (No Delirium)

Table 67.14. Confusion Assessment Method for the ICU (CAM-ICU).

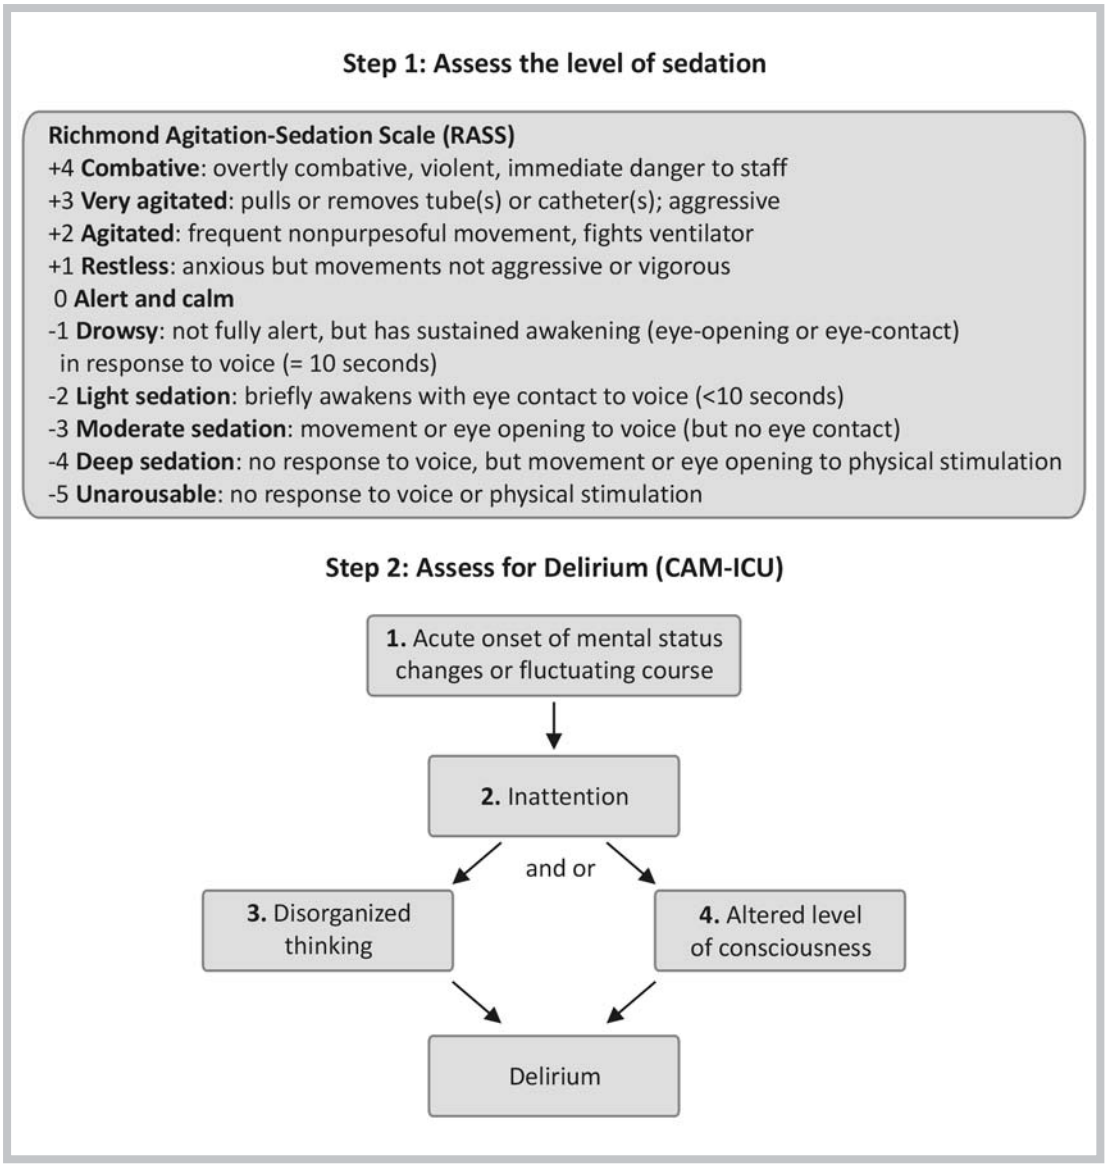

Figure 67.3. RASS and CAM-ICU for the Diagnosis of Delirium

67.2.4 Prevalence and Subtypes

The prevalence of delirium reported in medical and surgical ICU cohort studies has varied from 20% to 80%, depending upon severity of illness observed and diagnostic method used. Despite high prevalence rates in the ICU, delirium often goes unrecognized by clinicians or its symptoms are incorrectly attributed to dementia, or depression.
Delirium usually manifests as three subtypes; hyperactive, hypoactive, and mixed forms. However, there is a group of patients with subthreshhold symptoms or incomplete forms of the syndrome (subsyndromal delirium), whose symptoms do not fulfill the requirements of the DSM-IV or ICSDC defined criteria for delirium; subsyndromal delirium represents an intermediate state that is different from both clinical delirium and a normal

neurologic state, the mortality and ICU length of stay of these patients are significantly higher from those who have no symptoms of delirium.
Hyperactive delirium is characterized by restlessness, agitation, confusion, mood lability, psychotic symptoms, refusal of care and disruptive behaviours, whereas hypoactive delirium manifests with decreased responsiveness, lethargy, withdrawal, and apathy. Purely hyperactive delirium is rare (1.6%). Among non-ICU patient hyperactive delirium has been associated with a better prognosis than hypoactive delirium, but this relationship has not been evaluated thoroughly among ICU patients. In contrast, 43,5% of patients had purely hypoactive delirium, and 54,1% had mixed delirium. The hypoactive variant of delirium is less frequently recognized or is often dismissed as a transient, insignificant problem due to absence of disruptive, bizarre, and injurious behaviours. Hence, it represents a different challenge and requires greater skill in recognizing it because patients do not seemingly interrupt care delivery.

67.2.5 The Agitated Patient

Psychomotor agitation is a sign whose etiology should always be investigated. Agitation can result from psychiatric disorders (Table 67.15), as well as various organic disorders that may represent life threatening conditions. The exclusion of these organic causes is the first and crucial step in the evaluation on agitated patients; in all agitated patients the presence of delirium should be ruled out. In the ICU agitation is most commonly caused by delirium but may also result from fear, pain, patient-ventilator asynchrony, drug withdrawal or toxicity, hypoxia, CAS, or akathisia.
The agitated patient is usually a poor collaborator. The information provided by relatives or friends is very important in establishing the cause of agitation when a comprehensive history fails. It should be noted that in many cases drug-addicted or alcoholic patients deny or hide information about their addictions; a hospital stay of several days and hence restricted access to drugs or alcohol, often result in the emergence of unexpected withdrawal syndrome or delirium.
Motor and autonomic hyperactivity, anxiety and improper behaviours are usually the presenting symptoms of psychomotor agitation. Psychomotor agitation is not necessarily a synonym for violence. In most cases the agitated patient is not aggressive, however, disorganized and purposeless movements carry some potential risk of injury to both the patient and medical staff.
Akathisia ("inability to sit") is a syndrome characterized by unpleasant sensations of restlessness that manifests itself with an inability to sit still or remain motionless (i.e.

Non-psychiatric agitation	Psychiatric agitation

• Delirium
• Withdrawal syndromes
	• Psychotic disorders not associated with delirium:
	  ▪ Acute schizophrenia (at onset of disease, during treatment interruption or exacerbation)
	  ▪ Manic episode (bipolar disorder)
	  ▪ Delusional disorder (paranoia)
	• Others:
	  ▪ Personality disorders
	  ▪ Anguish crisis or panic attacks
	  ▪ Dissociative disorders
	  ▪ Phobias and adjustment disorder after life altering events

Table 67.15. Etiology of psychomotor agitation.

the patient paces the floor or jiggles the legs constantly). First noted in patients with Parkinson disease and senile dementia, akathisia is now observed most often in patients receiving neuroleptic drugs (e.g. haloperidol), or in some unmedicated patients with Parkinson disease; it can be also induced in normal individuals by the administration of L-dopa, or metoclopramide. Akathisia can be misinterpreted as anxiety, when in fact the causal relationship is inverse (the patient is nervous because he perceives that he can not stop moving). Akathisia should also be distinguished from agitation, otherwise antipsychotic administration may result in worsening symptoms; restless leg syndrome or depression with agitation are other differential diagnoses to keep in mind.

67.2.6 Prevention and Treatment of Delirium

The treatment of delirium begins with its prevention. Primary prevention is preferred; however, some degree of delirium is inevitable in the ICU. The prevention of delirium is essential in trying to reduce the morbidity, complications, and adverse outcomes caused by this condition. As delirium is most frequently multifactorial, successful preventive strategies are multi-component and aimed at reducing risk factors. However, it must be pointed out that, interventions aimed at preventing delirium have not been adequately studied in critically ill patients, on the other hand, a higher rate of incident delirium in critically ill patients (delirium present upon admission to the ICU or upon recovery from coma) compared with that observed in hospitalized patients without critical illness may indicate that preventive strategies that are effective in non-ICU patients may be less likely to prevent delirium in the ICU. The nature and number of delirium risk factors in ICU patients are different from those observed among other inpatients. Preventive interventions, therefore must address those risk factors that are most common in the ICU, including hypoxia, hypercapnia, hypoglycemia, shock, electrolyte abnormalities, infection, and exposure to sedative and analgesic medications.

67.2.7 General Preventive Measures

- Identify patients at high risk of delirium (predisposing/precipitating factors).
- Identify and correct sensory impairments: ensure patients have their glasses, hearing aid and dentures.
- Avoid prolonged immobility.
- Avoid physical restraints, if possible, as they often increase agitation. If restraint is unavoidable, observe appropriate guidelines.
- Encourage early mobilization.
- Timely removal of catheters and physical restrains.
- Early correction of dehydration.
- Avoid constipation.
- Detection and treatment of sleep disorders.
- Arrange treatments to allow for maximum periods of uninterrupted sleep.
- Quiet environment especially at rest times – noise reduction strategies (e.g.: use of vibrating pagers rather than call bells).
- Avoid psychoactive drugs; use them judiciously when needed (in the smallest effective dose and for the shortest time necessary).
- Avoid or minimize the use of medications with anticholinergic effect, or that trigger delirium.

- Manage discomfort and ensure adequate pain control.
- Provide environmental and personal orientation (communicate clearly and concisely: give repeated verbal reminders of the day, time and location, and identify key individuals, such as members of the treatment team and relatives).
- Provide clear signposts to patient's location, including clock, calendar (reorientation).
- Have familiar objects from the patient's home in the room (i.e., family photos).
- Involve family and caregivers to encourage feelings of security and orientation.
- Use a television or radio for relaxation and to help the patient maintain contact with the outside world.
- Explain the disease and all procedures and interventions that will take place.
- Encourage self care and participation in treatment (for example have the patient give feedback on pain).

67.2.8 Preventive Measures for Critically Ill Patients

- Adequate sedation (avoid over-sedation, promoting daily interruption of sedatives and analgesics or intermittent boluses rather than continuous infusions).
- Repositioning the patient.
- Reassurance (for fear, anxiety).
- Repositioning endotracheal tube (>2 cm from carina).
- Providing the patient with a writing board if unable to communicate.
- Early tracheostomy (reduces sedative use, and improves communication and patient mobility).
- Optimize pain control (both, inadequate analgesia and excessive opioids administration provide risks for developing delirium).
- Early diagnosis, prophylaxis and treatment of withdrawal's syndromes.

Pharmacological treatment for postoperative delirium prevention is currently under investigation. Reports from some studies demonstrated that the preoperative premedication with haloperidol or gabapentin either reduces the severity or the incidence of postoperative delirium; other drugs such cholinesterase's inhibitors (e.g., donepezil) have been also used for this purpose, but results did not reach statistical significance.

Analgesic medication play a vital role in maintaining patient comfort, and adequate pain control is likely to reduce risk for delirium, however, practitioners must strive to avoid over sedation by administering the drugs only as necessary. In fact, sedation protocols that use validated sedation scales, emphasizing intermittent boluses rather than continuous infusions, and promoting daily interruption of sedatives and analgesics significantly improve multiple clinical outcomes. Halting sedative infusions and allowing patients to "wake up" on a daily basis reduces the risks of accumulation of longer acting agents, duration of mechanical ventilation and length of stay. Nevertheless, daily sedation holds are not appropriate in all patients and are not a substitute, but an adjunct to appropriate sedation monitoring and sedative dose titration. Sedative drug choice is also important; for instance, a comparison of patients sedated with dexmedetomidine versus lorazepam demonstrated an increase in coma-free days and trend towards delirium-free days in the dexmedetomidine group. Furthermore, preliminary data from a multicenter randomized controlled trial reported that dexmedetomidine significantly decreased the incidence and duration of delirium in ICU patients compared with midazolam. The effect of these methods of sedation on delirium is the subject of ongoing investigations.

67.2.9 Managing the Agitated Patient

Agitation may be a distressing issue in ICU, since it is associated with potentially dangerous complications such as self-extubation, removal of arteria and venous catheters, increased systemic and myocardial oxygen consumption, and failure to participate in therapeutic interventions. An extremely agitated patient can hamper the workflow in the ward. Managing the disruptive behaviours is often demanding of time and attention and has been highlighted as a cause of stopping or abbreviating care delivery to another patient. Under these circumstances, the newcomer physician may feel urged to quickly end the agitation episode. However, medications only become necessary when other interventions are ineffective in controlling agitation, or to prevent patients endangering themselves or others. Whenever possible, an accurate and fast diagnosis of the cause of agitation should be performed before implementing any pharmacological treatment ("look around" before searching for a syringe).

The behavior of an agitated patient is impossible to predict, therefore, there are not rigid guidelines for the management of these cases. Usually, the risks of patient's behaviour are assessed at first in order to ensure his safety. Verbal containment, if possible, should precede the use of any other therapeutic procedure. In this phase, the first line of intervention is to develop dialogue with the patient, a companion or family members may also contribute. The attitude toward the agitated patient should be reassuring, and nonjudgmental, they should be approached with a soft and calm voice, while showing interest in their problems and making it clear that the intentions are to help them.

When the patient's agitated behavior poses a real danger to himself or others, and verbal containment does not seem to work, physical restraints are necessary; the control of an extremely agitated patient may require the efforts of 4 or more individuals. Once this point has been reached, we should explain that restriction is not a punishment, but a procedure for his safety, because he is unable to control his behavior.

67.2.10 Pharmacological Treatment

The treatment of delirium requires addressing the underlying causes; pharmacological treatment would be incomplete, or even ineffective, when the treatment of the underlying cause has not been initiated. The use of psychotropic drugs complicates the ongoing mental state assessment, and can also impair the patient's ability to understand and therefore cooperate with treatment. Thus, drug treatment should be reserved for 1) patients whose symptoms of delirium would threaten their own safety or the safety of others, 2) to relieve distress in a highly agitated or hallucinating patient, or 3) in order to carry out essential medical treatment or investigations.

Haloperidol (0.5-2 mg PO or IV every 4-6 hours as needed) remains the first-line treatment in many clinical guidelines for ICU-acquired or postoperative delirium. It has been proven to be useful in the treatment of both hyperactive or hypoactive subtypes. Clinical effects are observed within 30-60 min. after iv administration and last for as long as 4-8 hrs. The SCCM guidelines suggest that patients with hyperactive delirium should be treated with 2 mg intravenously, followed by repeated doses (doubling the previous dose) every 15 to 20 minutes while agitation persists. Once the agitation subsides, scheduled doses (every 4 to 6 hours) should be continued for a few days, followed by tapered doses for several days (up to 7 or 10 days upon symptoms fully resolve). Common doses for ICU patients range from 4 to 20 mg/day, but higher doses are frequently used for the treatment of acute agitation. It is important to bear in mind that, usually, the elderly population needs lower doses.

Haloperidol does not cause major respiratory depression, but may induce hypotension. Generally, intravenous use of haloperidol is associated with lower incidence of extrapiramydal adverse effects but a higher risk of developing Torsades de pointes. Therefore, patients receiving intravenous haloperidol should have ECG monitoring. A QTc interval >500 ms would suggest a need to stop haloperidol and eventually a referral to a cardiologist. Neuroleptic malignant syndrome (NMS) is a rare but a life- threatening neurological disorder most often caused by an adverse reaction to neuroleptic or antipsychotic drugs; NMS develops slowly over 24-72 hrs. and can last for up 10 days after discontinuation of the drug. Individuals using haloperidol and chlorpromazine are at risk of developing NMS. The use of haloperidol should also be avoided in case of hepatic failure, anticholinergic toxicity, and patients with Lewy body dementia.

The administration of haloperidol in delirium tremens is somewhat controversial since it reduces the threshold to seizures. However, some clinicians use it as adjunctive therapy with benzodiazepines to control psychiatric symptoms associated with this delirium such as anxiousness, hallucinations, and combativeness.

Droperidol, **chlorpromazine**, **levomepromazine** and **pimozide** have all been used in the treatment of hyperactive delirium. Levomepromazine and chlorpromazine have been used for very agitated delirious patients, largely because these drugs are more sedative compared to haloperidol, however, these two drugs are not recommended in hypoactive delirium because they cause excessive sedation; on the other hand, chlorpromazine causes local irritation, an effect to take into consideration at the time of peripheral intravenous administration.

Benzodiazepines are the treatment of choice for delirium tremens and alcohol withdrawal. So far, there is no evidence to support the use of benzodiazepines in the treatment of non-alcohol withdrawal related delirium among hospitalized patients, conversely, when benzodiazepines are used to treat agitation associated with delirium from other causes, they often make it worse, particularly in patients with dementia.

There are not studies showing one benzodiazepine to be more effective than another in treating delirium tremens. Selection of a benzodiazepines is dependent on several factors including route of administration, onset and duration of action, hepatic and renal function; lorazepam, for instance, does not have active metabolites, making it an attractive choice for patients with decreased hepatic or renal function. Doses of benzodiazepines used during delirium tremens may exceed that which is considered to be normal; genetic differences in patients may contribute to the variable response seen with these drugs.

Clonidine (an α-2 receptor agonist) does not stop the delirium or seizures associated with the withdrawal process, however, it is a good adjunctive therapy to treat the symptoms of autonomic hyperactivity (i.e., increased blood pressure and tachycardia).

Clomethiazole (Distraneurin®) is also an effective drug in the management of delirium tremens; however, its use in the ICU has been declining due to some unwanted side effects such as hypotension, severe respiratory depression, and increased bronchial secretions.

Atypical antipsychotics (for instance, **risperidone**, **quetiapine**, **olanzapine**, and **ziprazidone**), may also be helpful in the treatment of non-alcohol withdrawal related delirium, but only preliminary data exist supporting their use in the ICU. Comparative studies of haloperidol and atypical antipsychotics have failed to identify evidence of any advantage in terms of clinical efficacy. In a non-randomized trial that enrolled 73 medical and surgical ICU patients, olanzapine was compared to haloperidol; the authors reported that resolution of delirium symptoms was similar in both treatment groups, but more side effects were observed in patients treated with haloperidol. It has also been suggested that, few of these new anti-psychotic drugs have a faster onset of action than haloperidol. Unfortunately, many of these new anti-psychotics are only available as oral formulations.

68 Acute Hypertensive Response and Stroke

Alberto Maud [1], **Mustapha A. Ezzeddine** [1], **Adnan I. Qureshi** [1]

[1] Zeenat Qureshi Stroke Research Center, Department of Neurology, University of Minnesota, Minneapolis, Minnesota, USA

68.1 Introduction

Chronic arterial hypertension is the premier manageable risk factor for both hemorrhagic and ischemic stroke [1]. There is a direct and indirect association between chronic arterial hypertension and ischemic stroke. Hypertension is the most common risk factor for small subcortical infarct associated with small vessel disease in the brain [2]. Moreover, hypertension is a known risk factor that predispose for atherosclerosis in the large cervical and intracranial vessels, which constitute the most common etiology of acute ischemic stroke [3]. On the other hand, hypertension is the most important risk factor for spontaneous intracerebral hemorrhage and it has been associated with about 50% of all the intracerebral hemorrhages [4].

Elevated blood pressure is quite common in acute phase of ischemic or hemorrhagic stroke. This phenomenon, known as acute hypertensive response, is the elevation of blood pressure (BP) above normal and premorbid values that initially occurs within the first 24 hours of symptom onset in patients with stroke [5]. Management of acute hypertensive response in acute stroke involves physicians from different disciplines including but not limited to emergency physicians, intensivists, primary care physicians, neurologists, neurosurgeons, and cardiologists. In this chapter we will emphasize the importance of the elevation in blood pressure after ischemic and hemorrhagic stroke and we will discuss its epidemiology, pathophysiology, and current evidence of blood pressure management.

68.2 Definition

Acute hypertensive response is the elevation of blood pressure (BP) above normal; premorbid values that initially occurs within the first 24 hours of symptom onset in patients with stroke. The 2003 World Health Organization (WHO)/International Society of Hypertension (ISH) statement [6] and the Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) define hypertension on the basis of the presence of consistent BP >140/90 mmHg (multiple readings on separate days) [7]. This definition of hypertension is a threshold for the use of long-term antihypertensive treatment that is supported by evidence derived from randomized trials and clinic population-based data that demonstrate reduction in cardiovascular events with this threshold for treatment. The same definition cannot be applied in the case of acute hypertensive response, because the above-mentioned ascertainment criteria and rationale are not valid. The executive summary of the ISH statement on management of BP in acute stroke stated that high BP (>140/90 mmHg) is very common early after ischemic stroke (occurring in ≈75% of cases) and intracerebral hem-

orrhage (ICH >80%) and is independently associated with a poor functional outcome [8]. To maintain consistency with the ISH statement, acute hypertensive response is defined as «systolic BP >140 mmHg or diastolic BP of >90 mmHg demonstrated on 2 recordings taken 5 minutes apart within 24 hours of symptom onset.» This definition predominantly serves to provide a uniform standard for measuring prevalence and not for setting treatment thresholds for antihypertensive treatment, which may vary depending on stroke subtype and other considerations.

68.3 Epidemiology

Acute hypertensive response is reported in more than 60% of patients presenting with stroke in a nationally represented study from United States [9]. With approximately 15 million patients experiencing stroke worldwide each year, the acute hypertensive response may be expected in approximately 10 million patients per year [10]. In a systematic review of 18 studies, 52% of patients with stroke were reported to have high blood pressure at the time of the admission. The criteria used to define high BP varied considerably: systolic BP ranged from 150 to 200 mmHg and diastolic BP criteria from 90 to 115 mmHg [11]. In one of the largest studies in United States using the National Hospital Ambulatory Medical Care Survey, systolic BP >140 mmHg was observed in 63% of the 567, 704 adults with acute stroke, diastolic BP >90 mmHg in 28%, and mean arterial pressure (MAP) >107 mmHg in 38% of the patients [9]. In the same study, the subgroup analysis showed that 67% of the patients with ischemic stroke presented with elevated blood pressure compared to 75% and 100% of the patients with intracranial hemorrhage and subarachnoid hemorrhage, respectively.
Elevated blood pressure is common after stroke, particularly after intracerebral hemorrhage (ICH). It has been reported that up to one third of the patients presenting with acute stroke have elevated blood pressure and there is tendency to normalization within ten days with spontaneous reduction without any antihypertensive treatment [12]. Marked elevation of the blood pressure has been associated with poor clinical outcomes including death and disability in a retrospective study of 87 patients with ICH. In the same study the marked elevated blood pressure (systolic blood pressure >145 mmHg) during the admission and persistent inadequate blood pressure control were both associated with poor clinical outcome [11].

68.4 Pathophysiology

The brain requires constant influx of oxygen and is very susceptible to ischemic changes after even short time of oxygen deprivation. The regional cerebral blood flow (rCBF) needs to be kept steady in order to ensure a constant delivery of oxygen. Approximately 20% of the cardiac output is delivered to the brain. The rCBF is approximately 55 ml/100 g of tissue/minute, ranging from 20 ml/100 g of tissue/minute in the white matter to 70 ml/100 g of tissue/minute in the gray matter [13]. In the brain, the rCBFcan be maintained constant in spite of a significant variation in the cerebral perfusion pressure, which is mainly determined by the mean arterial pressure [14].
Under normal circumstances, changes in precapillary arteriolar diameter (<400 μm) maintain constant cerebral blood flow in the capillary bed between MAP of 60 and 150 mmHg [15]. A fast dynamic response to changes in pressure pulsations is followed

by a slow static response that restore rCBF after the initial dynamic response has settled by myogenic [16] (mechanogenic) and metabolic (chemogenic) mechanisms [17].
In chronic arterial hypertension, the lower end of the autoregulation curve is shifted toward high pressure, presumably because vessel wall thickening and luminal narrowing limit the capacity of the resistance vessels for dilation [18]. In acute stroke, autoregulation may be impaired in regions surrounding an acute lesion and even in the contralateral hemisphere due to dilation of cerebral resistance vessels in an attempt to increase rCBF in response to tissue ischemia and acidosis [19]. More recently, it has been shown that autoregulation is impaired for rapid changes (dynamic autoregulation) in systemic BP even when it is preserved for controlled changes [20]. Other conditions, such as cerebral vasospasm in subarachnoid hemorrhage, also cause arteriolar constriction, which shifts the autoregulatory range toward higher values [21]. In these circumstances (chronic hypertension and vasospasm) there is a clear shift of the autoregulatory curve towards the right. Thus, there is a potential risk of ischemic brain injury with sudden decrease in the cerebral perfusion pressure below the lower limit of the autoregulation [22]. In the presence of elevated intracranial pressure, MAP >60 mmHg may not be adequate to maintain constant cerebral blood flow in the capillary bed. The cerebral perfusion pressure measured as the difference between the mean arterial pressure and the intracranial pressure can underestimate the localized increased pressure and perfusion changes in focal stroke or localized ICH. In absence of a more sensitive method to evaluate the peristroke perfusion changes, the measure of the global perfusion pressure remains still useful. A perfusion pressure of 70 mmHg or higher has been used as a treatment threshold, mainly based on the extrapolation from head trauma patient's management [23].
