To my parents Mirtha and Justino
for giving me the life, education
and the opportunity to study and
acquire this wonderful profession.

To my kids, Facundo, Luciano, Josefina
and Alvaro who have suffered my absences
and for all the love given me every day.

To Veronica, my love, my friend,
my support, guidance, and
containment with whom if God
willing I share what I have left.

To all my colleagues and friends who
have shared with me over than 23 years
of hard and tireless work, uncertainties,
anxieties, sorrows and joys in the Intensive
Care Units where I have worked.

To the life...

Table of Contents

Prologue XXVII
Preface XXIX

SECTION I. Introduction to Neuroinjury

1 **Neuroscience Critical Care: Two Experts' Point of View** 3
1.1 History, Organization, and Vision for the Future: Prof. Mirski's Point of View 3
1.2 NICU Organization: Past, Present and Future: Prof. Robertson's Point of View 10
References 20

2 **Basic Anatomy Applied to the Interpretation of Axial Tomography of the Brain in Emergency Medicine** 27
2.1 Introduction 27
2.2 Development 27
2.3 Key Concepts 36
2.4 Appendix: Images 36
References 51
General References 51

3 **Physiological Basis for the Correct Interpretation of Different Situations in Acute Cerebral Injury** 53
3.1 Functional and Structural Organization of the Nervous System 53
3.2 The Blood-Brain Barrier (BBB) 55
3.3 Cerebrospinal Fluid (CSF) 56
3.4 Aquaporins (AQP) 57
3.5 Intracranial Pressure 58
3.6 Cerebral Volume/Pressure Curve (V/P). Cerebral Compliance 59
3.7 Intracranial Pressure Curve 60
3.8 Cerebral Oxygen Metabolism 61
3.9 Cerebral Blood Flow (CBF) 62
3.10 Oxygen Tissue Pressure ($ptiO_2$) 64
3.11 Cerebral Glucose Metabolism 65
3.12 Cerebral Temperature 65
3.13 Brain-systemic Temperature Gradient 66
3.14 Concept of Primary and Secondary Injury 68
General References 68

4 **Examination of the Critically Ill Neurological Patient** 71
4.1 Clinical Evaluation (or Examination) of the Critically Ill Neurological Patient 71
4.2 General Examination 72
4.3 Comprehensive Neurological Examination 74
4.4 Routine Investigations of the Neurocritical Patient 74

4.5 Focused Neurological Examination of Selected Topics 75
References 101
General References 102

5 Evaluation Scales in Neurocritically Ill Patients 105
5.1 Objectives 105
5.2 Introduction 105
5.3 Evaluation in the Acute Phase 105
5.4 Imaging-based Assessment Scales 114
5.5 Scale of Evolution, Evaluation of Consciousness in Advanced Stages of Brain Injury Outcome Scales 123
General References 129

SECTION 2. Neuromonitoring

6 Neuroimage Monitoring in the Management of Neurocritical Care Patients 135
6.1 Introduction 135
6.2 CT in Head-injured Patients 137
6.3 CT in Patients With Cerebrovascular Hemorrhagic Disease 145
6.4 CT in the Diagnosis of Acute Ischemic Cerebrovascular Diseases 152
6.5 Conclusions 156
References 156

7 Intracranial Pressure Monitoring. Acute Cerebral Injury: the First 48 Hours 159
7.1 Intracranial Pressure 159
7.2 Techniques for Monitoring Intracranial Pressure 160
7.3 The ICP Waveform 161
7.4 Elevated Intracranial Pressure and Pressure Waves 163
7.5 Cerebral Perfusion Pressure 165
7.6 Cerebral Autoregulation 165
7.7 Indications for ICP Monitoring 166
7.8 Conclusions 166
References 166

8 Update on Brain Tissue Oxygen Monitoring in TBI and Other Acute Cerebral Disorders 169
8.1 Introduction 169
8.2 Approaches to Monitoring Cerebral Oxygenation 170
8.3 Hyperemia and Arterial pCO_2 178
8.4 Approaches to Treatment 181
8.5 Early Detection and Treatment of Ischemia 206
8.6 Suggestions and Limitations 211
8.7 Conclusions 212
References 213

9 Monitoring Cerebral Blood Flow and Cerebral Autoregulation: Basic Principles, Techniques, Common Patterns and Interpretation of Results 225
9.1 Introduction 225
9.2 Physiology of Cerebral Circulation 225
9.3 Techniques to Measure Cerebral Blood Flow 227
9.4 CBF in Pathological Conditions 229
9.5 Key Concepts 230
References 231

10 The Current Role of Transcranial Doppler in the Intensive Care Unit. Indications, Bases for Its Correct Interpretation, Most Frequent Applications and Patterns 233
10.1 CBF Monitoring at the Bedside. Transcranial Doppler Ultrasound 233
10.2 Flow Velocity and Pulsatility Index. Normal Range and its Variations 235
10.3 Clinical Applications of Transcranial Doppler in Intensive Care Medicine 235
10.4 Transcranial Ultrasonographic Abnormalities in Neurocritical Patients 237
10.5 Extreme Expression of Intracranial Hypertension: Cerebral Circulatory Arrest 242
10.6 TCD as a Complementary (Auxiliary) Diagnostic Technique in Determining Brain Death 242
10.7 Summary of Changes in Cerebral Hemodynamics: Muñoz Chard 243
10.8 Assessment of Cerebrovascular Reactivity 244
10.9 Appendix 252
10.10 TCD in Evaluating Hemodynamics 256
10.11 Relationship Between CBF and CPP 258
References 259

11 Neurophysiologic Monitoring in Neurointensive Care: EEG, EMG, and Evoked Potentials 265
11.1 Introduction 265
11.2 Electroencephalography 265
11.3 Evoked Potential 266
11.4 Continuous Neurophysiological Monitoring (EEG-SEP) in the ICU 275
11.5 EMG in the ICU 279
References 281

12 Monitoring Brain Chemistry by Microdialysis During Neurointensive Care 285
12.1 Introduction 285
12.2 The Microdialysis Technique 285
12.3 Biochemical Markers of Ischemia and Cell Damage 287
12.4 Lactate/Pyruvate Ratio 288
12.5 Glycerol 288
12.6 Glutamate 289
12.7 Glucose 289
12.8 Implanting and Positioning of Microdialysis Catheters 290
12.9 Selecting Perfusion Flow 293
12.10 Multimodal Monitoring 293
12.11 Interpreting Microdialysis Data 293
12.12 Clinical Studies 294
12.13 Conclusions 298
References 299

SECTION 3. General Support

13 Fluid Therapy in Acute Brain Injury 305
13.1 Introduction 305
13.2 Fluids Commonly Used in Neurocritical Care 306
13.3 Use of Fluids in Neurocritical Care 310
13.4 Conclusions 312
References 312

14 The Metabolism of Sodium and Its Effect on the Brain 317
14.1 Introduction 317
14.2 Hyponatremia 318
14.3 Hypernatremia 325
14.4 Clinical Management and Treatment 326
General References 326

15 Hemodynamic Monitoring 329
15.1 Introduction 329
15.2 Indications and Complexity of Hemodynamic Monitoring 330
15.3 Definitions and Hemodynamic Parameters 330
15.4 Pressure Monitoring 332
15.5 Pulmonary Artery Pressure and the Swan-Ganz Catheter 334
References 345

16 Cardiac Arrhythmias in Nervous System Disorders 347
16.1 Introduction 347
16.2 Stroke 347
16.3 Paroxysmal Essential Hyper- and Hypopothassemia (Periodic Paralysis) 348
16.4 Dystrophy 349
16.5 Myotonic Muscular Dystrophy 350
16.6 Steinert Myotonic Dystrophy 350
16.7 Emery-Dreyfuss Muscular Dystrophy 351
16.8 Muscular Dystrophy of the Extremities and the Waist 351
16.9 Friederich's Ataxia 351
16.10 Kearns-Sayre Syndrome 352
16.11 Leber's Hereditary Optical Neuropathy 353
16.12 Guillain-Barré Syndrome 353
16.13 Myasthenia Gravis 353
16.14 Epilepsy 353
General References 358

17 Mechanical Ventilation in the Neurologic Critically Ill Patient 359
17.1 Introduction 359
17.2 Breathing Control and Respiratory Depression 359
17.3 Sedation 363
17.4 Hyperventilation 364
17.5 Lung Recruitability and Use of PEEP 367
17.6 ALI/ARDS and Ventilator-induced Lung Injury 369
17.7 Weaning 370
17.8 Tracheostomy 372
17.9 Conclusions 372
General References 372

18 Surgical Airway Management in the Neurocritically Ill Patient: Timing, Technique, and Complications 375
18.1 Introduction 375
18.2 Surgical Airway Management 375
18.3 Conclusions 379
References 380

19 Gastrointestinal Disorders in the Neurocritical Patient 381
19.1 Gastrointestinal Motility Disorders in the Neurocritical Patient 381
19.2 Common Gastroenterological Disorders in Severe Acute Neurological Illness . 385
General References 393

20 Nutritional Support in Critically Ill Patients 395
20.1 Introduction 395
20.2 Metabolism During Injury 395
20.3 Assessment of Nutritional Status 397
20.4 Anthropometric Measurement 397
20.5 Biochemical Measures (Biological Indicators) 400
20.6 Nutritional Requirements 405
20.7 Artificial Nutrition 408
20.8 Enteral Nutrition 409
20.9 Parenteral Nutrition 414
20.10 Assessment and Monitoring of Artificial Nutrition 420
20.11 Is There a Specific Nutritional Formulation for Patients with Brain Injury? 421
General References 423

21 Acute Renal Injury in the Neurocritical Patient 425
21.1 Introduction 425
21.2 Epidemiology of Acute Kidney Injury 425
21.3 Definition of AKI in Critically Ill Patients 425
21.4 Diagnosis of AKI in Critically Ill Patients 428
21.5 Common Causes of AKI in Critically Ill Patients 431
21.6 Prevention and Management of AKI in Critically Ill Patients 432
21.7 Indications and Initiation of Renal Replacement Therapy in AKI 437
21.8 Dose of Renal Replacement Therapy in Acute Kidney Injury 440
21.9 Methods of Renal Replacement Therapy in Acute Kidney Injury 442
21.10 Conclusions 444
General References 445

22 The Brain and the Abdomen: Closer Than You Think 451
22.1 Introduction 451
22.2 The Relationship Between IAP and ICP 451
22.3 Clinical Importance of IAH in Patients at Risk for ICH 456
22.4 Treatment Options 458
22.5 Clinical Recommendations 459
22.6 Conclusions 460
References 460

23 Endocrinology of Acute Brain Injury 465
23.1 Basic Anatomy, Physiology and Changes in Acute Brain Injuries 465
23.2 Endocrinology of Acute Brain Injury Secondary to Traumatic Brain Injury (TBI) and Subarachnoid Hemorrhage (SAH) 477
General References 483

24 Coagulation Disorders in the Neurocritical Patient 485
24.1 Introduction 485
24.2 Pathophysiology 485
24.3 Traumatic Brain Injury 485
24.4 Spontaneous Intracranial Hemorrhage 487

24.5 Ischemic Stroke 489
24.6 Subarachnoid Hemorrhage 489
24.7 Prophylaxis of Pulmonary Thromboembolism in Neurocritical Patients 489
General References 493

SECTION 4. Intracranial Hypertension

25 Pathophysiology of Intracranial Hypertension 497
25.1 General Concepts 497
25.2 Compliance 499
25.3 ICP Waves 500
25.4 Factors Which the ICP Depends on 501
25.5 Intracranial Hypertension Compensating Mechanisms 501
25.6 Effects of Intracranial Hypertension 502
25.7 Intracranial Pressure Gradients 503
25.8 Herniaton Syndrome 504
25.9 Elevated ICP 504
25.10 Hydrocephalus 504
General References 508

26 Cerebral Edema: State of the Art 511
26.1 Introduction 511
26.2 Causes of Edema 512
26.3 Methods to Measure Edema 515
26.4 Treatment 516
26.5 Conclusions 519
References 519

27 The Treatment of Intracranial Hypertension. Algorithm of Treatment and First Level Therapeutic Measures 521
27.1 Introduction 521
27.2 Neurotraumatic Patient Treatment in the Hospital 522
27.3 Multimodal Monitoring in Patients With Severe Traumatic Brain Injury 524
27.4 General Measures for Treating Brain Injured Patients 525
27.5 Specific Treatment of Intracranial Hypertension 526
27.6 Muscle Relaxation 527
27.7 Evacuation of Cerebrospinal Fluid 528
27.8 Hyperosmolar Solutions 530
27.9 Hyperventilation 532
27.10 Therapeutic Alternatives in the Treatment of Intracranial Hypertension. Second Level Measures: How Often do We Use Them? 535
27.11 Quantification of Intensity of Treatment Applied to Control I ntracranial Pressure: The Extended Therapy Intensity Level Scale 536
27.12 The Withdrawal of Treatment: A Reverse Stepwise Process 537
27.13 Case Report 538
27.14 Key Concepts 541
27.15 Acknowledgements 542
References 542

28 Second Level Measures for the Treatment of Intracranial Hypertension in Traumatic Brain Injury 547
28.1 Introduction 547
28.2 Etiology of Intracranial Hypertension 549
28.3 Intracranial Pressure Monitoring 549
28.4 Clinical Significance of the Pressure-Volume Curve 549
28.5 Where to Monitor ICP? The Problem of Intracranial Pressure Gradients 551
28.6 Stepped Versus Individualized Treatment 552
28.7 Types of the Therapeutic Measures 552
28.8 Barbiturates 554
28.9 Moderate Hypothermia 557
28.10 Decompressive Craniectomy 559
28.11 Acknowledgements 562
References 562

29 Non-conventional Therapeutics for the Treatment of Elevated Intracranial Pressure: Indomethacin and THAM 567
29.1 Indomethacin 567
29.2 Tromethamine (THAM or TRIS) 569
29.3 References 572

30 A Different Point of View in Intracranial Hypertension Management: the Lund Therapy 573
30.1 Introduction 573
30.2 Pathophysiology After Brain Trauma 574
30.3 Measures to Reduce Vasogenic Brain Edema 574
30.4 Decompressive Craniotomy and Other Surgical Measures 576
30.5 Microcirculation Around Contusions 576
30.6 Maintenance of Normovolemia to Improve Cerebral Microcirculation 576
30.7 Arterial Pressure and Plasma Volume Expanders 577
30.8 Albumin and Erythrocytes as Blood Volume Expanders 578
30.9 How to Determine Whether Intravascular Volume is Adequate 579
30.10 Other Measures to Improve Cerebral Microcirculation 579
30.11 Arterial, Plasma Oncotic and Cerebral Perfusion Pressure 580
30.12 Body Temperature Control 581
30.13 Nutrition 582
30.14 Clinical Application 582
References 584

31 A Critical Point of View in the Management of Intracranial Hypertension: Are All Therapeutic Tools Evidence Based? 587
31.1 Introduction 587
31.2 Sedation as a Therapy 588
31.3 Hyperventilation 589
31.4 Drainage of Cerebrospinal Fluid 589
31.5 Osmotherapy 590
31.6 Cerebral Perfusion Pressure 590
31.7 Hypothermia 591
31.8 Steroids 591
31.9 Albumin 593
31.10 Conclusions 593
References 593

SECTION 5. Traumatic Injury

32 Mild Traumatic Brain Injury 599
32.1 Introduction 599
32.2 Epidemiology 599
32.3 Classification 600
32.4 Radiological Diagnosis 604
32.5 Timing of Hospital Discharge 605
32.6 Post-traumatic Sequelae 606
32.7 Key Concepts 607
Acknowledgements 607
General References 607

33 Moderate Traumatic Brain Injury 609
33.1 Introduction 609
33.2 Epidemiology 609
33.3 Baseline Evaluation 609
33.4 Management Issues 610
33.5 Computerized Tomography 611
33.6 Intracranial Pressure Monitoring 611
33.7 Results 611
33.8 Final Considerations 612
General References 612

34 Medical Treatment of Severe Traumatic Brain Injury 615
34.1 Introduction 615
34.2 Epidemiology 615
34.3 Classification 616
34.4 Pathology of Brain Damage 617
34.5 Pathophysiology 620
34.6 Diagnosis of TBI 622
34.7 Treatment of TBI 624
34.8 Conclusions 635
General References 636

35 Surgical Management of Severe Traumatic Brain Injury 639
35.1 Introduction 639
35.2 Epidural Hematoma 639
35.3 Subdural Hematomas 642
35.4 Intra-axial Lesions 645
35.5 Contusion and Cerebral Hemorrhage 646
35.6 Delayed Intracerebral Hematoma 648
35.7 Lesions of the Posterior Fossa 648
35.8 Depressed Skull Fracture 649
35.9 Surgical Treatment of Increased ICP: Decompressive Craniectomy 650
References 655

36 Severe Traumatic Brain Injury: Pathophysiology and Management Guided by Multi-modal Monitoring 659
36.1 Introduction 659
36.2 Clinical and Cellular Pathophysiology of Severe Traumatic Brain Injury 659
36.3 Clinical Pathophysiology 661

36.4 Autoregulation 661
36.5 Secondary Brain Injury 663
36.6 Intracranial Pressure 663
36.7 Intracranial Hypertension, Monitoring Modalities, and Treatment Strategies 664
36.8 Conclusions 673
References 674

37 Prognosis in Traumatic Brain Injury 679
37.1 Introduction 679
37.2 Prognosis 681
37.3 Prognosis in Traumatic Brain Injury 683
37.4 Prognostic Models 686
37.5 CRASH Prognostic Models 687
37.6 Individual Predictors 688
37.7 Comparison With Previous Studies 691
37.8 Strengths and Weaknesses of This Study 692
37.9 Implications 693
37.10 Future Research 693
References 694

38 Surgical Treatment of Spinal Cord Injury 703
38.1 Introduction 703
38.2 Terminology 704
38.3 Initial Treatment 708
38.4 Spine Immobilization 708
38.5 Maintenance of Blood Pressure 709
38.6 Maintenance of Oxygenation 710
38.7 General Care of SCI Patients 711
38.8 Laboratory Evaluations 712
38.9 Surgical Treatment 715
38.10 Functional Independence Measure (FIM) 716
General References 718

39 Acute Spinal Cord Injury: Pathophysiology and Intensive Care Management 721
39.1 Introduction 721
39.2 Pathophysiology of Spinal Cord Injury 721
39.3 Acute Management of the Patient With Spinal Cord Injury 724
39.4 Conclusion 728
References 729

SECTION 6. Cerebrovascular Diseases

40 Stroke Units: Organization, Past, Present and Future 733
40.1 Objective 733
40.2 Historical Overview 733
40.3 Current Concept of the Stroke Unit 735
40.4 Evolution and Development of Stroke Units 737
40.5 Future: Stroke Networks and Stroke Centers 738
General References 742

41 Regional Stroke Systems of Care and the Role of Telemedicine in Supporting Acute Stroke Care: Case Study of the US system 745
41.1 Introduction 745
41.2 Conclusions 747
References 748

42 Acute Ischemic Stroke: General Approach 749
42.1 Introduction 749
42.2 Pathophysiology of Ischemic Stroke 749
42.3 The Ischemic Penumbra Area 751
42.4 Transient Ischemic Attack (TIA) 754
42.5 Atherosclerotic Carotid Disease 756
42.6 Cerebral Infarction 758
General References 771

43 Ischemic Penumbra: Role of Neuroimaging in Treatment Decision 777
43.1 Introduction 777
43.2 Definition of Ischemic Penumbra 777
43.3 Neuroimaging Tools to Assess Ischemic Penumbra 779
43.4 Clinical Relevance of Ischemic Penumbra: Using Penumbra as a Proof-of-concept 782
43.5 Future Analysis of Ischemic Penumbra 783
General References 784

44 Thrombolysis in Acute Ischemic Stroke 787
44.1 Introduction 787
44.2 Pathophysiology 787
44.3 Pre-hospital Care 787
44.4 Emergency Evaluation and Diagnosis of Acute Ischemic Stroke 788
44.5 General Medical Care 792
44.6 Treatment Considerations 793
44.7 Additional Considerations 802
44.8 Conclusions 803
Rerefences 803

45 Acute Management of Ischemic Vertebrobasilar Stroke 807
45.1 Introduction 807
45.2 Case Report 807
45.3 Vascular Anatomy 810
45.4 Pathophysiology 810
45.5 Presentation 810
45.6 Diagnostic Imaging 811
45.7 Prognosis of Acute Basilar Artery Occlusion 811
45.8 Development 811
45.9 Key Concepts 814

Prologue

This book deserves to my gratitude, more than my prologue.
Many years ago, when this project started, its aim was simple: to provide the physician with a quick and practical tool for consultation. However, the enormous generosity, selflessness and spirit of collaboration of great teachers and world opinion leaders in this subspecialty made it possible to transform it in what it is today.
Some time ago (I still remember well his e-mail), Prof. Stephan Mayer of Columbia, New York, in that period President of the Neurocritical Care Society, described the book as "magnum opus". In my humble opinion this definition was very exaggerated, but his words were like a shot of optimism that undoubtedly lead the way. My teachers and friends encouraged me, helped me, I held back, and therefore they all have my eternal gratitude. In particular, I'd like to mention two persons who had a great role in my professional life, with whom I shared most of my professional life, two great friends: Esteban Piacenza, who taught me how to take my first steps in intensive care, and Prof. Walter Nigri, neurosurgeon, who introduced me into the neurocritical care.
Of course it was not so easy. Editing a book of this magnitude is a Herculean task, only understandable by those who have done something similar. In addition, during its preparation I had to overcome a rough and long illness (and this is the reason for its delay). However, like everything one undertakes in life, it has a special flavor when the effort needed has been intense. So I'd like to recommend to potential readers two sentences that accompanied me throughout my life, especially during difficult periods and obviously while editing this book: «Persistence is the key to success» and «What's to come is better».
Simply thanks to all those who made possible to make this dream come true.

Daniel A. Godoy

Preface

«During revolutions scientists see new and different things when looking with familiar instruments in places they have looked before. It is rather as if the professional community had been suddenly transported to another planet where familiar objects are seen in a different light…» [1]
Thomas S. Kuhn

This volume, which we have the honor to introduce, presents the work of a group of international experts in neurocritical care. Dr. Daniel Godoy has completed thedaunting task of introducing the beginner and updating the specialist on current knowledge in brain injury. Anyone who has been involved in editorial projects will have experienced the trials and tribulations of uniting the efforts of many; Dr. Godoy's book is no exception. He has met this challenge patiently and tenaciously. Having known him for many years, we feel he is to be commended for his devotion and drive. His extraordinary interest in science has made him a well-known expert his field bringing about an ever-increasing level of activity in neurointensive care in Argentina.
Many of the contributors to this book are known personally to us, colleagues with different specialties who we also consider friends, having come together through a shared fascination with an undoubtedly complex and heterogeneous medical challenge: neurocritical care.
This book is dedicated to brain-injured and neurocritically ill patients. The management of these patients constitutes a growing subspecialty that remains unrecognized by many international medical associations but has played a prominent role in intensive care over the last two decades.
Neurocritical care as a subspecialty evolved from the need to provide highly specialized care to neurosurgical patients. Later, patients with severe traumatic brain injury (TBI), hemorrhagic stroke, and acute central nervous system disorders were included in this line of care. Each of these patients requires specialists who are knowledgeable of their particular clinical situations in addition to rapid and often complex management of intracranial hypertension, technical equipment, and skilled nurses [2]. Indeed, specialized nursing forms the backbone of modern neurocritical care units.
As with the management of other complex pathologies (e.g. neurovascular disorders, endoscopic surgery, skull base fractures, and pediatric neurology), subspecialization in neurosurgery is essential to improving outcome and reducing complications.
In neurosurgery, outcome is always improved when the patient is in the hands of an expert instead of a general, though versatile, neurosurgeon. However, some sectors of the

international intensive care societies still view neurocritical care subspecialization with skepticism, if not with mistrust. In our opinion, these attitudes reflect irrational fears and are at odds with scientific evidence in support of subspecialization. Several studies have shown that neurocritical care specialization reduces mortality, improves functional outcome in almost all diseases studied, and is cost-effective for the health care system [3]. This has been demonstrated in patients with severe TBI, spontaneous subarachnoid hemorrhage, intracerebral hematoma, and ischemic stroke [3-5]. Admittedly, in some cases it is not easy to discern whether the determinants of improved results are the specialized units themselves or the well-structured clinical management protocols. In patients with severe TBI, the rigorous application of the Brain Trauma Foundation guidelines has been shown to significantly reduce mortality [6]. What should be remembered, however, is that such protocols have been created using procedures designed by neurocritical care specialists. What has brought added value to subspecialization most is the human factor, as noted by Smith: "Members of a multidisciplinary team who care regularly for patients with acute brain injury are more likely to be aware of the adverse impact on the brain of secondary physiological insults and to be more obsessional about their prevention, recognition and treatment" [2].

Despite contradictions, doubts, and disagreements, neurointensive care has reached organizational levels unthinkable just a decade ago and neurointensive care units can now be found in nearly all countries. Nonetheless, the tempo of change varies and the models are diverse. The Neurocritical Care Society in the United States and the Canadian Neurocritical Care Society were founded in 2003 [3]. The European Society of Intensive Care Medicine has also established a neurointensive care section, the Neuro-Intensive Care and Emergency Medicine Section. Access to specialized accreditation is homogeneous, however, following several models and using methods of access, while in other countries no models have been implemented at all.

In our opinion, and contrary to popular belief, a well-planned subspecialization based on competencies as well as generic and specific skills will not restrict but rather widen the viewpoint of the specialist and add value to the care of neurocritically injured patients. This provides a driving force for translational research, an indispensable tool in the 21st century that increases knowledge and improves mid-term therapeutic strategies and prognosis. Translational research, which is promoted by the US National Institutes of Health (http://commonfund.nih.gov), is only feasible with a therapeutic approach using multidisciplinary teams with different perspectives and methodologies to obtain a comprehensive understanding of these patients. This allows new therapeutic strategies to move from bench to bedside and back again. To be successful, this kind of research requires teams to work in an atmosphere that fosters collegial effort among neurointensivists, neurosurgeons, and neurologists with a vocation for research in collaboration with basic researchers. This ideal scenario is only possible within the context of neurocritical care units. Who should lead these units would be a side issue were it not for contentious debate in some countries and in certain scientific societies. We feel that intensive care experts are the most qualified professionals to lead these groups and facilitate the collaboration of different specialists with the common goal of improving prognosis in neurocritically ill patients.

The many research projects carried out during the Decade of the Brain (1990-2000) have produced an enormous wealth of information, and our ability to understand the underlying pathophysiology of many of the conditions affecting TBI patients is challenged, even for our colleagues in neurocritical care. These rapid advances in neuroscience over the past 20 years have led to difficulties in filtering, reading, understanding, and assimilating the latest findings. One of the great advantages of this book is that it may serve both those wishing to enter the field of neurocritical care and specialists seeking a time-

ly update. This volume originated in Latin America, where health systems are heterogeneous and free universal health coverage is not yet a constitutional right in some countries. It is therefore important to underscore that specialization in neurocritical care is only valid in certain socio-economic contexts where health care priorities are well defined. What is desirable in certain circumstances may not be so in others. The adequate context for subspecialization is perhaps more typical in developed countries, with high-tech hospitals or academic organizations that provide incentives for the management and maintenance of high-cost units. In such settings, treatment should be optimal and auditable, and serve as a guide for the design and validation of intervention protocols at other centers with fewer resources.

It is a great honor for us to introduce readers to a work that will leave a significant mark on Latin American and international neurointensive care thanks to Dr. Godoy's commendable effort to make an English version available. It is important that a project of this scale come from Latin America because it serves as a proof t ofthe enthusiasm for this subspecialization, which has been solidly established in that part of the world over the past 15 years.

New generations of intensivists, neurosurgeons, neurologists, and anesthesiologists are facing new challenges. Perhaps the most difficult challenge is to modify the collective consciousness with the idea that the optimal management of brain-injured patients cannot be carried out without a multidisciplinary approach. This is currently not being taught during specialized training, nor is it accepted elsewhere in different scientific fields, where specialists perpetuate a sterile debate about their identities and delineate characteristics that divide rather than unite them.

We believe we are witnessing what Kuhn called a "paradigm shift" or a turning point in neurocritical care. Kuhn also noted that such changes are almost never brought about by new findings but rather by the synthesis and critical review of what is already known. Frequently, it is the observer's point of view, not the observed fact, that changes. Some evident examples in pathophysiology include cortical spreading depression described by Leão in 1944, basic concepts of brain edema first described by Klatzo in 1967, and the pathophysiology of cerebral vasospasm in spontaneous subarachnoid hemorrhage, all of which were far too summarily debated for decades. In the last five years, these three areas, to name just a few, have seen dramatic advancement in terms of knowledge about the mechanisms of brain injury that had long been elusive. Improved understanding has come about by re-examining long-cherished concepts through the use of new monitoring tools and methods in molecular biology. This increased knowledge opens new therapeutic expectations, an idea best summarized by Pang et al: "the application of what we know will have a greater impact on health and illness than any new drug or technology to be introduced in the next decade" [7].

Dr. Godoy has edited a volume that will serve as a starting point rather than a final goal, opening new inroads and stimulating the interest of readers in search of knowledge. We believe that the breadth of the topics covered, the careful selection of the authors, and the quality of each section will meet if not exceed expectations.

The management of acute cerebral injury has been very limited until the last decades. Before the introduction of the CT scan, there were surgical options for removing expanding hematomas only if suspected studying alterations of the brain vascular tree in angiography. Vascular neurosurgery was at the beginning, possibly not in the acute phase, and it took the microscope to become a viable option. On the medical side, supportive measures, including oxygenation and nutrition, were available, but nothing specific for the brain could be attempted.

When few pioneers started the continuous measurement of intracranial pressure in patients in Scandinavia [1] and France [2], the path toward medical treatment was opened, with a very consistent pattern: the availability of new technology (starting with ventricular catheters, for instance) offered new information. This information was confirmed and clarified in the experimental setting, with the development of animal models. Without this seminal work, summarized in the first ICP meeting in Hannover [3] clinical information (as neurologic symptoms and signs, or the previous neuropathological background) and experimental data could not have reached, and improved, daily clinical practice.

It has been a growing understanding of the pathological changes in the injured brain that has made the modern medical and surgical approach possible.

It took some time to apply the discoveries of the pioneers to the current practice (the artero-venous difference in oxygen content had been published during the second world war [4] and applied in neurointensive care only 30 years later), but the process started, and continues.

The book which I am introducing states this path in its title, and describes a management based on pathophysiology. It is with a mix of pride and anxiety that we may propose, nowadays, such a treatment founded on scientific understanding of what is normal and what is pathologically altered. Pride because the knowledge has advanced so much, and anxiety because our ignorance is still so endless.

The plan of the book is clear: since there is no treatment if the problem, and possibly its causes, are not identified, every therapy should be based on measurements. Neuromonitoring is the tool of trade in intensive care, and should incorporate cutting edge technology with patience, repeated clinical observation, careful identification of neuroworsening. On purpose, the clinical examination belongs to the introductory section, and an abundance of technology, with specific emphasis on the importance of intracranial pressure, comes in the following parts.

A major contribution of intensive care to brain-oriented strategies has been a comprehensive approach to systemic physiology. The patient with an injured brain can have

chances only if other organs and systems (as the lungs, and the acid-base equilibrium, etc.) are preserved. General support, and the interactions between the affected brain and other organs, are covered in a section devoted to "general support".
Further attention to this problems is given in section seven, where the interactions between systemic parameters (as glucose concentration or arterial pressure) and the brain are described.
The way the brain reacts to different insults has common aspects, as inflammatory responses, edema, etc., but also specific features. Sections five to nine summarize the most relevant pathologies, from ischemic to hemorrhagic lesions, trauma, tumors etc. and also mention new-comers, as the specific problems related to the expanding field of neuroradiological interventions.
Finally, there are "milestones that we should not forget". Neurointensive care does not exist without knowledgeable nurses. The intracranial pressure measurement starts (or unfortunately ends) with a catheter well maintained, and that becomes vital when the drainage of hydrocephalus is concerned. Dealing with patients with severe brain damage has plenty of ethical implications, up to the problems related to brain- death and organ donation.
All these aspects in a book. A book which arrives in an era of electronic information sharing, and in the field of neuroscience, one of the fastest moving. If completeness was the aim, the book will look as a library, and would become outdated tomorrow. But the aim is to be of practical use, and to assist the clinical practice of the busy physician. Then clarity and synthesis have been the priority, rather than academic perfection.
The intelligent reader will find what is necessary for starting, rather than finishing, his approach to neurointensive care.
If this book will reinforce interest and curiosity, suggesting further reading and research, it will have accomplished a valuable goal.

1.1 History, Organization, and Vision for the Future: Prof. Mirski's Point of View

1.1.1 Introduction

Neurocritical care, a subspecialty of medicine and neurology, principally deals with life-threatening diseases and trauma of the nervous system, including the brain, spinal cord and peripheral nerves. Its contemporaneous form can be traced back to the formal designation of Intensive Care Units (ICUs) during the 1980s, incorporating for the first time an interdisciplinary group of physicians from neurology, anesthesiology, and neurosurgery whose interests coincided with the management of neuroscience critical care patients. Such patients receive treatment for strokes, ruptured aneurysms, traumatic brain and spinal cord injury, seizures, swelling and infections of the brain, brain tumours, and respiratory muscle weakness. Besides dealing with critical illnesses of the nervous system, neurointensivists also manage co-morbidities and medical complications involving the heart, lung, kidneys or any other body system. Most neuroscience ICUs are a collaborative effort of a larger clinical and academic neuroscience cooperative where neurointensivists, neurosurgeons, neurologists, radiologists, pharmacists, physician extenders (e.g., nurse practitioners or physician assistants), critical care nurses, respiratory therapists, rehabilitation therapists, and social workers all work together to provide coordinated care for the critically ill neurologic patient. The success of a neuroscience ICU can usually be easily measured by how central the clinical domain has become to the management of neuroscience patients. In addition to the efficiency and quality of care brought about by subspecialty expertise, the neuroscience ICU often becomes the epicentre of interdisciplinary consultation, patient triage, consensus of care, and departmental administrative overlap. Furthering this process, the Neurocritical Care Society was founded in 2004 by a host of clinical neuroscience experts to promote quality care, professional collaboration, research, training, education and advocacy.

1.1.2 Brief History of Brain Injury, Neurologic Disease, and Neuroscience Critical Care

The origins of acute, "intensive" medical attention to the nervous system derive from physical evidence. Far before the earliest written records of medical practice, the first case of brain injury to the humanoid species dates to almost 1 million years ago in a

specimen of the semi-erect hominid *Australopithecus africanus* which had sustained a blow to the occiput, leaving behind a defect the size of an antelope humerus bone found near the skull – indicating that death had occurred by clubbing (the first evidence of a homicide). Pre-historic examples of trephination abound, many datable from 10,000 BC to 3000 BC, as the earliest physical documentation of medical therapeutics [1].

Although the Kahun Gynecological Papyrus (1800 BC) is recognized as the oldest record in the medical literature, the Edwin Smith Papyrus (1600 BC) [2], a copy of part of an ancient Egyptian textbook on trauma surgery, appears to have drawn on material at least 1000 years earlier [3]. Of the seven Egyptian papyri on the art of medicine (Edwin Smith, Hearst, Ebers, London, Berlin 3038, Carlsberg VIII, Chester Beatty VI), the Edwin Papyrus may be the sole recovered text to describe the management of neurological disease. Within its evocative analysis, the text contains the first descriptions of cranial sutures, the meninges – the brain's protective structures –, features of the cortical surface, and a narrative on cerebrospinal fluid, along with its intracranial pulsations. Skull fractures are classified as fissures, smashes, (comminuted), compound comminuted, and comminuted and depressed. Also described are basilar skull fractures with bleeding from the ears, and an account of a head injury resulting in aphasia, the first such neurological diagnosis, which was considered as an ominous sign. It is plainly evident from the text that the ancient Egyptians held a rational view of functional anatomy emanating from common practices based on mysticism found in many other contemporary sources of that period.

Records from other ancient civilizations, particularly those of the Greek and Roman Empires, reveal much about the characterization of neurological disease. Famous for his formal oath of medical practice, Hippocrates, himself the son of a physician (Heraclides), stressed the importance of the medical history, wound inspection and palpation [4]. Focusing on head trauma, Hippocrates described three mechanisms of primary injury: 1) attack by another; 2) extracranial or intracranial injury sustained in a fall; and 3) an injury from a projectile. Hippocrates categorized such injuries so that he could infer from his observations the mechanism of the trauma. He classified weapons as being "rounded, smooth surfaced, blunt, heavy and hard" which produce depressed fractures and contused brain tissue, "and are more disposed to suppurate, and to have a discharge, and take longer to become clean." Other weapons may be more "elongated, slender, sharp, and light," typically yielding superficial lacerated bleeding wounds "when they take place in the bone without fissure, contusion, or depression." [4].

Hippocrates offers a detailed description of the signs and symptoms of a victim befallen a mortal head wound but surviving initial injury. "Fever will generally come on if in winter, and in summer the fever usually seizes after seven days. And when this happens, the wound loses its colour, and the inflammation dies in it; and it becomes glutinous, and appears like a pickle." He goes on to mention that "convulsions seize the other side of the body; for, if the wound be situated on the left side, the convulsions will seize the right side of the body; or if the wound be on the right side of the head, the convulsion attacks the left." Finally, "blisters form on the tongue and he dies delirious."

Hippocrates even makes the first suggestion of therapeutic hypothermia, as he states that death from head trauma: "for the most part, some become apoplectic and die before the end of seven days, if in summer; and before fourteen, if in winter." [4].

Wound inspection and palpation, including head trauma, was also key to overall assessment. The finding of hair in a wound demonstrated that the underlying skull may have been damaged. Hippocrates also experimented with probing techniques to ascertain the significance of injury. There is evidence that he also recommended trephination for the management of skull fissures or fractures, with the intent to create a passage for draining excess blood or cerebrospinal fluid. Along such lines of practice, some historians even credit Hippocrates with being the first to treat hydrocephalus.

Aristotle described the brain meninges and the supratentorial versus the subtentorial compartments of the brain, although he did not understand the importance of the brain for neurological function. Celsus, in ancient Roman times, wrote on brain trauma and suggested that brain stem injuries were graver than those more cephalad. He recognized that intracranial hemorrhage could occur without frank trauma to the skull. Galen (Galen of Pergamum) gave a detailed account of medical anatomy (based on monkeys) that remained unsurpassed until the publication of the anatomic descriptions and illustrations of human dissections by Andreas Vesalius in 1543. In the context of neurophysiology and critical care, Galen perhaps made one of the first inferences to neurogenic asphyxia by defining the importance of the recurrent laryngeal nerves for vocal cord function [5].

Arabic culture made major contributions to medical practice. Influential practitioners such as Rhazes and Abul-Qasim Al-Zahran described neurological injuries, including intracranial bleeding, concussions, and skull fractures. Ominous signs and symptoms following traumatic brain injury included vomiting, convulsions, encephalopathy, and fever [1].

During the Medieval Period, Roger of Salerno (c. 1170) reported on trephination for head trauma but also described in detail the procedure and benefits of head wound debridement and cleansing [1]. Lanfrancus (1296) correctly assigned reversible neurological injury to mild trauma to the brain, and equated a grim prognosis of traumatic brain injury to the constellation of fever and seizures. Guy de Chauliac (1290) is credited with having successfully performed a limited brain resection following head trauma.

It was not until the Renaissance, however, that anatomic structures were brought into association with disease states and therapeutics were improved. With the advent of the printing press, concepts and material could be widely disseminated, fostering rapid advancement in all fields, including medicine and neurology. Although Vesalius's seminal work on anatomy was revolutionary for medicine, he is believed to have rarely performed formal dissection of the cerebrum removed from the cranium during his course of describing the neuroanatomic elements of the brain.

Much work was left to anatomists such as Thomas Willis who published his "Anatomy of the Brain" in 1664 followed by "Cerebral Pathology" in 1676. He coined the term "neurology", and his concepts continued to refine contemporary understanding of epilepsy and stroke/paralysis.

Jean Louis Petit (1674-1750) was perhaps the first to correlate increased intracranial pressure with hemorrhage, and that delayed loss of consciousness was pressure related as opposed to the initial unconscious state following impact to the head. Unfortunately, the causes of morbidity and mortality secondary to elevated intracranial pressure were not universally appreciated; throughout most of the 18th century, serious injury was correlated only with the presence of a skull fracture. It was therefore inconceivable to convict a criminal of murder if the victim had been killed by blows to the head but there was no evidence of skull fracture [1].

Coincident with investigations into reviving the head trauma victim, resuscitation of the medically dying patient was promulgated during the 16th century by Paracelsus and later by Vesalius. Although Galen had described long before that introducing air into the oropharynx could serve to inflate the lungs, the latter described a method for artificial ventilation by inserting a reed into the tracheal lumen [6]. By the 18th century, upon the discovery of oxygen (1774) and carbon dioxide (1754), the concept of respiration and ventilation was set on a new scientific foundation. Techniques in both positive and negative pressure ventilation were introduced during the early 19th century and were later refined during the poliomyelitis epidemic between 1918 and the 1950s. The famed negative pressure "iron lungs" from the 1920s onward were remarkable devices that saved

uncountable lives. Developed by Sir Henry Gauvain, an iron lung machine was first used at Boston Children's Hospital in 1928.

The management of respiratory failure in poliomyelitis was probably the first medical example of neurological critical care. Ironically, during the early decades of the 20th century, it was those physicians who were interested and trained in neurological disease who were usually the primary caregivers of such patients and so could be defined as being the first "neurointensivists". Some neurologists provided invasive therapeutics such as tracheostomy, bronchoscopy and even abdominal surgical procedures [7].

While neurosurgical procedures were slowly refined during the 19th century, a landmark contribution to the ability to visualize, and hence resect lesions within the brain, was Dr. Walter Dandy's innovation of air ventriculography, which he described in 1918, and the less invasive technique of pneumoencephalography, which he developed and published in 1919. For this achievement he was nominated for the Nobel Prize in 1933. These two diagnostic techniques spurred advances in neurosurgery, as Dr. Dandy became increasingly skilled in operating on the brain and spinal cord. In 1921 he described an operation for the removal of pineal region tumours, in 1922 the complete removal of tumours of the cerebellopontine angle, and in 1922 the use of endoscopy in the treatment of hydrocephalus ("cerebral ventriculoscopy"). In parallel to his operative skills, Dandy also devoted considerable attention to perioperative care and operative efficiency. With the creation of his famous "brain team" at Johns Hopkins, which would dominate clinical neurosurgery between the 1920s and the 1940s, his recognition of the need to provide subspecialty support for his post-operative patients led to the establishment of the first acknowledged surgical, as well as the first neurosurgical, intensive care unit (3 beds) in 1923.

Thereafter, post-operative neurosurgical wards became commonplace, although they functioned separately from the parallel development of post-trauma "shock units" during World War II and high acuity medicine of the 1930s and 1940s. The 1950s brought together the increased utility of mechanical ventilation and landmark innovations in cardiac resuscitation. In 1958, Baltimore City Hospital (Maryland, USA), now the Johns Hopkins Bayview Medical Center, opened the first integrated, fully staffed ICU in the U.S. under the direction of Dr. Peter Safar. At the time, only about 25% of hospitals (>300 beds) had an ICU care model, but by the late1960s nearly 95% of hospitals had one in place [8].

With further advances in neurosurgery, and the ability to manage critical illness, neurology and post-operative neurosurgery became increasingly commonplace and more neuroscience patients were being admitted to the ICU. By the early to mid 1980s there was recognition among some neurologists that once again there was a need for physicians within their specialty to assist in the management of such a hospital population. But since medical and surgical-anesthesiologist intensivists were often not savvy to the critical care needs of neuroscience patients, a niche opened for a new neurologist/neurosurgeon/anesthesiologist: the neurointensivist.

Through the 1980s and 1990s, four major centres of neuroscience ICU training emerged: Dr. Allan Ropper at Massachusetts General Hospital; Dr. Thomas Bleck at the University of Virginia at Charlottesville; Dr. Matthew Fink at Columbia University; and Dr. Daniel Hanley at Johns Hopkins. These four neurologists were instrumental in defining the subspecialty of neurocritical care in the U.S. Meanwhile, in Europe, Dr. Werner Hacke pioneered efforts to unite acute stroke management and neuroscience ICU care.

1.1.3 Organization to Accommodate Practice

Today, neurocritical care has become an established subspecialty: the NeuroCritical Care Society was founded in 2003 and publishes its own journal – *The Journal of Neurocriti-*

cal Care (PubMed); fellowship and specialty received accreditation by the United Council for Neurologic Subspecialties (UCNS); and a formal match fellowship selection process came into being in 2009.

The position of neurological intensive care can be viewed as a gradual coalition between three patient populations and their respective venues of management: the post-operative neurosurgical patient – the neurosurgical ward/ICU; the stroke population – the neurology ward/stroke unit; and the neurological patient – the ward and medical ICUs. The advancement of medical therapeutics in neurological care, especially in the treatment of seizures, ventilatory support for neuromuscular disease, and thrombolysis and interventional neuroradiological intervention in cerebrovascular disease have enabled the neurocritical care concept to gain ground as a subspecialty ICU arena. That stated, the overlap in care within each of these unit environments and the limited availability of trained neurointensivists have each contributed to the number of currently applied neuroscience ICU practice models.

The simplest provision of a neurointensivist is as a consultant physician to an ICU practice. Such physicians provide valuable input into the management of critically ill patients, but their focus of attention and authority is typically limited. In such a model of care, comprehensive ICU management remains the responsibility of a critical care team not under the control of the consultant. Yet, as more and more neurointensivists are trained and populate hospital domains previously without any neuroscience ICU support at all, this model is often the initial step to be taken.

In medical centres that tap into resources of neurosurgery and anesthesiology, it is more likely that neuroscience ICU care can be offered in a more comprehensive fashion, whether delivered in an open, semiclosed, or closed ICU model. Although the last clearly offers the most unified approach to patient management, it requires a very collegial relationship between the neuroscience departments, as well as hospital support for highly trained nursing staff and additional resources. The specific type of the incorporated model also has much to do with a medical centre's emphasis of care. In neurosurgically dominant facilities, attention must be directed to afford maximal efficiency to perioperative management and to facilitate bed availability and care protocols. Where neurological admissions are common, having efficient links between the Emergency Department and the ICU is paramount, and the integration of a stroke centre matrix is also vital. In larger settings, both neurosurgical and neurological needs are met. In the framework of acute neurosciences, the neuroscience ICU acts as a "hub" of clinical activity, with neurosurgery, acute neurology, stroke team, and interventional neuroradiol-

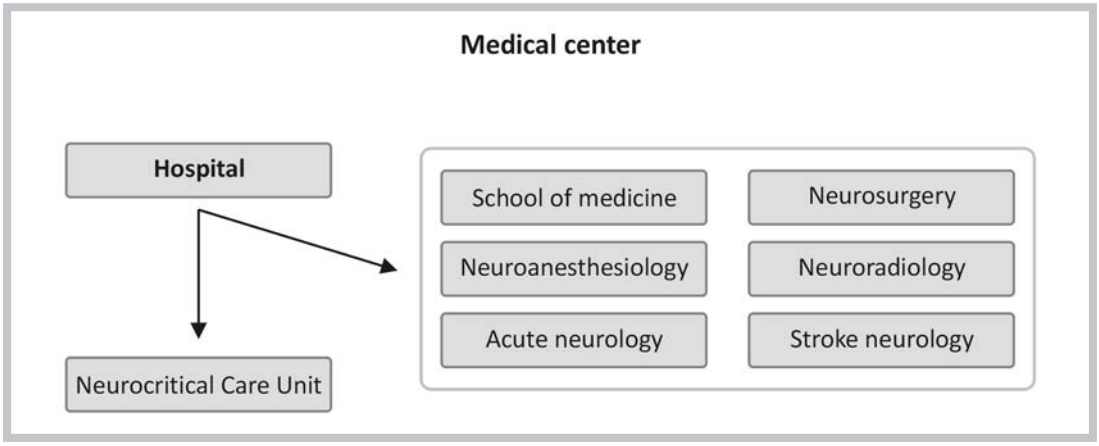

Figure 1.1. Acute interdisciplinary ICU program.

- Educational and training role: fellow, resident, NP
- Billing format: admitting MD, consultative
- Breaking out: lofty goals, academics

Table 1.1. **Neuroscience Intensive Care Unit: organizational perspective.**

ogy as the key spokes in the comprehensive acute neuroscience program (Figure 1.1).

As the neuroscience ICU becomes established and clinical activity increases, the staffing model becomes key to continued growth and success. Comprehensive care, the goal of any ICU team, is possible only with the provision of ample physician level coverage – attendings, nurse practitioners, fellows and residents – for 24/7 patient oversight. A variety of staffing models exists in U.S. neuroscience ICUs and is an important element in the organizational perspective and intent of the ICU (Table 1.1).

1.1.4 The Standalone Neuroscience ICU: The Hospital Versus the Physician Argument

As medical centres strive to grow their acute neuroscience programs, the debate of creating a subspecialty neuroscience ICU versus managing patients in a more generic model of critical care (general medical or surgical ICU) is often entertained. Arguments for both clinical domains can be made. The hospital argument against a subspecialty ICU is mainly justified by the increased inefficiency of the ICU system. Limited bed flexibility, staffing with ICU specific nurses, and increased physician coverage all increase the overall cost of ICU management (Table 1.2).

On the physician side, there are numerous overt and potential patient outcome benefits and financial remuneration to the medical centre that should offset the inefficiencies inherent to a subspecialty ICU system. These advantages can be summarized as 1) direct patient benefit in outcome measures as supported by published data; and 2) strengthening hospital neuroscience initiatives and efficiencies of care (Table 1.3). With regard to improved outcomes, there are several published comparative series that review patient care in both neurological and neurosurgical disease. In neurology, intracranial hemorrhage is the most common diagnosis as it accounts for the highest incidence of a homogeneous group of neurological admissions to a neuroscience ICU. Reports by Diringer et al. and Mirski et al. both support the benefit of a neurological subspecialty ICU in terms of decreased mortality, from an estimated 40-50% in a general ICU to a mean of about 20-25% [9,10]. Others groups have also reported the benefits of a subspecialty neuroscience ICU, with lower

- Administrative and political goals/conflicts
- Other ICUs – Patients selection
- Territorial issues
- Increases cost/patient
- Sacrifice bed efficiency
- Dilutes Intesivist coverage pool

Table 1.2. **Impediments towards a subspecialty neuroscience ICU.**

- Improvement in patient outcome
- Sensitive neurological evaluations
- Precise match therapeutics to neuropathophysiology
- Neurocritical trained nursing
- Cohesive and comprehensive rounds
- Neurological monitoring – capable and savy
- Hub of clinical neuroscience communication
- Neurological and neurosurgical priority
- Academic concentration
- Centrepiece – Acute Neuroscience Center of Excellence

Table 1.3. **Standalone Neuroscience ICU: the physician argument.**

mortality and improve ICU management [11-13].

Furthering the argument, the U.S. business community led an initiative to provide improved ICU care to their insured employees as a means to enhance quality of care and reduce spending. The Leapfrog Initiative http://www.leapfroggroup.org) lists ICU care metrics presumed to achieve these goals. Among them are several pertinent to the presence of an ICU intensivist: 1) intensivist(s) present in the ICU during daytime hours, days per week, with no other clinical duties during this time; 2) return rates of over 95% of pages within 5 minutes; and 3) reliance on a physician (e.g., fellow or resident) or a non-physician extender in the hospital and able to reach ICU patients in less than 5 minutes during non-daytime hours. In an environment clamouring for more physicians to specialize in critical care, the arrival of neurointensivists to direct and manage existing neuroscience ICUs (or neurosurgical units which are commonplace) makes good business sense. Modelling out such intensivist-driven care, Pronovost and colleagues at Johns Hopkins estimated a cost savings to a medical centre, beyond the additional expense of financing a subspecialty intensivist-driven ICU, of between $ 800,000 and $ 3,000,000. Even in a worst case scenario, the savings would exceed $ 1 million on average [14] (Table 1.4).

Revenues	• Clinical ICU professional fee • Other clinical revenue (e.g. consults, etc.) • Extramural salary support (e.g. research grants, etc.) • Neurophysiology laboratory (e.g. transcranial doppler, ultrasound) • Joint agreement (Medical Center and ICU) • Clinical trials, ICU courses
Expenses	• Salary and benefits • Additional (Faculty/fellow educational allotment) • Faculty direct overhead (physical plant) • Departmental overhead (administration) • Supplies and equipment

Table 1.4. **Potential areas of revenue and expense for a neuroscience ICU. Specific to this issue, comparison of the function and cost of care of a newly formed neuroscience ICU as compared with the same patient population cared for in a mixed medical-surgical ICU set up just 2 years earlier yielded substantial cost savings in length of stay and cost reduction in expenditures for radiology, pharmacy and laboratory testing services [10].**

1.1.5 Conclusions

Looking toward the future, the reality is that even if all the current academic fellowship training sites for neurocritical care continue to graduate several dozen subspecialty intensivists, their number will be too few to meet the demand within the acute neurosciences. In large, medium, and even smaller community hospitals, there will be a greater need for neurological expertise in the critical care environment as we promote newer therapies for acute stroke, head injury, and perioperative care. In general, much of this domain is beyond the usual training of a medical or surgical intensivist. That may indeed have to change. But currently neurological disease is not well addressed in ICU programs in the U.S., and too few neurologists seek engagement in a hospital critical care setting. The likely answer lies in the realm of the expanding demand and supply of telehealth solutions that can provide virtual bedside consultation directly between an intensivist or a surgeon and a neurointensivist. In the U.S. alone there is a disproportionate situation of a mere 50 well-staffed neuroscience ICUs amongst 6000 hospitals and their corresponding medical and surgical critical care areas. As a sudden genesis of first tier comprehensive neurological centres is unlikely, it appears reasonable to expect that the care provided in such domains must be directed outwards. That will very likely be the second evolution of neurological critical care.

1.2 NICU Organization: Past, Present and Future: Prof. Robertson's Point of View

I would like to see the day when somebody would be appointed surgeon somewhere who had no hands, for the operative part is the least part of the work.
Harvey Cushing

Neurocritical patient care draws a parallel line with the principles of general intensive care which requires a thorough understanding of the pathophysiology and focuses initially on the resuscitation of patients in extreme physiological deterioration. The focus of the initial approach is usually on the acute condition without considering in detail the patient's medical chronic condition. Then, the intensivist should gather the patient's medical history, essential to complement the assessment of his/her current physiological condition. General intensive medical care has been predicated on the ability to give time for a specific therapy to work or for restoring tissue to promote the recovery of organ function. However, there are few available effective therapies for brain injury (trauma, vascular, etc.): the limited plasticity of the fully mature brain should also be considered.

1.2.1 Past

The history of neurosurgery and the management of traumatic brain injury (TBI) are inextricably linked. Trepanation was sometimes named the "first surgical procedure", with the first reported trepanations found in Northern Africa and dating back to around 10000 BC [1]. There is abundant archeological evidence for the success of trepanation worldwide, with the Peruvian Pre-Columbian collection being perhaps the most noted [2]. Identifying the purpose of this practice isn't easy, but some answers include both medical reasons and mystical practices: treatment for headache after TBI [3], treatment for epilepsy, migraine or psychiatric disorders, and even "letting out the evil spirit."
It is prudent to mention that there is ample room for speculation in this area, and that the "after surgery" care provided by the "first neurosurgeons" also gives rise to controversy. Very likely, trepanation developed in different regions of the world independently. A precise starting point of the history of neurosurgery and neurocritical care surgery is a topic of discussion, and some medical historians have preferred to establish arbitrary phases in the history of neurosurgery [4] or characters or regions, without any current convention universally accepted.
To mention some from the ancient world: the Edwin Smith Surgical Papyrus is about 3700 years old and an alleged copy of a 5000-year-old manuscript (during Egypt's Old Kingdom [5]) describes injuries in the head, spine and/or spinal cord, as well as other neurological conditions. Of course, the father of modern medicine is the Greek Hippocrates of Cos who, in his treatise "On Injuries of the Head" written around 400 BC, described six specific types of TBI, treatments and even prognosis [6]. Six centuries later, Galen (129-200 AD), a Greek physician working in Rome, improved the trepanation technique based on the foundations of the Hippocratic body of works and collected, developed, and expanded all previous medical knowledge. His works became the basis of knowledge of the nervous system taught up until the Renaissance and into the late sixteenth century [7]. In the Middle Ages, neurosurgical developments, like all other scientific knowledge, were obscured by medical scholasticism, where metaphysical

explanations became prominent in medical schools and "Hippocratic/Galenic orthodoxy" prevailed. The subsequent translation of Greek and Latin writings into Arabic and back into Latin led to many misunderstandings, particularly in the anatomical works, and those new findings that differed from the ancient texts were unfortunately ignored. The lack of anatomical knowledge and poor surgical outcomes led physicians to recommend against brain surgery.

With the Scientific Revolution of the sixteenth to the nineteenth century, neuroanatomy based on direct observation returned, allowing new detailed descriptions of anatomy and physiology, including other vital organs such as the heart and vessels, as well as innovative approaches. The first published attempt (failed) to resurrect a dead patient, with the implicit hope that the brain would recover, can be attributed to Paracelsus in 1530. Jackson, in 1746, described the insertion of a tube into the airway to provide artificial respiration. He proposed the possibility that "it may be necessary to make an opening in the windpipe for this purpose."

Joseph Black discovered carbon dioxide in 1754, and Joseph Priestley discovered oxygen in 1774. Chaussier developed a device that administered oxygen to humans in 1780, which closely resembled the mask with reservoir bag in use today (but without a valve). Concern about possible adverse consequences of positive pressure ventilation and excessive oxygen administration began soon after its appearance, and still continues today. Negative pressure ventilation started with the first tank respirator invented in 1832 by Dalziel, and pursued by von Hauke 40 years later.

In 1880, Waldenburg invented the cuirass respirator which covers only the chest instead of the entire body below the neck. Bowditch invented the first mechanical ventilator in 1879, with several of his contemporaries making significant contributions [8].

Little progress was made during this period of almost 400 years owing to the lack of the concept of brain mapping, availability of anesthesia, and understanding of infections. The immediate need for trepanising after TBI was not appreciated and less importance was given to the neurological damage until the last decades of the nineteenth century. Hutchinson in 1867 published a series of works that introduced a new diagnostic sign for brain injury: third cranial nerve palsy. In that year, Lister published his first works on antisepsis.

1.2.2 Present

Modern neurosurgery can trace its origins back to the late nineteenth century. By 1880 a surgical environment free of infection was established, laying the scientific basis for deliberate surgical invasion of the central nervous system as we know it today. Results of surgical interventions, though imperfect, were significantly improved over previous useless treatments. The most important contributions to our understanding of the microscopic anatomy of the nervous system were made by Santiago Ramón y Cajal in a series of works that began in 1892. Neurologists fostered neurosurgical interventions by diagnosis and locating lesions. Since most of the surgeons lacked any neurological skill, they also helped the neurosurgeons in the operating room and postoperative care.

In 1920, Cushing talked about neurosurgery as a "new specialty", creating a separate entity, the American Association of Neurological Surgeons. He reported a 7.4% operative mortality in his series in Boston. At that time, European centres reported mortality rates between 40% and 50% [9], emphasizing the need for special training beyond general surgery, turning it into a national American model, with a subsequent demonstration of its success in training, treatment outcomes, and research productivity: Cushing's model became the global model.

The poliomyelitis epidemic with subsequent respiratory failure revived the development of negative pressure ventilators. Stewart and Rogoff improved the original concept of the tank in 1918. In 1929, Drinker and McKhann described further refinements, and Drinker's "iron lung" saved countless lives. The subsequent use of endotracheal tubes allowed wider use mechanical ventilators. In the polio epidemic of the 1950s, medical students frequently used the reservoir bag system to ventilate patients for weeks. The mechanical ventilator was first introduced by the Bennett Corporation in 1948. The ability to maintain the breathing of polio patients with any of these mechanical ventilation systems defined the start of modern neurocritical care.

Many neurologists became the family doctors for these patients. A battle began between neurologists and infectivologists over who should take care of patients with other forms of neurogenic respiratory failure, such as tetanus, botulism, Guillain-Barré syndrome, and myasthenia gravis. Fortunately, in the early 1950s, Salk developed the polio vaccine which, with the Sabin vaccine, led to the near eradication of this scourge from the face of the earth.

Again, medical historians face the question of the first general intensive care unit with three reasonable candidates: Johns Hopkins Hospital in Baltimore, Maryland, in 1928 [10], with a three-bed unit specialized in post-surgical care; Bjørn Ibsen, in Copenhagen, Denmark, in 1952 [11]; and Peter Safar in 1961 in Baltimore City Hospital, whose interest focused on cerebral protection and resuscitation. Therefore, the early generation of intensivists viewed neurological function as a major part of their responsibility [8]. At the University of Colorado, Earnest established a neurological ICU in 1969. Jackson led a course in intensive care for neurologists in Cleveland in the 1970s.

The Baylor College of Medicine opened its neurosurgical ICU in 1982 at Ben Taub General Hospital in the Texas Medical Center in Houston, and it is still one of the largest units specialized in neurotrauma critical care and research. Ropper, Kennedy, and Zervas opened a neurological/neurosurgical ICU at Massachusetts General Hospital and wrote the first textbook on neurocritical care in 1983 [12]. Hanley and Borel opened a neurocritical care unit with a training program at Johns Hopkins Hospital, Fink at Columbia, and Haley and Bleck at the University of Virginia in 1989. Although the first contemporary neurosurgical ICUs date back about 40 years, neurocritical care is a recently recognized specialty: in 2007, the United Council for Neurological Subspecialties approved neurocritical care as a subspecialty and the first certification exam was also featured that year.

Evolution of Technology in Neurocritical Care

Neurocritical care is an important and ongoing topic in research, education and medical practice. After brain injury, a key principle is that the primary lesion helps to determine the prognosis, but secondary injury (inflammation, edema, free radicals, etc.) also plays an important role in the outcome. Of paramount importance in neurointensive care is the close monitoring of the factors that usually ensue and contribute to the worsening of secondary injury, i.e., hypoxemia, hypotension, seizures, fever, and intracranial hypertension.

Initially, neurological ICUs (NICUs) between the 1960s and 1980s focused almost exclusively on the postoperative care of neurosurgical patients, and neuromonitoring was restricted mainly to serial neurologic examination and, in some units, monitoring of intracranial pressure (ICP). Often, these neurological examinations did not reveal changes in brain function until they were irreversible. The idea was to detect clinical deterioration as soon as possible, allowing early efforts to reverse or correct any damaging process. This era can be considered as the age of "clinical neuromonitoring" [13]. A brief description of the evolution of the technology typically used in modern neuromonitoring and management is provided here.

Intracranial Pressure Monitoring

The first published reports of left ventricular puncture date back to 1850. Over the next 100 years, the procedure was refined; with the addition of a manometer in 1948, the modern system of external ventricular drainage (ventriculostomy) was introduced, but its routine use began only in the early 1970s for treating Reye's syndrome and subarachnoid hemorrhage. In the early 1980s, several reports appeared showing better results in severe TBI with the use of ICP monitoring. In 1995, ICP monitoring was officially recommended for trauma victims with a Glasgow Coma Scale (GCS) score of 3-8 [14]. Typically, ventriculostomy is one of the first procedures taught to neurosurgery residents and it is still the most complex procedure carried out without supervision. Technology has now provided several new strategies to measure ICP non-invasively, but the need to place a ventriculostomy will continue.

Temperature and Brain Tissue Oxygen Monitoring

Clark introduced his semipermeable probe of polarographic cells in the 1960s. In the 1980s, Fleckenstein developed the $PbtO_2$ system used in LICOX systems. Since the temperature coefficient is required to calculate the value of oxygen, researchers assumed that rectal temperature reflected brain temperature. Studies carried out by the Baylor College of Medicine at Ben Taub General Hospital later found that brain temperature was consistently and significantly higher than core temperature after brain trauma [15]. The advent of new combined monitors has helped to underscore the importance of controlling fever in patients with severe TBI and to monitor the effectiveness of therapeutic hypothermia. Another new method uses fibre-optic technology and measures $PbtO_2$, $PbtCO_2$ and pH.

Monitoring of Jugular Venous Oxygen Saturation ($SjvO_2$)

Cerebral venous oxygenation was investigated as part of neuromonitoring for 70 years by Gibbs who started in 1935. Use of the fibre-optic catheter in TBI introduced in 1983 by Cruz in Brazil and Philadelphia led to the wider acceptance of $SvjO_2$ monitoring supported by validation studies which showed its usefulness in neurotrauma at the Baylor College of Medicine in Houston, Texas, in the 1990s.

Microdialysis

Devised in 1974 by Ungerstedt in Stockholm, Sweden, human brain microdialysis in neurointensive care has become by far the most widely used application of this minimally invasive technique. Since 1984, bedside analyzers have been used more in Europe than in the United States in patients with severe TBI and subarachnoid hemorrhage. The substances that can be potentially measured are innumerable: neurotransmitters/metabolites related to energy (the most common current application), markers of tissue damage and inflammation, drugs administered, etc. The first effort to reach consensus on the indications for microdialysis in neurointensive care was undertaken in Cambridge in 2000, with a follow-up meeting held at the Karolinska Institute in Stockholm in 2002.

Therapeutic Hypothermia

The first modern scientific report describing the clinical application of therapeutic hypothermia in a case series of patients with severe TBI was published by Fay in 1945. In the 1960s, Rosomoff and Safar carried out studies that discouraged its use because of the adverse effects with profound hypothermia (<30° C). But in the 1980s interest was revived using mild hypothermia with few and minor severe adverse effects thanks to improvements in the capabilities of ICUs to control and prevent side effects. Therapeutic

hypothermia is now used for neuroprotection and management of ICP, one of its most studied uses, and always deserves close neurointensive care. Theoretically, local hypothermia may have certain advantages over the adverse effects of systemic hypothermia, and this matter is still under development.

Electroencephalographic Monitoring (EEG)

Far from being unique to neurocritical care, EEG monitoring has become a common tool in NICUs. The first physiological studies were presented by Berger in 1920 in Germany. Gibbs published his first works in clinical EEG in 1935 in Boston at Massachusetts General Hospital, and Jennett in 1974 wrote his work on epilepsy after TBI. In the neurointensive care setting, continuous EEG (cEEG), short-term EEG, and new variants such as the compressed spectral array (CSA) and bispectral index (BIS) help in the diagnosis, prognosis and assessment of targeted therapy.

Neuroimaging

It would be hard to imagine modern neuroscience without the currently available neuroimaging techniques. Since its emergence in 1972 and thanks to the availability of computers, computed axial tomography (CT) easily replaced the archaic use of the angiogram to diagnose epidural hematoma, improving mortality and disability rates [16], transforming all the neurosciences, initially with a special clinical impact on neurotrauma. Neuroimaging is constantly evolving: mastering all new techniques seems impossible, but their usefulness in research and clinical practice remains undeniable. Radiology is one of the best examples of the impact of technology in today's medicine.

Neurocritical care shares with general critical care several important systemic monitoring tools, as well as therapies essential to closely monitor and improve the chances of survival and recovery during the acute phase of illness, and they have become the standard care recommended by management guidelines. Management includes invasive blood pressure (arterial line), CO_2 at the end of expiration ($ETCO_2$), pulse oximetry, mechanical ventilation, continuous electrocardiography, central venous catheter, vasoactive drugs, sedation, nutrition, prophylaxis for gastrointestinal hemorrhage, thrombosis, seizures, pressure ulcers, and infections among others, which are typically provided in conjunction with neuromonitoring, not to mention the irreplaceable role of the clinical laboratory.

Assessment Scales

Because critical care is focused on severely ill patients, where "severe" is not always easy to define, several sets of scales have been developed to help establish specifically how severe ill a patient is, thus facilitating the selection and evaluation of therapy, fulfilling criteria for entry into a research study, and to establish prognosis. Jennett and Teasdale published the Glasgow Coma Scale (GCS) in 1974, and Jennett the Glasgow Outcome Scale (GOS) in 1975 [17], both designed to clinically evaluate the central nervous system status in patients with neurotrauma. The APACHE scale (Acute Physiology and Chronic Health Evaluation) issued in 1981, replaced by APACHE II in 1985 by Knaus, was calculated from 12 routine physiological measurements (blood pressure, arterial pH, etc.) during the first 24 hours after admission. A refined scale known as APACHE III was published in 1992. SAPS II (Simplified Acute Physiology Score), devised by Le Gall in 1993, describes patient morbidity when comparing the results with other patients.

SAPS III is a system to predict a specific definition of mortality (e.g., 30-day mortality) when comparing groups of patients, but it requires computer calibration to achieve its functionality. The SOFA scale (Sequential Organ Failure Assessment Score) devised by

Vincent in 1996 [18] is used to track patients' status daily during their stay and to predict outcome and mortality; it evaluates the degree of failure of 6 organ systems (respiratory, cardiovascular, neurological, hepatic, renal and coagulation). The MPM scale (Mortality Probability Models), introduced by Lemeshow in 1988, predicts mortality at ICU admission, and an updated version (which requires no calibration) was introduced in 2005 [19]. The logistic model published by Narayan in 1988 uses multivariate analysis to predict the probability of positive or negative outcome in coma patients after severe TBI.

These are some of the most commonly used scales. There is still interest in developing new systems of scales or improving the existing ones in order to make them more accurate and specific. No scale is perfect or unlimited, and no scale is generally superior to good clinical judgment. Therefore, decisions in individual patients should never be taken based solely on a statistically derived scale of severity of injury. Where scale systems can be used is to estimate quantitatively the degree of acuteness in severe patients and to adjust the outcome assessments of hospitals [20].

The socioeconomic impact of general or specialized critical care undeniably derives from the fact that nearly 6 million adults are admitted to intensive care each year and that one out of 5 Americans dies in intensive care [21,22]. About 2% of the U.S. population are admitted to an intensive care unit each year, occupying 5-10% of all hospital beds but accounting for 20-35% of total hospital costs [23]. Despite its size, there is no formal standardization or federal monitoring of intensive care.

ICUs continue to have a significant local *colour*, with wide variation in staffing patterns. There is poor consensus on who should be admitted to an ICU, who should provide intensive care, and how much intensive the care should be delivered [24-28]. One third to one half of the U.S. population will enter an ICU during their last year of life [29,30], and a fifth will die there [31]. One aspect of the ICU on which there is little debate is that it is costly, absorbing about 1% of the U.S. gross domestic product [21,32]. There is also growing concern about the possible long-term sequelae of surviving critical illness [33,34].

Hence, it is essential to understand that intensive care is a significant part of a health care system, which is extremely large, extremely expensive, but not necessarily optimal. This is not always the case, as the U.S. health system is by far the most expensive in the world [35] but ranks 37th in overall performance and 72nd in population coverage [36]. ICUs are a smaller portion of health systems in other industrialized countries but still represent a significant and disproportionate segment of care and medical costs [37-39]. Even changes in how intensive care is proportionate may have public health ramifications that can affect an entire nation [40].

Together with the projection of the World Health Organization (WHO) that by 2020 road accidents, a major cause of TBI, will be the third leading cause of global burden of disease and injury, after ischemic heart disease and unipolar major depression [41], also the COMPACCS (Committee on Manpower for Pulmonary and Critical Care Societies) estimated that by 2020 the supply of pulmonologists will meet only 35% of the demand. By 2030, the gap will widen to 46% of demand. The shortage calculated for intensivists is 22% and 35% for 2020 and 2030, respectively [27].

This has placed the inevitable task on neurocritical care of proving its importance and, above all, its effectiveness. In 1989 and 1991, two studies conducted in England and the United States, respectively, documented considerable variability in the management of patients with severe TBI [42]: this led to the creation of TARN (Trauma Audit & Research Network) in Europe and the Guidelines for the Management of Severe Traumatic Brain Injury in the United States [14]. Subsequent publications comparing mortality before and after guidelines implementation showed a marked reduction in mortality [43-45],

with subsequent evaluations in 2000 and 2006 showing marked adherence to guidelines since 1991 [46].

In 1997, members of the Task Force of the European Society of Intensive Care Medicine published recommendations for the minimum requirements for intensive care in ICUs [43], emphasizing the fact that intensive care medicine depends on the tight interaction between human, technological and space resources. Since the creation of NICUs, data on long-term outcome and quality of life of survivors of NICUs have been limited. A recent study in Austria found, however, that TISS-28 (Therapeutic Intervention Scoring System) scores on admission and at discharge and age were independent predictors of poor outcome in this unselected representative population of neurocritical care [47].

Outcome measurement is a suitable tool to reflect the daily work of intensivists and to legitimize its important implications for the allocation of hospital resources. Given the association between mortality and the economic impact of such patients, a more detailed understanding of this patient population may facilitate care and management decisions [48]. The purpose of any recommendation is to provide guidance for those planning a new department or adapting an existing one. However, it should be clarified that most recommendations are not always based on well-documented scientific evidence, but rather express the view of experts involved in intensive care medicine and may require adjustment to local situations. Many existing intensive care departments may be unable to comply with some recommendations due to human and financial resource issues.

As an emerging subspecialty, neurocritical care is a highly specialized field which demands specialized staff. There is growing concern about the need for trained personnel in neurocritical care, emphasizing the trend toward more efficient and accurate practice patterns designed for neurocritically ill patients. Modern NICUs are not only a place for neurocritical patients but also a place where advanced medical technology is coupled with the understanding of organ dysfunction resulting from nervous system failure. Several different types of institution-dependent practices of NICUs have emerged, in part because of competition between neurointensivists, neurosurgeons, neurologists, and other intensive care physicians, resulting in three different models of NICU organization: open, closed and closed-cooperative (hybrid). The selection of “best practice” is still under discussion and under scrutiny.

The open NICU is probably the most common model, especially in private practice. It involves a neurointensivist with privileges to admit patients to a NICU but not responsible for all patients of a NICU. The neurosurgeon can admit patients directly to a NICU and consult other intensivists to manage ventilated patients. The open model may decline in tertiary centres but it may persist in smaller NICUs where there are fewer resources for *in situ* 24-hour supervision of an intensivist [49].

In addition, other factors driving these changes include reductions in salary [50], loss of the physician’s individual autonomy, sharper distinction between hospital-based and consulting-based practice, and the increasing emphasis on patient outcomes. Some authors have demonstrated shorter duration of ICU stay, improved mortality rates and greater team satisfaction with the closed model.

The closed NICU is the model where all neurological ICU patients are managed primarily by the neurointensivist. After discharge from a NICU, patients are attended by the neurologist or the neurosurgeon team. Some units also take care of non-neurological patients. Most procedures are carried out by the NICU team.

The hybrid NICU is where neurology/neurosurgery continues to have an active role in managing NICU patients (mainly with regard to informing the family and taking long-term management decisions). The NICU team handles routine situations and is re-

sponsible for most procedures [51]. This model is generally adopted in teaching hospitals.

TBI cases are medically complex, involving the physical, cognitive, behavioural, social and emotional aspects of survivors. Often catastrophic, these cases require substantial financial resources not only for the patient's survival but also to achieve optimum results in productive life, with a return to family responsibilities and work. TBI cases involve the injured person, his/her family, medical professionals including the attending physician and therapist, the attorney, the employer, the community resources, the source of resources, and usually the insurance company. The case management department facilitates the achievement of optimum results by engaging the collaboration of all parties involved, assessing priorities and options, coordinating services, and educating and communicating with all that concerns [52].

At the Ben Taub General Hospital (a Trauma Level 1 teaching hospital), our NICU has 16 beds managed by the Baylor College of Medicine and the staff of the Harris County Hospital District. It may be defined as a closed model, with a neurointensivist as medical director attending patients on the daily rounds, undertaken by the chief neurosurgeon of neurosurgery and neurosurgical residents (grades II, III, IV and chief resident), one or more temporary rotators (from general surgery, maxillofacial surgery, otolaryngology, plastic surgery, undergraduate medical students), a research team member, a physician assistant, the head nurse, the nursing administrator, and usually both a nurse from the previous shift and one from the following shift, joined once a week by the case manager, and the nutrition and rehabilitation staff.

The neurosurgery team performs the physical examination, writes progress notes and medical prescriptions, checks lab results and images, decides on admissions and discharges, performs most procedures and asks for consultations from other services when necessary. The medical director is available within the hospital 7 days a week during working hours and is reachable 24/7 by phone. The neurosurgery team is available within the hospital 24/7. The research team is available within the hospital during working hours and 24/7 by phone.

The nurse/patient ratio is 1:2, in a distribution of 13 contiguous beds arranged in a C shape, with a sink/bed ratio of 1:2, and a group of three additional isolation rooms that close the ring where the nurses' station and administrative assistant occupy the centre, with an additional team for the telemetry monitoring system. Other routine staff that is usually not present during the daily rounds consists of inhalation therapy staff, radiology technicians who operate a portable CT scanner (exclusive of the NICU) for simple skull CT in addition to xenon-CT in coordination with the research team, the team of nuclear medicine for blood cerebral flow scanning with radionuclide, bioengineering technicians, social workers, pharmacy staff, and cleaning staff familiar with the NICU environment.

Medical Staff

The appointment of a neurointensivist as medical director and the availability 24/7 within the hospital of a neurosurgeon for trauma patients have been shown to improve survival, mortality and outcome, increase efficiency, reduce the length of stay, reduce the use of resources, facilitate the implementation of protocols (drugs, ventilation weaning, etc.) and daily formal visits to the patients, lower the level of frustration for nurses, improve the layout and clinical record documentation [45,47,53-56]. In contrast, there are also data demonstrating that academic institutions in the United States that offer 24/7 coverage by staff within the hospital and other medical extensions as critical care support, either by pager or cell phone, do not offer any temporary change in mortality, length of NICU or hospital stay [57].

Non-medical Staff

The collaboration between the NICU physician and the nurse has been promoted as a way to improve care. Theoretically, this allows the contribution of both professionals and should produce decisions that lead to better outcomes because the decisions are based on more complete information. Collaboration is defined as physicians and nurses working together, sharing responsibility for solving problems and making decisions to formulate and carry out plans for patient care [58].

This can be conceptualized and measured at either the individual patient or the organizational level of the NICU, and both types of collaboration have been positively associated with patient's outcome in the neurocritical care setting [59]. The value of having nurses specialized in different ICUs has also been emphasized [58,60-62].

The importance of the nurse/patient ratio was highlighted in the European Prevalence of Infection in Intensive Care (EPIC) study conducted by the European Society of Critical Care Medicine, which suggested that minimizing the nurse/patient ratio reduced the spread of infections acquired in the ICU [63]. However, ICUs throughout the country are struggling to recruit and retain nurses. The projected growth rate of 6% in the supply of nurses will not match the 40% increase in demand by 2020 [64], and physician assistants (PAs) have been proposed as a partial solution to predicted shortages of doctors and nurses [65]. Although only about 6% of graduate PAs take advantage of advanced training programs [66], the example of effective functioning of PAs in surgical ICUs has been explored [67].

Research Team

Besides the undeniable importance of research to expand knowledge and enhance the practice of evidence-based medicine, placebo groups have demonstrated significantly improved outcomes when comparing data from the late 1980s: as we have seen, this course may be related to adherence to management guidelines, neuromonitoring and the presence of a specialized intensive care team; in theory, however, patients could benefit from having only closer monitoring as when they are enrolled in a research study. In fact, it has become a common joke among investigators when asked about their availability to be study subjects, expressing their enthusiasm to participate and, if possible, to choose to belong to the placebo group. Awareness of the society about the importance of research lies primarily with the research teams: the errors committed by this particular workforce can negatively impact on the desire of society to participate in the future.

Rehabilitation and Physical Therapy

The early rehabilitation program in the acute phase has been associated with improved cognitive functioning levels, shorter duration of coma, and shorter hospital stay of patients with severe TBI [68]. However, some authors have found no benefit gained from early rehabilitation in elderly patients or patients with pre-existing morbidity after TBI [68]. Additional work is needed to determine how physical rehabilitation impacts on specific medical issues, long-term outcome and cost of health care.

Case Management

Severe TBI is often considered catastrophic in terms of cost, recovery time, consequences and burden on society. The case manager's work in the long-term recovery after a disaster is to identify the needs of the survivor and connect him/her with resources, working with the committee for long-term recovery to do what is necessary to put patients back on their feet. The case manager works over the long term with the survivor to make

a thorough assessment of his/her needs to determine which ones are related to the disaster and then help the survivor to develop a recovery plan.
The relationship between the manager and the survivor is to advocate; in doing so, the development of the relationship is as important as the patient's needs. Because staff have experienced the largest growth compared with other hospital personnel, they also face the need to demonstrate their effectiveness. While this has also been explored [69], evidence for case management effectiveness is mixed. Some studies show a positive relationship [70,71], whereas there are conflicting results concerning the effects of case management on functional status, quality of life, family impact and other aspects of recovery. Further research is needed to resolve the doubts of the effectiveness of case management among TBI survivors and their families [69]. The value of the case management department at the patient's level is irrefutable, even though the evidence for its effectiveness on a large scale remains unclear.

Transport of Critically Ill Patients

Despite the enormous sophistication of NICUs, sometimes not all patient care can be carried out there. Patients may need to be transferred to the radiology department, operating room, or more importantly, to other medical centres with ICU facilities for specialized care. These situations can jeopardize patient safety, as demonstrated in several studies [72-74], where increased adverse events during transport between facilities were rare, although analysis of the data in greater detail revealed a number of preventable events.
Patients transferred over greater distances or receiving vasopressor drugs may be at increased risk for minor adverse events during flight. Improvement could be achieved through better communication between the referring and the receiving hospital, and through strict adherence to and the use of a checklist of published protocols. Patients transported between ICUs are still critically ill and should be handled as such. A transport environment presents challenges not faced in an ICU, and care provider capabilities are limited once outside the unit. The transport of critically ill patients should be avoided at all cost, and it is advisable to plan to have portable diagnostic equipment for radiology procedures or make transports shorter (e.g., having the operating room nearby on the same floor).

Trauma Centres

NICUs must have well-defined communication channels in order to work closely with emergency rooms and rescue services, especially in the care of neurotrauma patients. This has led to the creation of regional trauma care services, with a positive impact on survival, mortality, length of stay, outcome, and resource utilization. A Level 1 trauma centre requires the immediate availability of trauma surgeons, anesthesiologists, specialized doctors, nurses, and a resuscitation team. Its goals include providing complete trauma care, serving as a regional resource, and providing education and research. The positive relationship between trauma systems and neurosurgeons has also been documented [75].

1.2.3 Future

The future of NICUs and other specialized ICUs seems to be both amazing and disturbing. Neurointensive care is expanding, with much work still to be done and countless questions to solve, while facing shortages in financial and human resources, along with the rest of the health system: physicians should participate as active players by explor-

ing different solutions to the economical issues, while improving care in terms of outcome and cost-effectiveness. Having an *ideal* NICU is by definition impossible not only because of financial cuts but because patients, families, nurses and physicians have different perspectives on what an ideal ICU would be and what kind of culture would exist in an ideal ICU [76].

In the future, inputs from all these stakeholders will be required to help create an ideal ICU and the environment around the bed [77]. The NICU at Emory Hospital, Georgia, has explored a more patient/family-targeted approach, with rooms designed with enough space to perform complicated procedures at the bedside, eliminating the need to transport fragile patients elsewhere in the hospital. For the patient's family there are rooms equipped with a folding sofa, wireless Internet access, and TV adjacent to the patient's room. Separated by a glass wall, the rooms foster the family's role in the healing process. Amenities within the unit, such as showers, kitchen and laundry facilities, alleviate many of the daily pressures on families.

The future often depends on technological advances and the NICU is no exception: cECG with improved diagnostic accuracy, as in arrhythmia, reduced autonomic activity, accurate non-invasive continuous blood pressure monitoring, systemic arterial blood gas monitoring, venous blood gas monitoring in the superior sagittal sinus (SSS), monitoring of cerebral tissue oxygenation, online indirect calorimetry. In 30 to 100 years, nanotechnology will provide us with new tools able to monitor cell and tissue function with unparalleled detail [78], perform quantitative pupillometry [79], diagnose diffuse axonal injury (DAI), and predict the outcome with magnetic resonance imaging-diffusion tensor imaging (MRI-DTI) [80].

Two recently published studies examining the feasibility of telemedicine in the ICU and the associated outcome of patients [81,82] proposed telemedicine as a way to relieve the predicted shortage of neurointensivists. New biomarkers of damage in brain injury have been documented, such as the breakdown products of αII-spectrin (spectrin breakdown products [SBDP]) after severe TBI [83] and subarachnoid hemorrhage [84], along with the neuron-specific enolase, S100B, and myelin basic protein in ischemic and traumatic injury [85]. Advances in technological and neuroprotective agents have attracted the attention of researchers, but much clinical work remains to be done in trying to answer physiological questions in TBI patients, such as individualization of treatment and prognosis based on the stratification of the pathophysiology of injury, early intubation at the emergency scene, and hyperoxia as neuroprotective treatment, adequate hemoglobin concentration, appropriate prophylaxis for venous thromboembolism, detection and treatment of adrenal insufficiency that probably contributes to the outcome [86]. Also, health care will continue to feel the pervasive influence of computers (electronic medical records, lab results and electronic images). Developing countries where resources are even more limited should recognize the fact that simple data collection can help to improve the outcome despite low budgets [87], for example, detailing the incidence, the causes, the approaches and the results, while keeping in mind the guidelines for improving data quality in a database of brain injury [88].

2 Basic Anatomy Applied to the Interpretation of Axial Tomography of the Brain in Emergency Medicine

Maria Raquel Abdalla [1], Andres M. Rubiano [2]

[1] Radiologist- OIC Service. University Hospital of Neiva, Colombia
[2] Neurosurgeon of trauma and critical care. Consultant of Comité de Trauma y Sistemas de Emergencia (WHO). University Hospital of Neiva, Colombia

2.1 Introduction

At the time of acute brain injury, intracranial structures (meninges, brain, brain stem and cerebellum), the circulating blood volume and cerebrospinal fluid lose their "harmony" within the common area of the cranial vault, affecting its structures and vital areas, thus impairing mental functioning and then the autonomous system, rapidly leading to brain death and ultimately to the cessation of the body's vital functions. These structures bear a special relationship from the point of view of development, configuration, anatomy and localization. Therefore, it is essential that the health personnel in charge of the initial management of these patients possess a basic knowledge of brain anatomy for an adequate understanding of the process underlying neurological impairment after acute brain injury.

2.2 Development

2.2.1 Cranium

The cranium develops from day 22 of gestational age. The "cranial membrane" chondrifies (day 38) and by day 54 begins to ossify from 110 bone centres, generating 45 bones in the newborn, with subsequent fusion for the development of the 32 bones composing the adult cranium. Cranial growth is determined by the growth of brain tissue, which "pushes forward" ossification of the structures. Around the first year, 90% is completed and adult size may be reached at an age of about 6 to 7 years. The initial bone structure is a single-sheet structure. But after 4 years of age it is divided by the diploë, thus setting the basis for the so-called inner and outer cortical plates. The cranial "sutures" (remnants of the cranial growth centres) are active during labour. Afterwards, they follow cranial growth, which occurs especially during the first 3 years of life and permanently closes at about 6 years of age. They are divided into major (metopic, lambdoid, sagittal and coronal) and minor (squamous) plates located between the temporal bones. Between the sutures are the fontanels (spaces between the sutures) where ossification completes. Among these are the anterior or bregmatic one (diameter about 4 cm x 2.5 cm, closes around at 2 ½ years of age), and in the rear the lambdoid one (triangular, closes at around 3 months of age). In the lateral region, the anterolateral or sphenoi-

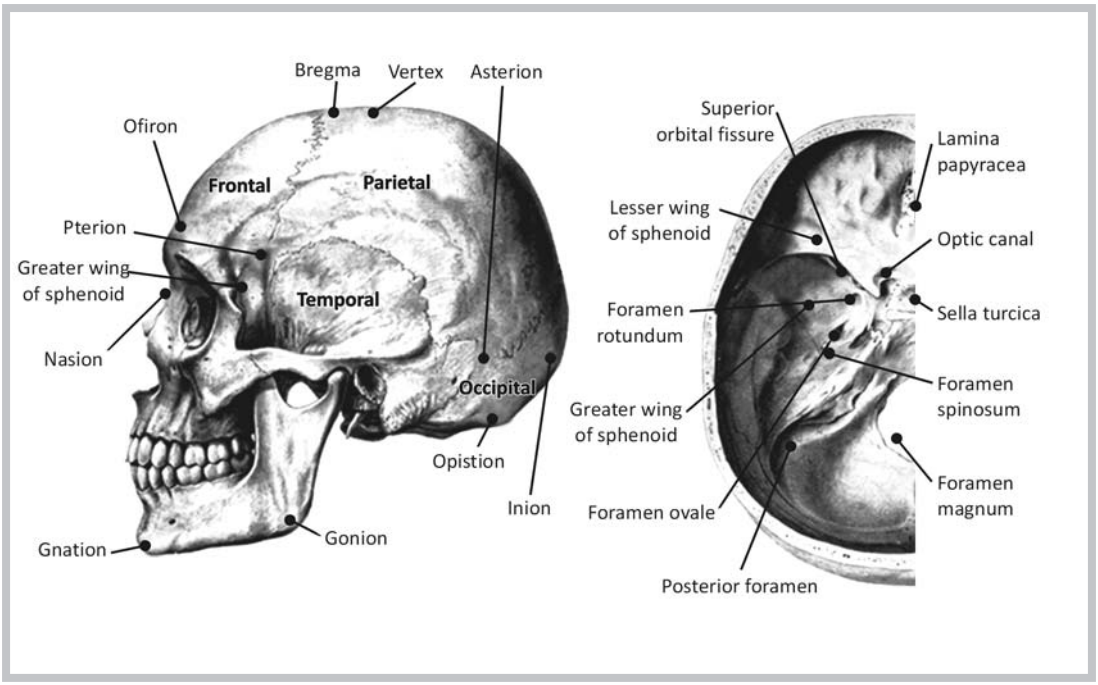

Figure 2.1. **Adult skull bones (side view), including anatomic landmarks for skull procedures. Internal axial view of the base of the skull (anterior, middle and posterior cranial fossa) with major holes of the base [1].**

dal fontanel and posterolateral or mastoid fontanels form. Once chronological maturity is reached, the cranial vault is divided into a group of four unpaired bones (frontal, ethmoid, sphenoid, and occipital) and two groups of paired bones (temporal and parietal). Each of these bones has, in turn, subdivisions (parts, faces, sheets, etc.) that are important as surgical reference points or "corridors" [1,2]. Within these anatomical structures we will detail foramina or holes that lead to vascular and neural key structures.

In the sphenoid bone is the **foramen rotundum**, from which the second portion of the V2 trigeminal nerve or superior maxillary nerve emerges from the cranium. The **foramen ovale**, through which the lesser petrosal nerve, the third portion of the trigeminal nerve, V3 or lower mandibular nerve emerge and the accessory meningeal artery enters and the **foramen spinosum**, through which the meningeal nerve (branch of V3) emerges and the middle meningeal artery enters (very important in trauma, as it is one of the most common causes of epidural bleeding).

If bleeding is out of control, this orifice usually has to be plugged with hemostatics to isolate the extracranial portion and stop the bleeding. In the occipital bone is the **jugular foramen**, where the inferior petrosal sinus emerges and the sigmoid sinus converges to become extracranially the jugular vein (jugular bulb) where the jugular oximetry catheter is placed, along with cranial nerves IX (glossopharyngeal), X (vagus or pneumogastric) and XI (spinal accessory). The posterior meningeal artery also enters through this hole [1,2,4].

These anatomical basics are very useful, especially when placing systems for monitoring intracranial pressure (ICP) in adult and pediatric patients. It is also important to consider some cranial landmarks employed to demarcate coordinates and approaches. Within these, we find, for example, the "pterion" and "asterion" (used to position exploratory burr holes) and the "nasion", where, measuring in anterior-posterior direction, a ventriculostomy catheter is inserted (Figure 2.1).

2.2.2 Brain (Forebrain, Cerebellum and Brainstem)

The brain begins to develop in embryonic life. On day 28, the neural development of the embryo is in the so-called "3-vesicle" stage:

- The prosencephalon (forebrain) gives rise to the telencephalon (cerebral hemispheres) and diencephalon (third ventricle, thalamus and hypothalamus).
- The mesencephalon (midbrain) gives rise to the mesencephalon itsef.
- The rhombencephalon (hindbrain) gives rise to the metencephalon (pons and cerebellum) and myelencephalon which, in turn, give rise to the bulb and part of the spinal cord. The neural tube then continues its development as the spinal cord and vertebral column.

Around day 35 of gestation, the 3-vesicle embryo progresses to the 5-vesicle stage (telencephalon, diencephalon, mesencephalon, metencephalon and myelencephalon), and at day 180 starts forming sulci through growth and myelination. The meninges, in turn, form two structures, the neural crest (arachnoid and pia mater) and the mesenchyme (dura mater). The final weight of the brain on completing growth is around 1300 g in women and 1400 g in men.

The areas of intra-cortical association continue to develop even into adulthood. Growth is set to fully develop structures of the neo-cortex such as the frontal lobes, where social learning is developed. The growth of association fibres occurs mainly through three structures: the fornix, corpus callosum and anterior commissure. The general divisions of the cerebral lobes are formed from the fissures (deeper sulci), and within each lobe there are subdivisions (gyri or convolutions) formed by less deep or smaller sulci.

The lateral or Sylvian fissure divides the frontal from the temporal lobe. It is about 7 cm long.

The central or Rolandic fissure starts inside in the middle of the hemisphere and is directed downward and forward to join the Sylvian fissure.

The sulcus callosomarginalis is inside, above the cingulate gyrus.

The calcarine fissure begins at the internal occipital pole and continues forward to the parieto-occipital sulcus.

The sulcus callosomarginalis, the Sylvian fissure, the parieto-occipital sulcus and the collateral sulcus are the only ones with 100% continuity. These, along with the Rolandic and the calcarine fissures, the pre-central and the inferior temporal sulci, are the only anatomical grooves that are generally constant and present a uniform pattern in human anatomical studies [1-3].

The frontal lobes are located between the Sylvian, the Rolandic and the sulcus callosomarginalis. The parietal lobes start from the Rolandic fissure and end in the external projection of the parieto-occipital sulcus and above the projection of the Sylvian fissure. The temporal lobes are below the Sylvian fissure and are separated from the occipital lobe by an imaginary line. They have five sulci: the superior temporal; the middle temporal; the inferior temporal; the rhinal; and the collateral.

On its basal face is the "uncus" of the hippocampus, in its anterior and posterior portions, a key structure in the development of uncal herniation due to displacement of this structure against the third cranial nerve and against the cerebral peduncle in the midbrain, thus compromising pupillary contraction (dilated pupil) and the pyramidal motor pathway (contralateral hemiparesis), peculiar of this syndrome. There is a lobe within the interior of the temporal lobe called the insular lobe or Island of Reil. It is at the bottom of the Sylvian fissure and is triangular in shape, with an anterior inferior apex and a superior base. The occipital lobes have a major sulcus (calcarine fissure) and two minor sulci: the transverse occipital and the temporal occipital [1-3].

Within the association structures are three major connections between the two hemispheres and the central fibres of association. In particular:

- **Corpus callosum**: about 7 to 10 cm long, located along the ventricular system, and consists of four parts: the rostrum (adjacent to the lamina terminalis); the knee linking the frontal lobes; the body joining the parietal and temporal lobes; and the splenium joining the temporal and occipital lobes.
- **Anterior commissure**: located behind the rostrum of the corpus callosum.
- **Posterior commissure**: situated at the posterior edge of the third ventricle above the aqueduct of Sylvius.
- **Superior longitudinal fascicle**: the longest of the association fibres, arches over the insular lobe and connects the frontal with the temporal and parietal lobes.
- **Uncinate fasciculus**: a large group of fibres inside the Island connecting the basal portion of the frontal lobe with the temporal lobe.
- **Inferior occipitofrontal fasciculus**: connects the frontal with the occipital lobe running along the side of the basal ganglia.
- **Cingulum**: located in the cingulate gyrus, starts from the rostrum of the corpus callosum and runs laterally in the parahippocampal gyrus.

The cerebellum is located behind the pons and the bulb. It is separated from the forebrain by the cerebellar tentorium, which is a splitting of dural tissue that separates the supratentorial from the infratentorial structures (anterior and middle fossae from the posterior fossa). It measures about 6 x 10 x 4 cm and weighs 140 g, which corresponds to 10% of brain weight. It connects to the brainstem via three branches or peduncles: the superior cerebellar or "brachium conjuntivum" (which joins the midbrain); the middle cerebellar or "brachium pontis" (which joins the pons); and the inferior cerebellar or restiform body (which joins the brainstem). Within its development, the fourth ventricle is formed just below. Functionally, the division is established through three lobes: anterior (posture and tone fibres); posterior (vestibular fibres of balance); and medium (fibres of voluntary movement) [1-4].

The brainstem consists of four structures: the diencephalon; the midbrain; the pons; and the medulla oblongata. The diencephalon corresponds to a triangular cavity. Its side wall is formed by the two thalami; the anterior side is the anterior commissure, the posterior side is the pineal gland and the posterior commissure; the base is formed by the tela chorioidea located between the two thalami, and the vertex is above the pituitary gland.

The thalamus is a paired nucleus measuring approximately 35 x 20 x 25 mm. In back of the diencephalon is the pineal gland or epiphysis located on the quadrigeminal plate, and the hypothalamus in the anterior part located on the floor of the third ventricle and limited by the optic chiasm and the lamina terminalis. It has two units: an anterior (parasympathetic activity) and a posterior (sympathetic activity) [1-4].

The midbrain begins to develop with the closing of the alar plates to form the fourth ventricle. The cells of the plates are arranged on the ventricle to form the quadrigeminal plate, and cells of the basal lamina form the tegmentum in the ventricular floor. The mantle layer forms the cerebral peduncles to connect to the thalamus and between them are the red nucleus and substantia nigra. The red nucleus, predominantly motor, is responsible for coordinating decorticate movement which is evident in patients with acute brain injury. The dorsal surface is formed by the superior and inferior quadrigeminal colliculi, connected to vision and hearing, through the fibres of the medial and lateral geniculate bodies, and the ventral surface formed by the cerebral peduncles. The medial surface has, in the inter-peduncular sulcus, the emergence of the third cranial nerve. The lower edge is attached to the pons and on the lateral face are the pontomesencephalic sulci [1-4].

The pons originates within the pontic flexure in the rhomboid fossa of the fourth ventricle. In the basal lamina are the motor nuclei of cranial nerves VI and VII. In the alar lamina of this region are several nuclei, such as the vestibular nuclei, which coordinate a movement called "decerebration" in patients with impaired higher motor functions, the cochlear nuclei, the inferior olivary nuclei, the solitary fascicle, and the descending nucleus of the V pair. It is located under the cerebral peduncles and in front of the cerebellum. On its anterior face is the basilar artery and the apparent origin of the V pair (trigeminal). On the lateral face are the middle cerebellar peduncles that are directed towards the cerebellum. On its lower face is the pontobulbar sulcus which separates it from the medulla oblongata [1-4].

The medulla oblongata originates from the myelencephalon. The alar lamina originates nuclei for the X and XII cranial nerves. It continues in the spinal cord and separates from it by the decussation of the pyramids, an area where the fibres from the pyramidal cells in the motor cortex cross over to the contralateral side. Its anterior portion is closely related to the odontoid process or apophysis of C2 (for this reason, a high cervical injury with impaction of the odontoid directly impairs the medullary respiratory centres). On its front face are the preolivary sulci, the apparent origin of the XII cranial nerves and the bulbar pyramids. On its posterior face are the posterior lateral sulci, an area of apparent origin of the IX, X and XI cranial nerves. There are also the colliculi of gracilis fasciculus and cuneatus fasciculus (posterior cords of the spinal cord). There is also the inferior cerebellar peduncle which connects it to the cerebellum, and part of the floor of the fourth ventricle, with the acoustic striae and hypoglossal and vagal trigones. On the lateral face is the olive, the seat of the inferior olivary nuclei, and the pontomedullary sulcus, the apparent origin of the VI, VII and VIII nerve pairs [1-4].

2.2.3 Brain (Arterial and Venous System)

Understanding the arterial and venous systems is fundamental for appreciating many aspects of the pathophysiology, monitoring, and treatment of acute brain injury. Cerebrovascular emergency, for example, requires quickly correlating the anatomical aspect and the clinical location, and this must be understood by all staff involved in caring for critically ill patients. Hereafter, we will describe in detail the nomenclature and location of the major cerebral vessels, both arterial and venous.

The internal carotid artery (ICA) originates at the bifurcation of the common carotid, usually at the level of the C1-C2 disc. It has four parts: C1 (**cervical**) runs from the bifurcation of the common carotid to the external orifice of the carotid canal of the skull; C2 (**petrous**) runs from the cranial carotid canal entrance to the entrance of the cavernous sinus inside the skull; C3 (**cavernous**) runs from the entrance to the exit of the cavernous sinus; and C4 (**supraclinoid**) runs from the exit of the cavernous sinus (entry into the subarachnoid space) to its division into the middle and anterior cerebral arteries.

The supraclinoid portion consists of three segments: the lower one is the ophthalmic segment (where the ophthalmic artery arises); the middle one is the communicating segment (where the posterior communicating artery arises); and the upper one is the choroidal segment (where the choroidal artery arises). The ophthalmic segment has four to seven perforating branches directed to the pituitary stalk (superior pituitary), the optic nerve, and the chiasm. The ophthalmic artery is located below the chiasm and has a very short intracranial segment of about 3 mm before it enters the orbit. The communicating segment has some inconstant perforating arteries directed to the chiasm and the optic nerve. The posterior communicating artery (PCoA) is very important because it forms the lateral wall of the circle of Willis (Figure 2.2) connecting the carotid with the

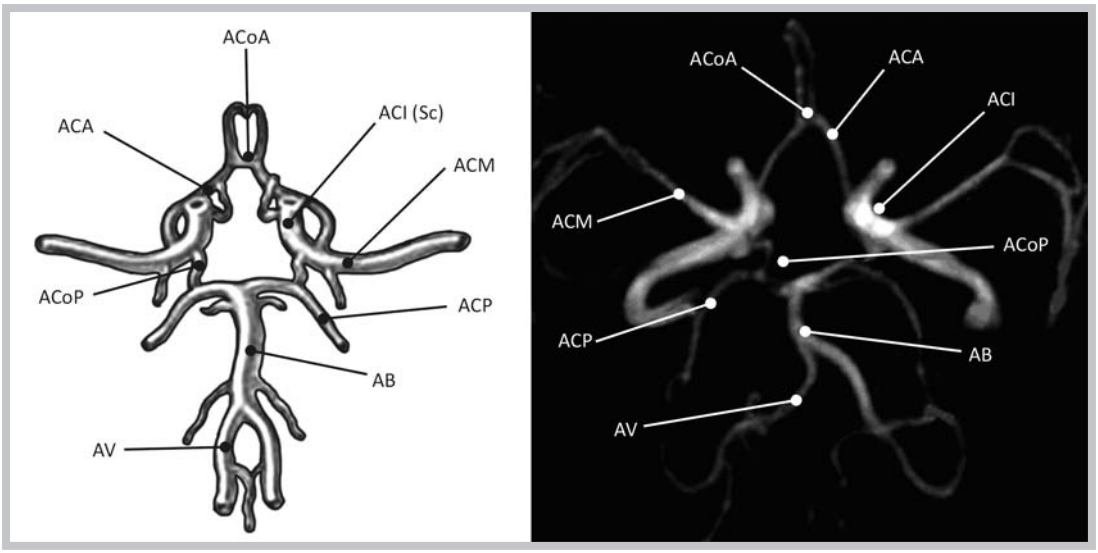

Figure 2.2. **Diagram and magnetic resonance angiography image of the arteries forming the Circle of Willis. From [1].**

ACA = anterior cerebral artery
ACoA = anterior communicating artery
BA = basilar artery
ICA (Sc) = supraclinoid internal carotid artery
MCA = middle cerebral artery
PCA = posterior cerebral artery
PCoA = posterior communicating artery
VA = vertebral artery

posterior cerebral artery, which comes from the infratentorial circulation and is a key element in collateral circulation in supratentorial cerebral ischemia [1,7,8,9].

The so-called "foetal configuration of the posterior communicating artery" occurs when the artery gives rise to the posterior cerebral artery (PCoA) rather than originate from the basilar system. This pattern t can occur in adults and is called such because it is normal in the cerebral circulation of the foetus. This segment can have about eight perforating branches directed to the third ventricle, thalamus, hypothalamus, internal capsule, pituitary stalk, and chiasm, among others. The choroidal segment has about four perforating arteries directed to the anterior perforated substance, the optic tract and the uncus. The anterior choroidal artery (AChA) provides irrigation to the choroid plexus within the ventricle temporal horn [1,12,13].

The middle cerebral artery (MCA) has an initial diameter of about 4 mm. It originates at the end of the Sylvian fissure on the inner surface of the temporal, lateral to the optic chiasm; at the level of the fissure it divides to direct to the temporal and parietal. It has four parts: M1 (sphenoidal) from the bifurcation of the ICA to the insular region within the Sylvian fissure; M2 (insular) is the segment within the Island of Reil; M3 (opercular) runs from the peri-insular region to the outside of the Sylvian fissure; and the M4 (cortical) goes from the exit through the Sylvian fissure until complete distribution on the outer face of the lobes, where it irrigates the vast majority of functional cortical areas. In 80% of cases, in the pre-bifurcation area of M1, the lenticulostriate arteries originate: they are important in hemorrhagic cerebrovascular events because they cause hypertensive hematomas at the basal ganglia level. There are approximately ten in each hemisphere [1,3,12].

The anterior cerebral artery (ACA) is smaller than the MCA. It is anterior and medial to the optic nerve. It projects forward between the two hemispheres, parallel to its contralateral, and they join through the anterior communicating artery (ACoA). It has five

parts: the A1 portion (precommunicating) from the origin to the anterior communicating artery; A2 (infracallosal) lies below the rostrum of the corpus callosum; A3 (precallosal) courses past the knee of the corpus callosum; A4 (supracallosal) runs above the corpus callosum; and A5 (postcallosal) located behind the splenium of the corpus callosum. The ACoA is the anterior portion of circle of Willis and is generally no longer than 3 mm. A1 has a branch often called the "recurrent artery of Heubner" which supplies the basal ganglia and internal capsule. This branch may be injured by searching for the ACoA during aneurysm surgery.

The pericallosal artery begins in the ACoA and around the corpus callosum. It includes the portions from A2 to A5. It has a branch called the callosomarginal artery that ascends and continues back through the cingulate sulcus. Usually it comes out of the A3 portion. The ACA also has cortical branches in the frontopolar, frontal and parietal regions [1-3].

The **vertebral arteries** (VA) originate from the subclavian arteries and enter the structure of the cervical spine through the vertebral foramen from C6, ascending to C2, where they curve medially to settle at the transverse process of C1 and then cross over the posterior arch. They enter the dura at the foramen magnum, giving rise to the **posterior spinal artery** and the **posterior meningeal artery**. The intradural segment of the VA is divided into two subsegments, the lateral and the anterior medullary, which then join with the contralateral to form the basilar artery. An additional main branch of the VA is the posterior inferior cerebellar artery (PICA) which supplies the medulla oblongata, the bottom of the fourth ventricle, the cerebellar tonsils, and the lower side of the cerebellum [1-4].

The **basilar artery** (BA) has its origin at the junction of the two VAs at the pyramidal tract of the medulla oblongata, and it ascends on the anterior surface of the pons in the so-called basilar sulcus. Its main branch is the **anterior inferior cerebellar artery** (AICA) which usually emerges in the lower third of the BA. It turns back and generally surrounds the pons, irrigating the lower two thirds of the pons and the upper third of the medulla oblongata. In the upper third of the basilar artery, before its bifurcation into the posterior cerebral arteries, the **superior cerebellar artery** emerges (SCA), which turns back on the upper level of the pons at the pontomesencephalic sulcus. This artery supplies the quadrigeminal lamina and the cerebral peduncles of the midbrain [7-9].

The **posterior cerebral artery** (PCA) emerges from the bifurcation of the basilar and meets the PCoA in the lateral region of the interpeduncular cistern. It goes through the crural and ambient cisterns in the so-called tentorial incisura (free space of the tentorium which surrounds the midbrain and connects the supratentorial and infratentorial spaces). It supplies the occipital region, thalamus, midbrain, and choroid plexus.

The P1 segment (pre-communicating) goes from the basilar bifurcation to the junction with the PcoA, is about 7 mm long, gives rise to the thalamoperforating, choroidal, quadrigeminal branches, and branches to the cerebral peduncles. The P2 segment

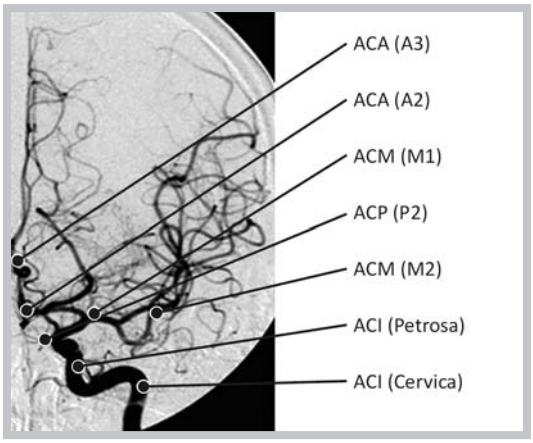

Figure 2.3. **Conventional angiography and interpretation scheme. From [1].**
ACA (A2-A3) = anterior cerebral artery, A2 and A3 portions
ACP (P2) = posterior cerebral artery P2 portion
ICA = internal carotid artery
MCA (M1-M2) = middle cerebral artery, M1 and M2 portions

(cisternal) is about 25 mm long, runs from the junction with the PCoA to the rear edge of the midbrain, and is subdivided into the P2A segment (crural) and the P2P segment (ambient). These segments give rise to the hippocampal, temporal, peduncular, choroidal, and thalamus branches. The P3 segment (quadrigeminal) is 20 mm long and runs from the posterior region of the midbrain to the calcarine fissure, crossing through the quadrigeminal cistern. It is divided into two terminal branches, the calcarine and parieto-occipital branches. The final segment, P4 (cortical), begins in the calcarine fissure on the inner surface of the occipital and runs in the occipital cortical region, giving rise to branches directed to the temporal and occipital regions [7-9]. Arterial relations are especially important in the interpretation of angiographic images in emergency situations, where it is essential to detect areas of vascular injury and collateral circulation (Figure 2.3).

The cerebral venous system comprises the surface segment (veins of the skin or scalp and muscle), the intermediate segment (veins of diploë and dura mater), and the deep segment (the cerebral veins). The surface segment generally has the same distribution as the arteries. The most important are the so-called emissary veins that connect the extracranial with intracranial drainage. In severe intracranial hypertension, especially in children, they are engorged at the frontal and temporal levels. They are located in the scalp and drain into the diploic veins which subsequently drain into the dural sinuses. In the intermediate segment are the diploic veins (venous lakes located within two cranial cortices), which are important because of the risk of air embolism in open fractures. Bleeding is easily controlled by filling the space between the two bony plates with hemostatic material. They are a frequent source of bleeding in depressed fractures. This segment also contains the meningeal arteries located between the skull and the dura. They run parallel to the arteries. They are also in the dural folds (e.g., the falx and the tentorium). The most frequent are the tentorial veins, which are a frequent source of bleeding in posterior fossa interventions [5,6,13].

The dural venous sinuses are intermediate and are grouped as follows: the **postero-superior group** comprises the superior and inferior sagittal, straight, lateral (transverse), sigmoid, tentorial and occipital sinuses; the **antero-inferior group** comprises the cavernous, sphenoparietal, intercavernous, superior petrosal and basilar sinuses.

The **superior longitudinal sinus (superior sagittal sinus)** spans the midline and runs from the frontal pole to the occipital prominence, where the confluence of sinuses is called “torcular Herophili”. It forms spaces called venous lacunae, where the meningeal veins converge and **are a source of active bleeding in fractures above the midline**. These lacunae have a triangular shape and contain the arachnoid granulations. The **inferior sagittal sinus (inferior longitudinal sinus)** starts at the lower edge of the falx cerebri (at the level of the crista galli), extends above the corpus callosum, and turns back to drain into the straight sinus. It mainly includes the draining of the pericallosal veins. The **straight sinus** originates at the splenium of the corpus callosum at the confluence of the inferior sagittal sinus and the vein of Galen. It continues posteroinferiorly in the dural junction of the falx and tentorium to come together usually in the left transverse sinus. The **transverse sinuses** originate in the torcular and run from the occipital protuberance, parallel to the outer tentorial edge; at the level of the crest of the petrous pyramid, they converge with the superior petrosal sinus to form the sigmoid sinuses. The right one is generally larger and receives drainage from the superior sagittal sinus, while the left one is smaller and receives drainage from the straight sinus. This factor should be taken into account when monitoring the jugular vein, as it originates from the sigmoid sinus drainage; therefore, the right jugular reflects more the cortical venous drainage and the left one the subcortical or deep venous drainage [5,6,13].

The **sigmoid sinuses** are the continuation of the confluence of the transverse sinus and the superior petrosal sinus. They extend along the bottom edge of the petrosal bone;

at the confluence with the inferior petrosal sinus, they enter the jugular foramen to form the internal jugular vein, where jugular venous bulb oxygen saturation is measured. The **occipital sinuses** originate from the transverse sinus, run parallel to the occipital, and drain into the sigmoid sinuses. The **tentorial sinuses** are not always present. There are two of them, with one usually located medially and the other one laterally. They are formed by the convergence of the tentorial, cerebellar, and occipital cortical veins. They have several drainage patterns. The **cavernous sinuses** are located on the sides of the sella turcica and communicate with each other through the anterior and posterior intercavernous sinuses located between the diaphragm sellae and the dura [10,11]. Recognizing them is important because they host the third portion of the internal carotid artery and cranial nerves III, IV, VI and the v1 and v2 branches of the V cranial nerve. The sphenoparietal sinuses accompany the anterior portion of the middle meningeal artery. They run through the lesser wing of the sphenoid bone and reach the cavernous sinus [10,11]. The **superior petrosal sinuses** pass along the tentorium and the edge of the petrosal bone, communicating medially with the cavernous sinus and laterally with the confluence of the transverse sinus and sigmoid sinus. The **basilar sinus** is a venous network located on the clivus. It communicates with the cavernous sinus and allows communication between the two groups of venous sinuses, upper and lower [5,6,12,13].

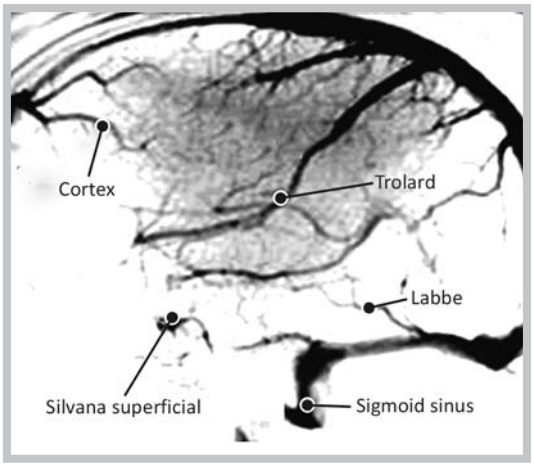

Figure 2.4. **Conventional angiogram in venous phase showing the superior and inferior anastomotic veins (Trolard and Labbe). From [1].**

The deep venous segment is subdivided into the superficial and the deep venous system. The superficial system is basically related to the cortical veins that drain mostly into the superior sagittal sinus. Within this group are the frontal, parietal (ascending and descending), temporal (ascending and descending) and occipital (lateral and medial) veins. Within this group of veins, especially at the temporal and parietal levels, attention is called to the superior and inferior "anastomotic veins":

- **Superior anastomotic vein (parietosylvian) or vein of Trolard** crosses the surface of the frontal and parietal lobes, creating an anastomosis between the Sylvian veins and the superior sagittal sinus. It may sometimes be double (Figure 2.4).
- **Inferior anastomotic vein (temporosylvian) or vein of Labbé** crosses the temporal connecting the sylvian veins with the transverse sinus. It may be double.
- **Superficial Sylvian vein** joins the previous two veins with the sphenoparietal sinus, creating a network connection between the major cerebral venous systems. Sometimes, it goes to the bottom of the Sylvian fissure directly to the cavernous sinus.

The deep venous system is formed mainly by the ventricular and the cisternal veins:

- In the anterior segment is the **basal vein of Rosenthal**, which accompanies the P2A segment of the PCA around the cerebral peduncles in the crural cistern.
- In the intermediate segment is the **great vein of Galen** formed by the confluence of the above-mentioned with the internal cerebral veins in the quadrigeminal region.
- In the posterior segment are the thalamic deep veins.

The ventricular veins are formed by tributaries of the internal cerebral veins, thalamus, basal ganglia, fornix and septum pellucidum. The **internal cerebral veins** are formed behind the foramen of Monro by the confluence of the thalamo-striatal and caudate veins.

They come together to join in the vein of Galen and **are an important intraventricular guide for detecting the foramen of Monro during endoscopic procedures**. There are also multiple cisternal veins draining into the basal vein. The vein of Galen drains into the straight sinus in the occipital region [5,6,12,13].

2.3 Key Concepts

The teams managing acute brain injury must have clear basic concepts of brain anatomy, particularly those related to the cerebral vasculature, their areas of substitution, and the functional correlations of these areas. The relationships of the cranial nerves, the holes (foramina) in the base and midline structures are also essential for a proper understanding of motor impairment and altered consciousness manifesting clinically in patients with acute brain dysfunction. Relationships such as those between the tentorial incisura and the midbrain, the temporal lobe, the third cranial nerve and the posterior cerebral artery in the pathophysiological process of cerebral hernia are examples of these essential anatomical concepts.

Neuromonitoring and emergency endovascular procedures also require an appreciation of the relationships between specific brain areas and structures according to standardized classification models developed by research groups in microsurgical anatomy, which become increasingly more familiar within the working groups of neurological care units. Normal variations, measures and differences present during the development of brain structures are important for the management of pediatric patients with acute injury in specialized units. The concepts provided in this chapter are based on definitions internationally accepted by the main groups of academic work in the area of neuroscience and should serve as a tool for correlation with subsequent chapters.

2.4 Appendix: Images

Computed axial tomography (CAT), developed by the English engineer Sir Godfrey Hounsfield in the late 1960s, was a major breakthrough in skull radiography in neurological intensive care units in the UK. Further advances in imaging techniques led to three-dimensional (3D) reconstruction of tissue and bone and computed tomography (CT) angiography with high-resolution images the brain.

With currently available technology, a CAT scan can be obtained in a few seconds, with cross-sectional and coronal images, multiplanar and 3D reconstruction at the workstation. Consistent with these new capabilities, the term “axial” has been replaced by “computed tomography.”

Computed tomography has become a highly useful, nearly indispensable tool in the management of emergency department patients, where careful clinical assessment and early confirmation of the initial diagnosis are essential: from imaging findings appropriate interventions can be initiated to change the course of a disease, thus hastening the patient’s recovery and improving outcome at discharge.

Brain CT can yield a wealth of information, as long as it is used wisely and according to established indications. The CT scanner consists of a tube that emits an X-ray beam, which, after passing through the patient, projects a shadow of the contents of the body onto the detectors on the opposite side. The attenuated radiation received by the detectors is the attenuation coefficients or “densities” of the tissues, which the scanner con-

verts into Hounsfield units (HU). This attenuation ranges over greys, from white (hyperdense) to black (hypodense). Expressed in HU, it is then interpreted by the scanner software (Table 2.1). The CT scanner can distinguish over 2000 shades of grey, as compared to the mere 30 the human eye can recognize.

In the Emergency Medical Unit, we must proceed quickly. As the initial medical diagnosis will be confirmed or ruled out on the basis of imaging findings, we must know which study is suitable for confirming our "suspicion."

Tissue	HU (-1000 to +1000)
Air	-1000
Fat	-60 to -100
Water	0 to +10
Brain: white matter	+20 to 35
Brain: grey matter	+30 to 40
Blood	+40 to + 80
Soft tissues	+50 to 80
Calcifications	+100 to +400
Bone	+1000
Metallic foreign bodies	More than +1000

Table 2.1. **Interpretation of the ranges of Hounsfield units (HU) according to tissue or element type.**

The American College of Radiology (ACR) convened imaging experts to draft consensus guidelines emergency room staff could apply in selecting the study most appropriate to evaluating a patient's clinical features.

We report here some indications from the document the neuroimaging panel issued concerning the situations where it is appropriate (suitable) to order a brain CT, which can be without contrast (simple, with bone and brain windows) and/or with contrast. Three-dimensional reconstructions of the brain are useful for elective surgery planning but not for emergencies. The following are the ACR recommendations.

Acute Ataxia

- In ataxia <3 hours, as a manifestation of cerebrovascular disease (CVD): CT angiography and CT imaging of the brain are needed. They are indicated with and without contrast, even when magnetic resonance imaging (MRI) studies may be preferred; otherwise, the beginning of treatment is delayed.
- Following head trauma, <24 hours: simple MRI of the head and CT of the temporal bone.

Cerebrovascular Disease

- All new or recent neurological deficits in the carotid or vertebrobasilar territory, stable or in progress, are to be considered an acute cerebrovascular event (CVE or stroke) and are only to be classified as transient ischemic attack (TIA) in retrospect, when symptoms resolve without intervention. In such cases, CT of the head (considering perfusion and concomitant assessment of the brain and vessels) may be ordered, together with CT angiography of the head and neck. MRI of the head with and without contrast is also indicated, as well as MR angiography (MRA) of the head and neck; otherwise, the beginning of treatment is delayed.
- When a subarachnoid hemorrhage is clinically suspected, CT of the head without contrast should be ordered, followed by CT angiography and cervicocerebral (vertebral, common carotid and its branches) arteriography for treatment planning.
- When intraparenchymal hemorrhage is clinically suspected, simple CT of the head is to be ordered.

Seizure Syndrome

- New-onset seizure: in emergency services, simple contrast-enhanced CT of the head should be ordered, as well as MRI when possible.

Focal Neurologic Deficit

- Single or multiple, sudden onset, stable or incompletely resolving, progressive, unexplained acute confusion, altered level of consciousness: in the emergency unit, CT of the head without contrast should be ordered, along with MRI of the head with and without contrast.

Headache

- Sudden onset of severe headache: CT of the head without contrast is the initially indicated study, then CT angiography or MRA with and without contrast.
- Suspected meningitis: CT of the head with and without contrast. Depending on availability, MRI should be ordered.
- New headache with suspected meningitis or encephalitis: CT of the head without contrast and MRI with and without contrast are indicated.
- In addition, some warning signs in headache should be considered:
  - Sudden onset.
  - Early morning on awakening.
  - Increase with Valsalva.
  - Onset in persons aged >45 years.
  - Signs of intracranial hypertension (IH).
  - Change in the pain pattern.
  - Abnormal neurologic examination.
  - Nonspecific diagnosis.
  - Elevated blood pressure.
- According to features over time: sudden onset headache, subacute headache gradually arising inside, important change of features, persistent headache in a patient with no history, headache awakening the patient (except cluster or hypnic headache); new in persons aged >50 years.
- According to associated signs and symptoms: fever, vomiting, pain, focalization, seizures, stiffneck, papilledema, pain and altered mental state.
- Pain and signs of temporal arteritis, headache increasing with Valsalva, recent headache in a patient with cancer (neo).

Vertigo and Hearing Loss

- In conductive hearing loss, to rule out temporal bone abnormalities and in patients with total deafness, or cochlear implant candidates in surgical planning; CT of the temporal bone without contrast should be ordered.
- In hearing loss with vertigo, history of meningitis or to rule out temporal bone anomalies, CT of the temporal bone without contrast should also be ordered.

Head Trauma

- When there is a closed head injury and carotid artery dissection is suspected, in addition to simple CT, MRA of the head and neck should also be ordered.
- All patients with head injury should undergo CT of the head without contrast.

Orbits and Visual Loss

- In amaurosis or visual acuity impairment related to a previous injury, CT of the head without contrast should be ordered.

NB: Always weigh the appropriateness versus the availability of the diagnostic method. This refers to avoiding postponing proper management of the patient, while waiting for the appropriate examination, if a useful alternative imaging method is available.

2.4.1 CT Technical Study

A brain scan is performed by placing the patient on the examination table to obtain images in the axial or the transverse plane, while taking the orbitomeatal line (Reid's base line) as a reference point (Figure 2.5). Slices are scheduled from the base of the skull to the vertex, 5 mm thick at the skull base (Figure 2.6A) in order to minimize artifacts, and 10 mm thick in the rest of the skull (Figure 2.6B).

Image contrast can be adjusted by varying the amplitude (width) of the window and the grey scale by changing the level (level) of the window. These are useful pa-

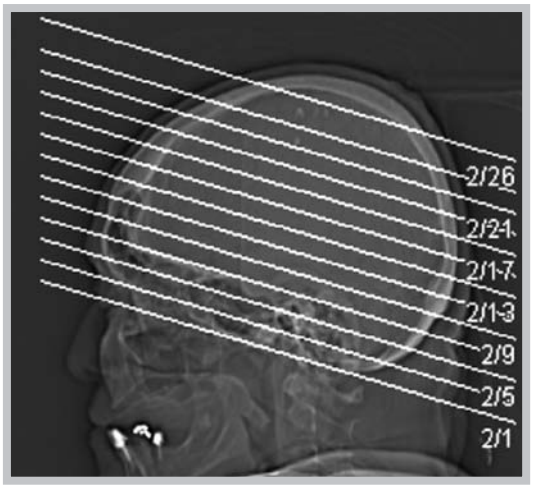

Figure 2.5. Image locator.

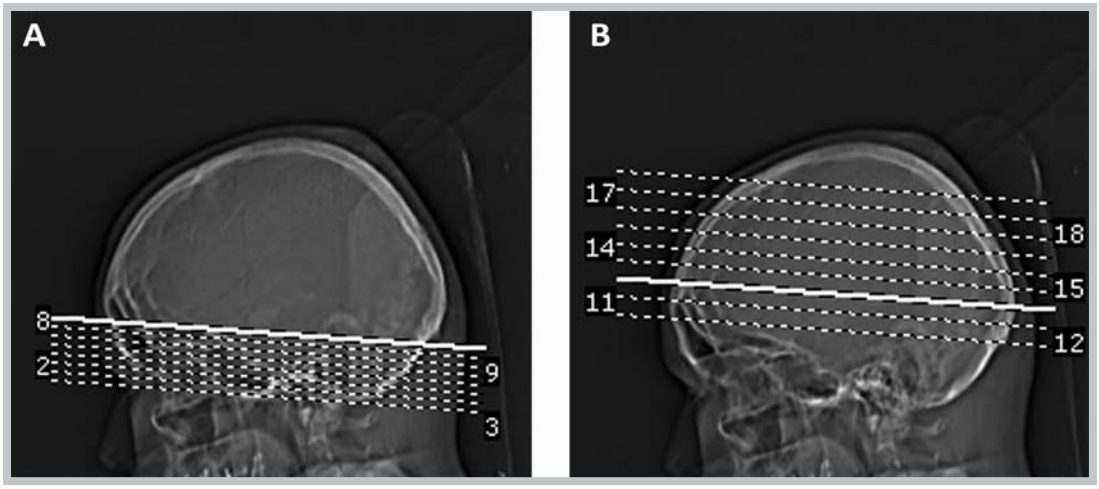

Figure 2.6. Reference lines (A and B).

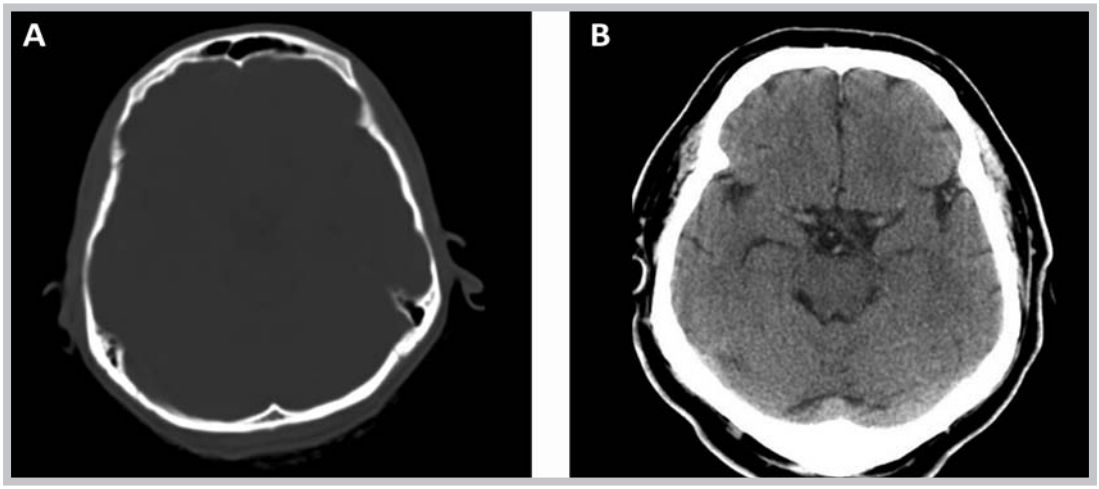

Figure 2.7. Image of bone (A) and brain (B) window.

	Width (HU)	Level (HU)

Brain window	80	40

Table 2.2. Bone and brain window.

rameters to select at the workstation for visualizing the tissue we need to evaluate (Figure 2.7). In this way, we modify the parameters to obtain the bone and brain window, as reported in Table 2.2. Parameters of the bone and brain window in CT scanning.

Generally, CT images of the head have very good resolution of tissues. Visualizing the skull base may be more difficult due to artifacts generated by the bone tissue in the posterior fossa, seen as hypodense bands, projected on the cerebellum, called beam-hardening artifacts. These, like other artifacts such as patient movement, partial volume and artifacts due to metal, can render diagnosis uncertain and simulate a pathology (Figure 2.8).

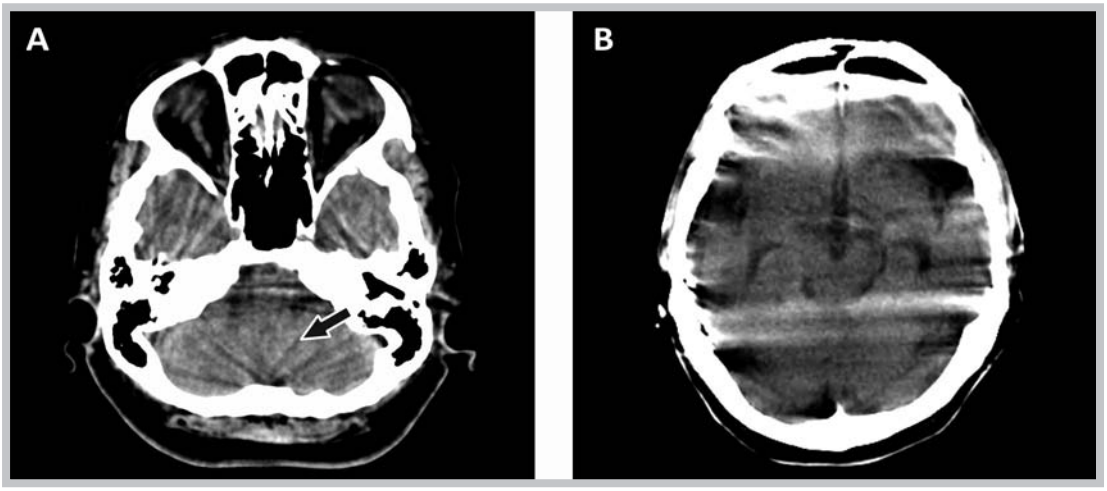

Figure 2.8. Artifacts in the posterior fossa (A) and movement artifacts (B).

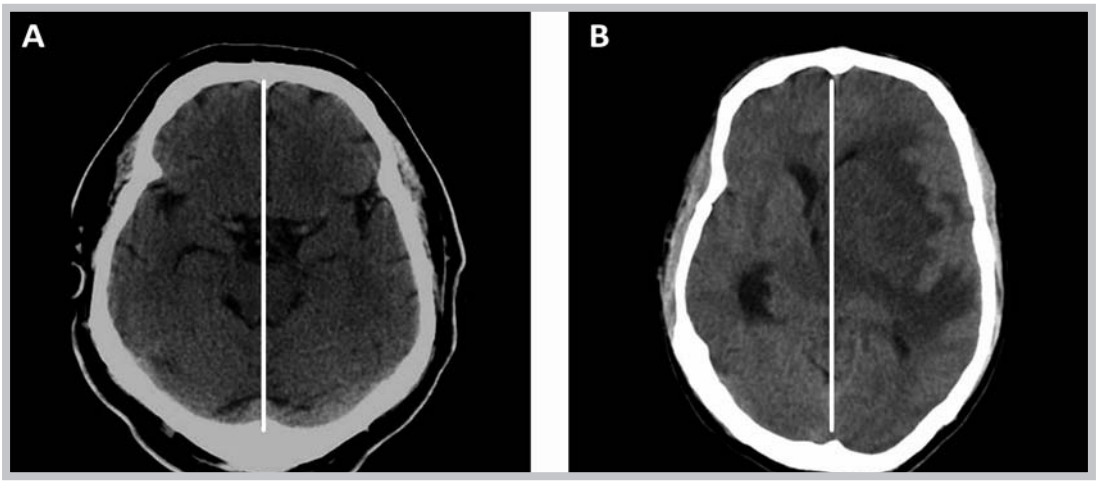

Figure 2.9. Centred (A) and displaced (B) midline.

2.4.2 Basic Radiologic Anatomy

Fortunately, tissue symmetry helps in evaluating a CT scan of the head. Both sides must be compared using the same logical order with which the examiner feels comfortable,

so that it is certain that all structures have been examined. We suggest performing an initial general evaluation and then to continue from the base of the skull to the vertex, checking each image from the centre to the periphery, starting with the brain window and then the bone window.

2.4.3 Midline

The first step is to check the central localization of the midline and to verify structure integrity (Figure 2.9).
In the evaluation of the midline, an imaginary straight line is projected along the anteroposterior (AP) axis, from the frontal crest to the occipital tubercle or to the torcular Herophili. This line should pass through the superior sagittal sinus, the falx cerebri, the corpus callosum, the vein of Galen, the septum pellucidum, the pineal, the third ventricle, the centre of the brainstem, the pituitary stalk and the cerebral aqueduct. Any deviation of structures from the midline should be interpreted as abnormal, especially if greater than 5 mm; asymmetries generating such deviations are to be sought in the brain parenchyma.

2.4.4 The Ventricular System and Cisterns

The ventricular system and the cisterns are reservoirs of cerebrospinal fluid (CSF), which has a fluid density from 0 to +10 HU (hypodense). The ventricular system consists of lateral ventricles, the third ventricle, the aqueduct of Sylvius and the fourth ventricle. The lateral ventricles are situated on either side of the midline, are generally symmetrical, have smooth edges, and consist of frontal horns (anterior), body, posterior horns, temporal horns and trigones or atria. The frontal horns have an angle between their axes; the temporal horns are usually small, almost imperceptible, and the occipital horns are bracket-shaped at the level of each respective lobe.
The atria are the junction between the body of the lateral ventricles and the posterior horns. The lateral ventricles are connected to each other and the third ventricle by the interventricular foramen or foramen of Monro, which is Y-shaped (Figure 2.10).

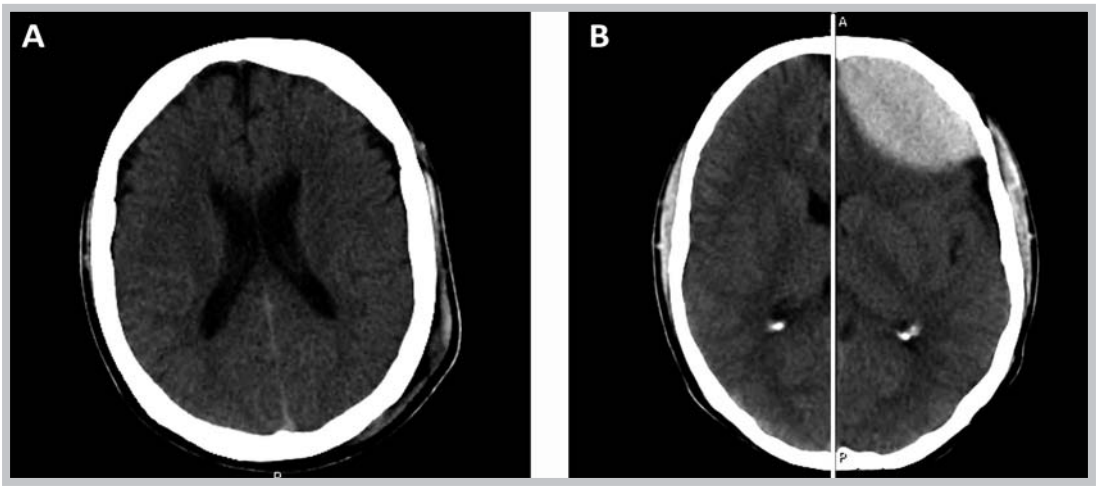

Figure 2.10. **Symmetrical (A) and asymmetrical (B) lateral ventricles.**

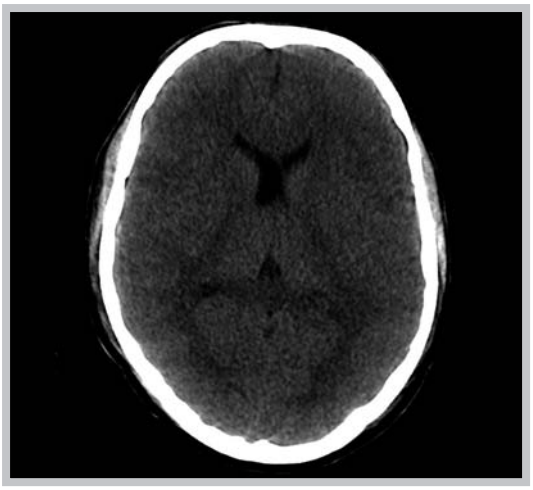

Figure 2.11. Asymmetrical frontal horns.

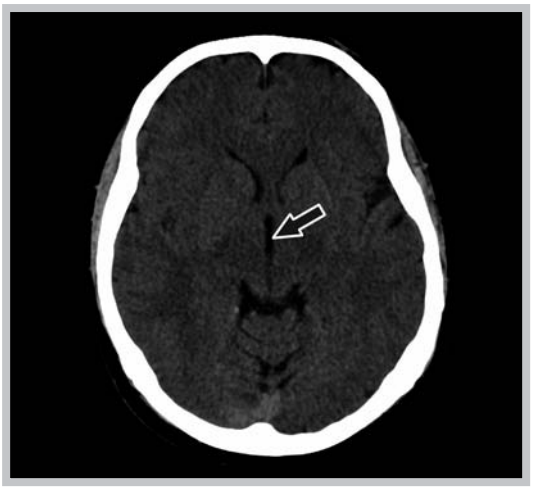

Figure 2.12. Third ventricle (arrow).

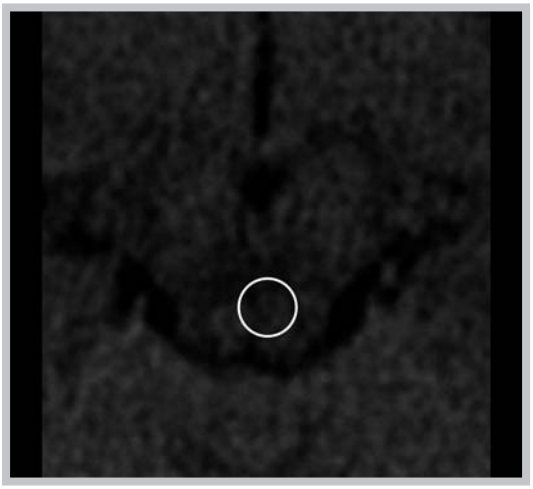

Figure 2.13. Aqueduct of Sylvius (shaded area).

Figure 2.14. Fourth ventricle (arrow).

Asymmetry in the size of the lateral ventricles should prompt an exhaustive search for space-occupying lesions, which reduce the amplitude of the ipsilateral ventricle (extra-axial collections, subacute phase of stroke, tumour, etc.), or for loss of tissue causing increased amplitude of the ipsilateral ventricle due to associated retraction changes (malacic area due to a previous stroke or tumour resection), whereas in the absence of apparent structural damage, ventricle asymmetry may be deemed a normal variant ("constitutive" variant) (Figures 2.11. and 2.12).

The third ventricle, evident in the midline, is a vertical cavity containing the interthalamic adhesion, just below the lateral ventricles, and is connected to the fourth ventricle through the aqueduct of Sylvius. It has several recesses: chiasmatic, infundibular, and suprapineal and pineal. It is important to remember that dilatation of the infundibular recess of the third ventricle is a reliable sign of acute hydrocephalus (Figures 2.13 and 2.14).

The fourth ventricle can be seen just between the middle cerebellar peduncles: it has the pons in front and the cerebellar vermis behind. The cavum septum pellucidum, the cavum vergae and the cavum velum interpositum are all normal variants in the ventricular system. The choroid plexus can be seen in the ventricular system, where the tela

chorioidea comes into contact with the ependyma, the roof of the third ventricle, the body and the temporal horn of the lateral ventricle, and the floor of the fourth ventricle. They may have calcifications and small cystic images of no pathological relevance (Figure 2.15).

The subarachnoid space lies between the pia mater and the arachnoid membrane. It contains CSF, which is compartmentalized in the cisternae thanks to membranes, septa or trabeculae. The cisternae are important because they contain key arterial and nervous structures.

Figure 2.15. Calcifications of the choroid plexus (lower arrow), pineal (middle arrow) and falx cerebri (upper arrow). The right frontal intraparenchymal calcification is not a normal variant, nor is the disproportionate expansion displayed in the lateral ventricles.

Supratentorial and Peritentorial Cisterns

- Suprasellar: infundibulum, optic chiasm and the circle of Willis.
- Interpeduncular: cranial nerve III and basilar artery.
- Ambient: cranial nerve IV, posterior cerebral artery (PCA2), superior cerebellar artery, basal vein of Rosenthal.
- Quadrigeminal: vein of Galen, posterior cerebral artery (PCA3), pineal, cranial nerve IV.
- Velum interpositum: internal cerebral veins.

Infratentorial Cisterns

- Prepontine: cranial nerves V and VI, basilar artery and anterior inferior cerebellar artery (AICA).
- Prebulbar: posterior inferior cerebellar artery (PICA), vertebral arteries, anterior spinal artery and cranial nerve XII.
- Superior cerebellar: branches of the superior cerebellar arteries and veins.
- Cisterna magna: cerebellar tonsils and branches of the PICA.
- Cerebellopontine angle: cranial nerves V, VII and VIII, AICA and petrosal vein.
- Cerebellar bulbar angle: cranial nerves IX, X and XI.

Fissures

- Interhemispheric: falx, inferior sagittal sinus and anterior cerebral artery.
- Sylvian (lateral fissure): middle cerebral artery (M1-3) and vein.

2.4.5 Basal Ganglia Region

The difference between grey and white matter is due to the presence of myelin in the white matter, which is paradoxically

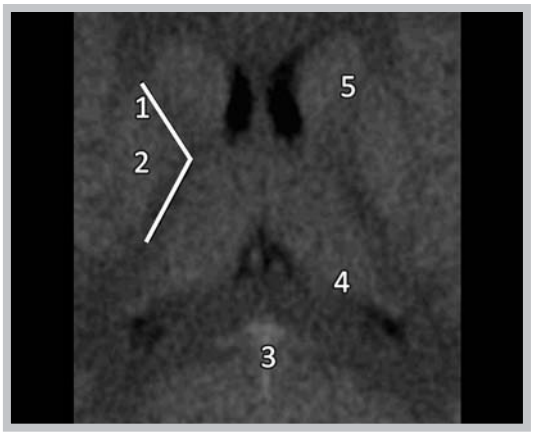

Figure 2.16. Grey basal ganglia.

5 = Caudate nucleus

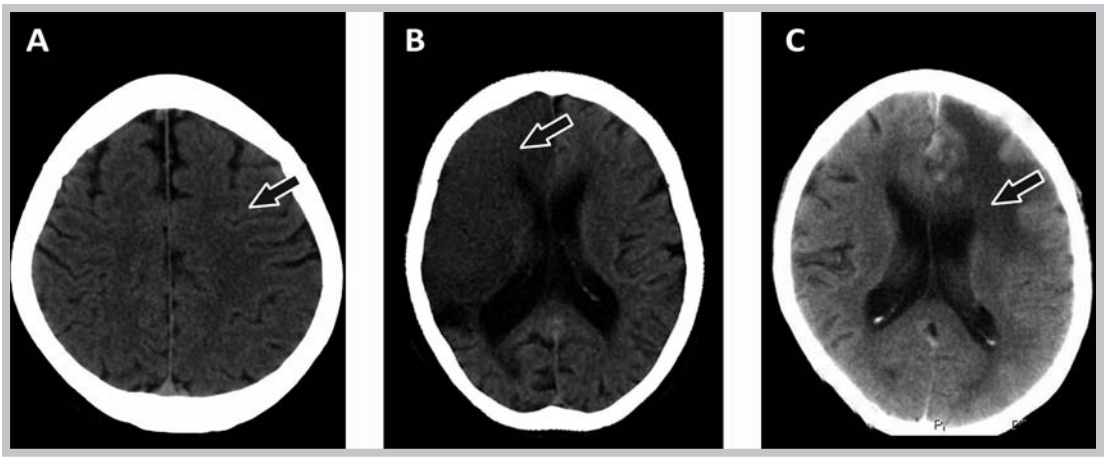

Figure 2.17. **(A) Sulci of the cerebral convexity, grey-white matter differentiation (red arrow). (B) Loss of grey-white matter differentiation due to cytotoxic edema (arrow). (C) Vasogenic edema (finger-like shape) (arrow).**

more "black" (hypodense) than the cortex, owing to its high fat content. Since the basal ganglia contain grey matter, they have the same density (isodense) as the cerebral cortex (+30 to +40 HU). They are separated by white matter tracts with lower density (+20 to +35 HU). Since the darkening of contrast between the white matter tracts and the grey nuclei suggests the presence of edema, it is very useful to evaluate these characteristic densities (Figure 2.16).

2.4.6 Cerebral Cortex and White Matter

Externally, the difference in the densities of the grey and white matter is essential for assessing the gyri, where we must clearly distinguish the cerebral cortex (higher density) from the subcortical white matter and verify the relative symmetry of the convexity sulci with the contralateral ones, the latter having liquid density. The loss of grey-white matter differentiation is abnormal and indicates edema (cytotoxic or vasogenic) or cortical dysplasia, and is associated with obliteration of the convexity sulci, whereas medial displacement, asymmetric or not, of this asymmetric line of transition indicates extra-axial collection (Figure 2.17).

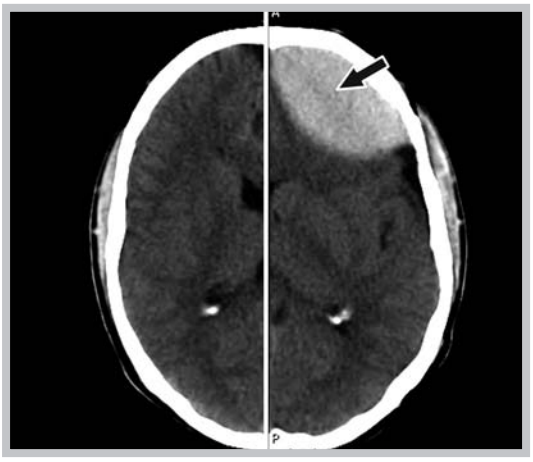

Figure 2.18. **Acute epidural hematoma (arrow). Convex with respect to the midline.**

The CSF contained in the convexity sulci or in those of the cerebellar folia changes in density (increases its density) when blood (subarachnoid hemorrhage) or purulent material (meningoencephalitis) is present. The extra-axial collections occupying the subdural space (under the dura mater) have a concave half-moon-like configuration with respect to the midline, whereas the epidural collections (external or outside the dura mater) have convex or biconvex lens settings (lentiform) (Figure 2.18). These collections of blood are highlighted by their higher density than that of the cortex in the acute phase (>5 days), are isodense to the cortex in the subacute

phase (5-15 days), and are less dense than the cortex in the chronic phase (>15 days). Finally, we present the anatomical structures present in the different slices in the transverse plane of a CT scan of the head without contrast and the circle of Willis in a contrast-enhanced CT scan of the head. These images may be a reliable reference point for image interpretation in the emergency department (Figures 2.19-2.41).

3.1 Functional and Structural Organization of the Nervous System

The nervous system is the most complex tissue of the human body. It controls and regulates numerous body functions, enabling us to interact with our environment. Within this signalling network, the brain works much as a database centre that processes the stimuli received by our sensory organs, allowing us to learn, remember, imagine, reason, and experience feelings.

From a functional point of view, the nervous system is composed of three elements: 1) neurons; 2) glia or supportive tissue; 3) blood vessels.

Neurons are the anatomo-functional unit of the nervous system. These highly specialized cells generate, transmit and receive signals along a vast communication system with other cells. The nervous system is formed by more than 9 million neurons that generate and conduct nervous impulses. The neural pool is maintained from birth, these cells have a distinctive feature: "cannot reproduce when damaged or destroyed". They have different shapes and are characterised by prolongations that can be grouped in two major classes:

- Dendrites or protoplasmatic prolongations that transmit nervous impulses to the cell body.
- Axons: unique, born of the cell body. Their grouping with others from other neurons, form the conduction pathway. Its primary function is to transmit the impulse from the cell body.

Since the dendrites transmit nerve impulses to the cell body, it is easy to understand that each neuron can receive stimuli from many different dendrites, but only one neuron can respond, because each neuron has only one axon.

According to their function, three types of neurons are distinguished:

- Afferent or sensory neurons that convert the external stimuli from the environment into internal electrical motor reflex loops and regulate involuntary activities such as breathing.
- Efferent or motor neurons carry nerve impulses away from the central nervous system (CNS) to effectors such as muscles or glands.
- Interneurons, multipolar neurons which join the afferent and efferent neurons into neural pathways.

A neuron's shape depends on its function, i.e., its position into the neuronal network and the contacts it receives. The neurons transmit information through a dense and articulated network across synapses where the impulse is mediated by neurotransmitters.

The term "**glial**" derives from the Greek word meaning "glue" or "union". The glia is a heterogeneous tissue that primarily provides physical support for neurons. Other glial cells regulate the brain's internal environment, especially the fluid surrounding neurons and others have cleaning, nutrition and defense functions. Unlike neurons, glial cells can divide and reproduce, so that they can take its place when a neuron dies. There are four types of neuroglial cells: oligodendrocytes, astrocytes, microglia, and ependymal cells. The main characteristics and functions of each type are described below.

Oligodendrocytes have a small number of prolongations and a small cellular body (the nucleus occupies the greatest part). They are mainly distributed in the white matter or at the end of nerve fibres (which is why they are called interfascicular oligodendrocytes) which synthesize the myelin sheath surrounding the axons in the CNS and the Swann cells in the peripheral nervous system (PNS). Some are thought to influence the biochemical media of the neurons. Satellite oligodendrocytes are other types of oligodendrocytes and are mainly found in the sensory and autonomic ganglia.

Ependymal cells line the ventricular cavities of the brain and the central canal of the spinal cord. On their surface in contact with the ventricles, they form a unique layer of cubical or cylindrical cells possessing microvilli and cilia which assist in the circulation of cerebrospinal fluid (CSF). The opposite cell surface forms part of the neural connective tissue.

Astrocytes are star-shaped glial cells in the brain and spinal cord. They derive primarily from the ectoderm and are twice more numerous than neurons. Their functions include biochemical support of the endothelial cells forming the blood-brain barrier, provision of nutrients to the nervous tissue, maintenance of the extracellular ion balance, and repair and scarring processes of the brain and spinal cord following traumatic injury. They have many ramifications and prolongations, known as podocytes, that surround the capillaries. They are vey important because they are thought to aid in the maintenance of the blood-brain barrier, forming high specialised regions that control the transport of glucose, oxygen, hormones and other substances essential for the nervous tissue.

There are two forms of astrocytes: protoplasmic, and fibrous. The former are found in the grey matter, possess a larger quantity of organelles, and exhibit short and highly branched cellular processes. The latter are predominantly located within the white matter, have relatively few organelles, and exhibit long unbranched cellular processes.

Astrocytes also envelope the neuronal synapses, forming a sort of network, thus regulating the ion concentration in the extracellular space.

Astrocytes possess uptake systems of neurotransmitters of high affinity, voltage-dependent ion channels, ability to generate and release neurotransmitters as well as the possibility to express in their membranes, a large number of receptors with the ability to respond to stimuli generated by the neuronal release of certain substances among which are glutamate, GABA, acetylcholine, norepinephrine and nitric oxide.

Astrocytes have the following functions:

- Assist in the elimination of cerebral metabolic waste products.
- Provide neurons with nutrients.
- Maintain extracellular space homeostasis (ions, pH).
- Are involved in the physical structuring of the brain, creating the network that sustains neurons.
- AMaintain the junction between neurons and capillaries coupling vascular and nerve functions.
- Together with endothelial cells, they form the blood-brain barrier.
- Neurogenesis.

Microglia are small cells with a dense and enlarged nucleus. Their long extensions branch into smaller vessels, lending them a ramified shape. They have a close relationship with blood vessels and are found throughout the CNS.

They store lipids, iron, and pigments and phagocytise waste products, which is why they are also known as scavenger cells. They can move and change their shape. They play a key role during embryonic development and in the secretion of growth factors which contribute to neuronal maturation and the survival of glial cells as a whole. They also assist in neuronal regeneration and plasticity. Generally, microglia are in a quiescent but alert state. When activated (like macrophages), they generate free oxygen radicals, proinflammatory proteins and cytokines such as interleukin 1 and tumour-like necrosis factor which can become detrimental for the nervous system.

3.2 The Blood-Brain Barrier (BBB)

The blood-brain barrier (BBB) was first described in 1885 by Paul Ehrlich, who experimentally demonstrated that following the injection of colorants (aniline dyes) all of the organs of some kinds of animals would stain, except the brain. The BBB forms not only a physical barrier, but also actively takes part in many different physiological, biochemical and enzymatic mechanisms that maintain homeostasis. The BBB is a dynamic structure that can quickly respond to different stimuli generated locally in the brain or the systemic circulation. Under normal circumstances, the functions of the BBB are:

- Isolation and protection of the brain against certain noxa.
- Selective transportation of substances.
- Monitoring of systemic chemical variations.
- Metabolization of different compounds.

The BBB works as both a physical and a metabolic barrier that isolates the CNS from the rest of the body. It is formed by specialized endothelial cells that cover the cerebral vascular system. This barrier have important clinical implications because an increase in its permeability can result in disease and for another side, the impermeability of an intact BBB can prevent the penetration of certain drugs, so, it is important to evaluate its degree of permeability. Several lines of evidence have suggested that astrocytic protein S100β is a potentially useful peripheral marker of BBB permeability.

From a morphologic point of view, the BBB consists of a layer of endothelial cells that covers nearly all cerebral blood vessels. The cells of the endothelium are united to each other through narrow junctions similar to those that can be found between the endothelium and astrocytes.

There are different types of junctions: a9 GAP junctions; b) adherent junctions; and c) narrow junctions.

GAP junctions are formed by transmembrane proteins (conexins) which connect the cytoplasm between endothelial cells. The adherent junctions are formed by proteins of the cadherin family, whereas the narrow junctions are composed of several membrane proteins of the zonula occludens family. The high protein expression of the narrow junctions is a fundamental and unique characteristic of the BBB, because they determine its impermeability to the majority of macromolecules.

The BBB has a very limited extracellular transportation (pinocytosis); nevertheless, it relies on highly developed specific carriers for different metabolites (e.g., glucose carrier GLUT-1). Furthermore, the BBB has many different enzymatic systems, such as the enzyme that catalyzes the conversion of $C0_2$ and H_20 into carbonic acid associated with numerous mitochondria with the high metabolic activity characteristic of endothelial cells. Closely related to endothelial cells, the podocytic processes (extensions of the astrocytes) play a protective role in the BBB, since they structure the endothelium into a barrier and regulate its response to hypoxia or hypoglycemia by modifying its permeability.

Thus, the BBB, although structurally composed of endothelial cells, is functionally regulated by neurons and glial cells.
Some specialized areas of the brain, including the hypothalamus, area postrema and subfornical and subcommissural organs, lie outside the BBB because the narrow junctions are absent. The region surrounding the ventricles and the circumventricular organs lacks the endothelium characteristic of the BBB. The choroid plexus and the neurohypophysis also lie outside the BBB. These areas are of fundamental relevance since they provide for hormonal transport and the transport of substances involved in fever onset, for example.

3.2.1 Transport Across the Blood-Brain Barrier

The permeability of the BBB depends on proprieties related to the BBB in itself and to the characteristics of various different substances. The permeability of most molecules can be predicted on the basis of their octanol/water partition coefficient. On this basis, we can distinguish two types of molecules:

- Lipophilic compounds (high partition coefficient) can easily access the brain.
- Hydrophilic compounds cannot pass the BBB and therefore cannot access the CNS (although impermeability is not total and a certain degree of diffusion exists).

Furthermore, the BBB is not permeable to high-molecular-weight compounds (MW 200-400) so, all proteins of the cerebrospinal fluid (CSF) such as albumin and immunoglobulin arise from serum ultrafiltration.
On the other hand, the majority of the hydrophilic compounds entering the CNS are proteins that pass by active or facilitate transportation. Their transport depends on ion channels, specific carriers, pumps energy-related and receptor-mediated endocytosis.
Glucose, amino acids and some intermediate metabolites enter the brain by facilitated transport, whereas larger molecules such as insulin, transferrin and other plasma proteins pass the BBB via absorptive endocytosis or with help of specialized receptors.
Further hindering our understanding, its has been noted that some highly permeable compounds are present in very low concentrations in the CNS. They are eliminated from the CNS through the blood by energy-dependent carriers such as p-glycoproteins (Pgp) in the luminal membrane of the endothelium. These mechanisms, which protect the brain, also contribute to drug resistance.

3.3 Cerebrospinal Fluid (CSF)

The brain cavity has an estimated capacity of 1600-1700 ml, 150 ml of which are occupied by CSF. The daily production of CSF is 500 ml at a rate of 0.35 ml per minute, two-thirds of which is produced by the choroid plexus and one third by the arachnoid membranes and the brain.
CSF secretion depends largely on active sodium transport in the choroid plexus. The choroid plexus epithelium secretes a major fraction of the CSF to the lumen of the ventricular system. The pivotal event in CSF secretion is the active transport of Na^+ from the epithelial cell to the CSF mediated by the apically positioned Na^+-K^+-ATPase. The apical Na^+-K^+-$2Cl^-$ cotransporter seems to contribute to Na^+ secretion, because bumetanide inhibits CSF formation when applied apically. At the same time, NKCC1 enriches the CSF with K^+ to feed the apical Na^+-K^+-ATPase. NKCC1 may alternatively take up ions from the CSF as part of regulatory cell volume increase. Cl^- is secreted through electrogenic mechanisms, likely involving one or more Cl^- channels. The above phenomenon creates

osmotic gradients that attract water. The inflow and outflow of water is tightly regulated by specific protein channels called aquaporins.

Na^+ is the main cation of CSF, and its concentration is similar to that of the plasma. In contrast, the Cl^- concentration is higher than that of the plasma because of the impermeability of the BBB to proteins and the so-called Donnan effect (the same quantity of negative and positive charges on both sides of a membrane). The normal amount of proteins ranges from 20 to 40 mg per 100 ml of CSF. The glucose reaches the CSF through a facilitated diffusion mechanism, through the GLUT transport system, its concentration being equal to 60% of that in the plasma. The CSF is limpid and colourless; its aspect is similar to water and it has practically no cells (about 8 lymphocytes/mm^3).

Experimental animal studies suggest that CSF production remains stable if the cerebral perfusion pressure (CPP = MABP – ICP) is between 50-60 mmHg, decreasing principally on the basis of blood pressure. The cells of the choroid plexus are innervated by the autonomic nervous system. The sympathetic activity is inhibitory, whereas the parasympathetic signal stimulates CSF production. Normally, only 25 ml of CSF circulate in the ventricular system; from this we can deduce that the CSF is completely replaced 3 times a day, that is to say, every 8 hours. Once in the lateral ventricles, the CSF circulates through the Monro hole to the third ventricle, which is connected to the fourth ventricle by the Sylvian aqueduct. Then the CSF drains from the fourth ventricle into the cisterna magna. The two lateral apertures (foramina of Magendie and Luschka), one on the left and one on the right, are the primary routes for drainage of CSF from the fourth ventricle into the cerebellopontine angle cistern, and subarachnoid space of the brain and spinal cord. From the basal cisterns the CSF re-enters systemic circulation and circulates toward the cortical subarachnoid space, where it is absorbed into the venous sinuses.

In 1891 Quincke was the first to measure CSF pressure by means of a water column manometer placed by lumbar puncture. In 1927, Fremont-Smith reported the values of CSF pressure in normotensive individuals without CNS pathologies. The normal CSF pressure is between 70 and 180 mmH_2O, with an average of 130 mmH_2O, equal to 10 mmHg in the horizontal position. Physiological variations are related to fluctuations in arterial blood pressure and breathing. The arterial pulsations are synchronously transmitted to the choroid plexus and then to the CSF, thus generating the intracranial pressure wave (this topic will be discussed in another Chapter).

The CSF has many different functions:

- Cushion effect. Since the brain and CSF have almost the same density, the brain "floats" in the CSF. Because of this proprety, the brain weighs 50 g (and not 1500 g) when suspended in CSF.
- Physical protection against direct or indirect impact.
- Maintain cerebral dynamics stable during changes in body position, breathing or fluctuations in arterial pressure.
- Transport substances such as neurotransmitters, hormones, etc.
- Actively assist in maintaining ion balance in the CNS.
- Since the brain has no lymphatic system, CSF assists in eliminating fluids, proteins, cells, and metabolic waste products.

3.4 Aquaporins (AQP)

The brain is composed of 70% by water, making its homeostasis essential for the survival of the cellular groups composing the CNS. Water movement across membranes is a fundamental process in all living organisms. Given this phenomenon and the impermeability of the BBB, how does the interchange of this vital element occur?

In 1988, Peter Agree discovered and described the water channel protein (aquaporin 1); this discovery earned him the Nobel prize for chemistry in 2003. Aquaporins are an integral membrane pore protein and conduct water molecules in and out of the cell. In general, they increase membrane permeability to water across facilitated diffusion, without energy costs, following osmotic gradients mainly generated by the active transport of sodium.

The brain has four types of aquaporins:

- AQP 1 is found on the epithelial cells of the choroid plexus, where they are concentrated at the apical pole; playing a principal role in CSF formation.
- AQP 4 is localized in the astrocytes and ependymal cells. They functions are: 1) BBB formation; 2) homeostatic control of water in the extracellular cerebral space; 3) regulation of extracellular potassium; 4) control of perivascular volume, a function that may be crucial for the maintenance of cells perfusion and oxygenation; 5) the high concentration of AQP4 in the hypothalamic region suggests that water channels have an active role in systemic regulation of water.
- AQP 9 can be found in astrocyte processes in the periventricular region of the parenchyma and the glia limitans bordering the subarachnoid space. It can assist in water movement between the CSF and the brain parenchyma.
- AQP 3, 5 and 8 are expressed in neuronal, astrocyte and oligodendrocyte cultures, respectively. Their physiologic role remains to be elucidated.

3.5 Intracranial Pressure

Intracranial pressure (ICP) is the pressure inside the skull and therefore in the brain tissue and the CSF as well. Each of the brain's components has a pressure. In an inextensible and rigid space, the ICP is the result of the pressure of each component of the cavity in which it is contained. According to the Monro-Kellie model, ICP is the sum of the pressure of the parenchyma, the CSF, and the blood contained inside the veins and arteries. Its value is constant.

ICP = parenchymal pressure + CSF pressure + pressure of cerebral blood volume

The percentage of the different components to ICP is:

- Glia: 700-900 ml = 45.5%.
- Neurons: 500-700 ml = 35.5%.
- Blood: 100-150 ml= 7.5%.
- CSF: 100-150 ml = 7.5%.
- Extracellular fluid: 50-70 ml = 3.5%.

Anatomically, the supratentorial space accounts for 50% of ICP, the intratentorial space for 30%, and the spinal space for 20%.

Normal values vary with age, body position, and clinical situation. In healthy persons the ICP is 7-15 mmHg In the horizontal position and negative (average, -10 mmHg) in the standing position. Normal values are 1.5-6 mmHg for term infants and 3-7 mmHg for young children.

To maintain ICP constant, any variation in the volume of one of the components will occur in relationship to a similar but opposite variation in the other components.

When this adaptation mechanism fails, the IPC rises. The structures integrating the cerebral parenchyma (glia, neurons) contribute little to the maintenance of normal ICP levels; only the CSF can contribute with a pressure gradient from the cerebral space.

The CSF and the blood contained in the cerebral veins (75% of the total blood volume) are the only components that can quickly and efficaciously decrease ICP levels by moving to the spinal compartment. Variation in CSF absorption or production doesn't play an important role. The arterial vascular compartment (25%) has a volume of 23 ml. This volume can decrease to 35% (15 ml) or increase to 172% (68 ml) depending on the decrease (vasoconstriction) or the increase (vasodilatation) in vessel diameter by means of the autoregulatory mechanism that keeps the cerebral blood flow (CBF) constant even when changes in cerebral perfusion pressure (CPP) occur (see below). Another powerful regulator of arterial vessel diameter is the partial pressure of carbon dioxide ($paCO_2$). For each mmHg of change in $paCO_2$, a blood volume change of 0.04 ml/100 g of brain tissue is produced.

Cerebral veins cannot be compressed (except in the presence of increase of ICP) and they do not react to the same stimulation as the arterial bed; for this reason, venous flow is the main determinant of intracerebral dynamics, since from its source to its mouth in the right atrium is a continuous system free of valves.

Importantly, the brain is composed of several small compartments divided by the dura mater. Therefore, the ICP is not uniformly equal in all the cavities, especially in pathological states when gradients between spaces can occur.

3.6 Cerebral Volume/Pressure Curve (V/P). Cerebral Compliance

The relationship between pressure and volume in the brain is not linear (Figure 3.1). This means that in physiological situations the brain volume can vary without causing variations in ICP thanks to compensative and mechanisms signalled previously; but after its maximum capacity has been reached, the IPC increases exponentially. In decompensated situations, even small changes in cerebral blood volume (e.g., 1 ml) can cause an increase of 7-8 mmHg in ICP. Two essential factors are not expressed in the curve: the magnitude and the time in which the changes occur. A slow-growing tumour allows the compensation mechanisms to actfully, so many remains asymptomatic because it does not change the V/P rate. In contrast, a rapidly expanding hematoma can quickly increase ICP.

Compliance is the expression of variations ICP in relationship to changes of intracranial volume:

$$\text{Compliance} = \Delta V / \Delta P$$

If the numerator changes and denominator remains unchanged, the compliance increases. This is what happens with aging. In the elderly the compliance is greater because the intracranial volume increases due to cerebral atrophy.

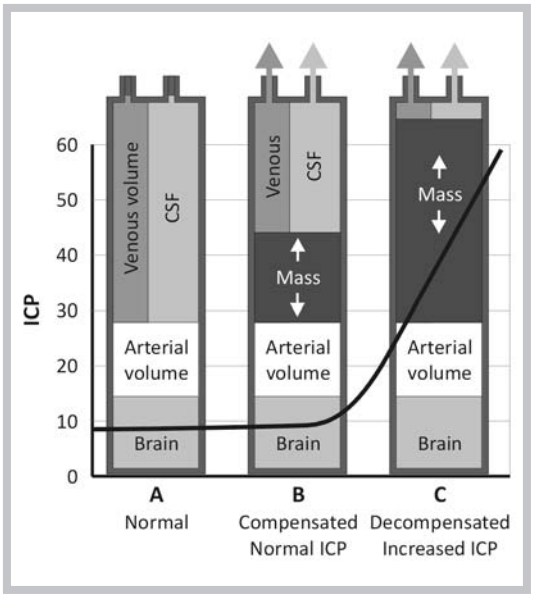

Figure 3.1. Pressure/volume curve.

On the contrary, if there is a minor increase in the numerator and a major increase in the denominator, the compliance decreases significantly.
An individual with adequate compliance has intact compensative mechanisms working. Figure 3.1 shows the three parts of the pressure-volume curve: the initial part of the curve is flat because compensatory reserves are adequate and ICP remains low despite increases in intracerebral volume (A and B in Figure 3.1).
When these compensatory mechanisms become exhausted, the pressure-volume curve turns rapidly upwards in an exponential fashion. Intracranial compliance is now critically reduced and a small increase in intracerebral volume causes a substantial increase in ICP (B and C in Figure 3.1).
Compliance should be evaluated together with ICP. There are two methods to obtain it, both of which are invasive and potentially related to risks (infections, herniation, bleeding):

- Intracranial pressure "reserve" test.
- Pression-volume index (PVI).

The intracranial pressure "reserve" test entails observing the variation in ICP while adding or removing 1 ml of fluids (saline solution of CSF). It's considered normal when the injection of 1 ml induces an increase of ICP ≤2 mmHg or when the ICP decreases with draining of 1 ml of CSF.
The pressure-volume index represents the quantity of intraventricular fluid that has to be injected to produce an ICP increase of 10 mmHg. Usually, it is equal to 25 ml. A value <10 ml indicates severely compromised compliance.

3.7 Intracranial Pressure Curve

The arterial waves hit the choroid plexus, thus generating intracranial pressure waves which are also influenced by pulsations originating from the great intracranial arteries and in a retrograde form by the venous system. The wave's components can be analysed obtain an approximately measure of the state of compliance.
The normal ICP wave has three well-defined and universally present peaks (Figure 3.2). The first reflects the arterial input, while the two others reflect venous input. The first is called the percussion wave (P1), which is well defined and wide. The second peak is P2, also known as tidal wave, and has a variable width. Finally comes the third peak (P3), often termed the dicrotic wave. As a general rule, as ICP rises, the described wave morphology changes, adopting a pyramidal shape with gradual disappearance of P1, P3 and marked rise of P2. Sometimes the ICP does not raise its absolute value but if it changes shape. If P2 is greater than or equal to P1, even with ICP values considered normal, the compliance is decreased (Figure 3.3).
In conclusion, the analysis of the ICP wave is a tool of great value to the investigation of altered states of compliance prior to dangerous increases in ICP.

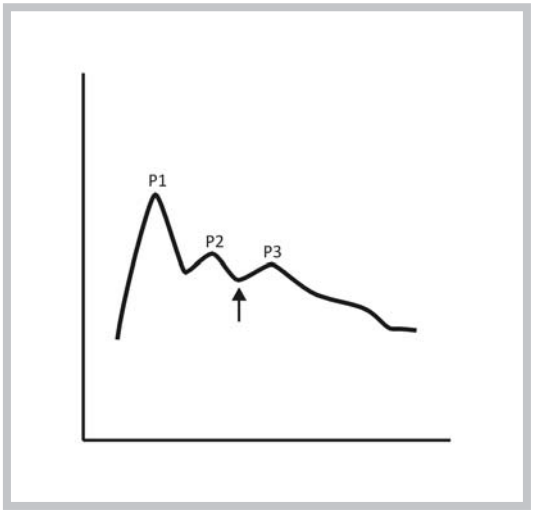

Figure 3.2. Intracranial pressure waves.

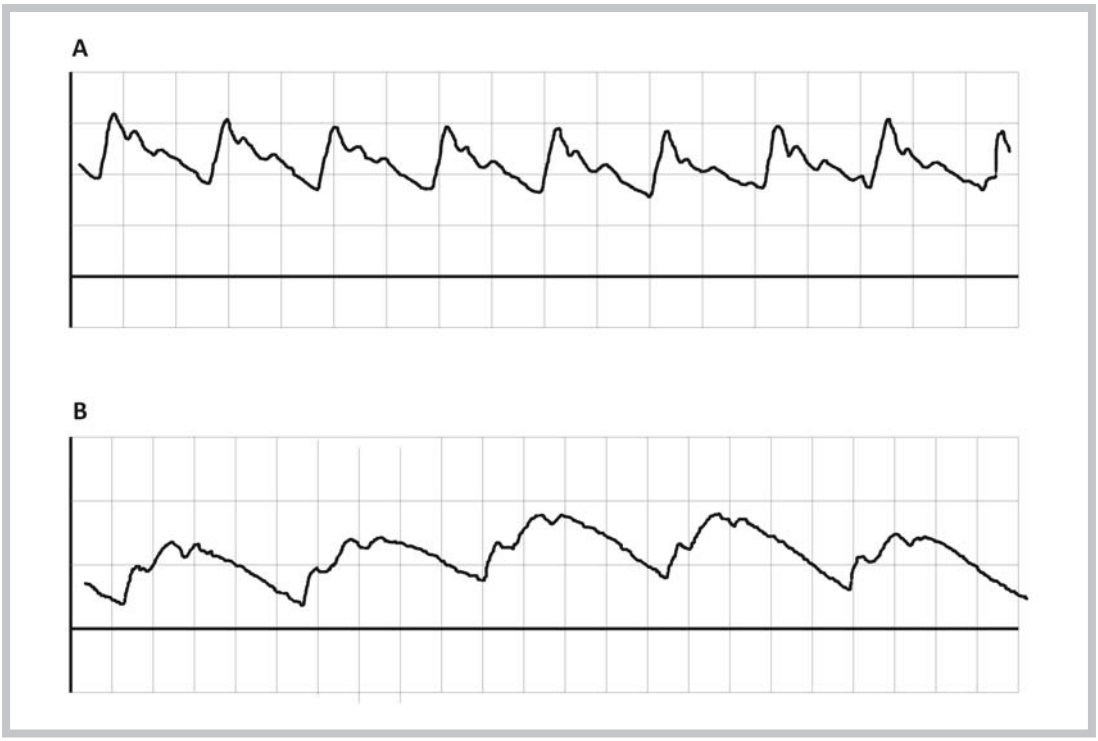

Figure 3.3. **Two patients with the same absolute ICP value (6 mmHg). (A) P1>P2>P3 indicates normal compliance. (B) P2>P1 indicates altered compliance.**

3.8 Cerebral Oxygen Metabolism

From a metabolic point of view, the brain is one of the most active and voracious organs of the human body. Although it does not perform mechanical work like skeletal or cardiac muscle, nor does it have complex enzymatic systems like the liver, it consumes 20% of total oxygen consumption.

The cerebral consumption of oxygen in a healthy and conscious individual is around 3.5 ml/100 g of tissue/min. Given that the brain weighs 1400 g on average, the total oxygen consumption is 49 ml/min. Consumption is maintained throughout a 24-hour period, even during sleep. Not all the oxygen provided is consumed, normally is extracted one-fifth to one-third that of the oxygen delivered. This difference underscores the great reserve capacity of the brain.

Oxygen is almost entirely used up in the mitochondrial oxidation of glucose to generate high energy phosphates. For each mol of oxygen, an equal amount of CO_2 is consumed, yielding a respiratory quotient of 1. The generated energy goes into maintaining the ion transmembrane gradients; therefore, the consumption of cerebral oxygen depends on cerebral activity. It has been estimated that 75% of the ATP produced is used to recover and maintain membrane potentials that take part in nervous impulse excitation and conduction. The remaining oxygen is used in several chemical reactions for the synthesis and metabolism of neurotransmitters, such as dopamine, serotonin and monoamines.

The gold standard for the measurement of cerebral metabolic rate of oxygen ($CMRO_2$) is positron emission tomography (PET), but in clinical practice it is calculated from the product of cerebral blood flow (CBF) the arterio-venous difference of oxygen ($AVDO_2$), according to the following formula:

$$CMRO_2 = CBF \times OEF$$

Though the brain does not store oxygen, it has a great need of oxygen and therefore requires its continuous supply. The availability of cerebral oxygen depends basically on two factors: the arterial content of oxygen (CaO_2) and the CBF.

3.9 Cerebral Blood Flow (CBF)

The average CBF in a healthy adult is about 55 ml of blood per 100 g of brain tissue per minute, or about 800 ml/min, corresponding to approximately 15% of the total basal cardiac output. To function adequately, the brain requires a CBF of about 54 ml/100 g brain tissue per minute. And because CBF depends on metabolic activity, CBF is greater in the gray matter (78 ml/100 g/min) than in the white matter (18 ml/100 g/min).
According to the Hagen-Poiseuille equation, the rate of laminar flow through a blood vessel is directly proportional to the existing pressure difference between the entrance and exit of the circuit (ΔP) and the diameter of the vessel (r), and inversely proportional to the viscosity of the circulating fluid (n).

$$\Delta P \times r^4$$

$$Flow = (\Delta P \times r^4) / (8 \times n \times l)$$

Under physiological conditions, the pressure gradient and the blood vessel diameter are the main determinants of CBF. The pressure gradient is obtained by calculating the difference between the mean arterial pressure (MAP) and the venous pressure; this is called the cerebral perfusion pressure (CPP). Because venous pressure is difficult to measure, ICP is measured instead. Accordingly, the CPP is obtained by calculating the difference between MAP and ICP as follows:

$$CPP = MAP - ICP$$

The cerebral blood vessels have the intrinsic capacity to maintain CBF constant, despite wide CPP fluctuations, in a range between 50 and 150 mmHg. This physiological property is called cerebral autoregulation.
Autoregulation of cerebral blood flow originates from the resistance of the arterioles which adapt their diameter in relation to different stimuli, thus determining cerebrovascular resistance (CVR). When the CPP increases to above 50 mmHg, the arterioles begin to contract, and the CVR increases in order to maintain CBF constant. By contrast, when the CPP decreases, the CVR decreases due to vasodilatation (Figure 3.4).
Under pathological conditions, the autoregulatory mechanism can be disrupted. When this happens, CBF passively follows CPP. This means that when MAP decreases, CBF decreases, and when MAP increases, CBF increases.
Thus, CBF is regulated by the control of the cerebral arteriolar tone, which is primarily modulated by CPP, in addition to other local factors such as $paCO_2$, paO_2, and pH. High CO_2 levels, acidosis and tissue hypoxia, and products of metabolic activity dilate the cerebral blood vessels and increase CBF. For this reason, the rate of formation of such products depends on the metabolic rate.
The metabolites that act in the regulation of the CBF are:

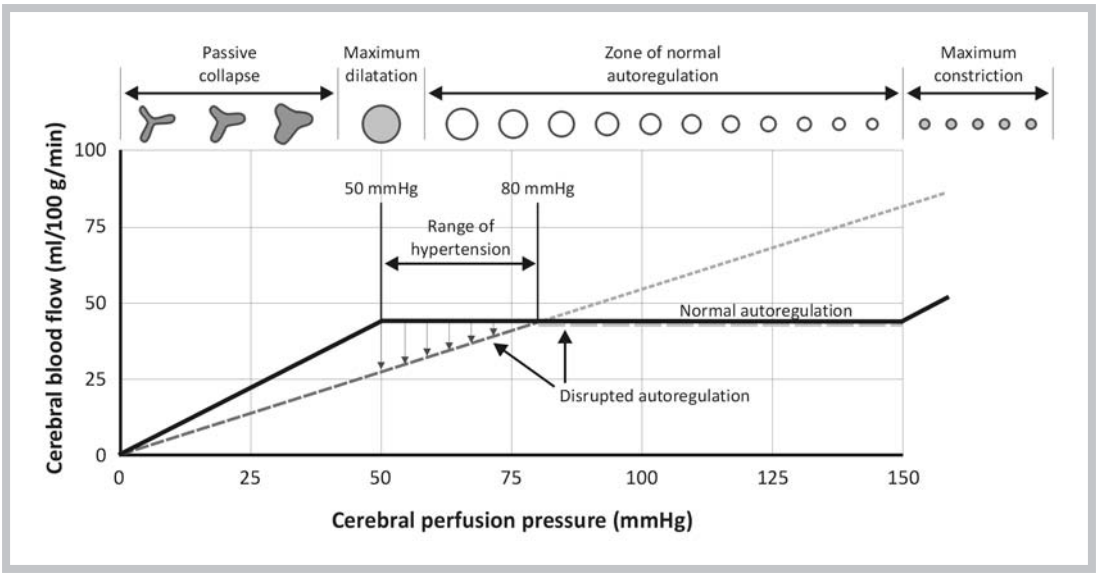

Figure 3.4. **Cerebral autoregulation curve.**

- CO_2: cerebral blood vessels are extremely sensitive to variations in CO_2 levels. This effect is related to the tissue pH values. As CO_2 levels increase, an acidic environment is created in the CSF, leading to arterial dilatation which, in turn, increases CBF.
- Potassium: a rise in perivascular potassium is a powerful stimulus to vasodilatation, as occurs, for example, in seizures or situations that cause tissue hypoxia.
- Adenosine: results from the degradation of ATP; it is a powerful vasodilator with prolonged action. Adenosine production is directly proportional to the degree and duration of tissue hypoxia.
- Nitric oxide: the cerebral vascular endothelium can express three types of enzymes called nitric oxide synthases which actively take part in CBF regulation and the transmission of impulses between neurons. It is frequently present in the prolongations of the astrocytes that form the synapses.
- Prostaglandins: another group of endogenous local acting autacoids. E2 prostaglandin and prostacyclins are both vasodilators. Experimental animal studies have demonstrated high levels of prostaglandins in CSF during arterial hypotension.

As mentioned, the brain needs a constant supply of oxygen. Oxygen transport from the air to the cerebral mitochondria depends on the correct functioning and integration of three systems: 1) respiratory; 2) circulatory; 3) hematologic.

Oxygen transport or availability (TO_2) to the brain is determined by the CBF and the arterial oxygen content (CaO_2). This depends on the main carrier: hemoglobin. Analyzing this protein, we will see that not only is its concentration important, but also its affinity for oxygen and capacity to transport it. Both properties are estimated by oxygen saturation and the oxygen-hemoglobin dissociation curve.

$$TO_2 = CBF \times CaO_2$$

$$CaO_2 = (Hgb \times 1.34 \times SaO_2) + (paO_2 \times 0.003)$$

Oxygen circulates from the atmosphere to the mitochondria by simple diffusion across concentration gradients. After crossing the alveolus-capillary barrier in the lungs, 95%

of oxygen reversibly binds to hemoglobin (Hgb), which is the main carrier of oxygen. The capacity to transport oxygen depends on the concentration of Hgb, which normally is around 15 g/100 ml of blood. Each gram of Hgb can transport 1.34 ml of oxygen.
The relationship between the carrying capacity and the amount really is transported in a given moment is referred to as arterial oxygen saturation. Its normal value is 97%.
The affinity of oxygen for Hgb is expressed by analysing the oxygen-hemoglobin dissociation curve. Its sigmoidal shape is unique: Hgb can bind to oxygen at the pulmonary level, transport it and then yield it to the cells in the capillary bed. Hemoglobin's affinity for oxygen is expressed by P50. P50 is the PO_2 corresponding to 50% saturation of Hgb. The normal value is 27 mmHg. If the P50 increases, the oxyhemoglobin dissociation curve shifts to the right.
An increased P50 indicates a rightward shift of the standard curve. This indicates a decreased affinity. In this case, the efficiency of oxygen delivery to the tissues is facilitated, as happens with an increase in body temperature, hydrogen ions, carbon dioxide or local acidosis oconcentration (the Bohr effect).
Thanks to this mechanism, the brain consumes only 33% of oxygen (cerebral oxygen extraction) and paO_2 decreases from 95 to 35 mmHg in the venous end of the capillary. Conversely, a lower P50 indicates a leftward shift and a higher affinity. A left shift of the curve is a sign of hemoglobin's increased affinity for oxygen (e.g., at the lungs). Similarly, a right shift reflects a decreased affinity.
Dissolved oxygen (paO_2) plays a secondary role in the global transport of oxygen. In order to calculate the arteriovenous oxygen difference, we need to know the oxygen content of mixed venous blood, which can be obtained with the following equation:

$$CvO_2 = (Hgb \times 1.34 \times SvO_2) + (pvO_2 \times 0.003)$$

Returning to equation 1, if:

$$CMRO_2 = CBF \times Da\text{-}vO_2$$

then:

$$Da\text{-}vO_2 = TMCO_2 / CBF$$

Ordinarily, the arteriovenous oxygen difference remains stable and equal to 4-8 ml O_2 for each 100 ml of blood. If oxygen consumption remains stable, changes in $Da\text{-}vO_2$ will reflect changes in CBF. So, if $Da\text{-}vO_2 < 4$, CBF exceeds the cerebral demand; this phenomenon is called hyperemia. Conversely, if $Da\text{-}vO_2 > 8$, this means that the oxygen supply to the brain has fallen below the demand, and this is what happens during ischemia.

3.10 Oxygen Tissue Pressure ($ptiO_2$)

Under normal conditions, there is a direct linear correlation between paO_2 and oxygen tissue pressure ($ptiO_2$). Since oxygen is consumed in the cells, $ptiO_2$ varies widely, from 90-95 mmHg in the capillaries to 30-35 mmHg in the venous district. Critical $ptiO_2$ in the brain is between 15 and 20 mmHg; nevertheless, the neuronal mitochondria require only 1.5 mmHg to maintain aerobic metabolism.
The reader is referred to the chapter on tissue oxygenation monitoring for a more detailed discussion of this topic.

3.11 Cerebral Glucose Metabolism

The brain has an enormous demand for energy. To meet this need, it requires a continuous and suitable supply of its two main nutrients: oxygen and glucose. Glucose is the basic fuel. Although the human brain accounts for only 2% of total body weight, it consumes 25% of total body glucose utilization. Only uses 10% of what is supplied.
Cerebral metabolic consumption of glucose is 5 ml per 100 g of cerebral parenchyma per minute, equal to 140 g/day.
There is a linear correlation between plasma and brain glucose concentration. The cerebral concentration is about 30% of the plasma concentration, depending on variations in blood levels. Since glucose does not readily cross the BBB, it requires a transport system. This system is formed by a family of specific, highly regulated proteins collectively referred to as glucose transporters (GLUT).
Several types are distinguished: GLUT 1 transports glucose to the endothelial cells, glial cells, and astrocytes; and GLUT 3 regulates glucose entry into the neurons. Both transport systems can increase their activity during neuronal activation to optimize glucose transport according to the supply needed.
Cerebral glucose consumption depends directly on brain activity and a sufficient supply of blood and oxygen. Since the brain lacks energy reserves, the small deposits of glycogen available mainly in the astrocytes are exhausted within about 2 minutes.
In certain circumstances, lactate and pyruvate formed during glucose metabolism can maintain neuronal activity. Nevertheless, neither crosses the BBB easily nor has specific carriers, and so cannot replace glucose as an energetic substrate in physiological situations. In some pathological states such as malnutrition or diabetes, blood ketone levels, such as acetoacetate and D-3-hydroxybutyrate in particular, are extremely high, and can be used by the brain as metabolic substrates.
Besides being the brain's primary energy source, glucose plays a major role in many other processes essential for cerebral cellular activity, including:

- Allow correct functioning of ion channels to maintain transmembrane transport.
- Production of nucleic acids, amino acids and lipids.
- Synthesis of hormones and neurotransmitters like glutamate, acetylcholine and γ-aminobutyric acid (GABA).

Cerebral energetic metabolism can be estimated by means of two techniques: the 2-deoxyglucose (2-DG) method and positron emission tomography (PET). Both have advanced our understanding of glucose with regard to: regional heterogeneity, and relationship with brain activity
The rate of glucose consumption by the gray matter varies between 5 and 15 mg per 100 g of tissue per minute, depending on the brain area studied and its specific function. By contrast, the average rate of glucose consumed by the white matter is only 1.5-2 mg/100 g/min.
Functional activity increases glucose consumption three times over the basal rate.

3.12 Cerebral Temperature

Homeothermic mammals like humans must maintain their core body temperature constant in order to survive. The body temperature depends on the balance between the production and dissipation of heat. The core temperature (trunk) varies throughout the day, from 36°C in the morning to 37.5°C in the evening. During sleep it decreases, as the rate of metabolism slows. However, the peripheral temperature (hands, feet, skin) var-

ies widely depending on environmental temperature. Some 90% of body heat is dissipated through the skin and 10% by breathing. Body heat dissipates by:

- Radiation: the most efficient. More than 60% of the heat produced is eliminated by the transmission of caloric energy by infrared radiation towards a body, object or air.
- Conduction: (5%) heat transfer by direct contact with another object of different temperature. Its effectiveness will depend on the interface surface between the two objects in contact and on the temperature gradients.
- Convection: loss of heat by air movement around the body.
- Evaporation: responsible for 20% of total heat losses. It depends on ambient humidity, exposed skin surface area, and perspiration. This mechanism is the only one that allows us to dissipate body heat when the room temperature is higher than the body temperature.

The cerebral temperature can have a static or dynamic behaviour noticeably different from the body's core temperature.

3.13 Brain-systemic Temperature Gradient

In general terms, there is a significant correlation between core temperature and cerebral temperature, albeit with differences in absolute values and speed of response. Owing to the great variability in cerebral temperature, predicting its behaviour may be impossible in some situations.

The gradient is positive when the cerebral temperature is greater than the core temperature and negative in the opposite case. In general, in injured patients, the core temperatures ranges between 36 and 38°C and there is a variable positive gradient of almost 0.3-0.5°C. In central hyperthermia, this gradient is amplified and can reach 2°C. A negative gradient occurs in spontaneous or induced hypothermia.

3.13.1 Intracerebral Gradients

The difference between the intraventricular temperature (deep) and the epidural (superficial) temperature can reach 4°C but is typically equal to 0.5°C, with the ventricular temperature being the higher of the two. The basal structures (more isolated) are warmer that those of the convexity. However, cerebral temperature is not stable, with local variations of 1 to 2°C in response to neuronal activation.

3.13.2 Factors Determining Cerebral Temperature

Factors which can affect the generation of a brain-systemic temperature gradient are: 1) cerebral blood flow; 2) temperature of the blood arriving to the brain; 3) local heat production; 4) heat isolation of the skull and other cover structures; and 5) core temperature regulation.

Cerebral Blood Flow (CBF)

CBF is the major factor responsible for the magnitude and direction of caloric interchange within the brain. The CBF is the "convective" route by which the core temperature arrives at the cerebral parenchyma. The dense capillary network of the cerebral tissue facilitates intracerebral cooling.

CBF supplies oxygen and glucose, and removes CO_2 from the cerebral tissue depending on metabolic demand. Added to these functions is the role it plays in heat "washout". A direct correlation exists between CBF, cerebral temperature, and the brain-systemic temperature gradient; thus, CBF acts as a thermal buffer.

If cerebral metabolism and temperature remain coupled, CBF rises during hyperthermia and decreases during hypothermia, when the changes in CBF predominate over those of $CMRO_2$. This relationship between CBF and cerebral temperature explains the thermopooling phenomenon, in which there is a disconnection between these variables. As a result, the brain overheats, being unable to dissipate the heat accumulated by the decrease in CBF. Another point to consider is the adaptation of the CBF over time.

Intracerebral Blood Temperature

Intracerebral blood temperature is usually 0.3 to 0.5°C less than the cerebral temperature and basically depends on two variables: core temperature and selective cerebral cooling.

Three mechanisms of selective brain cooling have been proposed:

- Pre-cooling of the arterial blood before it enters the skull due to contact with the jugular blood and the cavernous sinus, which are both cooler.
- Convective cooling by venous blood flow in the face.
- Evaporative cooling through the pharyngeal surface.

Local Heat Production

The brain consumes an enormous amount of energy and, as a result, it produces a great amount of heat. Neuronal activity requires 104 moles of ATP to transmit impulses through synapses and 107 moles to recharge a neuron after the potential of action. Almost all the energy consumed to maintain neuronal activity is transformed into heat. Evidence exists that, certain situations, the cerebral temperature is greater than the arterial temperature and that it rises before the entrance of the blood. For this reason, the available data suggest that its main heat source is the brain. Therefore, fluctuations in the intracerebral temperature result from neuronal activity.

Another important consideration is that cerebral oxygen consumption is independent of the oxygen consumption by the rest of the body. In severe neuroinjury, the $CMRO_2$ decreases proportionally to the degree of coma. But because the cerebral temperature is greater, this generates a consistent brain-systemic temperature gradient, probably as a result of increased glucose consumption, called hyperglycolysis, which increases the production of heat without consuming oxygen.

Thermal Isolation

The brain can be viewed as a box of thermal resonance with low conductivity and discharge high resistance to heat transmission.

It is isolated by: 1) scalp; 2) bone; 3) dura mater; 4) CSF.

The heat generated by the parenchyma is difficult to eliminate, as explained by the fact that the brain is not subject to superficial cooling. During neurosurgery, exposure to room temperature produces a noticeable cooling of the cerebral surface structures.

Thermal Regulation

Body temperature is controlled by the thermoregulatory centre in the hypothalamus. Injury to the centre can lead to thermoregulatory dysfunction and is generally associated with poor prognosis.

Systemic	Intracranial
• Arterial hypotension • Hypoxemia • Hypercapnia • Hypocapnia • Fever • Hyponatremia • Hypoglucemia • Hyperglucemia • Severe anemia • Acidosis • Intravascular coagulation • Systemic inflammatory response syndrome	• Intracranial hypotension • Delayed cerebral hematoma • Cerebral edema • Cerebral hyperemia • Vasospasm • Seizures

Table 3.1. Causes of secondary damage.

3.14 Concept of Primary and Secondary Injury

Primary damage occurs immediately after an injury, independently of its cause: ischemic, hemorrhagic, nontraumatic, or other. At the cellular level, damage can continue to develop during the first hours following the injury. The consequence of this phenomenon are functional or structural lesions, reversible or irreversible, focal or diffused. At the microscope, primary damage is characterized by laceration and retraction of the axons, rupture and vascular torsion. Axonal lesion constitutes the basic element of diffuse cerebral damage.

Secondary damage refers to additional damage caused by insults capable of aggravating and/or perpetuating the initial or primary damage. Its causes can be of intracranial or systemic origin. It can appear at any moment of the clinical course and due to primary injury doen't have specific treatment, prevention, detection and early treatment of secondary injuries is essential (Table 3.1).

4 Examination of the Critically Ill Neurological Patient

José Biller [1], Sarkis Morales-Vidal [2], Adolfo Ramirez-Zamora [3]

[1] Professor and Chair, Department of Neurology, Loyola University Chicago, Stritch School of Medicine, Maywood, IL, USA
[2] Assistant Professor, Department of Neurology, Loyola University Chicago, Stritch School of Medicine, Maywood, IL, USA
[3] Assistant Professor, Department of Neurology, Albany Medical Center, Albany, New York, USA

4.1 Clinical Evaluation (or Examination) of the Critically Ill Neurological Patient

The practice of neurointensive care is about the application of a methodological approach to basic routines. This includes attention to the standard ABC parameters (**A**irway, **B**reathing, **C**irculation). Since underinvestigating and undermonitoring will inevitably miss vital information, a comprehensive history and physical examination should always be obtained in a critically ill neurological patient.

4.1.1 How to Approach a Patient in the Neurological Intensive Care Unit

Because critically ill patients often have multiorgan dysfunction, the conventional approach of differential diagnosis, provisional diagnosis, investigations and final diagnosis is less relevant during acute care. In the neurological intensive care unit (NICU), however, most patients have a primary neurological disorder with medical co-morbidities as secondary complicating factors. Still, a thorough assessment of both the neurologic and systemic processes remains essential.

The Ward Rounds

The two most important parameters in the care of the critically ill neurological patient are team work and a problem-oriented approach.

History. The patient must first be stabilized. A detailed history should be obtained from eyewitnesses, paramedics or any other contacts that can furnish information about the sequence of events that led to the patient's critical state.

Sign out. If the first encounter with the patient is in the context of continuing care, a complete history should be obtained, including all the events that led to the patient's current status.

A	Airway
B	Breathing
C	Circulation
D	Disability – Glasgow Coma Scale
E	Electrolytes
F	Fluids: are they appropriate?
G	Gut: nutritional assessment
H	Hematological
I	Infection: microbiology and white blood cell (WBC) count
L	Lines: are sites clean? How long have they been in?
M	Medications: review, evaluate interactions
R	Relatives: inform relatives about patient status

Table 4.1. Problem list mnemonic.

Physical examination. Discussed later.
Review investigations. These include medications or other interventions, monitoring, laboratory and imaging studies.
List of problems and management plan. The problem sheet serves to focus the team's thoughts on an overall management strategy. A systematic approach can be created in different ways. Table 4.1 lists mnemonics to assess patient problems. Table 4.2 illustrates a systemic organ systems approach. Whenever possible, a systems-oriented approach is preferred in the NICU.

- Respiratory
- Cardiac
- Infectious
- Hematologic
- Metabolic
- Neurologic
- Alimentary
- General ICU (include ICU prophylaxis)
- Miscellaneous (allergic, orthopedic, etc.)

Table 4.2. Systems-based problem list.

4.2 General Examination

A complete physical examination should be performed during the initial evaluation after the patient has been stabilized and at least once daily in the clinically stable patient. A head-to-toe approach in the bedside examination is recommended (Table 4.3).

ABCs	• See above
Vital signs	
General examination	• Address patient by last name • Explain to the patient what you are going to do. Remember that many NICU patients may be paralyzed though not comatose • Is the patient resting comfortably or is he/she in distress?
Expose whole body	• Place the patient in an upright position (>30 degrees) if possible • Inspect skin and mucous membranes for jaundice, rashes, bruises or signs of dehydration • Inspect for pressure ulcers • Inspect intravascular lines (peripheral, central and arterial) for possible signs of infection • Inquire about frequent turning (Q2 hours)
Airway and head	• Natural airway • Artificial airway: cuff, type of tube and securing method, cuff pressure diameter • Inspect scalp, sinuses, mouth, ears, nasogastric (NG) tube, cervical nodes, eyes (any corneal ulceration as a result of drying?) • Inspect all invasive equipment sites: surgical drains; intercostal catheters (ICCs); intravenous (IV) lines, intra-arterial (IA) lines and endotracheal and tracheostomy tubes (ETTs)
Respiratory system	• Chest movement, respiratory rate, respiratory effort • Auscultate chest, particularly lung bases • Ability to cough • Secretions • Patient interaction with ventilator • Oxygenation (FiO_2, PaO_2, SaO_2) • Ventilator parameters • Chest drains • Chest X-ray – single best means of assessing respiratory status

Circulatory system, fluids and renal function	• Precordium • Neck veins • Peripheral pulses and rhythm • Peripheral edema • Auscultate precordium • Blood pressure • Urine output and other abnormal losses • Fluid input: volume and composition • Cardiac output • Is the patient on inotropes, vasopressors, vasodilators or other cardiovascular (CV) drugs? – Important in the interpretation of physical findings
Gastrointestinal system	• Inquire about NG aspirate • Efficacy of enteral feeding – is it being tolerated? • Bowel movements • Inspect for abdominal distension, wounds and drains • Inquire about the origin and the content of gastrointestinal (GI) drains • Palpate for tenderness and masses • Auscultate bowel sounds • Proper ulcer prophylaxis (e.g., H_2 antagonists or proton pump inhibitors) when indicated • Inquire about nutritional status (e.g., feeding route)
Limbs	• Any rashes, edema or wounds • Inspect wounds, remove dressing when possible • Examine for underlying fractures or peripheral neurological complications when appropriate
Nervous system	• Level of consciousness – preferable after stopping sedating medications • Brainstem reflexes • Look for lateralizing neurological signs • Glasgow Coma Scale (GCS) • Evaluate for possible seizure activity
Hematology	• Oozing or bleeding
Adequate thromboembolism prophylaxis	• Frequent turning • Mobilization • Graded compression stockings • Subcutaneous heparin, unfractionated heparin (UFH) or low-molecular weight heparin (LMWH) • Pneumatic full-length leg compression

Table 4.3. **Head-to-toe approach in the bedside examination.**

Some important physical findings in the general examination that can suggest an underlying critical condition deserve special attention. Bounding in the neck and precordium often indicates sepsis. An indentation ring on the skin, left after listening for bowel sounds with a stethoscope, indicates extensive peripheral edema. Blue discoloration, particularly in the knees, indicates peripheral cyanosis and compromised circulation. Attempts to breathe against the ventilator, despite what appears to be adequate minute volume, is often due to severe metabolic acidosis. Rapid deterioration in cardiorespiratory signs can indicate pneumothorax or pulmonary embolism.

Always assess airway adequacy, even if the patient has an endotracheal or tracheostomy tube in place. It may be kinked or blocked.

The preferred method to assess the level of consciousness in response to pain is with nail bed pressure. Vigorous stimulation of the outer part of the orbit can cause nerve palsies and sternal rub can cause unsightly bruising.

Mental status and language function	The patient exhibited normal attention and reasoning. There was no evidence of a thought disorder. Affect and mood were unremarkable. Speech was normal and prosody was intact. Verbal expression, comprehension, repetition, reading, and writing were intact. Immediate recall, recent and remote memory were intact. There was no right/left disorientation, finger agnosia, or dyscalculia
Cranial nerves	There was no anosmia. Visual fields were normal to confrontation and visual acuity was 20/20 OU. Funduscopy was unremarkable. Pupils were of equal size (OD – millimetres, OS – millimetres) and exhibited a normal direct and consensual response to light. There was no relative afferent papillary defect (RAPD). Ocular motility was full and no nystagmus was evident. Masticatory muscle strength was normal. Facial sensation was normal. Corneal reflexes were present (direct and consensual). Facial expression was unremarkable without hypomimia and there was no facial weakness or Bell's phenomenon. Hearing acuity was normal. Palatal movements and gag reflex were intact. There was no palatal myoclonus. Sternocleidomastoid and trapezii strength were normal. Tongue protruded in the midline and showed no atrophy, tremor or fasciculations
Motor examination (bulk, tone, strength)	Motor examination showed normal muscle bulk, tone, and strength throughout. Serial finger tapping and rapid alternating movements were normal. No adventitious movements were noted
Muscle stretch reflexes (MSRS)	Muscle stretch reflexes were symmetric and normoactive. Plantar responses were flexor bilaterally. No pathologic reflexes were appreciated
Sensory	Normal light-touch, pinprick, temperature, vibration, and position sense. Graphesthesia, stereognosis, and two-point discrimination were unremarkable. There was no extinction to double simultaneous tactile stimulation
Cerebellar and coordination	Coordination examination showed normal rapid alternating movements. Finger-finger, finger-nose, and heel-knee-shin testing were unremarkable
Romberg test	Romberg test was negative
Gait and station	Erect posture was normal. There was no postural instability. There was no festination. Tandem, heel, and toe walking were unremarkable

Table 4.4. Neurological examination.

4.3 Comprehensive Neurological Examination

Guidelines for a comprehensive neurological examination have been published by the American Academy of Neurology (AAN). Much information regarding a patient's mental status will be obtained during history taking.

This chapter is intended just as an overview of the neurological examination. For a more detailed description, which is beyond the scope of this chapter, one should refer to several texts designed for this purpose, including: DeMyer's The Neurologic Examination. A Programmed Text, Sixth Edition; DeJong's The Neurologic Examination by William W. Campbell; and Localization in Clinical Neurology by Paul W. Brazis, Joseph C. Masdeu and Jose Biller. Table 4.4 illustrates an example of a detailed normal neurological examination used at the Department of Neurology, Loyola University Medical Center.

4.4 Routine Investigations of the Neurocritical Patient

Several parameters, including laboratory testing (e.g., glucose levels), physiological (e.g., EKG) and imaging (e.g., chest X-ray), serve as an extension of the physical examination in the evaluation of the critically ill neurological patient. Table 4.5 summarizes these tests. Obtaining routine microbiologic tests daily is not recommended, since the results must be interpreted based on clinical impression.

Frequency	Test
Every four hours	Glucose levels
Daily	• Arterial blood gases • Potassium • Creatinine • Blood urea and nitrogen (BUN) • Sodium and chloride • Hemoglobin • White cell count and platelets • Magnesium • Calcium and phosphate • 12-lead EKG • Chest X-ray
Twice weekly	Liver function tests: serum billirubin, alkaline phosphatase, aminotransferase activities and serum albumin levels
Continuous monitoring	Cardiac telemetry, pulse oximetry, blood pressure, cardiac rhythm

Table 4.5. **Examinations in the critical ill neurological patient.**

Blood pressure	Maintain normotension
Symptoms and signs of myocardial ischemia	Continuous EKG monitoring Have low threshold to obtain 12-lead EKG and cardiac enzymes (troponins, CK-MB)
Cerebral ischemia	Frequent neurochecks
Hypoglossal neuropathy	Localized loss of conduction that causes short-term paralysis. There is no degeneration of the axon and complete recovery is usual
Early signs of bleeding around operative site	Risk of upper airway obstruction Intubation is extremely difficult; consider ear-nose-throat (ENT) consultation at this point

Table 4.6. **Key points to remember when taking care of the postoperative carotid endarterectomy patient.**

4.4.1 Monitoring Potential Complications in Intubated Patients

When evaluating intubated patients it is important to look for potential complications. General complications of endotracheal and tracheostomies are: malposition; dislodgment; disconnection; obstruction; infection; local damage to larynx and trachea; interference with humidification; and warming of inspired gases.

4.4.2 Postoperative Care Following Carotid Endarterectomy

Table 4.6 summarizes the most important points to remember when taking care of the postoperative carotid endarterectomy patient.

4.5 Focused Neurological Examination of Selected Topics

The neurological examination of the critically ill neurological patient should focus on the initial impression provided by the clinical history. The approach to a comatose patient differs from a history suggestive of acute cord compression. The following topics will summarize the recommended approach to a focused neurological exam depending on the initial suspected condition.

4.5.1 Coma

Syndromes of global cerebral dysfunction related to critical illness embrace such acute disorders as coma and delirium, and chronic processes with various degrees of cognitive impairment. Global cerebral dysfunction can result from direct cerebral damage, but in many instances it develops as a consequence of a systemic insult.
Coma often evolves into clinically diverse disorders of consciousness and must be differentiated from situations where awareness is preserved, as in the deafferentate state. Coma and delirium have been independently linked to increased short-term mortality.
Different terms have been used to describe disturbances of global cerebral dysfunction: coma, delirium, encephalopathy, acute confusional state, and ICU psychosis. Etiology-specific terms (e.g., septic encephalopathy or hepatic encephalopathy) have been used when there is a well-grounded suspicion regarding the causal mechanism.
There are two interconnected domains of neurologic function that describe consciousness: arousal or wakefulness, and awareness, often termed "the content of consciousness". Awareness, in turn, has many components, including perception, attention, memory, executive function, and motivation. The anatomic substrate of arousal is the ascending reticular activating system, a set of connections of neurons extending from the pontine and midbrain tegmentum and projecting to the cerebral hemispheres through the thalamus.
Coma is characterized by a profound disturbance of the reticular activating system. Duration of greater than 1 hour differentiates coma from transient states such as syncope or concussion. Coma is a transitional state that can evolve into recovery of consciousness, vegetative state, or brain death. Plum and Posner proposed a simple, four-part neurologic evaluation of the comatose patient [1]. These parameters are: assessment of the level of consciousness; brainstem function; motor activity; and respiratory pattern.

Activity	Score
Eye opening	
None	1 = Even to supra-orbital pressure
To pain	2 = Pain from sternum/limb/supra-orbital pressure
To speech	3 = Non-specific response, not necessarily to command
Spontaneous	4 = Eyes open, not necessarily aware
Motor response	
None	1 = To any pain; limbs remain flaccid
Extension	2 = Shoulder adducted and shoulder and forearm internally rotated
Flexor response	3 = Withdrawal response or assumption of hemiplegic posture
Withdrawal	4 = Arm withdraws to pain, shoulder abducts
Localizes pain	5 = Arm attempts to remove supra-orbital/chest pressure
Obeys commands	6 = Follows simple commands
Verbal response	
None	1 = No verbalization of any type
Incomprehensible	2 = Moans/groans, no speech
Inappropriate	3 = Intelligible, no sustained sentences
Confused	4 = Converses but confused, disoriented
Oriented	5 = Converses and oriented

Table 4.7. Glasgow Coma Scale [2].

Eye response (E)	E4 = Eyelids open or opened tracking or blinking to command E3 = Eyelids open but not tracking E2 = Eyelids closed, open to loud voice, not tracking E1 = Eyelids closed, open to pain, not tracking E0 = Eyelids remain closed with pain
Motor response (M)	M4 = Thumbs up, fist or peace sign to command M3 = Localizing to pain M2 = Flexion response to pain M1 = Exterior posturing M0 = No response to pain or generalized myoclonus status epilepticus
Brainstem reflexes (B)	B4 = Pupil and corneal reflexes present B3 = One pupil wide and fixed B2 = Pupil **or** corneal reflexes absent B1 = Pupil **and** corneal reflexes absent B0 = Absent pupil, corneal, and cough reflex
Respiration (R)	R4 = Not intubated, regular breathing pattern R3 = Not intubated, Cheyne-Stokes breathing pattern R2 = Not intubated, irregular breathing pattern R1 = Breathes above ventilator rate R0 = Breathes at ventilator rate or apnea

Table 4.8. **FOUR score coma scale [3,4].**

Terms such as somnolence, lethargy, obtundation and stupor have been used to describe different degrees of decreased level of consciousness. Nevertheless, the reliability of such terms is poor and their use should be discontinued in medical practice. The use of scoring systems such as the Glasgow Coma Scale (GCS, see Table 4.7) increases reliability and decreases interrater variability. Nonetheless, the GCS has limitations, including a low sensitivity to subtle changes in arousal, a failure to assess brainstem function, and the difficulty with obtaining a verbal score in intubated, sedated, or aphasic patients. Other scoring systems that incorporate brainstem findings include the **F**ull **O**utline of **U**nresponsiveness (**FOUR**) score (Table 4.8) and the Glasgow Liege Score. The GCS and the FOUR score can be used as part of the serial examination of the patient and are also useful measures for prognostication of outcome.

Although coma is frequently reported in clinical studies of patients who have primary neurologic dysfunction, fewer reports have evaluated the epidemiology and impact of coma in the general medical or surgical ICU. Up to 90% of postcardiac arrest patients are comatose for varying lengths of time. In a study of sepsis-associated encephalopathy, 16% of patients who had sepsis were comatose and the level of consciousness was closely associated with mortality. The presence of coma has prognostic significance in patients with either primary or secondary mechanisms of brain injury. Coma has been identified as a powerful predictor of death and functional outcomes in patients who have stroke, traumatic brain injury, or cardiac arrest.

Clinical Evaluation of the Comatose Patient: History

The cause of coma might be obvious during initial assessment (e.g., cardiac arrest, drug intoxication or trauma). If the cause is unclear, initial history taking should focus on the most potentially treatable causes of coma. The most pertinent information to gather is about circumstances and rapidity of neurological dysfunction, antecedent symptoms, medications, illicit drugs or alcohol use; and past medical history, particularly heart, liver, kidney, and lung disease. If information cannot be obtained from the patient, it is of paramount importance to contact family members and interrogate paramedics about the circumstances in which the patient was found.

General Physical Examination

After establishing adequacy of the ABCs, the next step should be to obtain vital signs (temperature, pulse, respiratory rate and pattern, and blood pressure). Obtaining glucose level should be done along with vital signs. The steps approach in the general examination was mentioned earlier. Some important findings in the general examination of the comatose patient are summarized in Table 4.9.

Finding	Neurological causes	Medical or other non-neurological causes
Increased body temperature (fever, hyperthermia)	• CNS infection (e.g., meningitis, meningoencephalitis, cerebral abscess) • Neuroleptic malignant syndrome • Serotonin syndrome • Malignant hyperthermia • Heat stroke (temperature can be as high as 42-44°C; associated with dry skin) • Anticholinergic drug intoxication (associated with dry skin) • Hypothalamic temperature-regulating centres (central fever)	• Systemic infection • Non-infectious inflammatory conditions (e.g., systemic lupus erythematosus, thrombotic thrombocytopenic purpura)

Decreased body temperature	• Hypothalamic damage
	• Hypothermia itself causes coma only when the temperature is <31° C
	• Wernicke's encephalopathy
	• Myxedema coma
	• Panhypopituitarism
	• Thyroid encephalopathy
	• Acute renal failure (Addisonian crisis)
		• Environmental
		• Sepsis (peripheral circulatory failure)
		• Drug intoxication:
		  · alcoholic
		  · barbiturate
		  · sedative
		  · phenothiazine
		• Hypoglycemia
		• Hypothyroidism

Hypoventilation	• Medullary cardiorespiratory centre structural damage (e.g., ischemic stroke, hemorrhage, compression due to cerebellar herniation) • Upper cervical spinal cord damage	
Tachypnea		• Systemic acidosis • Pneumonia
Shallow, slow, but regular breathing		• Metabolic encephalopathy • Drug depression
Cheyne-Stokes respirations (crescendo/decrescendo with alternating apnoea episodes)	• Bihemispheric damage (usually accompanies "light coma")	• Heart failure • Severely ill elderly patient
Rapid, deep (Kussmaul) breathing	• Pontomesencephalic lesions	• Metabolic acidosis
Ataxic breathing	• Progressive rostrocaudal damage of the brainstem • Agonal gasps indicate medullary damage	
Arterial hypertension	• Reactive hypertension from intracranial hemorrhage, ischemic stroke or as part of the Cushing reaction	• Hypertensive encephalopathy

Arterial hypotension	• NOTE: In adults, intracranial hemorrhage would not lead to hypotension since the cranial cavity is not large enough	• Cardiogenic shock • Hypovolemic shock • Septic shock • Others: alcohol or barbiturate intoxication; profound hypothyroidism; Addisonian crisis
Raccoon's eyes, Battle sign, otorrhoea, rhinorrhoea,	• Skull base fracture	
Petechia, ecchymosis	• Meningococcemia	• Coagulopathy that can result in intracranial hemorrhage, e.g.: thrombotic thrombocytopenic purpura, bleeding diathesis
Purpura with fever and nucal rigidity	• Meningoencephalitis	
Splinter, plantar hemorrhages. Rhot spots		• Endocarditis that can result in cardioembolism of infective material and resultant brain abscess and infectious vasculitis
Funduscopic examination: subhyaloid hemorrhages	• Subarachnoid hemorrhage	
Funduscopic examination: papilledema	• Increased intracranial pressure	

Table 4.9. **Summary of general physical examination.**

Focused Neurological Examination

General observation of the patient should be followed by assessment of level of arousal, brainstem reflexes and muscle tone.

Level of Arousal

The threshold for arousal and the optimal motor response is evaluated by applying a sequence of increasingly intense stimuli to each side of the body. Serial examinations are useful to detect variability in the level of consciousness. A moderate stimulus to arousal is tickling the nostrils with a cotton wisp. Nail bed or knuckle pressure is another form of painful stimulation. The GCS and/or the FOUR score provide a quantitative measure of the level of arousal. Even though the GCS was initially designed to evaluate traumatic brain injury, the scale (as well as the newer FOUR score) can be utilized in serial assessment of non-traumatic causes of coma.

Differential Diagnosis of Coma

Coma must be differentiated from brain death, vegetative state, minimally conscious state (MCS), akinetic mutism, pharmacologically induced states of decreased arousal, and the locked-in syndrome (LIS). Table 4.10 summarizes the differences between these clinical states.

Definition	Level of consciousness	Brainstem functions	Motor function	Note
Brain death				
Complete and irreversible loss of brain and brainstem function	Abolition of consciousness	Absent cranial nerve activity Absent spontaneous breathing	Absent motor function	Before a diagnosis can be made, conditions that can confound neurologic assessment must be ruled out, in particular: • Physiologic or metabolic derangements • Severe hypothermia (temperature <32°C) • Recent exposure to toxic or pharmacologic agents that might impair consciousness or neuromuscular transmission
Vegetative state				
Global impairment of consciousness, wherein awareness of self or the environment is absent, but signs of arousal are retained. Results from extensive damage to the cerebral cortex, with relative sparing of the brainstem	Opens eyes spontaneously, but does not react in any meaningful way to environmental cues. Does not follow any commands	Intact reflex brainstem activity, including breathing		Vegetative state longer than 1 month is classified as a persistent vegetative state
Minimally conscious state (MCS)				
Occurs in the setting of catastrophic hemispheric brain injury, with intact brainstem function and preservation of some corticocortical and corticothalamic circuits	Global alteration of consciousness with elements of arousal. Intermittent evidence of self or environmental awareness. Might sporadically follow commands, attend to recognizable objects or voices, initiate meaningful speech, or engage in purposeful movement	Intact		Long-term outcomes of patients in MCS have not been studied well

Akinetic mutism				
Typically the result of injury to the bilateral frontal lobes	Profound deficiency in executive function Unable to initiate speech Does not exhibit any motor or verbal response to verbal or noxious stimulus		Unable to initiate movement Seems on the verge of initiating activity, yet this is never accomplished	Neurologic recovery has been reported
Pharmacologically induced coma				
Deliberate induction of a coma-like state with the use of sedative or anesthetic agents	Virtually any clinical evidence of brain or brainstem activity can be abolished	Virtually any clinical evidence of brain or brainstem activity can be abolished		Agents commonly used for pharmacologically induced coma include barbiturates, propofol, and midazolam. Confounds the clinician's ability to diagnose coma or even brain death
Locked-in syndrome (LIS)				
Focal injury to the ventral pons	Preserved arousal and awareness	Anarthria Preserved vertical eye movements and eye blinking Alternative presentations may occur in patients with injury of the rostral pons and midbrain, in whom even eye movements are lost (''total LIS'')	Quadriplegia	In its classic presentation, patients with LIS can express themselves only by blinking and with vertical eye movements States analogous to LIS: • Guillain-Barré syndrome • Neuromuscular-blocking drugs without appropriate sedation

Table 4.10. **Differences between brain death, vegetative state, minimally conscious state (MCS), akinetic mutism, pharmacologically induced states of decreased arousal, and the locked-in syndrome (LIS).**

Brainstem Reflexes

Easily examined brainstem reflexes are pupillary light reflexes, eye movements (spontaneous and elicited), corneal reflex, and respiratory pattern. If these brainstem activities are preserved, the lesion causing coma is probably due to bilateral hemispheric dysfunction. At the other end of the spectrum, the absence of these reflexes indicates a lesion primarily originating or externally affecting (e.g., transtentorial herniation) the brainstem.

Respiratory Patterns

In comparison to other brainstem signs, these are of less localizing value. See the table above for a summary of abnormal respiratory patterns. Aside from the abnormal respiratory patterns mentioned above, other cyclic breathing variations have been described but their importance is less significant.

Pupillary Signs

Pupil shape, size, symmetry and response to light provide valuable information about brainstem function. Pupillary reactions are examined with a bright, diffuse light (not an ophthalmoscope). Normal size, reactive and round pupils fundamentally exclude midbrain damage.

Table 4.11 summarizes the localization value of pupillary abnormalities in a comatose patient. As a general rule, the pupillary light reflex is resistant to metabolic disturbances. An exception to this rule is pharmacologic iridoplegia. Administration of 1% pilocarpine can be used to differentiate pharmacologic iridoplegia (failure to constrict) from anoxic pupillary dilatation (preserved response). The ciliospinal reflex, instead of pharmacological dilation, can be used as an alternative method to dilate the pupils. It is important to recognize the patient in a locked-in state due to a midbrain syndrome with abnormal pupillary abnormalities or due to profound peripheral neuropathy as occurs in a patient with severe Guillain-Barré syndrome.

Abnormal pupillary finding	Lesion localization
Reactive and bilaterally small (1-2.5 mm) but not pinpoint pupils	• Metabolic encephalopathies • Bilateral hemispheric lesions (e.g., hydrocephalus or thalamic hemorrhage)
Small and reactive	• Diencephalon (“diencephalic pupils”) • Sleep can also cause this finding • Metabolic coma
Oval and slightly eccentric pupil	• Transitional sign that accompanies early midbrain-third nerve compression

Midposition, unreactive and hippus (spontaneous oscillations in size). Pupils become larger with ciliospinal response	• Midbrain tectum (structural lesion of midbrain or oculomotor nerve)
	• Pharmacologic iridoplegia:
	  ▪ Atropine (e.g., during cardiopulmonary arrest)
	  ▪ Glutethimide
	  ▪ Barbiturates
	  ▪ Succinylcholine
	  ▪ Lidocaine
	  ▪ Phenothiazines
	  ▪ Methanol
	  ▪ Aminoglycosides

Midposition, irregular, unreactive and displacement of one pupil to one side (corectopia)	• Midbrain tegmentum
Unilateral or bilateral oval pupils. May be fixed to light	• Oculomotor or pupillomotor fibres
Large, unreactive and dilated (due to sparing of the sympathetic pathways) pupil ipsilateral to the side of the lesion (Hutchinson’s pupil)	• Fascicular or compressive peripheral cranial nerve III palsy
Pinpoint (<1 mm) and reactive	• Pons (due to sympathetic damage and parasympathetic irritation) • Narcotic or barbiturate overdose • NB: Response to naloxone and the presence of reflex eye movements distinguish these two entities
Ipsilateral Horner syndrome	• Hypothalamic damage • Lateral pontine • Lateral medullary • Ventrolateral cervical cord

Table 4.11. **Localization value of pupillary abnormalities in a comatose patient.**

Ocular Movements

Spontaneous Eye Movements

Elevate patient eyelids and note the resting position and spontaneous movements of the globes. Lid tone progressively decreases as coma deepens. Table 4.12 summarizes spontaneous eye movement abnormalities.

Brainstem reflex eye movements and the corneal reflexes

The physiological arch of the oculocephalic reflexes relays signals through the ocular motor nuclei and their midbrain, pons and medulla interconnections. During a normal response, the examiner observes evoked eye movements in the direction opposite to head movement (either vertical or horizontal head movement). These reflexes are normally inhibited or suppressed in the alert patient. Intact oculocephalic reflexes in a comatose patient indicate intact brainstem function and imply that the underling etiology of coma is cerebral bihemispheric dysfunction. The absence of these reflexes indicates brainstem damage in most cases. Overdoses of certain drugs can also result in absent oculocephalic reflexes. If the cause is due to a drug reaction, pupillary size and light reaction would be normal in most cases.

The vestibulo-ocular response (also called the oculovestibular response) tests the physiological integrity of similar brainstem tracts, but the initial stimulus is thermal and is therefore also referred to as “caloric” testing. Thermal stimulus is stronger than head movements. After documenting intact tympanic membranes, the auditory canal is instilled with 50 ml of cool water with the patient’s head angled 30 degrees to the horizontal plane. This stimulus induces convection currents in the labyrinths that travel through the vestibular nerve to the brainstem pathways that stimulate the brainstem oculomo-

Abnormal spontaneous eye movements	Lesion localization
Horizontal divergence of the eyes at rest	• Normal in drowsiness
Conjugate horizontal ocular deviation to one side	• Ipisilateral frontal lobe lesion • Contralateral pons lesion • Contralateral frontal lobe irritation (e.g., seizure activity) • Other: contralateral hemisphere lesion, paradoxical response ("wrong-way eyes")
Periodic alternating gaze (ping-pong pupil) or conjugate horizontal roving	• Bihemispheric damage • Posterior fossa (rare)
Repetitive divergence	• Metabolic encephalopathy
Nystagmoid movements of one eye	• Middle pons lesion • Lower pons lesion
Small amplitude vertical eye movements	• Diffuse encephalopathy
Ocular bobbing	• Pontine lesion • Posterior fossa • Diffuse encephalopathy

Inverse ocular bobbing ("ocular dipping")	• Diffuse encephalopathy:
	  ▪ Anoxic brain injury
	  ▪ Post status epilepticus

Reverse ocular bobbing	• Diffuse encephalopathy • Pontine lesion (rarely)
Converse ocular bobbing	• Diffuse encephalopathy • Pontine lesion (rarely)
Pretectal pseudobobbing (V-pattern)	• Pretectal lesion
Vertical ocular myoclonus	• Pontine lesion

Table 4.12. **Spontaneous eye movement abnormalities.**

tor nuclei. The normal response is a brief latency, followed by ipsilateral horizontal tonic eye deviation and contralateral horizontal nystagmus to the side of cool-water irrigation (sensory nerve stimulation), respectively. One mnemonic medical students use to remember the response of nystagmus to thermal stimulation is COWS (Cold Opposite, Warm Same). A common error when interpreting clinical findings is to "reverse the concept" of the normal direction of the tonic and nystagmus response to cold water. Loss of tonic conjugate eye deviation indicates brainstem damage. The absence of nystagmus in spite of tonic conjugate eye deviation indicates that the cerebral hemispheres are dysfunctional or metabolically inhibited.

The blink reflex is probably mediated by the superior colliculus. It is elicited by stimulating the eye with bright light. A tonically retracted eyelid suggests pontine damage (particularly infarction) as a result of failure to inhibit the levator palpebrae muscles. The normal response to stimulation of the cornea by gentle touch with a wisp of cotton is a brief bilateral lid closure. The corneal reflexes depend on the pathway integrity between the fifth (afferent) and both seventh (efferent) cranial nerves in the pons. In conjunction with reflex eye movements, the corneal reflex is useful in clinical tests to evaluate pontine function. CNS depressant drugs can diminish or eliminate the corneal responses quickly after reflex eye movements are affected but before the pupillary light reflex is dysfunctional.

Motor Activity of the Body and Limbs

The localizing value of clinical observation of limb movements, tone and reflexes is less clear than the other neurological examination findings mentioned above. Metabolic coma is the most common cause of bilateral decerebrate (extensor) and decorticate (flexor) posturing. Also, the value of other motor findings (e.g., hemiparesis due to hypoglycemia) can be misleading.

Motor response should be elicited by assessing first for spontaneous movements followed by the response to increasing degrees of stimulus (verbal, then non-painful sensory, then painful stimulus). The man-in-the-barrel syndrome (bilateral arm weakness with spared lower extremity strength) suggests an anoxic lesion affecting the watershed area of the anterior cerebral and middle cerebral artery. Decorticate rigidity (arm adduction, elbow flexion, pronation and flexion of the wrist, and hip and knee extension) suggest a contralateral diencephalic and cerebral hemispheric lesion. Decerebrate rigidity (elbow extension, wrist flexion and pronation, and extension of the hip, knee and feet plantar flexion) can be due to a severe metabolic disorder or a structural upper brainstem lesion (below red nucleus but with intact pontine reticular formation).

Opisthotonus (periodic hyperextension of the trunk and hyperpronation of the arms, usually in response to painful stimulus) suggests dysfunction of the corticoreticular fibers (between the upper and lower colliculus) and has been described in cases of traumatic brain injury and tetanus. In neonates, opisthotonus is most likely secondary to meningitis, kernicterus or tetanus. Lesions in the pontine tegmentum can cause abnormal extension of the arms usually associated with weak flexion of the lower extremities. A flaccid quadriplegia, particularly if associated with areflexia, can be due to poliomyelitis or poliomyelitis-like syndromes (e.g., West Nile virus [WNV]), critical illness neuropathy, critical illness myopathy, or due to an acute demyelinating or axonal neuropathy (e.g., Guillain-Barré syndrome).

4.5.2 Evaluating the Patient With Suspected Central Nervous System Infection

The approach to the patient with suspected CNS infection begins with an evaluation of the clinical features that provide critical information leading to etiologic diagnosis. Iden-

tifying infectious agents in CNS infection depends largely on cerebrospinal fluid (CSF) and blood culture analyses, but biopsy of brain, spinal cord, or meningeal tissue may occasionally be needed

Clinical Presentation

Table 4.13 summarizes the main CNS infectious syndromes that should be suspected in the critically ill neurological patient.

Clinical history	Physical exam	Risk factors	Comments
Acute septic meningitis			
Classic triad: fever, neck stiffness, altered mental status Triad has a low sensitivity for diagnosis; only 44% of cases have the full triad. 95% of episodes had at least two of the four symptoms of headache, fever, neck stiffness, and altered mental status. Seizures reported in 5-28% of cases	Potential lack of a febrile response in elderly patients, the immunocompromised or patients inadequately treated with antibiotics Cranial nerve palsies Signs of increased intracranial pressure (ICP)	Risk factors for unfavourable outcome: • advanced age • presence of osteitis or sinusitis • absence of rash • low admission GCS • tachycardia • positive blood cultures • elevated erythrocyte sedimentation rate • thrombocytopenia • low CSF white cell count	Mortality and morbidity rates of 25 and 60%, respectively The best parameter to differentiate viral from bacterial meningitis is **severity** (defined by one of four findings at admission: altered consciousness, seizures, focal neurologic findings, and shock) and CSF absolute neutrophil count >1000/mm^3 were predictive of bacterial meningitis
Encephalitis			
• Should be suspected in a febrile patient presenting with altered mental status or other signs of diffuse cerebral dysfunction • Headaches • Myalgia • History of mild respiratory infection • Seizures, both focal and generalized, are a common manifestation	• Fever • Decreased level of consciousness may be followed by focal neurological signs • Parotitis associated with mumps • Herpetic rash associated with HSE • Signs of increased ICP	• Mosquito vector (e.g., WNV) • HIV • Blood transfusions and donated organs	• Most commonly caused by viruses (HSV, VZV, CMV, and WNV among others) • Immune-mediated conditions such as ADEM, paraneoplastic or autoimmune limbic encephalitis also cause encephalitis. • HSE is the most important form of treatable encephalitis
Brain abscess			
• Commonly present with site-specific focal neurologic deficits, such as aphasia and weakness • Seizures in up to 40% of cases (59)	• Fever less common than in meningitis • Neck stiffness in 25% of cases (indicates associated meningitis) • Focal examination may be absent. • Signs of increased ICP		• Brain abscesses are focal, purulent infections of brain parenchyma

Cranial epidural abscess			
• Headache • Fever • Nausea	• Fever • Signs of increased ICP	• Trauma • Neurosurgery • Nearby infections, e.g., meningitis, sinusitis • Other extra-cranial sources	• Extra-axial infection in the virtual space between the dura mater and the skull • Usually occurs in the frontal region • The most common infectious pathogens include streptococci, staphylococci, and anaerobes; infections are often polymicrobial
Subdural empyema			
• Altered level of consciousness • Focal neurologic deficits • Seizures	• Fever • Signs of increased ICP	• Sources of infection include: ▪ Paranasal sinuses ▪ Hematogenous spread through emissary veins in the subdural space ▪ Postoperative setting	• An infection in the potential space between the dura mater and the arachnoid mater • Unlike the epidural space, the subdural space is less restrictive than the epidural space, resulting in a wider spread of empyema, which can cause inflammation of the brain parenchyma, septic thrombophlebitis, and venous infarction • High mortality rate (34%)
Ventriculitis			
• Headache • Fever • Nausea	• Fever • Signs of increased ICP	• Bacterial meningitis • CSF shunt • External ventricular drainage (EVD) • Other intracranial device	• Infection of the ventricular system of the brain • Complication of meningitis in 30% of adult cases • The most common pathogens involved in EVD and CSF shunt infections are gram-positive organisms such as *Staphylococcus epidermidis* and *S. aureus*

Table 4.13. **Main CNS infectious syndromes that should be suspected in the critically ill neurological patient.**

ADEM = acute disseminated encephalomyelitis
CMV = cytomegalovirus
HIV = human immunodeficiency virus
HSE = herpes simplex encephalitis
HSV = herpes simplex virus
ICP = increased intracranial pressure
VZV = varicella-zoster virus
WMV = West Nile virus

4.5.3 Intracranial Hypertension and Herniation Syndromes

Clinical signs and symptoms suggesting increased intracranial pressure include headache, nausea and vomiting, and bradycardia with or without increases in arterial blood pressure. Brain herniation corresponds to a shift of the normal brain through or across regions to another site due to mass effect. It is usually the result of focal structural pathology (e.g., tumour, trauma, infection, etc.), but it can also be due to a diffuse, more physiological process (e.g., encephalitis). Four major categories of herniation syndromes are distinguished: transtentorial, subfalcine, foramen magnum, and alar or sphenoid herniation.

Brain imaging serves as an extension to the clinical examination in the evaluation of these syndromes. Either CT or MRI of the brain can reveal signs of impending herniation before patients start demonstrating clinical signs. Although the use of "screening brain imaging" for possible or probable brain herniation in high-risk patients has not been validated, it is done frequently as a matter of routine. An example of this situation is ordering a "follow-up CT head" in a patient admitted with putaminal hemorrhage who is otherwise clinically doing well. Tables 4.14-4.16 summarize the clinical and imaging findings, as well as the potential complications of the mayor types of herniation syndromes.

Clinical findings	Imaging findings	Complications
• Ipsilateral dilated pupil • Contralateral hemiparesis • Ipsilateral hemiparesis if Kernohan's notch is present (false localizer)	• Ipsilateral ambient cistern widening • Ipsilateral prepontine cistern widening • Uncus extending into the suprasellar cistern • Contralateral temporal horn widening	• Occipital infarct due to posterior cerebral artery compression

Table 4.14. Transtentorial herniation (central or uncal).

Clinical findings	Imaging findings	Complications
• Nausea • Vomiting • Obtundation	• Spinning top appearance of midbrain • Narrowing of bilateral ambient cisterns • Filling of the quadrigeminal plate cistern	• Hydrocephalus • Rapid onset of obtundation and possibility of death

Table 4.15. Ascending cerebellar transtentorial herniation.

Clinical findings	Imaging findings	Complications
• Headache • Contralateral leg weakness	• Amputation of the ipsilateral aspect of the frontal horn • Asymmetric anterior falx • Obliteration of the ipsilateral atrium of the lateral ventricle • Septum pellucidum shift	• Ipsilateral anterior cerebral artery (ACA) infarction as ACA is entrapped under the falx • Other associated herniations

Table 4.16. Subfalcine herniation.

Clinical findings	Imaging findings	Complications
• Bilateral arm dysesthesia • Obtundation	• Cerebellar tonsils at the level of the dens on axial images • Cerebellar tonsils on sagittal images 5 mm below the foramen magnum in adults; 7 mm below in children	• Obtundation • Death

Table 4.17. Cerebellar tonsils herniation (foramen magnum herniation).

4.5.4 Acute Ischemic Stroke

History

This topic is covered in more detail in a separate chapter. The neurointensivist must always keep in mind the diagnosis of ischemic stroke when the initial presentation reveals an acute focal neurological deficit. The clinical approach to a patient with an acute focal neurological deficit should be systematic. The first step is localization of the lesion. This is of paramount importance, since obtaining the wrong imaging study could result in permanent but otherwise preventable neurological damage. There is a tendency for the general practitioner to assume that an acute focal neurological deficit means acute ischemic stroke. It is of utmost importance to always consider the possibility of a "stroke mimic." Table 4.18 lists common acute stroke mimics.

Table 4.19 lists the salient elements from history taking of a suspected stroke patient. Establishing the time of symptom onset is essential in order to decide patient eligibility for IV thrombolysis or endovascular therapy. Ideally, symptom onset is obtained directly from the patient. The use of cues (e.g., "before or after going to the bathroom?" or "before or after breakfast?") may be helpful for inferring an estimated time of onset from those circumstances in which the precise time of symptom onset is difficult to establish.

Obtaining history from eyewitnesses, preferably family members, is of utmost importance to corroborate the patient's report or to establish the time of symptom onset. Reaching a family member by telephone may be necessary if no one is immediately available. If a precise time of symptom onset is impossible to determine, history should focus on identifying when the patient was last seen neurologically normal. In patients awakening with symptoms, the time of onset becomes the time at which they were last seen normal (i.e., when they went to sleep). If the presentation is "waxing and waning symptoms" suggestive of transient ischemic attack/s; it is necessary to ensure complete resolution before the clock can be "reset."

A detailed description of the nature of symptom onset should be obtained. Abrupt onset suggests a vascular etiology, whereas "marching symptoms" (beginning in one region and gradually spreading to involve other areas) may support an alternate etiology (i.e., seizure or migraine). Inquiry should be made regarding risk factors for vascular disease, as well as any history of seizures, migraine, insulin use or drug abuse that may support an alternate cause for the patient's symptoms. Eligibility for thrombolysis must be ob-

- Seizures (postictal state)
- Hypoglycemia
- Metabolic encephalopathy
- Exacerbation of previous deficits
- Intracranial neoplasia
- Intracranial abscess
- Other intracranial mass lesion
- Hemiplegic migraine
- Subarachnoid hemorrhage
- Hypertensive encephalopathy
- Peripheral vestibulopathy
- Conversion reaction

Table 4.18. Common acute stroke mimics.

History of present illness	• Time of symptom onset • Evolution of symptoms • Convulsions or loss of consciousness at onset • Headaches • Chest pain
Past medical history	• Prior intracranial hemorrhage • Recent stroke • Recent head trauma • Recent myocardial infarction
Past surgical history	• Recent surgical puncture • Arterial puncture (non-compressible)
Medications	• Anticoagulant therapy
Review of systems	• Gastrointestinal or genitourinary bleeding

Table 4.19. Salient elements from history taking of a suspected stroke patient.

Left middle cerebral artery	• Right gaze and head preference • Aphasia • Right hemiparesis • Right hemisensory loss • Right homonymous hemianopsia
Right middle cerebral artery	• Left gaze and head preference • Left hemiparesis • Left hemisensory loss • Left spatial hemineglect • Anosognosia • Left homonymous hemianopsia
Left anterior cerebral artery	• Abulia • Incontinence (usually due to bilateral damage) • Right hemiparesis • Aphasia (transcortical motor or sensory) • Callosal apraxia
Right anterior cerebral artery	• Abulia • Incontinence (usually due to bilateral damage) • Left hemiparesis • Callosal apraxia
Left posterior cerebral artery	• Right homonymous hemianopsia • Pure alexia (alexia without agraphia)
Right posterior cerebral artery	• Left homonymous hemianopsia • Left visual neglect
Vertebrobasilar system	• Binocular blindness (e.g., due to the tip of basilar occlusion) • Diplopia • Dizziness/vertigo • Nausea • Dysarthria/dysphagia • Hemiparesis or quadriparesis • Hemisensory loss • Limb or truncal ataxia • Long tracts and cranial nerve findings (sensory or motor) • Decreased level of consciousness
Small vessel disease (lacunar stroke)	• Pure sensorimotor • Pure motor • Pure sensory • Ataxia-hemiparesis

Table 4.20. **Clinical signs and symptoms of the most common arterial ischemic stroke syndromes.**

tained in a structured fashion to minimize the possibility of overlooking critical information.

Some accompanying symptoms that suggest other diagnosis warrant further exploration. Thunderclap headache should alert the clinician to the possibility of subarachnoid hemorrhage. Small bleeds or sentinel leaks from unruptured intracranial aneurysms may not be evident on the CT scan. Additional evaluation with lumbar puncture to rule out the presence of subarachnoid hemorrhage may be warranted.

Focused Neurological Examination

The examination should focus on identifying signs of lateralized hemispheric or brainstem dysfunction consistent with focal cerebral ischemia. Phenomenological presenta-

tions of ischemic compromise in different anatomical regions of the cerebral and spinal circulation are extensive. Table 4.20 summarizes the clinical signs and symptoms of the most common arterial ischemic stroke syndromes.

The National Institute of Health (NIH) Stroke Scale (NIHSS) is a 15-item scale that assesses key components of the standard neurological examination and measures stroke severity. The scale should be performed rapidly and it serves to predict short-term and long-term neurologic outcomes. Table 4.21 illustrates the components of the NIHSS. Its drawbacks include a lack of detailed cranial nerve assessment, sensitivity for mild deficits (e.g., hand dexterity), underestimation of stroke severity in right hemispheric as well as posterior circulation ischemic strokes, and pertinent changes in serial neurological exams.

1a	Level of consciousness (LOC)	0=alert and responsive; 1=arousable to minor stimulation; 2=arousable only to painful stimulation; 3=reflex responses
1b	LOC questions: ask patient's age and month. Must be exact	0=both correct; 1=one correct; 2=neither correct
1c	Commands: open/close eyes, grip and release non-paretic hand	0=both correct; 1=one correct; 2=neither correct
2	Best gaze: horizontal extraocular movement by voluntary or doll's eye	0=normal; 1=partial gaze palsy; abnormal gaze in one or both eyes; 2=forced eye deviation or total paresis which cannot be overcome by doll's eye
3	Visual field: use visual field threat if necessary. If monocular, score field of good eye	0=no visual loss; 1=partial hemianopia, quadrantanopia, extinction; 2=complete hemianopia; 3=bilateral hemianopia or blindness
4	Facial palsy: if stuporous, check symmetry of grimace to pain. Paralysis (lower face)	0=normal; 1=minor paralysis (normal looking face, asymmetric smile); 2=partial; 3=complete paralysis (upper and lower face)
5	Motor arm: arms outstretched 90° (sitting) or 45° (supine) for 10 sec. Encourage best effort, note paretic side	0=no drift; 1=drift but does not hit bed; 2=some antigravity effort, but cannot sustain; 3=no antigravity effort, but even minimal movements count; 4=no movement at all; X=unable to assess due to amputation, fusion, etc.
6	Motor leg: raise leg to 30° supine for 5 sec	
7	Limb ataxia: check finger-nose- finger; heel-shin; score only if out of proportion with paresis	0=no ataxia (or aphasic, hemiplegic); 1=ataxia in upper or lower extremity; 2=ataxia in upper and lower extremity; X=unable to assess as above
8	Sensory: use safety pin. Check grimace or withdrawal if stuporous. Score only stroke related losses	0=normal; 1=mild to moderate unilateral loss but patient aware of touch (or aphasic, confused); 2=total loss, patient unaware of touch. Coma, bilateral loss
9	Best language: describe cookie jar picture, name objects, read sentences. May use repeating, writing, stereognosis	0= normal; 1=mild-mod aphasia (comprehensible); 2=severe aphasia (almost no information exchanged); 3=mute, global aphasia, coma
10	Dysarthria: read list of words	0=normal; 1=mild-mod slurred; 2=severe, unintelligible or mute; X=intubation or mechanical barrier
11	Extinction/neglect: simultaneously touch patient on both hands, show fingers in both visual fields, ask about deficit, left hand	0=normal, none detected (or visual loss alone; 1=neglects or extinguishes to double simultaneous stimulation in any modality; 2=profound neglect in more than one modality

Table 4.21. National Institute of Health Stroke Scale (NIHSS) [5].

The neurovascular examination can reveal clues of the underlying mechanism of ischemic stroke. The presence of a cervical bruit, cardiac murmur, or irregular heart rhythm suggests artery-to-artery thromboembolism or cardioembolism, respectively. Unequal extremity pulses suggest aortic dissection. Funduscopic examination may reveal signs of chronic hypertensive arterial disease or endocarditis. Signs of head or neck trauma suggest occult cervical spine injury.

Further Evaluation

Brain imaging is the only reliable means to differentiate between ischemic and hemorrhagic stroke and is therefore mandatory prior to thrombolytic therapy. Refer to the chapter on stroke for further discussion on neuroimaging of acute stroke. As previously mentioned, the main purpose of evaluating a patient with suspected acute ischemic stroke is to determine the eligibility for thrombolysis.

Table 4.22 lists the inclusion and exclusion criteria for the use of intravenous thrombolysis after thrombolysis within 3 hours of symptom onset. Intravenous recombinant tissue plasminogen activator (r-tPA; alteplase) is also recommended in selected patients with acute ischemic stroke within 3 to 4.5 hours of symptom onset.

After stabilizing and admitting the patient it is important to estimate disease severity and likelihood of recovery of the neurological deficit. Scales commonly use to evaluate prognosis in patients with stroke are available by accessing www.strokecenter.org.

Inclusion criteria	• Clinical diagnosis of ischemic stroke causing measurable neurologic deficit • Onset of symptoms <3 h before beginning treatment; if the exact time of stroke onset is not known, it is defined as the last time the patient was known to be normal.
Exclusion criteria	**Patient's history** • Stroke or head trauma in the previous 3 months • Any history of intracranial hemorrhage • Major surgery in the previous 14 days • Gastrointestinal or urinary tract bleeding in the previous 21 days • Myocardial infarction in the previous 3 months • Arterial puncture at a non-compressible site in the previous 7 days **Clinical** • Minor or rapidly improving neurologic deficits (controversial) • Seizure at the onset of stroke is an exclusion if the residual impairments are due to postictal phenomenon; seizure is not an exclusion if the clinician is convinced that residual impairments are due to stroke and not to postictal phenomenon • Symptoms suggestive of subarachnoid hemorrhage • Persistent elevated blood pressure (systolic ≥185 mmHg, diastolic ≥110 mmHg) • Active bleeding or acute trauma (fracture) on examination **Laboratory** • Platelets <100,000/mm^3 • Serum glucose <50 mg/dl (<2.8 mmol/l) • International normalized ratio (INR) >1.7 or prothombin time >15 seconds if on oral anticoagulant • Elevated partial thromboplastin time (aPTT) if on heparin **Head CT** • Evidence of hemorrhage • Evidence of major early infarct signs such as diffuse swelling of the affected hemisphere, parenchymal hypodensity and/or effacement of >33% of the middle cerebral artery territory

Table 4.22. **Inclusion and exclusion criteria for the use of intravenous thrombolysis.**

4.5.5 Intracranial Hemorrhage (Subarachnoid and Intraparenchymal Hemorrhage)

Intracranial hemorrhage can be the result of bleeding into different compartments, including the epidural space, the subdural space, the subarachnoid space, the intraparenchymal space and the intraventricular space. Detailed history about symptoms onset, medical risk factors, anticoagulation, drug abuse, and head trauma should be obtained. Overall, the most common cause of intracranial hemorrhage is trauma, but the cause varies depending on the specific location. Given the numerous possible locations and the variety of potential causes of intracranial hemorrhage, associated clinical presentations are diverse. Suspected diagnosis depends on the presence of appropriate signs and symptoms, pertinent patient history (hypertension, prior hemorrhage, drug use, anticoagulation, and trauma) and appropriate diagnostic imaging. Once intracranial hemorrhage is suspected, a head imaging study must be obtained immediately. In most cases, CT of the head is the initial imaging test of choice. Preliminary laboratory testing should include coagulation parameters (prothrombin time [PT], international normalized ratio [INR], and partial thomboplastin time [PTT]), complete blood cell count, electrolytes, liver function tests and drug screen.

The most common cause of subarachnoid hemorrhage (SAH) is head trauma. Worldwide, the incidence of nontraumatic SAH is approximately 6/100,000/year. It is more commonly seen in patients less than 60 years of age. The principal cause of spontaneous SAH is a ruptured aneurysm (85%). Several factors influence the incidence of developing SAH (e.g., gender, race, and family history of SAH). Women are at greater risk of developing SAH than men and blacks are at greater risk than whites.

First-degree relatives with a history of SAH is the most important nonmodifiable risk factor. Important modifiable risk factors are heavy alcohol consumption, hypertension, and smoking. Headache is the most common presenting complaint for SAH.

The classical presentation of nontraumatic SAH is an acute severe “thunderclap” headache that usually is described by patients as “the worst headache of my life.” Headache usually reaches maximum intensity over seconds to a few minutes. Conversely, only 1 in 10 patients presenting with thunderclap headache actually have SAH. In up to 33% of SAH cases, headache may be the sole presenting symptom. Signs and symptoms of meningeal irritation can also occur, including meningismus, photophobia, prominent neck or upper back pain, seizures, and obtundation. Serious consequences can occur as a result of failure to detect acute aneurysmal SAH, exposing the patient to

Grade	Neurological status
I	Asymptomatic or minimal headache and slight nucal rigidity
II	Moderate to severe headache; nuchal rigidity; no neurologic deficit except cranial nerve palsy
III	Drowsy; minimal neurologic deficit
IV	Stuporous; moderate to severe hemiparesis; possibly early decrebrate rigidity and vegetative disturbances
V	Deep coma; decrebrate rigidity; moribund appearance

Table 4.23. Hunt and Hess Classification Scale [6].

WFNS Grade	Glasgow Coma Scale Score	Major focal deficit
0	-	-
1	15	Absent
2	13-14	Absent
3	13-14	Present
4	7-12	Absent or present
5	3-6	Absent or present

Table 4.24. World Federation of Neurologic Surgeons (WFNS) Subarachnoid Hemorrhage Grade [7].

a risk of recurrent SAH of up to 50% in the first year. The patient's level of consciousness is a cardinal determinant of outcome after SAH and can affect treatment decisions as well as prognostication.

The Hunt and Hess grade (Table 4.23) and the World Federation of Neurological Surgeons scoring system (Table 4.24) are the most frequently used assessment scales [6,7]. Cases of cranial neuropathies may represent elevated intracranial pressure (abducens or oculomotor nerve palsy) or aneurysmal compression (oculomotor nerve compression due to a posterior communicating artery or superior cerebellar artery aneurysm). The amount of SAH is evaluated with the Fischer grading system, which has a prognostic value in predicting the risk of vasospasm and overall patient outcome (Table 4.25) [8].

Fisher Group	Blood on Computed Tomography
1	No subarachnoid blood detected
2	Diffuse or vertical layers ≤1 mm thick
3	Localized clot and/or vertical layer >1 mm
4	Intracerebral or intraventricular clot with diffuse or no SAH

Table 4.25. Fisher Grading Scale [8].

Hypertension is the most common cause underlying nontraumatic intracerebral hemorrhages (50-60%). Cerebral amyloid angiopathy (CAA) is the second most common cause of nontraumatic intraparenchymal hemorrhage. The incidence of both (hypertensive hemorrhage and CAA) increases with age. Other causes of parenchymal hemorrhage are venous thrombosis, underlying neoplasm (either primary or metastatic), vascular lesion (e.g., vascular malformations), and inflammatory lesions (e.g., herpes simplex infection, aspergilosis). Common presenting symptoms of intraparenchymal hemorrhage include nausea and vomiting, headache, seizure activity, altered cognition, with or without associated focal neurologic deficits. When the volume of the hemorrhage is large, clinical sequelae often reflect the local mass effect, any associated herniation (transfalcine, transtentorial, and tonsillar), hydrocephalus, diffuse intraventricular extension, and/or diffuse increased intracranial pressure.

The volume of intracerebral hemorrhage can be calculated in cubic centimetres using the following equation: Volume = (A X B C)/2, where A is the maximal diameter of hematoma in centimetres on its largest axial cut; B is its diameter in centimetres in the dimension perpendicular to A on the same axial cut; and C is the height of slices on which the hematoma is visible (excluding the first and last cuts just showing its extremes) by the slice thickness of the CT scans in centimetres. The estimated hematoma volume in cubic centimetres is an important prognostic indicator.

4.5.6 Overview Motor Examination in the Critically Ill Patient

Motor function examination in the NICU setting is a critical component of daily evaluation. Spontaneous and stimulus-induced movements of the face and extremities should be observed in detail. Motor deficits may affect a single limb (monoplegia), one hemibody (hemiplegia), bilateral lower limbs (paraplegia) or all four extremities (tetra or quadriplegia). The distribution, progression and onset of deficits are important to properly localize the possible pathology. The initial step in assessment is to determine if a central process or a peripheral neuromuscular problem is the cause of weakness. This may be difficult, as patient presentation may be complicated by encephalopathy, intubation or sedation in the ICU setting.

Clinical examination should concentrate on findings, such as muscle wasting or swelling, muscle tenderness, muscle tone, fasciculations, myokymia, percussion myotonia, tendon reflexes, and skin lesions. Important skin lesions include the heliotrope rash of dermatomyositis (DM), exanthematous rashes associated with viral infections, purpura or

petechiae, telangiectasias, digital ulcers or splinter hemorrhages, and Janeway's lesions or Osler's nodes in infective endocarditis.

The most common neurologic complications in the ICU are metabolic encephalopathy, seizures, hypoxic-ischemic encephalopathy, and stroke. Some can manifest with generalized weakness. Nonetheless, generalized weakness in is associated more commonly with neuromuscular or peripheral nerve injury. Careful clinical examination aids to localize limb weakness to spinal cord, roots, plexus or peripheral nerves.

Since the differential diagnosis of a patient presenting with acute flaccid paralysis in the NICU setting is quite large, clinical, epidemiologic, biochemical studies, neuroimaging, and electrophysiologic studies help to delineate the etiology (Table 4.26).

When assessing a patient with motor weakness, the patient's age may point towards inflammatory or demyelinating lesions, which are more common in the young as opposed to neoplastic and vascular etiologies in the elderly. The Guillain-Barrè syndrome (GBC) manifests with subacute onset of progressive weakness over days to weeks. Botulism mimics GBS but has additional features of ophthalmoplegia, with pupillary involvement and autonomic features such as dry mouth and paralytic ileus. Rapid nerve stimulation on electromyography/nerve conduction velocity (EMG/NCV) testing shows features of a presynaptic neuromuscular junction disorder. Botulinum toxin can be identified in stool, serum, or suspected food samples.

Marked asymmetry and acute rapid progression of symptoms should always alert the clinician to consider cerebrovascular disease in the differential diagnosis of a peripheral neuropathic process. Posterior circulation strokes (especially pontine infarctions) can result in a locked-in state, where patients are able to communicate only via eye blinks. Multiple strokes can be seen in patients who have underlying infective endocarditis or have undergone cardiac surgery. Asymmetric weakness is another feature which may help in the differential diagnosis, as poliomyelitis or polio-like virus infection (including West Nile virus) cause asymmetric paresis. West Nile Virus infection results in a meningoencephalitis and acute flaccid asymmetric paralysis, accompanied by fever, encephalopathy and predominantly proximal, asymmetric weakness. Electrophysiologic studies show evidence of axonopathy, and CSF analysis shows lymphocytic pleocytosis with elevated proteins.

The distribution of weakness may point toward a specific diagnosis, such as acute intermittent porphyria, in which patients present with painful, often asymmetric weakness frequently beginning in the upper extremities. Patients usually experience severe colicky abdominal pain accompanied by psychiatric disturbances prior to the development of neuropathy. The combination of abdominal pain and neuropathy makes this clinical presentation similar to heavy metal intoxication.

Magnesium is a competitive blocker of calcium at the presynaptic junction, preventing calcium entry into the presynaptic neurons. Hypermagnesemia should be suspected in patients with renal failure and taking receive magnesium-containing laxatives or antacids or patients with eclampsia who receive magnesium sulphate for seizure control.

Peripheral neuropathy is a well-recognized consequence of systemic vasculitis due to peripheral nerve infarction with Wallerian degeneration. Rarely, neuropathy is the sole manifestation of vasculitis, referred to as nonsystemic vasculitic neuropathy. Patients present with painful, stepwise progressive, distal-predominant, asymmetric or multifocal neuropathy, with sensorimotor deficits evolving over months to years. Laboratory tests often indicate features of systemic inflammation, such as an elevated sedimentation rate or positive anti-neutrophil cytoplasmic antibodies. Peripheral neuropathies associated with HIV infection can be divided into three major groups: distal, symmetric peripheral neuropathy; chronic, relapsing polyradiculoneuropathy; and more rarely as mononeuritis multiplex.

Diagnosis	Clues in diagnosis	Treatment
Guillain-Barré Syndrome	Antecedent "flu-like" illness, vaccination	IVIG or plasma exchange
Spinal cord compression	History of trauma or cancer	Corticosteroids and surgical decompression
Basilar artery occlusion	Cardiovascular risk factors, prior history of stroke	Thrombolytic or thrombus removal treatment if appropriate, antiplatelets
Vasculitic neuropathy	History of systemic vasculitis or rheumatologic disorder	Immunosuppressant drugs
Myasthenia gravis	Muscle fatigability, ocular and bulbar involvement	Anticholinesterase drugs, plasma exchange or IVIG
Hypophosphatemia	Chronic alcoholism, intravenous hyperalimentation without phosphate, and chronic ingestion of antacids	Phosphate supplementation
Hypermagnesemia	Renal failure, eclampsia	Cessation of magnesium therapy, hemodialysis or IV calcium
Polio-like viral infections including West Nile virus	Summer months; asymmetric weakness and rapid progression of symptoms	Supportive treatment
Critical illness neuromyopathy and/or myopathy	NICU admission, sepsis, multiorgan dysfunction syndrome, status asthmaticus, NMB agents	Supportive treatment
Botulism	Contaminated food exposure, honey	Antitoxin administration and supportive care
Lyme disease	Recent travel to endemic areas, tick bites	Antibiotics
HIV infection	Risk factor, prior history of drug abuse or blood transfusion	HAART
CMV infection in the immunocompromised	Solid organ transplant, HIV infection	Ganciclovir or foscarnet
Inflammatory myopathies	Rash, proximal weakness, high CPK	Corticosteroids, immunosuppressant drugs
Heavy metal intoxications (arsenic, gold, thallium)	Occupational exposure	Elimination of continued exposure, dimercaptosuccinic acid or penicillamine
Paraneoplastic disorders	Known history of cancer	Treatment of primary malignancy

Table 4.26. **Common causes of acute flaccid paralysis in the ICU.**

HAART = highly active antiretroviral therapy
IVIG = intravenous immunoglobulin
NMB = denotes neuromuscular blockage

Inflammatory myopathies may manifest as preferential and prominent proximal muscle weakness and rash without involvement of the face or ocular muscles. The rash is erythematous, periorbital, and purplish and can be accompanied by rashes over the knuckles (Gottron's sign) or subcutaneous calcification. CK levels often are significantly elevated. Rhabdomyolysis often presents with focal rather than generalized weakness. This entity should be considered in the presence of arterial occlusion, compartment syndromes or trauma. It often manifests with swollen, tender muscles, focal weakness, and elevated CK levels (>10,000 IU).

The lack of sensory complaints and abnormalities during sensory examination provide powerful localizing information. Spinal cord lesions, regardless of the cause, usually re-

sult in sensory as well as motor dysfunction. History of known malignancy and associated lower back pain at the time of presentation may suggest metastatic epidural spinal cord compression.

Progressive polyradiculomyelopathy due to infection with cytomegalovirus (CMV) presents with rapid onset lower extremity and sacral paresthesias. Progressive paraparesis ensues rapidly, with concomitant areflexia, ascending sensory loss, and sphincter dysfunction. It generally occurs with advanced immunodeficiency. An important clue to the presence of this potentially treatable illness is a polymorphonuclear pleocytosis in the CSF.

Electromyography (EMG) and nerve conduction studies (NCS) serve as an extension of the physical examination and often allow refinement of the diagnosis. It needs to be emphasized, however, that electrodiagnostic testing may be insensitive in the acute period but after 4-5 days. EMG/NCS testing provides accurate localization of the motor unit lesion, establishes the presence or absence of demyelination or conduction block, and helps establish a prognosis. Electrodiagnostic testing may confirm the lack of sensory involvement and asymmetry.

Magnetic resonance imaging (MRI) of the brain or spinal cord should help to determine whether the process is central in origin. CSF analysis is usually indicated in suspected acute idiopathic neuropathies or myopathies. CSF protein in the Guillain-Barré syndrome is elevated without pleocytosis, but this is a non-specific finding. If CSF pleocytosis is present, HIV infection, Lyme disease, cytomegalovirus (CMV), West Nile virus (WNV) or leptomeningeal carcinomatosis should be considered in the differential diagnosis. Serologic testing should be guided by the presumptive diagnosis, as many metabolic abnormalities leading to weakness can be excluded with initial chemistries. The combination of elevated liver enzymes and pancytopoenia should trigger an investigation of arsenic intoxication.

4.5.7 Acute Spinal Cord Injury

The most common cause of acute spinal cord injury is trauma secondary to motor vehicle accidents, falls, recreational injuries or acts of violence. The appropriate localization of the spinal cord lesion requires understanding spinal cord and vertebral anatomy, organization and blood supply. Since spinal cord injuries are common in patients with polytrauma, MRI should be considered in these patients. Non-traumatic cord compression encompasses a variety of etiologies and clinical presentations and includes compressive, malignant, infectious, vascular and inflammatory causes.

Careful examination for overlying vertebral spine tenderness may suggest an underlying destructive process such as a neoplasm or infection as the etiology, and pain that lessens with sitting or standing is suggestive of a malignancy. Acute intervention for spinal disk disease is rare with only 0.25-1.0% of patients presenting with rapidly deteriorating neurological symptoms.

Spinal-cord compression due to malignant disease accounts for approximately 20,000 cases annually in the United States. It is a relatively common complication of cancer and may be the presenting sign in up to 30% of patients. The most common level of metastatic epidural spinal cord compression (MESCC) involvement is the thoracic spine (59-78%), followed by the lumbar (16-33%) and the cervical spine (4-15%), while multiple levels are involved in up to half of patients. Most patients present with back pain, which worsen after a period of lying down because of distension of the epidural venous plexus. MESCC at or above the conus medullaris leads to weakness of the upper motor neuron and is usually symmetric. Usually, the iliopsoas muscles are preferentially affected, and

weakness is most severe with thoracic MESCC. Treatment consists of rapid initiation of corticosteroid therapy, followed by direct decompressive and maximal-debulking surgery with intra-operative stabilization of the spine (in appropriate cases) and postoperative radiation therapy. The use of high-dose steroids based on the Bracken protocol (30 mg/kg methylprednisolone in the first hour, followed by 5.4 mg/kg methylprednisolone in the next 23 h in patients presenting within 8 h of spinal cord injury) has been much debated.

Despite flaws in the initial studies and subsequent criticism, such treatment is still common practice in the US. Nevertheless, it is appropriate to give at least high doses of dexamethasone in patients with suspected traumatic or nontraumatic (especially related to tumour) cord compression pending a definitive diagnosis. Steroid administration need not be deferred till after imaging, but it should be given empirically. All patients with suspected spinal cord injuries should also be assessed for urinary and rectal tone. Urinary function can be assessed by measuring the residual amount of urine after voluntary voiding. A volume >100 ml of urine found by straight catheterization is considered an abnormal post-void residual.

4.5.8 Spinal Cord Syndromes

Complete Cord Transection

The finding of a sensory level with pinprick loss is the most valuable finding to identify the spinal cord as the lesion site in a patient with weakness. Weakness, either paraplegia or tetraplegia, occurs below the level of the lesion due to interruption of the descending corticospinal tracts. Sensory loss involving all modalities below the level of the lesion is noticed. Initially, the paralysis may be flaccid and areflexive because of spinal shock, but hypertonic, hyperreflexive paraplegia or tetraplegia eventually occurs, with bilateral extensor toe signs, loss of superficial abdominal and cremasteric reflexes, and extensor and flexor spasms. Urinary and rectal sphincter dysfunction with incontinence, sexual dysfunction, and signs of autonomic dysfunction can also be demonstrated below the level of the lesion.

Brown-Sequard Syndrome

A hemisection of the spinal cord results in the Brown-Sequard syndrome (BSS), with loss of pain and temperature sensation contralateral to the side of injury due to interruption of the crossed spinothalamic tract. Usually, a clinical sensory level is one or two segments below the level of the lesion, reflecting the ascending nature of this crossing tract.

Below the lesion site there is ipsilateral loss of proprioceptive function due to interruption of the ascending fibres of the posterior columns. Ipsilateral weakness below the lesion reflects the interruption of the descending corticospinal tract. Only a limited number of patients in the NICU setting have the pure form of BSS. Far more often the Brown-Sequard plus syndrome is seen, with a relative ipsilateral hemiplegia and a relative contralateral hemi-analgesia.

Anterior Spinal Artery Syndrome

The vascular nature of this syndrome is reflected in its abrupt onset occurring within minutes or hours from its initiation. Clinically, the syndrome presents with back or neck pain and at times in a radicular pattern, usually followed by a flaccid paraplegia and less commonly tetraplegia. Urinary and bowel incontinence are usually present. A sensory

level to temperature and pinprick reflects involvement of the spinothalamic tracts bilaterally, but posterior column modalities of sensation remain relatively intact. The initial motor presentation progresses from a flaccid paraplegia to one of spasticity with hyperreflexia and Babinski signs.

Central Cord Syndrome

The central cord syndrome is characterized by disproportionately more motor impairment of the upper than in the lower extremities, bladder dysfunction, usually urinary retention, and varying degrees of sensory loss below the level of the lesion. The syndrome is classically known to affect older persons with cervical spondylosis and a hyperextension injury, wherein the cord is compressed between the bony spurs anteriorly and the infolded ligament flavus posteriorly.

Posterior Column Syndrome

This process involving the posterior columns is characterized by loss of position sense, vibration sense, and two-point discrimination. The lack of proprioceptive information and feedback to the motor system affects the muscle groups required for discriminative movements, resulting in a sensory ataxia. Gait is described as ataxic (or stomping), and the deficit can be more prominent in darkness or with eyes closed, as visual cues can no longer assist in maintaining body balance. The affected limbs may become hypotonic but are usually not weak. At times, other spinal cord lesions can produce a truncal ataxia but without the associated proprioceptive difficulties. In such cases, spinocerebellar tract dysfunction, as a manifestation of spinal cord compression, appears to be responsible for this clinical syndrome.
With dysfunction of the posterior columns in the cervical region, neck flexion may elicit an electric-like sensation that radiates down the back or into the arms (Lhermitte's sign). It is thought to represent increased mechanosensitivity of the dorsal columns, with neck flexion further activating those sensory pathways.

4.5.9 Guillain-Barré Syndrome

Once used interchangeably with the term "acute inflammatory demyelinating polyneuropathy (AIDP)", the Guillain-Barré syndrome (GBS) now encompasses any acute, idiopathic inflammatory polyneuropathy that produces progressive muscle weakness and areflexia, regardless of whether the underlying neuropathy is demyelinating or axonal. The annual incidence of GBS is reported to be 1.2-2.3 per 100,000 in different parts of the world and accounts for one of the most common causes of paralysis among NICU patients. The constellation of rapidly progressive symmetrical weakness in the arms and legs, with or without sensory disturbances, with or without involvement of respiratory or cranial nerve muscles, hyporeflexia or areflexia, in the absence of a CSF cellular reaction, remains the hallmark for the clinical diagnosis of GBS. The most frequently identified cause of infection is *Campylobacter jejuni*. Other well-defined infections related to GBS are cytomegalovirus, Epstein-Barr virus, *Mycoplasma pneumoniae*, and *Hemophilus influenzae*. GBS represents a true case of molecular mimicry and antibody cross-reactivity. The diagnosis is usually made on clinical grounds, with CSF typically showing normal pressure, few (<10 mm^3) or no pleocytosis with elevated protein concentration. EMG/NCV shows nerve conduction abnormalities with conduction block, prolonged F waves, absent H waves or evidence of proximal demyelination at the root level and somewhat typical sural sparing.

There are a number of other GBS variant patterns. The Miller-Fischer variant accounts for approximately 5% of all cases of GBS. Patients develop the triad of ophthalmoplegia, ataxia, and areflexia, with varying degrees of limb weakness associated with IgG antibodies to GQ1b. Although there is usually bilateral involvement of the oculomotor, trochlear, and abducens nerves, partial and asymmetric syndromes also exist. Facial and bulbar weakness is also common. Other variants are acute motor axonal neuropathy (AMAN), acute sensory neuropathy (ASAN), acute sensorimotor axonal neuropathies (AMSAN), and pharyngeal-cervical-brachial neuropathy. Generally, the non-demyelinating (axonal) variants are associated with a worse prognosis for recovery.
Rapidly progressive weakness is the core clinical feature of GBS. Typically, weakness peaks within 4 weeks, but neurological deficits often worsen within 2 weeks, followed by a plateau phase of varying duration from days to several weeks. In 10% of cases the plateau phase may persist for months. This phase is followed by a usually much slower recovery phase of varying duration, usually within 6 months. About 65% of patients have persistent minor problems, such as weakness, fatigue or distal numbness. Permanent disabling weakness or severe neurological deficits occur in about 5-10 % of patients.

4.5.10 Myasthenia Gravis

Myasthenia gravis (MG) is an autoimmune disorder of neuromuscular transmission involving the production of autoantibodies directed against the nicotinic acetylcholine receptor. The hallmark of the disease is fluctuating or fatigable muscle weakness. Acetylcholine receptors antibodies are detectable in the serum of 80-90 % of persons affected with the disorder. The most common symptoms of focal muscle dysfunction, in order of decreasing frequency, involve the ocular, bulbar, neck, limb, girdle distal limb and trunk muscles. Patients present with ptosis, diplopia, dysarthria, dysphagia or dyspnoea. The symptoms tend to progress later in the day and improve with rest. Iatrogenic MG has been associated with the use of D-penicillamine, alpha-interferon therapy, and chronic graft versus host disease (GVHD) in bone marrow transplantation patients. Respiratory failure is the presenting symptom in 1% of cases.
The diagnosis is based on a history of fluctuating weakness with corroborating findings on examination. The most commonly used confirmatory study is the Edrophonium (Tensilon) test. The use of this rapidly acting anticholinesterase drug (5-10 mg IV over 1 min) should improve muscle power within minutes.
Electrophysiological testing is widely available and provides further confirmatory evidence. Slow repetitive motor nerve stimulation will demonstrate a decline in muscle action potentials. Single-fibre EMG has a sensitivity of about 90%. Acetylcholine receptor (AchR) antibodies are highly specific for MG and are detected in about 80% of patients. About 15% of MG patients do not harbour these antibodies. The anti-muscle specific tyrosine kinase (MuSK) antibody needs to be considered in patients presenting with AchR-seronegative clinical syndromes. Patients with MuSK-MG have marked weakness and atrophy, especially of the facial or oropharyngeal muscles. They tend to present with respiratory symptoms or neck extension weakness. They may respond poorly to acetylcholinesterase inhibitor therapy and develop profuse fasciculations with acetylcholinesterase inhibitors.
The long-term natural course of MG is not clearly established other than being highly variable. Symptoms may remain confined to ocular muscles in 15-20% of cases (ocular myasthenia), but most patients with initial ocular involvement develop generalized

forms of the disease within 1 year. Maximal weakness occurs within 2-3 years into the disease, but spontaneous remission has been observed. Table 4.27 lists the drugs to avoid in patients with MG.

Critical Illness Polyneuropathy/Myopathy

Critical illness polyneuropathy (CIP) and its muscle counterpart, critical illness myopathy (CIM) are among the most common disorders resulting in weakness in ICU patients. CIP is a predominantly motor, axonal polyneuropathy occurring in 30-60% of patients who are critically ill with sepsis, multiorgan dysfunction syndrome, status asthmaticus and receiving medications, such as NMB agents, corticosteroids, and cytotoxic drugs. In severe CIP, patients have flaccid areflexic quadriparesis with weak or absent limb movements, even when the limbs are stimulated distally by pressure over the nail beds. Patients with CIM/ CIP typically have sparing of the cranial nerves and a variable sensory examination. Often, the only clinical sign of CIP is respiratory muscle weakness which manifests as difficulty in weaning from the mechanical ventilator after pulmonary or cardiac causes are excluded. The polyneuropathy tends to be more severe the longer the stay in the ICU.

Nerve conduction studies show low compound muscle action potential (CMAP) amplitudes, with preservation of sensory nerve action potential (SNAP) amplitudes in CIM and absent SNAPs in CIP. The duration of the compound muscle action potential (CMAP) may be prolonged, suggesting primary dysfunction of the muscle fibre membrane in addition to denervation. Even in the more advanced stages of CIP, conduction velocity and distal latencies remain relatively normal, emphasizing the purely axonal, degenerative nature of the neuropathy.

Unlike patients with CIP or CIM, those with GBS have weakness prior to ICU admission, conspicuous cranial nerve involvement, and evidence of demyelination on nerve conduction studies. The pathogenic mechanism underlying CIP is unknown. Primary axonal damage may be due to involvement of axonal transport systems, which are known to be energy-dependent; this fact may explain why distal nerve segments are predominantly involved.

- Propanolol
- Quinidine
- Quinidine, quinine
- Quinine
- Quinolones
- Telithromycin

Table 4.27. Drugs to avoid in patients with MG.

Critical illness myopathy may occur independently of, or in association with, CIP. The major feature is diffuse flaccid weakness involving all limb muscles and the neck flexors, as well as the facial muscles and diaphragm, which often makes weaning patients off the mechanical ventilator difficult. Ophthalmoplegia may also be present. Nerve conduction studies reveal low-amplitude CMAPs, some of which may be of long duration. Fibrillation potentials and positive sharp waves will be present in both CIM and CIP. In CIM, motor unit potentials are of low amplitude and short duration, with high-frequency components. Markedly elevated CK levels suggest a necrotizing myopathy. Muscle biopsy is helpful in subtyping CIM. Neither the nerve nor the muscle shows any evi-

Frequency	Main clinical features	EMG features	Muscle enzymes	Muscle biopsy	Outcome
Thick-filament myosin loss					
Common with steroids, neuromuscular blocking agents, and sepsis	Flaccid limbs and respiratory weakness	Abnormal spontaneous activity	Mildly elevated	Loss of thick (myosin) filaments	Good
Rhabdomyolysis					
Rare	Flaccid limbs	Near normal	Markedly elevated (myoglobinuria)	Normal or mild necrosis	Good
Necrotizing myopathy of intensive care					
Rare	Flaccid weakness and myoglobinuria	Severe myopathy	Markedly elevated, myoglobinuria	Marked necrosis	Poor
Disuse (cachectic) myopathy					
Common?	Muscle wasting	Normal	Normal	Normal or type II fibre atrophy	Good
Combined polyneuropathy and myopathy					
Common	Flaccid limbs and respiratory weakness	Indicate combined polyneuropathy and myopathy	Variable	Denervation atrophy and myopathy	Variable

Table 4.28. Critical illness myopathy.

dence of inflammatory changes. Four main subtypes of crtitical illness have been identified on muscle biopsy: necrotizing, cachectic, acute rhabdomyolysis, and thick filament (myosin) loss type (Table 4.28).

The use of IV corticosteroids or neuromuscular-blocking agents has been associated with the development of CIM as compared to the use of these agents in patients with CIP. Treatment of these syndromes mainly is supportive and rests on aggressive management of the underlying sepsis or the systemic inflammatory response syndrome (SIRS). Intravenous immunoglobulin (IVIg) is not useful in patients with CIP or CIM. The long-term outcome after CIP is better than that after CIM.

5 Evaluation Scales in Neurocritically Ill Patients

Jose M Dominguez-Roldan [1], Walter Videtta [2], Claudio Garcia Alfaro [1], Juana Maria Barrera Chacon [1], Modesto Romero Lopez [2]

5.1 Objectives

Accurate assessment of the clinical condition of critically ill neurological patients is an essential part of intensive care. The application of clinical rating scales and the evaluation of their results have become common practice for health professionals caring for severely ill neurological patients. Evaluation scales serve different purposes. Understanding their implications is essential for communication between professionals from different areas and institutions. This chapter describes and discusses the most frequently used scales in assessing acute and subacute critical neurological patients.

5.2 Introduction

The usefulness of clinical rating scales and outcome is manifold. Comparison between different series of patients is possible. Some scales are clinical, others are based on images, and others still use a combination of different variables. Scales may be useful for classifying patients, establishing prognosis, helping in decision making. For example, the Fisher scale is used specifically to assess the risk of vasospasm in patients with spontaneous subarachnoid hemorrhage (SAH). In patients with traumatic brain injury (TBI), a score on the Glasgow Coma Scale (GCS) <9, GCS=9-12, GCS=14-15 will reflect severe, moderate, or mild illness, respectively. This has implications for decision making: patients with severe TBI and a GCS ≤8 must be intubated and mechanical ventilation initiated. Some of the scales are specific to certain diseases and seek to assess their clinical aspects. In contrast, other scales are more generic and are applicable not only for evaluating different diseases but also different stages of neurological processes. For example the GCS, which was initially devised for assessing patients with TBI, has been extended to include other pathologies such as neurological damage of vascular origin.

5.3 Evaluation in the Acute Phase

5.3.1 Clinical Scales for the Evaluation of Altered Consciousness

Assessment schemes for the evaluation of consciousness disorders provide quantitative measures of the severity of coma in the acute phase and have proved useful in studies predicting functional sequelae after hospital discharge. The development of coma scales continued in response to the need for reliable, standardized data that could in-

form safe therapeutic measures and facilitate the design of protocols for clinical performance. Point scales serve to: 1) standardize levels of awareness in clinical research, thus allowing their comparison and replication across studies; 2) monitor the clinical course of the disease; 3) facilitate performance and decision making; and 4) predict outcome.
One advantage of coma scales is that they allow statistical analysis of the data for testing their reliability, validity and clinical significance. One drawback of point scales is that each measure is based on the clinician's experience, knowledge and observation. The ideal coma scale should meet the requirements of: 1) high validity; 2) classification of severity; 3) reliability; 4) linearity (additivity and homogeneity); 5) association with disease outcome; 6) ease of application; 7) simplicity; 8) yield; and 9) minimum redundancy.
Even with the use of these scales, however, the assessment of coma is not without controversy. Different scales have been designed to improve the GCS. For example, the Glasgow-Liège Scale evaluates indicators of brainstem function.
Other requirements of any assessment tool are that the scale items are representative of each construct, are clearly observable, and have a clear clinical interpretation. From the assumption that normal consciousness and coma constitute two ends on a continuum of human brain functional states and that consciousness involves two distinct but related attributes (alertness and content), some degree of caution is necessary when evaluating responsiveness since any response will need to be set somewhere along this continuum. From this, we can infer that, depending on the alterations in central nervous system (CNS) function, a scale will have different answers that may correspond to some alteration of consciousness. Since alertness and monitoring overlap, identifying specific indicators for exclusive categories in scale design is difficult. The result is the conceptualization of alertness and vigilance variables as one entity. In addition to indicators of neurological functions, other variables in medical and neurological examination seek to capture aspects of the etiology and diagnosis of coma motor responses, such as pupillary size and reactivity and ocular motility.
In reality what we actually see, however, are the pathophysiological and neuroanatomical correlates that provide a reliable localization and characterization of the illness. The responses to each item are organized hierarchically on a continuum from normal responses to a progressive impairment of brain function that ends in brain stem reflex movements or even their absence.
The higher functions (contents of consciousness) refer to a wide range of human behavioural characteristics such as cognitive, emotional, and sensory perception, motor functions, etc.).

Glasgow Coma Scale

The Glasgow Coma Scale (GCS) is widely used for assessing the level of consciousness in patients with neurological disorders of diverse etiology. Originally developed by Jennett and Tesdale and published in 1974, it measures the level of consciousness in TBI patients. Although the original scale had a maximum score of 14 points, with subsequent refinements the authors expanded the section on the assessment of motor response to 6 points (initially consisting of a maximum of 5 points). The descriptors currently included in the GCS evaluate: 1) motor activity; 2) verbal response; and 3) eye opening (Table 5.1). The total score is the sum of the points assigned for each activity examined (range, 3-15). The severity of head injury can be established by scoring sections. There is also consensus that a patient with a GCS score <9 will have a level of consciousness that can be considered as "coma". A description of the scale scoring system is given below.
Eye opening: 4 points are assigned for spontaneous eye opening; these patients still have eye fixation and eye tracking, although it is not necessary to consider the existence of eye opening. The presence of eye opening and staring suggests an intact optic path-

Score	1	2	3	4	5	6
Eyes	Does not open eyes	Opens eyes in response to painful stimuli	Opens eyes in response to voice	Opens eyes spontaneously		
Verbal	Makes no sounds	Incomprehensible sounds	Utters inappropriate words	Confused, disoriented	Oriented, converses normally	
Motor	Makes no movements	Extension to painful stimuli	Abnormal flexion to painful stimuli	Flexion Withdrawal to painful stimuli	Localizes painful stimuli	Obeys commands

Table 5.1. **Glasgow Coma Scale (GCS).**

way and visual cortex; 3 points are recorded if the patient opens his eyes in response to a verbal command. This usually occurs in patients with drowsiness who respond to an auditory stimulus to open their eyes. A score of 2 points is recorded when the patient opens his/her eyes only in response to painful stimuli. These states are compatible with more severe brain dysfunction. A score of 1 is recorded when there is no eye opening in response to various intense stimuli.

Motor response: this is the most important section of the GCS from which the level of stimulus processing at the neuraxis can be inferred more accurately. Clinical examination of motor response in certain patients can be likened to an examination by somaesthetic evoked potentials. The integrated motor responses within the GCS (GCSm) may suggest the highest level of neural signal processing in patients with acquired acute brain damage.

On stimulation, the limb should be brought to cross the midline. Alternatively, if the upper limb has been placed on the root of the lower limb and the stimulus is applied to the upper chest, the hand will be elevated above the umbilical line. The score reflects an intact cortex and cortical pathways but is associated with brain dysfunction within a hemisphere. When there is a simple withdrawal response to pain or a stereotyped or classifiable response, 4 points are assigned, which should suggest cortico-subcortical location as the highest level of neurological processing. It should be remembered that to establish that the patient actually performs a "withdrawal response" the browser should monitor the elbow movement. Accordingly, a response is considered as "withdrawn" if the elbow is away from the axis of the body, regardless of whether that movement is associated with a forearm flexion. The typical response in flexion (bending or decortication) (rated with 3 points) is a motor response to noxious stimuli. It should be noted that decorticate flexion of the elbow involves the approach toward the major axis of the body associated with a forearm and often bending flexion of the wrist. This type of response is often observed in subacute neurological processes of vascular origin not common in traumatic events. A motor response is assigned 2 points if, after nociceptive stimulation, the patient performs a pronoextension extensor response of the upper limb, from which it can be inferred that the highest level of processing does not exceed the mesencephalic level. A score of 1 is recorded for the absence of motor response to painful stimuli; this indicates very severe bilateral hemispheric involvement or brainstem damage. Elicitation of the verbal response in intubated patients should not be limited to a repertoire of three questions that explore temporo-spatial orientation: "What is your name?", "Where are you?" and "What year is it?". If the patient speaks in an oriented and conversant manner, the maximum score of 5 is recorded, 4 points will be given when the patient is disoriented and conversant, 3 points when words are inappropriate (intelligible but inappropriate to the situation); 2 points for unintelligible sounds, and 1 point for no verbal response.

The GCS measures the degree of neurological dysfunction as a global function of "consciousness" at the time of examination. However, its prognostic value in TBI and other acute neurological processes mainly relates to the score after all extracranial factors that can influence the level of consciousness have been controlled. The effect that certain factors may have on the level of consciousness is well known. Hypotension, hypoxia, sedative drugs, toxic or postcritical state can all influence the GCS score. The GCS, which may be called "Score Collection Glasgow", or first aid, has the same prognostic ability as the Glasgow score obtained once these factors have been controlled.

Notes for Using the Glasgow Coma Scale

As initially described, the GCS was, and retains its main indication in the evaluation of decreased level of consciousness in patients in the acute phase of TBI. The ubiquity of the scale has facilitated its spread to other groups of severe neurological processes of diverse etiology such as ischemic or hemorrhagic cerebrovascular accidents, CNS infections, or acute complications of intracranial neoplasms. It is also often applied in other circumstances for evaluating only functional alterations of cerebral metabolism or causes of a systemic nature, coma, renal failure, hepatic, pulmonary, metabolic diseases, in the context of septic shock. It is also useful in cases of alcohol intoxication or drug abuse.

The GCS has also been combined with other scales to assess acute and severe neurological conditions. Thus, in evaluating patients with spontaneous SAH, the GCS has been included in one of the major scales assessing its severity, the scale of the World Federation of Neurosurgeons.

Limitations of the Glasgow Coma Scale

There are some limitations to the implementation of the GCS. For example, neurological disorders not directly altering the level of consciousness may interfere with the examination: for instance, aphasia, sensory deficits such as deafness or blindness, psychiatric disorders, and mental deficit can all add to the difficulty of the clinical examination. The verbal component of the GCS may be precluded in intubated patients. In such cases, the verbal component can be removed from the scale, and an "I" (intubated) noted on the evaluation form, without assessing this parameter, or otherwise make inferences from other responses. Hence, eye opening in response to verbal commands and pain is assigned an overall score of 12 points, while the total GCS score is 7 points for eye opening in response to pain and stereotyped flexing of the extremities.

Another possible limitation to the GCS is the fact that the motor component may also present difficulties in evaluation due to the presence of immobilizing splints or traction for the treatment of orthopedic injuries. Other difficulties in motor evaluation include motor deficits, such as pyramidal tract lesions or intracerebral lesions which do not affect consciousness but can alter the motor response. So it is not uncommon to find patients with motor responses resulting from diffuse axonal injury type which interfere with the evaluation of consciousness according to the GCS. You can see how some patients with axonal injury similar to pronoextension objectified in the responses of decortication, but with a different meaning. In the case of decerebrate bending, a mechanism involved in the genesis of motor response is the cessation of the connection between the cerebral cortex and the reticular substance due to an acute hemispheric process that intercepts the control and inhibition of intrinsic muscle tone and the substance, manifested by an abnormal motor response. In contrast, in patients with diffuse axonal injury and pronoextension these responses often manifest as spontaneous activity due to diencephalic substance that directly stimulates the brainstem internuncial neurons, generating pronoextension responses. Such situations and others like them must be taken into account when assessing the state of consciousness in patients with axo-

nal injury. Only then can a judicious interpretation be made of the meaning of this type of response.

The ocular component of the GCS may be difficult to assess in patients with facial trauma in which the upper third of the facial mass is seriously injured or eyelid edema occludes the eyelids and makes eye opening impossible, or also in patients presenting with congenital or acquired amaurosis, as well. In such cases, consideration should be given to the component of eye opening; assessment of the level of consciousness will have a maximum total of 11 points, including verbal and motor response.

In any case, it should be noted that of the three sections composing the GCS, the motor component has the highest profile and greatest weight in the evaluation of global CNS dysfunction. For some authors, the motor component of the GCS itself contains all the necessary information even in cases suggesting that, given the prognostic capacity of this section, it would replace the entirety of the scale in predicting the evolution of TBI patients

Training in the application of the GCS is key to increasing its reliability. Its application by a well-trained staff ensures adequate reliability, although major disagreements have been described: one series reported that between 20 and 35% of patients evaluated were rated differently and by different evaluators. It is therefore important not only to adequately train the examiners but also harmonize interpretation of the responses and the intensity and characteristics of the stimuli applies to the patient.

Although the GCS has a capacity of major global prediction when analyzing large series of patients, it should not be used in predicting the prognosis of specific individuals with critical neurological process such as TBI. In fact, we find patients with very low scores due to the development of acute extra-axial lesions, extradural hematoma, who, when treated quickly and the masses are evacuated, will have a good long-term prognosis. Consequently, the ability to forecast the GCS should be used primarily in the study of patient groups.

Innsbruck Coma Scale

Like the GCS, the Innsbruck Coma Scale (ICS) was developed to evaluate TBI patients. The ICS is a summative scale; scores

Item	Factor	Score
Eye opening	Spontaneous	3
	To acoustic stimuli	2
	To painful stimuli	1
	None	0

range from 0 to 23 points, with a minimum score of 0 (no response) and a maximum of 23 (patient oriented). The scale takes the same values (Table 5.2) as the GCS for ocular and motor responses, in addition to eye position, pupil size, pupil response to light, and oral automatisms. In the lower ranges of scores in the evaluation of the patient on admission, the ICS is highly predictive of patient mortality at 21 days of stay.

Edinburgh Coma Scale-2

The Edinburgh Coma Scale-2 (E2CS) is the best answer as long as the patient is considered valid to classify according to an ordinal system, where a higher score indicates lower level of consciousness. The system assigns a single score in a continuous exploration from a lack of any response to the responses of patient orientation. It has the advantage over previous scales that it does not add co-variable factors. Its shows good correlation with the GCS and the Glasgow Outcome Scale (GOS) for mortality and morbidity levels organized in a proper order. For 1 to 3, the ratio increases rapidly for morbidity, but mortality is <30% for a score of 5, then non-linear up to 100% with a score of 10. A drawback to the E2CS is that it assumes that in patients obeying orders the verbal response is preserved in the absence of obtaining the same or the wrong answer. Another drawback is that an intubated patient cannot be expected to give a verbal response, unless, perhaps a response is elicited and a lower score assigned. The scale takes the values specified in Table 5.3.

	Item	Score
The patient answers to a set of questions about temporal and personal orientation	Answers correctly to both	0
	Answers correctly to either	1
	Answers incorrectly to both	2
Two sets of commands (close and open hands, close and open eyes)	Obeys correctly to both	3

Other Scales

The Glasgow Coma Scale-Liège (Born, 1988), designed on the GCS, is based on the fact that, in the first 24 hours after brain injury, the study of the brainstem reflexes index provides a good prognosis and that early mortality rates are associated with brainstem reflex disorders (Table 5.4).

The Reaction Level Scale (RLS85) (Table 5.5) is another scale that assesses the level of response in patients with acute brain injury. It was developed for use in instances where evaluation can be problematic, as in intubated patients or patients with

Best eye response (1-4)	1. No eye opening 2. Eye opening to pain 3. Eye opening to verbal command 4. Eyes open spontaneously
Best verbal response (1-5)	1. No verbal response 2. Incomprehensible sounds 3. Inappropriate words 4. Confused 5. Orientated
Best motor response (1-6)	1. No motor response 2. Stereotyped extension to pain 3. Stereotyped flexion to pain 4. Withdrawal from pain 5. Localizing pain 6. Obeys commands
Brainstem reflexes (0-5)	0. No brainstem reflex 1. Oculocardiac reflex 2. Horizontal oculocephalic or oculovestibular reflex 3. Pupillary light reflex 4. Vertical oculocephalic or oculovestibular reflex 5. Fronto-orbicular reflex

Table 5.4. Glasgow Liege Scale (GLS).

Grade	Description
1	Alert, with no delay in response (responds without stimulus)
2	Drowsy or confused, but responds to light stimulation
3	Very drowsy or confused, but responds to strong stimulation
4	Unconscious; localizes (moves a hand towards) a painful stimulus but does not ward it off
5	Unconscious; makes withdrawing movements following a painful stimulus
6	Unconscious; stereotypic flexion movements following painful stimuliery
7	Unconscious; stereotypic extension movements following painful stimuli
8	Unconscious; no response to painful stimuli

Table 5.5. **Reaction Level Scale (RLS85).**

eye swelling. The scale has a good reliability for various etiologies of brain injury such as head trauma and stroke. The main assumption in the scale's design is that there is a continuum in the level of consciousness, alertness and orientation to non-response to noxious stimulation. Similarly, it is assumed that the reverse sequence must occur in the patient with impaired recovery of consciousness. Based on theoretical considerations and clinics, each change in degree on the scale can be considered a reflection of a real change in the patient's condition. It is also assumed valid to consider the best response of the patient. The scale has 8 categories of bedside assessment.

5.3.2 Hunt and Hess Scale

Based on the classification of Botterell and Lougheed, the Hunt and Hess scale was published in 1968 and has been several subsequently amended. It was initially designed to determine the risk of surgery that a ruptured aneurysm and timing of surgery carry. Although several factors such as age and number of days elapsed since bleeding are involved, WE Hunt and RM Hess estimated that the intensity of meningeal inflammation, the severity of neurological deficit, and the presence or absence of neurological disease were clinical data that were better able to predict surgical risk. The scale was derived from the data on 275 consecutive patients and surgical intervention, either early (in patients with grades I and II), or delayed (reserved for patients with grade III or higher awaiting neurological improvement). Neither patient age nor aneurysm location were determinants of surgical risk. The number of days since bleeding was not considered an important prognostic element.

The Hunt and Hess classification is structured on 5 grades depending on the level of intensity of clinical manifestations such as headache, stiff neck, focal neurologic deficit or altered level of consciousness (Table 5.6). The first 2 grades include patients without altered consciousness or stiff neck graded as minimal to moderate while headache can be graded mild or moderate to severe. Such patients have no focal deficits but may have paralysis resulting from cranial nerve compression due to aneurysmal growth. Grade I and II patients were submitted to early surgery in the Hunt and Hess series.

Grade	Description
I	Asymptomatic, mild headache, slight nuchal rigidity
II	Moderate to severe headache, nuchal rigidity, no neurologic deficit other than cranial nerve palsy
III	Drowsiness/confusion, mild focal neurologic deficit
IV	Stupor, moderate-severe hemiparesis
V	Coma, decerebrate posturing

Table 5.6. **Hunt and Hess Scale.**

Indications for the Use of the Hunt and Hess Scale

The principal indication for the Hunt and Hess scale is to predict surgical-risk patients with recent subarachnoid hemorrhage (SAH). According to initial studies, an increase in the clinical grade is associated with an increased risk of mortality. However, this scale was developed before the implementation of navigation techniques or endovascular coiling. Therefore, the recommendation that aneurysm exclusion techniques should be limited to Hunt and Hess <grade III have become obsolete, owing to the significantly lower risk for patient undergoing an endovascular technique. Although not intended for this purpose, the scale has been frequently used to assess the overall clinical risk of SAH. However, new scales may be more accurate in predicting surgical risk.

Limitations of the Hunt and Hess Scale

As discussed above, the Hunt and Hess scale was not intended as a predictor of the clinical course of patients with spontaneous SAH, although it often has been used for such purposes.

The Hunt and Hess scale should be used judiciously in those patients in whom the level of consciousness may be affected not only by the bleeding but also by its accompanying complications. It's not uncommon to see patients with SAH and spontaneous seizures in whom the level of consciousness during and after the seizures is influenced by the epileptic activity and not by a decreased level of consciousness produced directly by bleeding. The development of hydrocephalus, which progress over time, also significantly influences the level of consciousness, without implying a worsening of prognosis derived directly from SAH but indirectly from hydrocephalus. After placement of a cerebrospinal fluid shunt, consciousness returns to the previous level in relation to the SAH. That "restored" level of consciousness should be the one that really establishes the clinical prognosis.

Certain symptoms such as stiff neck or headache pain, for example, have a subjective component. Probably it is the subjectivity of both the physician and the patient in the interpretation of certain symptoms included on the Hunt and Hess scale that justifies in part the further development of other scales such as the World Federation of Neurological Surgeons (WFNS), with its more quantitative measurements that were introduced to overcome the problem of interobserver variability in the interpretation of certain signs and symptoms.

5.3.3 World Federation of Neurological Surgeons Scale

This scale was introduced in 1988 in an attempt to have a simple scale that could estimate the prognosis of a patient with SAH and could be used as a means to quantify changes in the patient's clinical status throughout the acute phase. The scale needed to be reliable and, above all, allow its combination with other methods of clinical evaluation of SAH, which until then had been developed along the lines of Hunt and Hess for the Cooperative study.

The WFNS Scale was developed on the basis of the GCS. Unlike the Hunt and Hess scale, it does not take into consideration the presence of signs such as stiff neck or symptoms such as headache. The Surgeons Committee had to choose at the outset between the proposed Kassell and Torner stratification (5 grades) and that of Jagger et al. (7 grades) of spontaneous SAH, agreeing finally on the scheme presented in Table 5.7.

As can be seen from the table, set up in 5 grades, an unruptured aneurysm was considered as one grade, the GCS was taken for assessing level of consciousness, given the scale's widespread application in the evaluation of head injury, and was used only for high-grade focal deficits (aphasia, hemiparesis, and hemiplegia), which differ in grades II and III on this scale.

Grade	Glasgow Coma Scare score	Motor deficit
I	15	Absent
II	14-13	Absent
III	14-13	Present
IV	12-7	Present or absent
V	6-3	Present or absent

Table 5.7. **World Federation of Neurological Surgeons scale.**

Special attention should be drawn to the fact that ptosis and ocular adduction difficulty (third cranial nerve palsy or oculomotor internal) are not considered suggestive of focal data but instead the result of direct compression of the third cranial nerve due to the growth of the aneurysm in the posterior circulation, thus keeping the patient in group II on the WFNS scale. The WFNS scale provides some advantages over the Hunt and Hess scale, such as greater simplicity and lower interobserver variability.

The WFNS scale was later modified by Sano and Tamura to improve the discriminatory power of each grade. With this modification, the WFNS scale was restructured into 6 grades by subdividing grade III and redefining grades I and II. In this new scheme, patients with a GCS score of 15 and neurologically intact are categorized in grade I, although some may have cranial nerve palsies that do not involve increasing severity (as in third nerve palsy secondary to the sudden growth of aneurysms of the posterior communicating arteries). Grade II patients, including those with a GCS score of 15, have a clinically intense headache and/or stiff neck. Grade III, (GCS score 13-14) is divided into two subgroups: IIIA if no focal deficit and IIIB if focal deficit is present. In grade IV (GCS score 7-12), the upper and lower scores coincide with the WFNS scale, without changing the GCS score for patients with sufficient consciousness but may lose the swallow reflex and so will require admission to the ICU. Finally, grade V (GCS score <7) includes patients in deep coma with abnormal motor reactions.

Indications for Use and Limitations of the WFNS Scale

The WFNS scale should be used for the evaluation of the clinical severity of patients with spontaneous SAH during the acute phase. The WFNS clinical scale is now better able to establish the prognosis of patients after neurological examination in the acute period of SAH.

Possible limitations of the WFNS scale are: 1) absence of clinical significance in the scale because highly symptomatic patients with severe headache and severe neck stiffness, who are nevertheless classified as grade I, may not have altered level of consciousness or motor deficits; 2) assessment of the level of awareness is important for the prediction of death and disability; however, the presence of focal signs such as hemiplegia, hemiparesis and/or aphasia is important in the development of disabilities ensuing from acute neurological process, making it less reliable in predicting mortality; 3) detected inconsistencies in the cut-off scores on the GCS to differentiate between grade II and III and IV characteristic of these groups because they have the same neurological status with the only difference being the focus. Group IV has a much broader neurological status comprising a GCS score of 7 and a GCS score 12 which denotes a confused state; 4) adds defects attributable to the GCS. Thus, it is advisable to collect individual components of the GCS (eye, motor and verbal responses) as the same overall score; the different prognoses will depend on the score of each of the three components.

5.3.4 The Johns Hopkins Classification

One of the more recently developed scales for the assessment of patients with spontaneous SAH is the Johns Hopkins classification published by Tamargo R et al. in 1997 (Table 5.8) and proposed as an alternative to the two most commonly used scales hitherto, Hunt and Hess and WFNS.

Based on the GCS, and like the WFNS scale, it attempts to discern the severity within the group of patients with grade IV SAH on the WFNS scale. On the latter, grade IV is made up of patients with severe coma, a score of 6, and others with much less involvement (score of 12) that only have a certain degree of drowsiness. In contrast, the Johns Hopkins scale segregates patients with a GCS score of 6 to 8 (grade IV) from those with a score <6 (grade V).

The Johns Hopkins scale solves the problem of classification of patients with very different prognoses within the same group, and differentiating between mild, moderate and severe illness, compared with the lack of resolution that the WFNS scale has. Although the scale has not been evaluated in large series, it is remarkable for its simplicity and ease of use by clinicians.

The indications for its use are similar to those mentioned for the WFNS scale, i.e., evaluation of the severity and clinical impact of SAH bleeding. Like all scales, including the GCS, there are limitations to its use.

Grade	Description
0	Unruptured aneurysm
I	15 points GCS
II	12-14 points GCS
III	9-11 points GCS and/o focal deficit
IV	6-8 points GCS
V	3-5 points GCS

Table 5.8. Johns Hopkins scale.

5.4 Imaging-based Assessment Scales

5.4.1 Traumatic Coma Data Bank Scale

The Traumatic Coma Data Bank (TCDB) scale is currently the most widespread tool in the evaluation of computed tomography (CT) of TBI. The scale was presented in 1991 by Marshall, et al. and was initially developed to evaluate through CT images in the acute phase of patients with head injury, intracranial lesions in these patients. The classification is intended to include the universe of all patients with closed head injuries and classify them according to prognostic features and therapeutic orientations. The initial justification for the development of the scale was twofold: to establish subgroups of patients with head trauma who have a similar risk of neurological impairment, and to identify groups of trauma patients with similar clinical medium and long-term prognosis. The scale was developed exclusively for blunt trauma, excluding injuries caused by firearms, and was initially implemented only for patients with severe head trauma, i.e., with a GCS ≤8. It has a direct relationship with the level of consciousness disorder as assessed by GCS, specifically the GCSm and different categories of the TCDB classification. Likewise, the various levels of this classification scheme are associated with mortality rates significantly different from each other. According to CT findings, the diagnostic classification includes six categories, four of which pertain to predominantly diffuse lesions and predominantly focal injuries. Diffuse lesions (types I to IV) may include low-volume mass lesions (limit, 25 cc), but with diffuse brain injury as a predominant lesion. Also considered for this classification in addition to the mass lesion volume are: midline shift (more or

Cathegory	Cranial CT
Diffuse injury I (pathology not visible)	No visible pathology on CT
Diffuse injury II	Cisterns present with midline displacement of 0-5 mm and/or dense lesions present. No injuries or mixed high density of more than 25 cc. Bone fragments and foreign bodies can be present
Diffuse injury III (swelling)	Cisterns compressed or absent with midline shift of 0-5 mm. No injuries or mixed high density of more than 25 cc
Diffuse injury IV (shift)	Displacement of the midline of more than 5 mm. No injuries or mixed high density of more than 25 cc
Evacuated mass lesion	Any lesion surgically evacuated
Non evacuated mass lesion	Injury high or mixed density of more than 25 cc not surgically evacuated

Table 5.9. **The Traumatic Coma Data Bank (TCDB) scale.**

less than 5 mm) and compression of mesencephalic cisterns. One advantage of the TCDB scale is its widespread use in centres caring for TBI patients. Besides its clinical applicability, another factor contributing to its dissemination is that there is a high correlation between CT scan readers when analyzing the images in trauma patients. This degree of agreement is higher when there are mass lesions and when lesions are classifiable as diffuse brain injury (grades I to IV). Table 5.9 presents the different categories of the TCDB classification.

As mentioned above, the different categories are associated with different rates of mortality; the mechanism most probably involved is the presence of intracranial hypertension. Thus, mortality increases progressively in the different categories of diffuse injury, reaching a mortality of 56% in type IV diffuse lesions, comparable to the mortality of injured patients with evacuated masses (53%). In grade III and IV diffuse injury, the most important predictor of evolution is the intracranial pressure, whereas in the other age groups, the GCS and pupil reactivity predict the prognosis better. It is therefore evident that the TCDB classification informs us of the likelihood of intracranial hypertension and mortality; however, there are many other factors such as patient age, previous trauma, and comorbidities which also have a role in the outcome.

Indications for Use and Limitations of the Traumatic Coma Data Bank Scale

The TCDB scale should be used for estimating the risk of death and intracranial hypertension in patients who have suffered a head injury. It was designed to be applied to the first CT scan obtained during the acute phase of injury, since the TCDB classification includes only primary traumatic injuries. On the other hand, although the scheme was developed for evaluating patients with severe head trauma, i.e., with a GCS score ≤8, its use has been extended to other groups of TBI patients (moderate and mild) to describe intracranial lesions. Moreover, although the TCDB scale was not designed for that purpose, certain categories in the scheme are associated with certain therapeutic or monitoring procedures. Thus, the presence of type III diffuse injury is associated with the presence of intracranial hypertension, and linked to intracranial pressure monitoring. Similarly, the presence of space-occupying lesions (<25 cm^3) requires a surgical therapeutic approach, which undertaken or not, leads to a reclassification of the patient within the TCDB classification.

It should be noted that the TCDB classification is a dynamic rating system; therefore, given the possibility of development of traumatic intracranial lesions either spontaneously

or during intervening events, it is possible to reclassify patients throughout the process. Thus, in patients in whom a CT scan was obtained immediately after trauma, the scan may not show intracranial lesions that can develop during the first 3-12 hours after the trauma. So some authors propose a reclassification based on the features of the last or the worst CT performed in the acute phase.

There are some other limitations of the TCDB classification. The classification takes a primarily surgical approach without considering some TBI of great clinical relevance and, above all, of great prognostic importance. This is the case of traumatic subarachnoid hemorrhage (tSAH), which currently enjoys a significant prognostic role, and was not considered in the initial TCDB classification. Currently, traumatic SAH is usually classified as diffuse brain injury type II. Other injuries often not sufficiently weighted in the classification are tomographic lesions associated with diffuse axonal injury, especially those located in the brainstem or corpus callosum. According to the TCDB classification, the presence of such lesions, often small hemorrhagic lesions on the CT scan, would be included under type II diffuse injury, which could lead to prognostic expectations anyway, but may be established a priori by the tomographic images. It is well known that in patients with diffuse axonal injury mainly affecting central brain structures, the prognosis for recovery in the medium term is uncertain. Conversely, larger hemorrhagic lesions due to concussions may be associated in general with a better clinical outcome. Hence, the TCBD classification is less powerful when used for evaluating mild TBI.

5.4.2 Greene Scale for Assessing Posttraumatic Subarachnoid Hemorrhage

The presence of tSAH on a CT scan has gained increasing relevance. Although an association between prognosis and the presence of tSAH has been demonstrated, it is equally true that there is consensus on how to classify and evaluate the presence of such lesions on the CT scan. Moreover, the clinical significance of posttraumatic SAH differs from spontaneous SAH owing both to blood volume and location. In most trauma cases, the subarachnoid blood does not usually enter the basal cisterns but rather mixes with the supratentorial and spinal fluid surrounding the cerebral hemispheres. Less frequently it is located at the level of the cisterns of the skull base, where bleeding is probably due to a different mechanism.

Greene et al. proposed in 1995 a model for weighing and assessing the severity of this entity based on a series of 252 patients at St. Joseph's Hospital and Medical Center in Arizona enrolled over 3 years. The study included only patients with non-penetrating head wounds and abnormal CT, regardless of the degree of altered consciousness. Although the study was not designed to show a scaled analysis of SAH itself, the aim was to study whether CT findings can be considered useful in the evaluation of traumatic SAH. The main contributions of this study are that it established a systematic way to analyze traumatic SAH and that it defined a severity scale for traumatic SAH in terms of intensity in association with other pathological findings on the CT scan.

The proposed scale of CT analysis focuses on the presence or not of SAH and, if present, the evaluation of its thickness (≤5 mm or >5 mm), and its location. The anatomical locations imaged for the presence of subarachnoid blood are the interhemispheric fissure, fissure frontobasal, frontal fissure, occipitoparietal fissure, base of the Sylvian fissure, Sylvian fissure, insular cistern, suprasellar cistern, ambiens cistern, interpeduncular cistern, prepontine cistern, transverse cerebral fissure, supracerebellar cistern, and cerebral convexity. With this type of analysis, we can distinguish between those regions including the basal cisterns, vertical regions of cerebrospinal fluid, the Sylvian fissure and

bleeding. Based on this distinction, the location is classified in a hierarchical manner and assigned scores of 1 to 3, where 1 refers to the presence of traumatic SAH in the hemispheric region only, 2 only located in the basal region, and 3 presence of SAH in the basal interhemispheric regions. Besides these aspects, also evaluated are the presence or absence of associated brain edema, obliteration of basal cisterns associated with SAH, mass lesions such as epidural or subdural hematoma, or the presence of concussion and midline shift >5 mm, or ≤5 mm (toward the septum pellucidum). Table 5.10 shows the Greene Scale for the classification of tSAH.

Grade	Description
1	Traumatic SAH ≤5 mm
2	Traumatic SAH >5 mm
3A	Traumatic SAH ≤5 mm, median line deviation ≤5 mm and mass lesion
3B	Traumatic SAH ≤5 mm, median line deviation >5 mm and mass lesion
4A	Traumatic SAH >5 mm, median line deviation ≤5 mm and mass lesion
4B	Traumatic SAH >5 mm, median line deviation >5 mm and mass lesion

Table 5.10. **Greene classification of traumatic subarachnoid hemorrhage.**

Greene KA et al. found a direct relationship between the degree on the scale and the level of consciousness (GCS) on admission of the patient. The scale also correlated statistically with the outcome, as measured by the Glasgow Outcome Scale (GOS).
The significance of SAH in patients with TBI is different in patients with spontaneous subarachnoid bleeding due to rupture of intracranial aneurysms. Both its location and because of its pathophysiology, the relationship between posttraumatic vasospasm and SAH is not as clear as it is in spontaneous SAH. Traumatic SAH is a marker of a brain damage mechanism of relevance. Thus, the presence on CT of traumatic SAH has been considered an element suggestive of mechanisms of acceleration/deceleration in the genesis of trauma, and therefore not infrequently associated with the presence of diffuse axonal injury.

5.4.3 Gennarelli Scale for Rating Diffuse Axonal Injury

Gennarelli developed a scale based on previous anatomo-pathological findings by Adams in patients with diffuse axonal injury. It was the primary basis for classifying diffuse axonal injury and scales with radiological and clinical variables were later developed. Table 5.11 presents the Gennarelli classification based on pathologic findings from studies in primates, which was subsequently modified. Although initial studies were conducted in experimental animals, the results were then extrapolated to imaging studies using CT, in which it was observed that CT showed moderate sensitivity for the detection of white matter lesions accompanying diffuse axonal injury. These chances of detecting axonal injury were later exploited with the advent of magnetic resonance imaging (MRI).
The Gennarelli scale for evaluating diffuse axonal injury is currently the most widely used tool for assessing injury severity, as it indicates a direct relationship between the lesion severity and long-term neurological and functional outcomes.
In 1987, Gentry et al., using MRI studies in the acute phase of injury and comparing the radiographic findings with clinical findings, described traumatic axonal injury lesions and their most frequent locations: lobar white matter (frontal, temporal, parietal and occipital), corpus callosum (splenium, body and knee), corona radiata (anterior and posterior), capsula (internal and external), brain stem and cerebellum.
The radiological approach to the study by Gentry along with Gennarelli's anatomical classification allows stratification of lesions secondary to diffuse axonal injury along a sliding scale, so that peripheral lesions in the lobar white matter are classified in the range of the

less serious, while central brain lesions and those of the brainstem are associated with greater clinical severity.

Grade	Description
I	Deep small hematoma diffused in crerebral hemispheres These lesions are widely distributed in the white matter of the hemispheres (including the corpus callosum), stem and cerebellum. In less severe cases, it affects only the paramedian white matter
II	Since this is a staging of the same problem, grade II lesions are observed only after the Grade I lesions are present, when hemorragic lesions aggregate in the corpus callosum
III	Grade I and II lesions are present. Furthermore, focal hemorrhagic lesions are present in the dorsal lateral quadrant of the midbrain or upper third of the bulge

Table 5.11. **Morphological classification of axonal diffuse region. Gennarelli classification modified.**

5.4.4 Fisher Scale

Developed by Fisher et al. in 1980, this scale assesses the location and extent of SAH visualized by CT, based on the observed changes in CT scans of a verified case of ruptured intracranial aneurysms, and the relationship with cerebral vasospasm (Table 5.12).

Divided into 4 grades, the scale relates the amount of blood visualized on a CT scan at the level of the cisterns, sulci and ventricles, with the possibility of developing arteriospasm. Analysis of the presence of blood should include at least the following locations: 1) frontal interhemispheric fissure, including the immediate region of the genu of the corpus callosum; 2) basal frontal fissure, including the inferomedial boundary region of the hemisphere, close to the anterior communicating artery; 3) occipitoparietal fissure (posterior interhemispheric fissure); 4) base of the Sylvian fissure (horizontal portion of the Sylvian fissure around the proximal middle cerebral artery bifurcation); 5) Sylvian cistern (bottom of the Sylvian fissure adjacent to its base and the main divisions of the middle cerebral artery); 6) insular cistern (subarachnoid space vertically oriented on the surface of insula); 7) part of the Sylvian fissure oriented horizontally and superimposed on the upper surface of the temporal lobe; 8) suprasellar cistern (region of the circle of Willis); 9) ambiens cistern (perimesencephalic space vertically oriented); 10); quadrigeminal cistern (subarachnoid space adjacent to the quadrigeminal bodies); 11) transverse cerebral fissure between the corpus callosum and the fornix above and below the diencephalon; 13) prepontine cistern located ventral to the base of the pons and superior cerebellar cistern; 14) surface of the brain.

In cases where the amount of blood that is not noticeable or is so diffuse that it forms clots >1 inch thick (grade 1 and 2, respectively), the rate of vasospasm is very low. In cases where the accumulation of blood is greater (grade 3), the risk of vasospasm increases as does ischemic neurological deterioration even more if blood occupies

Grade	Appearance of hemorrhage
1	None evident
2	Less than 1 mm thick
3	More than 1 mm thick
4	Diffuse or none with intraventricular hemorrhage or parenchymal extension

Table 5.12. **Fischer scale.**

Grade	Criteria
1	Absence of subarachnoid hemorrhage and ventricular invasion
2	Minimal subarachnoid hemorrhage without ventricular invasion
3	Minimal subarachnoid hemorrhage with ventricular invasion in both lateral ventricules
4	Dense subarachnoid hemorrhage with ventricular invasion in both lateral ventricules

Table 5.13. **Fischer revised scale.**

the wells in the vertical plane (interhemispheric fissure, insular cistern, ambiens cistern) or >3 x 5 mm in the longitudinal cisterns (Sylvian and interpeduncular).

Indications for Use and Limitations of Fisher's Scale

The Fisher scale has its main indication in assessing the risk of developing vasospasm according to CT findings in the acute phase of aneurysmal SAH, and so may n estimate of the risk of developing ischemic focal neurological deficits associated with this situation. The Fisher scale should not be used as a scale to estimate clinical severity or for evaluating neurological complications of spontaneous SAH. Furthermore, accurate estimation of the amount of subarachnoid bleeding as assessed by CT is not always easy. The problems for quantification are diverse: 1) irregular size of the cisterns and fissures; 2) planes that do not correspond to the inclination of the CT court; 3) difference in blood concentration in each of these regions; 4) inaccuracy in measuring the intensity in Hounsfield units (HU) due to the frequent coexistence of partial volume effect due to both the proximity of the bone and the cerebral cortex; and 5) increasing trend of isodensity of bleeding with the time.

5.4.5 Graeb Scale

In 1982 Graeb published a retrospective study of CT findings of 68 patients with intraventricular hemorrhage caused by aneurysm rupture (25%), trauma (25%), hypertensive hemorrhage (20%) and other miscellaneous causes. The mortality rate was 50%, whereas 21% of patients who recovered didn't have sequelae or had only mild disability. Since the development of hydrocephalus is an important factor in the prognosis of patients with blood in the ventricles, the authors proposed a classification to assess its risk. The classification is based on the amount of blood invading the ventricles (Table 5.14). One consideration to take in mind is the "blood-filled and expanded ventricle " which implies that the presence of ventricular dilation is directly attributable to bleeding, and not to the possible co-existence of hydrocephalus. The maximum score is 12 points, and there is some consensus that a score ≥7 allow us to evaluate this bleeding as high risk, frequently associated with a severe clinical picture. The risk of hydrocephalus is low when the score is between 1 and 4, moderate between 5-8, and severe when the total score is 9 to 12.

The main objective of Graeb's Scale is to quantify intraventricular blood associated with spontaneous SAH, intraparenchymal hematomas, or other processes such as tumours, and arteriovenous malformations; therefore, it may be used to estimate the risk of developing obstructive hydrocephalus.

	Item	Score
Lateral right ventricle	Traces of blood	1
	Less than half of the ventricle filled with blood	2
	More than half of the ventricle filled with blood	3
	Ventricle filled with blood and expanded	4
Lateral left ventricle	Traces of blood	1
	Less than half of the ventricle filled with blood	2
	More than half of the ventricle filled with blood	3
	Ventricle filled with blood and expanded	4
III ventricle	Blood present, ventricle size normal	1
	Ventricle filled with blood and expanded	2
IV ventricle	Blood present, ventricle size normal	1
	Ventricle filled with blood and expanded	2

Table 5.14. Graeb grading scale.

5.4.6 Le Roux Scale

In 1992, Le Roux published the results of a series of patients with intraventricular hemorrhage secondary to head injury. This study utilized a risk scale somewhat similar to that Graeb had published 10 years earlier. The study population was 43 patients. The blood was distributed in one or both ventricles in 25 patients; in the third or fourth ventricle in 4, and in all the ventricles in 14. There were also 3 intracerebral hematomas and 14 in the basal ganglia. The presence of ventricular blood in each ventricle was evaluated on a scale with a score between 0 (no ventricular hemorrhage) and 4 (maximum degree of ventricular invasion), with a total score range from 0 to16 (Table 5.15).

Item	Score
Traces of blood	1
Less than half of the ventricle filled with blood	2
More than half of the ventricle filled with blood	3
Ventricle filled and expanded with blood	4

Table 5.15. Le Roux grading scale.

5.4.7 Spetzler-Martin Scale

This scale was devised by Spetzler and Martin in 1986 to establish surgical risk and treatment recommendations for arteriovenous malformations (AVM). It combines clinical and radiological variables.

This grading system (Table 5.16) establishes the risk of morbidity and mortality and the most appropriate form of treatment of AVM. AVMs are classified according to the total score, based on the following criteria: size of nidus, type of venous drainage, and eloquence of adjacent brain area.

The size of the lesion is usually determined by the size of the malformation, which is defined on angiography: small, <3 cm (1 point); medium, 3-6 cm (2 points); and large, ≥6 cm (3 points). In general the overall AVM size is related to the number of afferent arteries.

The pattern of venous drainage is also determined by arteriography. A superficial directed to cortical venous system, straight or transverse sinus is assigned 0 points; a deep pattern (deep venous drainage, internal, basal cerebral veins or cerebellar or paracentral veins) is assigned 1 point.

The following regions are considered eloquent: sensorimotor cortex, language and visual area; hypothalamus; thalamus; internal capsule; brainstem, cerebellar peduncles; and deep nuclei. An AVM affecting an eloquent areas is assigned 1 point and 0 if no eloquent areas are affected.

	Item	Score
Size of arteriovenous malformations	Small (<3 cm)	1
	Medium (3-6 cm)	2
	Large (>6 cm)	3
Location	Noneloquent site	0
	Eloquent site	1
Venouse drainage	Superficial	0
	Deep	1

Table 5.16. Spetzler Martin Grading scale.

5.4.8 NIH Stroke Scale (NIHSS)

The National Institutes of Health Stroke Scale (NIHSS) is a systematic assessment tool that provides a quantitative measure of stroke-related neurologic deficit. The NIHSS was originally designed as a research tool, but now has other potential utilizations such as: clinical assessment, determining treatment appropriateness (thrombolytics), and predicting outcome.

Variable	Definition	Score
Level of consciousness	Alert	0
	Somnolent	1
	Stupor	2
	Coma	3
Level of consciousness (questions)	Answers both questions correctly	0
	Answers one question correctly	1
	Answers neither question correctly	2
Level of consciousness (commands)	Performs both tasks correctly	0
	Performs one task correctly	1
	Performs neither task correctly	2
Best gaze	Normal	0
	Partial gaze palsy	1
	Forced deviation	2
Visual	No visual loss	0
	Partial hemianopia	1
	Complete hemianopia	2
	Bilateral hemianopia	3
Facial palsy	Normal	0
	Minor paralysis	1
	Partial paralysis	2
	Complete paralysis of one or both sides	3
Motor arm	No drift	0
	Drift	1
	Some effort against gravity	2
	No effort against gravity	3
	No movement	4
Motor leg	No drift	0
	Drift	1
	Some effort against gravity	2
	No effort against gravity	3
	No movement	4
Limb ataxia	Absent	0
	Present in one limb	1
	Present in two limbs	2
Sensory	Normal	0
	Mild-to-moderate sensory loss	1
	Severe or total sensory loss	2
Best language	No aphasia	0
	Mild-to-moderate aphasia	1
	Severe aphasia	2
	Mute, global aphasia	3
Dysarthria	Normal	0
	Mild-to-moderate dysarthria	1
	Severe dysarthria	2
Extinction and inattention	No abnormality	0
	Visual, tactile, auditory, spatial, or personal inattention	1
	Profound hemi-inattention or extinction to more than one modality	2

Table 5.17. NIH ictus scale.

The NIHSS can be used as a clinical aid to evaluate and document neurological status in acute stroke patients, and it is valid for predicting lesion size and stroke severity. The scale is designed to be a simple, valid, and reliable tool that can be used at bedside from physicians or nurses.
The scale is composed of 15 items for neurologic examination to evaluate the effect of cerebral ischemia on levels of consciousness, language, neglect, visual-field loss, extra-ocular movement, motor strength, ataxia, dysarthria, and sensory loss. Each item on the scale is scored from 3 to 5 with 0 as normal (Table 5.17). Assessment takes less than 10 minutes to complete.

5.4.9 ICH Score

In 2000 Hemphill, working at the University of California, San Francisco (UCSF), developed an outcome risk stratification scale (the ICH Score) based on 5 variables determined to be independent predictors of 30-day mortality. The variables are: GCS, age, localization, volume of hemorrhage, and presence of intraventricular extension of bleeding. Each parameter is assigned points according to the strength of association with outcome. The ICH Score is the sum of the points of the various characteristics (Table 5.18).
The GCS was divided into 3 subgroups (GCS scores of 3-4, 5-12, and 13-15) to reflect the influence of the GCS score on outcome. Age ≥80 years was also strongly associated with 30-day mortality, so1 point was assigned for this situation. Intraventricular hemorrhage (VH), infratentorial origin of ICH, and ICH volume had relatively similar strengths of outcome association. IVH and infratentorial origin of ICH are dichotomous variables with points assigned only when present. ICH volume was dichotomized to <30 and ≥30 cm^3. Thirty cubic centimetres was chosen because it represented a cut-off point for increased mortality in the UCSF ICH cohort.
The ICH Score was an accurate predictor of outcome assessed as 30-day mortality. The range of ICH scores was 0 to 5. No patient with a score of 0 died, whereas all patients with an score of 5 died. Thirty-day mortality rates for patients with 1, 2, 3, and 4 points were 13%, 26%, 72%, and 97%, respectively. This grading scale has been validated worldwide.

	Component	Points
GCS score	3-4	2
	5-12	1
	13-15	0
ICH volume, cm^3	≥30	1
	<30	0
Intraventricular hemorrhage	Yes	1
	No	0
Infratentorial origin of ICH	Yes	1
	No	0
Age, years	≥80	1
	<80	0
Total ICH Score		0–6

Table 5.18. Determination of the ICH score.

5.5 Scale of Evolution, Evaluation of Consciousness in Advanced Stages of Brain Injury Outcome Scales

5.5.1 Glasgow Outcome Scale (GOS), GOS-Extended and Extended Glasgow Outcome Scale of Edinburgh (EEGOS)

The need to evaluate the health outcomes in patients who had suffered brain damage was the major reason that Jennett and Bond developed a 5-point scale that included neurological dysfunction is both intellectual and physical aggression produced by the brain. In 1975 the Glasgow Functional Outcome (GOS) scale was introduced (Table 5.19). It is now a general evaluator of spontaneous and traumatic brain lesions. Researchers working on the development of the scale considered impaired social interaction of the patients as the most important element that could evaluate the final results of the clinical process. For practical purposes, the scale includes 5 categories, ranging from Category I (death of the individual) to category V (good recovery). Category II includes persistent vegetative state, meaning a patient with no cerebral cortex functions and no reasonable behaviour even if it does not necessarily imply that the cerebral cortex is not grossly intact. Category III includes patients with severe disability, defined generically as "conscious but disabled". This implies that such patients are independent for activities of daily living despite cognitive deficits or physical deficits. Category IV includes patients with moderate disability defined as "disabled but independent patient." Such patients can travel by public transport and can perform work in a suitable environment and therefore are independent in these activities, but can present physical and intellectual abilities or personality changes. Category V includes patients with good recovery. Such patients return to their pre-injury activity well without cerebral deficits or with smaller physical or psychological deficits.

The categories in the original scale were considered by some as too broad and therefore felt they could include within the same category patients with significant clinical differences. In 1981 a new version of the scale, the Glasgow Outcome Scale-Extended, was developed which includes 8 points on the scale. Death, vegetative state, complete dependence on others, dependence on others for some activities, inability to return to work or participate in social activities, return to work with reduced capacity, and reduced participation in social activities, good recovery with mild mental and social deficits and good recovery with no deficit. The extended GOS scale (GOS-E) was completed by introducing the implementation of a standardized interview format that improves the reliability and validity of results. Thus, these corrections to the original scale were intended to solve, on the one hand, the low sensitivity to reflect changes experienced by the patient, and on the other, the low reliability due to the absence of a structured interview. Compared with the GOS, the GOS-E has shown greater sensitivity to assess changes due to mild and moderate injuries.

In addition to the above, also worthy of mention is an expanded version of GOS, the so-called extended GOS Edinburgh (EEGOS) and Signorini Hellaell proposed in 1997. It establishes an 8-point scale divided into a summation of functional, behavioural, cognitive and of physical parameters.

The GOS and GOS-E scales were designed to describe the social impact that occurs

Grade	Description
1	Death
2	Vegetative state
3	Severe disability
4	Moderate disability
5	Good recovery

Table 5.19. Glasgow Outcome Scale.

as a result of brain damage of traumatic origin rather than vascular origin. Currently they are still employed in the evaluation of neurologic and mental disabilities resulting from brain damage of any origin. Important to note is how much of the GOS and the GOS-E presents the individual's interaction with his or her environment. So, the dysfunction that may occur in this interaction may be due to psychological, physical deficits, or both.

However, these scales have attracted criticism that they focus more on physical aspects than neuropsychological deficits, and this despite the recommendations of the scales' authors, pointing to the increasing impact of intellectual changes on physical limitations in terms of disability caused by brain damage. These scales have also received criticism that they are difficulty to use especially in children with head injuries.

5.5.2 Revised Neurological Assessment Instrument (NAIr)

The Neurological Evaluation Scale revised uses different elements to assess consciousness. The theoretical basis of the scale incorporates the physiological and neuroanatomical correlates of levels of consciousness based primarily on Plum and Posner´s publications. The scale was originally designed to assess neurological function in adults with acute brain injury. The scale items were selected to capture different aspects of the CNS and assess awareness along a continuum from alertness to coma. The clinical variables reflect the brain state, respiratory rate, pupil size and reactivity, eye movements and motor responses, operationalized nervous system functions, neuroanatomical and physiological correlations that facilitate the identification of pathology. The responses in each category are organized hierarchically, ranging from normal reflexes to the brain and progressive dysfunction of brainstem structures. The level of awareness concerning the characteristics of degree of alertness related to the brainstem reticular formation and adjacent structures ranging from the half-bridge to the hypothalamus. This level cognitive functions and emotional concerns have significant roles in attention, memory and executive functions. Eye opening, counselling skills and communication, and behavioural responses reflect a measure of vigilance. The behaviour of localization involves the integration of functions of the brainstem and cerebral cortex of both hemispheres, the spinal cord and peripheral structures. This involves the integration of motor responses and eye functions of the pupils. The original scale consisted of 10 items. The selection of these criteria was based on strong correlations with the GCS and predictive validity criteria with the GOS.

Based on the nature of consciousness and the need for establishing a minimum alert sequence to apply the scale, one must first examine the response of eye opening, eye items, and the contents of alertness, evaluating the motor responses in the last phase. When used by trained observers, evaluation with the NAIr takes <3 minutes. The evaluation study of the NAIr scale included patients with conditions of different etiology. The study population was 39 patients, of which 18 presented with stroke, 12 with brain tumours, 7 with metabolic encephalopathies, and 2 with TBI. The mean age was 60 years (range, 20-87). The authors reported no significant differences between patients with structural or metabolic injury and suggested that the instrument is valid for the evaluation of both types of patients. They recommend that the items to be included are motionless pupil in mid-position as the lowest score of the scale in the category of ocular motility, which is associated with a lesion located in the lateral pontine tegmentum. The NAIr is a summative scale, with scores ranging from 8-37, with a minimum of 8 (no answers) to 37 (oriented patient). The scale items take the values specified in Table 5.20. The scale combines 8 items reflecting motor activity, verbal and brainstem function. The

results show that the NAIr is a valid scale (r=0.9189, Pearson coefficient), reliable (r=0.9057, Pearson coefficient) and easy to administer, in the assessment of awareness levels in adults with structural or metabolic brain injury.

Variable	Description	Score
Eye opening	Spontaneous	5
	Voice	4
	Voice and touch	3
	Pain	2
	Without response	1
Pupils reactivity	Light	3
	Slow	2
	No reactivity	1
Verbal communication (orientation)	Appropriate language, orientated	5
	Appropriate language, disorientated	4
	Confused, inappropriate words	3
	Inappropriate sounds	2
	Without response	1
Differential size of the pupils in millimeters	1 mm	5
	2 mm	4
	3 mm	3
	4 mm	2
	>4 mm	1
Eye motility	Ocular motility	5
	Spontaneous fixations to order	4
	Horizontal or vertical nistagmus	3
	Conjunction with lateral deviation	2
	Lack of coordination of both eyes	1
Motor response (arms)	Normal	5
	Does not obeys to commands and doesn't localize	4
	Flexion	3
	Extension	2
	Without response	1
Motor response (legs)	Normal	5
	Does not obeys to commands and doesn't localize	4
	Flexion	3
	Extension	2
	Without response	1
Responses to verbal or tactile stimulation	Oriented and recognizes stimuli	5
	Scared, attempts to locate the stimulus source	4
	Restless	3
	Low activation, subtle movements	2
	No answer	1

Table 5.20. NAIr scale.

5.5.3 Behavioural Assessment Scale (NAS)

The Behavioural Assessment Scale was developed to measure the range of behavioural functions ranging from alert to coma. The authors assessed 60 patients under the effect of sedation for maxillofacial interventions. The scale was compared with the GCS and the key test of WAIS numbers. Statistical analysis showed: a Pearson correlation coefficient of 0.97 ($p < 0.05$) for interobserver reliability, correlation coefficient, -0.90 ($p < 0.05$) for the correlation between the NAS and the GCS; a Pearson correlation coefficient -0.62 ($p < 0.05$) for the correlation between the NAS and the key test of the WAIS numbers. The latter was taken as a measure of behavioural validity. The scale is reliable and valid. The NAS differentiates between two levels of sedation: high and mild sedation. Furthermore, the scale discriminates between different levels of sedation in patients with mild sedation.

In its standard form, the scale is a brief interview conducted by an observer to evaluate four categories of responses: alert/sedation, orientation, speech and motor responses. If the patient is asleep, the evaluator tries to wake him by calling him by name in a normal tone. If the patient does not respond, he is woken up. If the patient is awake, the observer must induce pain by placing pressure on a fingernail with a pencil or other hard object. Otherwise a response to painful stimulus can be elicited by pinching the trapezius muscle in the side of the base of the neck. During the interview, the patient is asked: his or her name, where he or she is including the name of the city, and the date, including year, month and day of the week. The question of why he or she is here evaluates

Item	Description	Score
Alertness/sedation (defects in the perception of the environment, drowsiness)	Not present, awake and alert	1
	Alert patient but slow, sleepy voice answered	2
	Asleep, arousable to touch and voice	3
	Arousable only to pain	4
	Not arousable to pain	5
Level of orientation (confusion or loss of appropriate personal associations, spatial and temporal)	Normal, facing the person, space and time	1
	Oriented to person and place, but not in time	2
	Oriented in person, but not in place and time	3
	Oriented or not the person, place and time, but awake	4
	No answer	5
Level of communication (poor articulation, pronunciation or substitution of sounds that affect the intelligibility regardless of context)	Normal	1
	Forced speaking with pronunciation errors but intelligible	2
	Forced speaking with moderate errors even if some words are intelligible	3
	Unintelligible speaking, poorly pronounced	4
	No answer	5
Psychomotor level (loss of spontaneous movement, decreased facial expression, decreased emotional tone)	Normal	1
	Moderate speed and slow movements, blunted affect	2
	Movements and moderate to severely speed slow, low energy and oscillation of affection	3
	No spontaneous movements	4

Table 5.21. NAS evaluation scale.

aspects of speech, and consistency of thought. The patient is ask to repeat the phrase "neither yes or no, but not" taken from the Spanish version of the Folstein Mini Mental State Exam.

The NAS (range, 4-19) is the sum of the scores for each of the 4 categories that the scale assesses. A score of 19 represents non-response for each category. Of the 4 categories, the study of the scale, orientation highlights (confusion or loss of ability to be personal, spatially and temporally). The categories alert, oriented and speaks explain 97% of the variance. The category of motor responses is only 2%. That is, of the 4 categories, 3 seem essential to the overall score. The scale's authors suggest that the NAS may be appropriate to the extent that it measures changes in the levels of neurobehavioral functions of patients during the recovery process and monitors them (Table 5.21).

5.5.4 Ranchos Los Amigos Levels of Cognitive Functioning Scale

Cognitive Scale developed by the Rancho Los Amigos (LOCF) is used to classify patients with brain injury according to their behaviour. It is based on the deterioration of the brain capacity to process information after brain injury. Generally, as a result of severe brain injury there is unusual behaviour and difficulty in self control. This scale describes the stages of recovery from coma to independent functioning on 8 levels, ranging from lack of answers to an patient awake, oriented, and resolved with appropriate behaviours. The scale takes the values shown in Table 5.22. It has good properties of concurrent validity and test-retest unreliability. However, it does not reflect small changes in cognitive functions and has very broad categories where a patient can be in several at one time. Another drawback of the scale is that it does not measure physical function.

Level	Response
I	No response
II	Generalized response
III	Localized response
IV	Confused-agitated
V	Confused-inappropriate
VI	Confused-appropriate
VII	Automatic-appropriate
VIII	Purposeful-appropriate

Table 5.22. **Ranchos Los Amigos Scale of Cognitive Functioning.**

5.5.5 Disability Rating Scale

The Disability Rating Scale (DRS) assesses 8 items from alertness, awareness and capacity of motor responses to cognitive skills for self-care and personal independence and social adaptability. Several studies have shown its reliability, validity and good yield. It is classified into 10 levels of disability: no disability, disability, mild, moderate, moderately severe, severe disability, severe, vegetative state, severe vegetative state patient died. The scale variables are shown in Table 5.23.

5.5.6 Coma/Near-Coma Scale

Coma/Near-Coma (CNC) scale was designed to measure small clinical changes in patients with severe brain injury of traumatic and nontraumatic origin, with features close to the vegetative state or in this state. Many of the patients in a vegetative state have a stable phase (in terms of clinical rehabilitation), some are better and others are worse or die. A scale that reflects small changes has a prognostic value and views the outcome of

the disease as the great value to all involved in the rehabilitation of these patients. Moreover, this scale is helpful in making therapeutic decisions by the patient management clinical team, in addition to funding agencies responsible for the care and rehabilitation treatment of patients. The scale was intended to be an extension of the CNC lev-

Variable	Description	Score
Eye opening	Spontaneous	0

	Moderately dependent-moderate assistance (person in home)	3
	Markedly dependent-assist all major activities, all times	4
	Totally sependent-24 hour nursing care	5
"Employability" (as a full time worker, homemaker, or student)	Not restricted	0
	Selected jobs, competitive	1
	Sheltered workshop, non-competitive	2
	Not employable	3

Table 5.23. Disability Rating Scale (DRS).

els Disability Scale with more discriminative power in patients in a vegetative state. In fact, it was initially recommended for use in patients with scores between 21 and 26 on the Disability Scale. The scale is divided into 5 levels (no comma, near-coma, coma, moderate, severe and extreme) as is the score for the 11 items that compose it. These items reflect the observations of sensory and perceptual reflex responses.

The information provided on this scale is useful for reducing the risk in advance to guide patients to lower levels of care or withdraw from more intense rehabilitation programs. The scale was designed to provide rapid assessment of reliable and valid progress or deterioration in patients with severe brain injury. In the evaluation of coma and vegetative states, the rehabilitation staff reports that the scale is useful for discriminating between patients with low or very low awareness and those who will progress beyond these levels. The scale is easy and quick to apply. It allows the omission of some items such as the vocal response in patients with a tracheotomy, without losing reliability and ability to predict clinical changes.

For each variable a small scale test is performed with the patient, some of which require up to 5 trials. Each scale variable is assigned a score of 0, 2 or 4. The score on the scale indicates classify the patient according to 5 levels of consciousness: no comma, near-coma, coma, moderate, and severe. The scale evaluates the following: responses to auditory stimuli, verbal orders, a light stimulus for light stimulus orientation, defence reflex, olfactory responses in orientation to tactile contact, nasal reflex, moderate pain, strong pain, and vocalization.

6.1 Introduction

The development of the CT scanner was not only a milestone in medical diagnoses, but also a key piece in the development of modern neurology. The British engineer Godfrey Newbold Hounsfield was the director of the team that developed the first applicable CT scanner prototype. In 1967, Allan M. Cormack published the first relevant paper that was the point of departure for the works of Hounsfield, who designed the first feasible CT scanner in 1972. That same year, Hounsfield put into operation the first CT scanning device that combined electronic calculation techniques and X-ray procedures, ushering in the most important advance in radiological diagnosis since the discovery of X-rays in 1885 by the German physicist Wilhelm Konrad Roentgen.

For the machine to work appropriately, the body part under study had to be completely immersed in water. Early CT studies took almost 24 hours to complete. In 1973 the first cerebral CT scanner in a clinical setting was installed at the Mayo Clinic in the United States. In 1979 Hounsfield received recognition for his research with the Nobel prize in Physiology or Medicine, along with the Most Excellent Order of the British Empire in 1979 for the invention of the CT scan.

The clinical impact of CT scanning increased over the years, transforming the concept of the intervening diagnosis based on image findings. As it gained application in other areas of medicine, it revolutionized neurology and neurosurgery and launched the development of new areas of knowledge such as neurocritical care medicine.

The physics of CT is similar to that of conventional radiology: the radiated X-rays cross the human body; the radiation is visualized on a film and measured with a specific device. Unlike conventional radiology, radiation in CT is not collected on a radiographic film but by radiation detectors. The rotational motion of an X-ray tube around the human body, while the radiation detector turns in the opposite direction, makes the human anatomy visible. The radiation detector consists of a measurement system that quantifies the X-ray intensity the organism tissues have absorbed.

The basic elements of a CT scanner are: a bed where the patient is positioned; an X-ray generator (gantry) where the X-ray tube is located; the electronic detectors that measure the radiation intensity; and a computer that converts into images the radiation measured by the detectors.

The radiation received by the detectors is recorded by an analogical-digital converter that turns it into a binary signal for processing by a computer. Collimation of the system allows for varying the thicknesses of the slices. The radiation absorption coefficients

of the body tissues are associated to each other in pixels along a grey scale which are shown in a radiological image.

Each axial slice is composed of a number determined by volumetric elements with specific radiation absorption. Each volumetric element, called a voxel, is composed of three-dimensional elements. On the scanner screen the image is reproduced in two-dimensional elements called pixels.

The intensity of radiation absorption is expressed in Hounsfield units or HU (unit of radiation absorption). There are 2000 levels of radiation absorption, ranging from the air to the bone (maximum and minimum radiation absorption; for example, water absorbs 0 HU). In CT scans of the intracranial structures in a healthy individual, the radiation absorption is between 0 and +50 HU. Figure 6.1 presents the scale of radiation absorption of various different intracranial structures. The cerebral white matter absorbs approximately +25 HU, grey matter absorbs +40 HU, while the cerebrospinal fluid absorbs between 0 and +5 HU.

In pathological situations, recent intracranial hematomas may absorb +70 HU or more due to their hypercellularity, the ferric component of hemoglobin, and the concentration of calcic elements. Therefore, the radiation absorption is high and shows up as a hyperdense image. In ischemic or edematous areas of the brain, these regions have a lower radiation absorptive capacity, with absorption of +20 HU or less. Therefore, the range of values of Hounsfield units that we should select to study intracranial physiological structures must be between 0 and +50 HU, including in this exam the cerebrospinal fluid, normal brain, or hypodense brain (as in brain damage of ischemic origin). If the diagnosis includes the possible presence of hemorrhagic lesions, the range of HU should be set between 0 and +100 HU. Within this range, hemorrhagic injuries can be observed as images with less radiological density than skull bone.

The range of HU values is called a "window." In addition, the computer system enables the operator to decide which anatomical structure corresponds to the grey scale medium (between black and white; a scale of 40 levels of grey are easily perceptible to the human eye). If the operator decides that the medium average is a normal cerebral tissue (around +45 HU), the grey matter can be observed as a hyperdense image. Inversely, areas such as the white matter or injuries with larger water content, as in brain edema, can be observed as hypodense images.

Another relevant technical aspect of CT scanning is the orientation of the slice to the major axis of the body. Before selecting the slice orientation, we should establish the diagnostic suspicion and the potential intracranial location of the lesion. In general, the standard slice orientation for acute neurocritical patients should be the cantomeatal orientation, which follows an imaginary line from the external auditory channel to the eye. Other orientations such as the neuro-orbitary, the biauricular orientation, and the occipital-temporal orientation can also be useful in the diagnosis of other types of intracranial lesions in neurocritical patients.

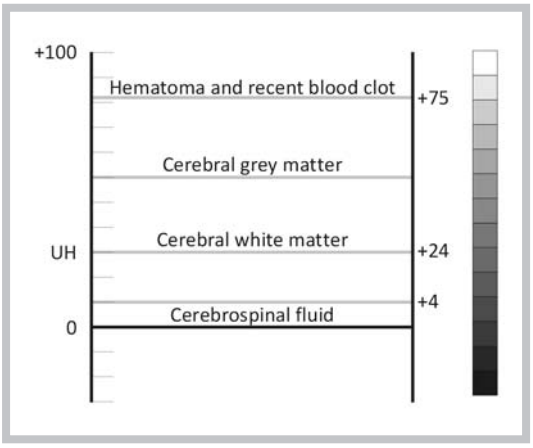

Figure 6.1. **Scale of absorption of intensity of intracranial structures expressed in Hounsfield Units (HU).**

A standard CT scan will include a scout view (simple X-ray image in a sagittal section) and a series of CT slices on the axial axis. In CT studies in critical emergencies,

4-8 mm thickness slices in the supratentorial region and 4 mm slices in the posterior fossa are advisable; however, intravenous contrast material should not be used unless brain abscess, isodense subdural hematoma or other lesions are suspected.

6.2 CT in Head-injured Patients

A significant advance in the diagnosis of consequences of head injury was the ability to scan and monitor intracranial pressure. In the early 1980s the usefulness of CT in head-injured patients was proved not only because of the efficacy of the CT scan to demonstrate the presence of hemorrhagic intracranial lesions amenable to surgical removal, but also its capacity to evidence other kinds of lesions with prognostic relevance.
The technical aspects of CT in patients with head injuries does not substantially differ from those of other neurological critical situations: a window between +90 HU and +100 HU; centre in +40 HU; cantomeatal orientation; 4-8 mm slices in the supratentorial region; and 4 mm slices in the infratentorial region, without the use of intravenous contrast material. A scout view of the cervical spine should be also included. A CT scan with a bone-like window must complete the radiological exam in order to diagnose the possible presence of injuries or cranial fractures. The frequent association of ffacial injuries with head injury, makes advisable a facial CT scan, including paranasal sinus.
There are several approaches to interpreting the CT scan of patients with head injury in the acute phase. The most widely used classification of CT scan findings in such patients is the Traumatic Coma Data Bank classification (TCDB) (Table 6.1). According to this scheme, injuries are categorized into two basic groups: 1) diffuse lesions, including low-volume intracranial space-occupying lesions and diffuse brain damage prevailing over the focal damage; 2) high-volume intracranial space-occupying lesions.
The first group comprises predominantly diffuse injuries or predominantly focal lesions without significant mass effect (known as diffuse brain injury) and is further subdivided into four categories. In high-volume focal lesions (volume >25 ml), mass effect can be due to purely hemorrhagic lesions or mixed density lesions. These injuries are grouped into two categories depending on whether they can be surgically removed or not.
The TCDB classification takes into account a direct relationship between four diagnostic categories of diffuse brain injury and the risk of death. Similarly, when the TCDB system is used together with the traditional classification of intracranial hemorrhages (epidural hematoma, subdural hematoma, intracerebral hematoma), the risk is higher if accom-

Category	CT scan
Diffuse injury I (no visible pathology)	No visible intracranial pathology seen
Diffuse injury II	Cisterns present with midline shift 0-5 mm and/or lesion densities present; no high or mixed density lesion >25 ml; may include bone fragments and foreign bodies
Diffuse injury III (swelling)	Cisterns compressed or absent with midline shift 0-5 mm; no high or mixed density lesion >25 ml
Diffuse injury IV (midline shift)	Midline shift >5 mm, no high or mixed density lesion >25 ml
Evacuated mass	Any lesion that can be surgically evacuated
Non-evacuated mass	High or mixed density lesion >25 ml that cannot be surgically evacuated

Table 6.1. **Classification of CT findings according to the Traumatic Coma Data Bank classification.**

panied by intracranial hypertension. According to the TCDB's designers there is a direct relationship between the Glasgow Coma Scale (GCS) score (mainly its motor component) and categorization according to the TCDB classification. The TCDB authors admit that the scheme's categories are arbitrary; however, they underline the high prognostic value of the four groups of diffuse brain injury the classification distinguishes (Table 6.1):

- CT scan normal for age and previous health status (diffuse brain injury I).
- Pathological CT scan with mixed or low-volume hypodense lesions (<25 ml) without compression of the cisterns or significant midline shift (0-5 mm) (diffuse brain injury II).
- CT scan with or without injuries similar to diffuse brain injury type II but in which there is compression or absence of the cisterns (diffuse brain injury type III or diffuse injury with cerebral swelling).
- Pathological CT scan with mixed or low-volume hypodense lesions (<25 ml) but with midline shift >5 mm (diffuse brain injury IV or diffuse brain injury with midline shift).

The TCDB classification has been criticized for its fundamentally surgical orientation, omitting in the analysis of the CT scan some injuries that cannot be surgically treated but with a known impact on prognosis.

In the TCDB classification, diffuse axonal injuries localized mainly next to the midline are considered as small-volume hemispheric injuries, in spite of the differences in clinical prognosis. Similarly, brainstem injuries (of significant relevance for prognosis) are not included. Nevertheless, the TCDB classification is universally accepted and has become a standard reference for CT evaluation of traumatic brain injury. On the other hand, one of the advantages of the TCBD classification is its high level of interobserver agreement, where the degree of concordance in mass lesions (concordance, 0,94-0,91) is higher than in diffuse brain injury (categories I-IV) (concordance, 0,71-0,67).

Some of the limitations of implementing the TCDB classification have been overcome in daily clinical practice. Traumatic subarachnoid hemorrhage, which has a recognized impact on prognosis, is included among type II lesions; and significant brainstem injuries are considered as unclassifiable injuries in the TCDB system.

When using the TCDB scheme it is advisable not to classify mass injuries in numeric expressions as in diffuse lesions, which definitely fall under diffuse brain injuries I-IV. High-volume mass injuries do not have a numerical categorization.

It should also be remembered that the TCDB system is a dynamic classification and can therefore vary in each patient depending on the clinical course. Accordingly, if the volume of a diffuse brain injury type II increases, it should be reclassified as a mass injury (evacuated or not evacuated).

In patients with head injury, interpretation of the CT scan should be extended beyond categorization by the TCDB scheme to include other levels of analysis. From a pathophysiological perspective, study of the CT scan of a head-injured patient should include the search for the presence or absence of anatomic structures. This first exam should include a revision of normal cerebral structures and the normal location and amount of cerebrospinal fluid. Only thereafter should the analysis of pathological images start. Table 6.2 illustrates a systematic protocol for interpreting pathological lesions on the CT scan. The protocol includes the following lesions: 1) high-volume hemorrhagic injuries and, therefore, potentially surgically evacuable lesions; 2) hypodense lesions of different cause (hypodensities of vascular distribution, simple contusions, etc.); 3) single or multiple injuries, frequently of low volume and usually associated with diffuse axonal injury. This step in the description of lesions on the CT scan must be followed by a second step in which the presence or absence of pathophysiological conditions frequently associated with head injury (e.g., intracranial hypertension, cerebral herniation or others) must be inferred.

Hemorrhagic injuries that are potentially surgically removable	• Subdural hematoma • Epidural hematoma • Hemorrhagic contusion/intraparenchymal hematoma
Hypodense space-occupying injuries	• Simple contusion • Hemispheric swelling • Hypodensities with vascular distribution
Lesions frequently correlated with axonal injury	• Injury of the corpus callosum • Injury of the brainstem/mesencephalon • Lesions of the basal nucleus • Intraventricular hemorrhage • Subarachnoid hemorrhage • Injuries of the grey matter/white matter interface

Table 6.2. **Initial data to analyze on the CT scan of head-injured patients.**

6.2.1 Potentially Removable Hemorrhagic Lesions

There are several types of hemorrhagic injuries consequent to head injury, each of which with different clinical and prognostic meanings. Hyperdense lesions, as an extra element in the intracranial content, have been frequently associated with space-occupying mass lesions, and intracranial hypertension by analogy to neoplasms. Often, the increased volume accompanying such lesions after head trauma will lead to intracranial hypertension. Another point to consider is that the presence of such a lesion is a marker for the presence of other lesions, less eloquent on the CT scan but with relevant prognostic significance. Table 6.3 lists hemorrhagic injuries commonly detected in the CT scan of head-injured patients.

- Hematoma epidural
- Subdural hematoma
- Hemorrhagic contusion
- Intracerebral hematoma
- Hemorrhagic injuries associated with diffuse axonal injury:
  - Hemorrhage of the corpus callosum
  - Capsular hemorrhage
  - Intraventricular hemorrhage
- Subarachnoid hemorrhage

Table 6.3. **Most frequent hemorrhagic injuries after traumatic brain injury.**

6.2.2 Epidural Hematoma

Epidural hematoma is an extra-axial hemorrhage in the external region of the dura mater. It carries two main risks: it can evolve into a rapid-growing intracranial lesion and it may reach a very high volume. Subsequently, epidural hematoma carries a high risk of intracranial hypertension, with the consequent risk of compression of cerebral structures of clinical (mesencephalon, brainstem) and functional importance. At attenuation values of approximately 50-100 HU, the morphology of an epidural hematoma is typically a biconvex lens (Figure 6.2), generally with clear-cut borders and usually adjacent to a fracture

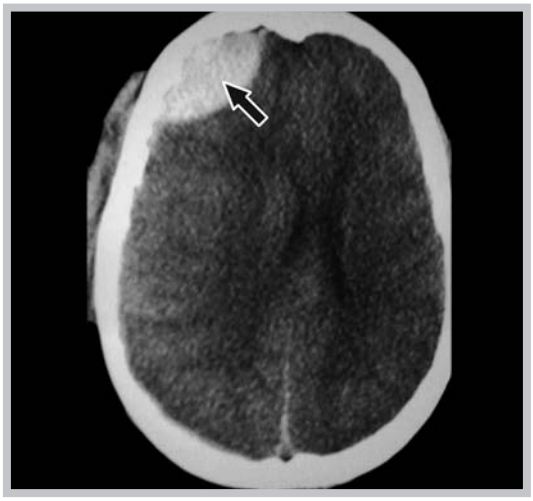

Figure 6.2. **Frontal epidural hematoma. Morphology of biconvex lens (black arrow). Midline shift.**

Figure 6.3. **Extensive right parieto-occipital subdural hematoma. Typical morphology (black arrow). No midline shift.**

line. The density is frequently homogenous. Usually unilateral, it can increase substantially in volume, compressing the ipsilateral ventricle and shifting the septum pellucidum significantly.

The presence of a heterogeneous epidural hematoma suggests active bleeding. The most frequent location is the temporoparietal region (75% of epidural supratentorial hematomas occur next to the temporal bone). In most cases, epidural hematoma results from damage of the meningeal arteries. Less frequent localizations are the frontal and occipital regions (8 and 5% of all epidural hematomas, respectively). Posterior fossa epidural hematomas have a higher incidence than subdural or vertex hematomas and suggest damage to the sagittal venous sinus or lateral venous sinus.

Besides morphology, other data can aid in the differential diagnosis between epidural hematoma and subdural hematoma. If a hematoma crosses major sutures of the skull and extends to both sides of the tentorium, the probability of an epidural location of the hematoma is higher than subdural. The coexistence of ipsilateral epidural and subdural hematomas is not uncommonly associated with epidural hematoma; however, much more frequent is epidural hematoma and contralateral subdural hematoma, which results from blow and counterblow injuries.

In most cases, epidural hematoma is the only intracranial lesion observed after traumatic brain injury. Its association with significant intra-axial lesions is less than 15%. Prompt surgical evacuation of epidural hematoma is normally associated with good prognosis. Irrespective of the surgical delay in this type of injury, a correlation exists between delay and increased mortality. Similarly, epidural hematomas >2 cm, with areas of different densities (suggestive of active bleeding) and midline shift are usually associated with poor outcome unless promptly removed.

6.2.3 Subdural Hematoma

Subdural hematoma may be considered similar to epidural hematoma because it arises in adjacent anatomical structures; however, it carries a different prognosis and pathogenetic meaning. There are small superficial cerebral veins that flow toward the large venous sinuses, crossing the subarachnoid and the subdural spaces. These veins are relatively straight lines and very susceptible to rotation, deceleration and traction motions that occur in traumatic brain injury. Tearing of bridging veins is the most common cause of hematoma in the subdural space. This virtual space is only evident due to the mechanism of increased pressure that allows it to be revealed. A less frequent mechanism of subdural hematoma is cerebral contusion adjacent to the subdural space, with bleeding into the subarachnoid-pia mater space.

Occasionally, subdural hematomas can be observed after rupture of a large intracerebral hematoma in the subdural space. Although a subdural hematoma can arise in the cranial region that has been directly hit, it is more commonly found in the counterblow re-

gions. Typically, the morphology of subdural hematoma on a CT scan is a hyperdense lesion next to the bone, with a lens convergent-shaped opacity of homogenous density; at high attenuation it appears on the CT scan with less neat borders than an epidural hematoma. Acute subdural hematomas (Figure 6.3) are more frequently located at a brain convexity, mainly in the parietal region and less frequently in the frontal lobe and occipital area. Sometimes, subdural hematomas can be difficult to identify on the CT scan due to subjacent cranial bone. In order to minimize this effect, the signal amplitude and the CT scan window need to be adjusted to better identify the injury.

The second most frequent location of subdural hematoma is the tentorium, evidenced as an asymmetry in the typical "Y" morphology of the tentorium surrounding the vermis. Less frequent is an interhemispheric location (due to laceration of the veins draining into the sagittal sinus). Interhemispheric subdural hematomas are frequently associated with coagulopathy or platelet dysfunction. It is not unusual to observe acute subdural hematomas of atypical morphology. Sometimes, acute subdural hematomas of heterogeneous density, with a mixture of low and high attenuation areas, suggest active bleeding or a subarachnoid leak into the subdural space. Frequently, hyperacute subdural hematomas do not present a morphology typical of subdural hematoma, but a lens-shaped form instead. Although the exact mechanism underlying this morphology is unclear, intense bleeding (minutes after the accident) and blockage of the subdural space due to arachnoid adherences are thought to be involved. One characteristic of acute traumatic subdural hematoma is its frequent association with other intracranial lesions. Posttraumatic acute subdural hematoma is seldom an isolated lesion. Like single traumatic intracranial lesions, posttraumatic acute subdural hematomas are not usually associated with relevant trauma, anticoagulant or anti-platelet aggregation therapy. In more than 80% of traumatic injuries, subdural hematomas and intracerebral lesions are adjacent, the latter sometimes involved in the genesis of the subdural hematoma. This is one of the reasons why traumatic subdural hematomas have a worse prognosis than epidural hematomas. The poor prognosis of subdural hematoma is mainly due to two factors: mass effect (surgical evacuation in the first 4 hours after trauma carries a better prognosis); and its association with other intracranial lesions that result in compression of the lateral ventricles, midline shift, and intracranial hypertension among others.

6.2.4 Cerebral Contusion and Cerebral Hematoma

Cerebral contusion is the second most frequent intracranial lesion after head trauma. Cerebral contusion can be defined as a cerebral lesion due to a direct blow to the head. CT scans of cerebral contusions show images of a mixture of hypo- and hyperdensities due to dispersed multiple petechial injuries in the damaged area, associated with areas of edema and/or tissue necrosis (Figure 6.4). Depending on its location and the mechanism of injury, cerebral contusions can be classified into different groups. When the contusion results from the direct effect of bone impact on the brain, the contusion underlies the

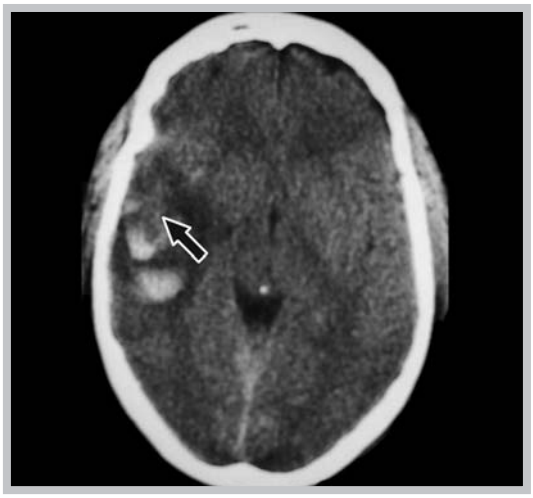

Figure 6.4. **Image of mixed contusion in the right temporal lobe (black arrow).**

bone. Cerebral contusions resulting from counterblow may be located in the contralateral region of impact. The precise mechanism of injury is not clear; however, the gradients of negative pressure generated during the blow may play an important role.
Although cerebral contusions can occur in any part of the brain, the regions most often affected in traumatic brain injury are the inferior areas of the frontal and the temporal lobes. This is probably due to the regions sliding over the surface of the anterior and temporal fossa during sudden acceleration/deceleration accompanying the trauma. The regions most often involved are the brain areas subjacent to bones (inferior frontal bone, petrosal crest, etc.). The parasagittal region is also frequently damaged, whereas the cerebellum and occipital areas are less often affected.
Intracerebral hematoma is seen on the CT scan as a hyperdense intracerebral area with sharp borders at an attenuation between +70 and +90 HU. If an intracerebral hematoma is observed on the CT scan, it has to be >25 ml in volume to be included in the TCDB classification as a significant mass lesion. This value is arbitrary and probably reflects more a distinction of surgical relevance rather than a neuroanatomical difference. The CT scan can show key characteristics of an intraparenchymal cerebral hematoma to aid in deciding whether to remove the hematoma. Besides volume, tomographic data need to be taken into consideration in hematoma removal. A midline shift of >7 mm is a relevant element to support the decision for surgical removal. The location of cerebral contusions is also important when establishing the indication for surgery. Voluminous hemorrhagic contusions in the temporal lobe compressing the basal cisterns, even without midline shifting, correlate with sudden deterioration in consciousness. Therefore, this kind of cerebral contusion must also be considered as potentially surgically removable.

6.2.5 Increase in Cerebral Volume After Traumatic Brain Injury

Increased cerebral volume due to either brain edema or a rise in cerebral blood volume causes the cerebrospinal fluid (CSF) to move out of the skull toward the spinal spaces. On the CT scan the increase in cerebral volume is mainly shown by the absence of CSF in its usual position. Absent or decreased CSF on the CT scan may not only be due to brain edema but it can be also associated with an intracranial increase of the intravascular compartment, which frequently occurs in posttraumatic cerebral hyperemia.

Figure 6.5. **Image suggesting intracranial hypertension (black circle), with absence of the ambiens cistern.**

For the tomographic diagnosis of an increase in cerebral volume, the following data are relevant: absence or decrease in the size of the ambiens cistern, absence or decrease in the size of the third ventricle, absence or decrease in the size of the lateral ventricles, absence of perihemispheric CSF (Figures 6.5 and 6.6), and/or decrease in the size of the cistern of the great cerebral vein of Galen.
Some practical aspects should be considered before evaluating the absence of CSF as a clue to increased cerebral volume. When estimating the size of the lateral ventricles, the patient's age should always be taken into account: CSF volume is lower in the lateral ventricles of young

patients. The absence of perihemispheric CSF is a sensitive finding to establish the suspicion of increased cerebral blood volume; however, this high sensitivity is accompanied by a low specificity because the cerebrospinal spaces can be reduced by hypoventilation and/or other mechanisms that will transiently increase cerebral blood volume.

In contrast, the decrease or absence of the basal cisterns and a decrease in the size of the third ventricle (specifically defined as a relevant element suggestive of type III injury in the TCDB classification) are the most specific indicators of an increase in cerebral volume due to a pathological mechanism. Analysis of the cistern of the internal cerebral vein deserves special mention, as it is often present even in patients with intracranial hypertension and cerebral herniation. Its absence is highly suggestive of large supratentorial masses not always clearly visible on the CT scan, like subdural hematomas close to the vertex.

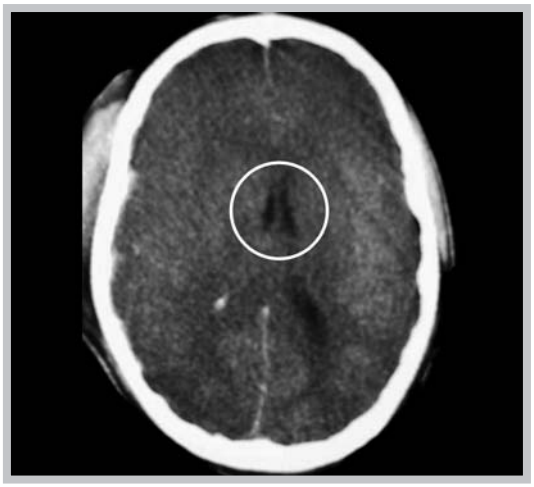

Figure 6.6. **Generalized increase in cerebral volume. Absence of the cerebral sulci. Decrease in the size of the lateral ventricles (black circle).**

6.2.6 Injuries Compatible With Diffuse Axonal Injury

The term diffuse axonal injury was coined by S.J. Strich in 1956 to describe a series of injuries, usually of small volume, subsequent to head injury and sometimes associated with severe neurological dysfunction and occasionally irreversible. Some authors hold that there is a certain degree of axonal injury in all severely head-injured patients. The predominant locations of diffuse axonal injury are: the parasagittal white matter close to the grey matter; the corpus callosum; the pontine-mesencephalic union; and the cerebellar peduncles. In white matter damage, the most frequent location is the frontal region and periventricular regions of the temporal lobes, normally next to the temporal horn of the lateral ventricle.

Adams classifies axonal diffuse injury into three grades of severity: mild, moderate and severe. In this classification scheme, mild injury (grade I) is characterized by microscopic changes in the white matter of the cerebral cortex, the corpus callosum, the brainstem and occasionally the cerebellum. Moderate diffuse axonal injury (grade II) is defined as the presence of evident focal changes in the corpus callosum. Severe axonal diffuse in-

Degree	Description
I	Evidence of axonal injury consisting of small lesions in the white matter of the cerebral hemispheres, the corpus callosum, the brain stem and, occasionally, the cerebellum
II	Focal macroscopic lesions in the inferior part of the corpus callosum, sometimes on one side of the midline but extending over several centimetres rostrocaudal, and in the white matter of the cerebral hemispheres
III	I and II degree lesions may be present, as well as evidence of hemorrhagic focal injuries in a dorsal lateral quadrant of the mesencephalon or the superior third part of the protuberance

Table 6.4. **Morphologic classification of diffuse axonal injury based on Gennarelli's classification.**

jury (grade III) comprises grade II lesions plus injuries in the dorsolateral region of the brainstem, usually in the superior cerebellar peduncles.

Table 6.4 shows the modified Gennarelli's classification system. Gennarelli's classification is based on anatomical findings; however, it is the basis for radiological approaches to the classification of diffuse axonal injury. In addition to the elements included in Gennarelli's classification, injuries in the anterior commissure, the septum pellucidum and the fornix are frequently associated with corpus callosum lesions.

The principal mechanism involved in diffuse axonal injury is the shearing of the axonal structures or the stretching of these regions in which axons are predominant. Diffuse axonal injury is generated by rotation and acceleration/deceleration movements of the skull, which stretch and break the nerve fibers. It is accepted that the severity of diffuse axonal injury is higher after oblique and lateral impacts of the head than after a sagittal impact.

CT is not the best radiological technique for the diagnosis of diffuse axonal injury. Often, small hypodense lesions will not show up on a CT scan because the lesions present an attenuation indistinguishable from normal cerebral tissue. Nevertheless, the CT scan can be useful to suspect the existence of diffuse axonal injury as much for radiological direct signs as indirect signs. The CT scan can more easily reveal diffuse axonal injuries with hemorrhagic components, and it is less sensitive in the diagnosis when radiological hypodensity predominates. Since most axonal diffuse injuries are small lesions and less than 30% of them are hemorrhagic, CT is not the best method for their diagnosis.

The most frequent locations of diffuse axonal injury are the lobar white matter, the corpus callosum, and the brainstem. The junction between the grey matter and the white lobar matter, because of the abrupt change in tissue density, is the zone where axonal diffuse injuries are most frequently observed. They appear as small ovoid lesions with their major axis directed towards the axon affected. This type of injury has a certain predilection for the parasagittal region.

The area with the second highest incidence of axonal diffuse injury is the corpus callosum and the splenius zone in particular. The two hypotheses that reasonably explain this localization are: 1). The direct impact of the falx cerebri on the corpus callosum; 2). The rotational forces transmitted to the corpus callosum.

Diffuse axonal injury in the corpus callosum most often appears as a focal lesion, midline placed, frequently situated on the splenius and less often in the body or the genu of the corpus callosum. Occasionally, it is accompanied by intraventricular bleeding due to rupture of subependymal veins.

Diffuse axonal injury can be accurately diagnosed using magnetic resonance instead of CT. Magnetic resonance is sensitive enough to detect hemorrhagic and non-hemorrhagic lesions; however, several sequences are necessary to obtain a precise diagnosis.

Brainstem lesions, the most severe axonal diffuse injuries, are usually associated with multiple hemorrhages in the white matter and the corpus callosum. For this reason, they are considered sensitive indicators of axonal diffuse injury. The most frequent location of diffuse axonal injury in the brainstem is the dorsolateral region of the mesencephalon, although it is sometimes difficult on a CT scan to differentiate between the mesencephalon and the perimesencephalon) (Figures 6.7 and 6.8). Also frequent are injuries in the posterior limb of the internal capsule due to small lacerations of the lenticulostriate arteries that irrigate this zone. Less frequent injuries are those of the lenticular nucleus, the external capsula and/or the thalamus.

In patients with axonal diffuse injury, there are other radiological signs that, although not strictly injuries of the cerebral parenchyma, are usually associated with axonal damage. Among these, intraventricular hemorrhage and subarachnoid hemorrhage should be mentioned. Intraventricular hemorrhage is often produced by blood coming from a

cerebral hematoma into the intraventricular space and less frequently due to laceration of the subependymal veins. The clinical picture of this injury depends on concomitant injuries and/or the presence of hydrocephalus.

Posttraumatic subarachnoid hemorrhage appears on the CT scan as a hyperdense area of irregular distribution that spreads out around the cerebral hemispheres and into the cistern spaces; it can be caused by blow and counterblow injuries and can be observed in sites distant to the area of impact. Typical locations are the interpeduncularis cistern and the sulcus lateralis (fissure of Sylvius), often without generating mass effect. The clinical picture of posttraumatic subarachnoid hemorrhage is related to the risk of vasospasm and the symptoms arising from concomitant injuries. Traumatic subarachnoid hemorrhage has been demonstrated to be an independent factor for poor prognosis after traumatic brain injury. The coexistence of these lesions on a CT scan is associated with very poor outcome.

Diffuse axonal damage, because it produces defects in intrahemispheric and interhemispheric communication, is one of the most clinically relevant findings in the prognosis of head-injured patients. In general, complete recovery varies individually. Nevertheless, an inverse relationship has been observed between the Glasgow Coma Scale (GCS) score at admission and the Glasgow Outcome Scale (GOS), with a worse functional outcome for patients with brainstem injuries.

6.3 CT in Patients With Cerebrovascular Hemorrhagic Disease

6.3.1 Spontaneous Subarachnoid Hemorrhage

Spontaneous subarachnoid hemorrhage is a hemorrhagic cerebral disease that can be easily diagnosed at CT. The present generation of scanners can establish a diagnosis of intracranial subarachnoid hemorrhage in almost 100% of cases. The absence of subarachnoid blood on a CT scan, associated with bleeding demonstrated by lumbar

puncture, correlates with low hematocrit (<23%), in which bleeding can be principally isodense. Where CT cannot be diagnostic for subarachnoid hemorrhage is in patients with severe coagulopathy or in those under anticoagulation therapy.

Similarly, subarachnoid hemorrhage detected by lumbar puncture without evidence of blood on the CT scan should prompt us to suspect subarachnoid hemorrhage due to extra-cranial bleeding (arteriovenous spinal malformation, etc.). It is also possible that blood not appearing in the subarachnoid space on the CT scan could be due to the occurrence of bleeding several days before; nevertheless, blood in the subarachnoid space can be detected on the CT scan even at the end of the first week after bleeding in almost 50% of cases.

Within days after the hemorrhage, the blood in the subarachnoid space decreases and the subarachnoid hemorrhage observed on the CT scan becomes isodense in relation to the parenchyma, which appears as a false image of obliteration of the cortical subarachnoid spaces and basal cisterns, simulating diffuse brain edema and suggesting an increase in intracranial pressure.

Magnetic resonance imaging (MRI) is more sensitive than CT to detect small subarachnoid hemorrhages in the subarachnoid spaces. An additional advantage is MRI's ability to identify small calcifications sometimes associated with vascular disease.

One of the classic classification systems for the evaluation of spontaneous subarachnoid hemorrhage according to CT scan findings is Fisher's classification (Table 6.5). Fisher designed this system to predict the development of vasospasm according to four risk categories from lowest to highest as follows: 1) no subarachnoid hemorrhage; 2) diffuse bleeding or a thin blood layer in the vertical subarachnoid structures <1 mm thick; 3) localized clots and/or vertical layers of blood in the subarachnoid vertical structures >1 mm thick; 4) diffuse bleeding or absence of subarachnoid blood but with intracerebral clots or intraventricular hemorrhage.

According to Fischer's classification, the presence of blood should be checked in at least the following locations: 1) frontal intercerebral fissure, including the region next to the genu of corpus callosum; 2) basal frontal fissure, including the inferomedial region of the hemisphere next to the region of the anterior communicating artery; 3) parieto-occipital fissure (posterior intercerebral fissure); 4) base of the sylvian fissure, (horizontal portion of the sylvian fissure around the proximal part of the middle cerebral artery and its bifurcation); 5) sylvian cistern (inferior part of the sylvian fissure adjacent to the middle cerebral artery); 6) insular cistern (subarachnoid space guided vertically on the surface of the insula); 7) sylvian fissure (part of the sylvian fissure superior to the surface of the temporal lobe); 8) suprasellar cistern (Circle of Willis region); 9) ambiens cistern (perimesencephalic space vertically guided); 10) quadrigeminal cistern (subarachnoid space adjacent to the quadrigeminal bodies); 11) cerebral transverse fissure between the corpus callosum, fornix and diencephalon; 12) prepontine cistern ventral to the base of the protuberance; 13) cerebellar superior cistern on the surface of the brain.

Degree	Characteristics
1	No bleeding on the CT scan
2	Diffuse bleeding or thin blood layer in any one of the vertical subarachnoid structures (intercerebral fissure, insular cistern, cistern ambiens) <1 mm thick
3	Localized clots and/or vertical layers of blood in the subarachnoid vertical structures ≥1 mm thick
4	Diffuse bleeding or absence of subarachnoid blood, but with intracerebral or intraventricular clots

Table 6.5. Fisher's scale.

Grade	Characteristics
0	No subarachnoid hemorrhage or intraventricular hemorrhage
1	Minimal/thin subarachnoid hemorrhage, no intraventricular hemorrhage in both lateral ventricles
2	Minimal/thin subarachnoid hemorrhage, with intraventricular hemorrhage in both lateral ventricles
3	Thick subarachnoid hemorrhage, no intraventricular hemorrhage in both lateral ventricles
4	Thick subarachnoid hemorrhage, with intraventricular hemorrhage in both lateral ventricles

Table 6.6. **Revised Fisher's scale.**

Fisher's classification was derived from a study that had limitations which aroused objections, including: 1) it did not involve a consecutive series of patients, which can be inferred from the high incidence of vasospasm in the series; 2) the high rate of patients grouped in risk category I probably due to the scanner generation in use at that time; 3) the inclusion of patients within 1-5 days after clinical signs of bleeding, which probably facilitated the clearance of blood in the subarachnoid space and therefore on the CT scan.

A later modified Fisher's Scale (Table 6.6) incorporated elements known to influence the etiology of cerebral ischemia. These elements quantify the intensity of subarachnoid hemorrhage (including the impact of intraventricular hemorrhage on prognosis). Their relevance for prognosis in the prediction of neurological deficits after subarachnoid hemorrhage has been also tested.

The magnitude of blood on the CT scan after a subarachnoid hemorrhage is a general indicator of the severity of the clinical process (Figures 6.9 and 6.10).

Patients with subarachnoid hemorrhage with relevant bleeding on a CT scan have a worse outcome. In fact, Fisher's classification seeks to establish a direct relationship between the amount of bleeding visible on the CT scan and the risk of vasospasm over the following days.

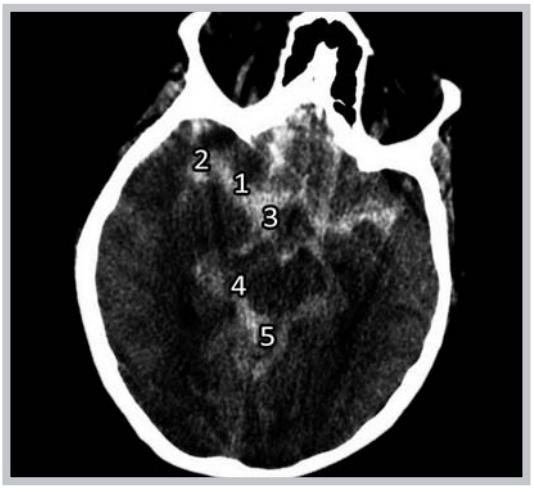

Figure 6.9. **Spontaneous subarachnoid hemorrhage with bleeding in the sylvian fissure.**

1 = Trunk
2 = Sylvian fissure (lateral)
3 = Suprasellar cistern
4 = Ambiens cistern
5 = Quadrigeminal cistern

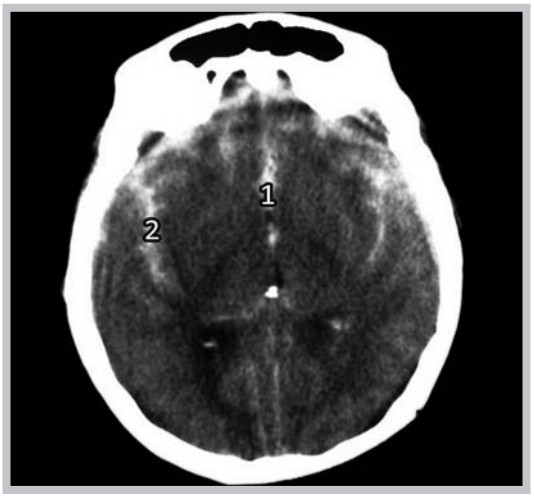

Figure 6.10. **Spontaneous subarachnoid hemorrhage with bleeding.**

1 = Intercerebral fissure
2 = Sylvian fissure (lateral)

Estimating the exact amount of blood in the subarachnoid space on a CT scan is not easy because of: 1) irregular distribution of cisterns and fissures; 2) CT cross-sections do not correspond to the anatomical distribution of the subarachnoid spaces; 3) different amounts of blood in the subarachnoid regions; 4) inaccuracy in the measurement of the intensity in HU or the frequent coexistence of the partial volume effect; 5) progressive tendency to isodensity of bleeding over time.

To quantify the intensity of the bleeding in the basal cisterns in patients with subarachnoid hemorrhage, Hijdra et al. developed a quantitative system that could be used to score the extent of bleeding in 10 subarachnoid spaces close to the circle of Willis. Blood should be quantified in the following spaces: frontal intercerebral fissure; lateral sylvian fissures; basal sylvian fissures; suprasellar cistern (bilateral quantification); ambiens cistern (bilateral quantification); and quadrigeminal cistern. Bleeding intensity is scored as follows: no blood in the subarachnoid space (0); small quantity of blood (1); moderate quantity (2); a subarachnoid space completely filled with blood (3).

The range of the intensity of a subarachnoid hemorrhage is between 1 and 30 points on this scale. The location of bleeding on a CT scan in subarachnoid hemorrhage can aid in detecting an aneurysm in the circle of Willis. In a bleeding aneurysm of the anterior communicating artery, the hyperdensity is usually located in the suprasellar cistern and the frontal intercerebral fissure, with spread to the frontal regions and less frequently to the pericallosal cistern and the sylvian fissure. In severe bleeding of the anterior communicating artery, intracerebral hematomas in the frontobasal regions are frequently observed. A bleeding internal carotid artery aneurysm in the supraclinoid segment shows a variety of locations of blood on the CT scan, including: the suprasellar cistern; the interpeduncularis cistern; the sylvian fissure; and the anterior intercerebral fissure. In middle cerebral artery bleeding, the most frequent locations of blood are the sylvian fissure and the suprasellar cistern. Intracerebral hematomas in the parasylvian areas are also common in sylvian aneurysms. Hemorrhage due to an aneurysm of the distal segments of the basilar artery often evidences blood in the suprasellar cistern, the perimesencephalic cistern, and the interpeduncular cistern, while in bleeding aneurysms of the posteroinferior cerebellar artery, blood is typically revealed in the prepontine and the pericerebellar cistern.

6.3.2 CT in the Diagnosis of Intraventricular Hemorrhage

Intraventricular hemorrhage is a frequent finding after a subarachnoid hemorrhage. The higher incidence of intraventricular bleeding after an aneurysm rupture is associated with an aneurysm of the anterior communicating artery in which the lateral ventricles and the third and fourth ventricles are flooded with blood. This type of bleeding is also frequent in rupture of carotid aneurysms and sylvian aneurysms. In subarachnoid hemorrhage due to an aneurysm of the posteroinferior cerebellar artery, the bleeding often affects the third and fourth ventricles, without extension to the lateral ventricles. The increase in resistance to the physiological circulation of CSF due to ventricular bleeding and altered fluid reabsorption frequently correlates with hydrocephalus.

Severe spontaneous intracerebral hemorrhage is also frequently associated with ventricular bleeding. The incidence of intraventricular hemorrhage is higher in thalamic hematoma or in putamina hematoma with thalamic extension. In interventricular hemorrhage associated with brain injury, the incidence is lower than in cerebrovascular hemorrhagic disease. Traumatic intraventricular hemorrhage is often associated with mechanisms of acceleration/deceleration that frequently cause diffuse axonal injury and is often due to rupture of the subependymal veins.

Site	Characteristics	Score
Right lateral ventricle	Trace of blood or mild bleeding	1
	Less than half of the ventricle filled with blood	2
	More than half of the ventricle filled with blood	3
	Ventricle filled with blood and expanded	4
Right lateral ventricle	Trace of blood or mild bleeding	1
	Less than half of the ventricle filled with blood	2
	More than half of the ventricle filled with blood	3
	Ventricle filled with blood and expanded	4
Third ventricle	Blood present, ventricle size normal	1
	Ventricle filled with blood and expanded	2
Fourth ventricle	Blood present, ventricle size normal	1
	Ventricle filled with blood and expanded	2

Table 6.7. **Graeb's scale. Each lateral ventricle is scored separately. The maximum score is 12 points.**

In 1982, Graeb et al. reported on the relevance of interventricular bleeding in acute neurological patients and developed a classification scheme to quantify intraventricular bleeding in patients with cerebrovascular disease and head trauma. Because of the high incidence of intraventricular bleeding in subarachnoid hemorrhage and spontaneous intracerebral hemorrhage, Graeb's classification is chiefly used in patients with spontaneous intracranial hemorrhagic. Table 6.7 illustrates the scoring system according to CT scan findings.

The maximum score is assigned for blood flooding the lateral ventricles, including also the presence of blood in the third and fourth ventricles. It is important to emphasize that "ventricles full of blood and expanded" indicates the presence of a ventricular dilatation directly attributable to bleeding and not to the possible coexistence of hydrocephalus. The maximum score is 12 points. There is general consensus that a score >7 implies intraventricular bleeding associated with clinical severity.

A similar scale described by Le Roux et al., although initially used to assess ventricular hemorrhage associated with traumatic brain injury, has been frequently used to evaluate intraventricular hemorrhages due to spontaneous subarachnoid hemorrhage. Le Roux's scale quantifies between 1 (minimal quantity of blood) and 4 (completely full ventricle) the invasion by blood into the third, fourth and each of the lateral ventricles. The score range on the Le Roux scale is 1-16 points.

6.3.3 CT in Spontaneous Intracerebral Hematoma

Compared with normal parenchyma, spontaneous intracerebral hematoma appears on the CT scan as a hyperdense area inside the cerebral parenchyma, usually generating mass effect. The hyperdensity is due to the presence of hemoglobin (90%) and only partially to the iron concentration (8%). Clot retraction causes a substantial increase in blood cell volume and therefore an increase in radiological density (+90-100 HU). Generally, small-volume intracerebral hematomas present with a rounded or oval shape, with relatively neat borders, whereas high-volume hematomas show irregular and indistinct borders, as well as asymmetric morphology. In 88% of cases, spontaneous intracerebral hemorrhage occurs inside the cerebral hemispheres, 8% in the cerebellum, and 4% in the brainstem.

The precise location of intracerebral hematoma on the CT scan is relevant to determine:

- Etiology, pathogenesis of the hematoma and its possible association with arterial hypertension. These last hematomas are usually located in the basal ganglia, whereas hematomas with an etiology other than hypertension, as for example, neoplasia or arteriovenous malformations, will vary in location (lobar hematoma, posterior fossa, etc.).
- Clinical picture should agree with the location of the hematoma in terms of the brain structures affected by the bleeding.
- Outcome, which obviously correlates with the location and extension of the intracerebral hemorrhage.
- Treatment which will differ according to hematoma location and volume, the clinical picture, etc.

Hypertensive hematomas are more often situated in the putamen (lateral location) and the thalamus (medial location). Thalamic hematomas account for 15-25% of these hematomas, often smaller than putaminal hematomas due to the smaller size of the nucleus and due to its fibre content, which makes the diffusion of blood difficult. Most putaminal hematomas (60%) present with ventricular bleeding which in more severe cases spreads out toward the mesencephalon.

Putaminal hematoma has a higher incidence than mesencephalic hematoma. Most high-volume putaminal hematomas tend to affect adjacent neurological structures (Figure 6.11) and only a low percentage (17%) remain confined exclusively to the putamen. Around 10% extend to the external capsula. Putaminal-capsulae hematomas have a worse outcome when they extend to the semi-oval centre. Nevertheless, the poorest prognosis is associated with putaminal hematomas with hemispheric extension (20% of cases) and putaminal-thalamic hematomas (about 20% of these hematomas). The former tend to extend toward the cerebral hemispheres and the corona radiate, the latter also to the thalamus and the intraventricular space.

Lobar intracerebral hemorrhage (Figure 6.12) has a predominant parietal (30%) and frontal location (20%), although they can sometimes be situated in more than one cerebral lobe. Less frequently they are found in the occipital region (15%). The intraventricular extension of bleeding is less frequent in lobar hematomas than in basal ganglia hematomas.

Figure 6.11. **Left putaminal hematoma (black arrow) with compression of the external capsule and ventricular bleeding.**

CT in patients with spontaneous intracerebral hemorrhage does not differ from that for head-injured patients, except that in the cases of hypertensive etiology, contrast-enhanced CT is advisable. Generally speaking, the use of contrast-enhanced CT scan is indicated in: 1) patients younger than 40 years of age; 2) patients without a clinical history of high blood pressure; 3) hematoma of atypical morphology or with extensive invasion of the subarachnoid or subdural space; 4) patients with previous comorbidities such as neoplasms, bacterial endocarditis, arteritis or others.

In spontaneous intracerebral hemorrhage the volume of the bleeding is recognized as a key element with a better prognosis and therapeutic relevance. The location also has relevance for prognosis and ther-

apeutic approach. Table 6.8 lists the most frequent topographic locations of spontaneous idiopathic intracerebral hematoma. Evaluation of the CT scan of a patient with a high-volume spontaneous intracerebral hematoma would be incomplete without an analysis of the phenomena that the hematoma generates in adjacent and contiguous brain structures. Here it is essential to evaluate: midline shift, effacement of the cerebral sulci, and compression of the cisterns of the skull base. The ambiens cistern is frequently compressed in high-volume spontaneous intracerebal hemorrhages, and compression or absence of the cistern suggests a high risk of transtentorial herniation. In hematomas of the posterior fossa, estimating the volume is especially relevant due to potential compression or disappearance of the cerebellar superior cistern and the magna cistern.

Figure 6.12. Occipital lobar hematoma (black arrow) with ventricular bleeding.

Among the major factors in the outcome of cerebral spontaneous hematoma there are its volume and its influence on key brain structures. There are several methods to facilitate quantification of intracerebral hematoma volume.

Broderick's Formula. Investigating the influence of the volume (ml) of spontaneous intracerebral hemorrhage 30 days after bleeding, Broderick et al. used the formula of the ellipsoid: 4/3 ∏ABC, wherein A is the largest diameter of the hemorrhage (cm); B the diameter of the hemorrhage 90º to A, and C the height (cm) of the hematoma calculated by multiplying the number of slices involved with the slice in thickness.

Formula of Kothari. In 1996 Kothari et al. developed a method to estimate hematoma volume on the CT scan according to the ABC/2 method, wherein A is the greatest hemor-

Lobar hematoma	• Parietal • Frontal • Occipital
Thalamus	• Type I: Thalamus • Type II: Thalamus and internal capsule • Type III: Thalamus extending to mesencephalon/hypothalamus
Caudate nucleus hematoma	
Putamen nucleus hematoma	• Putamen nucleus • Lateral putaminal hematoma • Anterior putaminal hematoma • Posterior putaminal hematoma • Medial putaminal hematoma • Putaminal-thalamic hematoma • Putaminal-hemispheric hematoma
Cerebellar hematoma	• Vermis • Cerebellar hemisphere hematoma • Vermis and cerebellar hemisphere hematoma
Brainstem hematoma	

Table 6.8. Classification of spontaneous intracerebral hematomas according to CT scan findings.

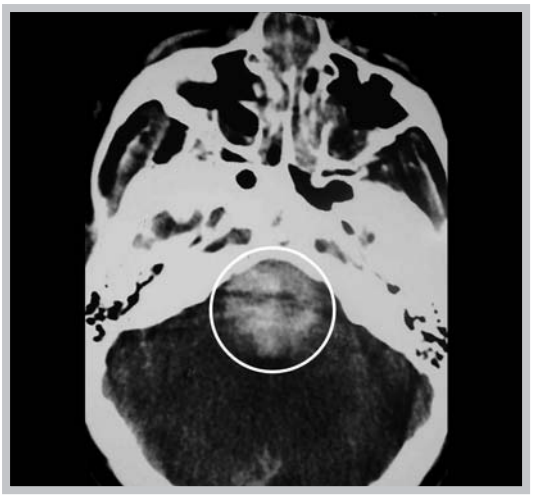

Figure 6.13. **Hematoma of the brainstem (black circle).**

rhage diameter by CT; B is the diameter of the 90 degrees to A; and C is the approximate number of 10-mm CT slices where the hematoma can be observed. With regard to C, if one slice of the hemorrhagic area is >75% of the area observed in slice A, the value of C is 1. If the area is between 25 and 75% of the maximum area, C is 0.5; if the area is <25%, then C is not considered at this level. In all cases, the values of A and B are measured in centimetres on the CT image, bringing the values nearer to 0.5 cm.

Formula of the sphere. A simpler way to calculate hematoma volume is by approximation of the volume by "transforming" the hematoma into a sphere. To do this, the diameters A, B and C are estimated, and the average thereof is calculated. Once one diameter is known, the formula is used to calculate the sphere. The formula is: volume of the sphere $4/3\prod r^2$, wherein r is the average radius of the theoretical sphere. In patients with acute neurological deficit, CT is useful to rule out the presence of infratentorial hematoma. A cerebellar hematoma can be located in the cerebellar hemispheres, the vermis or in both. According its location and size, cerebellar hematoma can be amenable to surgical treatment. Therefore, it is very important to make an early diagnosis of the size of volume and diameter of a cerebellar hematoma. Mesencephalic and brainstem hematomas are only susceptible to medical treatment, and in many cases are associated with poor outcome (Figure 6.13).

6.4 CT in the Diagnosis of Acute Ischemic Cerebrovascular Diseases

The early diagnosis of acute ischemic cerebral disease is based on the CT scan. Despite the limitations of CT in the early diagnosis of some ischemic brain lesions, an imaging study should be performed as an emergency procedure before the suspicion of acute ischemic cerebrovascular disease. Therapeutic and prognostic implications can be derived from an early CT scan and accurate interpretation of the images. Accuracy in the diagnosis of ischemic stroke is high when CT and MRI are combined. Nevertheless, the lack of accessibility to MRI in most hospitals means that CT is the most useful technique for emergency department physicians.

CT scan findings in patients with neurological deficits due to ischemic stroke are not always correlated with the clinical picture. Patients with eloquent deficits may not have clear pathological findings on the CT scan. Similarly, it is not infrequent to find on the CT scan of these patients some clinically silent ischemic lesions (probably old lesions). CT can be very useful not only to establish a diagnosis of cerebral ischemia secondary to occlusion of a great vascular territory, for example, the middle cerebral artery, etc, but also of small terminal arterial territories (Heubner's artery, perforating arteries, etc.). CT can also evidence ischemia of border vascular territories (watershed infarct), for exam-

ple, the territory between the middle cerebral artery and the anterior cerebral artery, the region of the girus angularis, etc.

A CT scan without contrast, with a window between 0 and +70 HU, may be a standard procedure in the first approach to a patient with suspected acute ischemic stroke. On the other hand, a window between +0 and +70 HU provides a higher number of the "range of grey" to distinguish between normal cerebral structures and hypodense cerebral structures resulting from cerebral ischemia. CT without contrast is significantly less useful in the diagnosis of cerebral ischemia in the posterior fossa processes due to the lack of spatial resolution and the radiological bone-generated artifacts. Apart from the clinical presentation, the clinical data that should be considered in order to identify cerebral ischemia signs on the CT scan of a patient with acute cerebrovascular symptoms are: 1) location of hypodense areas; 2) morphology of hypodense areas; 3) the presence of mass effect.

Table 6.9 illustrates a schematic approach to a patient with suspected acute ischemia. The vascular territories most frequently affected in acute ischemic diseases are the middle/cerebral artery, the posterior cerebral artery, the anterior cerebral artery, and the basilar artery.

The early changes that occur after acute cerebral ischemia must often be inferred from indirect radiological signs. The radiological signs start in the grey matter, with decreasing radiological intensity. Therefore, a decrease in the differentiation between white matter and grey matter is a frequently described sign suggestive of ischemia. Direct measurement of the radiation absorption units on CT scan can aid in the diagnosis of ischemia. In normal conditions, the grey matter has an attenuation coefficient between +30 and +35 HU, while that of the white matter is between +20 and +25 HU. In ischemia, the attenuation decreases and the contrast between the grey matter and the white matter is lower.

The sensitivity of a CT study can be improved by decreasing the radiological window to a nonstandard window. For example, a window of +50 HU and a centre in +35 HU improves the discriminating capacity without losing specificity. The loss of differentiation

CT scan in the early phase of ischemic stroke	Early hypodensity	• Lack of definition of the insular cortex: "insular ribbon sign" • Hypodensity of the lentiform nucleus • Other hypodensities
	Early signs of mass effect	• Effacement of the cerebral sulci • Effacement the lateral ventricle • Compression of the rhombencephalon
	Hyperdensity of the middle cerebral artery, basilar artery	
CT scan in the late phase of ischemic stroke	Location of hypodensity	• Middle cerebral artery: subcortical, subcortical • Other arterial territories • Watershed ischemia
	Size of the infarct	• Estimation of volume • Percentage of the vascular affected territory: • Less than 1/3 • More than 1/3
	Hemorrhagic transformation	• None • Petechial • Hematoma • Mass effect

Table 6.9. **CT scan findings in ischemic stroke.**

between the white matter and the grey matter in the insular cortex, the hypodensity of the lenticular nucleus or the effacement of sulci can often be detected in the first 6 hours after stroke in almost 80% of patients with occlusion of the great intracranial arteries.

Radiological signs suggestive of acute ischemia in the territory of the middle cerebral artery are:

- The insular ribbon sign in which the ribbed edge of the insular cortex (grey matter), which is normally slightly hyperdense, disappears, becoming indistinguishable from the white matter. The absence of perfusion in this territory is due to decreased blood flow to the cortical insular area, turning it isodense as compared to the adjacent white matter.
- The decrease in radiological intensity (relative hypodensity) of territories of the basal nucleus, mainly of the lenticular nucleus and posterior limb of the internal capsule.
- Occasionally, acute ischemia can be diagnosed from the observation of embolic material in the middle cerebral artery or anyone of its branches. This material, more radio-intense than the normal brain tissue, can be evidenced in the proximal middle cerebral artery as a linear hyper-density (hyperdense middle cerebral artery sign). Some studies have demonstrated the high specificity of this sign as a key evidence for middle cerebral artery occlusion, but its sensitivity is <30%.

Embolic hyperdense material in the more distal branches of the middle cerebral artery (sign of the middle cerebral artery) inside the sylvian fissure can sometimes be observed. Some authors give more value to this sign than to the hyperdense middle cerebral artery because it can be present in 15% of patients in which the CT scan was performed within the 3 first hours. The presence of embolic material in the middle cerebral artery has been associated with a worse clinical outcome after fibrinolytic therapy. The sign of the hyperdense artery can be also observed in the basilar artery (Figure 6.14).

In acute cerebrovascular disease, CT findings such as early signs of cerebral ischemia (early signs of infarct) and signs of arterial occlusion (sign of vascular hyperdensity) can aid in making treatment decisions. Tomographic evidence of edema and mass effect is associated with a significant increment in hemorrhagic risk after thrombolytic treatment. Estimating the percentage of ischemic territory is also relevant. It has been observed that after recombinant tissue plasminogen activator (rt-PA) fibrinolysis, the risk of poor outcome is higher in cases presenting hypodense areas more than one third of the territory of the middle cerebral artery.

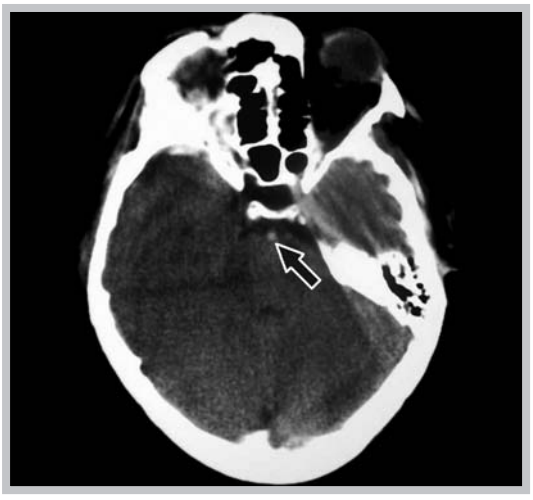

Figure 6.14. **Thrombus in the basilar artery (arterial hyperdensity) (black arrow).**

In massive cerebral infarction, it is also important to note any signs of cerebral suffering, intracranial hypertension, or risk of cerebral herniation.

These signs are similar to those described in the section on traumatic brain injury. Therapies such as decompressive craniectomy are partially based on CT scan findings. The quantification of the midline shift, the decrease in perihemispheric CSF, and the presence of subtle or advanced signs of cerebral herniation are also relevant.

6.4.1 Magnetic Resonance Imaging

Nuclear magnetic resonance (NMR), or magnetic resonance imaging (MRI), is a noninvasive and non-ionizing radiation procedure that has a unique way of contrasting tissues and offers higher spatial resolution. MRI uses radio waves and strong magnets. The technique is based on the interaction between the external magnetic field and the core with a magnetic moment different from zero. The hydrogen nucleus seems to be the best target for MRI, as it has the following advantages: 1) present in all the nuclei in human tissues and generates more signal; 2) gives the best contrast. The magnetic field forces the hydrogen atoms in the body to align in a certain way (similar to the way a compass needle moves when held near a magnet). Radio waves are sent toward the aligned hydrogen atoms, they bounce back, and a computer records the signal. Different types of tissues send back different signals. Each tissue, according to its abundance of protons and the time lapse between stimulation and return to rest (T1 and T2 sequences), emits a signal of varying intensity that is captured by the equipment. Classic MRI sequences called spin echo are being replaced by fast turbo spin, spin echo or echo, since they are faster and retain many of the signal's characteristics.
The following table details the basic signs of some tissues in the study of the central nervous system in different spin echo sequences. T1 and T2 and fluid-attenuated inversion recovery (FLAIR) is widely used because of it high sensitivity and an inversion time (the water), so that the water in the cavities and the CSF have a low FLAIR signal (black). This enhances sensitivity, particularly for subtle cortical and periventricular lesions, which may go unnoticed in T2 sequences (Table 6.10).

Requences	T1	T2	FLAIR
Water in the cavities	↓	↑	↓
Edema (free water)	↓	↑	↑
Grey matter	Grey	Grey	Light grey
White matter	White	Black	Dark grey
Calcium	↑/↓	↓	↓
Fat	↑	↑	↑
Sensibility	↓	↑	↑↑
Resolution	↑↑	↑	↓

Table 6.10. MRI sequences.

6.4.2 Advantages of MRI

Better spatial resolution and contrast of different brain structures. It provides excellent anatomic images of the posterior fossa and allows simultaneous measurement of cerebral blood flow and volume. It can visualize the arterial and venous vasculature and its anatomic relationships. It allows early detection of ischemic injury and increased water content. Higher sensitivity and specificity to show diseases of the spinal cord. Better long-term predictive power in relation to CT.

6.4.3 Disadvantages of MRI

It takes time (''Time is brain''). It cannot be performed in complex patients with pacemakers, prostheses or alongside standard equipment in critical care units. If other organ systems need to be studied at the same time, the information provided is not as complete as with CT. It does not have good resolution for bones or blood in the subarachnoid spaces. It is not available in all centres and is expensive. It usually requires a neuroradiologist to assist in the interpretation of the results and decide which sequence is most convenient.

6.4.4 Indications for Emergency

Pathologies of the posterior fossa, vertebrobasilar territory:

- Ischemic stroke and previous thrombolysis.
- Diffuse axonal injury.
- Subdural hematomas of the vertex or isodense areas.
- Herpetic encephalitis.
- Multiple sclerosis.
- Spinal cord injury.
- Cerebral venous thrombosis.
- Brain tumours.
- Secondary brain hemorrhage (arteriovenous malformation, cavernomas, etc.).

6.5 Conclusions

CT, a key technique in the development of neurocritical care, must be a part of special training for doctors involved in the management of acute neurological patients.
The technical specifications of the CT scan are key components for improving the performance of the diagnosis for neurocritical patients.
CT scan findings of head-injured patients must be assessed against the criteria of the TCDB classification and with a pathophysiological approach.
For the analysis of the CT scan in spontaneous subarachnoid hemorrhage, Fisher's scale, modified Fisher's scale, and Hijdra's scale must be used.
The CT scan in patients with acute cerebrovascular ischemic diseases can be valuable in formulating the prognosis and therapeutic strategy.

7 Intracranial Pressure Monitoring. Acute Cerebral Injury: the First 48 Hours

Cherylee WJ Chang [1]

[1] Medical Director, Neuroscience Institute/Neurocritical Care. Director, Stroke Center, The Queen's Medical Center, Honolulu. Associate Clinical Professor of Medicine and Surgery, University of Hawaii, Manoa; John A. Burns School of Medicine. President, Neurocritical Care Society

7.1 Intracranial Pressure

An understanding of the principles that determine ICP and its waveforms are important for optimal management of a patient with intracranial hypertension. Intracranial pressure is determined by the effects of atmospheric pressure, the volume of the intracranial contents, the hydrostatic pressures determined by the effect of gravity or weight on the mass of the craniospinal axis, and the elastance of the brain.

The Monro-Kellie hypothesis describes the skull as a semi-closed compartment containing the brain and interstitial fluid, cerebrospinal fluid (CSF), and blood. In a normal adult, approximately 87% of the intracranial space is occupied by the brain, 4% by the blood (60 ml), and 9% by the CSF which is estimated to be about 100-150 ml. Water composes approximately 80-90% of the volume, since the brain parenchyma contains 75-80% water.

Increases in the volume of an intracranial component, such as intravascular blood during vasodilation, or in a pathological condition, such as extravascular blood, tumour or edema, must result in the displacement of other intracranial components such as the CSF or intravascular blood (vasoconstriction) to maintain ICP normal. The CSF flows from the ventricles to the cisterna magna, basilar cisterns and subarachnoid space of the brain and spinal cord and is removed by bulk flow reabsorption over the convexities of the hemispheres in the arachnoid villi found in the walls of the dural veins. Higher hydrostatic pressure in the CSF space can drive the bulk flow and displace CSF by increasing reabsorption. At CSF pressures <5 mmHg, CSF reabsorption may diminish or cease. Increased dural sinus pressure may potentially also decrease CSF reabsorption.

Patient positioning, such as placing a patient in a head-down or Trendelenberg position, can cause an increase in ICP by increasing the hydrostatic pressure of the brain due to gravity. In addition, this position may impede venous outflow. Such venous congestion increases cerebral venous blood volume and, depending on cerebral elastance, it can also increase ICP.

Elastance describes the relationship of ICP as a result of a change in volume. The elastance of the craniospinal axis is dependent on the distension of the dura mater and, primarily, on the displacement of fluids (e.g., blood or CSF). In brain atrophy, elastance is low and changes in volume may little effect ICP. However, when compensatory mechanisms are overwhelmed, even small changes in volume may cause large increases in ICP. Normal ICP ranges between 5 and 10 mmHg. The upper limit of normal in adults and older children is 15 mmHg. During a Valsalva maneuver or sneezing, the ICP can exceed 30-50 mmHg, but it rapidly returns to normal in a brain with normal elastance.

7.2 Techniques for Monitoring Intracranial Pressure

There are various options for monitoring ICP invasively either placed intraoperatively or, more commonly, at the bedside through a burr hole. Anatomic locations of placement include ventricular, parenchymal, subarachnoid, subdural and epidural sites (Figure 7.1). Modalities include: 1) fluid-coupled monitoring; 2) fiberoptic monitoring which utilizes a reflected laser beam; and 3) piezoelectric crystal transducers which, when compressed, produce a voltage proportional to the degree of compression.

Fibre optic and piezoelectric monitors do not require other external transducers and are calibrated or "zeroed" prior to intracranial placement. These monitors are placed into the brain parenchyma and have the advantage that changes in the head of bed do not require re-levelling of a transducer. However, there may be some drift in the system over time, which causes inaccurate readings, and these monitors cannot be recalibrated. If inaccuracy due to drift is suspected, the intraparenchymal component of the monitor must be replaced with the attendant costs and potential complications of reinsertion. These monitors also have no ability to drain CSF.

The zero point for the fibre optic or electronic monitor is at the tip of the catheter. If the monitor is placed deeply compared to a more superficial placement, the measured ICP may be higher by several mmHg due to the hydrostatic weight of the brain above the monitor tip.

A fluid-coupled ventricular monitor is positioned with its tip in the frontal horn of a lateral ventricle. It is connected to an external strain gauge transducer and can be recalibrated and used to drain CSF, which will help with the treatment of intracranial hypertension. Both reliable and accurate, this technique is traditionally considered the gold standard for ICP monitoring. The transducer is calibrated to the level of the foramen of Monro. The tragus, which lies just anterior to the external auditory meatus, serves as the external anatomical landmark for the foramen of Monro. One disadvantage of a fluid-coupled monitor is potential obstruction by brain tissue, blood or bone especially during placement. Other drawbacks are that air within the system will dampen the waveform and artificially lower the pressure, and changes in head position require re-zeroing the transducer. When the ventricles are small and significantly compressed, placement of an intraventricular catheter may be difficult. Fluid-coupling also increases the risk of infection. Some studies have shown that the risk of infection increases with lon-

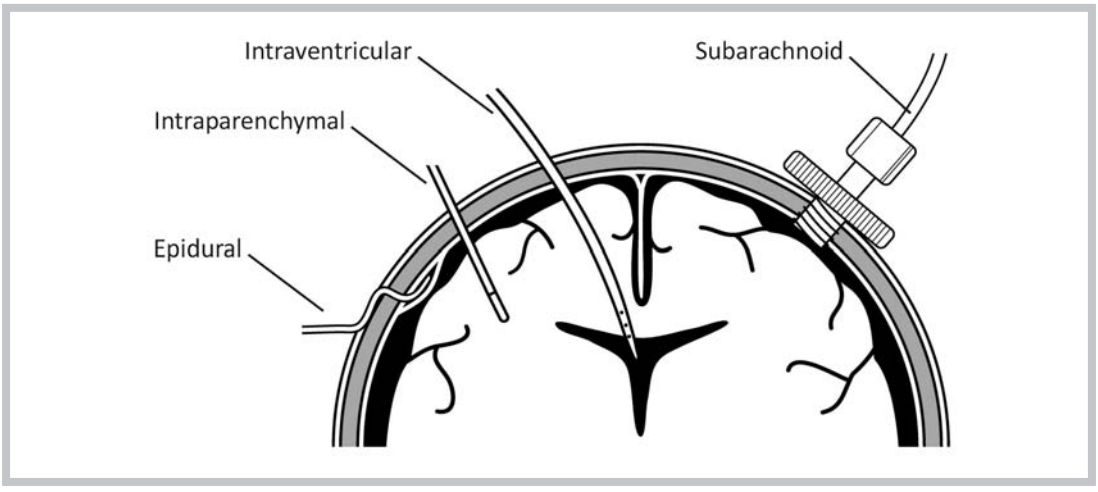

Figure 7.1. Intracranial pressure monitoring placement.

ger duration of catheter placement; however, other studies have reported that infectious risk is highest within the first 10 days and decreases thereafter. This would suggest that the infection is introduced at the time of catheter insertion. Periodic flushing with antimicrobials or routine replacement do not appear to reduce the risk of infection. The use of prophylactic antibiotics is often limited to periprocedural administration just prior to placement, since antimicrobial treatment for the duration the catheter is in place likely increases the risk of resistant organisms and may not reduce the risk of catheter-related ventriculitis. Removing the catheter as soon as possible and minimizing the frequency of opening and accessing the system may reduce the risk of infection. Subcutaneous tunnelling of the catheter away from the insertion site may also lower the risk of infection. Newer antibiotic-impregnated catheters are available.

A subarachnoid screw or bolt is a fluid-coupled metal tube secured in the skull through a burr hole and is connected to an external pressure transducer. These do not effectively drain the CSF and are less accurate than a ventricular monitor, since at higher pressures the screw becomes obstructed with brain tissue.

Subdural monitors can be placed during surgery but are not typically used as they can become obstructed and are considered less accurate.

Epidural catheters are also less accurate due to compartmentalization by the dura from the intraparenchymal space. Because there is a theoretically lower risk of hemorrhage during placement compared to an intraparenchymal monitor, epidural catheters were historically used in patients with coagulopathy who required urgent monitoring (e.g., hepatic encephalopathy and cerebral edema). But because of their inaccuracy, they are not commonly used today.

The semi-rigid dura mater creates compartments within the cranium. The falx cerebri, which is a sagittal fold of the dura mater, splits the supratentorium into two halves. The tentorium cerebelli is a fold of the dura mater that separates the occipital lobes from the cerebellum. The free edges of the tentorium cerebri bilaterally leave an opening that is traversed by the midbrain. Understanding the semi-rigid nature of the dura creating these compartments is relevant during ICP monitoring, since pressure differentials occur in different compartments. A parenchymal monitor in a frontal lobe may not detect elevation of pressure on the contralateral side or infratentorially in the cerebellum. Similarly, a fluid-coupled catheter placed into a lateral ventricle and passed too deeply past the third ventricle may not detect intracranial hypertension occurring in the supratentorium.

Lumbar drains cannot reliably measure intracranial pressure in herniation, when the intracranial and intraspinal spaces become further compartmentalized. In addition, placement of a lumbar catheter can precipitate cerebral herniation when ICP is high and removing CSF from below can create a pressure gradient with a downward shift of the brain.

7.3 The ICP Waveform

Cardiac and respiratory activity creates the pulsatile components of the ICP waveform. The normal ICP waveform has three major components: the percussion wave (P1); the tidal wave (P2); and the dicrotic wave (P3) (Figure 7.2). The percussion wave is the most constant in amplitude and results from systolic pulsation in the large intracranial arteries. The second or tidal wave (P2) is a result of the elastance of the brain. P2 and the dicrotic wave (P3) are separated by the dicrotic notch, which corresponds to the dicrotic notch of the arterial pressure waveform due to closure of the aortic valve during diasto-

le. The dicrotic wave is considered venous in origin. Respiratory contribution to ICP has a tidal variation that is dependent on changes in cerebral venous outflow due to intrapleural pressures that result from changes in intrathoracic and intraabdominal pressure during the ventilatory cycle.

The morphology and pulse pressure of the ICP waveform can be indicative of pathological states. As noted above, elastance describes the change in pressure per unit change in volume. Elastance is dependent on the capacity to displace CSF or intravascular blood when one component of the intracranial compartment increases. Since the ICP waveform results from a bolus of blood from the heart into the intracranial vault, the waveform reflects the elastance. When the elastance increases, the pulse amplitude of the ICP waveform also increases (Figure 7.3).

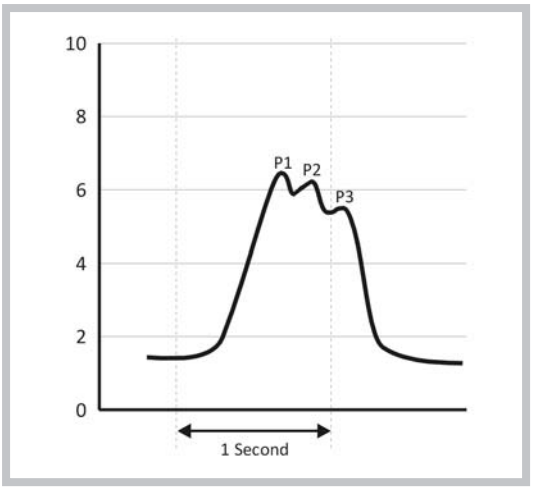

Figure 7.2. **Normal ICP waveform (in mmHg). P1 corresponds to the percussion wave, P2 the tidal wave, and P3 the dicrotic wave.**

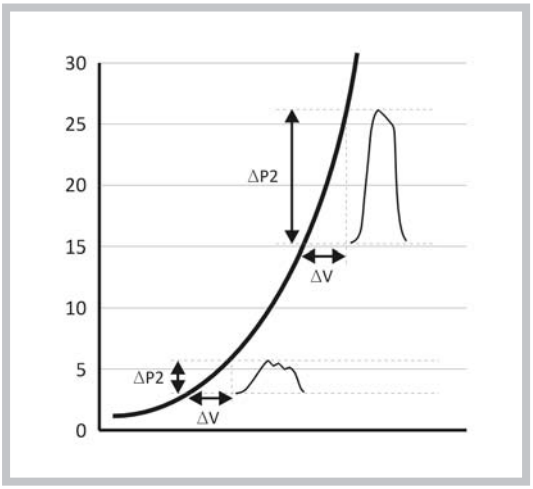

Figure 7.3. **Volume to pressure relationship curve. At low elastance, a change in volume, as depicted by ΔV, increases the intracranial pressure (ICP) by ΔP1; however, at higher elastance when there is less ability for the brain to displace other intracranial components, the same ΔV results in a much greater change in pressure: ΔP2>>ΔP1. Of note is that the pulse pressure of the waveform is much greater and the waveform morphology changes such that the percussion and tidal wave become confluent.**

Attempts have been made to predict impending intracranial hypertension when the pressure level is still normal. Increasing elastance is indicative of impending intracranial hypertension. Techniques to detect this include: 1) measurement of the pressure response to the infusion or withdrawal of fluid; 2) ICP pulse amplitude analysis; and 3) ICP waveform analysis.

There are various methods for the instillation or withdrawal of fluid or CSF to evaluate the pressure response. Marmarou proposed the “pressure-volume index” (PVI), wherein a standard amount of fluid is instilled to determine the volume of fluid needed to raise the opening pressure 10 times. In this calculation, the mathematical log of the ICP is linearly related to the volume with a slope equal to the PVI. A decrease in the PVI indicates increasing elastance and correlates with the development of intracranial hypertension and poorer outcome. Miller induced a “volume-pressure response” by rapidly infusing a set amount of fluid into the CSF space, from which he observed that a greater than 3 mmHg rise in pressure for each millilitre infused would predict increasing elastance and worsening ICP. The obvious complications associated with this technique are infection and potential precipitation of sustained ICP elevation, also known as plateau waves, described below.

Another method to detect impending intracranial hypertension that does not re-

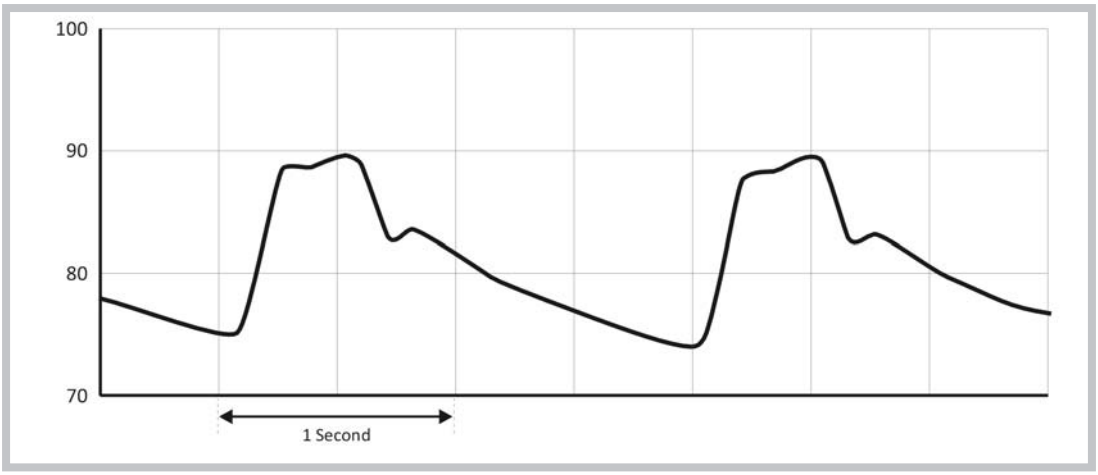

Figure 7.4. **Elevated intracranial pressure wave (in mmHg). Note the change in morphology from the normal pressure wave seen in Figure 2. The tidal wave, P2, increases in amplitude and becomes confluent with P1, the percussion wave. The pulse pressure, or the difference between the lowest and highest amplitudes of the waveform, is also larger.**

quire infusion of fluid into the CSF is analysis of the pulse amplitude and variance in ICP. Increasing pulse amplitude and increased ICP variance can be caused by worsening elastance or cerebral vasodilation. It has been proposed that a cardiac to respiratory wave amplitude ratio >2 indicates cerebral vasodilation, while a lower ratio is indicative of increasing elastance.

Finally, when ICP is elevated, the waveform morphology changes further. P2, the tidal wave, becomes more prominent, increases in amplitude, and merges with P1, which results in a widening and rounding of the waveform (Figure 7.4).

But even with the use of these various techniques, the clinical relevance of determining increasing elastance is unclear, since it is uncertain which therapies should be initiated, and how aggressive they should be, to prevent worsening of ICP.

7.4 Elevated Intracranial Pressure and Pressure Waves

Lundberg observed the ICP waveforms of 143 patients with intracranial tumours, spontaneous hemorrhages or head trauma and described three patterns of ICP waveforms as a function of pressure and time (Figure 7.5).

The Lundberg A wave, also called a plateau wave, persists for 5 to 20 minutes at amplitudes of 50 to 100 mmHg. Lundberg B waves are moderately elevated to about 50 mmHg and persist only over 30 seconds to a few minutes. Lundberg C waves occur approximately 6 to 10 times a minute and have amplitudes of 20 mmHg.

Lundberg hypothesized that the A wave is a result of cerebral autoregulation and an increase in CBV due to vasodilation. Elevation in ICP results in decreased cerebral perfusion pressure. Cerebral vessels dilate to maintain cerebral blood flow constant. This results in prolonged elevation of ICP and the plateau wave. This prolonged elevation may be aborted by draining the CSF or other rapid maneuvers to lower ICP. When elastance is high, hypercarbia or other maneuvers that cause cerebral vasodilation can produce plateau waves. The plateau wave may eventually resolve spontaneously, as the prolonged elevation of ICP results in cerebral ischemia which, in turn, produces an adrenergic discharge, an increase in mean arterial pressure (MAP), and restoration of CPP. When the

CPP is adequate, the cerebral vessels constrict and CBV and ICP both decrease. Since ischemia is often associated with Lundberg A waves, they may be associated with permanent cerebral injury. Cerebral ischemia may result in more edema and increased elastance. Plateau waves may be a sign of impending herniation.

Lundberg B waves have no significant clinical effects, but they are considered a sign of cerebral dysfunction. They are seen in comatose patients with Cheyne-Stokes respirations. Variation in CBF occurs in synchrony with B waves. In animal studies, B waves are associated with oscillations in the diameter of the pial vessels and CBV but not with blood pressure or $paCO_2$.

Lundberg C waves correlate with Traube-Hering waves, which are rhythmic oscillations in blood pressure that occur every 6 to 10 times per minute as a result of fluctuations in vasomotor tone and they are independent of the respiratory cycle. They are seen in normal individuals and are not pathological.

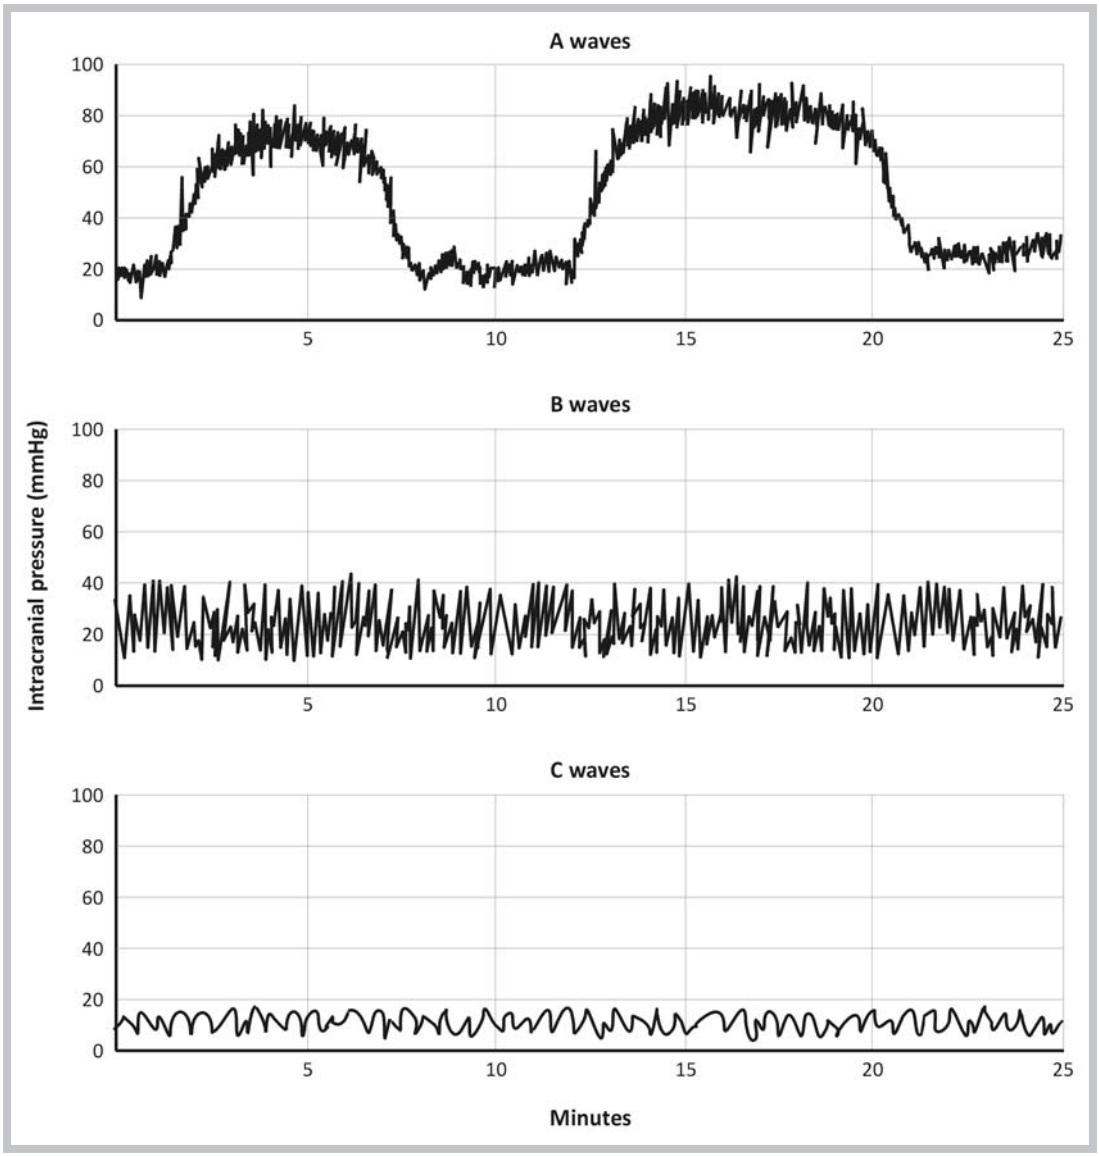

Figure 7.5. Lundberg waveforms.

7.5 Cerebral Perfusion Pressure

Cerebral perfusion pressure (CPP) can be calculated with placement of an ICP monitor. CPP is the difference between MAP and ICP. When measuring systemic MAP by an invasive technique, the fluid-coupled transducer is zeroed at the phlebostatic axis in the midaxillary line; however, when measuring MAP to determine the CPP, the invasive arterial line transducer, similarly to the fluid-coupled ICP monitor, is calibrated to the tragus, which corresponds to the foramen of Monro.

Normal CPP is between 70 and 100 mmHg. A CPP of 50-60 may be adequate, but ischemia ensues at a CPP <40 mmHg.

When the central venous pressure (CVP) is elevated, venous outflow from the brain is impeded. The resultant increase in CBV elevates ICP. When the CVP exceeds the ICP, the CPP is instead determined by calculating the difference between the MAP and the CVP.

Positive end-expiratory pressure (PEEP) during mechanical ventilation can affect ICP but it is less frequently seen that one might expect. For PEEP to be clinically relevant to ICP, it must increase the intrapleural pressure. This occurs in patients with compliant lungs but poor chest wall compliance. Studies suggest that ICP is affected by PEEP in situations where PEEP exceeds 20 cmH_20 and when the chest wall is stiff. In this situation, the right atrial pressure and the superior vena cava pressure both increase and venous outflow from the brain is reduced. In conditions where the mean airway pressure is elevated with increased intrapleural pressure, ICP may be affected in the same manner.

Intraabdominal hypertension and the abdominal compartment syndrome seen in multitrauma or patients with severe ileus can also increase ICP by increasing intrapleural pressure. This pressure is transmitted across the walls of the thoracic vasculature. The CVP rises and again impedes cerebral venous outflow, impeding venous return from the brain and increasing ICP. Elevated intraabdominal pressure also reduces venous return to the heart and can decrease systemic blood pressure, thereby also causing a decrease in CPP.

7.6 Cerebral Autoregulation

In steady-state conditions, cerebral blood vessels dilate or constrict to maintain cerebral blood flow constant. When cerebral autoregulation is intact, vasoconstriction ensues with rising MAP to maintain CBF at approximately 50 mg/100g/min. When the blood pressure decreases, vasodilation will maintain CBF at the same level. In normotensive individuals, autoregulation typically occurs between a MAP of 50-150 mmHg (Figure 7.6). The relevance of this for ICP occurs at times of low compliance or high elastance, when increases in MAP result in vasoconstriction which decreases both CBF and CBV, thereby lowering ICP. Conversely, low blood pressures cause autoregulatory cerebral vasodilation and increased ICP (Figure 7.7).

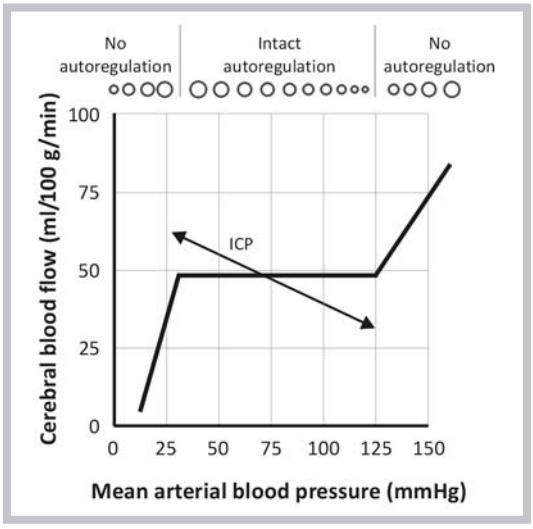

Figure 7.6. Normal autoregulation curve.

In the pathological state, autoregulation is disrupted and CBF cannot be maintained constant. In this situation, decreases in blood pressure directly result in decreased CBF and ischemia. Increases in MAP will increase both CBF and CBV and can result in elevation of ICP. Increases in MAP will also raise the risk of cerebral edema and hemorrhage.

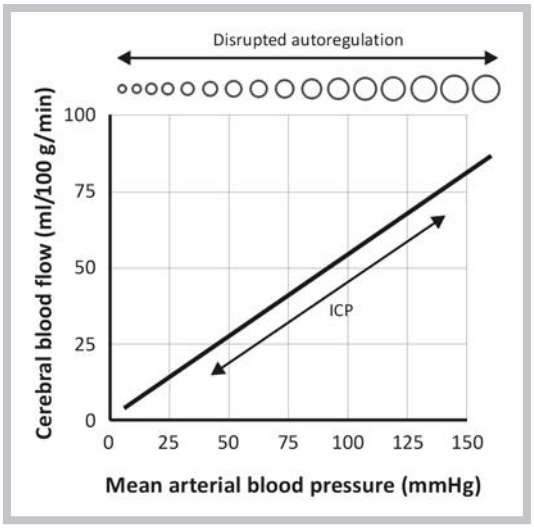

Figure 7.7. **Disrupted autoregulation. Autoregulatory curve in areas of brain injury, such as the core of an ischemic stroke or an area of cerebral contusion in traumatic brain injury, where the cerebral vasculature is disrupted.**

7.7 Indications for ICP Monitoring

Since secondary brain injury such as ischemia can occur in patients with intracranial hypertension, traumatic brain injury (TBI) guidelines recommend the placement of a monitor when the Glasgow Coma Scale score is ≤8 in a patient with an abnormal computed tomography (CT) scan or even when the scan is normal but the patient is aged over 40 years, has unilateral or bilateral motor posturing or systolic blood pressure <90 mmHg. Normal ICP is <10 mmHg. In the Traumatic Coma Data Bank, 72% of patients with severe TBI had an ICP >20 mmHg. Since numerous studies have shown worsened outcome with ICP above 20-25 mmHg, the published guidelines use this as the threshold to treat.

There are no randomized clinical trials to create a strong level of evidence supporting the use of ICP monitoring in other disease states such as ischemic and hemorrhagic stroke (ICH). However, ICP monitoring is considered an option in the 2007 American Heart Association/American Stroke Association guidelines for the management of spontaneous ICH in adults. There are some data to support the use of monitors in hepatic encephalopathy stage IV patients. A contraindication to placement of an ICP monitor is a bleeding diathesis or coagulopathy.

7.8 Conclusions

Intracranial pressure monitoring may be helpful in managing patients with suspected intracranial hypertension. Treating elevated ICP and maintaining adequate CPP may prevent secondary brain injury due to ischemia. An ICP monitor can detect elevations in cerebral pressure before a clinically significant herniation syndrome occurs. Familiarity with the types of monitors available and recognition of waveforms and their patterns can help the clinician to troubleshoot the technical problems that occur during monitoring and to detect worsening of edema.

8.1 Introduction

Traumatic brain injury (TBI) is one of the leading causes of mortality and morbidity in the developing and developed countries [1-3], and its impact on the economy, family and personal life is huge. In the developed countries, preventive measures, education, organization of health care and treatment based on invasive and non-invasive monitoring have reduced morbidity and mortality [4-7]. In some developing countries, improvements have come about only in some specialized centres mainly through the better organization of health systems and from the prevention and correction of common secondary injury factors such as hypotension and hypoxia [2,8,9].

The implementation of intracranial pressure monitoring is recommended in severely injured patients. Besides guiding treatment to reduce intracranial hypertension (ICH), it may even be beneficial simply by favouring increased contact with patients and by offering a better understanding of the disease process [10,11]. However, ICP monitoring is costly and many specialists in the developing countries, although not openly discussed, consider such invasive neurological monitoring a low priority, or even superfluous, in an era of scarce budgets, organization and time [11-13]. Such attitudes are reflected in comments often heard from physicians – such as: "I prefer the CT scan", or "There are flaws in calibration", or "The waves are full of artefacts" – and in complaints from administrative staff – such as: "Too much time is spent on this kind of monitoring" [1,13]. Attempts to introduce new monitoring methods to evaluate blood flow and metabolism, such as cerebral oxygenation, are met with even greater controversy [14-17].

The introduction of brain oxygen monitoring as a method to prevent or detect ischemia has followed a similar course as ICP, with many factors unavoidably contributing to mistrust and doubt as to its utility [15,17-19]. TBI is a notoriously heterogeneous disease with a very mixed pathology and variations in severity and histopathology in different areas. In a post mortem neuropathological study, Teasdale and Graham [20,21] described diffuse axonal injury in 92% of cases, hypoxic injury in 54%, focal lesions in 94% and congestion in 28%. In most patients, four or more abnormalities co-existed. Because of such heterogeneity, we do not really know what kind of monitoring is specific for and representative of a given type of brain injury [22,23]. For example, the Glasgow Coma Scale (GCS) provides an indication of severity and prognosis, but it does not identify the specific type of injury nor the kind of monitoring to implement [22,24]. The same GCS score may be observed in different types of injury. Moreover, computed tomography (CT) imaging yields only a momentary picture and is not continuous [22]. There is urgent need for a more multimodal approach to capture and monitor the disease profile [17,25].

The first reports of brain tissue oxygen monitoring ($ptbO_2$) date back 15 years [15], and studies continue to describe the technique and explore associations with other monitoring modalities and different imaging studies [26-29]. Some report on treatment response, but few build on previous experience, for example, taking the time curve into consideration [16,30,31]. Starting in 2009, papers began to appear in the US in which $ptbO_2$ was proposed as a guide for treatment [16,17,32], but they failed to sufficiently take into account the heterogeneity of TBI and cerebral aneurysms. Nor did they relate treatment thresholds to the known profiles of $ptbO_2$ trend differentiation underlying the causes of low oxygen tension values [16,31]). These indiscriminate approaches highlight the complexity of TBI and suggest that we should focus on strategies targeted to the needs of the individual patient rather than on standardized solutions which may be correct for an **average** patient but may not apply to others. The interpretation of findings and how these are translated into clinical practice for the individual patient is therefore relevant when evaluating the cost-benefit ratio of this monitoring system.

Compared to studies from the developed countries, several conducted in Latin America reported that $ptbO_2$ monitoring showed a higher occurrence of secondary injury factors [33-37]. Outcome improved [34-37] but not to the same level as in the most experienced centres [16,17]. It is unknown whether the improved outcome observed after the introduction of brain tissue oxygen monitoring in the developing countries is attributable to a more cohesive team effort and attention to care or to specific treatment goals. Whatever the cause of the decline in mortality, the experience of the developing countries is sufficient to motivate the purchase of monitoring equipment. Greater familiarity with multimodality monitoring can guide the therapeutic decisions by neurosurgeons and intensivists along the time evolution curve and monitoring trends, regardless of clinical grade or sedation level. Within our collaboration, we have compared the experience with $ptbO_2$ monitoring between developed and less developed regions. In this review, we will describe the classical initial reports on $ptbO_2$ monitoring and the more recently published studies. We will define which standards of analysis of $ptbO_2$ can help us to define better treatment approaches. Based on our over 15 years of experience in monitoring $ptbO_2$ we will compare current developments and trends against initial experience. We will also review new areas of application, limitations, and briefly discuss the position of local measurement approaches, such as $ptbO_2$, in relation to more global approaches, such as jugular oximetry.

8.2 Approaches to Monitoring Cerebral Oxygenation

Two different approaches to the study of cerebral oxygenation can be distinguished: global and regional. In global monitoring, oxygen saturation is measured in cerebral venous blood by means of continuous or intermittent monitoring of SjO_2 (jugular bulb oxyhemoglobin saturation) and derived parameters. The most common technique for regional monitoring is to measure the brain oxygen tension ($ptbO_2$). Near-infrared spectroscopy (NIRS), which combines a mix of global and regional monitoring, will not be addressed in this review, as it has not been adequately validated for TBI [38]. The purpose of global monitoring (SjO_2) is to ensure general cerebral oxygenation. In local monitoring ($ptbO_2$) the aim can be either to position the probe in a relatively undamaged part of the brain [39], in which case the values obtained reflect global cerebral oxygenation [15], or to position the probe in the penumbra of a lesion, with the intent to guide therapy to limit the development of local secondary damage [39,40] (Figure 8.1).

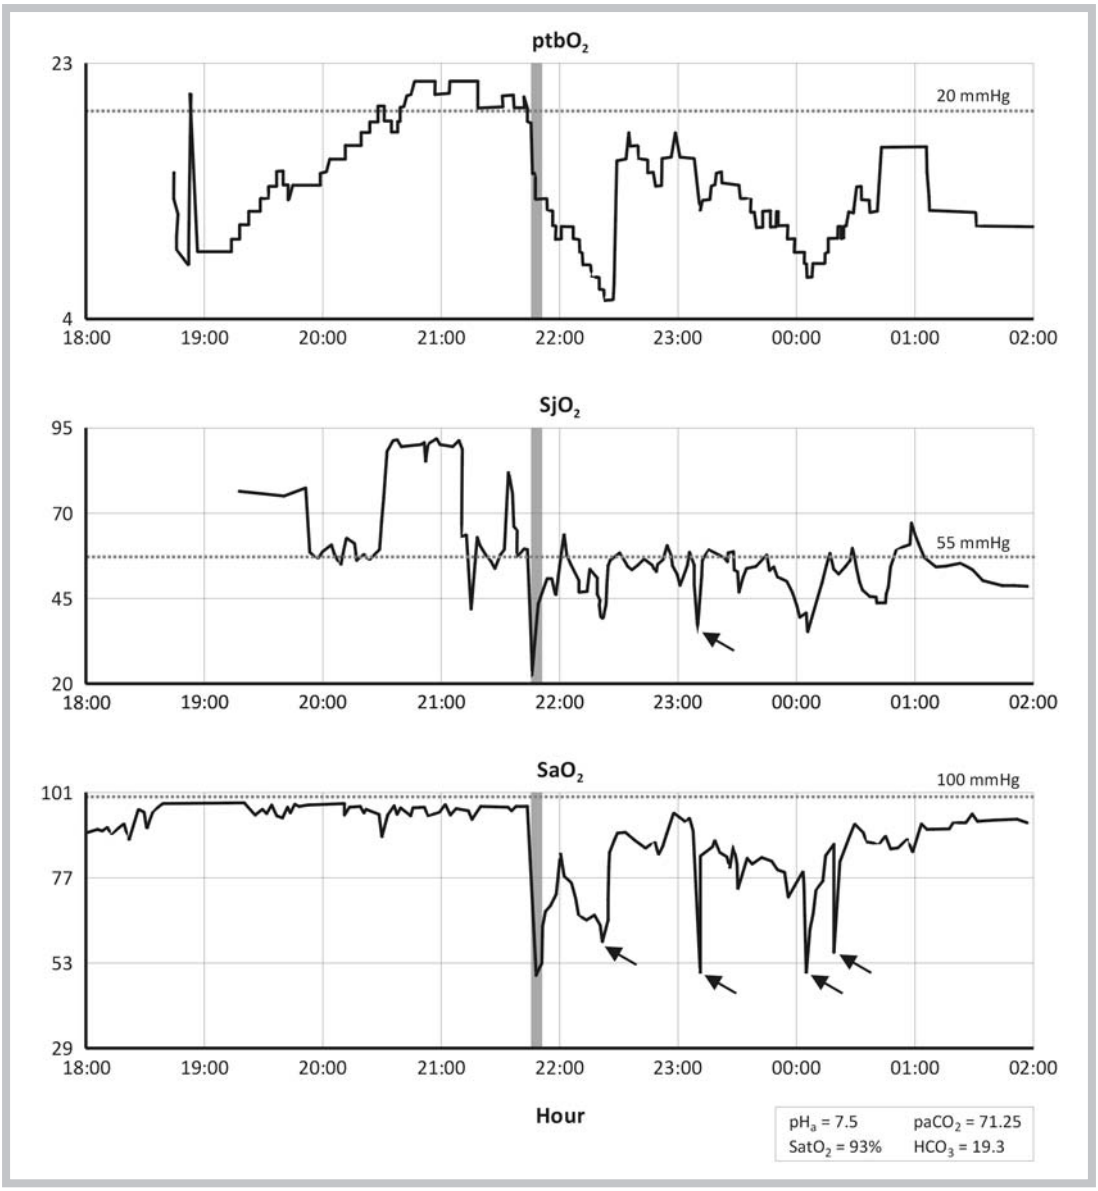

Figure 8.1. **Multiple episodes of systemic hypoxia with ischemic brain. In 30% of cases, these episodes are related to systemic desaturation (lower Figure, SaO_2 and arrows). Decrease in SjO_2 (gray arrow) shows foreseen events. The answer in tissue oxigenation shows a a decrease of more than 20 mmHg after 21 hours. The starting "hyperemia" peak (SjO_2 >85%) is related to psychometric agitation and should be read in relation to median arterial pressure.**

8.2.1 Global Approach: Jugular Bulb Oxygen Saturation

Introducing a catheter into the jugular venous bulb provides access to cerebral venous blood and thus permits indirect measurement of brain metabolism and/or an estimate of the amount of oxygen bound to hemoglobin. This amount is expressed as a percentage rather than by the partial pressure. According to the saturation curve of hemoglobin and oxyhemoglobin at the venous end, a partial pressure of oxygen of 40 torr corresponds to a saturation of 75% [42]. The frequent occurrence of artefacts and the wide variability in venous drainage of the brain produce inconsistencies in the values mea-

sured and reduce the reliability of SjO_2 measurements [43]; nonetheless, the knowledge derived from SjO_2 measurement can be useful in neurocritical care. It is essential that the catheter be positioned (and maintained) in the jugular bulb, as placement in a more proximal position can contaminate it with extracerebral venous blood, making values inaccurate and non-representative of the cerebral condition. By applying the Fick principle to this monitoring technique, changes in cerebral blood flow (CBF) can be inferred, adding more information to support the treatment of TBI and other entities than would be available from ICP monitoring alone [44,45]. Such inferences are valid only when the rate of oxygen consumption and transport, the amount of dissolved oxygen in the blood, the hemoglobin level, and the degree of decoupling of the saturation curve of hemoglobin are all stable [42,46]. Under evolving conditions, these factors need to be considered when interpreting SjO_2 – a step which is not always taken. The global cerebral oxygen status in healthy individuals reflects the balance between oxygen supply and demand and is dependent on cerebral blood flow and metabolism. The cerebral metabolic rate of oxygen ($CMRO_2$), expressed as ml/100 g/min, is calculated by multiplying CBF by the oxygen content difference between arterial and venous jugular oxygen (ΔAjO_2). The equation is expressed as:

$$CMRO_2 = CBF \times \Delta AjO_2 \text{ or } CMRO_2 = CBF \times (CaO_2 - CjO_2)$$

where: CaO_2 = arterial oxygen content; CjO_2 = jugular venous oxygen content; and ΔAjO_2 = arteriovenous jugular difference of oxygen.

In normal conditions, when metabolism is coupled with flow, the $CMRO_2$ will not change [47]; hence, ΔAjO_2 is constant. The normal value is 6.3±1.2 vol. /100 ml of blood [47,48]. In pathological conditions, however, CBF regulation may be abnormal and the coupling between flow and metabolism partly lost. For example, in patients with TBI, CBF can be increased or decreased regardless of $CMRO_2$ [48,49]. Assuming a normal arterial oxygen content, narrowing of the ΔAjO_2 with a SjO_2 >75% indicates that the CBF is too high (>50 ml/100 mg/min) in relation to metabolic requirements and suggests hyperemia. Hyperemic values would be considered when the ΔAjO_2 is <4 ml/dl. Conversely, a wide ΔAjO_2 >9 ml/dl or a low SjO_2 <55% suggests that the CBF is too low to meet metabolic needs and is indicative of hypoperfusion [48].

When regulatory mechanisms are intact, there is an inverse relationship between ΔAjO_2 and CBF. When CBF falls, the brain extracts a greater amount of oxygen and ΔAjO_2 increases. However, when oxygen extraction is already high and the compensatory mechanisms are exhausted, a further decrease in CBF causes a decrease in $CMRO_2$. Therefore, in cerebral ischemia, the oxygen uptake is dependent on the input and the relationship between CBF and ΔAjO_2 and it is also unpredictable. This situation is associated with increased lac-

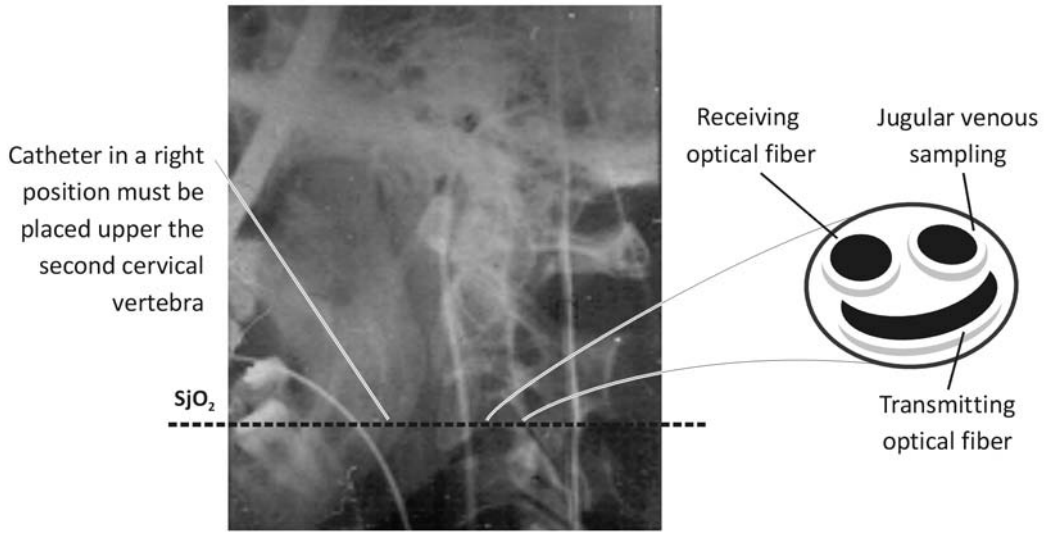
Normal parameters	Hypoperfusion	Hyperemia	References
ΔAjO_2 2.9-6.3±1.2 ml/dl or 1-3 µmol/ml	6.8 ml/dl or 3 µmol/ml	<3 ml/dl or <3 µmol/ml	[48]
CBF 42±12 ml/100 g/min	23 ml/100 g/min	53 ml/100gr/min	[48]
SjO_2 60-75%	<55%	75%	[50,51]
Lactate oxygen index=LOI $AV\Delta/Aj\Delta O_2$ <0.8	Lactate index ≥0.8 Ischemic-infarct pattern	Normal LOI	[40,54]
Cerebral Oxygen Extraction=CEO 35% (24-42%) adults 26% (17-35%) infants	>35%	<26%	[51,52,53]

Table 8.1. Normal and pathological oxygen values in TBI.

tic acid production and can be detected by calculating the lactate-oxygen index (AVΔL/AjΔO_2). A lactate-oxygen index ≥0.8 indicates the presence of ischemia [40,48,54].

In TBI patients, a ΔAjO_2 <2.9 ml/dl corresponds to an average CBF of 53±18 ml/100 g/min, a ΔAjO_2 between 2.9 ml/dl and 6.8 ml/dl corresponds to a CBF of around 42±12 ml/100 g/min, and a ΔAjO_2 >6.8 ml/dl corresponds to a CBF of about 23 ml/100 g/min [48]. Although calculating ΔAjO_2 provides detailed information, drawing blood involves a heavy workload, so continuous SjO_2 monitoring is preferable.

In summary, the SjO_2 can be influenced by many variables involved in global oxygen supply and consumption. It reflects the balance between cerebral oxygen supply and metabolic rate when oxyhemoglobin saturation, hemoglobin concentration and the hemoglobin dissociation curve remain constant. A decrease in SjO_2 reflects a decrease in oxygen supply to the brain or increased metabolic activity. Any disturbance that increases the demand or decreases the oxygen supply may decrease SjO_2. Likewise, a disorder that decreases $CMRO_2$ or increases the oxygen supply can increase the SjO_2.



SjO_2 <55%

- Is it an artifact? (May need catheter repositioning, recalibration of continuous fiberoptic catheter
- Recollect blood sample/Correct estimated value
- Consider the corrected calculated SjO_2 value
- Select the parameter:
  - SjO_2 <55% for 15 minutes
  - ΔAjO_2 > 6.8 vols.
  - ECO_2 > 24
  - $CMRO_2$ increased or decreased
- Before the treatment decision, take into account other parameters: ICP, mean ABP, level of sedation ICP, CPP, ptO_2, anemia, vascular autoregulation and clinical condition

SjO_2 >75%

- Is it an artifact?
- Recollect blood sample/Correct estimated value
- Consider the corrected calculated SjO_2 value
- Select the parameter:
  - SjO_2 >75%
  - ΔAjO_2 <3 vols.
  - ECO_2 >42%
  - $CMRO_2$ decreased
- Before the treatment decision, take into account other parameters: ICP, mean ABP, level of sedation ICP, CPP, ptO_2, anemia, vascular autoregulation and clinical condition

Figure 8.2. **Key points in SjO_2 monitoring. Main questions and management flow chart.**

For a better understanding of the relationship between CBF and $CMRO_2$, we may consider cerebral hyperemia as being similar to the hyperdynamic state in sepsis, in which cardiac output is high with a narrow ΔAjO_2, with poor oxygen consumption and arteriovenous shunting [55]. In contrast, prolonged ΔAjO_2 with SjO_2 <65%, corresponds to a hypodynamic state, with pump failure and extensive extraction [56]. Clearly, this is only a comparison, because the vascular autoregulation in the brain is very different from that in other parts of the body (Figure 8.2).

8.2.2 Practical Approach: Hyperemia with SjO_2 >75%

To properly interpret SjO_2 measurements, it is necessary to consider other variables of multimodality monitoring, and ICP monitoring in particular. A SjO_2 >75 % (ΔAjO_2 <3 vols.) which coincides with an increase in ICP should be initially treated with rapid correction of hyperthermia, if present, and a moderate degree of hyperventilation [57,58] ($PaCO_2$ 30-35 mmHg) as the main agent. Increased sedation may be appropriate if levels are considered insufficient to reduce agitation [59,60]. Prior to initiating treatment, it is necessary to:

- Check for possible jugular catheter malposition.
- Check the calibration: ensure that the value estimated by the fiberoptic catheter does not vary by more than 4% compared to the saturation measured by the co-oximeter, while slowly withdrawing blood from the catheter tip [43].

It is recommended to calibrate the SjO_2 monitor with the co-oximeter every 6 hours when changes in SjO_2 occur and prior to initiating therapeutic changes. Rotation movements of the neck or cervical extension facilitate the loss of the optical signal, since the fiberoptic catheter then touches the walls of the vein (Figure 8.3).

Clots can also alter the light transmission of the optical fibre [43]. Table 8.2 shows important factors for the treatment decisions of patients with SjO_2 >75 % and SjO_2 <55 % by means of other elements of multimodality monitoring.

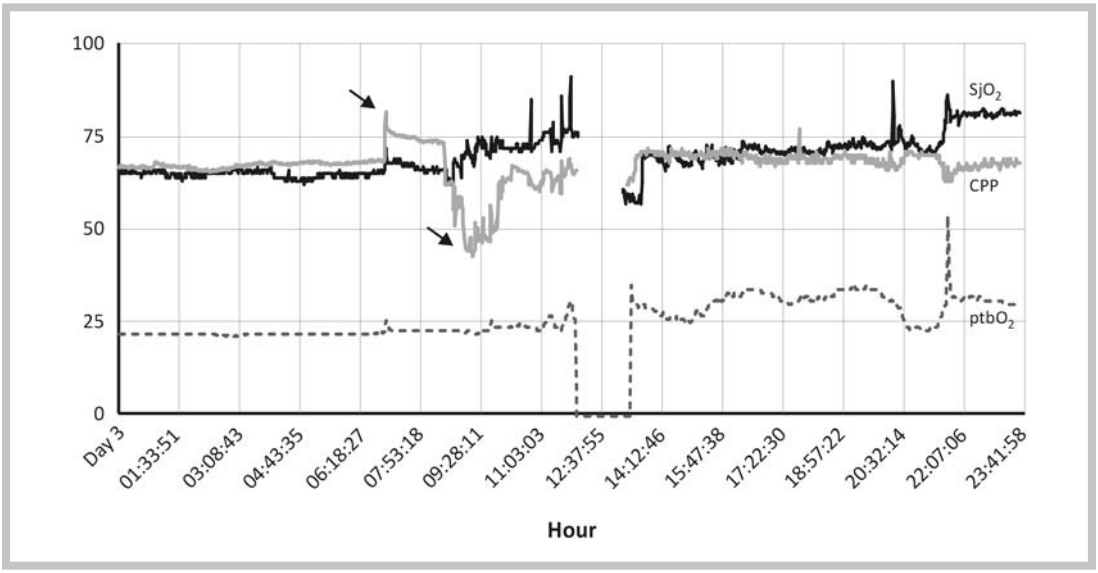


Figure 8.3. **SjO_2 monitoring and common artefacts. During the bath, SjO_2 (previously increased with CPP, first arrow) decreased by 45 mmHg (second arrow). No consistent variation in CCP in relation to $ptbO_2$ was observed. With the fast and inexplicable fall of SjO_2, blood was extracted and SjO_2 changed. Between 6.18 and 7.53 hrs, with the aspiration of secretions, SjO_2 increased, suggesting hyperemia. The period of monitor disconnection shows $ptbO_2$ reliability and recalibration of SjO_2 (registered between 12.37 and 14.12 hrs).**

Factors favoring SjO_2>75%	Factors favoring SjO_2 <55%

• Permissive hypercarbia
• Psychomotor agitation and pain
• Postoperative areas
• Underlying surgery
• Defective vascular autoregulation
• Decreased cerebral metabolic rate
• Venous outflow obstruction or cranial cervical
• Seizures
• Metabolic acidosis
• Hyperoxemia 100%
• Uncal herniation and brain death
• Alveolar recruitment with CO_2 retention
• Fever poorly controlled
• Spesis
• Common artifacts:
  ▪ Bath immersion
  ▪ Mobilization of the catheter
  ▪ Catheter lumen obstruction
  ▪ Patient transfer
  ▪ Suctioning
	• Arterial hypotension
	• Hypocapnia <30 mmHg
	• Intracranial hypertension
	• Decreased CBF
	• Real hypoxia with or without hypotension
	• CSF Leake
	• Oversedation
	• Low cardiac output
	• Hypothermia
	• Chills after removal of hypotermia
	• Cerebral vasospasm
	• Dehydration and Hypovolemia
	• Heart failure
	• Increased viscosity
	• Common artifacts:
	  ▪ Bath immersion
	  ▪ Mobilization of the catheter
	  ▪ Obstruction of the light emitted
	  ▪ Patient transfer
	  ▪ Suctioning

Table 8.2. **Factors decisions in Hyperemia and Hypoperfusion interpreted by SjO2 in TBI.**

8.2.3 Theoretical Approach: Hyperemia With SjO_2 >75%

Hyperemia is common in the immediate postoperative period after craniotomy [61]. The CBF in the area adjacent to a craniotomy may increase which – particularly in combination with an increase in blood pressure – can lead to vasogenic edema. When the brain

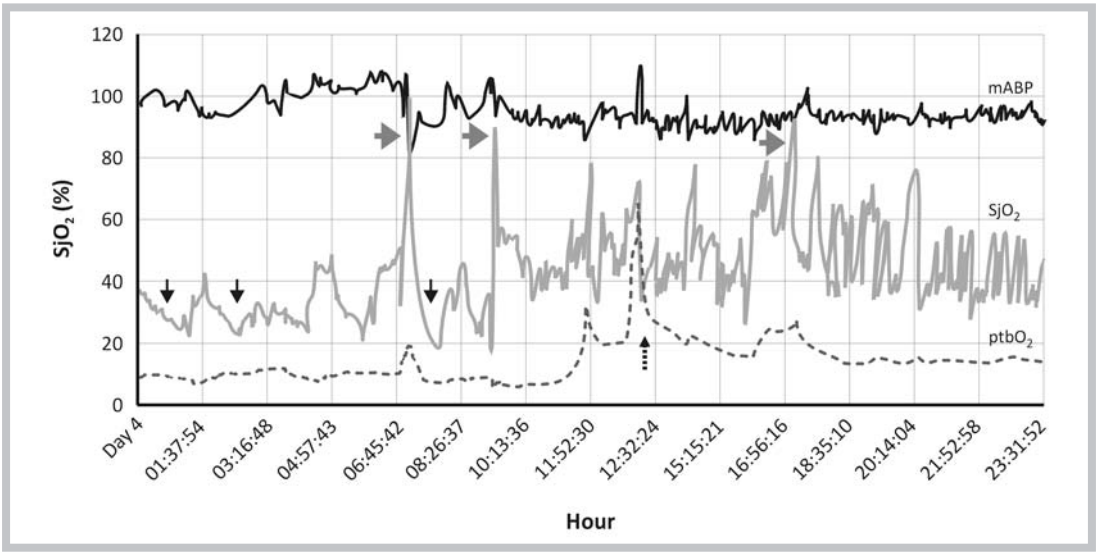

Figure 8.4. **Male, 15 years old, with GCS 8, CT Scan with diffuse small hemorrhagic points after traffic accident. Several events of hyperemia (gray arrows) and hypoperfusion (black arrows) in TBI patient, not fully sedated and febrile. The repercussion in $ptbO_2$ was evident; $ptbO_2$ decreased by 5 mmHg with an associated reaction in SjO_2. Dotted arrow shows fest FiO_2 100%. The blood pressure had an increasing pattern trend. Hypoperfusion (black arrows).**

is decompressed following the removal of a space-occupying lesion [5], the ICP decreases, sometimes leading to an abrupt increase in perfusion. This type of hyperemia can be indirectly detected with SjO_2 (high values), but SjO_2 may later decrease when the metabolic reserve is exhausted and CBF has become insufficient [62,63]. Blood pressure control becomes critical at this moment in order to limit the development of vasogenic edema. Because agitation and pain may cause increased blood pressure, it is better to initiate appropriate levels of sedation and analgesia before treating hypertension with antihypertensive drugs such as nifedipine or nicardipine [64-66] (Figure 8.4).

in 30% of patients with severe TBI, nursing procedures such as tracheal suctioning in the first 36 hours posttrauma increased blood pressure, ICP and SjO_2. ICP remained elevated for 11±6.1 minutes by 5 mmHg or more (mean increase of 16.6±10.2 mmHg) and SjO_2

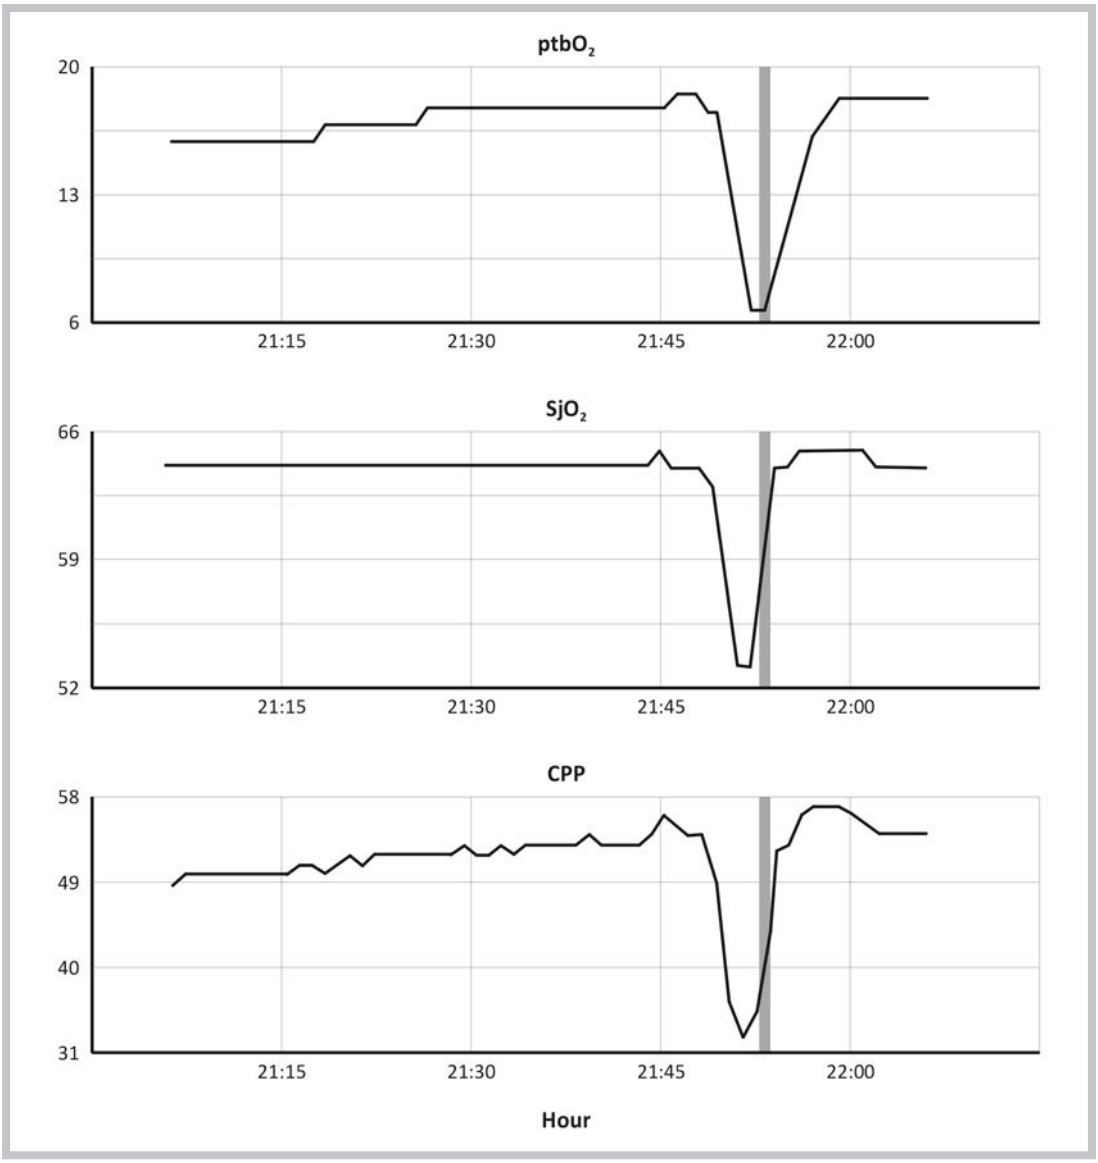

Figure 8.5. **Evident disfunction in cerebrovascular autoregulation. The cerebrovascular autoregulation is dependent from the cerebral pressure perfusion (CPP), especially in cases with vasopressors. In this case, CPP was really low, below the normal range. SjO_2 and $ptbO_2$ decreased at the same time of CPP (21.45 h).**

for 15.0±12.4 minutes, rising from 62±10 to 77±10%. The blood pressure increased for at least 10 minutes (average, 16.0±8.0 minutes) during and after 94 of the 120 aspirations, resulting in an increase in cerebral perfusion pressure (CPP) from 80.7±11.9 to 97.4±18 mmHg. The sustained rise in SjO_2, with increased perfusion pressure during and after suctioning, suggests disturbed vascular autoregulation [67]. The impact that such events may have on outcome is uncertain. Sometimes, autoregulation can partially self-regulate; increasing the blood pressure with vasopressors may reduce ICP and improve the SjO_2.

It should be remembered, however, that a single determination of SjO_2 >75% by itself does not imply a correct CPP nor does it define the prognosis [68].

Much can be learned about the incidence of hyperemia in TBI as determined by SjO_2 from studies by Robertson et al. [69]. A total of 2799 samples were taken from 450 patients in the first 5 days after trauma. Normal values were found in 342 patients (76%), high values (>75%) in 86 (19.1%), and low values (<55%) in 22 (4.9%) (Figure 8.6).

The distribution of SjO_2 values was found to change over time. On days 1 to 5 posttrauma, about 30% of patients had a SjO_2 >75%. No clear correlation was found between SjO_2 and CBF, however [42,69]. Low CBF values occurred at high values of saturation and high CBF values at lower SjO_2 values. Patients with an average SjO_2 >75% had a poorer outcome, most likely secondary to a depressed metabolic rate rather than due to hyperemic CBF. In this study, SjO_2 >75% was not clearly associated with hyperemia, although some authors consider it a major cause of intracranial hypertension [70,71].

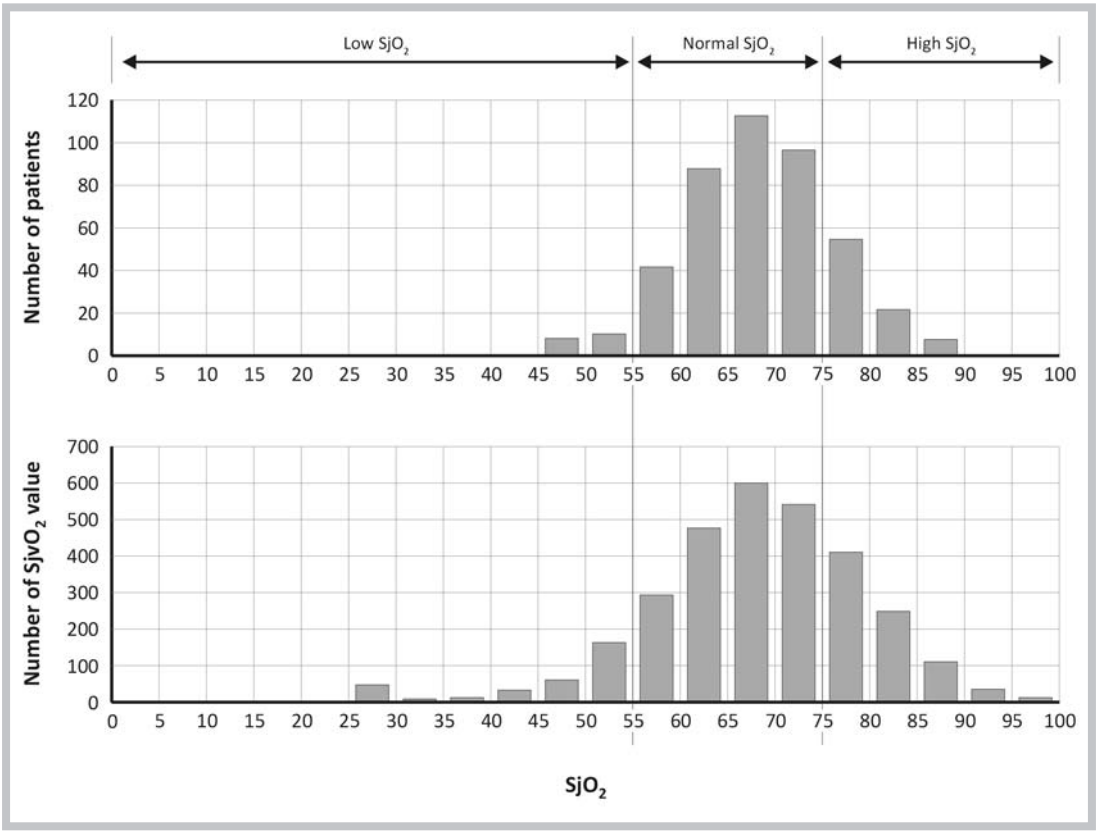

Figure 8.6. **Graphs showing the distribution of the SjO_2 values among the 450 patients (upper) and distribution of the 2799 SjO_2 individual measurements (lower), with division into three groups with low, normal, and high SjO_2 values.**

Also, a wide range of CPP values was found at elevated SjO_2 values, indicating that hyperemia cannot be accurately identified by measuring SjO_2. Regional CBF can be high in some parts of the brain but low in others [49,72]. These findings stand in contrast to those of other studies, where a closer association between SjO_2 and hyperemia was found in smaller groups of patients. What we can conclude is that hyperventilation or other treatments to induce vasoconstriction should be initiated to decrease suspected hyperemia if patients are adequately monitored [59,60]. This makes a strong case for multimodality monitoring as a basis for treatment decisions [73].

In 1982, Chan [49] investigated the association between CPP and SjO_2 in 41 TBI patients by means of continuous transcranial Doppler measurement to determine the optimal CPP level. At a given SjO_2 level, the average velocity in the middle cerebral artery was measured and the pulsatility index calculated. The pulsatility index is defined as:

Pulsatility index: systolic velocity – diastolic velocity/mean velocity

(normal value = 0.9±0.2 in 20 subjects)

Regression analysis demonstrated that a decreased CPP, due either to an increase in ICP or a drop in blood pressure, increased the pulsatility index and reduced the SjO_2. Decreases in SjO_2 occurred more frequently at CPP levels <70 mmHg. At CPP levels >70 mmHg, however, there was no correlation between the pulsatility index and SjO_2. Transcranial Doppler studies and calculation of the pulsatility index may therefore provide support in the search for an optimal CPP at a given level of SjO_2.

8.3 Hyperemia and Arterial pCO_2

Vascular tonus is strongly dependent on arterial pCO_2. Increasing pCO_2 and hypercarbia ($PaCO_2$ >45 mmHg) causes vasodilatation, with an increase in cerebral blood volume and an increase in CBF. For each mmHg increase in $PaCO_2$, CBF increases by 3 to 4% and cerebral blood volume by 0.72±0.42 [74,75]. Changes in arterial CO_2 concentration affect its influence not only on vascular tone through changes in pH, but also through altered concentrations of adenosine and nitric oxide mediators which are considered mediators of vascular tonus [76]. An increase in $PaCO_2$ raises ICP because increases in blood volume lower the volume-pressure index (see explanation in Annex 1) and spatial compensation capability.

The reduced reserve capacity to deal with increased volume at higher levels of arterial pCO_2 has direct relevance for clinical management [59,60]. In situations of increased arterial pCO_2, relatively minor and otherwise innocent increases in cerebral blood volume, which may be caused by the use of positive end-expiratory pressure (PEEP), venous obstruction, flexing of the neck or recruitment maneuvers, may lead to an unacceptable increase in ICP [77,80]. Therefore, caution is recommended in the use of permissive hypercapnia and lung-protective maneuvers in these situations [81].

Pulmonary problems caused by aspiration, contusion, rib fractures and atelectasis are common in TBI patients. Adjuvant CO_2 retention with a decreased vital capacity and an increase in dead space may cause secondary brain damage due to increased cerebral blood volume, ICP and SjO_2. Acute elevations of arterial pCO_2 which increase ICP can generally best be managed by short-duration manual ventilation with an Ambu bag. Monitoring the effect of such maneuvers is important, as excessive vasoconstriction may result in cerebral ischemic events (Figure 8.7).

There are reports of the use of airway pressure release ventilation (APRV) mode to protect against elevation of ICP and to promote the elimination of pCO_2 [82,83]. Impor-

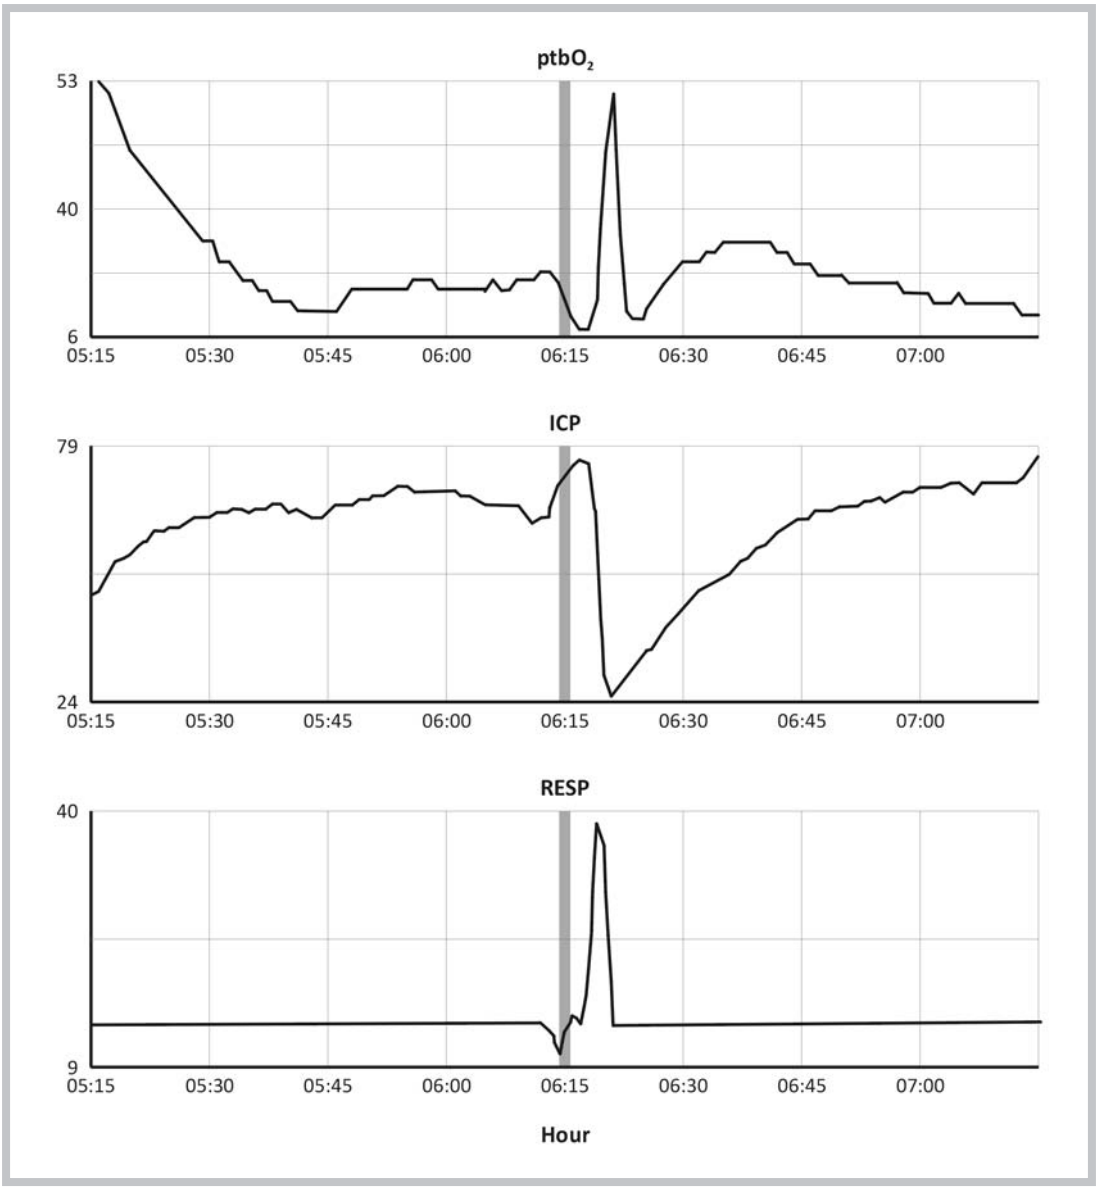

Figure 8.7. **Refractary ICP and hyperventilation maneuver. The Ambu bag maneuver decreased ICP from 79 to 24 mmHg (6.15 hour). The initial elevation of mean ICP (5.15 h) was associated with a dropping trend of $ptbO_2$. Later $ptbO_2$ reached 53 mmHg with hyperoxia FiO_2 100%. With Ambu bag maneuver (RESP=40) ICP decreased for around 15 minutes (6.15 h), and $ptbO_2$ had a "superficial" improving pattern.**

tantly, however, any process that increases the alveolar pressure will also increase the pressure in the pulmonary artery and veins, thus carrying some risk for hypercarbia and suboptimal perfusion due to increased alveolar dead space. Much uncertainty exists on the effects of alveolar plateau pressure levels and the consequent production of CO_2 during recruitment maneuvers in ICP.

An artificial maneuver that may mimic hyperemia is the administration of 100% oxygen prior to suctioning procedures. In hyperoxia, SjO_2 increases markedly, thus potentially minimizing the risk of temporal dysperfusion and cerebral hypoxia in compromized patients [84,85] (Figure 8.8).

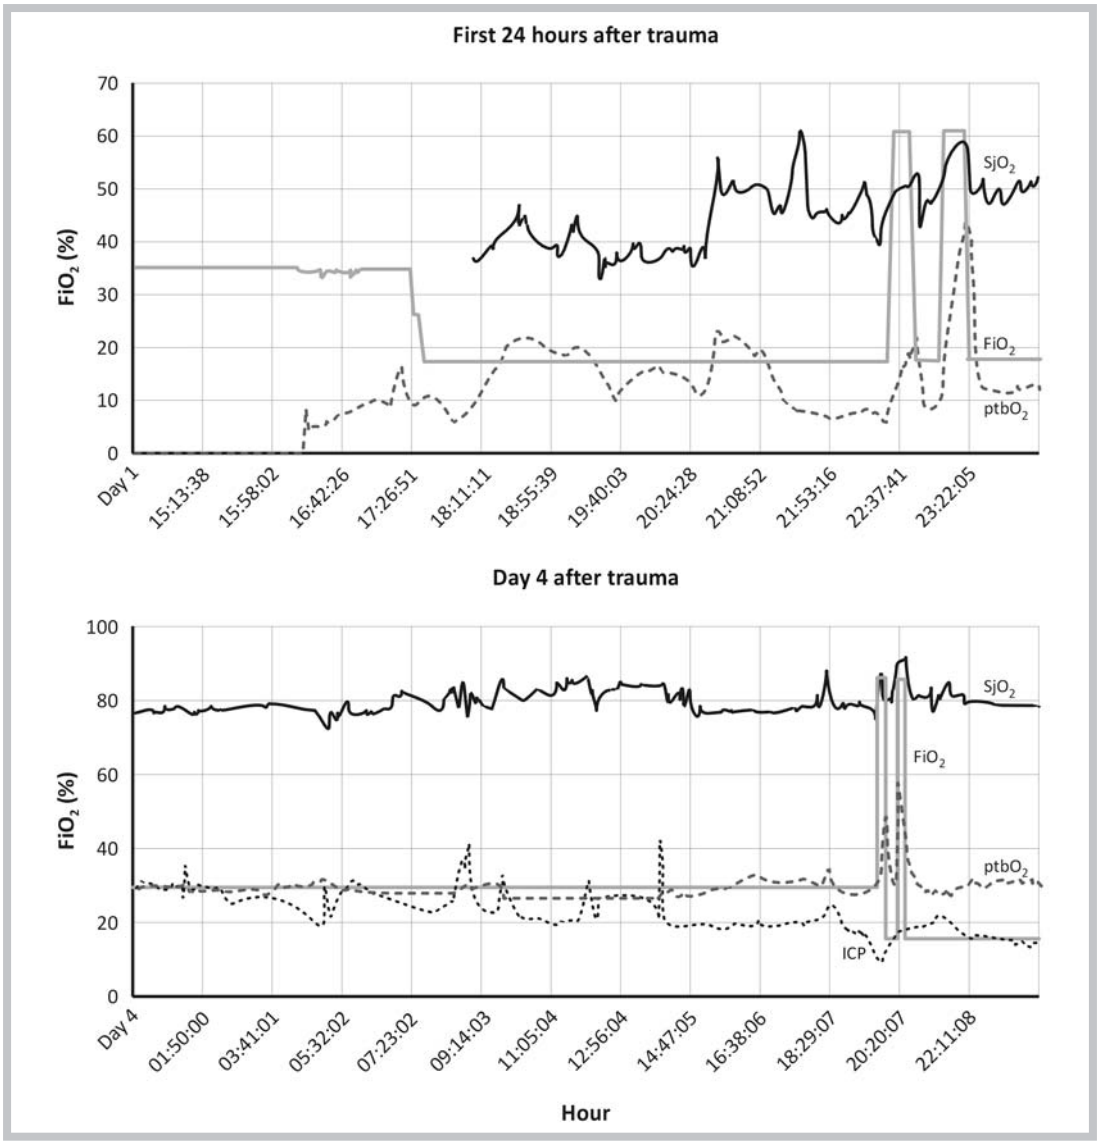

Figure 8.8. **Ischemic pattern and hyperoxia response. On the initial 24 hours after trauma the oxygen parameters SjO_2 an $ptbO_2$ shows lower values (SjO2= 55 % and $ptbO_2$= 15mmHg). From 18.11 until 22.59 abnormal lower values were observed. With hyperoxia 100 % FiO_2 both parameters increased: $ptbO_2$ reached 40 mmHg and SjO_2 60%. The main suggestion for treatment will be to find the main cause of deterioration. Ischemic pattern an hyperoxia response. On day 4 after trauma the ischemic pattern improves. ICP decreased progressively, $ptbO_2$ and SjO_2 had a better trend. With FiO_2 100 % both parameters increased, $ptbO_2$ reached 50 mmHg and SjO_2 90%, (20.20 hrs), with a hyperemia response. The appearance of hyperemia was unmasked by FiO_2 % 100 and better condition of this subdural hematoma, GCS 4, with isocoric and reactive pupils.**

The response is immediate and oxygenation can be maintained for the duration of suctioning procedures. The use of SjO_2 monitoring can therefore provide opportunities for quantifying the quality of nursing activities and permits the verification of adequate preoxygenation prior to suctioning procedures. Hyperoxemia with delivery of 100% FiO_2 as a therapeutic maneuver has been proposed by various groups [84-87]. Increasing PaO_2 has been shown to decrease tissue lactate as measured by microdialysis [88]. Its effects on metabolism appear promising, but possible oxygen toxicity should be considered [89].

8.4 Approaches to Treatment

For treating injuries from a pathophysiologic perspective, Cruz proposed three stages of altered oxygen consumption in relation to CBF and SjO_2:

- When a decrease in neuronal activity, aerobic metabolism and CO_2 production leads to a proportionate decrease in CBF, cerebral oxygen extraction remains normal. This indicates a good balance between flow and metabolism.
- When the CBF is low in relation to oxygen consumption, cerebral oxygen extraction increases to compensate for the low flow state, and this condition represents oligaemic cerebral hypoxia.
- When the CBF is relatively high in relation to oxygen consumption (defective metabolic autoregulation), cerebral oxygen extraction decreases. This condition represents relative hyperperfusion or "luxury perfusion" [90].

Treatment for elevated ICP can be differentiated according to each of the above scenarios. In hyperemic flow with decreased cerebral extraction, Cruz proposed the concept of "optimized hyperventilation", in which hyperventilation is targeted to decrease $PaCO_2$ to levels <25 mmHg or even <20 mmHg [52]. This approach remains controversial because of the high risk of cerebral ischemia in the acute phase after injury and because of the heterogeneity of CBF in different areas of the brain.

The concept of optimized hyperventilation assumes that vasodilatation and CBF are homogeneous; however, this is not necessarily the case. Caution is therefore recommended when using optimized hyperventilation under the supervision of SjO_2 and it should be used with moderation [59,60].

By contrast, optimized hyperventilation is inappropriate when the ICP is >20 mmHg and associated with increased or normal brain oxygen extraction. Cruz proposed the use of manitol, whilst other other authors recommended either hypertonic solution or barbiturate coma [52,91].

Summary of Hyperemia as Indicated by SjO_2 >75%

- High SjO_2 values are primarily caused by a low cerebral metabolic rate.
- Hyperemia as indicated by SjO_2 >75% occurs predominantly after the first 48 hours.
- Although hyperemia may be a cause of intracranial hypertension, high SjO_2 values are also found in patients with normal ICP.
- The pathophysiologic mechanisms underlying hyperemia are potentially reversible through respiratory modifications and metabolic intervention.
- Hyperemia as indicated by a high SjO_2 can be associated with severe disturbances in cerebral autoregulation.
- Prior to initiating treatment for high SjO_2 values, calibration errors should be excluded.

8.4.1 Practical Approach: Hypoperfusion due to SjO_2 <55-60%

Low SjO_2 values, which reflect increased oxygen extraction in relation to flow, are indicative of an increased risk of ischemia [50]. The therapeutic approaches in these patients should be aimed to increase oxygen delivery. In patients with raised ICP and a SjO_2 <55%, we recommend correcting hemoglobin levels as a first step if these are low. Whilst a restricted approach to transfusion is currently recommended in general trauma following the demonstration of a lower mortality, it should also be remembered that brain trauma is a different situation [93,94].

Cerebral ischemia is particularly frequent in TBI patients with anemia and cerebral hypoperfusion. Much evidence exists that cerebral ischemia is a commonly encountered

problem after TBI, particularly in the first 24 hours [50]. In this period, low CBF values and low values of jugular venous saturation (<65%) have been shown to occur frequently. Short-duration hypotensive episodes often cause SjO_2 to fall to values <65%, illustrating the deleterious effect of low blood pressure on cerebral oxygenation[95]. In their histopathology studies, Teasdale et al. demonstrated the presence of cerebral ischemia in over 90% of cases [96].

More recently, magnetic resonance imaging (MRI) studies have shown that hypotension after TBI is associated with neuronal loss in the thalamic region [97, 98]. In a study by Robertson et al. [50,95], hypotension was the leading cause of episodes of jugular venous desaturation. Insufficient cerebral oxygenation and insufficient blood flow due to hypotensive insults are an important cause of secondary brain damage after TBI.

The effects of such secondary insults may be greatest in patients with intracranial hematoma. Many patients with cerebral contusion or intracranial hematoma show secondary deterioration and often present with the clinical syndrome of "talk and deteriorate" [99]. This illustrates that outcome is not only determined by the primary lesion and serves to highlight the possibly devastating influence secondary brain damage can have. Reports from the Manchester Emergency Services highlighted poorer outcome in moderate TBI patients with associated systemic injuries [100]. The priority of preventing and treating cerebral ischemia is to target appropriate levels of blood pressure and arterial oxygenation. Critical decreases in SjO_2 <50% for 10 minutes or longer are absolute indications for instituting vigorous therapy [50]. Early therapeutic interventions aimed to avert such critical episodes are strongly recommended.

Prevention and treatment of cerebral hypoperfusion requires adequate fluid resuscitation and the combined use of vasopressors. Various authors state a preference for the use of norepinephrine [101-103], as the drug is more selective and its effects more constant (see section on regional monitoring). Rosner devised eight rules to identify the best point of perfusion level based on multimodality monitoring [104] (Table 8.3).

- The abnormal brain frequently needs more CPP
- The Cushing response to increased ICP consists of an increase in mABP. This response is produced for inadequate blood flow. The systemic hypertension results, which improves blood flow to needed levels. In chronic hypertensive patient is that these apparently extreme levels of systemic pressure are frequently maintained quite well, as long as the physician does not interfere. High blood pressure are a necessity. A similar situation exists in young children, they become quite hypertensive, this hypertension is a clear cut/guide to what their brains seem require at any given moment
- Lundberg A-waves or plateau waves indicate that CPP is inadequate. It is important to recognize the occurrence of such waves
- Artificially raising or stabilizing CPP at a constant level above the threshold will eliminate these waves.
- If CPP is above the lower limits of autoregulation, then ICP will vary inversely with CPP. With vasopressor use an increase in mABP will benefit ICP, with a lower descendent pattern; such is described in Figure 8.9.
- The pinch maneuver induce pain stimulus, which promotes transit hypertension similar, than vasopressor response. If painful stimulation promotes a decreased in ICP and increasing tendency in BP, this maneuver can be used for an evaluations of autoregulation curve that patient is functioning. In conditions of plenary sedation this maneuver is not really evaluated. In some cases the pain maneuver may associate with arousal and an increase in $CMRO_2$ and ICP, with a detrimental response
- CPP versus PVI. The PVI index (Pressure-Volume Index) measures the compliance of the brain (Marmarou Index) This parameter calculate at multiple different cerebral perfusion pressures may provide a quantitate estimate of whether a patient is on the healthy versus low side of the autoregulatory curve. If PVI is plotted at multiple CPP levels and the slope is positive then the suggestions is that patient is on the healthy side of autoregulation curve. If the patient had a poor compliance, the patient is in dangerous position
- The SjO_2 and $ptbO_2$ offers a new approach for a better optimization of CPP. This approach is discussed in $ptbO_2$ section

Table 8.3. **Rosner's rules to identify the best point of perfusion level based on multimodality monitoring.**

The optimal CPP level can vary between individual patients. Several studies suggest aiming at values of 60 to 70 mmHg [104,105] and international guidelines recommend maintaining CPP >60 mmHg [59,60], although lower levels may be considered acceptable in selected patients. When taking SjO_2 into account, it should be remembered that the detection of desaturation events requires continuous monitoring as short-duration episodes, which may be very harmful and are not detected by intermittent monitoring [106]. Desaturation events can occur in up to 40% of TBI patients.

In patients with low SjO_2 values, therapeutic modalities that may increase vasoconstriction, such as hyperventilation, should be avoided. Also, it is advisable to frequently reassess the acid-base balance, specifically with regard to $paCO_2$ and respiratory alkalosis, by means of regular blood gas analysis and continuous monitoring of end-tidal CO_2.

Following the correction and optimization of systemic parameters (anemia, hyperthermia, arterial pCO_2 and arterial blood pressure), every effort should be made to determine

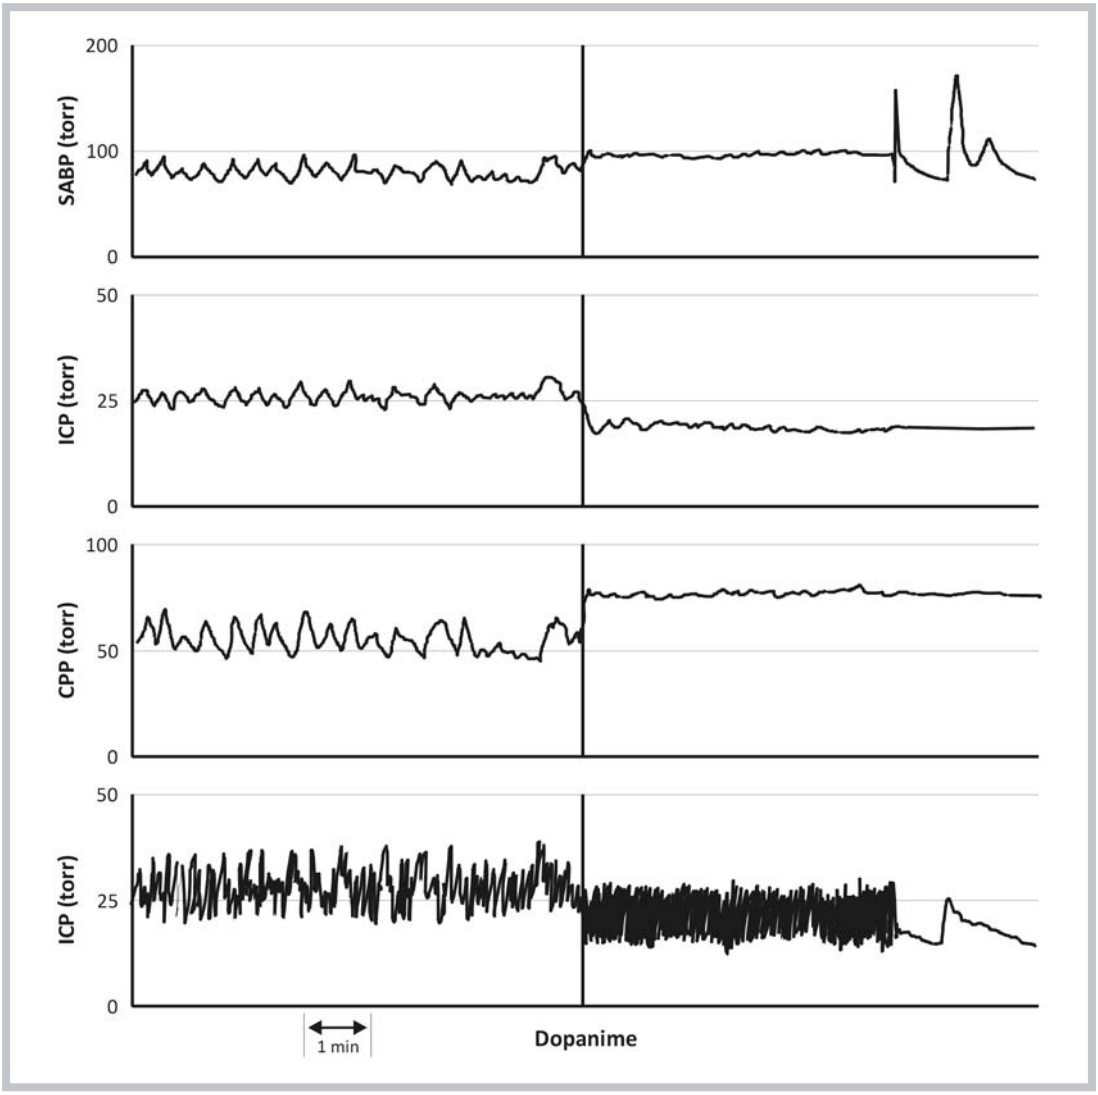

Figure 8.9. **The vasopressor effect of dopamine decreases ICP. Upper panels show sistolic arterial blood pressure (SABP), ICP, and CPP. The insufficient systolic blood pressure around 90 mmHg was not the better combination with ICP of 35 mmHg. Vasopressor effort decreased ICP to 20-25 mmHg.**

the cause of desaturation in order to target therapy more appropriately. If low blood pressure is the problem, this should be corrected; if a low CPP has resulted from increased ICP, then the management should be primarily directed at treating the raised ICP.

8.4.2 Theoretical Approach: Avoiding Risks of Hyperventilation in Patients with Hypoperfusion (SjO_2 <55%)

Lowering arterial pCO_2 by hyperventilation is a recognized and effective approach to reduce elevated ICP [107]. The mechanism of action is by reduction of cerebral blood volume owing to vasoconstriction. Experimental studies using a cranial window have clearly confirmed that vasoconstriction of the pial arteries results from hyperventilation [108]. Studies using electroencephalography (EEG), however, showed that, whilst decreasing ICP, hyperventilation also produces flattening of wave form activity on the EEG [109].

Clinical evidence also exists that hyperventilation may compromise cerebral blood flow and oxygenation. In the first 24 hours after injury, global CBF is reduced in 30-70% of patients with severe TBI. In such patients the risk of cerebral ischemia on instituting hyperventilation may be particularly high [110]. An early work by Obrist [111] demonstrated that hyperventilation to an arterial pCO_2 of 23.2±2.8 mmHg reduced CBF to 18.6±4.4 ml/100 g/min and increased arterial venous content differences by 10.5±0.7 vols. %.

Subsequent studies have shown that hyperventilation is the second most common cause of desaturation following a hypotensive episode [50,51]. Deliberate or inadvertent hyperventilation episodes may occur during the entire clinical course, extending from the injury site to the emergency room and the intensive care unit. The risk of hyperventilation is particularly high during transport [112] and is not always recognized.

In a descriptive study investigating the effects of hyperventilation in 21 patients in Mexico City, we found that in 82.6% of 97 samples the arterial pCO_2 was <30 mmHg and SjO_2 <65% in 45% of the samples [113]. These studies were performed using intermittent SjO_2 monitoring with a co-oximeter, and the real incidence of jugular desaturation was probably underestimated. A strong case can be made for implementing further education and awareness to prevent and correct the “routine” use of hyperventilation, and this approach should be supported by motivation and training.

Level II guideline recommendations advise against hyperventilation in patients without elevated ICP. This recommendation is based on a relatively small number of patients, but the real impact of hyperventilation on outcome after TBI is uncertain. We suggest that hyperventilation may be definitely deleterious in some patients, but – if monitored closely – it may be beneficial in others.

There are well-documented risks associated with the use of hyperventilation to decrease CBF, to decrease brain oxygen tension, and to cause jugular desaturation [50,59,60]. More recent studies using positron emission tomography (PET) have shown that $CMRO_2$ is unaffected by moderate hyperventilation [114]. Microdialysis studies, however, have shown that short-duration hyperventilation in the first 24 hours after injury can increase brain lactate and decrease cerebral extraction of oxygen [115]. Uncertainty exists about which patients may and which will not benefit from hyperventilation. Caution in the use of hyperventilation is advisable. The following recommendations can be made:

- Avoid hyperventilation in the first 24 hours after trauma and during transport. When applied, use hyperventilation only for short periods [59,60].
- Do not exceed a moderate level of hyperventilation ($paCO_2$ 30-35 mmHg) [59,60].
- Closely monitor and assess the end-tidal CO_2 and/or arterial blood gasses at least every 6 hours.

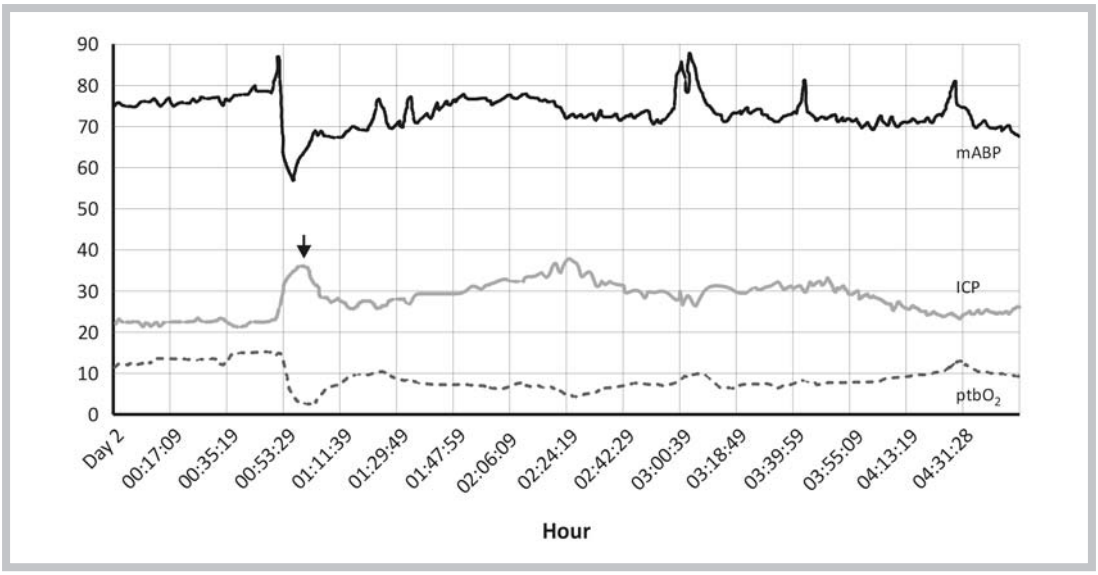

Figure 8.10. Effect of adrenergic activation in oxygen pressure tissue and ICP. A male, 15 years old, was injured by a car while riding a bicycle. The initial GCS was 8, EMV: 3, 3,2. He had a right tibia fracture and fractures of 3th and 4th left ribs, with compressed perimesecephalic cisterns in the CT scan. The ICP increased (arrow) until 35 mmHg during the bone fixation procedure, for insufficient anesthesia, $ptbO_2$ decreased (00.53 hour). The mABP rose until 90 mmHg, later decreased 60 mmHg. Probably $ptbO_2$ decreased for secondary hypovolemia associated with ICP elevation, beside initial MABP around 70 mmHg.

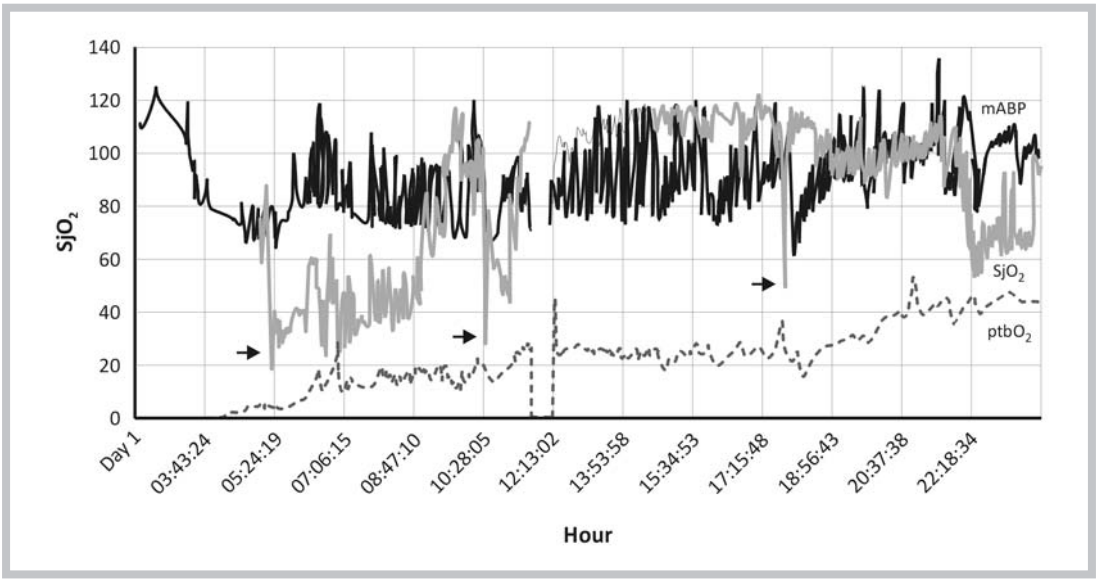

Figure 8.11. Initial correction of hypoperfusion and late hyperemia in SjO_2. 58-year-old male, GCS = 6, 3-meter fall. On the admission his pupils were reactive. The CT scan showed diffuse hemorrhagic points with left parietal contusion and a middle line deviation of no more than 5 mm. Apparently the injuries were not really severe, it seemed that ICP was below 20 mmHg on the initial 24 hours after trauma. However, from 3.34 hours until 9.30 hours the oxygenation parameters showed marked hypoperfusion. Beside, mean arterial blood pressure (mABP) was higher than 60 mmHg. Later, SjO_2 showed hyperemia (SjO_2 >75%) not correlated with normal ICP. The mean ICP was below 20 mmHg. During this stage the mABP was 80-120 mmHg. The main cause of this vascular autoregulation was probably a higher arterial blood pressure. Three months after the trauma the GOS was 4. Arrows: fiberoptic SjO_2 calibration.

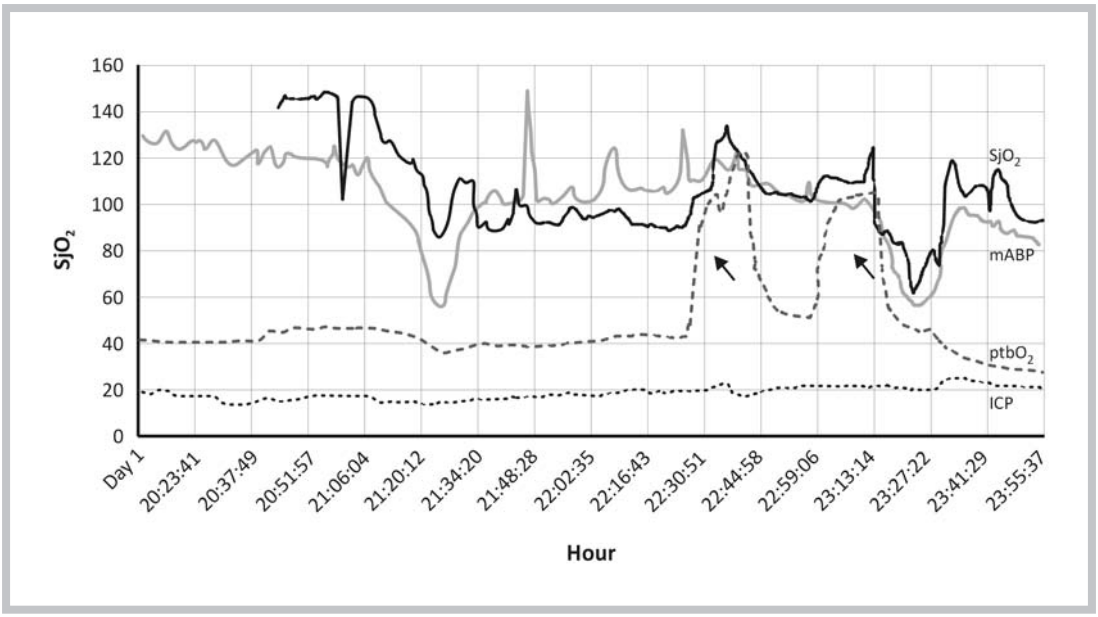

Figure 8.12. **Hypotension and hypoperfusion in a hypertensive patient with TBI. In TBI the main secondary injury factor associated with a poor outcome is hypotension. In this patient, GCS 7, with isocoric pupils (negative/positive), the mean arterial blood pressure decreased from 120 to 50 mmHg (20.00 to 21.20 hours) with associated effect in SjO_2 and $ptbO_2$. Apparently the main effect was observed in SjO_2 which persisted until the first maneuver 100 % FiO_2 (first arrow); SjO_2 increased until 80%, together with mean arterial blood pressure higher than 100 mmHg (22.44 hour). These hemodynamic changes indicate a severe affection. However, the ICP was normal. In chronic hypertension the key point for BP must be interpreted in relation with ICP, in order to test the vascular autoregulation limit. In the first initial 24 hour after trauma, sudden changes in hypotension and hypertension induce severe edema. The sudden hemodynamic change greatly increased ICP. On day 3, ICP reached 35 mmHg. Three months after trauma, GOS was 3 points.**

These considerations illustrate that an understanding of the underlying pathophysiology in TBI patients is complex and that treatment approaches may carry both benefits and risks. Current insights into pathophysiology and results from multimodality monitoring strongly support the concept of a more individualized approach, instead of standardized protocols, in managing TBI patients.

Applying personalized approaches requires a full understanding of the ongoing pathophysiology. In the absence of dedicated multimodality monitoring, we do not know whether the patients may be in an oligaemic or a hyperperfusion state. And although important, ICP monitoring only provides information on a single parameter. It should be remembered that prophylactic hyperventilation will not prevent increases in ICP [59]and that hyperventilation may decrease cerebral oxygenation, as measured by brain tissue oxygen pressure, in patients with normal and those with elevated ICP [59,60].

Further insight into the pathophysiology of individual patients can be gained from measuring both global (SjO_2) and regional (brain tissue oxygen pressure) cerebral oxygen parameters. Examples of different treatment approaches are summarized in the figures (Figures 8.10-8.12).

These examples are not evidence-based but rather represent the consensus of experts experienced in TBI treatment and with a history of participation in clinical trials and research.

8.4.3 Regional Approach: Brain Tissue Oxygen Pressure

The regional approach relies on brain tissue oxygen monitoring, commonly abbreviated as $ptbO_2$, $ptiO_2$, or $PbrO_2$. In this section we shall use the abbreviation $ptbO_2$ (partial pressure of brain oxygen tension).

8.4.4 Development of a Clark-type Electrode for Measuring Brain Tissue Oxygenation

The technology for $ptbO_2$ measurement originated from studies on photosynthesis. In 1938, Blinks and Skow used a platinum electrode as a cathode for measuring pCO_2 in plant tissue [116]. Brink, Davies and Bronk attempted this technique in human tissue, but "the metal poisoned the blood" [117]. This report prompted Clark (Figure 8.13) to cover the cathode and anode with polyethylene to "prevent intoxication" [118].

The polyethylene covering effectively reduced oxygen consumption by the electrode and facilitated the diffusion of environmental oxygen to the electrode. Since 1954 the Clark electrode has been used in the measurement of blood gases.

Although Clark attempted to monitor oxygen tension in the brain with this method, it was not until 1980 that Dr. W. Fleckenstein in Germany further refined the methodology for use in tissue measurements in experiments first on small animals and then on humans [119]. Measurement in both the brain parenchyma and the cerebrospinal fluid (CSF) showed higher levels of pO_2 in the CSF compared to the parenchyma, with a much greater and more rapid influence of arterial pO_2 on measured values. This was probably due to the rich vascularization of the choroid plexus where no blood-brain barrier is present. Reperfusion studies showed a much slower recovery of brain tissue pO_2 following global ischemia than in the CSF. It was therefore concluded that brain tissue measurements would provide greater relevance to cerebral oxygenation in clinical use [120].

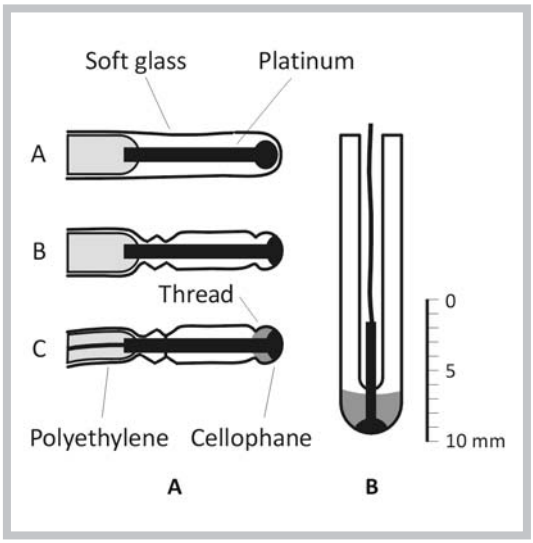

Figure 8.13. **Catheter components: A) Catheter covered by cellophane. B) Catheter distal portion. A shiny platinum cathode covered with a layer of cellophane has been found to be suitable for the direct measurement of oxygen tension in whole blood by polarographic procedures. The cellophane covering prevents the undesirable effects of the red cells which interfere with oxygen tension measurements using a bare platinum electrode, and in addition nearly abolishes the "stirring effect". A tiny cathode of this type (2 mm diameter and 8 mm long) mounted on a catheter can be passed into the major blood vessels and the chambers of the heart, for continuous recording of oxygen tension. Such cathodes are easily calibrated and are stable, reproducible and sensitive.**

The basic principle behind the Clark-type electrode is that environmental oxygen diffuses through the polyethylene covering into a chamber containing a gold or platinum electrode immersed in an electrolyte solution. In the chamber, the oxygen is converted to OH^- at the gold cathode to produce an electric potential that can be measured. Re-

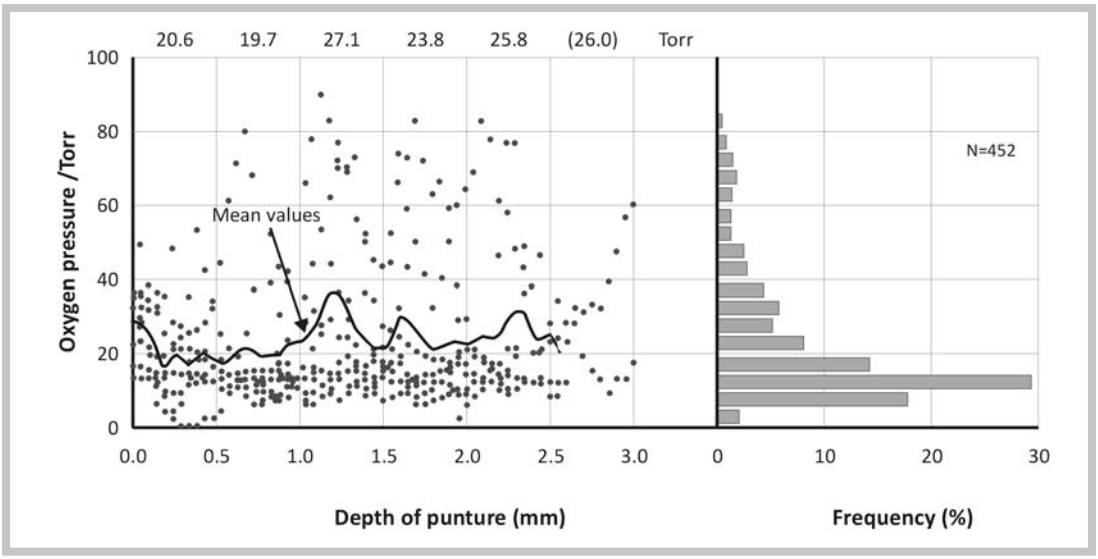

Figure 8.14. **Heterogeneity and $ptbO_2$ in experimental kidney (rat). Values of nine punctures in relation to the depth of the puncture. Significant heterogeneity for surface anesthesia. Low values coexist with values close to paO_2 pressure.**

duction of water with oxygen within this chamber is expressed according to the chemical reaction:

$$2H_2O + O_2 \rightarrow 4OH^-$$

thus providing 4 OH and generating the electric potential.

Initially, the electrodes were designed as fast-response systems to measure the electric potential very locally. This permitted study into the heterogeneity of cerebral pO_2 and related cerebrovascular distribution, which could be expressed as $ptbO_2$ histograms. The great heterogeneity of $ptbO_2$ in brain tissue, however, made this approach difficult for clinical use.

For clinical application a catheter was designed with a larger measurement area and a slower response, thus averaging local heterogeneity and providing an average oxygen tension within a specific area of the brain from which oxygen could diffuse to the catheter. The $ptbO_2$ thus measured can be considered as the average of values of thousands of capillaries surrounding the catheter, i.e., 200-10000 fields created by local diffusion. The $ptbO_2$ reflects the balance between available oxygen flowing through the tissue microvasculature and local consumption. In other words, it is the partial pressure of oxygen in the extravascular and extracellular interstitial space. It does not measure the intracellular oxygen concentration in cell bodies. Normal values of $ptbO_2$ measured with the Clark catheter technology are within the range of 20 to 40 mmHg, with an average of 25-27 mmHg at normal ICP and CPP levels [121,127,131] (Figure 8.14).

8.4.5 Factors Influencing Brain Tissue Oxygen Tension

$ptbO_2$ responds directly to oxygen tension in the blood and the number and diameter of capillaries per volume of measured tissue. More parameters are described in the following sections: FiO_2, temperature, pressure perfusion, hemoglobin, $paCO_2$, ICP, vascular autoregulation, etc. [122-131] (see Table 8.4 and Figure 8.15).

Local factors influencing $ptbO_2$	• Oxygen consumption of neurons and glia cells • Conditions of diffusion and gradients of oxygen: at capillary, venular, arteriolar of the brain tissue area • Number of perfused capillaries per volume of tissue supplied • Longitude and diameter of the capillary irrigated • Rate and microflow pattern: vascular autoregulation • Release of oxygen for the hemoglobin
Systemic factors influencing $ptbO_2$	• Arterial blood pressure, intracranial pressure, cerebral pressure perfusion • $PaCO_2$, temperature, % fraction oxygen, hemoglobin content, p50, blood • Viscosity, hematocrit, SaO_2, venous saturation

Table 8.4. **What is measured: local and systemic factors?**

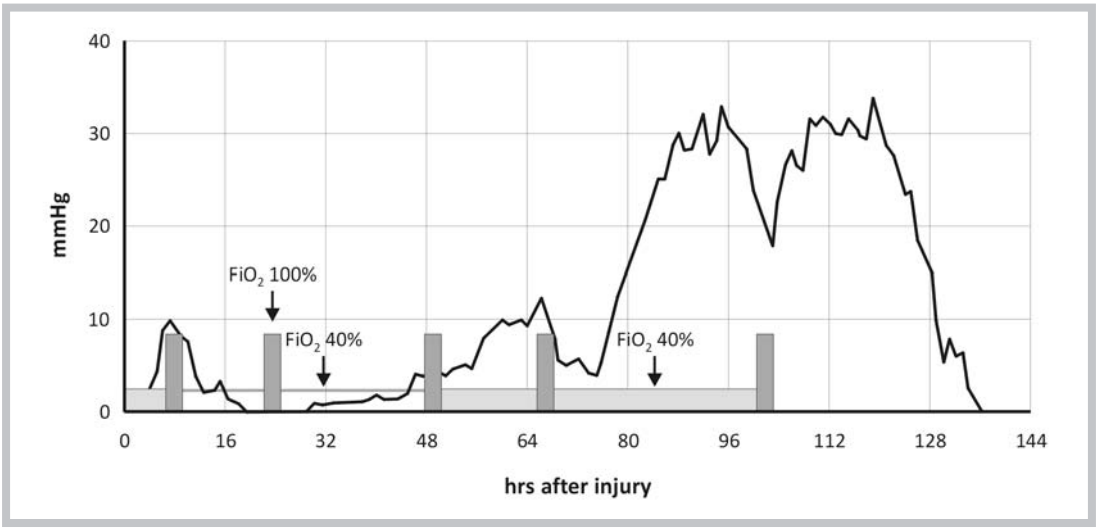

Figure 8.15. **Influence of anemia and FiO_2 100% on $ptbO_2$ in severe TBI.**

Here we report an explanatory case. In the last summer a 24-year-old male crashed with his auto into a tree. Three hours after the trauma he arrived into the hospital with a GCS 6: O1, M4, V:1. He was intubated outside the hospital due to insufficient spontaneous breathing. The paramedics reported a femoral and also a right frontal fracture. The abdominal ultrasonography did not report bleeding. The mediastinum was widened and he had no hip fractures.

The initial CT scan showed lesions in the orbit, ethmoidal and frontal sinuses. The basal cisterns were filled with blood and air. There was a small left parietal hematoma and blood in the third horn of the right ventricle and in the Sylvian fissure. The parenchyma showed diffuse hemorrhagic points in both hemispheres. The X ray chest showed a left lung contusion. The initial ICP was 20 mmHg. The pupils were dilated. He was treated with vasopressors and fluid replacement. In the second scan ofthe second day there was a large left hypodense area on the irrigation areas of the middle cerebral artery, an anterior frontal contusion, and a small left parietal subdural hematoma. Later he developed diabetes insipidus with sodium of 150 Meq. 6 days after the admision the ICP was 40 mmHg.

The initial pHa was 7.24, paO_2 180 mmHg (24.1 kPa), $paCO_2$ 47.6 mmHg (5.64 kPa) with baseline FiO_2 65%, the ventilator was programmed with 15 breaths per min and MV 10.000 ml, Hb 6.4 g. After treatment with vasopressors, mABP reached 77 mmHg, HR 142 per min., CPP 57 mmHg, SaO_2 99%, $paCO_2$ 36.7 mmHg (4.9 kPa). The initial $ptbO_2$ was 1 mmHg; 15 minutes after oxygen 100%, it increased to 3 mmHg and two hours lat-

er, with the same maneuver, it increased to 10 mmHg, with a mABP of 85 mmHg. The trend line of pHa was in correlation with $ptbO_2$, suggesting a better metabolism with poor oxygen caused by anemia. On the second day of admission the body temperature was 39°C. Due to the patient's religion (Jehovah's Witness), the family did not allow a blood transfusion until four days after admission, when doctors finally managed to persuade the family.

On the fifth day of hospitalization a SPECT was performed, and the $ptbO_2$ increased to 30 mmHg. The initial 24 hours of $ptbO_2$ monitoring suggested a global pattern, but on the last day the $ptbO_2$ of 30 mmHg indicated a local $ptbO_2$ pattern.

8.4.6 The Purpose of $PtbO_2$ Measurement: A Surrogate for Global Oxygenation or to Save the Penumbra?

The $ptbO_2$ reflects global cerebral oxygenation if the catheter tip is placed in a relatively undamaged part of the white matter; the validity of this concept has been confirmed in studies with single-photon emission computed tomography (SPECT), SjO_2, regional CBF and ΔAjO_2 [132,133]. This approach may be called *pars pro toto* in which measurements taken in a small part are representative of the global situation. Several studies have shown that this approach may even provide more accurate information than SjO_2 for the detection of ischemic events [134]. Others, however, have suggested that $ptbO_2$ may be better suited to capture events associated with hypotension and that SjO_2 may be more sensitive to the effects of hyperventilation. Ultimately, both approaches may be considered complementary.

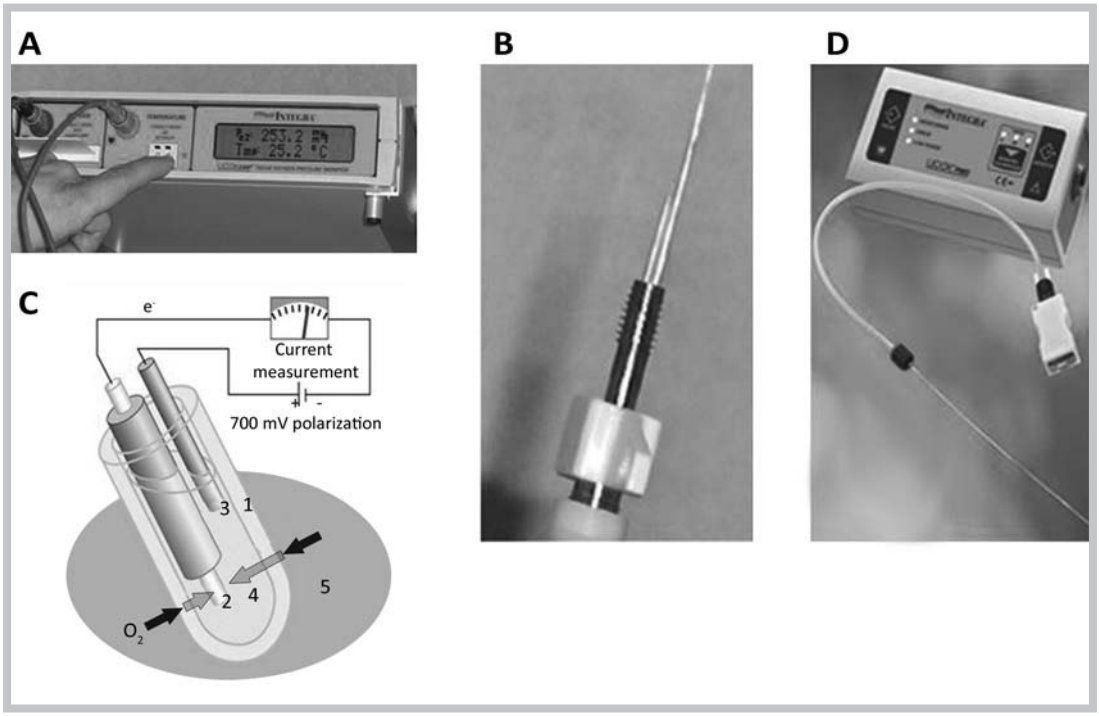

Figure 8.16. **Licox System. (A). Licox Monitor. (B). Oxygen catheter with attached ICP catheter. (C). Components of the catheter tip: 1) Polyethylene cover, 2) Cathode: gold electrode, 3) Anode: silver electrode, 4) Environment electrolyte, 5) Brain tissue environment with surrounding oxygen. (D). Monitoring module MPO and Licox oxygen catheter which is connected to the bedside monitor.**

Some authors recommend deliberate placement of the brain tissue oxygen probe in the penumbra area of a contusional or an ischemic area. The intent with this approach is to measure local values in the attempt to save valuable tissue and to prevent contusion or lesion expansion. Stocchetti et al. [123,137] successfully increased mean arterial pressure (MAP) to improve local perfusion of areas surrounding contusions. Catheter position in the penumbra area was confirmed by CT scanning. Although the benefit of this approach has not been subjected to double blind randomized studies, the concept is appealing and holds potential. Its clinical application will necessarily remain restricted to surgically treated cases, as positioning in the penumbra area is otherwise difficult.

8.4.7 Techniques for Monitoring $ptbO_2$

The most widely used technique for monitoring brain tissue oxygen tension is the Licox device, marketed by Integra. It uses a modern version of the original Clark-type electrode developed by Dr. Fleckenstein for brain tissue monitoring. A large body of clinical experience with this approach now exists, with extensive reports on its stability, safety [138], use as a monitor and as a guide to brain oxygen targeted therapy (Figure 8.16).

The only other currently available device we are aware of is that marketed by Raumedic [139], which is based on a different technology. Because it has become available only in recent years, comparison of results obtained with the Raumedic sensor and the Licox sensor are unavailable (Figure 8.16, Figure 8.17 and Table 8.5)

Until a few years ago, the Neurotrend catheter was marketed but has since been withdrawn from the market. The Neurotrend catheter provided simultaneous measurement of pH, pcO_2, $ptbO_2$, and brain temperature. There are comparative

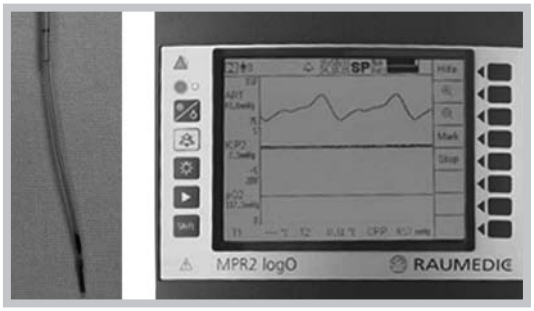

Figure 8.17. **Raumedic System. Recently introduced, it measures simultaneously ICP, brain temperature and oxygenation in a single catheter. Applying an optical technique, denominate "fluorescence", it catches the circulating cerebral oxygen. At the tip of the catheter is a luminophore, which captures the signal. After absorbing the light, with some energy the phosphor enters a state of excitement that is later modified to a state of relaxation. Relaxation involves the dissipation of energy throughout the swing and emission of a photon of lower energy and longer wavelength (fluorescence). To put it in another way, we can say that the oxygen is trapped; the oxygen saturation of the hemoglobin molecule makes the accuracy and greater magnitude of oxygen measurements.**

Characteristics	Licox	Neurovent
Storage	Refrigerator	Air ambient
Oxygen consumption	Yes	No
Electrolitic consumption	Yes	No
Monitoring time	Restricted	Without limit
ICP and temperature in the same catheter	No	Yes
Diameter	1.5/0.49 mm	5 Fr/1.65 mm
Catchment area	13 mm^2	22 mm^2
T/90-35°C	<200 s	<200 s

Table 8.5. **Comparison between Licox (Integra) and Neurovent (Raumedic) systems.**

studies between the results obtained with the Neurotrend versus the Licox catheter. In 49 Licox catheters of 42 patients, data free artefacts were obtained in 37 (88%) patients, whereas in 50 Neurotrend catheters of 35 patients, data free of artefacts were obtained in 14 (40%) patients. The incidence of catheter ruptured for the screw and malfunction was higher for Neurotrend catheter (20 and 8%, respectively) than for the Licox device (0 and 2%, respectively) [140]. The authors reported two hematomas occurring in 99 catheters but did not provide further analysis [140]. There was no difference in the safety profile of the two devices. In general, approximately 5 to 10 mmHg higher values were reported with use of the Neurotrend catheter as compared to the Licox catheter. This observation should be taken into consideration when comparing studies using the two devices.

Stability and safety of Licox catheters:

- Two iatrogenic hematomas have been reported in 2 patients, with surgical consequences (1.7%).
- No infections were reported after 6.7±3.9 days.
- The complications rate (e.g., dislocation) was 13.6%.
- The average adaptation time was 79.0±51 minutes.
- The maximum error was 1.07±2.14%, tested at temperatures between 22 and 37 C° and an oxygen pressure of 0. 44 and 150 mmHg; this number is irrelevant for everyday clinical practice.
- The zero error at the end of monitoring, tested by dipping the catheter into a solution without oxygen was 0.21±0.25 mmHg. This error is insignificant for clinical practice.
- Excluding data from the first hour, these results are reliable in 100% of cases [138].

8.4.8 Practical Aspects of Implantation

Oxygen probes can be introduced during a surgical procedure or through a dedicated burr hole. In the latter case, the intent is usually to monitor a relatively undamaged part of the brain in the right frontal region when possible. When inserted through a dedicated burr hole, fixation is best obtained with a subarachnoid screw through which the catheter can be introduced into the brain. Single lumen and multilumen screws permit the introduction of other catheters, e.g., ICP, brain temperature or CBF catheters. Since pO_2 monitoring with a Clark-type electrode is influenced by temperature (for each °C $ptbO_2$ changes by approximately 4%, temperature correction is required. To do this, one may use direct measurement of brain temperature or manually input core temperature values from the measured core temperature. Currently available pO_2 catheters ordinarily combine pO_2 sensors and a brain temperature sensor to automatically correct temperature, making the device much simpler in general clinical use (Figure 8.16).

Drilling the screw insertion hole into the skull demands meticulous technique to completely remove any bony rim and to puncture the Dura adequately. CSF output confirms good access. When using a multilumen screw, the central catheter should be inserted first. Prior to insertion, the catheter must be calibrated according to the manufacturer's specifications. Each catheter has specific settings for determining temperature, humidity, barometric pressure, oxygen content, and nitrogen level. These values are contained on a chip which comes with the catheter and which is inserted into the monitoring device. This matrix automatically sets the catheter's unique calibration values.

Following insertion and fixation, an equilibration time must elapse before the measured values can be considered reliable and representative of cerebral oxygenation. The "run-in time" can vary between patients, but stable values are generally obtained within 1 to 2 hours (Figure 8.18).

Accurate catheter functioning should be evaluated by performing an oxygen challenge test (increasing FiO_2 to 100% for 10 min). Normally, the oxygen challenge test will lead to a substantial increase in brain tissue oxygen, thus confirming adequate catheter functioning [141]. Catheter malposition or malfunction should be suspected in the absence of a catheter response to increasing FiO_2. Low values and an absence of response to an oxygen challenge test may be caused by a small local hematoma around the probe tip.

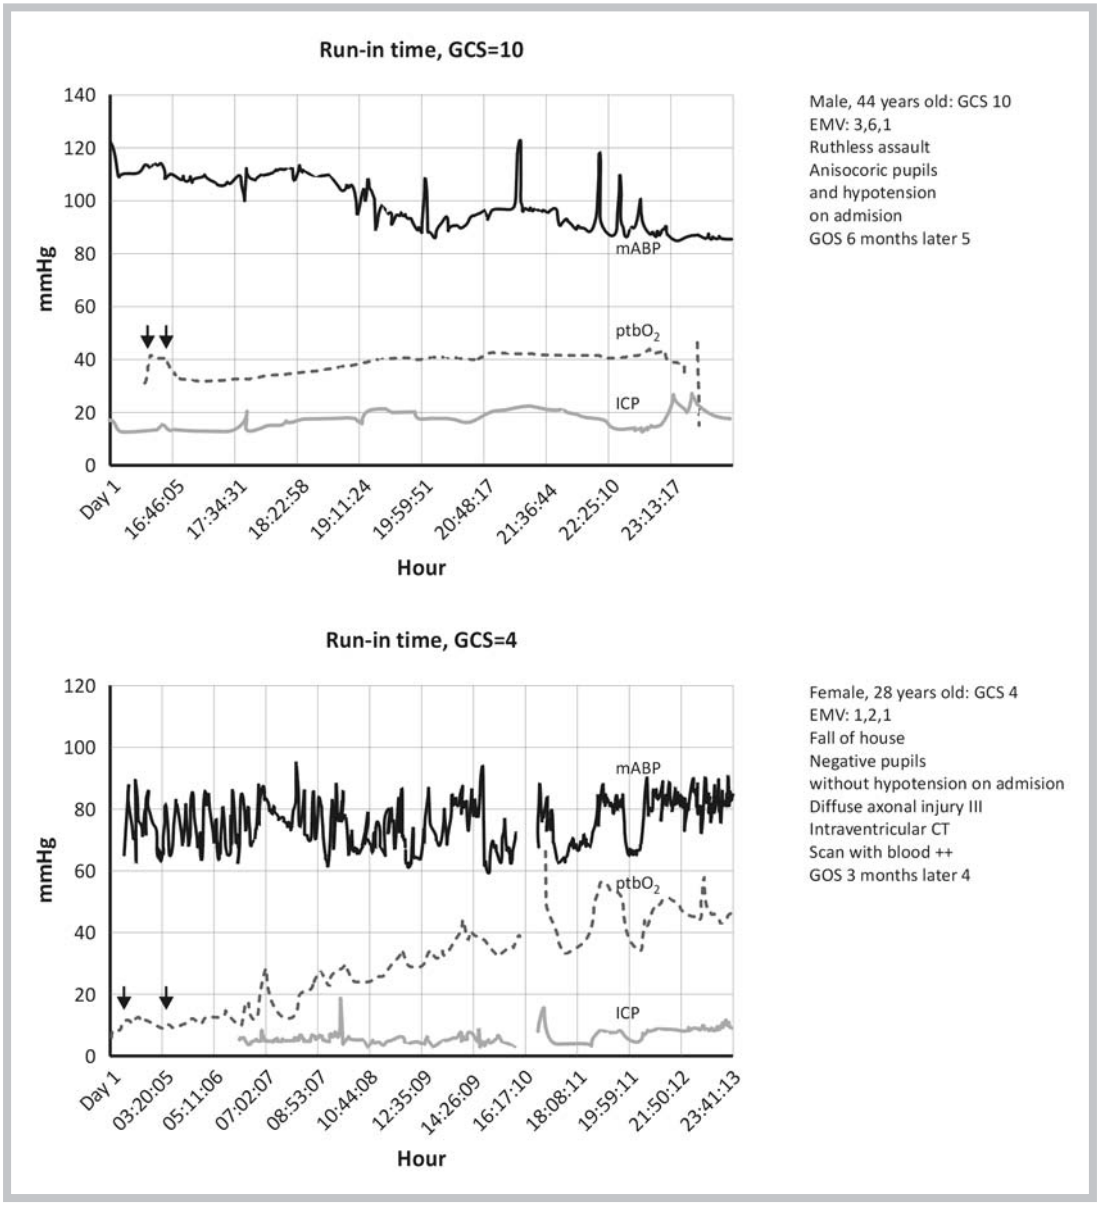

Figure 8.18. **Run-in time and GCS. The term ”run-in time” was coined by the Rotterdam group and corresponds to the effective $ptbO_2$ stabilization time after catheter insertion. This period represents the damage caused by the insertion of tissue oxygen catheter. In patients with better Glasgow Coma Scale, we have observed a lower stabilization time than in patients with less GCS score. Apparently, the run-in time is also affected by the presence of secondary injury factors. It is assumed that a longer run-in time period could be associated with hypotension and hypoxia. These two images show these associated factors. Arrows show the run-in time period.**

Alternatively, excluding technical malfunction, the probe may be positioned in non-perfused unviable tissue, otherwise CBF may be seriously compromised. The catheter position should be confirmed in all instances by routine CT follow-up.
In TBI, monitoring should be started as early as possible, as low CBF and the risk of secondary ischemia is greatest within the first 24 hours; the recommended duration of monitoring is generally the same as that required for invasive monitoring, including ICP monitoring [110].

8.4.9 Tissue Oxygenation Monitoring and Clinical Qualities

A monitoring technique is evaluated by the quality and relevance of the information that it provides. Quality parameters include accuracy, utility and reliability. Monitoring of the partial pressure of oxygen in the brain tissue is relevant for interpreting the pathophysiology of TBI and can aid in individualizing the treatment towards the needs of a given patient. The accuracy, reliability and utility of this technique have been extensively studied in the clinical setting [15,18,10,142].

8.4.10 Clinical Accuracy

To properly understand the concept of oxygen supply and consumption as studied by $ptbO_2$ monitoring, some knowledge of intracranial and extracranial pathophysiology, especially hemodynamic and cellular metabolism, is required [42,44-46,143]. The partial pressure of brain tissue oxygen is dependent on CBF and oxygen delivery and consumption. Concepts included in the SjO_2 section are also applicable. We refer to this section and the references [40,43,48,54].
In clinical practice, the indication for ICU admission and monitoring in a TBI patient is determined by the severity of the patient's condition as expressed by the GCS level, CT scan findings, pupillary reactivity, secondary insults, and the potential risks for deterioration [21,23,25,100]. In their extensive studies, the Rotterdam group found no clear association between the poststabilization of GCS scores and $ptbO_2$ in patients with severe or moderate TBI. This may be interpreted as indicating that oxygen status may be disturbed at all levels of severity. Moreover, we should remember that tissue oxygenation is heterogeneous in both normal and pathologic situations [27,29]. In TBI patients, brain tissue oxygen may be relatively normal in some regions, whilst in others there may be ischemic conditions with low $ptbO_2$ values. It should be noted that the intent of $ptbO_2$ monitoring as performed by the Rotterdam group was to monitor in a relatively undamaged part of the brain [15,144].
In contrast, the Houston group preferentially placed the catheter in close proximity to a brain contusion. With this approach, a clearer relationship was found between $ptbO_2$ and GCS, especially with regard to the motor component [136]. Moreover, they found a significant relationship between lower $ptbO_2$ values and outcome when the probe was positioned in the penumbra of (operated) mass lesions. Further studies are required to determine the pros and cons of monitoring in the penumbra versus in a relatively undamaged part of the brain where $ptbO_2$ may be considered more representative of global cerebral oxygenation.
The relationship between pupillary response and $ptbO_2$ was studied by the Rotterdam group [15,144]. They found an association between lower $ptbO_2$ values and a negative response of both pupils in the initial 24 hours after injury, suggesting an association between lower values and more severe injury. After 24 hours there was a mixed pattern and no apparent difference between lower and higher $ptbO_2$.

More recent studies have not addressed the relationship between pupillary reactivity and $ptbO_2$ in much detail. Pre-admission hypotensive episodes are closely related to poorer outcome. Although the relationship between lower blood pressure levels and poorer outcome is continuous, particular attention has been paid in the literature to episodes of systolic blood pressure ≤90 mmHg [8,100]. The relationship between pre-ad-

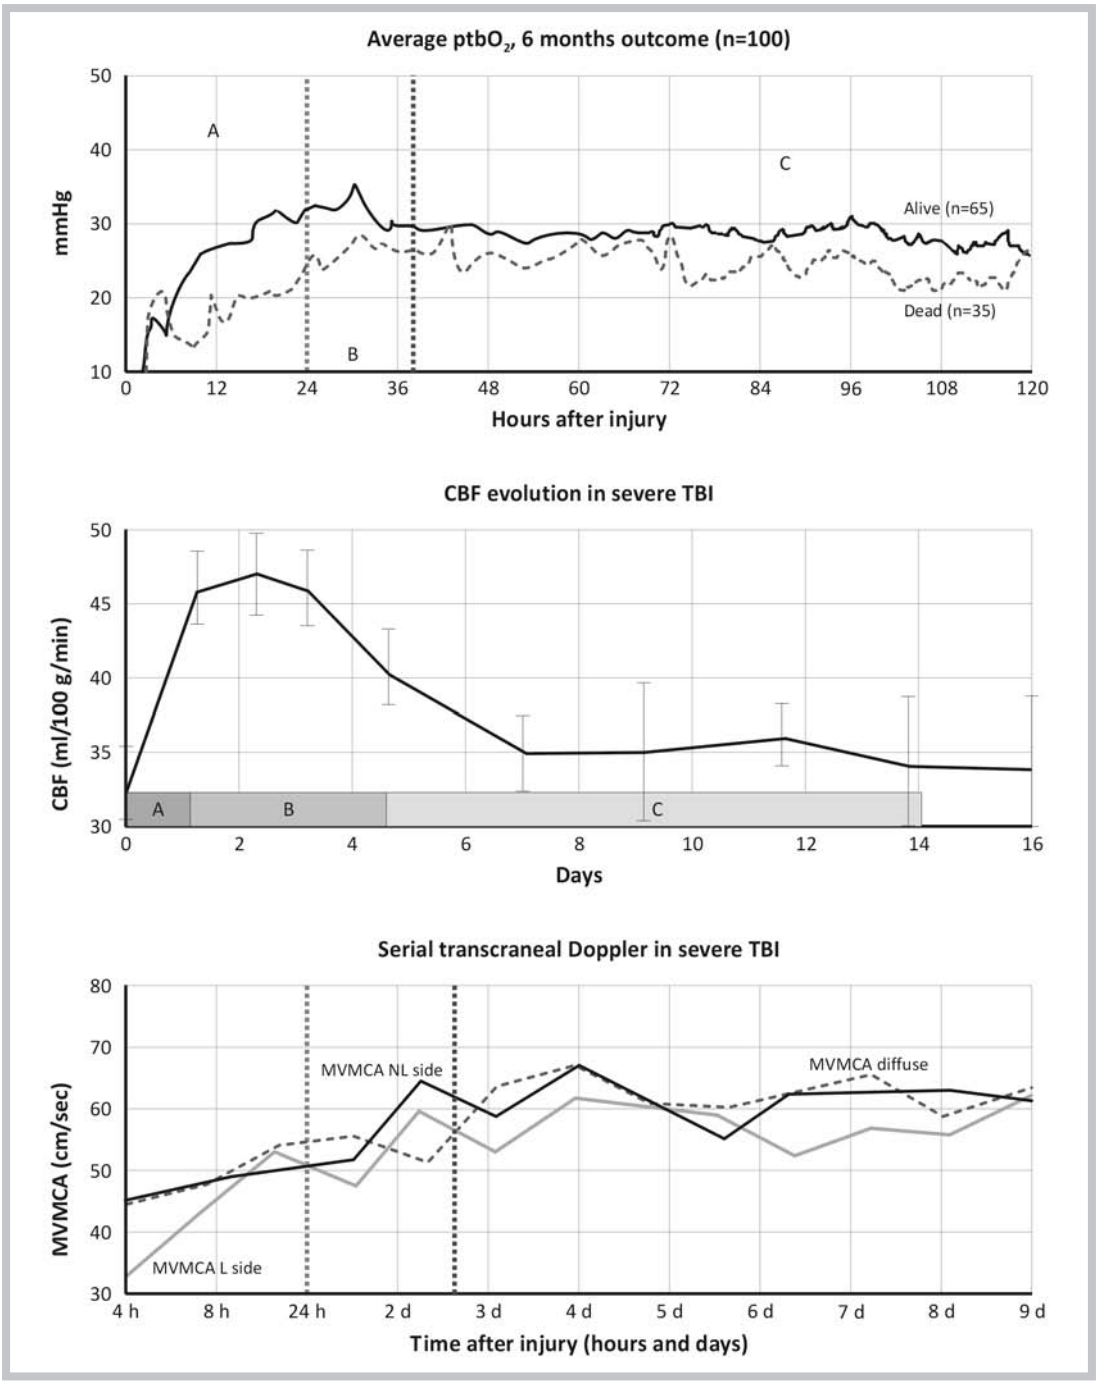

Figure 8.19. **Patterns over time of $ptbO_2$, CBF, and serial TCD.**
MVMCA = mean velocitiy middle cerebral artery non-lesion

mission hypotensive insults and $ptbO_2$ is weak. This is easily explained by the fact that hypotensive episodes may have been already corrected by the time that monitoring was initiated. Nevertheless, experimental and clinical studies have documented that $ptbO_2$ monitoring after shock trauma can be a useful guide to improve oxygen delivery.

Studies by the Rotterdam group have clearly shown lower values of $ptbO_2$ in nonsurvivors versus survivors during the first 24 hours after injury [144]. Over the next days, however, there was no clear difference in the average values between the groups. This lack of association with outcome in later phases of monitoring could be seen as poor specificity of the technique, but it further demonstrates the heterogeneous nature of TBI and highlights the evolution of changes in CBF and brain oxygen tension over time.

A 3-phase pattern in the evolution of CBF over time has been described by several authors [15,145,146]. This pattern has also been demonstrated in $ptbO_2$ monitoring by recent publications, in which the intent was to optimize oxygenation with vasopressors, fluid, and respiratory measures, as well as to improve ICP and cerebral perfusion pressure [16,20,30,147,148]. In the absence of an "optimization intention", this evolutionary picture of $ptbO_2$ may be different (Figure 8.19).

According to the Rotterdam studies, low $ptbO_2$ values are most often observed during the first 24 hours after injury. In a series of 100 patients, values <15 mmHg occurred in 57 patients, values <10 mmHg in 42, and values ≤5 mmHg in 22. It was subsequently suggested that this period can be characterized by "oxygen depression". In the 36-48-hours after injury, the average $ptbO_2$ values increased to approximately 46 mmHg. This period was therefore considered to represent an "overshoot" likely due to vasodilation secondary to the initial ischemia. Over the following days, the average tissue oxygen remained stable at around 30 mmHg and was considered as the "stabilization stage". The three phases of evolution of brain tissue oxygen over time are summarized in Table 8.6.

The evolution of $ptbO_2$ values over time corresponds to that described for CBF, Transcra¬nial Doppler and SjO_2 (Figure 8.19) [15]. Further work is needed to determine appropriate thresholds for initiating treatment to improve cerebral oxygenation. Such thresholds might conceptually be different for the three evolutionary phases described after TBI. In general, thresholds of 10-15 mmHg have been proposed [15,18,19,142,144]. Such critical levels may need to be individualized, as they can vary between patients and over time. Evolution over time is a highly relevant factor and not always recognized in studies. Many do not report the time of monitoring initiation [30], the stage of $ptbO_2$ evolution [17,30], the duration of trends or report only average values [16,17]. We have found that an individualized analysis may yield additional relevant insights.

Therefore, $ptbO_2$ monitoring in TBI ought to be interpreted on an individual basis to obtain better insight into the pathophysiological status. Noratam et al. [17] described a different pattern of $ptbO_2$evolution over 5 days of monitoring, which may be explained by the inclusion of patients with less severe conditions (GCS 13-15). They described the main abnormalities of $ptbO_2$ levels only after the initial 24 hours, unlike observations by other studies and different from several studies on CBF, TCD and other techniques [110,145-146].

The Rotterdam group found no relationship between patient age and $ptbO_2$, whereas the Robertson group did [15,136]. This difference may be explained by the fact that they preferentially placed the probe in the penumbra of a damaged area, thus introducing bias toward older patients. The Stocchetti group described lower mean $ptbO_2$ in the pericontusional tissue (19.7±2.1 mmHg) than in normal appearing tissue (25.5±1.5 mmHg; p <0.05), despite a higher cerebral perfusion pressure (73.7±2.3 versus 67.4±1.4 mmHg; p <0.05) in these pa-

Depression	Overshoot	Stabilization

Table 8.6. Evolution of $ptbO_2$ over time.

tients; therefore, probe position is an important factor in the interpretation of results and it also influences prognosis [41] (Figure 8.20).

Lower $ptbO_2$ values have also been reported in patients with compressed basal cisterns on CT examination. The prognostic value of low $ptbO_2$ values has been studied in multivariate logistic

Regression analysis. These studies confirmed an independent prognostic effect of $ptbO_2$; the probability of death increased 3.8 times (95% confidence interval [CI] 1.6-8.9; P=0.002) when the $ptbO_2$ was <10 mmHg for a total period of 30 minutes during the first 24 hours after trauma. Patients with a $ptbO_2$ >10 mmHg had a 2.8 higher chance of favourable outcome (95% CI 1.2-6.3; P=0.015).

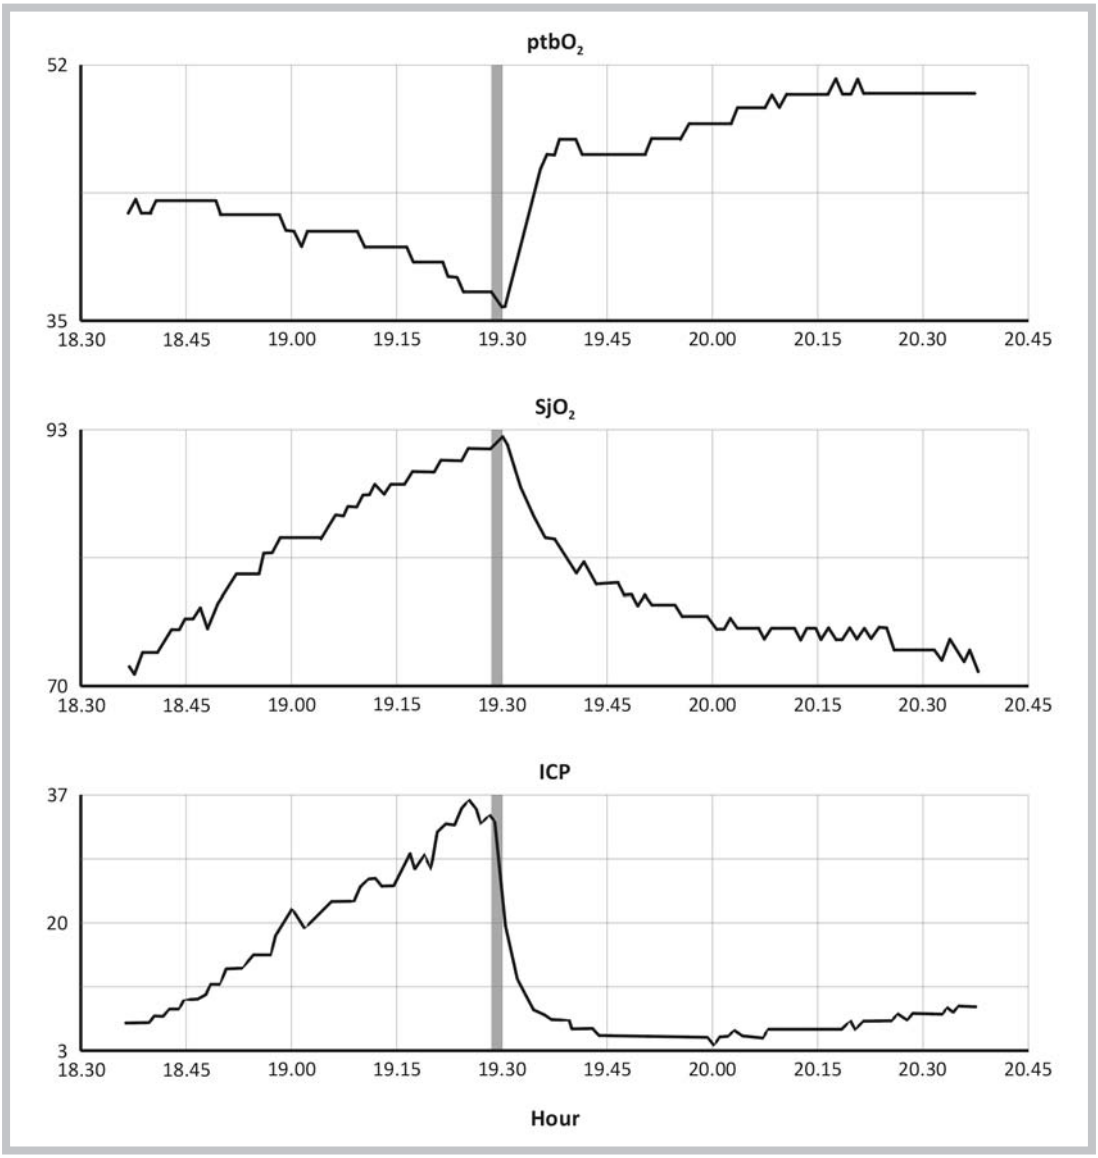

Figure 8.20. **Global and local oxygen parameters. There is a different trend for SjO_2 and $ptbO_2$. After ICP increasing until 36 mmHg (19.30 hours), also SjO_2 incrases, while $ptbO_2$pattern decreases to 36 mmHg. This response was caused by the different position of these two parameters. The local one was measured in the healthy brain, while the global parameter was positioned in the damaged brain.**

Increasing depth and longer duration of low $ptbO_2$ values are related to a higher risk of death and unfavourable outcome: a doubling of mortality was noted in patients with a $ptbO_2$ <5 mmHg for 30 minutes, in those with moderate hypoxia (<10 mmHg) after 1 hour and 45 minutes, and in those with milder tissue hypoxia (<15 mmHg) after 4 hours. Other studies have shown similar results [27,105,142].

Lower $ptbO_2$ values are also associated with poorer cognitive functioning in survivors, resulting in more problems in work re-integration [149]. These results clearly demonstrate an association between brain tissue hypoxia and increased mortality and poorer outcome in survivors [15, 142,144,150]. It is likely that this association is causal. Thus, it would seem appropriate to prevent brain tissue hypoxia from occurring, and if it does, to correct it rapidly. As a consequence, the concept of oxygen-targeted management was introduced.

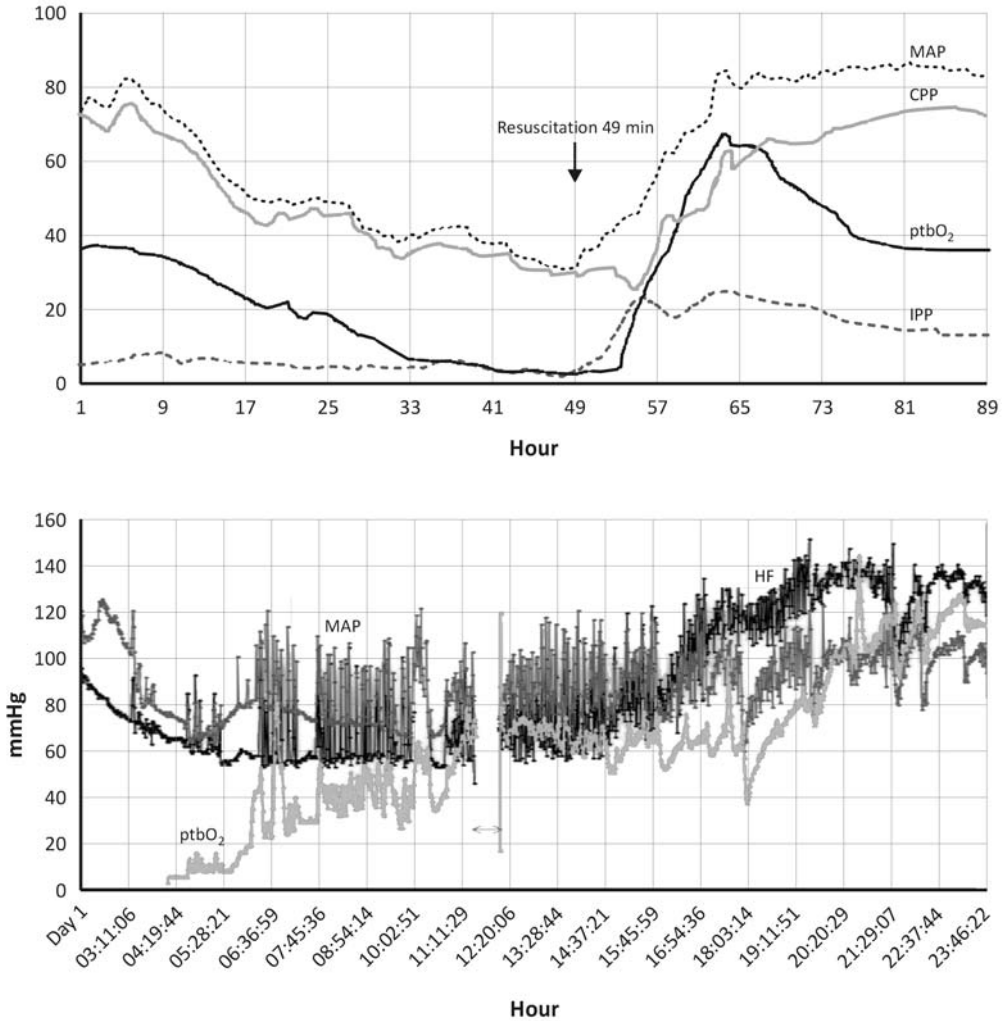

Figure 8.21. **Hypotension in experimental and clinical shock. The correlation between hypoperfusion induced by bleeding and $ptbO_2$ is very close. With the improvement in hypovolemia, tissue oxygenation improves. Lower figure: in clinical situation $ptbO_2$ follows the increasing trend of mean arterial pressure (MAP).**

8.4.11 Improving Cerebral Oxygenation

There are various different approaches to increase brain tissue pO_2:

- Increase arterial blood pressure (and cerebral perfusion pressure).
- Increase arterial oxygen content and/or partial oxygen pressure.
- Decrease metabolism.

8.4.12 Increasing Blood Pressure to Improve Oxygen Delivery

The rationale for increasing blood pressure to improve $ptbO_2$ stems from the assumption that by improving blood pressure the driving force behind cerebral perfusion will in-

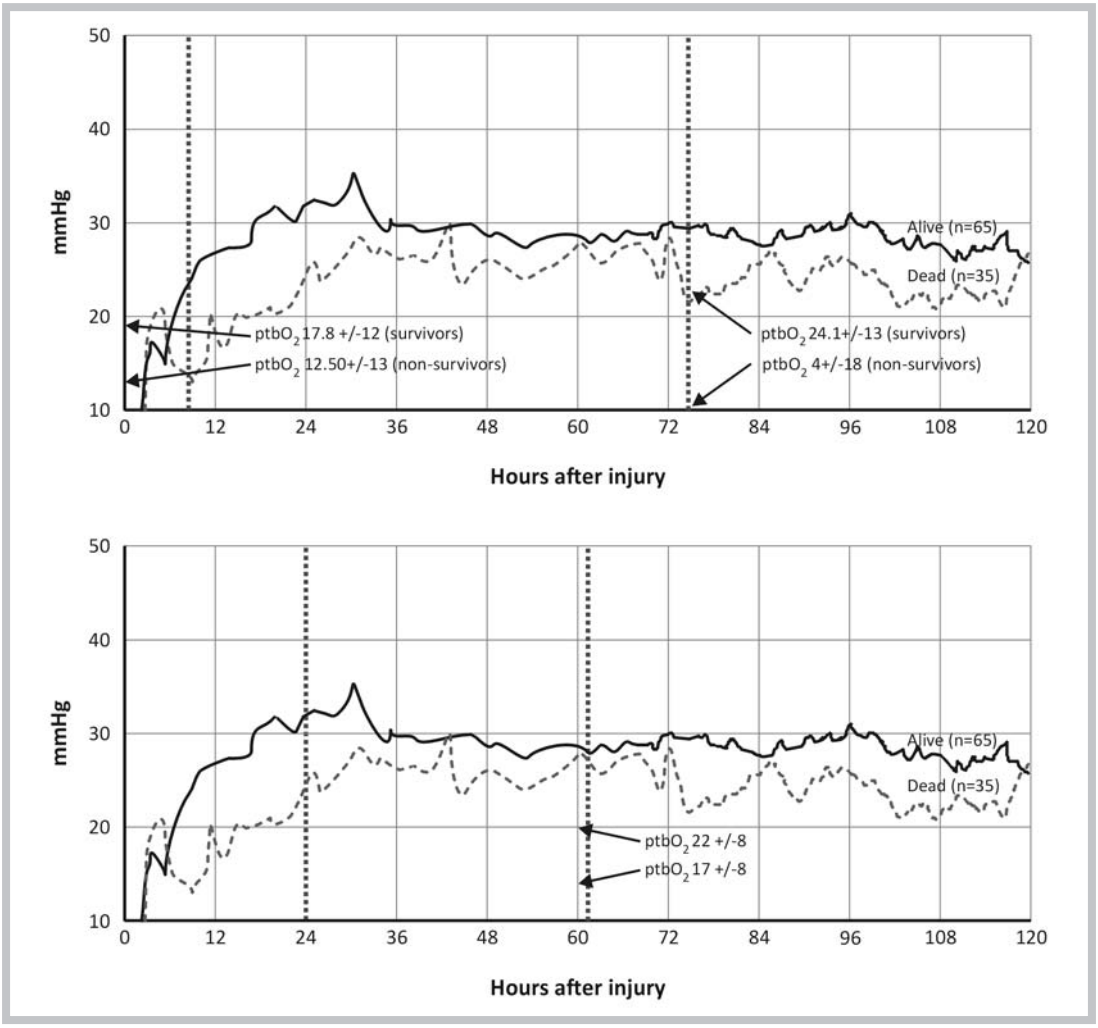

Figure 8.22. **$PtbO_2$ trend over time and vasopressor influence in severe TBI. Using the Rotterdam $ptbO_2$ trend in time, the influence of two norepinephrine trials is comparing with the natural $ptbO_2$ evolution. (A). The first trail tested the $ptbO_2$ response on the initial 24 hours in comparison with the 72 hours response. For the natural $ptbO_2$ response, the initial 6 hours response was higher than the 72 hours, and secondly it has the same evolution of CBF [30]. (B). The authors tested $ptbO_2$ response only on a mean of 62 hours over time, $ptbO_2$ increased 5 mmHg. This maneuver does not increase the $CMRO_2$ response. This maneuver should be related to the outcome. Therefore the best $ptbO_2$/CPP response with vasopressors occurred on the initial 24 hours [31].**

crease and result in better tissue perfusion and oxygenation. Its practical efficacy will, however, be influenced by individual factors such as the time after injury and the degree to which autoregulation is disturbed [15,30,140,147,151]. The results from two studies illustrate the time-dependency of the effectiveness of increasing blood pressure [30,147]. Increasing blood pressure with norepinephrine during the "depression stage" after injury produced an average increase in $ptbO_2$ of 7 mmHg, with a 30% increase in mean arterial pressure and improved cerebral perfusion. No data exist that specifically describe the response of $ptbO_2$ to vasopressors during the overshoot phase. The Cambridge group described an increase of 5 mmHg after vasopressors administration at 72 hours after injury. What can be concluded is that vasopressor administration effectively increases $ptbO_2$ at any time after injury [30] (Figure 8.21, Figure 8.22 and Table 8.7).

In principle, $ptbO_2$ is considered indicative of better tissue oxygenation. This is not completely correct, however, as increasing blood pressure does not necessarily translate into a reduction in ischemia. Hypoxic regions of the brain may not be capable of extracting sufficient oxygen due to oxygen diffusion gradients resulting in a diffusion barrier [152]. Microvascular collapse and vascular edema may contribute to this diffusion barrier [153]. The efficacy of increasing blood pressure to improve $ptbO_2$ will also depend on the degree to which autoregulation is intact or disturbed [154]. In patients with disturbed autoregulation, increasing blood pressure may increase ICP and edema, thus impeding the diffusion barrier to oxygen. In patients with more intact autoregulation, increasing blood pressure will decrease ICP and improve oxygenation.

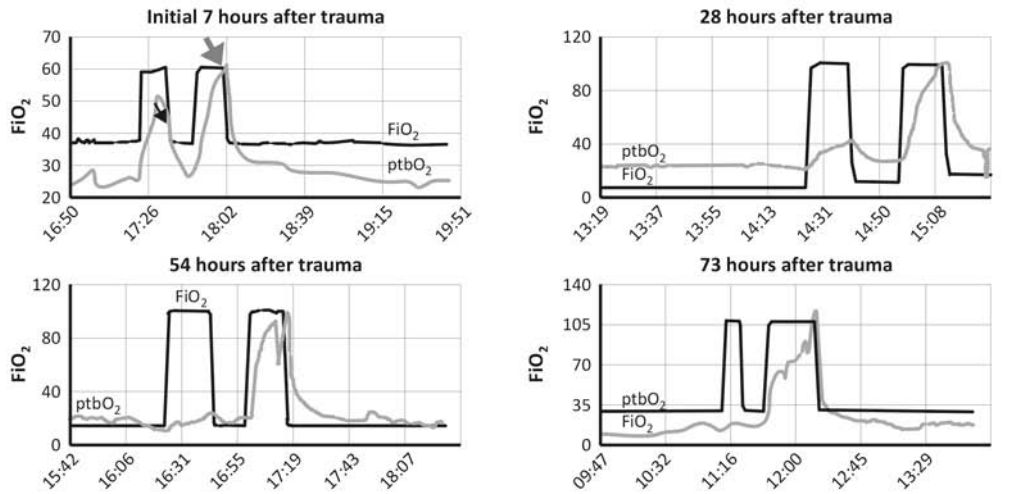
Careful interpretation of monitoring can aid in the identification of patients who may benefit from the use of vasopressors to improve oxygenation [152] (Figure 8.22). Unfortunately, few cases have been studied during the critical period of the first 24 hours. Further studies are needed to identify which patient subgroups are at particular risk of ischemia and may likely respond to this treatment modality. PET studies can demonstrate response to vasopressor therapy and have demonstrated a decreased volume of ischemia [152]. In a select series of 53 TBI patients, 25 historical controls were treated with ICP monitoring and 28 additionally received monitoring and treatment for tissue oxygenation. The ICP and CPP levels were comparable between the two groups. The outcome was different, with a mortality rate of 44% for the first group and 25% for the second. This study reported a significantly better outcome ($P < 0.05$) in the monitored group. Despite the relatively small sample size and the lack of a randomized design, the study results support the concept of oxygen-targeted management [155].

When considering whether to increase blood pressure in order to improve brain perfusion and oxygenation, attention should be given to the choice of vasopressors. One study has shown that CPP increased after norepinephrine administration but not with dopamine. With norepinephrine a significant reduction was observed in oxygen extraction (37±11 versus 33±12 ml/l) and a significant increase in tissue pO_2 (19.5±2.5 versus 23.3±8.3 mmHg). Response to the challenge test with dopamine was more variable than with norepinephrine [101,103).

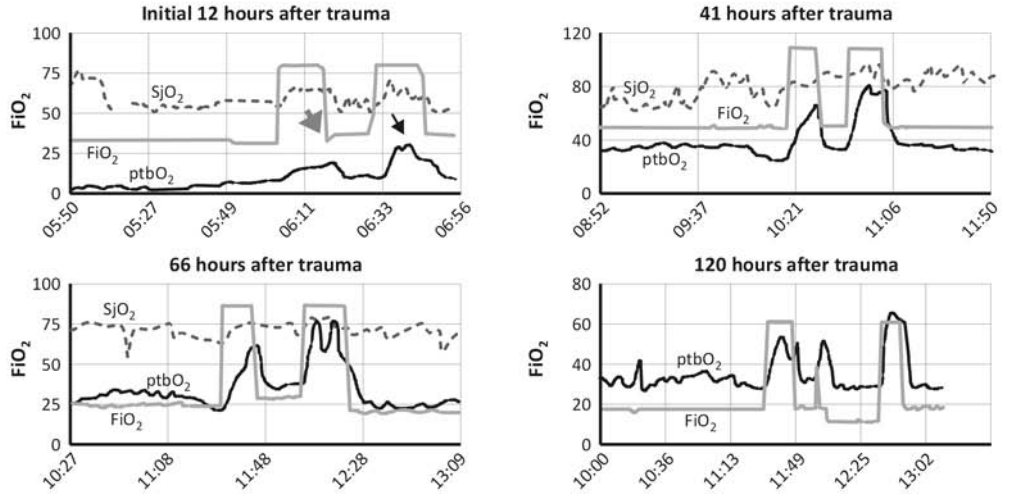
Mannitol is effective in reducing ICP, and it also improves microcirculation by decreasing blood viscosity. One would expect that the decrease in ICP and improved microcirculation could potentially improve $ptbO_2$, but this has not been confirmed in clinical studies [15,156]. However, the use of hypertonic saline in hypotensive patients improves arterial blood pressure and oxygenation, with a reduction of 45% in ICP that persists for 6 hours [157]. The important clinical conclusion from such observations is that oxygen monitoring should be used in addition to ICP monitoring, as the two modalities provide different types of information.

8.4.13 Increasing Arterial Oxygen Pressure and/or Content to Improve Cerebral Oxygenation

Increasing the fraction of inspired oxygen (FiO_2) is highly effective in increasing the partial tissue oxygen pressure. The response to the increase is immediate. We investigated the response to oxygen in 41 TBI patients with a GCS ≤8 by means of a standardised approach: FiO_2 was increased for 15 minutes and the observed changes quantified. The response was expressed as oxygen reactivity and related to outcome at 6 months. In a total of 145 tests, the baseline $ptbO_2$ ranged between 4 and 15 mmHg and the arterial paO_2 between 73 and 237 mmHg. After 15 minutes of 100% FiO_2 administration, the $ptbO_2$ increased to a minimum of 9.1 and the maximum 200 mmHg and the arterial pO_2 from 196 to 499 mmHg. We observed three different patterns of response: response type A was characterized by a sharp increase in $ptbO_2$, reaching a plateau within several minutes; pattern B by the lack of a plateau; and pattern C by a short-duration plateau, followed by a subsequent increase. Patterns characterized by a plateau (type A) were considered to have more stable regulatory mechanisms. This pattern observed in the first 24 hours after injury was associated with a more favourable outcome ($P=0.06$). Patients with high oxygen reactivity (1.03±0.6) during the first 24 hours had a poorer outcome compared to those with lower reactivity (0.61±0.51; $P=0.02$). The association between higher O_2 reactivity and poorer outcome may reflect more severe disturbances of autoregulatory mechanisms [126].



28-year-old female, fallen from a horse, GCS 4. CT scan with diffuse axonal injury; normal middle line structures; intraventricular blood in the right side; subarachnoid hemorrhage in the convexity; mesenceph. cisterns present. The four figures show a progressive increasing pattern in $ptbO_2$ (gray arrow). The initial (7 hours after trauma) ptO_2 was 60 mmHg; in the following days reached 100 and 120 mmHg. These responses were produced with a FiO_2 100% during 15 minutes without pharmacological relaxation. The 4th graph shows a sequence of spontaneous hyperventilation. The initial wave (black arrow) was produced with 100% oxygen plus hyperventilation during 15 minutes (20% more of tidal volume). The sequence describes a decreasing trend in ptO_2, from 60 to 20 mmHg. Apparently hyperventilation test induced a tremendous tissues response, which was unmasked by FiO_2 100%.
The hyperventilation reactivity is unpredictable. The GOS 6 months after trauma was 4. These reactivity tests can be used as therapeutic tools to prevent damage, baceuse hyperventilation has particular reactivity in some cases.



59-year-old male, fallen from a roof (three meters high). CT scan with bilateral temporal subdural hematomas, with midline structures deviation right to left, mesenceph cistern absent. The initial ptO_2 and SjO_2 show an ischemic pattern; with FiO_2 80%, ptO_2 reached 30 mmHg and SjO_2 70%; in the last days ptO_2 and SjO_2 were in normal range. On day 5, SjO_2 was removed incidentally. Some publications suggest hyperoxia as a treatment during the initial 24 hours after trauma. In this patient an initial global ischemic pattern is evident. Hyperoxia increased in both tests: hyperventilation test plus FiO_2 80% (gray arrow) and hyperoxia test without hyperventilation (black arrow), therefore hyperventilation it is not an acceptable tool especially in the initial 24 fours after trauma. Hyperventilation plus FiO_2 is a better protection maneuver. The patient was alive after 6 months of trauma.

Figure 8.23. **Hyperoxia and $ptbO_2$ response in TBI: two examples. Hyperoxia in TBI is not completely understood. Two possible scenarios are have been suggested. In one case, hyperoxia is a good treatment since it decreases the toxic metabolites and promotes oxide reduction. In the other, it gives no benefit and probably can cause damage. Neither of these hypotheses have been proved. Regardless of the absence of approved therapeutic guidelines, hyperoxia is used such as a "helmet" for brain protection, especially in the initial 24 hours after trauma under $ptbO_2$ monitoring.**

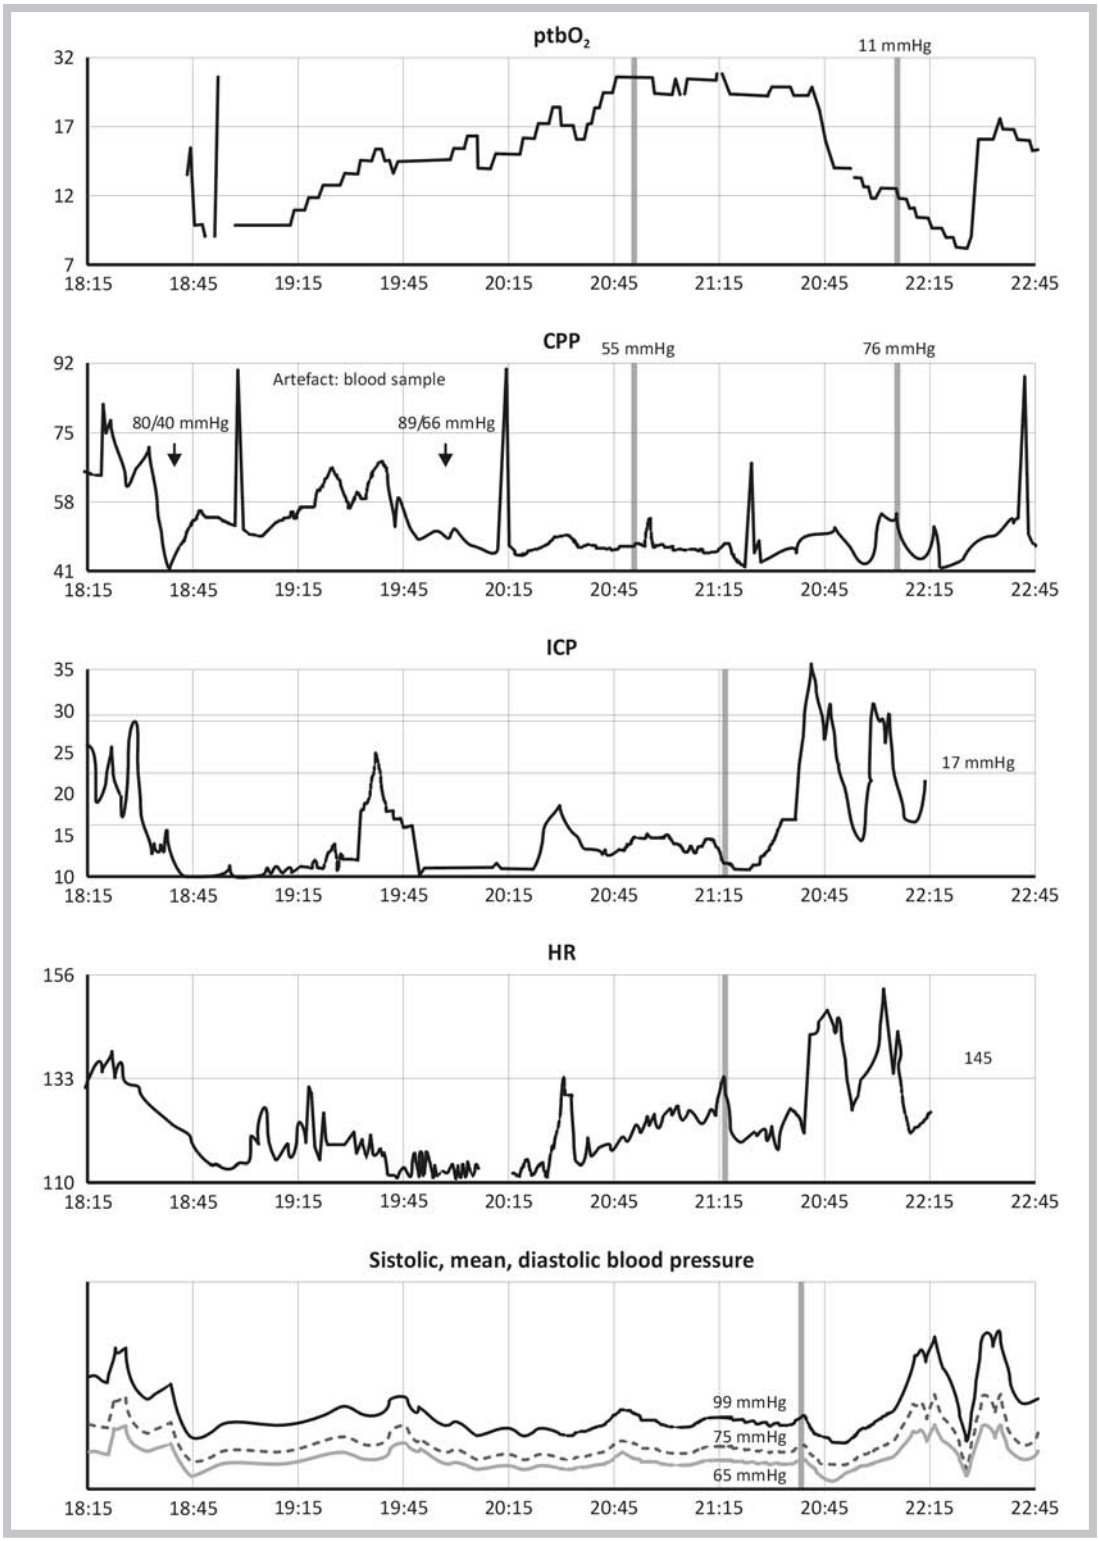


Figure 8.24. 31-year-old male, on admission: bronchoaspiration. For four hours, $ptbO_2$ <20 mmHg, with peaks <10 mmHg for 15 minutes. Hypotension contributed to a low PPC. Hypertension (180/110 mmHg) caused an increase in ICP, suggesting vascular autoregulation. The response was a decrease in ptO_2.

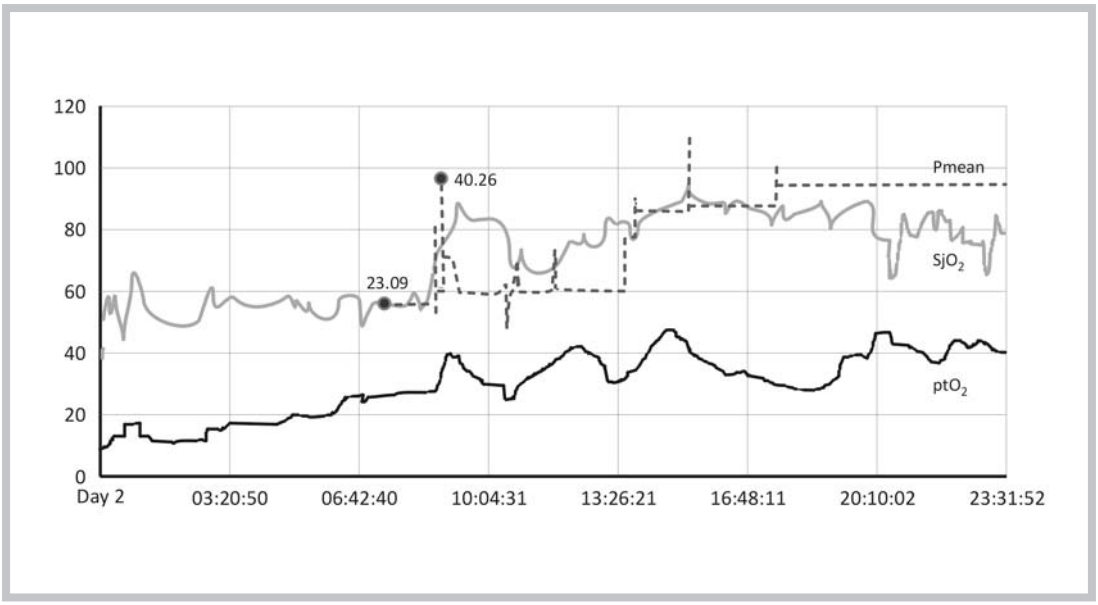

Figure 8.25. **Alveolar recruitment maneuver monitored by SjO_2 and $ptbO_2$. Poor initial respiratory response to ventilatory treatment, with impairment in global and regional cerebral oxygenation, and with improvement after alveolar recruitment. Pmean was increased to 23 mmHg and 40 mmHg progressively, oxygenation response was satisfactory: SjO_2 from 43 to 85% and $ptbO_2$ from 8 to 40 mmHg. Later Pmean decreased (both regional and global parameters). A more stable oxygenation was obtained with Pmean = 40 mmHg. An integrated monitoring, including ICP, is essential to avoid serious risks.**

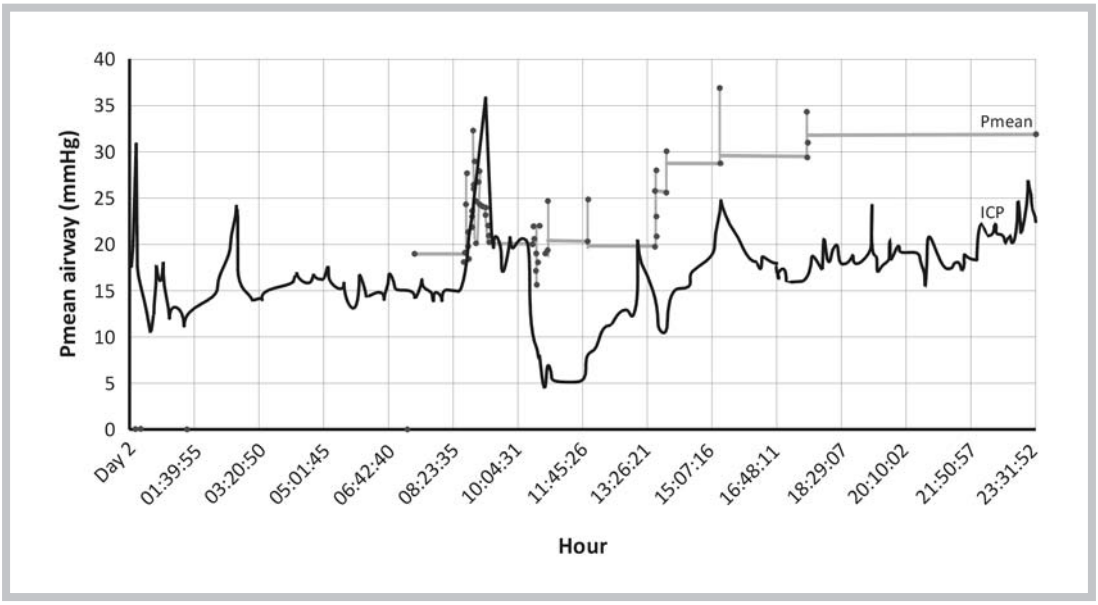

Figure 8.26. **ICP response to the increase in intrathoracic pressure consecutive to increased Pmean can be deleterious. If there is no integrated monitoring of regional and global tissue oxygenation, continuous end-tidal CO_2, MAP, ICP and frequent blood gas controls is not possible to observe the effects of mechanical ventilation on cerebral oxygenation and the spatial dynamics of the brain. In this case (severe TBI and bronchoaspiration), with alveolar recruitment ICP reached 35 mmHg, then after 5 minutes decreased to 5 mmHg with consequent hyperventilation; subsequently remained <25 mmHg. Alveolar recruitment is needed to improve cerebral oxygenation.**

The clinical efficacy of hyperoxia in the treatment of TBI is still under study [158-160] (Figure 8.23). We recommend short periods (15-20 min) of hyperoxia (FiO_2 100%) during resuscitation and as treatment for unexplained tissue hypoxia [59]. The concept of using hyperoxia to increase cerebral oxygenation is controversial. Advocates refer to studies by Bullock et al. that showed a decrease in lactate in the extracellular fluid as measured by microdialysis after 1 hour of FiO_2 100%. This suggests that the increase in FiO_2 produces increments in mitochondrial oxygen, improves oxygen diffusion, and increases $CMRO_2$ [159,161].

Others, however, state that hyperoxia does not increase the oxygen content of blood, which is considered a critical parameter for oxygen delivery. Arterial oxygen content (CaO_2) is determined by the sum of oxygen bound to hemoglobin (Hgb x O_2 saturation) and the oxygen dissolved in the plasma (arterial oxygen tension [PaO_2] x 0.003). At a normal hematocrit and oxygen tension, CaO_2 values are approximately 15 vol %. Under physiological O_2 tension, the amount of oxygen dissolved in plasma is negligible, however, normobaric hyperoxia may increase the amount of dissolved oxygen by approximately 0.5-1 vol >%, whilst hyperbaric oxygen can increase the oxygen content more substantially [162-163].

Therefore, doubts exist whether the improvement of $ptbO_2$ seen with hyperoxia really translates into improved oxygen delivery. In a recent study comparing the impact of 24 hours of breathing 100% oxygen in 52 patients with severe TBI versus historical controls, the groups were well matched for age, sex, postresuscitation GCS, and ICP during the first 12 hours after injury. Both groups were monitored with microdialysis and brain tissue O_2 sensors. In the hyperoxia-treated group, ICP was lower, dialysate glucose levels higher, and lactate and lactate-pyruvate ratios lower. The magnitude of the difference in ICP was not clinically significant (12 vs. 15 mmHg) and the implications of the biochemical changes are unknown. At 6 months after injury, the mean GCS score in the hyperoxia-treated patients was higher than in the control group (3.2 versus 2.8) but these differences were not statistically significant. Studies with hyperbaric oxygen show encouraging results [161]. Controversies persist on the user of hyperoxia, however.

Alveolar recruitment maneuvers may be more effective in improving cerebral oxygenation. Recruitment maneuvers favour increased tissue oxygenation not simply as a result of the increased fraction of inspired oxygen, but more particularly as PEEP can improve oxygen transfer over the lungs. The use of PEEP has been described in patients without intracranial hypertension [164-166]. Increasing PEEP from 5 to 15 cmH_2O increased SpO_2 from 95.5±2.1 to 98.6±1.2% (P=0.0001) and $PtbO_2$ from 27.8±6.5 to 33.9±6.7 mmHg (P=0.0001), without a significant effect on ICP and CPP (8.3±4.4 to 8.7±4.4 mmHg; P=0.14 and 94.8±8.2 to 94.6±8.0 mmHg; P=0.78), respectively [33]. In patients with intracranial hypertension, however, the risk of increasing ICP and decreasing CPP cannot be excluded. In such patients, multiparameter monitoring, including ICP and $ptbO_2$ is recommended; this may help prevent secondary complications due to elevations in ICP potentially produced by alveolar recruitment maneuvers (Figure 8.25, Figure 8.26).

The oxygen-carrying capacity of blood can be improved by blood transfusion. However, $ptbO_2$ can diminish rather than increase, especially after the transfusion of blood older than 19 days [167]. The baseline $ptbO_2$ level may be relevant to the response after blood transfusion. Murillo Cabezas et al. reported that blood transfusions produced an increase in $ptbO_2$ in all patients with a baseline <15 mmHg, whilst an increase was only observed in 75% of patients with a baseline $ptbO_2$ >15 mmHg (P <0.01). The relative increment in $ptbO_2$ after 3 hours was correlated with the baseline $ptbO_2$ (r^2 0.17; P=0.001) [168].

8.4.14 Reducing Metabolism to Protect the Brain From Ischemia

Cerebral metabolism may be reduced by sedatives (barbiturates, propofol) or by hypothermia. Both approaches are effective in reducing oxygen demand and ICP. Conflicting results are reported for $ptbO_2$. One small study on the effect of barbiturates on patients with refractory intracranial hypertension claimed improvement in cerebral oxygenation in 6 out of 8 patients [169.170]. Others, however, reported a significant decrease in tissue oxygenation after barbiturate administration; a possible explanation for this is the increased occurrence of pneumonia in patients treated with barbiturates and myocardial depression. Propofol given in a dose to induce EEG burst suppression does not appear to affect tissue oxygenation [171].
Results on the effect on $ptbO_2$ of hypothermia are conflicting. A study of hypothermia in 30 trial patients reported that $ptbO_2$ decreased with hypothermia, with greater intensity at <35°C. In another study the effect of moderate hypothermia (34-36°C) was studied in 33 patients with raised ICP (≥20 mmHg). In these patients hypothermia led to a decrease in $ptbO_2$from 33±24 to 30±22 mmHg. Conversely, in a study involving 72 TBI patients which focused on the occurrence of hyperthermia, it was reported that "hyperthermia does not appear to reduce $ptbO_2$ or to increase tissue episodes of hypoxia". This provides evidence for the conclusion that "hyperthermia may worsen the prognosis of TBI through mechanisms that do not involve oxygen" [172-174]. The ostensibly adverse effect of hypothermia on brain tissue oxygenation can be explained by a decreased perfusion during hypothermia due to pulmonary and cardiac effects. This emphasizes the importance of monitoring also to detect adverse consequences and complications of instituted treatments.

8.5 Early Detection and Treatment of Ischemia

Ischemia is one of the main factors involved in the development of secondary damage after TBI. Cerebral ischemia may result from systemic insults (e.g., hypoxia and hypotension) and intrinsic pathophysiologic mechanisms. Excessive hyperventilation is a major cause of ischemia due to vasoconstriction. Although it often occurs inadvertently, it may also be deliberate as treatment to reduce ICP. Monitoring $ptbO_2$ when using hyperventilation is recommended to safeguard against cerebral ischemia (Figure 8.27, Figure 8.28). We investigated the effect on $ptbO_2$ by reducing $paCO_2$ under standardized approaches: in patients ventilated because of severe TBI, increasing the tidal volume by 20% reduced $paCO_2$ by an average of 3.8±1.7 mmHg from a baseline of 32.3±3.5 mmHg. On the first day after injury, reactivity was low (0.8±2.3 mmHg) and increased over subsequent days; on day 5 the change was 61±4.4 mmHg. Higher reactivity was correlated with poorer outcome [175]. The lower reactivity in the earlier phases after injury can be explained by the more prominent arteriolar narrowing during the first 24 hours, indicative of metabolic depression or pathologic vasoconstriction and possibly caused by the swelling of podocytes of astrocytes. In such a state of vasoconstriction, the range of hyperventilation on day 1 was unable to induce any greater vasoconstriction. With time, however, the vessel diameter increased and the effects could be seen more clearly.
Although from a clinical perspective, the risk of moderate hyperventilation seems to be greatest in the first 24 hours after injury, we found that in 15% of the patients, hyperventilation induced a paradoxical response by increasing $ptbO_2$.This paradoxical response would seem to indicate a redistribution of CBF following hyperventilation [175-177]. This phenomenon likely represents the steal mechanism and has consequently

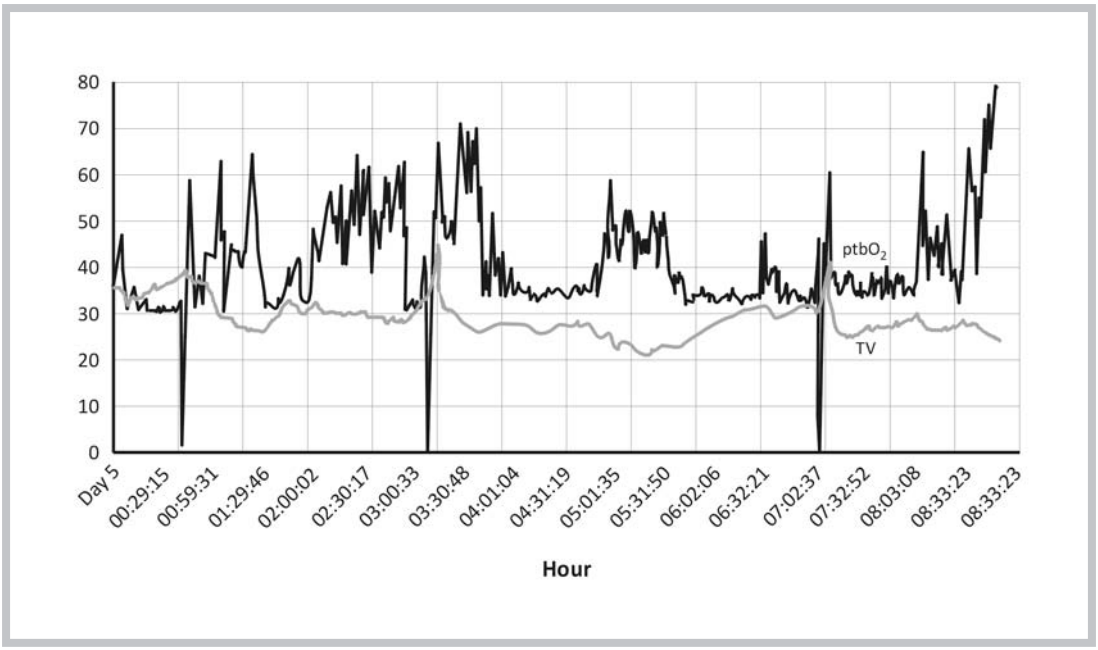

Figure 8.27. **TBI patient in pressure support 5 days after trauma. The prognosis in TBI is influenced by several secondary factors; one of the most important but less studied is hyperventilation. Patients in pressure support frequently show periods of ischemia induced by hyperventilation. In this case the patient was in the weaning period after 5 days of ventilation. Around 4.46 hours the TV increased until 550 ml, with a consequence decreased $ptbO_2$. With a continuous monitoring of TV and $ptbO_2$ it is possible to understand the real influence of hyperventilation.**

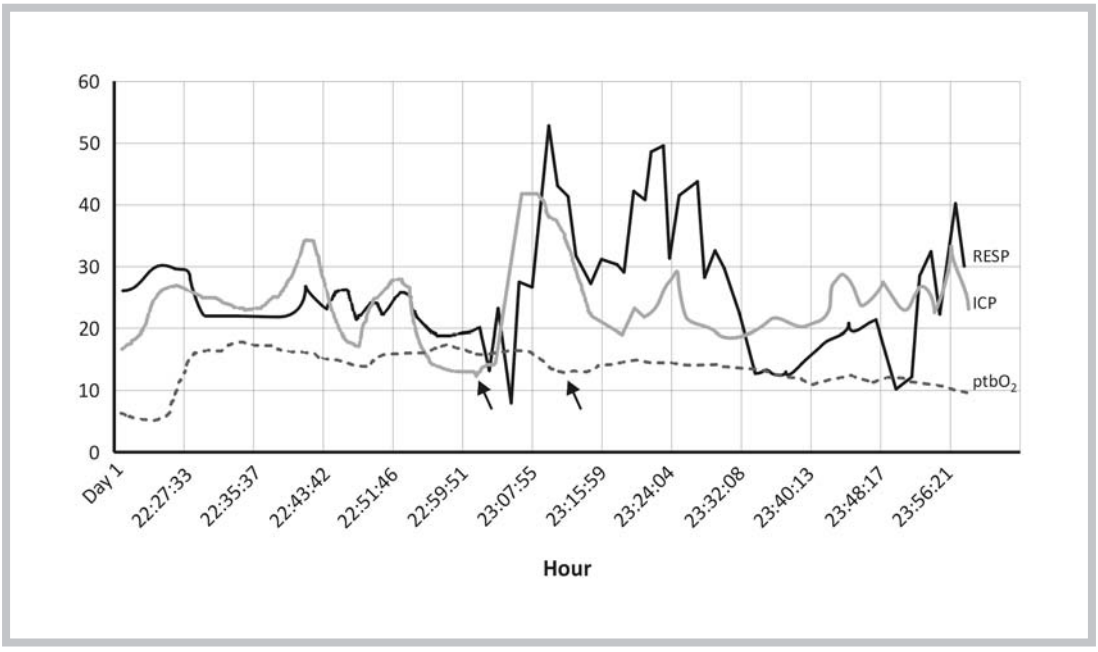

Figure 8.28. **Several events of ischemia induced by hyperventilation. Continuous recording of $ptbO_2$, RESP, and ICP shows multiples episodes of hyperventilation with the potentially damage in brain metabolism. In this Figure it is evident the absence of $eTCO_2$ monitoring in order to avoid more damage. The ICP response induced by hyperventilation always shows a decreasing pattern with a sacrificed $ptbO_2$.**

been called the “Robin Hood phenomenon”, which might be considered a warning sign (Figure 8.24)

Interpretation of response to hyperventilation is complex and requires insight into brain metabolism and vascular autoregulation. Studies with PET and combined EEG and evoked potential monitoring have shown the adverse effects of hyperventilation [107,109,110,178]. The reduction in CBF and $CMRO_2$ resulting from hyperventilation poses challenges in the care of trauma patients, and this would seem to indicate exhaustion of physiologic reserves and a compromise of oxidative metabolism. Whilst recognising the complexity of interpreting the effect of hyperventilation on $ptbO_2$, we consider $ptbO_2$ monitoring indicated in patients treated with hyperventilation.

8.5.1 Relationship between SjO_2 and $ptbO_2$

Prior to the implementation of $ptbO_2$ monitoring, SjO_2 monitoring was routinely employed in neurointensive care. This technique was prone to many artefacts, primarily due to light errors subsequent to catheter malposition, which made multiple calibrations necessary. Almost 65% of the data suffered from artefacts. Such problems do not occur with $ptbO_2$ monitoring. Both techniques offer complementary information in neurocritical care. $PtbO_2$ is a local technique for monitoring in areas considered at risk, whilst SjO_2 monitoring offers a more global approach. In combination, these techniques facilitate monitoring and targeted intervention against ischemia.

In our experience with 45 patients monitored with both parameters, we began monitoring on average at 7.5 hours (range, 2.5-12) after injury. The average recording time was 110 hours (range, 15.8-144). The SjO_2 catheter was calibrated *in vivo* every 8 hours.

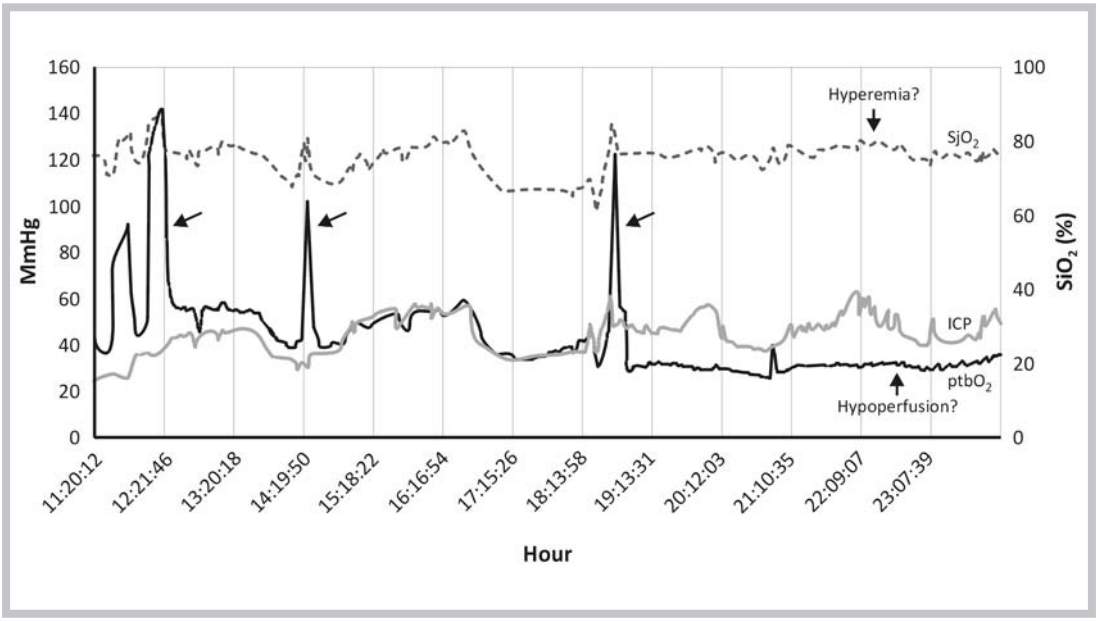

Figure 8.29. **Synchronic correlation between $ptbO_2$ and SjO_2 directed by ICP. 37-year-old female, anisocoric pupils: pos/neg and poor outcome. The initial evolution shows a similar pattern, with an increasing and decreasing trend in ICP, SjO_2 and $ptbO_2$, even in hypotension moments, hyperoxia, hyperventilation until 20.04 hours, later the highest ICP of 60 mmHg (22.02 hours induced in SjO_2 a possible hyperemia event, but but hypoperfusion in $ptbO_2$. This ambiguous pattern is due to the regional and global monitoring of both parameters and the severity of the TBI.**

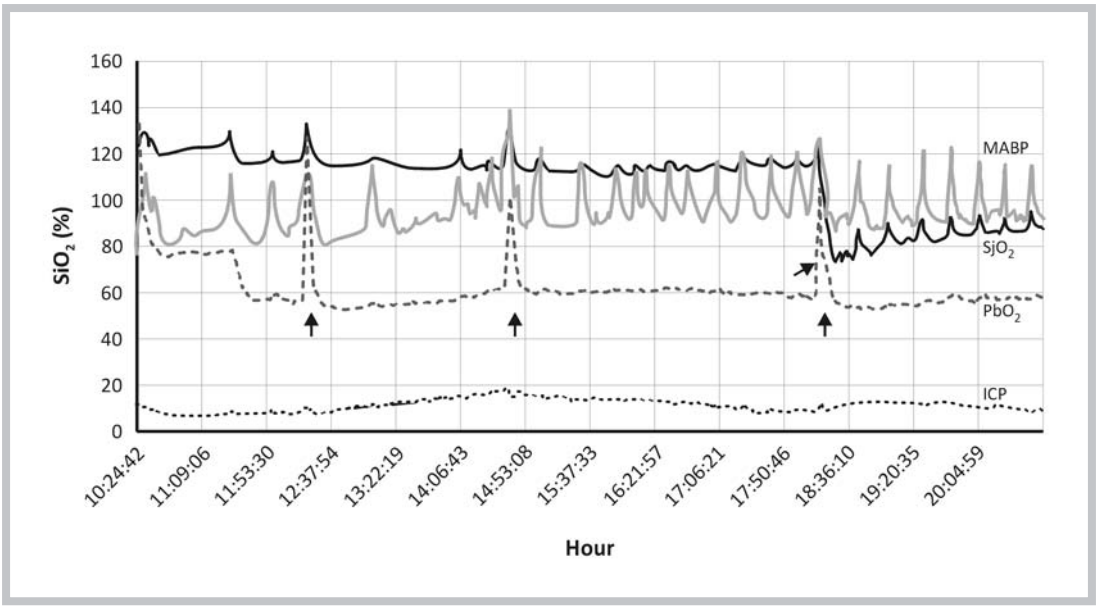

Figure 8.30. **SjO_2 oscillations dependent of blood pressure, with small changes in $ptbO_2$. TBI patient, GCS 13 on the admission, not completely sedated, with poor outcome. The oscillated mean blood pressure (mABP), with several fluctuations between 80-120 mmHg, induced normal fluctuations in SjO_2. At 18.13 a desaturation event occurred, with small $ptbO_2$ repercussion. Arrows show preoxygenation FiO_2 100% maneuvers.**

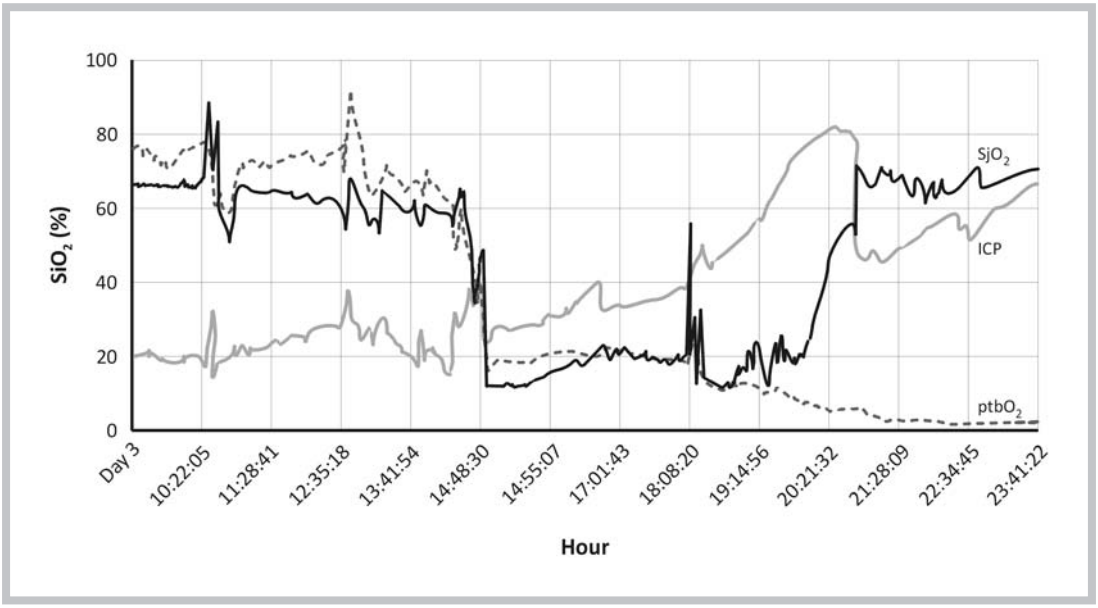

Figure 8.31. **Dramatic evolution of TBI patient with GCS 13. 83-year-old male, fallen during a sport race. GCS 13: E:3; M:5; V:5. With anisocoric pupils: post/neg. On the CT scan the perimesencephalic cisterns was compressed, with subarachnoid hemorrhage in the convexity and cisterns; frontotemporal contusion in the left side, without midline shift. The ICP on day 3 showed several spikes: 30 mmHg, progressively increased until 40 mmHg (14.51 hours), and later 50 mmHg (20.21 hour). A tremendous high $ptbO_2$ of 91.7 mmHg with a decline SjO_2 70%, showed the heterogeneity pattern of this injury. In a decline trend SjO_2 and $ptbO_2$ the patient shows a new ICP wave (14.48 hours) which produced a severe ischemic event. Later there was dissociation between SjO_2 and $ptbO_2$ in herniation moment. The $ptbO_2$ was in the frontal lobe of the lobe of the same temporal contusion.**

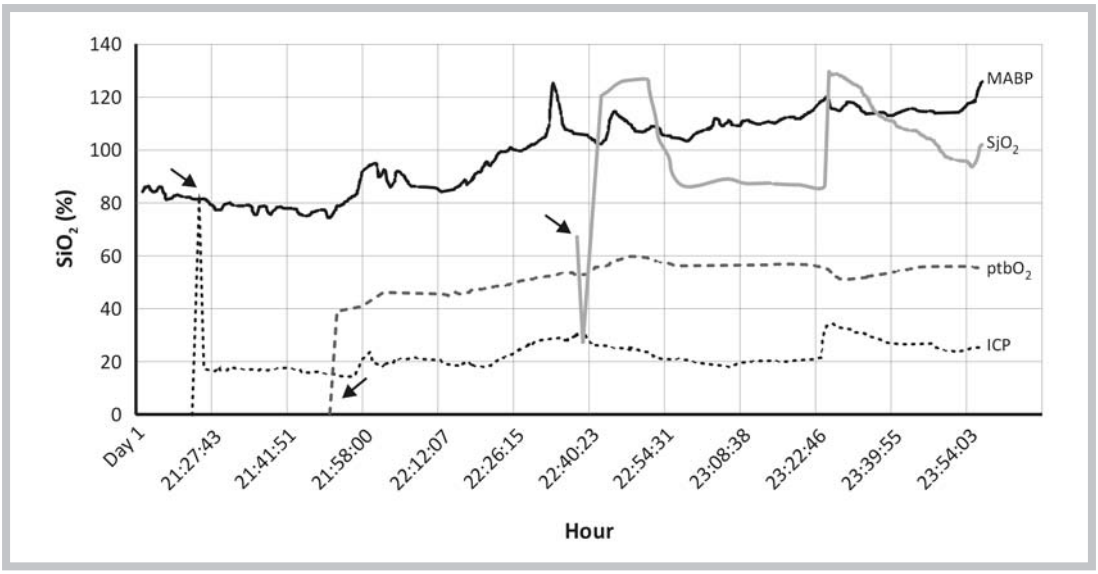

Figure 8.32. **Validity of $ptbO_2$ values and run-in time. In this case: a short and high run-in time. The $ptbO_2$ calibration test postinsercion had a good correlation with solution calibration. These tests show the substantial validity of the high $ptbO_2$. Arrows indicate the insertion technique of $ptbO_2$, ICP and SjO_2. The influence of chronic hypertension and ICP peaks (22.40 hour and 23.32 hour) influenced $ptbO_2$ and SjO_2 values.**

Substantial readjustment of the settings of more than 10% was required in 25% of all calibrations. The evolution pattern of SjO_2 in the first 24 hours after trauma was similar to that observed with $ptbO_2$ monitoring. The SjO_2 was approximately 65% in the initial 24 hours after trauma, increasing to 80% after 60 hours. The correlation between both techniques was 0.30±0.25 (range 0.13-0.72). The highest correlation between the

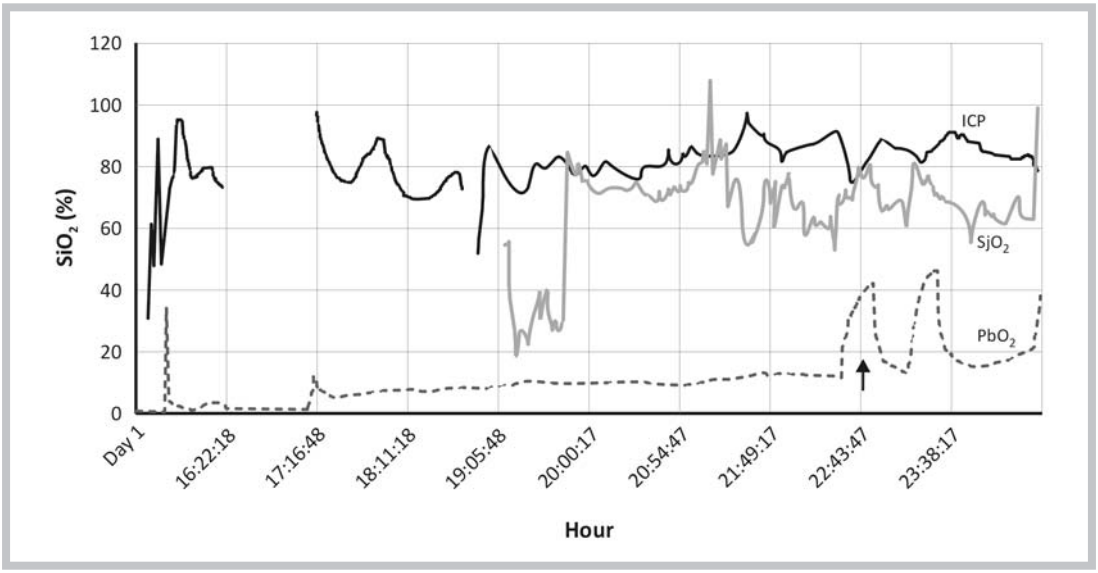

Figure 8.33. **$ptbO_2$ and SjO_2 trend in case of high ICP: there is no doubt about the predictive value of both parameters. $ptbO_2$ had a long run-in time and also a longer period <15 mmHg, with a high oxygen reactivity in test 100 % FiO_2, even during low $ptbO_2$ (arrow) (22.16-23.11 hour). $ptbO_2$ increased up to 95 mmHg. It was evident that CPP had a strong correlation with $ptbO_2$, instead of SjO_2. The high oxygen reactivity associated with low values means that cerebral oxygen consumption is decreasing.**

techniques occurred during periods of hyperoxemia and hyperventilation. Low SjO_2 values were not always accompanied by low $ptbO_2$ values, and an inverse relationship was sometimes noted [15]. When the $ptbO_2$ catheter was implanted in a relatively undamaged part of the brain, discordant values between the techniques were common. Discrepancies between the two techniques were also noted in the diagnosis of brain death, brain herniation, psychomotor excitation, sudden episodes of raised ICP. Figures 8.29, 8.30, 8.31, and 8.32 show some examples.

Both techniques are recommended for monitoring the risk of ischemia. The interpretation of hyperemia by $ptbO_2$ monitoring is not fully explored and is confounded by effects of high FiO_2. Therefore, it is necessary to exclude the effects of FiO_2 when a possible hyperemic state is suspected. In our experience, monitoring does not adequately capture hyperemia. Hyperemic status, as evidenced by high SjO_2 and small $AVDO_2$, often has normal $ptbO_2$ values, but in some special cases when the vascular autoregulation is affected the $ptbO_2$ it may be high (Figure 8.33).

In conclusion, the interpretation of hyperemia must be based on global CBF values and not on the results of $ptbO_2$ monitoring. The parameter of oxygen partial pressure in the tissue is composed of three elements: arterial paO_2; venous oxygen pressure; and tissue oxygen. It does not reflect only CBF. Tissue hypoxia may occur with global hyperemia (SjO_2 >75% or $AVDO_2$ <3). SjO_2 values do not differentiate between situations of hyperemia or extensive tissue infarction. If the $ptbO_2$ catheter is inserted into an infarcted area, with no or very limited oxygen consumption, low values may occur, whilst high SjO_2 values can be observed. Sahuquillo, describing 244 simultaneous jugular and $ptbO_2$ measurements, reported 31 episodes of tissue hypoxia <15 mmHg (12.7% of episodes) in a presumed hyperemic state. We conclude that both techniques offer complementary information [179].

8.6 Suggestions and Limitations

In the last sections we compared the early publications on $ptbO_2$ monitoring (Rotterdam group) with the more recent literature, described new applications of $ptbO_2$, and briefly discussed some aspects of SjO_2.

Traumatic brain ischemia is an important target for therapy as it can worsen the primary injury and lead to poorer outcome. A Clark-type electrode inserted into a relatively undamaged part of the brain can be employed to monitor for ischemia and to optimize treatment. When the electrode is placed in the penumbra of a damaged area, therapy can be aimed to protect tissue at risk. Initial studies suggested lower mortality in patients without impairment of brain oxygenation. With the new technological advances in the Clark catheter – produced 10 years later –the measured area has been augmented, the random uncertainty reduced, and the reliability of this technique further improved. There are, however, no randomized clinical trials to confirm a clinical benefit of $ptbO_2$, ICP and other hemodynamic monitoring techniques. Centres using these techniques report decreased mortality, improved oxygen delivery and/or a better balance between intake and oxygen consumption [15,18,19]. Perhaps the greatest benefit is that, when combined, these monitoring techniques afford greater insight into the on going pathophysiology and the understanding of the complex pattern of brain injury, thus offering opportunities for more individualized and targeted management.

To obtain more definitive results, collaboration between researchers for database integration and cooperative multicentre studies are needed. In other words, sharing goals, with acceptable patient groups to achieve representative samples. In the absence of co-

operative studies, results will remain dispersed and it will be impossible to adequately face the challenges of personalizing treatment based on a monitoring strategy. At most, 20 groups around the world are actively involved in this area of research, and we strongly encourage collaboration.

In comparison to cardiology, sample sizes in studies on $ptbO_2$ monitoring are relatively small and few have a randomized design. Recent interest has focused on monitoring at later periods after injury, whilst results already obtained in the 1980s have demonstrated that the initial 24 hours after trauma are critical and that low brain tissue oxygen values are particularly prevalent in this period [15,24]. Standardization of terminology is also required. In the Ovid database, 938 manuscripts were identified by the English abbreviation "$ptiO_2$", whilst a search utilizing the search term "brain tissue oxygen monitoring" yielded almost 10,000 reports.

Despite initial publications describing the prognostic value of $ptbO_2$ monitoring and the association between clinical and monitoring values, relatively few studies since then have focused on these relevant aspects. Much work is needed to define specific ptO_2 thresholds for treatment and how these may differ between white and grey matter and according the time elapsed since injury. The debate remains open as to whether monitoring should be performed preferentially in a relatively undamaged part of the brain, and be taken as representative of more global cerebral oxygenation, or in the penumbra of a lesion, with the intent to preserve this tissue at increased risk.

Our knowledge of the pathophysiologic mechanisms underlying the results of $ptbO_2$ measurement is still relatively incomplete and the heterogeneity and variability of brain tissue oxygen distribution may confound their interpretation. We should further recognize that also with the more recently produced catheter, a certain equilibration time, often termed the "run-in time", is required, thus limiting its use immediately after insertion. Although from a theoretical perspective the use of multiple catheters placed in different regions might be preferred, this is pragmatically impossible and would pose too high a risk to patients. Nevertheless, we feel that the current status of $ptbO_2$ monitoring has advanced to a level that it can be considered part of routine clinical monitoring.

To gain optimal benefit, however, education and learning are prerequisite to creating a team with knowledge of oxygen supply and consumption. Appropriate implementation of the technology requires much more than a simple working group composed of a doctor and a nurse plugging in the connection between monitor and equipment. Multidisciplinary collaboration and involvement of Intensive therapy experts for advanced data integration and analysis should be encouraged.

8.7 Conclusions

$PtbO_2$ monitoring reflects overall oxygenation after TBI if the probe is positioned in a relatively undamaged part of the brain. In these situations, initially low values within the first 24 hours after injury are common, reflecting a decrease in CBF possibly due to increased vascular resistance or decreased metabolism. Low initial values in this period are independently associated with poorer outcome at 6 months. In pragmatic terms, $ptbO_2$ monitoring is easier to perform and less prone to artefacts than SjO_2 monitoring. Both techniques, however, yield potentially different information and should be considered complementary.

The use of $ptbO_2$ monitoring to safeguard against ischemia in the use of hyperventilation to treat raised ICP is now widely recognized. The adverse effects of even small decreases in blood pressure or changes in arterial oxygenation can now be monitored

more closely and accurately. Furthermore, evaluating changes in brain tissue oxygen subsequent to changes in blood pressure or ventilation status offers insights into autoregulation and CO_2 reactivity. We recommend that it should be used only in units experienced in ICP monitoring and where potential complications can be treated neurosurgically [15,33-36].

Monitoring $ptbO_2$ cannot replace ICP monitoring; instead, it should be seen as an addition that provides more insight into the ongoing pathophysiology in a given patient. We consider the benefits of cerebral oxygenation monitoring to greatly outweigh the risks. Multidisciplinary and international collaboration between study groups is strongly encouraged to advance our standards of care and to facilitate personalised management.

9 Monitoring Cerebral Blood Flow and Cerebral Autoregulation: Basic Principles, Techniques, Common Patterns and Interpretation of Results

José I Suárez [1]

[1] Neurology and Neurosurgery Professor. Department of Neurology. Division of Vascular Neurology and Neurocritical Care. Baylor College of Medicine. Houston, TX, USA

9.1 Introduction

The successful management of patients with brain injury requires an understanding of the physiological principles of cerebral blood flow (CBF). Ignoring these principles can lead to deleterious events in the neurocritically-ill patient [1,2]. Two examples suffice to illustrate this point: 1) a patient presents with an acute ischemic stroke and a systolic blood pressure of 180 mmHg which is aggressively lowered to 120 mmHg, resulting in extension of the stroke; and 2) a patient with subarachnoid hemorrhage has a mean arterial blood pressure of 125 mmHg which is aggressively lowered to 100 mmHg on the seventh day of hospitalization, leading to diffuse cerebral ischemia. It is important to realize that CBF is closely linked to brain metabolism in most circumstances and that the treatments initiated by clinicians have to maintain a balance between the systemic events and the normal delivery of oxygen to the brain.

9.2 Physiology of Cerebral Circulation

The brain of a human adult weighs approximately 1200-1400 g which accounts for only 2-3% of the total body weight. Despite this the brain receives about 20% of the total cardiac output. This is mainly due to the fact that the cerebral metabolic rate for oxygen ($CMRO_2$) is high and that the brain utilizes glucose as the major substrate to meet its energy needs. Neurons are very active and consume most of the available energy, while the glial cells utilize only 10% although they make up 50% of brain weight [3]. The average CBF is approximately 50 ml/100 g brain tissue per minute. The cerebral ischemia threshold value is <20 ml/100 g/min. Irreversible brain damage or stroke occurs when the CBF falls to <10-15 ml/100 g/min. From this it follows that between levels of 15 and 20 ml/100 g/min the changes are reversible. This area has been called the penumbra. In other words, in situations of severe ischemia there is a central area or core, which represents infarction, and a peripheral area which represents ischemia without neuronal death. This concept is very important because the primary goal of therapeutic interventions in the neurocritical care unit is to preserve the periphery or penumbra while trying to lessen the core.

Because the brain has no energy reserves, its function relies almost exclusively on the delivery of oxygen and glucose, which implies that CBF, $CMRO_2$ and cerebral oxygen extraction are coupled under normal physiological conditions. These factors have been implicated in the Fick principle devised by Adolf Fick in 1870 [4]. Based on the principle of conservation of mass, the equation provides a simple way to determine that the amount of a substance detected by an organ per unit of time is equal to the organ blood flow multiplied by the difference between arterial and venous concentration. Applied to the brain, Fick's equation is derived as follows:

$CMRO_2 = CBF \times AVDO_2$, where $AVDO_2$ is the difference in arterio-venous oxygen.

How does the brain keep the coupling of these parts intact in normal situations?
To compensate for the metabolic rate, fluctuations in cerebral perfusion pressure (CPP) and changes in blood viscosity, the diameter of the cerebral blood vessels changes to maintain a constant $AVDO_2$, which has been termed autoregulation of CBF (Figure 9.1) [5]. Although the exact mechanisms underlying such autoregulation have not been fully elucidated, the two most accepted are myogenic and metabolic in origin. According to the former, pressure changes through the vascular wall lead to changes in arteriole diameter. The latter is based on the hypothesis that changes in the microenvironment alter vasomotor response. These changes are mediated by $PaCO_2$, PaO_2, and tissue temperature. There is also evidence that sympathetic nerve activity, blood rheology, and chronic hypertension have an important effect on CBF autoregulation (Table 9.1). It is important to take these factors into account when the patient enters the neurocritical care unit. Specific situations include:

- Cerebral edema in patients with increased $PaCO_2$ and body temperature can trigger an increase in intracranial pressure (ICP).
- In patients with hypertensive encephalopathy, there is most certainly maximum vasoconstriction in the arterioles. A rapid decrease in the MAP to normal levels can cause global cerebral ischemia.

Factors	Changes in CBF
CPP	CPP increase (usually >25 mmHg) or significant decrease in mean arterial pressure (<60 mmHg) leads to decreased CBF
$PaCO_2$	$PaCO_2$-arteriolar response mediated by changes in extracellular pH. CBF changes 3-4% for every 1% change in $PaCO_2$. The relationship is almost linear up to 100-120 mmHg $PaCO_2$
PaO_2	CBF increases dramatically when PaO_2 falls to <50 mmHg
Brain temperature	Tissue temperature increases $CMRO_2$ 6-7% per degree C rise in temperature. Hypothermia decreases $CMRO_2$
Innervation-sympathetic nervous system	Sympathetic nerve activation of the sympathetic alpha adrenergic nerves shifts the autoregulation curve to the right (more vasoconstriction), while denervation shifts it to the left
Chronic hypertension	Chronic hemodynamic changes lead to changes in the structure of arterioles. The self-regulatory curve is shifted to the right. There is greater tolerance to increases in blood pressure but lower tolerance to decreases
Blood viscosity	In normotensive conditions, a fall in hematocrit from 35 to 25% leads to an increase of 30% in CBF. Falling pressure leads to a loss of the relationship. Compensatory vasodilation mechanisms are lost when hematocrit is decreased by 19%

Table 9.1. **Physiological and pathological factors affecting CBF autoregulation.**

- A decrease in the MAP can cause irreversible damage, leading to cerebral ischemia in patients with lesions with mass effect.

After this introduction and review of the physiology of the cerebral vasculature, let's now explore the different methods at our disposal to determine CBF in our patients in the neurocritical care unit.

9.3 Techniques to Measure Cerebral Blood Flow

Practical and efficient measurement of CBF is difficult. Such impediment limits the information needed to determine the evolution of deleterious factors which may affect neuronal viability. One potential adverse events of this would be a delay in therapeutic interventions that could

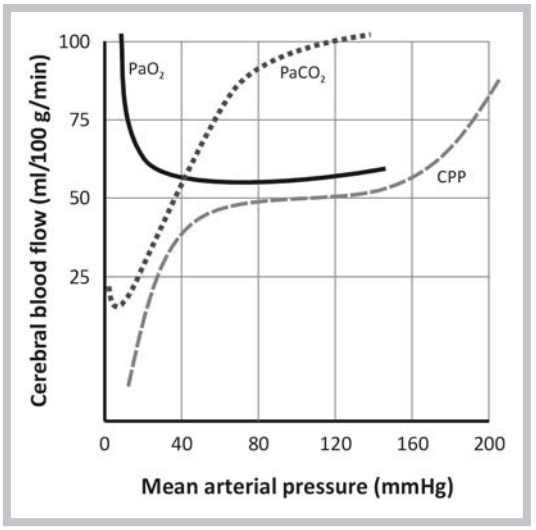

Figure 9.1. **Under physiological conditions, the brain maintains CBF within normal limits through autoregulation when the CPP is between 40 and 140 mmHg. Other factors that independently affect CBF are the PaO_2 and $PaCO_2$. This diagram, drawn by the author, is based on a figure taken from [5].**

Method	Advantages	Disadvantages
Neurologic examination	May be repeated as needed	Cannot detect early changes in CBF
CPP	Can be measured continuously	Needs ICP catheter insertion and depends on the CVR
EEG	Not invasive and can be continuously measured	Interference may be an issue and costly equipment is needed for data analysis
Fick's Principle	Allows direct measurement of CBF and is considered the gold standard	Invasive, determines global CBF and requires manual sampling
$Xenon^{133}$	May be repeated as needed	Poor resolution and does not allow proper evaluation of CBF in subcortical structures
Xenon-enhanced CT	Measures regional CBF and may be repeated as needed	Expensive, technically difficult, and has the anesthetic effects of xenon
PET	Allows measurement of cerebral blood volume, tissue oxygen extraction, and $CMRO_2$	Expensive, not readily accessible; requires skilled personnel and patient transport out of the neurocritical unit
MRI and perfusion CT	Measures CBF and cerebral blood volume	Allows qualitative measurement; depends on comparison of data from the two cerebral hemispheres
TCD	Portable, inexpensive, and allows continuous measurement	Measures the speed of blood flow but not CBF; is operator-dependent and acoustic windows; allows only study of the basal arteries of the circle of Willis
Thermal diffusion flowmetry	Allows continuous and quantitative real-time CBF measurement in the area of interest	Requires insertion of a catheter and allows only measurement of local CBF

Table 9.2. **Comparison of different methods of measuring CBF in a neurocritical care unit.**

$CMRO_2$ = cerebral metabolic rate for oxygen
CPP = cerebral perfusion pressure
CVR = cerebral vascular resistance
CT = computed tomography
EEG = electroencephalography
ICP = intracranial pressure
PET = positron emission tomography
MRI = magnetic resonance imaging
TCD = transcranial doppler sonography

potentially reverse or prevent ischemic insults. AAn ideal technique of CBF measurement must meet the following requisites: portable, repeatable, and inexpensive. Since no currently available technology meets all these requirements, we are forced to use methods that are not always optimal (Table 9.2).

The neurologic examination can reveal altered level of consciousness or changes indicating that CBF is below acceptable thresholds for normal neuronal function. Early assessment is vital because when clinical changes are evident, irreversible changes have probably already occurred [2].

Measurement of CPP has been used as a substitute for evaluating CBF as this is directly related to CPP and inversely related to cerebral vascular resistance (CVR) according to the following equation:

$$CBF = CPP / CVR$$

From a practical standpoint, CVR is not easy to determine. Therefore, the CPP is derived from the difference between mean arterial pressure (MAP) and ICP:

$$CPP = MAP – ICP$$

Normal CPP values are between 55 and 70 mmHg [6]. It should be noted that a normal CPP can be used as a surrogate marker of normal CBF as long as the CVR is also normal. For example, if the CVR is high, as occurs in cerebral vasospasm, then a normal CPP may be associated with cerebral ischemia. Similarly, if the CVR is low, a normal CPP could lead to cerebral hyperemia.

Continuous electroencephalography (EEG) monitoring can furnish data complementary to neurological findings to detect early changes in CBF. Because CBF changes in a predictable manner in situations of cerebral ischemia, such alterations may prompt the neurointensivist to intervene early [7,8]. At CBF levels between 16 and 22 ml/100 g/min there is a predominance of slow waves, followed by a decrease in the amplitude when the CBF is 11-19 ml/100 g/min which can reach an almost total reduction on the EEG tracing when levels are <10 ml/100 g/min.

The first technique for the quantitative measurement of CBF, as devised by Kety and Schmidt, was based on the Fick method described above and used nitrous oxide as a marker as this gas is metabolically inert and diffuses quickly in the brain [9]. The gas is inhaled and blood samples are obtained from an artery or a jugular vein. The technique relies on two conditions: a continuous CBF and freedom from contamination of jugular samples with extracerebral blood. Inhaled or intravenous administration of xenon^{133} has also been used for similar measurements. The advantage of this technique is that you have a small portable unit, but the disadvantage is that the partition coefficient of the blood-brain barrier for this material is abnormal in pathological conditions.

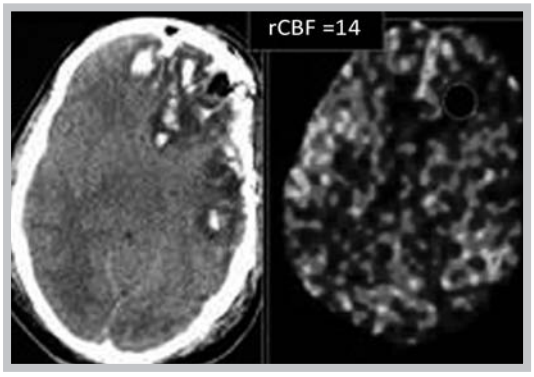

Figure 9.2. **Xenon-enhanced CT scan in a patient with severe traumatic brain injury. Note the significant decrease in CBF in the left frontal region which, if not corrected, can lead to cerebral ischemia with subsequent infarction. Courtesy of Dr. Claudia Robertson, Ben Taub Hospital, Houston, Texas.**

Xenon-enhanced computed tomography (CT) offers the advantages that once the gas is inhaled it acts as a contrast medium

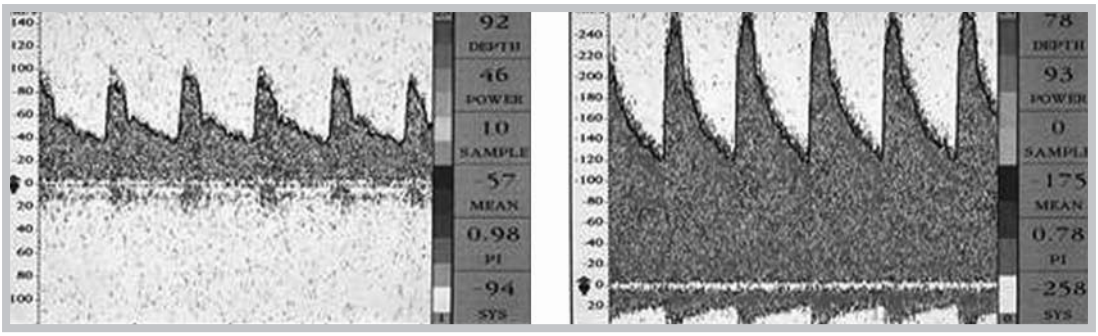

Figure 9.3. **Transcranial Doppler of a patient with a subarachnoid hemorrhage. The left panel shows the tracing on day 3 and the right panel the tracing on day 7 when the patient was in a confusional state, with double vision and tetraparesis. The right panel shows a basilar artery vasospasm.**

for cerebral CT and it has a higher spatial resolution, so that regional CBF can be measured [10] (Figure 9.2).

Other advances in diagnostic imaging have allowed us to use positron emission tomography (PET) and magnetic resonance imaging (MRI). Although advances in these techniques continue, there remain limitations to their use (Table 9.2).

The last two CBF measurement tools we will mention are transcranial Doppler ultrasound (TCD) and thermal diffusion flowmetry [11-16]. TD measures CBF velocity, from which CBF can be estimated if the amount of blood flow through the cerebral vessels is measured simultaneously. However, the cerebral blood flow velocity rate is used in clinical practice. A detailed analysis of blood flow velocity, the pulsatility index are obtained to detect cerebral vasopasm in patients with subarachnoid hemorrhage (Figure 9.3), the pattern of collateral circulation in the circle of Willis in patients with vascular stenosis, arterial reperfusion status after thrombolysis in patients with acute ischemic stroke, and progression to cerebral circulatory arrest.

Thermal diffusion flowmetry allows us to calculate an index of cortical blood flow by measuring the dispersion of heat delivered through a catheter per unit of time. The major advantage of this technique is that it can continuously determine CBF based on a very simple principle (Table 9.2).

9.4 CBF in Pathological Conditions

Secondary injury resulting from a decrease in CBF to a critical level can lead to poorer clinical outcomes. The following paragraphs present the data from studies in which CBF was measured in such common brain diseases as severe traumatic brain injury, seizures, subarachnoid hemorrhage, acute ischemic stroke, and stroke or intracerebral hemorrhage. Importantly, there is considerable controversy regarding the use of data from the CBF measurement methods discussed above. For instance, there have been reports of important variability in the methodology and the definition of CBF thresholds for the diagnosis of cerebral ischemia in several clinical conditions such as severe traumatic brain injury and acute ischemic stroke [17,18].

In the initial phase of severe traumatic brain injury, there is a decrease in CBF in 50-60% of patients [19]. However, this does not always indicate that the patient is suffering from cerebral ischemia. To determine this, $AVDO_2$ data are also needed, which show that in approximately 27% of cases the delivery does not meet the demand. It has also been shown that in the first days after trauma, some patients have hyperemia, i.e., in-

creased CBF beyond the metabolic requirement [20]. Both ischemia and hyperemia may increase ICP, leading to disastrous results for the patient. It follows that proper management of CBF is essential, and most researchers agree that a CPP of 55-70 mmHg is sufficient to maintain brain function.

In patients with subarachnoid hemorrhage and altered level of consciousness there is a greater decrease in CBF than in those who arrive alert. This reduction can occur in the first two days after the initial event and may gradually continue for the first weeks. The critical point in the management and monitoring of CBF in these patients is during cerebral vasospasm. The most commonly used method, as discussed above, is TCD which demonstrated increases in flow rate (usually >200 cm/sec). The absolute value is not necessarily the best indication of vasospasm but instead the changes with increases >50 cm/sec over a 24-hour period. The usual management of vasospasm includes hypertensive therapy according to the hypothesis that it will increase CBF. However, we must emphasize that the autoregulation mechanism is altered, and, whether global or focal, it is difficult from a clinical perspective to determine if the therapy causes an increase or a decrease in CBF steal from areas with normal vasoreactivity [11,12].

PET studies in patients with acute stroke [21] have shown that CBF can follow various patterns:

- Increased cerebral blood volume to maintain normal CBF (normal or autoregulation).
- Increased oxygen extraction in response to a decrease in CBF to maintain $CMRO_2$ (oligohemia).
- Increased oxygen extraction to compensate for a decrease in CBF and $CMRO_2$ (ischemia).
- CBF and $CMRO_2$ with very low oxygen extraction (irreversible ischemic injury).

There is a growing body of evidence that supports the concept of a penumbra surrounding a central area of infarction. This means that the peripheral area is still viable and that all efforts should be undertaken to preserve it with thrombolytic therapy or to increase MAP.

In patients with intracerebral hemorrhage, it is uncertain whether there is cerebral ischemia around the hematoma. Several studies have shown that CBF and $CMRO_2$ decrease in proportion to each other, which has been called a brain in “hibernation” [22]. As hypertension is common during the acute period, it was postulated that aggressive treatment can lead to cerebral ischemia and poor clinical outcome. However, this has not been demonstrated and, indeed, there is evidence showing that a greater decrease in MAP improved clinical outcomes most likely due to a lower proportion of cerebral rebleeding [23].

Finally, we shall look at CBF during seizures, which has been studied since the 1930s following the discovery by Penfield that they alter the local environment [24]. Later it was found that CBF decreases during the interictal period in the affected temporal lobe or the entire ipsilateral hemisphere, with significant increases during the seizure, followed by a decrease in the postictal period [25]. There are very few studies to date that have correlated the coupling of delivery and demand, but preliminary studies indicate that it may occur or that there may be a decoupling.

9.5 Key Concepts

The brain autoregulates CBF to maintain a constant supply of glucose and oxygen in response to changes in the brain’s microenvironment. The major factors in this process are $PaCO_2$, PaO_2, tissue temperature, ICP, and CPP. They must be standardized or controlled

to prevent CBF from falling to critical levels which potentially lead to irreversible brain injury. Furthermore, in patients with chronic hypertension the autoregulation curve is shifted to the right, which means that "normal" CPP can result in ischemia in such patients. There are several methods to measure CBF in the neurocritical care unit. The most common are physical examination, CPP, EEG, xenon-enhanced CT, MRI, TCD, and thermal diffusion flowmetry. All these techniques have advantages and disadvantages, and there are no definitive data on their predictive value with respect to the diagnosis of cerebral ischemia and their impact on clinical outcomes.

10 The Current Role of Transcranial Doppler in the Intensive Care Unit. Indications, Bases for Its Correct Interpretation, Most Frequent Applications and Patterns

Corina Puppo [1], Leandro Moraes [1]

[1] Clinics Hospital, Universidad de la República School of Medicine, Montevideo, Uruguay

10.1 CBF Monitoring at the Bedside. Transcranial Doppler Ultrasound

In the mid-nineteenth century, Christian Andreas Doppler described the effect that bears his name. He showed that it is possible to measure the velocity of a moving object based on the measurement of the variation in the frequency (Doppler shift or Doppler frequency shift) and wavelength (light, sound, electromagnetic) that experiences a wave on reflection from the object.

Spencer and Reid used and popularized the Doppler effect to obtain information from the circulation in different blood vessels using ultrasound. Cerebral circulation was not possible to assess at an earlier stage because it was interpreted that the ultrasound could not pass through the skull. In 1982, Aaslid and colleagues introduced transcranial Doppler (TCD) in clinical practice to evaluate cerebral hemodynamics using ultrasound waves of 2 MHz, the smallest frequency used in medicine to that date. They were able to show that it is possible to measure the velocity and direction of cerebral blood flow (CBF) in several intracranial blood vessels through an intact skull and noninvasively [2-4]:

- The proximal segments of the arteries which make up the circle of Willis.
- The arteries that give rise to them (carotids and vertebral arteries).
- Their major branches.
- The major cerebral veins and venous sinuses.

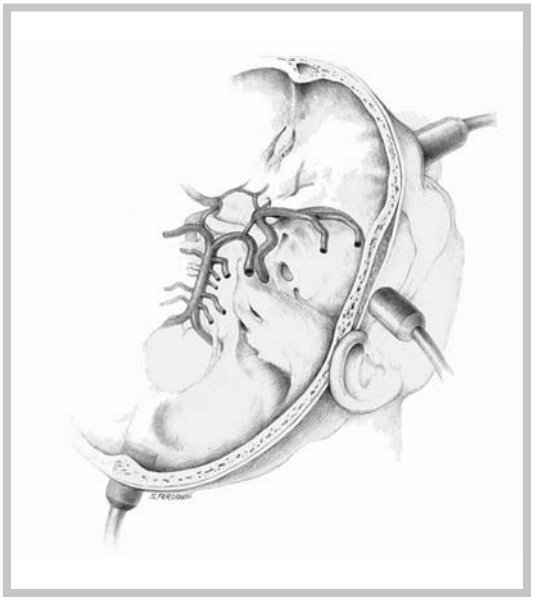

Figure 10.1. Insonation bone windows through which the arteries giving rise to the circle of Willis and its major branches can be studied: transforaminal, transtemporal and transorbital insonation windows.

IThe vessels that can be studied with TCD are:

- Proximal segments of the arteries making up the circle of Willlis.
- The arteries that gives them rise(carotids and vertebral arteries).
- Their major branches.
- It also allows blood flow circulation at major cerebral veins and venous sinuses to be assessed.

In experienced hands, this tool provides considerable amount of information in "real time" (excellent temporal resolution). It is also fast, simple, non-invasive, reproducible and feasible to perform at the bedside as often as the patient condition requires it, or even in a continuous way. All these features make the technique extremely valuable in the critical care setting. It is the only non-invasive technology available today that allows neurointensive care physicians or neuro-emergencists to monitor the intracranial hemodynamic characteristics at the patient´s bedside, without transfers (avoiding associated risks), in real time, noninvasively, through the intact skull. In this way the functional/dynamic information provided by this technique complements very well the static data provided by a CT or MRI.

What variable does TCD measure? As anticipated above, TCD measures Cerebral Blood Flow Velocity (FV) and its direction in the large basal cerebral arteries (Willis circle and main branches). In order to simplify the evaluation of FV a "spectral envelope" corresponding to the maximum flow velocity throughout the pulse cycle is created. Three specific points can be recognized in this envelope: peak systolic, end diastolic and mean flow velocity. The relationships between these velocities define indices (pulsatility and resistance index). Mean flow velocities and their relationships with velocities obtained from respective extra-cranial segments of carotid and vertebral arteries define different cerebral hemodynamic patterns. More information about ultrasound physics and specific characteristics of the technique are attached at the end of the chapter (see Appendix).

It is essential to note that FV as measured by TCD, is not synonymous with cerebral blood flow (CBF). CBF represents a flow (in mL/sec, and FV represents a velocity, in cm/sec. Although absolute values of CBF cannot be measured with TCD, changes in FV during continuous monitoring reflect proportional changes in CBF. This means that during continuous monitoring, if FV doubles, CBF has doubled, if the FV decreases by half means that the CBF has halved. However, we cannot know the absolute numeric value of these flows.

When studying cerebral hemodynamics in critically ill patients, it is important to assess the results in light of the systemic hemodynamics (arterial pressure), the presence of drugs (sedation, analgesics, vasopressors) or pathophysiological changes which act on the cerebral circulation (temperature, hemoglobin). It is also desirable to perform multiple neuromonitoring. This allows the simultaneous assessment of several variables. The parameters thus obtained allow a deeper evaluation of existing alterations. Other – invasive- variables which complement the information provided by TCD ultrasonography are ICP, cerebral oxygenation (global, by JSO_2, and local, by $PtiO_2$), continuous or intermittent EEG, etc.

Increase in velocity	Decrease in velocity
• Hyperflow • Vasospasm • Seizures • Anemia • Hypertension associated with loss of autoregulation • Fever • Arteriovenous malformation • Preeclampsia • Younger age • Decompressive craniectomy	• Intracranial hypertension • Decreased perfusion pressure • Hypocapnia • Drugs (indomethacin) • Hypotension associated with loss of autoregulation • Hypoxia • Cerebral circulatory arrest • Hypothermia • Older age

Table 10.1. **Factors causing an increase or a decrease in CBFV.**

10.2 Flow Velocity and Pulsatility Index. Normal Range and its Variations

Normal flow velocities vary in different vessels. In addition, they vary with age, systemic and/or cerebral hemodynamics, physicochemical characteristics of blood (viscosity), etc. FV oscillates between 30 and 80 cm/s, approximately. For example, in the adult group, FV in the middle cerebral artery (MCA) is 58±12 cm/s. FV in the basilar artery is 36±12 cm/s.

Side to side (right to left) variations has been detected in normal individuals, but differences above 15% should not be interpreted as normal. A daily variation is also possible but should be assumed as normal only if it is lower than 10 cm/s.

10.3 Clinical Applications of Transcranial Doppler in Intensive Care Medicine

TCD is an important non-invasive diagnostic tool in evaluating patients with cerebrovascular disease. In Intensive Care its use is particularly aimed to detection and monitoring of changes in cerebral hemodynamic in subarachnoid hemorrhage (SAH), ischemic and hemorrhagic stroke, traumatic brain injury (TBI) and other diseases not so frequent but equally serious, such as meningitis and encephalitis, severe vasculitis, etc. The most frequent disturbances of cerebral hemodynamic in these patients are secondary to increased intracranial pressure and the possible development of cerebral circulatory arrest (CCA), cerebral vasospasm, hyperemia, and impaired cerebrovascular reactivity (autoregulation and CO_2 reactivity). In the intensive care unit there are many technical difficulties, related to: 1) the multiple monitoring systems which surround the patients, with wires and catheters, respirators; 2) the difficulties of positioning non collaborating patients. The fundamental interest in the neurocritical care patient is often to evaluate the alterations of cerebral hemodynamic globally, or to search for assimetries. To diagnose these alterations it is enough to insonate middle cerebral arteries bilaterally, and the basilar artery in the posterior sector. However, if the main interest is the study of a localized disturbance, such as vasospasm, the evaluation should be detailed along each vessel.

TCD has a broad spectrum of clinical applications. In neurocritical patients, its major applications are:

- To confirm or exclude the existence of intracranial hypertension (ICH) in many clinical scenarios, assisting in the decision making process on the indication of invasive monitoring of ICP [5-14].
- To diagnose cerebral circulatory arrest (CCA) [15-21] (with very high specificity), avoiding invasive procedures or transfers, thus helping in the diagnosis of brain death.
- To help in the diagnosis and monitoring of cerebral vasospasm. Vasospasm is one of the main SAH neurological complications and appears quite frequently in the course of this disease, but is also important to remember that vasospasm has been demonstrated in the evolution of TBI and CNS infections [26-30].
- In the stroke patient, the TCD can provide immediate information about the status of cerebral hemodynamics, evidence if there is vascular stenosis (partial occlusion) or complete occlusion, can monitor the time course of recanalization when performing thrombolytics, and even enhance the action of these drugs. In addition it can pro-

vide information regarding the pathophysiological mechanism of stroke, such as the existence of microemboli and detect the presence of right-left shunt in cryptogenic stroke. Finally, it is also possible to evaluate the cerebral circulatory reserve and the status of cerebral autoregulation, thus helping the clinician in the management, monitoring of treatment and prognostic assessment.

In the ICU is common that many of the variables which are able to influence the intracranial hemodynamic are altered, so that the probable influence on the founded FV should be taken into account. But the most important factor, given its hazard, which should always be thought as a cause of a low FV is the rise in intracranial pressure.

10.3.1 Pulsatility Index and Resistance Index

From the FV waveform systolic, diastolic and mean velocities can be calculated. Analysing the relationship of these velocities various indices of cerebrovascular resistance can be calculated. Pulsatility index (PI) and resistance index (RI) are widely used and complement the characterization of sonographic patterns.

The IP is calculated using the following formula:

$$PI = (FV_s - FV_d) / FV_m$$

TCD ultrasound software usually calculates PI and time-averaged mean velocities for each sonogram and displays them on the screen.

RI is calculated using the following formula:

$$RI = (FV_s - FV_d) / FV_s$$

These indices are very helpful when assessing a particular patient, especially in intensive care medicine. Intracranial hypertension slows the flow velocity, preventing the normal flow of blood through the cerebral vascular bed. Velocities are affected and decrease mainly in diastole, which is the period of the cardiac cycle in which blood enters into the brain circuit with less power. This leads to a relatively greater increase in the FV_s ($FV_s - FV_d$) and explains that the PI or RI indices increase when ICP is going up. There are other factors able to descend the FV in the absence of intracranial hypertension, which are factors that act directly on the arteriolar resistance (diameter). Therefore, when either of these two indices is above the normal value the physician should act promptly searching for the presence of any factor that could be affecting the normal blood flow circulation, such as:

- Intracranial hypertension leading to a decrease in the cerebral perfusion pressure (CPP).
- Increased cerebrovascular resistance from another source, such as the presence of a cerebral circulation vasoconstrictor (ie, hypocapnia, indomethacin).
- Bradycardia. In this situation, the time between heartbeats is greater, so that the diastolic velocity decreases for a longer period, until it reaches the new wave pulse, increasing the velocity-gap ($FV_s - FV_d$).
- Vascular stiffness (rigidity); in the absence of energy absorption by the arterial wall, the FV_s goes up while the FV_d goes down.

The most widely used of the two indices is the PI. Its normal value varies between 0.60 and 1.20. Although the normal maximum value is 1.20, clinically is reasonable to suspect the presence of significant intracranial pressure increase and seek their cause when the index is above 1.00. The PI findings during the acute phase of TBI have been corre-

lated with the prognosis. An increase in PI, mainly when is associated with a decrease in FV_d, indicates a poor CPP. Several clinical studies in adults and children who have suffered head injury (different degrees of severity) have shown worse outcomes associated with low flow velocities (less than 25 cm/s in children) and raised PI (above 1.3 or 1.5) [34-36].

The pathological process triggered by the acute and severe CNS disease can affect the cerebral circulation in many and complex different ways. Under certain conditions specific changes prevail. For example, vasospasm is known as a frequent complication of SAH, but that does not mean that there is no vasospasm in other neurological diseases, or that vasospasm is the only cerebral hemodynamic complication of SAH. On the other hand, different alterations often coexist and the physician should have them in mind, knowing that in many circumstances different alterations act in an opposite directions leading to a ¨pseudonormal ultrasound pattern¨ (also called mixed pattern).

Doppler pathological patterns are not related to specific diseases, but to its pathophysiological impact on cerebral circulation. Therefore, the impact of the most frequent alterations: intracranial hypertension and vasospasm, on FV and PI will be first described. Finally, some reference to different acute neurological conditions (SAH, TBI, stroke) will be added, with a schematic analysis of the hemodynamic changes that may be encountered during their course.

10.4 Transcranial Ultrasonographic Abnormalities in Neurocritical Patients

TCD ultrasonography provides valuable information about the effect on cerebral circulation of the pathophysiological changes produced by neurological injuries. It detects abnormal modifications consistent with increased intracranial pressure, cerebral circulatory arrest, vasospasm, hyperemia and impaired cerebrovascular reactivity.

The different patterns to be analyzed are:

- High-velocity pattern.
- Low-velocity pattern.
- High-resistance pattern.
- Cerebral Circulatory Arrest (CCA) pattern.

10.4.1 High-velocity Patterns

Both hyperemia and vasospasm are evident in TCD sonogram as an increase in flow velocity.

Vasospasm Vasospasm of cerebral arteries may be focal or diffuse. Its first hemodynamic consequence is a decrease in the pressure loss through the stenotic segment. If the cerebrovascular autoregulatory mechanism works, local CBF can be maintained at the expense of a dilatation of distal small autoregulatory vessels. The same amount of blood (per unit time) passes through an arterial segment whose lumen has fallen. Therefore, the blood must pass more rapidly (compensatory response). This velocity augmentation occurs, therefore, in the stenotic segment. If we measure CBF rather than flow velocity, we would find it preserved if autoregulation is working properly, or decreased if autoregulation is defective/impaired or if it is maintained but not enough to compensate a very severe spasm. It must be **emphasized that in the case of vasospasm, CBF is not increased.**

Hyperemia. In this case **CBF is increased**, regardless of whether the cause is (greater brain metabolic demand or ¨luxury perfusion¨), more blood than in normal conditions is passing through a normal/increased vessel calibre. Therefore, it circulates faster.

High Velocity Differential Diagnosis

As it has been mentioned before, an increased FV may correspond to vasospasm or hyperemia. Is it possible to distinguish them? Lindegaard [37] proposed to study the relationship between the FV in the intracranial affected vessel and the velocity in the extracranial vessel supplying blood to it. As vasospasm is an alteration of the intracranial arteries which have been in contact with subrachnoid blood, flow velocity increases in the compromised intracranial artery, but not in the extracranial one, therefore the rate between the two velocities increases. On the other hand, if the velocity increase is due to hyperemia, the increase in FV is seen in both, the intracranial and extracranial vessels. Therefore, the relationship between these velocities remains normal. These concepts are the basis of Soustiel [38] and Lindegaard indexes, for the anterior and posterior sectors, respectively.

Anterior circulation: Mean FV in the middle cerebral artery (MCA FV_m) is compared with the corresponding value in the ipsilateral extracranial internal carotid artery (ICA) at the entrance of the skull base (ICA FV_m). This relationship MCA / ICA is known as Lindegaard Index (LI), or hemispheric index. An LI >3 indicates vasospasm and if >6 severe vasospasm. Values <2 (normal) indicate hyperemia.

Posterior circulation: FV in the basilar artery (BA) is compared with corresponding value in the extracranial vertebral arteries (EVA) that supplies it, known as BA / EVA index or Soustiel index. The cut-off value is 2**.**

Time Course of Vasospasm and CBFV-related Changes

Vasospasm, which occurs in several pathological conditions (SAH, TEC, meningitis, etc.), is an abnormal and dynamic process. In SAH it begins around the 4th day after bleeding, has a maximum between the 7th and 10th day, and disappears around the end of the third week after the bleeding. It may progress to a mild degree and then improve, or increase to a point where regional cerebral autoregulation cannot compensate for the decrease in regional perfusion pressure, and consequently CBF decreases in the area irrigated by the affected artery eventually resulting in clinical signs of ischemia, depending on the extent, topography and collateral circulation. During the phase in which CBF is maintained, vessel lumen reduction is accompanied by a compensatory increase in flow velocity (see appendix). When vasospasm further increases, flow starts to decrease due to the inability of the regional autoregulatory mechanism to compensate for the higher drop in regional CPP. This point is known as **critical vasospasm**. High velocity starts to decrease (**could be interpreted as improving vasospasm**) and in some cases flow ceases. It is important to note here the importance of performing a daily monitoring of these patients, since at this stage a normal flow velocity (in just one study) should not be interpreted as vasospasm absence. At this stage, a third factor also plays a crucial role: blood flow through the narrowed vessel. Additionally, it should be noticed that the rise of the arterial blood pressure in a patient whose regional perfusion pressure has decreased below the lower limit of autoregulation may increase flow through the stenotic segment, increasing FV again. This increase does not signify a worsening but an improvement of the situation. In summary, not always an initial FV decrease has to be interpreted as an indicator of vasospasm improvement, nor an increase in CBF as vasospasm worsening, but the values must be interpreted in light of the clinical and therapeutic maneuvers, taking always into account the values of patient's arterial blood pressure, and ICP-CPP if available [39].

TCD in Subarachnoid Hemorrhage

TCD is widely used for screening and monitoring vasospasm in SAH due to its simplicity, lack of invasiveness and the possibility of being performed at bedside. In patients with good clinical grade, the usefulness of TCD is most often the diagnosis and follow-up of cerebral arteries vasospasm. This technique has an excellent diagnostic specificity and an acceptable sensitivity for cerebral vasospasm. It allows an early diagnosis before clinical neurological deficit occurs. This study should be performed daily (or every two days) during the first week (after bleeding) to be able to demonstrate vasospasm onset and monitor its progress and clinical impact. As it has been previously mentioned, the typical diagnostic vasospasm pattern is characterized by an increased cerebral blood flow velocity (FV). This increase begins between days 3 and 10, reaches its maximum between days 11 and 20, and finally returns to normal within 4 weeks [40].

Many studies in SAH patients have found diagnostic velocities at different arteries.

Middle Cerebral Artery (MCA)

Aaslid and colleagues initially described three degrees of vasospasm in SAH: mild, moderate and severe with velocity limits of 120 and 200 cm/s. At the same time he emphasized Lindegaard index as an essential complement of these values. LI limits described by this author were 3 and 6 to distinguish between the three grades of vasospasm [41]. According to Vora et al., FV greater than 200 cm/s is an index of severe vasospasm, and FV lower than 120 cm/s is an index of mild vasospasm, or absence of vasospasm [19,42]. Another related study investigated velocity values associated with angiographic or clinical vasospasm, finding a threshold of 100 cm/s when angiographic vasospasm was evident (sensitivity and specificity of 1.00 and 0.75 respectively), and of 160 cm/s when clinical vasospasm was detected (sensitivity and specificity of 100%) [43].

Other studies have evaluated the percentage of velocity change comparing to a control TCD assessment (ICU admission) [44].

Other Vessels Insonated Through the Temporal Window

Anterior cerebral artery (ACA) and posterior cerebral artery (PCA): considering as a cut-off value 110 cm/s for the PCA and 130 cm/s for the ACA, specificity is very good (93% and 100%, respectively). However, the sensitivity, due to a number of anatomical and technical factors, is not reliable. This means that if TCD results are normal vasospasm can not be excluded. Since often ACA vasospasm does not associate MCA compromise, especially after an anterior communicating aneurysm rupture, great caution should be given to make treatment decisions based only on a negative test for vasospasm diagnosis [45].

Other Vessels Insonated Through the Posterior Window

n this sector FV ≥ 60 cm/s is indicative of vasospasm in both arteries (vertebral and basilar), with low sensitivity and high specificity for the vertebral artery [46]. For the basilar artery, a value of 85 cm/s has 90% specificity and 50% sensitivity. When considering a limit of 80 cm/s for the diagnosis of vertebral artery vasospasm and 95 cm/s for the basilar artery, the specificity and positive predictive value goes up to 100% [47,48].

It is important to remember that in SAH patients very often multiple changes in cerebral hemodynamic coexist (including vasospasm), mainly in those with greater clinical severity (poor grade SAH). Intracranial hypertension, frequently associated with hydrocephalus or brain swelling, vasospasm, hyperemia triggered by non-convulsive epileptic activity or impaired cerebral autoregulation, systemic disorders (spontaneous or generated by our treatment) like fever, sepsis, hyponatremia, anemia, hypercapnia, hypocapnia, hypovolemia, hypervolemia, hypertension, hypoxemia. All these variables may cause intracranial hemodynamic changes and make TCD interpretation a real challenge for doctors. For example, the frequent association between a) **vasospasm** (typically increases FV and reduces the PI) and b) **intracranial hypertension** (decreases FV and increases PI) re-

sults in a tricky "**pseudo normal pattern**". It is also common that these patients have severe systemic complications, including sepsis, which may be accompanied by an hyperdynamic state with cerebral hyperemia. Hence, it is crucial to use the mentioned indices (PI and/or RI) in order to be able to detect how greatly all these systemic disturbances are affecting (or not) the TCD pattern. These indices significantly improve the specificity of the high-velocity pattern in the diagnosis of vasospasm. It is also necessary to evaluate the TCD results in the light of the patient clinical and systemic neuromonitoring (ICP, CPP, PtO_2 if available) situation.

High-velocity Pattern in Traumatic Brain Injury

Although the main cause of poor outcome in severe TBI is high ICP (especially refractory ICH), which is not responsible for high velocity pattern, this pattern has often been reported in this context. TBI is an extremely heterogeneous disease in which the risk of simplifying a complex and dynamic pathological process is always present and physicians should keep this in mind. However, in everyday practice, it is useful to recognize the intracranial hemodynamic changes described by Martin et al. They found, in a large group of TBI patients, three consecutive ultrasonographic patterns: hypoperfusion, hyperemia and vasospasm (Figure 10.2).

Other Causes of High-velocity Patterns

Inflammatory and infectious disorders, such as cerebral vasculitis, encephalitis and meningitis, often present high-velocity patterns caused by focal (at different topography) or diffuse artery narrowing. Vasospasm is also possible in these scenarios.

Cerebral arteriovenous malformations (AVM) show a high velocity pattern explained by the existence of multiple arterio-venous low resistance shunts.

Arterial blood flow selectively passes with high velocity through these dilated veins, creating a chronically hypoperfused brain area where small arterioles and precapillary sphincters dilate as a compensatory mechanism, to maximise blood entrance and to offset chronic hypoperfusion.

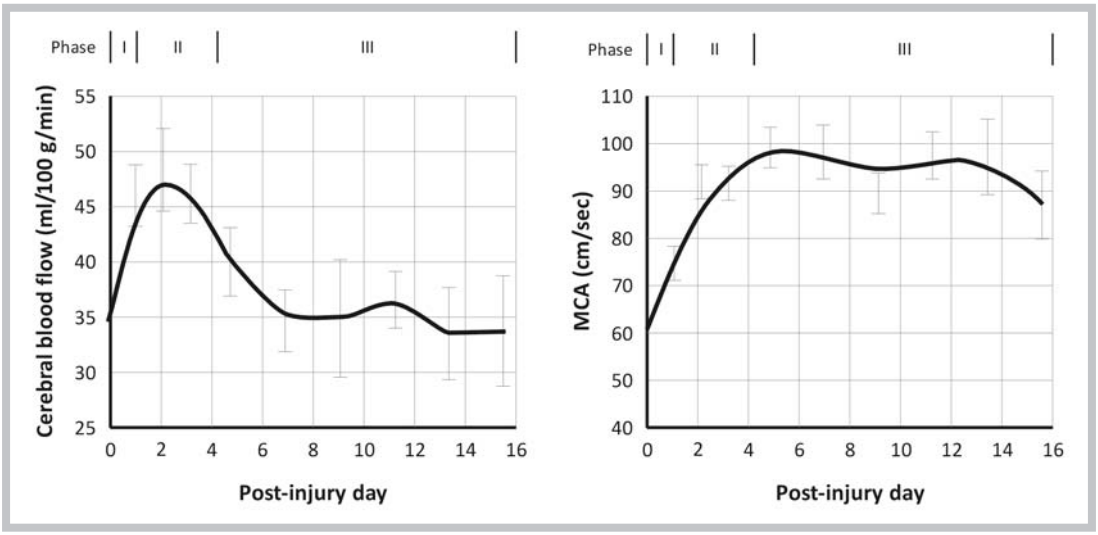

Figure 10.2. **Phases found in cerebral hemodynamics in a group of severe TBI patients. Phase I, first 24 hours, hypoperfusion with low velocity. Phase II, high velocity and CBF: hyperemia stage. Phase III, high velocity, but low CBF: vasospasm stage. Note how a high velocity in the TCD does not make a diagnosis of vasospasm by itself.**

During the postoperative period, after AVM excision, when chronic hypoperfusion is corrected, special attention should be paid to systemic hypertension. A severe hyperperfusion syndrome (high sonographic velocity pattern with a LI <2) followed by brain edema and hemorrhage can be triggered by high or even normal blood pressure levels. This situation is known as circulatory "breakthrough". It can eventually lead to brain edema and intracranial hypertension. The same complications can appear whenever a correction of a chronic hypoperfusion state is performed, as after carotid endarterectomy.

Low-velocity Pattern: Intracranial Hypertension

ICH may complicate the course of many acute neurological diseases. In relation to pressure, according to the following formula, an ICP increase leads to a CPP decrease:

$$CPP = MAP – ICP$$

Thus, when the ICP equals the diastolic blood pressure, brain perfusion stops in diastole, and when the ICP equals the systolic blood pressure, perfusion stops completely. It should be emphasised that TCD measures FV and can indirectly estimate relative changes of the cerebral blood flow. Broadly speaking, the fundamental concept is that an ICP increase impairs the inflow of blood into the brain. Therefore, FV decreases. The first portion of the sonogram which is affected is the end diastolic velocity. Velocity is slowed in this part because it is the portion of the pulse wave during which the blood flows with lower energy. Initially peak systolic velocity increases due to cardiac compensation. As the CVR indices (PI and RI) depend on the differential velocity ($FV_s – FV_d$) they go up. When ICP increases more, all velocities decrease, but the principally affected one is always the diastolic velocity, leading to a progressive increase of the PI. This pattern of low velocity with increased PI is called **high-resistance pattern**. Although it can have several causes, when detected in a neurocritical patient, the treating physician **should always suspect the presence of intracranial hypertension and act accordingly.** An example is provided in Figure 10.3.

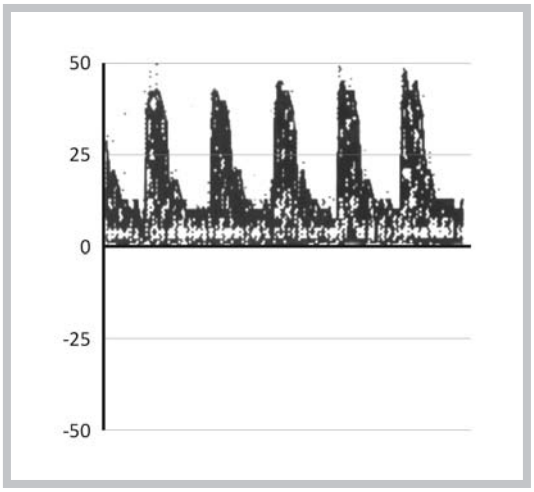

Figure 10.3. **Example of a high resistance sonogram in the MCA in a 66 y.o female, after removal of a parasagittal meningioma complicated by a hematoma in the surgical site. GCS 3 under thiopental. Note the low FV (24 cm/s) and the increased PI (1.58). This study raises suspicion about the presence of ICH, and rule out the cerebral circulatory arrest diagnosis in a patient without the possibility of being clinically evaluated for being under the influence of thiopental.**

Other Causes of a Low-velocity Pattern

In intensive care medicine, a low velocity pattern may be due, in addition to ICH, to:

- Arterial hypotension below the buffering capacity of the autoregulatory mechanism (severe shock of any etiology or relative hypotension in a chronic hypertensive patient with the inferior autoregulatory threshold shifted to the right). If this is the only factor causing the low velocity, the PI can be normal or decreased.
- Presence of small resistance vessels vasoconstrictor mechanisms or drugs (hypocapnia, indomethacin). It is accompanied by increased IP.

- In the first stage of TBI (24hs, see Martin´s diagram, hypoperfusion phase) there is a cerebral flow velocity reduction. The underlying mechanisms are still unclear. Some investigators have interpreted it as a cause of cerebral ischemia, but modern theories attribute it to a decreased demand by the injured brain.

10.5 Extreme Expression of Intracranial Hypertension: Cerebral Circulatory Arrest

Increases in ICP are accompanied by a decrease in all flow velocities. This phenomenon affects the diastolic phase earlier and more intensely, soon resulting in the cessation of diastolic flow (systolic peaks). A reverberating diastolic flow can then be seen (the flow that entered in systole is turned back during diastole). In the next stage there is a minimal movement of blood, only at the beginning of systole, which is known as systolic spikes. Subsequently, the flow ceases completely (the ultrasound beam cannot detect anyt blood movement). Reverberating flow and systolic spikes patterns correspond to what is accepted as “cerebral circulatory arrest” (Figure 10.3). When this pattern is found bilaterally in the anterior circulation and in the posterior sector and these alterations persist for at least 30 minutes (is not a transitory state), it can be used to support the diagnosis of brain death.

10.6 TCD as a Complementary (Auxiliary) Diagnostic Technique in Determining Brain Death

Most patients who progress to brain death have suffered severe intracranial hypertension with a concomitant decrease in cerebral perfusion pressure. This generates a glob-

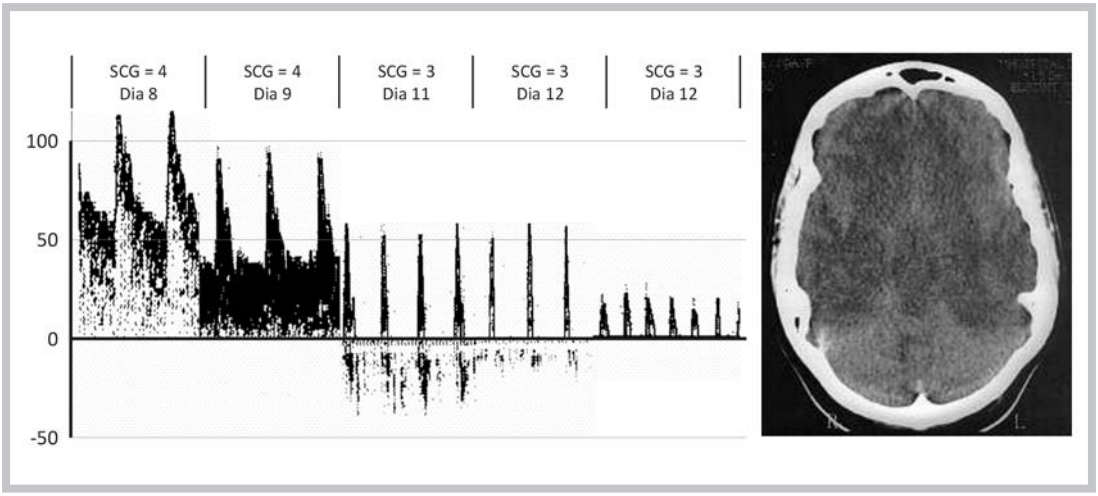

Figure 10.4. **Typical TCD alterations ending in a cerebral circulatory arrest pattern in a 17-year-old girl with asthma after successful resuscitation from a hypoxic cardiac circulatory arrest. She eventually progressed to brain death (clinical diagnosis) on the 12th day. The first sonogram (left) is normal. The second shows the high-resistance pattern followed by the reverberating pattern. Finally, the third sonogram shows the systolic spikes pattern. An anoxic-ischemic brain injury may take weeks to evolve, to crebral circulatory arrest, as seen in this example. The head CT shows a white cerebellum with diffuse swelling (images from our archives).**

al brain ischemia and ends in the irreversible loss of life-sustaining functions. The time course of the blood flow changes can be followed with TCD until a cerebral circulatory arrest pattern can ultimately be identified. An example of typical TCD alterations is provided in Figure 10.4.

10.7 Summary of Changes in Cerebral Hemodynamics: Muñoz Chard

The classification scheme of Muñoz [49], presented in Figure 10.5, classifies alterations of cerebral hemodynamics into three different categories corresponding to pathological PI values (increased or decreased), pathological CBFV values (high or decreased), and normal values.
The diagram is helpful for interpreting the results of a transcranial ultrasound. It highlights five main patterns:

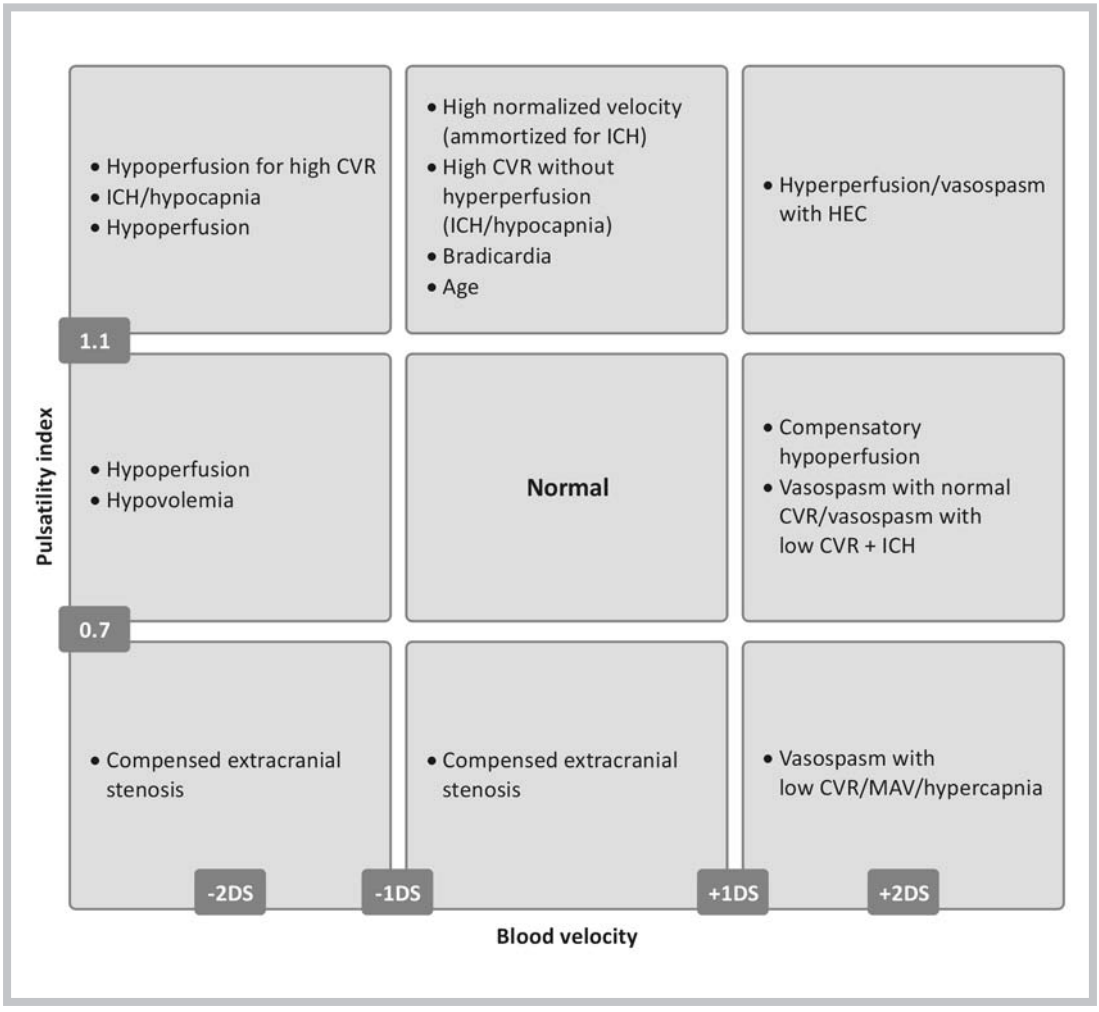

Figure 10.5. The classification scheme of Muñoz [49].

- Normal or pseudonormal pattern (FV_m and PI normal for patient age and the insonated vessel).
- Low velocity pattern (FV_m lower than 1 SD of the normal velocity value of the insonated vessel at the patient´s age). It Implies a reduction of cerebral blood flow (CBF) coupled or not to brain metabolism. The decrease in CBF may depend on many factors, both systemic (hypotension, hypothermia, etc.) or intracranial ones (intracranial hypertension, etc.).
- High-velocity pattern (FV_m greater than 1 SD of the normal velocity value of the insonated vessel at the patient´s age). It does not necessarily imply an increase in CBF. Two situations can be distinguished: hyperemia (a real increase in CBF) and vasospasm (CBF constant or low).
- High-pulsatility pattern (high PI) is caused by an increase in cerebrovascular resistance (CVR) distal to the insonated point. The increase in CVR may be active (vasoconstriction) or passive (vascular bed compression due to intracranial hypertension). Its extreme expression is the cerebral circulatory arrest pattern.
- Low-pulsatility pattern (low PI) is caused by a reduction in CVR distal to the insonated point. The reduced CVR may be related to a low-resistance vascular bed of anatomic origin (arteriovenous malformations) or a state of vasodilation induced by different etiologies (ischemia, drugs, hypercapnia, etc.).

The patterns are considered as symmetrical or asymmetrical depending on whether they are detected bilaterally or unilaterally, respectively.

10.8 Assessment of Cerebrovascular Reactivity

Under normal conditions, cerebral blood flow resistance in the vascular bed is low in the conductance vessels (large arteries and their main branches) and in the venous sector. The main areas that generate resistance to flow are the arteriolar sector, the leptomeningeal arterioles and the precapillary sphincters, where a pressure drop of 80% normally occurs. This area of the vascular bed also has the property to vary small vessel resistance by vasoconstriction or vasodilation (potentially), leading or not to changes in CBF depending on the stimulus the vessels are responding to. Owing to its vascular reactive properties, it is referred to as the “area of cerebrovascular resistance”.

Cerebrovascular reactivity is defined as the ability of the arteriolar bed to respond to different stimuli with changes in cerebrovascular resistance. Depending on the stimulus, four types of cerebrovascular reactivity can be distinguished:

- CO_2 reactivity.
- Metabolic reactivity.
- Reactivity to drugs.
- Cerebral autoregulation (CA).

In the first three types, changes in cerebrovascular resistance lead to higher or lower CBF, either regionally or globally, according to the stimulus and where it acts. In contrast, in cerebral autoregulation, the resistance modifications tend to keep the CBF constant while the stimulus (blood pressure) changes. Vascular reactivity can be manipulated clinically to generate changes in cerebral blood volume (CBV), CBF, and intracranial pressure. Therefore, its assessment is often useful to gain an idea of how the CVR area is going to respond to different therapeutic options (maneuvers or drugs) widely used in this clinical scenario. Its evaluation also has prognostic value. The more severe the injury, the more impaired the reactivity, the worse the patient outcome.

10.8.1 Autoregulation

Cerebral autoregulation (CA) or pressor cerebrovascular reactivity is the capacity of the vascular bed to maintain, by vasoactive responses, cerebral blood flow (CBF) constant between two CPP "thresholds", the upper and lower limits of CA, where:

$$CBF = CPP/CVR$$

and, if ICP is normal:

$$CBF = MAP/CVR$$

The last equation clearly shows that CA requires that changes in CVR be proportional to changes in mean arterial pressure (MAP) to maintain CBF constant (see appendix).

Cerebral Autoregulation

There are two main ways to assess cerebral autoregulation:

- "Static" CA takes into account the magnitude of the CBF response in relation to the degree of CPP variation, without considering relevant the time course of this response.
- "Dynamic" CA takes into account the time course of the CBF response to sudden changes in CPP (**the time the cerebral vessels need to dilate and return the CBF to baseline**).

In summary, to evaluate CA, changes in CPP or MAP (if ICP monitoring is not available) have to be simultaneously compared with changes in CBF. Changes in flow velocity are proportional to changes in CBF, provided that the cross sectional area of the insonated artery does not change during the study. This has been demonstrated by several researchers, including Giller.

Static Autoregulation

Static autoregulation refers to CBF changes independent of time, as described by Lassen's classical curve. To study this type of autoregulation, it is necessary to generate a slow change in MAP and evaluate the response of CBF. MAP can be increased (approximately 20 mmHg) by infusing a vasopressor agent without direct action on the central nervous system (CNS), preferably phenylephrine (PE) or noradrenaline (NA). Several values of CPP (or MAP) and the corresponding values of FV for a period of approximately 20-30 minutes are recorded. Maintaining ta stable PCO_2 during the study is crucial. Sedation should be used. Other variables which may influence the cerebrovascular response should also be monitored (i.e., temperature, SO_2). The expected response of the cerebral circulation, which tends to maintain CBF constant while MAP is rising, is accomplished by the contraction of the small vessels, arterioles and precapillary sphincters, leading to augmentation of CVR.

There are different ways to express the change in flow relative to the change in pressure:

- The **slope of the best fit line between both variables**. In this case, a change in CBF (as a percentage of baseline CBF) is calculated per mmHg of CPP increase.
- The **correlation coefficient between both variables.** Positive values tending to 1 indicate impaired autoregulation (pressure-flow passive relationship). In contrast, values close to zero or negative ones indicate good autoregulation or active vessel response (pressure-flow independent relationship).
- The **cerebrovascular resistance behaviour** (instead that the change in flow) in relation to the change in CPP or MAP. In this case, the results should be interpreted in

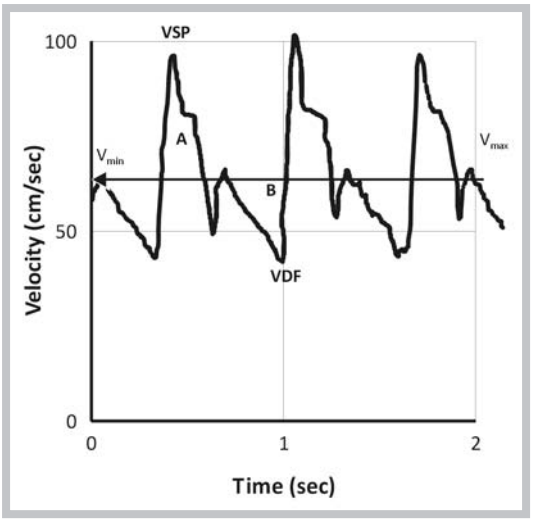

Figure 10.6. **Autoregulation as expressed by the velocity slope.**

reverse: the more the resistance increases (while MAP is rising), the better the autoregulation.

Figure 10.6 shows autoregulation as expressed by the velocity slope.

Three ranges have been defined: slope variation <0.4% per mmHg of change in CPP corresponds to preservation of autoregulation; an intermediate group (0.4-0.9%); and a third range with a slope >0.9% corresponding to impaired/abolished autoregulation. The lack of consensus on the way investigators evaluate CA makes it difficult to compare results across different studies. For example, a velocity slope of nearly zero expresses an excellent static autoregulation (as in the above example). However, if the same result is shown as a change in CVR (rather than a change in flow velocity), the same response would be expressed as a resistance index (i.e.RoR, rate of regulation).

$$RoR = [\%\ \text{change in CVR} / \%\ \text{change BP}] \times 100$$

If CA is preserved, a direct proportional change in CVR (1% increase in resistance for every 1% increase in BP) would be expected (RoR = 100 means excellent CA), since flow stability is due to the increase in CVR when AP increases.

There are excellent reviews of methods for measuring CA by R. Panerai (Leicester University, UK).

Dynamic Autoregulation

Dynamic CA evaluates the time-course and extent of CBF changes elicited by sudden and sharp CPP changes. We emphasize that TCD, thanks to its excellent time-resolution, is the ideal method for this assessment, displaying the changes in FV while the CPP change is taking place. Since it is the first method, and practically the only one so far, that allows this "on line" assessment, the concept of dynamic CAR (DCA) and the methods for its evaluation has emerged almost simultaneously with the rise of TCD. The change in the CPP can be generated by a change of ICP or BP. In clinical research, for ethical reasons, only BP manipulation is used. Therefore, DCA in critically ill patients has been evaluated through the temporal course of CBF changes caused by a sudden and provoked drop in BP. Recently (last decade), spontaneous BP oscillations have gained considerable research and clinical importance.

Some of the methods used to evaluate DCA are: Giller's test or transient hyperemic response test, Aaslid transient hypotension, and continuous monitoring of spontaneous changes using a moving correlation index of cerebral perfusion pressure and middle cerebral artery flow velocity.

The Transient Carotid Compression Test or Giller's Maneuver [50] (Transient hyperemic response test [TRHT])

This method is based on a short (5 sec) and sharp compression of the extracranial internal carotid artery (at the base of the neck) while evaluating the change in the FV in the ipsilateral MCA (carotid terminal branch). Carotid compression reduces the flow in the

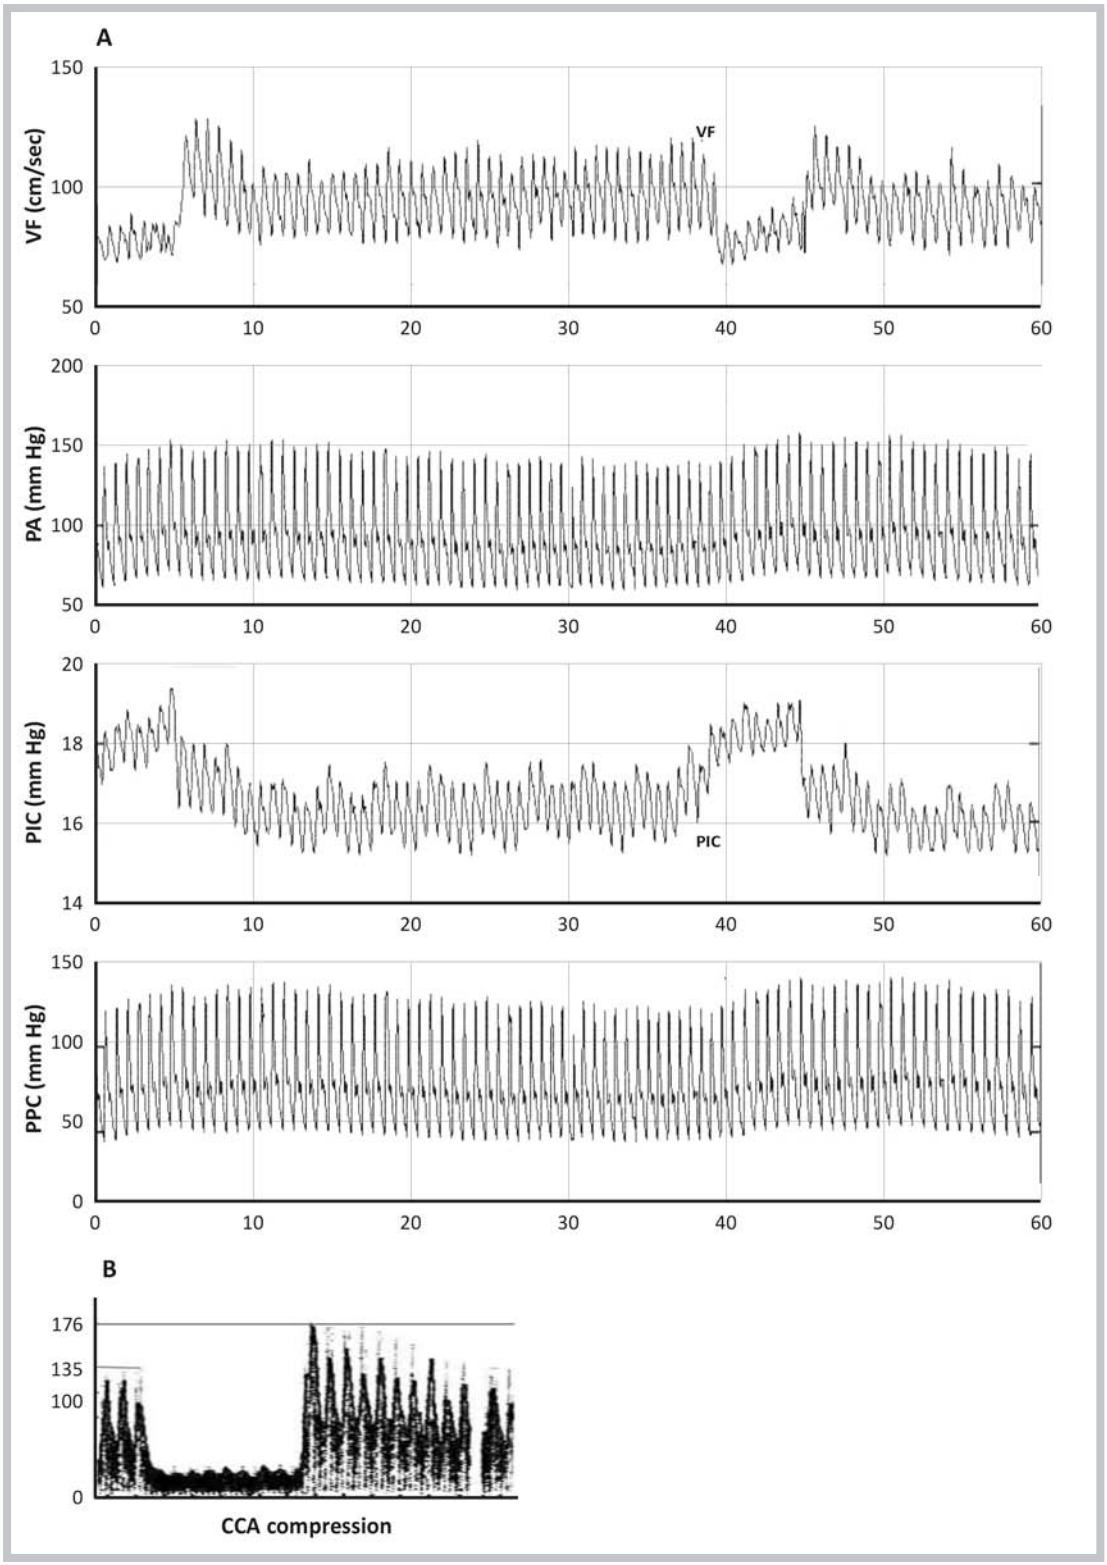

Figure 10.7. **(A). Giller test result recorded by our in-house acquisition data software (CONTINE). (B). Changes in the velocity as seen on the TCD screen (15 s).**

Figure 10.8. **Aaslid's maneuver in a volunteer.**

MCA territory, thereby reducing the CPP in the territory supplied by the artery. If DCA is intact, a rapid vasodilation response of small blood vessels occurs which tends to maintain CBF constant. Sudden release of compression produces a transient hyperemic response as the CPP normalizes and acts on a dilated vascular bed. This hyperemic response is detected by TCD as an increased flow velocity at the insonated ipsilateral MCA. If DCA is impaired, then compensatory vasodilation is minimal or absent. Accepted indicators of preserved DCA are values ≥1.1 according to the formula: FV post-compression/FV pre-compression.

Compression is applied to the base of the neck to avoid compressing the carotid bulb or the carotid bifurcation. The Giller test is one of the easiest tests to assess DCA. It has been widely used [51-54] and its results are reproducible, provided that the duration of compression is at least 5 seconds.

The figure on the left shows a Giller test recorded by our acquisition data software (CONTINE). In this example, a good DCA exists. A rapid increase in ICP is observed (lower arrow). This ICP increment can be explained by the vasodilation of the small arteriolar resistance vessels, leading to an increase in cerebral blood volume. Since compression is applied to the ICA and the blood pressure is recorded in the radial artery, the **regional change in blood pressure** is not detected. However, a change in the CPP due to the ICP-related change is visible.

The right figure shows the changes in the FV (15 s). It is another example of good DCA.

Aaslid Test or Cuff Deflation Test

In this case, systolic blood pressure manipulation is done using the thigh cuffs method. Two cuffs are inflated bilaterally at the proximal thighs, above the patient's systolic pressure, keeping them inflated for 3 minutes and releasing them suddenly. This maneuver elicites a reactive hyperemia in the legs vascular bed so that after releasing the compression the venous return decreases by "pooling" blood at the lower limbs and a sudden systolic blood pressure fall follows immediately after the compression is released. The magnitude of the drop in BP is usually around 20 mmHg. A drop exceeding 10 mmHg is considered a sufficient stimulus. FV in the insonated MCA (proportional to the CBF) also

drops. In healthy volunteers, with intact DCA, FV recovers within 15 seconds, while blood pressure takes more than twice to return to baseline. It is clear that normal CA responds immediately to preserve CBF regardless of systemic blood pressure regulatory mechanisms.

Figure 10.8 shows Aaslid's maneuver in a volunteer. The thigh cuffs remain inflated for 3 min and a fixed transducer records FV in the MCA. Wide Velcro ® fasteners are used to permit rapid cuff release. (there are also specially designed cuffs with a greater diameter and wide connectors that allow faster deflation). Clamps are placed to maintain the cuff fully inflated during the 3 min.

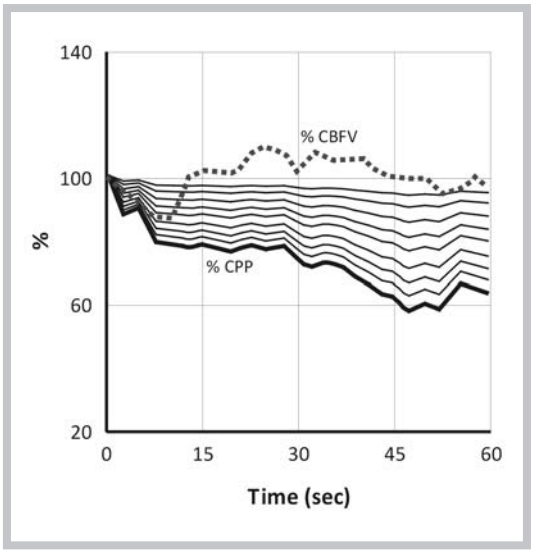

Figure 10.9. **Ten hypothetical curves and two real FV and CPP curves in a patient with intact DCA, ARI = 9 [57]. Real FV curve = dotted line % CBFV; real CPP curve = black line % CPP.**

Test limitations:

- Continuous blood pressure monitoring is required, which is not a problem in critically ill patients but it could be outside the ICU. For patients without arterial catheterization (invasive blood pressure monitoring not available), continuous monitoring can be performed using noninvasive devices based on plethysmography (Finapres).
- Inability to induce a significant drop in blood pressure, particularly in patients with peripheral vascular disease.
- It is contraindicated in patients with lower limb pathologies (i.e., fractures or deep venous thrombosis [DVT]).

The results are evaluated in different ways. Aaslid, who coined the term "dynamic autoregulation", initially measured the resistance recovery slope [55]. Tiecks and coworkers, from the same gropu, later described a comparison between the pressure drop and the immediate CVR response (first initial seconds), making a comparison between responses, rather than an absolute assessment of flow velocity behaviour [56]. Our group has also compared the CPP-FV response based on the Tiecks concept but using a slower variable sampling, CPP and FV recorded every 2.5 seconds (maximum allowed by our monitors), over a 1 minute-period (Figure 10.9). We also graduated the response in 10 levels, dynamic autoregulation index (ARI) from zero to a maximum of 9 [57].

In patients with impaired CA (ARI <5), MCA FV takes longer to recover, and it passively follows the systemic BP recovery when DCA is completely lost (ARI = 0).

Monitoring the Response to Spontaneous Pressure Changes

Researchers from Cambridge University have created a method by which the CBF response to oscillations in spontaneous blood pressure is evaluated by calculating Pearson's correlation coefficient between FV and CPP every 4 minutes (Pearson correlation coefficient varies between 1 and -1, wherein zero or negative values mean independence of FV from CPI and positive values indicate CPP-FV passive behaviour). In each 4-minute period, several CPP and FV pairs (40-50) are correlated (Figure 10.10).

If the correlation coefficient is close to 1, this means that the FV varies passively and directly following CPP oscillation CA is impaired. In contrast, zero or negative correlation

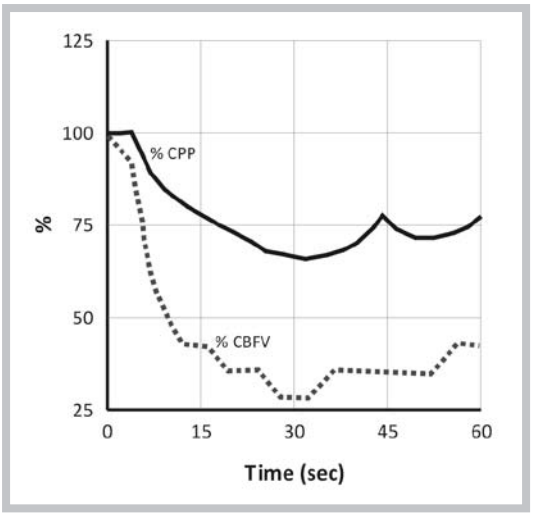

Figure 10.10. **Ten hypothetical curves and two real FV and CPP curves in a patient with intact DCA, ARI=9 [57].**

coefficients indicate an active response or good/intact CA (FV is independent of CPP changes). Each 4-minute interval overlaps to the following one every 4 seconds (sequentially) along the entire period of monitoring (around 1 hour). The final average result (including all 4-minute interval averages) is taken as representative of the patient's DCA status. To calculate optimal CPP, each 4-minute interval coefficient is plotted in relation to CPP intervals of 5 mmHg. The CPP interval corresponding to the lowest correlation coefficient identifies the patient's optimal/best CPP (range of CPP within the lower and upper limit of autoregulation or CBF plateau phase). This method has gained growing interest from neurointensivists, since it can potentially guide CPP therapy and individualize treatment.

10.8.2 CO_2 Reactivity

Arterial pCO_2 is a strong stimulus of the CVR (mentioned above). On the one hand, hypercapnia dilates small resistance vessels in the cerebral circulatory bed, resulting in hyperemia and augmentation of CBV. On the other, hypocapnia constricts small resistance vessels, thus slowing (decreasing) CBF. Under normal conditions, CBF varies 5% per mmHg increase or decrease of the pCO_2. In severe TBI patients, impaired CO_2 reactivity has been demonstrated to be associated with poor outcome.

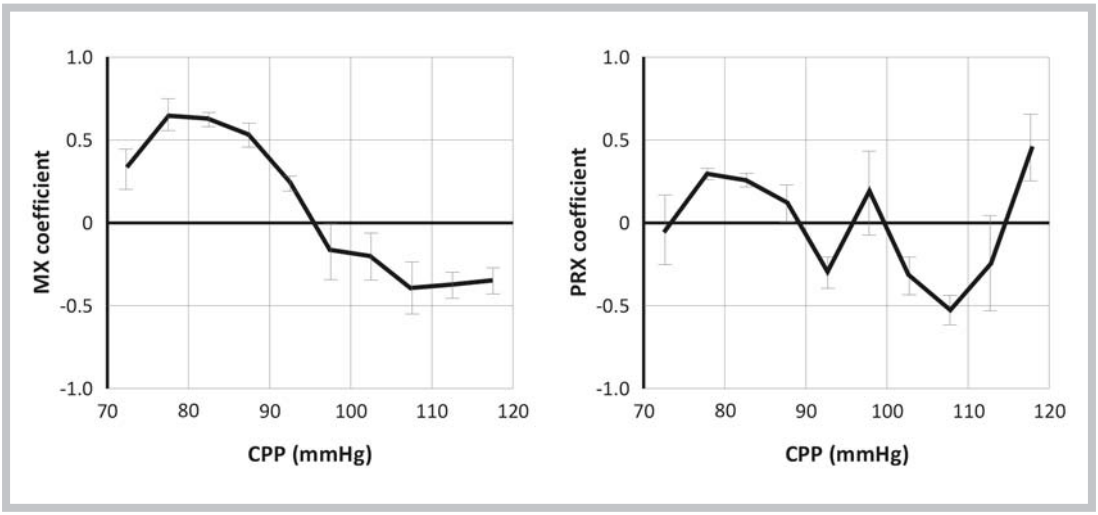

Figure 10.11. **In this case the graph shows that the lowest correlation coefficients (best CA) are located in the right part of the register where the pressure is higher. However, note that in the PRx register (bottom) the recorded higher pressure levels deteriorates the index indicating that at this point the AR threshold has been exceeded.**

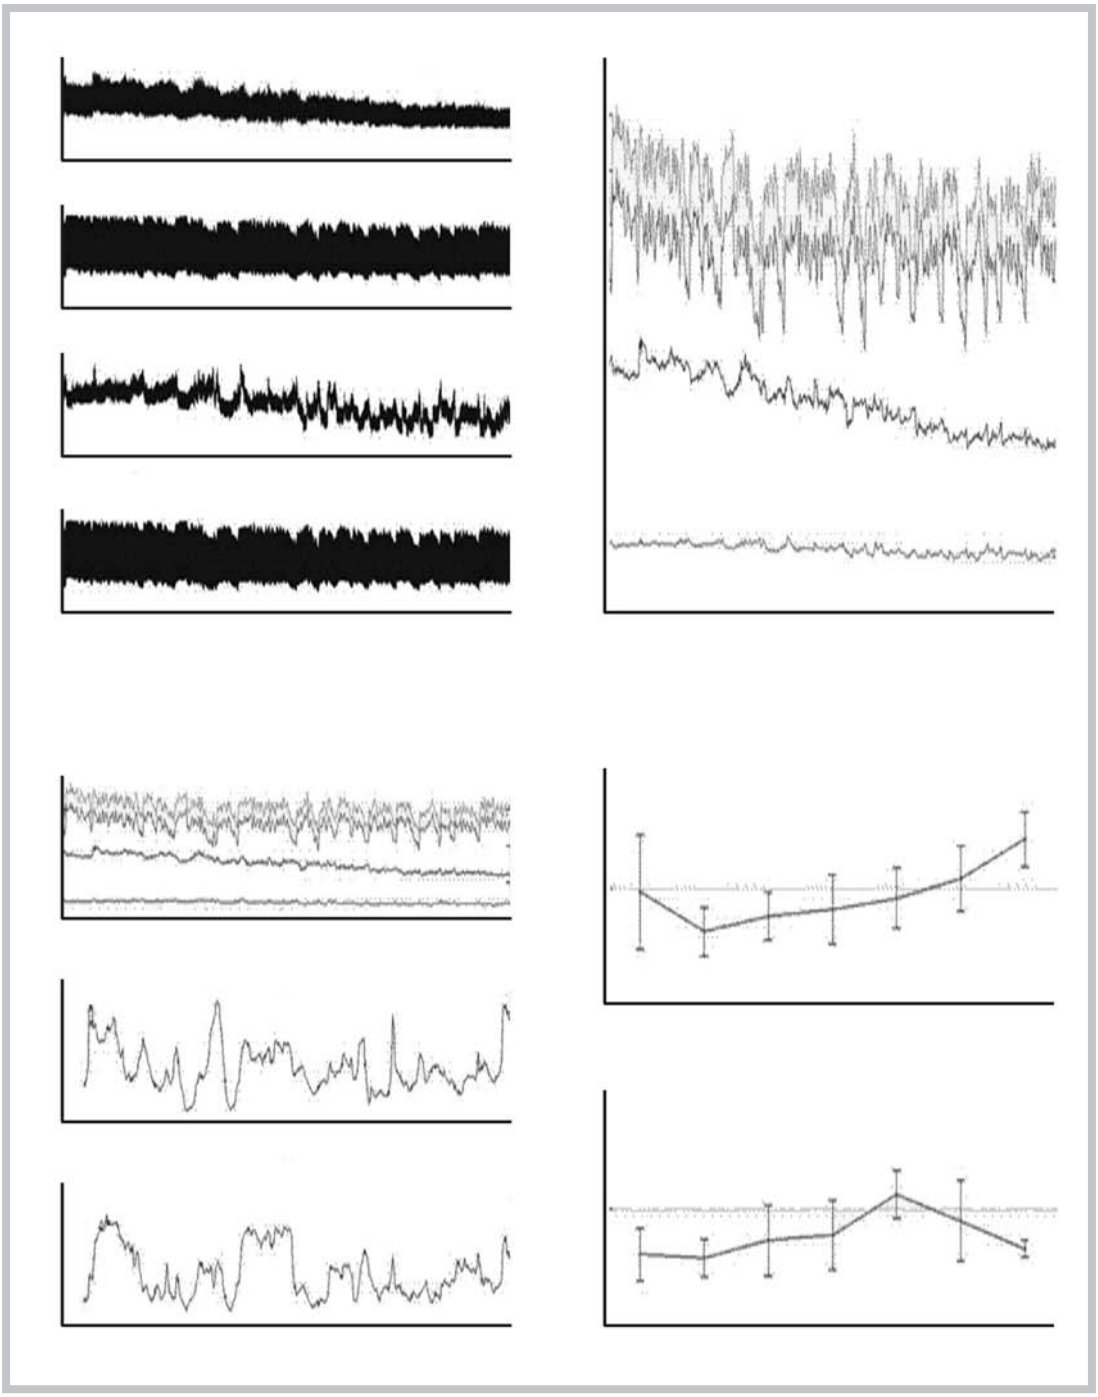

Figure 10.12. Optimal CPP calculated by our in-house software. A 47-year-old woman, Hunt-Hess 3, Fisher 3 SAH; MCA aneurysm clipping and decompression. One hour continuous monitoring of CAR. (A) Acquired variables (from the top): CBFV, BP, ICP and CPP (MAP – ICP). Spontaneous oscillations of the 3 variables can be seen. (B) Average values of the previous variables (from the top): MAP, CPP, $CBFV_m$ and ICP. (C) Above: the four variables together. Middle: Mx (moving correlation coefficient between CBFV and CPP). Bottom: PRx (moving correlation coefficient between ICP and MAP). (D) Optimal CPP; correlation coefficients on the y axis: Mx (top) and PRx (bottom), and blood pressure on the x axis. In this patient, the best CAR (corresponding to the lowest indices) was found when CPP and MAP values were low (see text).

In normal subjects, the percentage of flow velocity variation in the MCA to changes in $ETCO_2$ closely approximates the changes in CBF, indicating that vasomotor response is limited to the small arterioles, without alteration in the insonated artery diameter. FV changes elicited by pCO_2 manipulation (minute ventilation modifications) are used to calculate the CO_2 reactivity index [58]. CO_2 manipulation should be applied with extreme caution in patients with severe brain injury since even small pCO_2 changes can have deleterious effects on cerebral hemodynamics. Hypoventilation in the context of impaired cerebral compliance can cause an increase in CBV, leading to severe ICH. Conversely, hyperventilation, which can decrease CBV and ICP, always carries the risk of cerebral ischemia. These facts highlight multimodal neuromonitoring importance in this complex clinical scenario.

10.8.3 Reactivity to Drugs

Some drugs exert direct action on CVR while others act first on brain metabolism and secondarily on CVR. Indomethacin (member of the former group), a non-steroidal anti-inflammatory drug, exerts its action, at least partially, through inhibition of cyclo-oxygenase enzyme [59]. It causes vasoconstriction in the CVR area, thus leading to CBF and CBV reduction and potentially ICP drop too. In our experience, indomethacin caused a 28% decrease in FV in severe TBI patients. In addition, ICP was reduced and DCA improved significantly [60].

10.9 Appendix

In order to properly perform and interpret a TCD examination, the operator must have a thorough understanding of the:

- Physical basis of ultrasound in medicine.
- Cerebral basal artery anatomy (Willis polygon) and physiology.
- Possible pathophysiological disturbances in this particular area.

10.9.1 Physical Basis of TCD: the Doppler Effect

The Doppler Effect is the wave frequency shift (sound, light, etc.) when reflected by a moving object. This frequency change is called the “Doppler shift” or “Doppler frequency shift.” From this change in frequency it is possible to measure in real time the velocity of blood particles circulating in blood vessels.

Waves. Ultrasound

A wave is a disturbance or oscillation that travels through spacetime, accompanied by a transfer of energy. It is characterized by its frequency, wavelength and amplitude. The frequency is inversely proportional to the wavelength, and is expressed in Hertz (Hz). 1 Hz = one wave per second. Amplitude is the magnitude of the wave – how high it goes on the y axis. Doppler techniques in medical diagnosis **use ultrasound waves**. Ultrasound refers to the sound whose frequency is higher than the frequency of the sound audible by the human ear. The frequency of ultrasound waves used in medicine is on the order of megahertzs (MHz), i.e., one million waves per second, often between 2 and 8 MHz. TCD is based on the lowest ultrasound frequency waves among those used in medicine to date: 2 MHz. The higher the frequency (used), the better the spatial resolution

(of the method). In TCD the low frequency waves make bone penetration possible, but at the same time negatively affect the spatial resolution of the technique.

Angle of Insonation

If the direction of the ultrasonic beam is not exactly the same as the direction of the blood flow velocity, the measured velocity is lower than the real velocity. This is due to the **angle of insonation** between both vectors. The measured velocity should be divided by the **cosine of the angle of insonation** to determine the real velocity. If the angle is 0°, the error is nonexistent (cosine of zero ° = 1); the larger the angle, the greater the difference between the real and the measured velocity (**at an angle of 15° the cosine remains more than 0, 96; error <4%**). If the angle is 90°, the cosine is 0, and blood flow cannot be detected by the operator. According to the most frequent anatomic conditions between the acoustic windows and the insonated cerebral vessel, the angle of insonation is usually <30°, which results in an acceptable low error. In clinical practice, this error can be minimized by changing the angle of insonation until the highest possible velocity at each insonated point is detected (Figure 10.13). This higher velocity corresponds to the lower angle of insonation and therefore is the closest to the real velocity. Finally, while recognizing the importance of these theoretical disquisitions, what really matters at the patient bedside is not the exact (absolute) flow velocity value, but the relative changes that may take place over time. Likewise, it is important to know that the angle of insonation does not alter the relationship between the different velocities (FV_s, FV_d, FV_m) but **impacts on them equally**, without altering the value of PI and/or the RI. These are the main reasons why this issue is far from being clinically important.

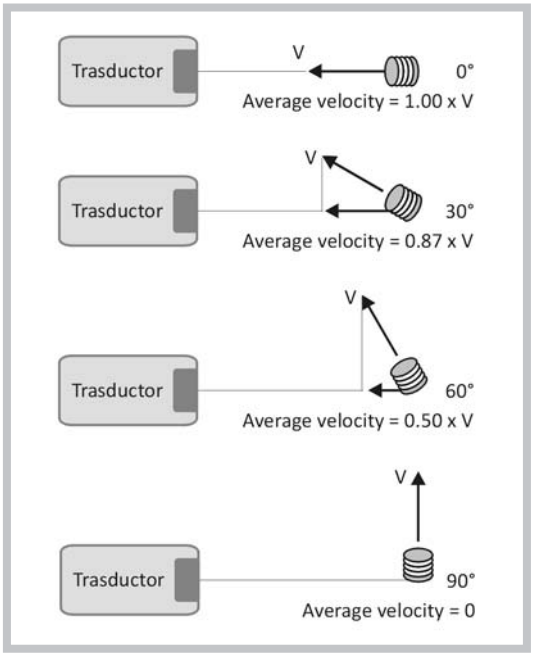

Figure 10.13. **Angle of insonation: angle between the emitted ultrasound beam and the blood flow velocity vector. Note that between 0° and 30° the influence of the angle is low or minimal.**

10.9.2 Basic TCD Recording

The basic TCD study of an intracranial artery shows a flow velocity waveform in relation to time. By convention, if blood flow moves toward the transducer, a positive signal (wave) is recorded, while if it moves away from the transducer, a negative signal is seen on the screen. Since blood particles (mainly red blood cells) travel at dif-

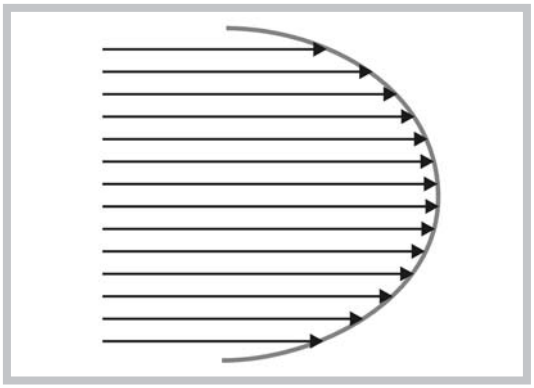

Figure 10.14. **Red blood cells travelling at different velocitys in laminar flow through a vessel. Note how the erythrocytes in the centre of the vessel move faster (higher velocity).**

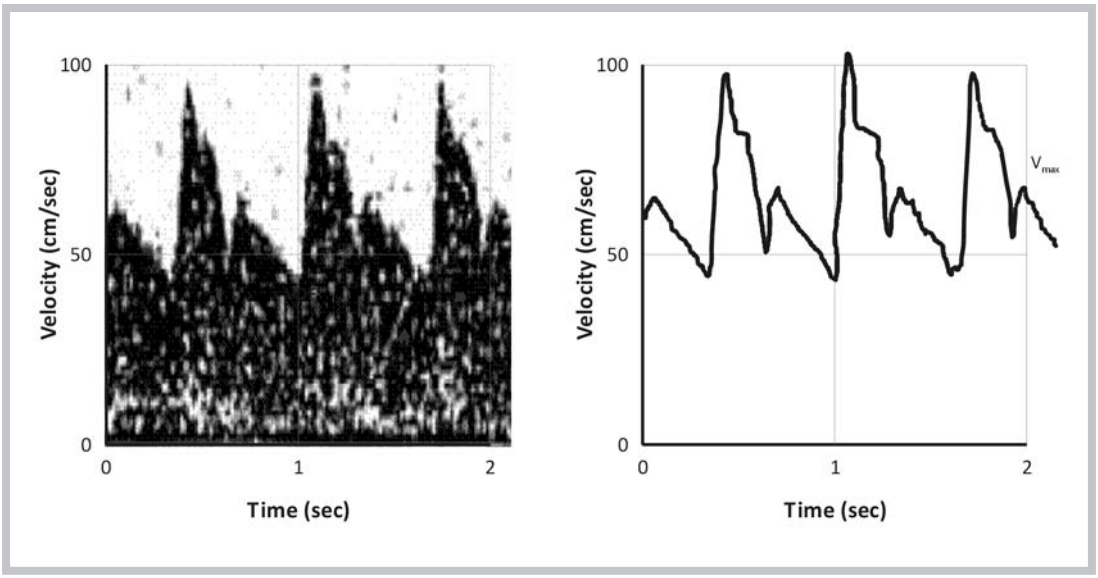

Figure 10.15. An example of a MCA sonogram.

ferent velocities, a single line cannot be displayed, so that a "velocity spectrum" is shown (mixture of many frequency components). To simplify the evaluation of this sonogram, the spectral envelope corresponding to the maximum velocity during the cardiac cycle is created, indicating the velocity of the fastest blood particles which, in laminar flow conditions, are those circulating in the centre of the blood flow through the vessel (Figure 10.14).

The obtained envelope curve begins and ends without decreasing to zero velocity at any point in the cardiac cycle. This means that cerebral blood flow at the major cerebral arteries is continuous, not stopping at any moment under normal conditions. Various different velocities are measured to calculate the indices: peak systolic blood flow velocity (FV_s); end-diastolic blood flow velocity (FV_d); mean blood flow velocity (FV_m). TCD is used to study blood flow velocity in the main cerebral arteries at the base of the brain (MCA, ACA, PCA, vertebral artery [VA] and basilarl artery [BA]), the communicating arteries, and the main branches (collateral circulation) of the all these arteries.

The vessels are insonated through acoustic windows which are areas of the skull where the bone is thinner (temporal and occipital windows) and/or where there are natural cranial openings (fontanelle and orbital windows) that allow the passage of ultrasound waves. The transducer emits a beam of ultrasound waves and receives the waves returning after reflection from the moving particles at a certain depth, analyzes the changes, and displays the results on a screen that shows veloci ties (y axis) in relation to time (x axis) (see Appendix for a detailed explanation). The ultrasound beam is directed to a target vessel and the beam angle and depth are adjusted to detect and analyze the target vascular segment of a particular cerebral artery. Figure 10.15 gives an example of a MCA sonogram. The spectral envelope is detailed. The flow velocity increases rapidly in the systolic phase where it reaches a maximum, after which it begins to decrease, falling more slowly in the diastolic phase, until it rises again, pushed forward by a new wave pulse.

From each envelope certain points of interest are recognized that characterize the flow pattern: peak systolic velocity (FV_s); end-diastolic velocity (FV_d); and mean velocity (FV_m) (Figure 10.16).

The key features of a normal TCD sonogram are: velocities are always positive and the flow velocity (envelope) never reaches 0, or, in other words, the flow velocity does not stop (cease) or reverberate under normal conditions. As the resistance in the brain vasculature is lower than in the systemic (extracranial) vasculature, the end-diastolic velocity in the former is greater than in the latter (peripheral arteries), the PI and RI values are lower (check indices formulas). Arterial bifurcations are easily recognized because two flow velocity signals (waveforms) seen on the screen travel in opposite directions (towards and away from the transducer or positive and negative signal respectively).
Since TCD ultrasound is pulsed, it allows to study the target vessels at different depths along their course.
Each cerebral artery can be recognized according to different complementary factors

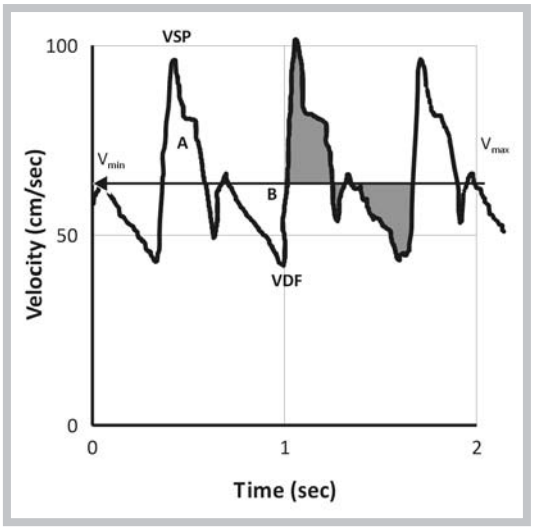

Figure 10.16. **Spectral contour points defining the peak systolic velocity (FV_s), end diastolic velocity (FV_d), and mean velocity (FV_m). he average velocity is the one which divides the surfaces in two similar areas (colored in gray).**

- The **acoustic window** in use.

- The relation with **vascular bifurcations.**

Normal velocitys vary from one cerebral artery to another and with certain physiological variables as well. velocities change with age, being higher in childhood and then declining with age. Normal values in healthy adults for three age groups are shown in Table 10.2.

Artery (depth in mm)	FV_s (cm/s)	FV_d (cm/s)	FV_m (cm/s)	Age (years)
MCA (50 mm)	95±14	46±7	58±8	<40
	91±17	44±10	58±12	40-60
	78±15	32±9	45±11	>60
ACA (70 mm)	76±17	36±9	47±14	<40
	86±20	41±7	53±11	40-60
	73±20	34±9	45±14	>60
PCA (60 mm)	53±11	26±7	34±8	<40
	60±21	29±8	37±10	40-60
	51±12	22±7	30±9	>60
VA/BA (75 mm)	56±8	27±5	35±8	<40
	60±17	29±8	36±12	40-60
	51±19	21±9	31±12	>60

Table 10.2. **Normal values in healthy adults for three age groups [61].**

Other important variables that influence blood flow velocity in the cerebral arteries are the blood pressure, pCO_2, pCO_2, temperature, heart rate, viscosity (its major determinant is the hematocrit), etc.

Peak systolic velocity is the velocity that corresponds to the highest point in the upward sector of the envelope curve. It is related to the force of systolic contraction. End-diastolic velocity is the lowest point of the downward sector of the envelope curve, before starting a new systolic phase (or cardiac cycle). This velocity is related to CVR and represents the outflow velocity from the intracranial circuit. Compared with flow velocity in extracranial vessels, the velocity (FV_d) in the intracranial circuit is higher, indicating that cerebral circulation is a system of lower vascular resistance. Under normal conditions, FV_d never reaches 0. Summarizing, the normal blood flow in the intracranial arteries travels in one direction, does not have any reverse or stopping point during a cardiac cycle, and the end-diastolic velocity is high compared with the arteries of the rest of the circulatory system.

The FV_m is calculated mathematically as the time average FV of the envelope. It can also be calculated graphically in the Doppler sonogram.

The Gosling pulsatility index (PI) is given by the formula $PI = (FV_s – FV_d)/FV_m$. It is related to CVR. PI increase can be triggered by multiple factors among which are: increased CVR, ICH, hyperventilation, bradycardia, increased blood viscosity, vascular stiffness and age.

10.10 TCD in Evaluating Hemodynamics

10.10.1 Difference Between Flow Velocity and Flow

It is essential to note that every Doppler technique measures flow velocity. In the case of TCD, it measures cerebral blood flow velocity (FV). **FV and CBF are two different entities**. FV is measured in cm/s and CBF is measured in ml x min^{-1} x 100 g^{-1} (i.e., 60 cm seg speed ACM^{-1} and FSC^{-1} x 100 g = 50 ml x min^{-1}). **Although the absolute values of CBF cannot be measured with TCD, changes in flow velocity reflect proportional changes in blood flow**. This statement is true provided that the vessel diameter (at the insonated point) and the angle of insonation remain unchanged. If both conditions are met, a change from a velocity of 40 cm/s to 80 cm/s indicates that CBF has doubled (although the absolute flow value is unknown).

To be able to correctly interpret changes in intracranial hemodynamics using TCD, it is important to keep the concept in mind that TCD assesses flow velocity (distance/time), measured in cm/s, but not flow (volume/time). Unfortunately, TCD technology does not have enough spatial resolution to accurately measure the diameter. If this technical limitations could be overcome, the product (FV x sectional area of the insonated vessel) would easily calculate CBF.

There is another hemodynamical important concept: Based on the equation CBF = FV. area, where: FV = CBF/area, it can be inferred that whenever the insonated artery diameter (and therefore the cross-sectional area of the vessel) remains constant, changes in CBF are equivalent to proportional changes in flow velocity. This concept is useful to assess relative changes in flow during the study of cerebrovascular reactivity. To study this extraordinary ability of cerebral vessels, different stimuli are applied to the small vessels that regulate CVR (resistance vessels), which open or close the “tap” that facilitates or impedes the passage of blood through the insonated vessel (conductance vessel). However, because the diameter of the insonated artery remains constant, the velocity changes in the insonated artery segment indicate changes in the CBF that passes through it.

Transcranial Doppler

- Measures CBF velocity in the large vessels of the circle of Willis and its branches.
- Estimates relative changes in CBF as long as no changes in cross sectional area of the insonated vessel.
- Differentiate when referring to:
  - CVR, represented mainly by small arterioles and precapillary sphincters. These small vessels represent more than 80% of the total resistance to blood flow through cerebral vascular tree. They constrict or dialte rapidly when exposed to differentl stimuli (blood pressure, CO_2, indomethacin, seizures, etc.).. When these small blood vessels constrict resistance increases and the passes more slowly through the large insonated vessel, whose cross-sectional area has not changed. TCD shows low circulatory velocities with high PI. In these cases the change in velocity is proportional to the change in flow.
  - The insonated vessel (large vessel of the base of the brain) generates minimum resistance to the passage of blood and its diameter changes slowly, usually over days, in response to inflammatory processes, eg. inflammation caused by blood contact with the adventitial surface of vessels during SAH. When vasospasm starts, large vessel diameter decreases, and consequently distal small vessels dilate to maintain the flow, ie CVR. Therefore, flow passes faster through the insonated spastic vessel, because distal resistance decreases (the sluice is opened). That's why, during vasospasm, while there's no ICH, an increase in flow velocity is accompanied by a decreased IP. In this case a flow velocity increase does not imply increased flow, but rather its maintenance.

Conversely, while the CBF passing through a given conductance vessel remains constant, the reduction in the cross-sectional area of the vessel (i.e., SAH vasospasm or atherosclerotic/vasculitic intracranial stenosis) is accompanied by an increase in velocity at the insonated segment (explained by the principle of continuity):

$$F = V_1 \times A_1 = V_2 \times A_2$$

Since flow is equal to velocity multiplied by the cross-sectional area of the vessel, if the flow does not change, a decrease in vessel diameter is accompanied by an increase in velocity, and vice versa.

A reduction in arterial diameter produces a pressure drop between both ends of the narrowed (stenotic or constricted) segment, leading to a fall in perfusion pressure in the distribution territory of that vessel. The difference in pressure (ΔP) between these two points, rather than absolute pressure, determines the flow. But resistance also plays a critical role. The resistance factors are the conditions that hamper the blood flow: viscosity (n), length of the narrowed segment (l) and **vessel radius** (r). Resistance (R) to flow exerted by the spastic (narrowed) segment is expressed by **Poiseuille's law** [62,63]:

$$R = 8 \times n \times l / \pi \times r^4$$

Flow is directly proportional to the pressure difference between the two end points of the narrowed vessel and inversely proportional to the resistance created by the narrowed segment.

$$F = \Delta P / R$$

and substituting R:

$$F = \Delta P \times \pi \times r^4 / 8 \times n \times l$$

where

$$\Delta P = F\ 8 \times n \times l / \pi \times r^4$$

That is, for a given blood viscosity, if $CBF_{regional}$ remains constant, the pressure drop generated by a spastic segment would be proportional to the length of the spastic segment and inversely proportional to the fourth power of the radius. This pressure drop is (potentially) counterbalanced by the $AR_{regional}$ (cerebrovascular reactivity pressure). If there is good $AR_{regional}$, an active vascular response (with vasodilator capacity) of the small arterioles will be seen. Such vasodilation tends to maintain $CBF_{regional}$ relatively constant. If vasospasm continues to rise and/or the $AR_{regional}$ is impaired, the $CPP_{regional}$ drop exceeds the lower limit of AR and resistance cannot drop more the $CBF_{regional}$ begins to descend. From this point onward, since both CBF and arterial diameter are no longer constant, TCD interpretation becomes more difficult. Figure 10.17 [64] shows the evolution of the V_{max} and CBF as the arterial diameter decreases (from right to left). The lower curve of each panel shows the changes for a MAP of 100 mmHg, and the upper curve for an induced MAP of 140 mmHg (induced hypertension). Initially, as the diameter decreases, the CBFregional remains constant owing to active autoregulatory compensation (pressure reactivity [CAR]), so that the velocity increases (simultaneously). Once the autoregulatory compensation is outweighed by the pressure drop caused by a more severe stenosis, CBF begins to fall (point known as critical vasospasm) and the velocity remains almost unchanged but then also begins to decline. If at that time the doctor increases the patient's BP, a CBF increase is likely to occur since the fact of being situated below the lower limit of AR allows the CBF to passively and rapidly increase with increasing the BP. It is important to understand and remember this concept, since the increase in flow velocity does not represent a worsening of vasospasm in this case, but rather an improvement in CBF.

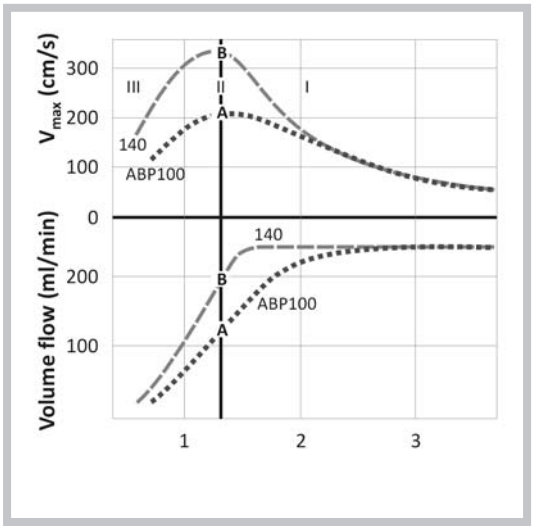

Figure 10.17. **Evolution of the V_{max} and CBF as the arterial diameter decreases (from right to left).**

10.11 Relationship Between CBF and CPP

The relationship between CBF and CPP is given by Ohm's law of hemodynamics:

$$CBF = CPP / CVR$$

where CVR is the cerebrovascular resistance mainly determined by the arteriolar resistance.

Given that:

$$CPP = MAP – ICP$$

the CBF can also be expressed as:

$$CBF = (MAP – ICP) / CVR$$

Under conditions where ICP and cerebrovascular compliance are both normal, this term can be omitted, so that:

$$CBF = MAP / CVR$$

10.11.1 Limitations of the Technique

As with any diagnostic technique, TCD has certain limitations that we can minimize by understanding the physical basis of the method:

- It is **operator-dependent**, so that an adequate interpretation of the findings and the time needed to conduct the study depend on the expertise of the examiner.
- In a low percentage of cases the temporal acoustic window is impermeable to the ultrasound beam due to the the skull physical characteristics bone. This usually occurs in 5-15% of patients and **varies with the experience and patience of the operator**. The acoustic window becomes more impermeable in women over 60 years of age. In some cases, this can be partially solved by insonating through other windows.
- In inexperienced hands, the common anatomic variations of the circle of Willis may result in errors in the correct identification of cerebral vessels.
- Disturbances (noise interferences) caused by monitoring devices are minimal (or insignificant). In our experience, we have had some difficulties only in pediatric patients while trying to demonstrate a CCA pattern, in which the ventilator (cycle) can interfere with the identification of very small systolic spikes, which can be detected only in the expiratory phase, making it sometimes necessary to disconnect the patient (for just a few seconds) to identify the pattern.
- When studying a non-intubated patient with mild depression of consciousness who does not cooperate (involuntary/voluntary movements and/or involuntary breathing sounds, etc.) trying to find an appropriate acoustic window can also be more difficult.

11 Neurophysiologic Monitoring in Neurointensive Care: EEG, EMG, and Evoked Potentials

Aldo Amantini [1], Antonello Grippo [1], Selvaggia Fossi [1]

[1] Unit of Clinical Neurophysiology, DAI Neurological Sciences, University of Florence – Az. Ospedaliera Universitaria Careggi, Florence, Italy

11.1 Introduction

Electrophysiological tests (electroencephalography [EEG] and evoked potentials [EP]) provide a functional evaluation of the central nervous system [CNS], support the clinical evaluation, and are complementary to imaging tests (computed tomography [CT], and magnetic resonance imaging [MRI]). In a comatose patient, neurophysiological alterations may occur without evidence of structural injury: there are CNS lesions which are left out of neurophysiological investigation [1].

In the context of neurophysiological methods used in the ICU, this chapter will describe evoked potentials and EEG, which, in our opinion, provide most information, and we will describe their usefulness for diagnosis, prognosis and monitoring. In addition we will discuss the use of electromyography/electroneurography (EMG/ENG) to diagnose generalized hyposthenia arising during the ICU stay. The International Federation of Clinical Neurophysiology Guidelines [1] indicate the standards for the use of EEG and evoked potentials during coma and in unresponsive states. One of the most recent guidelines on clinical neurophysiology in the ICU [2] recommends that some tests (EEG, short and long latency EP, EMG) should not be used as standard tests, but rather selected on the basis of evidence.

11.2 Electroencephalography

EEG measures cortical bioelectric activity. It is generated from the spatial and temporal summation of excitatory and inhibitory postsynaptic potentials of the superficial cortical layers (mainly the pyramidal cells of layers III and V) and is modulated by thalamocortical transmission. EEG involves placing electrodes on the scalp according to the international 10-20 system to explore the greatest areas of the cerebral hemispheres [3].

Rationale for the use of EEG in the ICU is related to the following considerations:

- It is closely related to brain metabolism.
- It is sensitive to the most common causes of brain damage (hypoxia/ischemia).
- It detects brain dysfunction already at an irreversible stage.
- It relates to brain topography.
- It is the best available method to record critical epileptic activity and for differential diagnosis with many non-epileptic motor manifestations.
- It is the only method to diagnose non-convulsive seizures.

The intensive care unit poses many technical difficulties for EEG acquisition; therefore it is important to descrive some technical details about EEG recording. The technician who

performs the EEG should be an expert not only in EEG testing, but also in the laboratory diagnosis of neurological diseases.
There are no specific electrodes for EEG recording in the ICU: they are chosen according to the duration of the recording, the conditions of the scalp, and the alertness of the patient.
EEG skull caps can have an array of electrodes or needle electrodes incorporated. Positioning a skull cap fitted with electrodes is not normally problematic, but it requires skin integrity. A cap with needles is recommended in patients undergoing craniotomy or for monitoring brain activity. In this case, the EEG assembly will include at least 8 electrodes, F-C-T-O (or P if there is significant orthostatic edema of the scalp) suited to the presence of obstacles (injuries, craniotomies, drainages, monitoring probes). It is advisable to apply a fixed recording and stimulation protocol. An example of an EEG registration protocol in the ICU is: duration of at least 30 minutes, 5 minutes of initial recording without stimulation, followed by the evaluation of reactivity to different types of stimuli: acoustic, nociceptive, and passive eye opening. Each type of stimulus should be administered at least twice and the recording should last at least 5 minutes after stimulus end. In the differential diagnosis of motor manifestations, a video-polygraph is required. If there are critical manifestations of EEG or unexpected clinical features (e.g., non-convulsive status epilepticus), the recording will last longer than 30 minutes and any observed motor manifestation will be recorded. Finally, correct test interpretation will rely on: cause of coma, time elapsed since the beginning of coma, Glasgow Coma Scale (GCS) score, neuroimaging, and ongoing sedation.

11.3 Evoked Potential

Evoked potential (EP) is defined as a change in the electrical potential in a sensory organ along the peripheral afferent pathway and at the intracerebral level in response to a transient stimulus quantified in physical parameters (intensity, duration, frequency). There are several types of evoked potential for sensory, somatosensory, acoustic and visual modalities. In general, the evoked potential width is lower than the spontaneous EEG activity, so that mathematical averaging methods are needed to extract these signals from background noise (not only biological, but also environmental EEG-EMG) and render them easily identifiable in their wave shape, made by several subsequent components with negative-positive polarity.
Evoked potentials can be classified as exogenous or obligatory when they depend mainly on the physical characteristics of the stimulus, or endogenous or event-related when they rely on the stimulus processing by the subject (stimulus categorization, discrimination between several stimuli, storage, decision-making task). Exogenous evoked potentials originate mainly from specific primary and periprimary cortical areas, while obligatory potentials are generated in parietal and frontal polymodal association areas.
The classification of evoked potential according to a latency criterion is extremely useful because it defines the components according to different anatomical topography (peripheral, subcortical, intracortical in primary and secondary areas) and a different sensitivity to sedatives and anesthetics. In general, components are classified as short, medium and long-latency (within 10 ms, 10-50 ms, and over 100 ms, respectively), but such time limits may differ slightly depending on the sensory modality.
The early components of evoked potential are used during the acute phase of brain damage when, because of sedation, curarization, or the severity of coma itself, clinical assessment is difficult. Such components are substantially resistant to sedation, which

facilitates the recording because muscle and movement artefacts can be removed. The long latency and cognitive components are more applicable in a postacute phase, since they are extremely sensitive to neurosedation and require clinical optimization to be recordable (remission of any pharmacological effect, resolution of septic-dysmetabolic abnormalities).

The short-latency evoked potential most frequently used in the ICU is short-latency somatosensory evoked potentials (SEPs) and brainstem auditory evoked potentials (BAEPs): SEPs afford the advantage of having peripheral, spinal, brainstem and, intracortical components which are easily identifiable in all subjects and permit exploration of the transmission of a large tract of the CNS. BAEPs explore a small portion of the acoustic transmission at the bulbopontine level; the identification of peripheral afference, wave I in particular, can often be problematic. Another limitation is that primary cortical responses are difficult to identify. In fact, the generators of these components reside in the depth of the Sylvian fissure (Brodmann areas 41 and 42) and so are unlikely to be recorded with surface electrodes, unlike the early cortical SEPs, whose generators lie on the convexity of the postcentral gyrus (area 2 b in particular). In addition, acoustic myogenic reflexes, which cannot be eliminated by averaging methods, have latencies similar to those of early cortical acoustic components and can therefore mask them.

Despite such problems, the most commonly used EP in the ICU in recent years, and for which there is a greater evidence of their clinical usefulness, are short-latency SEPs in stimulation of the upper limb. Short-latency SEPs are sensitive to both traumatic structural damage and hypoxic-ischemic damage, and are able to indicate lesion topography. But beyond that, in the absence of severe lesions along the somatosensory afferent pathways, from which an index of the "global" brain function can be extrapolated at the brainstem, thalamocortical and intracortical transmission level of both hemispheres (Figure 11.1).

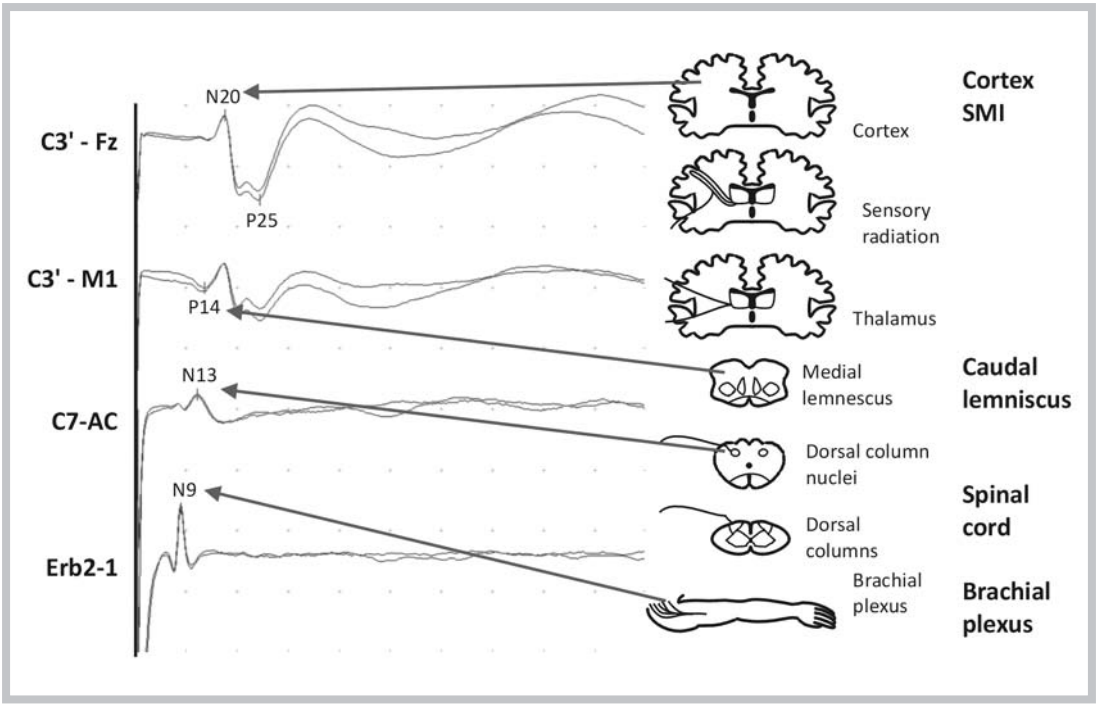

Figure 11.1. **Extracranial (brachial plexus, N9, and cervical spinal, N13, potentials), intracranial lemniscus (P14), and intracortical (N20-P25) SEP components.**

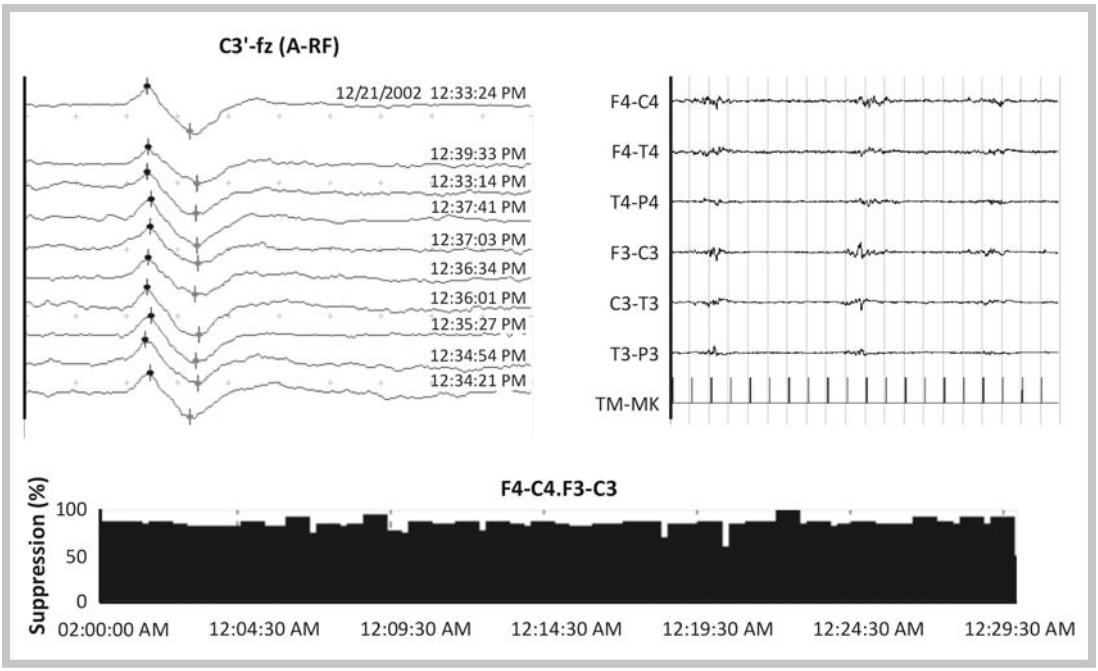

Figure 11.2. **During a continuous infusion of thiopental sodium (TPS), with a suppression of about 90%, which precludes EEG evaluation for clinical purposes, the early components of SEPs are well measurable in their latency and amplitude parameters.**

This information is very useful in the neurocritical patient, who is often poorly clinically evaluable because of pharmacological sedation, curarization, or the severity of coma itself. SEPs have the additional advantage of being resistant to anesthetics, having a waveform easily interpretable and comparable at subsequent tests (Figure 11.2).

Because we believe that a reason for the underuse of SEPs in the ICU is due to major technical difficulties of recording in that environment and the perceived lower reliability of the test result, more precise technical information is necessary about their recording.

First, it is necessary that the neuropathophysiology technician and the neurophysiologist have experience in recording and interpretation of evoked potentials in the laboratory for neurological diagnosis, in addition to specific training in the intensive care field.

It is also necessary that the technician communicates the problems encountered during the examination: obstacles to stimulation in conventional locations; excessive environmental artifacts or patient-related artifacts; and the need to perform sedation or curarization to optimize the recording.

Intradermal needle electrodes or silver chloride cup electrodes are used, possibly braided to reduce artifacts.

The recording apparatus for SEPs should have at least 2 channels (4 recommended). For full specifications on amplifiers and averaging and electrical safety, please refer to the guidelines reported in Suppl. 8 of *Muscle and Nerve*, 1999 (S123-138).

We want to stress the importance of some methodological aspects:

- Stimulus frequency: 3-5 Hz; analysis time: 50 or 100 ms (with the lowest frequency of stimulation and the greater analysis time also intermediate-latency intracortical components subsequent to N20-P25 are more identifiable; analysis time of 100 ms is therefore necessary to determine the absence of any cortical response).
- Number of mediated responses: 200-400, depending on recording conditions (signal-to-noise ratio) and identifiable components. At least two sets of repeatable responses

must be obtained. It is advisable to obtain a larger number of repeatable series when altered patterns of clinical relevance are detected (absence of cortical SEP).

- Stimulus intensity: in cases of curarization the evaluation of response width from Erb's point or cortical allows to verify that the stimulus intensity is supramaximal.

To record SEPs with median nerve stimulation the electrodes are placed at Erb's point (contralateral Erb), at the spinous process Cv7 (referred to antecollis) and C3'-C4' (referring to Fz and the ipsilateral mastoid) (Figure 11.3). A non-cephalic reference can be used, but this creates more artifacts. We also suggest the use of the Fz reference because, even though the latter produces a greater variability of interindividual width, it prevents the influence of subcortical potentials and reduces the interference contamination. In addition, the Fz reference allows the recognition of cortical responses even when their presence is questionable considering only the tracks with mastoid reference. It is also important to establish the criteria for SEPs abnormality (Figure 11.3):

- Absence of mandatory components (N9 in an ipsicontralateral derivation from Erb's point, N20 in a derivation with Fz reference, P14 in a derivation with auricular or mastoid reference, N13 in a derivation with AC reference) (Figure 11.3C). This criterion implies that there must be adequate technical conditions to identify a component

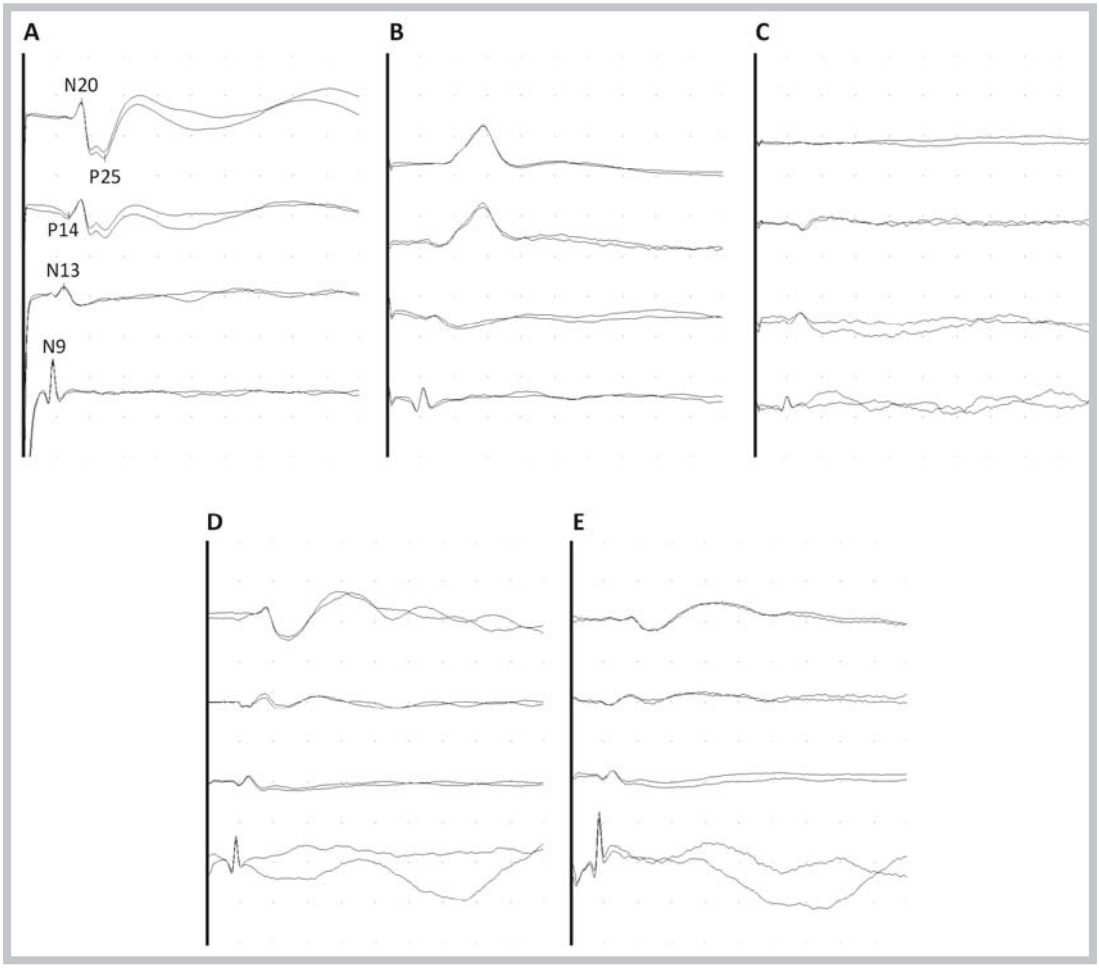

Figure 11.3. **Example of SEP classification. (A). Normal SEP. (B). Pathological SEP because of an increase in the transmission time. (C). Absent cortical SEP, considering both Fz and mastoid reference. (D) and (E). Pathological width asymmetry (>50%) of the cortical SEP between the two hemispheres with normal transmission time [4].**

if present. Sometimes not being able to replicate some of the responses (especially spinal and subcortical) in the presence of excessive artifacts is a technical limitation rather than an abnormality of the patient.

- Extension of interpeak latencies (N9-N13, N13-N20 and P14-N20). Generally, reference is made to the limits of 2.5-3.0 standard deviation (SD) of average values for each laboratory (Figure 11.3B). The problem of not having homogeneous normative data for patients in the ICU must be considered. In addition, many non-pathological factors can interfere with the interpeak latencies (temperature, therapy, etc.).
- Asymmetries. In the absence of a change in latency, a variation in the width should be viewed with caution, given the high variability in normal subjects for both absolute values and the interside asymmetry itself (Figure 11.3D-E). However, we consider it useful for the N20 cortical component to accept as pathological a reduction in width of more than 50% of the contralateral.

The EEG and the EPs can be used for both diagnosis/prognosis and monitoring the evolution of brain damage or the occurrence of secondary damage. Discontinuous evaluation is sufficient for the former, while continuous neurophysiological evaluation is required for the latter in oder to obtain more detailed clinical data.

11.3.1 Using EEG and EP for Diagnostic and Prognostic Purposes

Diagnosis

Although EEG is underused in coma [5], its diagnostic utility is confirmed in clinical practice for differential diagnosis at the bedside (metabolic, infectious, drug, and epileptic causes).

EEG is the best available method to diagnose epileptic activity: the increased use of EEG and continuous EEG (CEEG) in the ICU has revealed a surprisingly high incidence (8-28%) of non-convulsive seizures and non-convulsive status epilepticus in patients with acute brain damage [6]. EEG is the only method available to diagnose such conditions and to guide their treatment. Young [5] proposed the most commonly followed primary and secondary diagnostic criteria. These criteria have been recently reviewed by Chong and Hirsch [7].

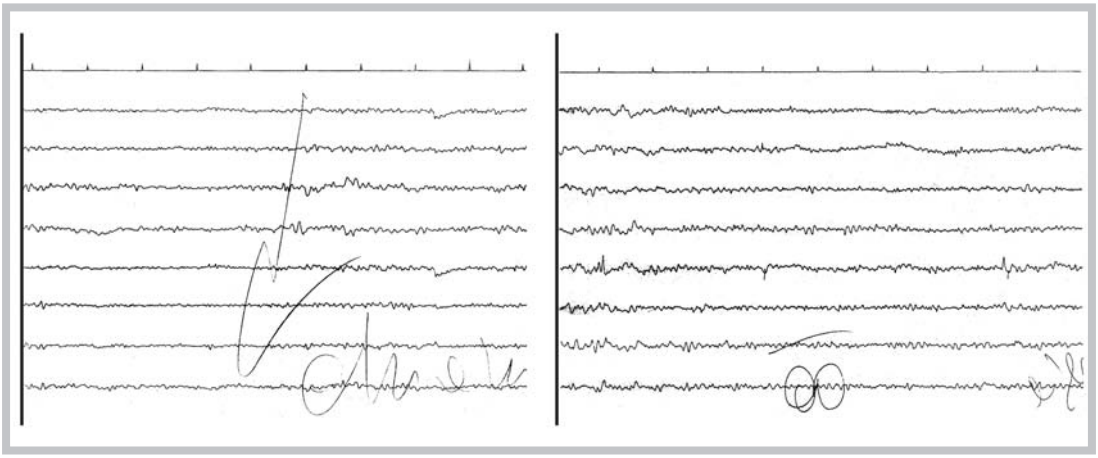

Figure 11.4. **Locked-in due to a ventral pons-midbrain ischemic lesion. The left tracing shows passive eye opening with a slight desynchronization of alpha rhythm. The right tracing shows how the acoustic stimulus generates a "paradoxical" alpha rhythm. The presence of a reactive alpha rhythm confirms the diagnosis of locked-in.**

EEG is useful for the differential diagnosis of motor manifestations in ICU patients who may have a wide variety of non-epileptic involuntary and semi-voluntary movements such as tremors, spasms, tetanic spasms, septic rigor, stiffness due to neuroleptics, extrapyramidal movements, ischemic tremors, tonic head and eye deviations, and abnormal posturing.

Besides providing indications on the etiopathogenesis of coma (when it is not known), EEG findings may also be diagnostic of the effective state of consciousness. Its contribution is decisive in determining the depth of coma beyond the clinical evidence and highlighting the discrepancy between the apparent clinical status and the effective depth of the consciousness disturbance in particular conditions (traumatic and vascular locked-in states, neuromyopathy in critically ill patients, frontal syndrome or associations thereof).

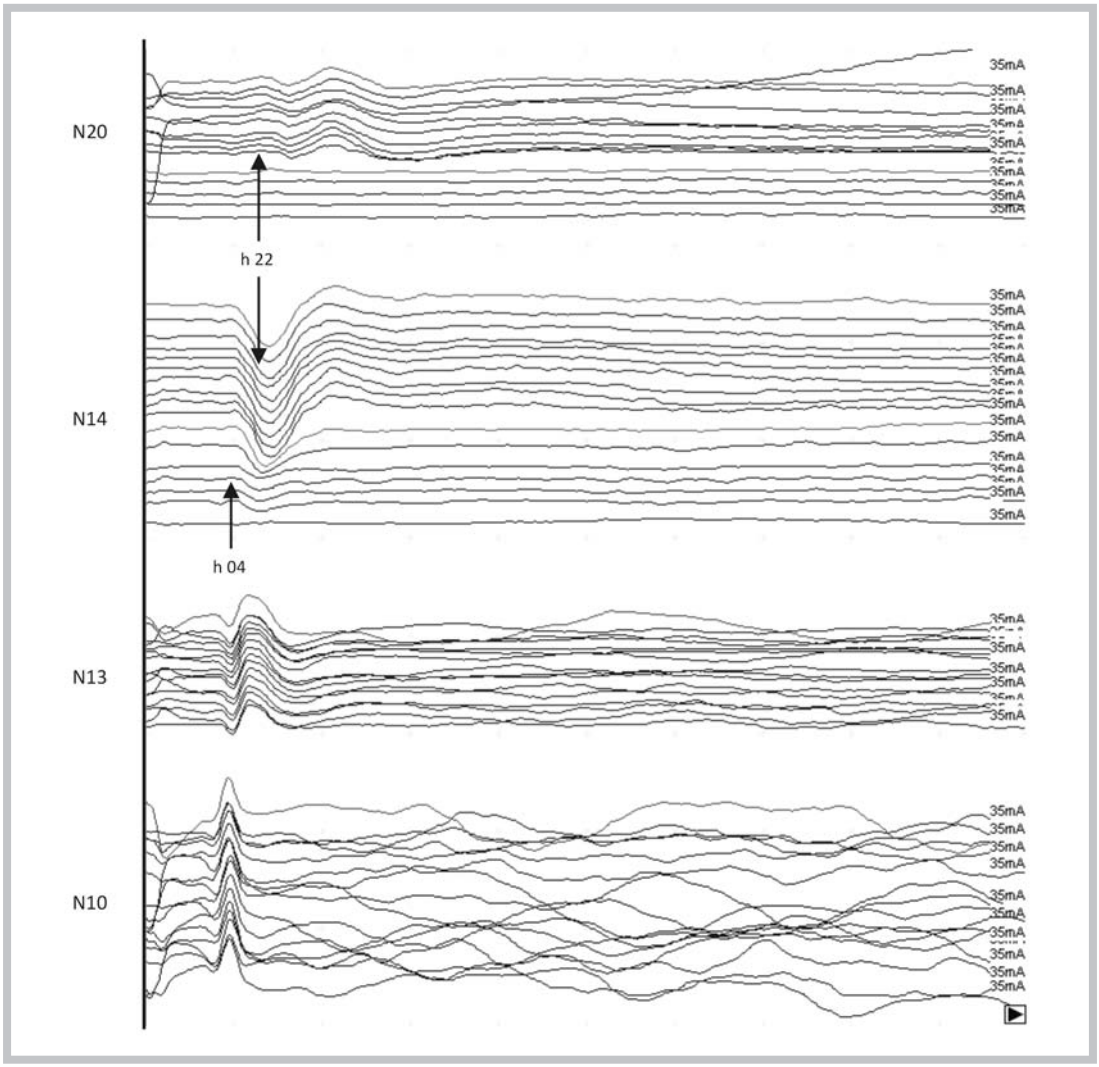

Figure 11.5. **Post-traumatic coma: rostrocaudal deterioration in a patient who could not be evaluated clinically or by EEG because he/she was under profound neurosedation (thiopental sodium infusion) until the night before. At 22 h the N20 intracortical component disappeared; 6 hours later, with the disappearance of the P14 bulbar component, the SEP pattern of brain death (extracranial components unchanged) is evident. Transcranial Doppler (TCD) performed 2 hours later confirmed the absence of intracranial blood flow.**

Considering only the motor responses, in the absence of an EEG, it is very difficult to determine the real consciousness disturbance in these conditions [1,8]. Logically, the EEG data must be integrated with neuroimaging and other neurophysiological tests. The presence and/or duration of coma may be overestimated considering the clinical evaluation alone (Figure 11.4).

Furthermore, EEG is one of the tests to confirm the diagnosis of brain death in some countries [9]. It is should be noted that the short-latency EP, and SEPs in particular, are considered by some authors to be very useful for the diagnosis of brain death when "confounding" factors are present, as in drug neurosedation, which invalidate and render the clinical criteria alone and EEG insufficient.

Changes in SEPs reliably reflect the rostrocaudal deterioration of brain damage until brain death, with loss, first, of intracortical components, and then of the caudal lemniscus component (P14), which reflects bulbar generator activity. The loss of all intracranial components (N20 and P14), when first recorded, associated with conservation of extracranial components (N13, N10) is the SEPs pattern of brain death (Figure 11.5).

As indicated in European guidelines [2], the short latency EP improve the timeliness, safety and the reliability of the diagnosis of brain death, especially when this cannot be made using conventional criteria.

Prognosis

A systematic review of EEG scales for the classification of coma severity [5,10,11,12,13,14] is beyond the scope of this chapter. Suffice it to state that all these classifications are based on the assessment of the background activity, the presence of reactivity and variability, and the detection of special patterns.

The Synek's classification (1988, 1990) [13,15] divides into three categories with different prognostic significance (favourable, uncertain, unfavourable) the EEG patterns most frequently found in post-traumatic coma and hypoxic-ischemic coma (Table 11.1).

It is useful to briefly mention the epidemiology of the two different types of coma. The first generally has a poor prognosis on awakening, as 70-80% of patients experience death or a vegetative state. In the second type about 60% of patients awaken, with 30% mortality (the latter mostly early). Therefore, in the first type the early prognosis of unfavourable outcome will be more important, while in the second, in addition to the recovery of a state of consciousness, the early prognosis of residual disability will be very useful.

Favourable significance	Uncertain significance	Unfavourable significance
Grade 1	Grade 2, non-reactive	Low amplitude, grade 3
Grade 2, reactive	Grade 3, diffuse delta non-reactive/(reactive)	Burst-suppression, grade 4
		Epileptiform discharges, grade 4
		Low output, grade 4
		Isoelectric, grade 5
Spindle pattern coma, grade 3	Epileptiform discharges, grade 3	Alpha pattern coma, non-reactive
Frontal rhythmic delta reactive/non-reactive	Alpha coma, reactive	Theta pattern coma
		BIPLEDs, PEDs

Table 11.1. **Synek's classification of prognostic categories of EEG patterns in post-traumatic and hypoxic-ischemic coma. [13].**

11.3.2 Hypoxic-ischemic Coma

It should be noted that EEG is more useful in the prognosis of hypoxic-ischemic coma, as the frequency of special or low voltage patterns falling in the category with a poor prognosis is very high for this type of coma. It proves less useful in the post-traumatic phase, when the most frequent EEG pattern is characterized by irregular, often non-reactive dominant medium voltage delta, belonging to the class of uncertain prognostic significance (Figure 11.6).

When preparing to make an early prognosis of hypoxic-ischemic coma, we must consider at least six meta-analyses on the evidence of the usefulness of short-latency EP and in particular of SEPs [16,17,18,19]. All studies agree in indicating that the bilateral ab-

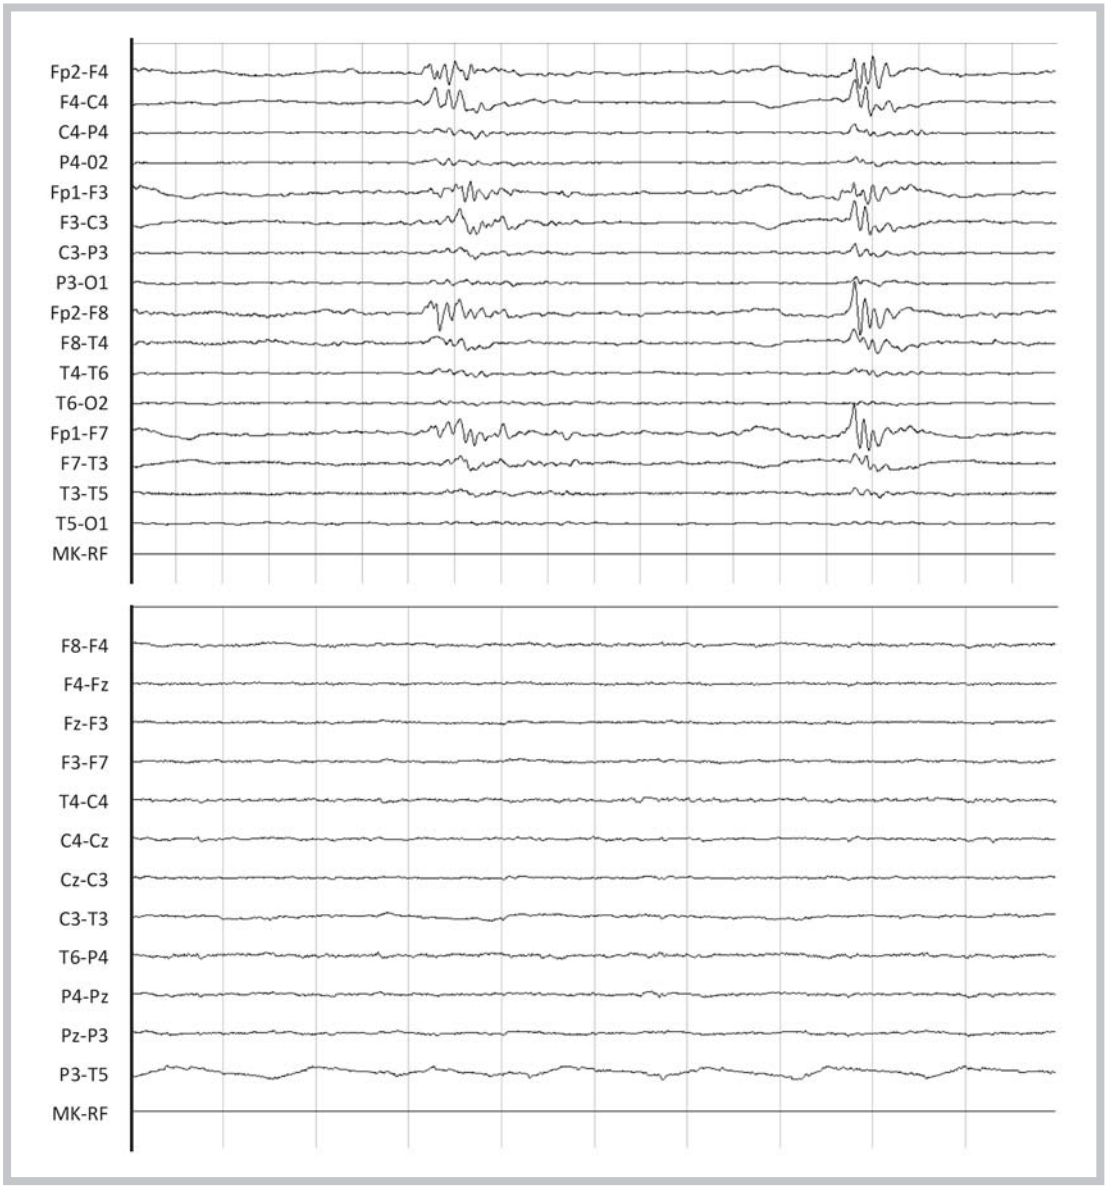

Figure 11.6. **EEG burst suppression pattern (left tracing) at 24 hours in hypoxic-ischemic coma (Glasgow Coma Scale score [GCS] = 4), which at 48 hours is transformed into low voltage pattern (right tracing).**

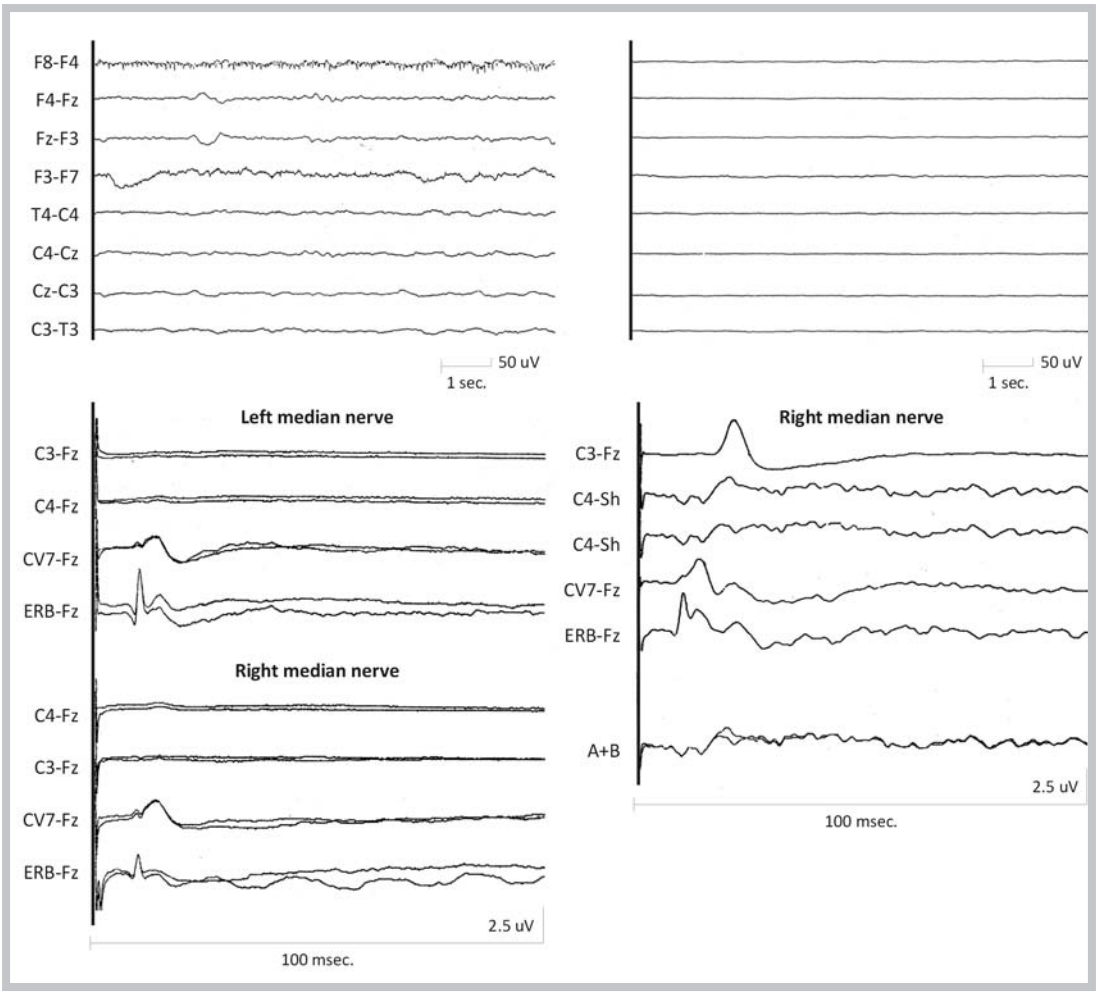

Figure 11.7. **(A). EEG recording of theta delta non-reactive activity and a SEP pattern absent in both hemispheres. (B). Low-voltage EEG/absence of cortical electrical activity and SEPs bilaterally present, albeit simplified.**

sence of cortical SEP has 100% adverse prognostic significance (all patients die or remain in a vegetative state). Zandbergen et al. [16] proposed "clinical" guidelines for the prognosis of unfavourable outcome of hypoxic-ischemic coma, postponing the prognostic assessment to 72 hours and limiting SEPs recording in patients with absent photomotor or with M 1-3/GCS. A proposal for European guidelines on the use of neurophysiological tests in the ICU recommends an evaluation already at 24 hours [2]. A report by the American Academy of Neurology found the SEPs among the most reliable prognostic tests in hypoxic-ischemic coma [20], but does not include EEG for which there is less evidence in the literature. We believe instead that the two tests complement each other, and albeit infrequently, EEG can provide information on unfavourable outcome not obtainable with SEPs alone (Figure 11.7).

In our hospital we have implemented an EEG-SEP protocol agreed upon with interventional cardiologists and the general intensive care unit for the early prognosis of hypoxic-ischemic coma. The protocol includes an EEG-SEP recording at 24 hours in a patient with a motor GCS ≤3: in EEG-SEP patterns unfavourable for the recovery of consciousness (bilateral absence of SEPs, severe EEG abnormalities), given the clinical importance of this finding, we perform a confirmatory test at 48-72 hours.

The clinical usefulness of early prognosis is, in case of negative patterns, that it discourages aggressive interventions for hemodynamics in severely unstable patients, informs the family early on outcome and refers patients to low-intensity rehabilitation facilities after discharge from the ICU.

11.3.3 Post-traumatic Coma

As mentioned, EEG and GCS itself are less reliable as early prognostic indicators in post-traumatic coma compared with hypoxic-ischemic coma [21]. Neurosedation in the early stage hinders clinical evaluation of the patient and makes the underlying EEG activity and reactivity less interpretable. Early SEPs do not have these limitations and are sensitive only to structural damage. A meta-analysis by Robinson et al [18] not only confirms the highly unfavourable prognostic value of absent SEP patterns in post-traumatic coma (90-95% of non-"awakening" in bilateral absence of SEPs) but also highlights the favourable prognostic significance of the normal pattern SEP (over 90% of "awakening" in bilaterally normal SEPs).

By classifying the pattern of SEP alterations in both hemispheres (Figure 11.3) it is possible to group the changes into three categories with different prognostic significance: Grade 1 [(NN, NP): normal] with favourable prognosis; Grade 3 [(AA): absent] with poor prognosis; and Grade 2 [(NA, PP, AA): preserved] with uncertain prognosis. It should be noted that grades 1 and 3 allow correct classification in 65-70% of patients with severe post-traumatic coma. In addition, the normal pattern (grade 1) in our series has a positive predictive index of "awakening" of more than 90% and good functional recovery according to the Glasgow Outcome Scale (GOS) of more than 80% [4].

In our series, a severe disability according to the GOS is associated, in nearly 100% of cases, with absent mono- or bilateral SEPs. Thus, a SEP performed already at 24-48 hours after severe head injury can predict two very divergent paths according to the length of stay in the ICU and subsequent rehabilitation processes in patients with normal SEP and absent or severely hypovolted SEP.

Finally, a comparative meta-analysis examined which was the best single early indicator of prognosis from among SEP, computed tomography (CT), EEG and GCS and photomotor reflex in post-traumatic and hypoxic-ischemic coma [22]. The work selected 26 comparable studies including over 800 patients and concluded that SEP is the best single prognostic indicator. Based on this evidence SEPs should always be associated with clinical tests for determining early prognosis of coma due to acute brain damage.

11.4 Continuous Neurophysiological Monitoring (EEG-SEP) in the ICU

As mentioned at the beginning of this chapter, continuous neurophysiological monitoring is required to establish clinical and therapeutic strategies in the comatose patient. Its purpose is to identify early the evolution of primary brain damage or the possible occurrence of secondary complications.

The demand for a greater use of such monitoring has several reasons:

- The growing interest and neurological involvement in neuroresuscitation.
- The widespread application of neurophysiological methods in intraoperative monitoring.
- Technological innovation and the benefits provided by digital EEG (processing by analysis of quantitative EEG signal, ease of storage and network transmission).

11.4.1 EEG Monitoring

The diagnosis and treatment of status epilepticus have been verified as indications for the use of continuous EEG in the ICU. The incidence of seizures (NCS, non-convulsive seizures) and non-convulsive status epilepticus (NCSE) in the ICU is very high (Table 11.2) and is certainly underestimated in the absence of prolonged or continuous EEG recordings.

Drislane et al. [30] reported the high incidence of NCSE in medical and surgical ICUs (heart surgery in particular) and the delay in EEG diagnosis, even in the presence of a previous clinical crisis.

The diagnosis of NCS and NCSE is made by conventional EEG interpretation (see Young criteria, reviewed by Chong, discussed above), but quantitative EEG (QEEG) may provide a useful tool for even inexperienced personnel to monitor the therapy effectiveness (Figure 11.8).

- 11-51% NCS patients in ICU [23]
- 34% NCS and 3/4 NCSE in acute brain damage [24]
- 12% NCS or NCSE in severe head injury [25]
- 22, 8 and 28% NCS, respectively, in head injury, ischemic stroke, and intracranial hemorrhage [26]
- 8% NCSE in comatose patients in the absence of critical clinical manifestations [27]
- 12-53% NCSE after treatment of a GCSE sometimes with considerable delay in diagnosis [28,29]

Table 11.2. Frequency of crisis and non-convulsive status epilepticus in the ICU.

GCSE = generalized convulsive status epilepticus
NCS = non-convulsive seizures
NCSE = non-convulsive status epilepticus

For the diagnosis of refractory status epilepticus it is necessary to look for a persistent NCSE. Continuous EEG monitoring can be useful to assess the effectiveness of therapy and establish the duration of treatment and methods of reduction and withdrawal of therapy.

Recently, the use of CEEG has found an indication, still potential, in the evaluation of stroke and diagnosis of vasospasm and delayed cerebral ischemia in SAH. Diffuse attenuation of all frequencies without an increase in delta is considered a high risk EEG pattern in extensive ischemic lesions for the occurrence of malignant brain edema [31]. According to Vespa et al. [32], the trend of alpha relative variation can predict the onset of vasospasm by even more than 2 days before diagnosis with transcranial doppler (TCD) and angiography. In addition, various QEEG parameters in SAH have been considered possible indicators of vasospasm and ischemia, such as total power (1-30 Hz), alpha ratio (6-14/1-20 Hz) and alpha/delta ratio (8-13/1-4 Hz) [26,32,33].

Jordan [31] reported the clinical impact of CEEG in 200 randomized patients monitored in the ICU on three clinical decisions such as starting or changing anti-epileptic therapy, transporting patients for CT or magnetic resonance imaging (MRI) and interventions on hemodynamics in order to optimize cerebral perfusion pressure. This impact was decisive in 51%, complementary 31%, and irrelevant in 18% of cases.

Concerning the indications for the usefulness of continuous EEG in the ICU (conventional and QEEG), there is sufficient evidence for the diagnosis and treatment of NCS and NCSE, there are pilot studies on its usefulness for the diagnosis of acute ischemia, while data are very limited on its usefulness for prognosis and absent for monitoring of the evolution of acute brain injury [34].

Despite the extensive use of SEPs in intraoperative monitoring, and the demonstrated prognostic utility of SEP in acute brain injury (close correlation between changes in SEPs in early phase and brain damage, which then affects the prognosis) there are very few studies on continuous monitoring of SEP in the ICU [35,36]. This is even more surprising considering that for the most common monitoring in acute severe brain injury, intracranial pressure (ICP), there is insufficient evidence for a close causal relationship between ICP increases and neurological damage [37].

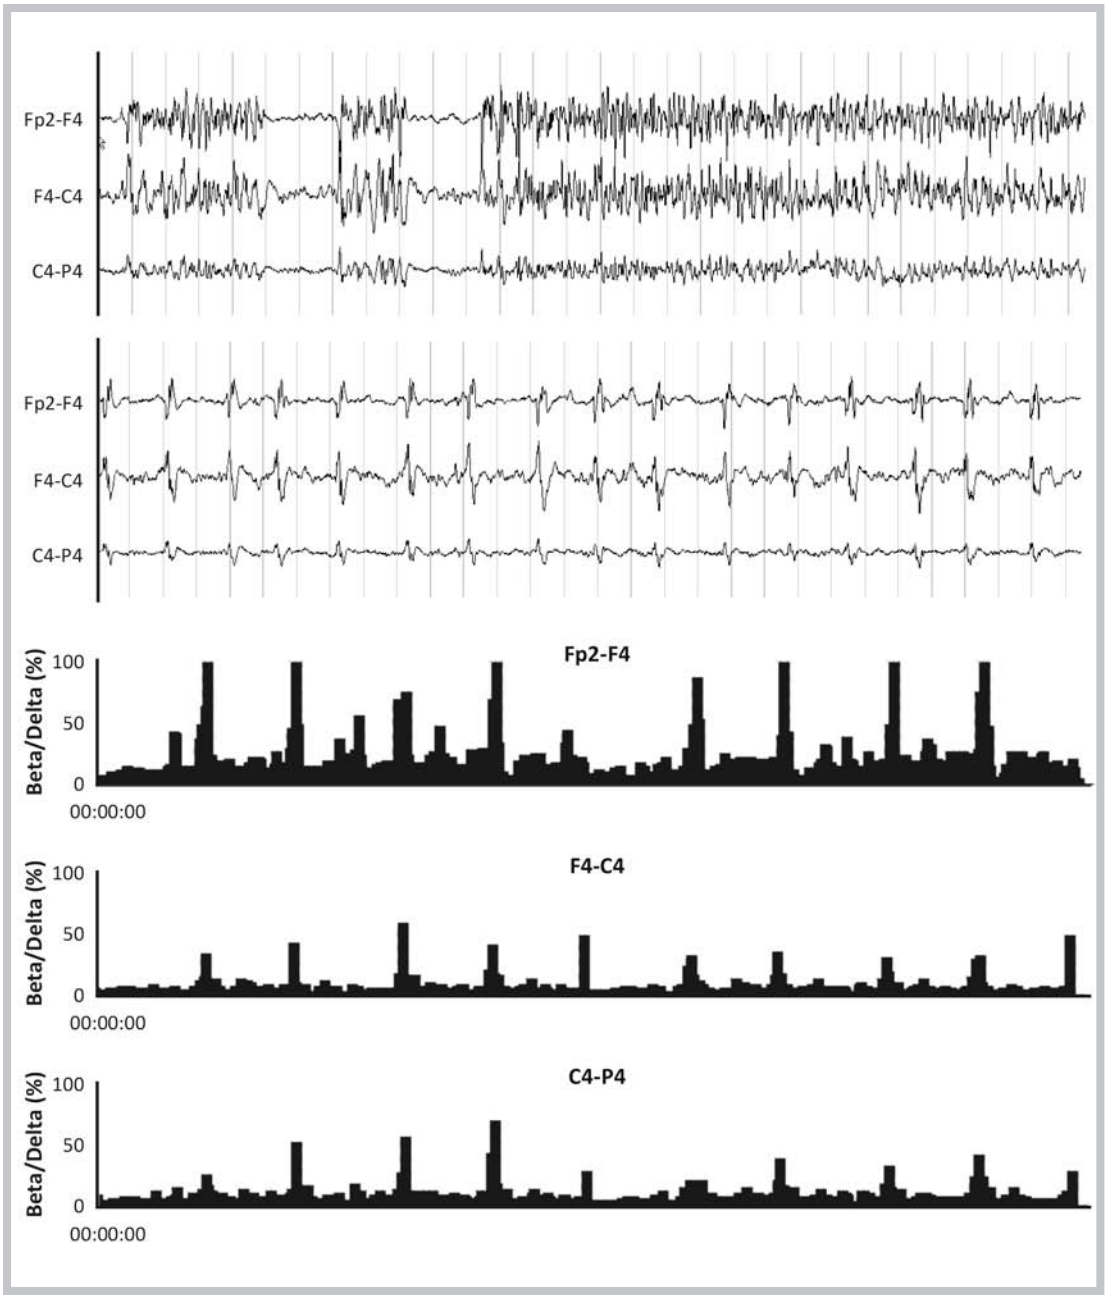

Figure 11.8. **NCSE in a patient with subarachnoid hemorrhage (SAH) due to rupture of an anterior communicating artery aneurysm. Conventional EEG tracings showing both critical (multiple-spike discharge) and intercritical ([PLED] periodic lateralized eileptiform discharges) activities in fronto-central areas (right panel). (Lower panels) QEEG with trending bar visualization of seizures (each bar is made up of a power ratio with the fastest critical frequencies in the numerator and the slowest frequencies of intercritical activities in the denominator. For every crisis there is a power peak up). The QEEG represents 1 hour of compressed EEG.**

In addition to the aforementioned clinical rationale, the "technical" rational for continuous SEP monitoring in the ICU is to couple the high sensitivity and variability of EEG with the stability of SEPs, with the advantage of their easy translatability in quantitative trends of latency and amplitude, easily assessed even by unskilled personnel. This could

facilitate timely clinical interpretation of the high-risk pattern for the onset of an acute or progressive neurological deterioration.

Based on this rationale, in our hospital we perform continuous EEG-SEP monitoring in comatose patients (GCS <9) admitted to the neuroresuscitation department for head trauma and intracranial bleeding and monitored for ICP [38,39]. The registration protocol provides for the performance of alternating cycles of EEG and SEPs, with alternate stimulation of the left and right median nerve, and the monitoring of both hemispheres (latency trends and amplitude for the SEPs with alarms, which can be set).

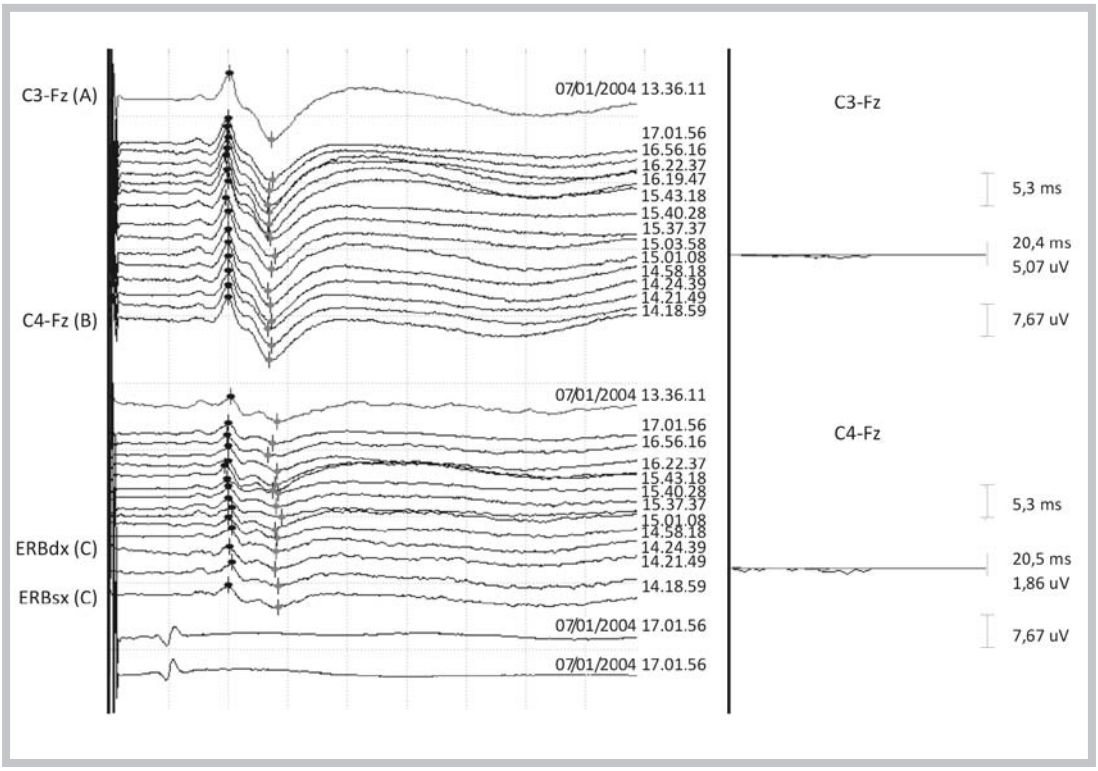

Figure 11.9. **Stable SEP monitoring on both hemispheres in a patient in coma after a SAH with favourable evolution (right side: quantitative trends of latency and amplitude of cortical response).**

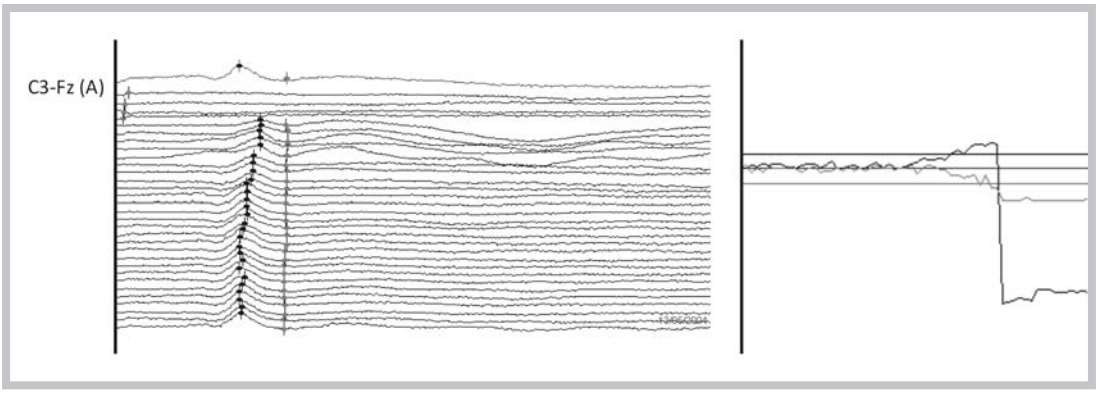

Figure 11.10. **SEP tracing of the left hemisphere in a patient in a coma due to head trauma. Note the progressive reduction in amplitude and increased latency until the disappearance of the cortical response due to the gradual onset of severe intracranial pressure due to increasing cerebral edema.**

In over continuously monitored 80 patients we observed that all patients resulted clinically stable (assessed by serial CT and GCS) and that the SEPs did showed no significant change in latency and amplitude except those induced by neurosedation (Figure 11.9). Conversely, whenever clinical deterioration occurred (18%), the SEPs showed significant changes in latency and amplitude (Figure 11.10), with different patterns such as sudden disappearance or progressive decrease in the amplitude of cortical SEPs.

When we evaluated the correlation between changes in SEPs and trend values of ICP, we found that the changes in SEP may precede or follow an increase in ICP, likely depending on the different pathogenic mechanism underlying the onset of neurological deterioration. In addition, confirming the ominous prognostic significance of an absent SEP pattern, 12 out of 13 patients who could not be monitored owing to the bilateral absence of SEPs in the basic recording died in the ICU and one remained in a vegetative state at 6 months after discharge.

We also observed that while the SEPs (stable or deteriorating) correlated with the outcomes of our patients in the acute phase (stability or progression of primary damage and/or onset of secondary complications), the trend of the ICP values, calculated as average values of maximum daily ICP, presented a lower correlation with the outcome.

This experience leads us to believe that neurophysiological monitoring is an ideal complement to other physiological parameters monitored in the ICU: while ICP is merely an index of blood pressure (from which a hemodynamic concept of cerebral perfusion is extrapolated), CEEG-SEP monitoring reflects, ultimately, the ability of neurons to extract oxygen and, therefore, the extent to which the brain parenchyma remains metabolically active during acute cerebral damage. The association of neurophysiological monitoring with ICP and TCD monitoring may help to optimize the choice and timing of treatment in individual patients.

11.5 EMG in the ICU

The causes of overall muscle weakness most commonly found in the ICU can be divided into pre-existing and arising during hospitalization itself. Many neuromuscular diseases can lead to ICU admission (Guillain-Barré syndrome, myasthenia gravis, amyotrophic lateral sclerosis, etc.). But in this chapter we will deal only with overall muscle weaknesses associated with respiratory muscle weakness which arise during the ICU stay. Some neuromuscular disorders may be revealed (myasthenia) or precipitated (rhabdomyolysis) by infections or drugs used in the ICU [40]. Other causes of weakness are post-surgical complications (e.g., spinal cord ischemia after aortic surgery). Critical illness polyneuromyopathy (CIPM) is still the most important cause of ICU-acquired weakness [41]. This condition was initially described as critical illness polyneuropathy (CIP), but a predominant muscle involvement was later reported (CIM, critical illness myopathy). Today, they are considered as a single nosological entity (CIPM). The onset of muscle weakness is often not detected because of the severity of critical illness (concurrent septic encephalopathy) and because of sedation. Often, overall hypotonia and poor or absent motor responses of the limbs are present but with conservation, in most cases, of facial expression and head movement. Moreover, central motor deficits can coexist in the same patient (e.g., brain damage with lesions of the pyramidal tract).

Neuromyopathy develops during sepsis or multiorgan failure (MOF) in up to 70% of critically ill patients. Pre-existing diseases (asthma, chronic obstructive pulmonary disease [COPD], diabetes, renal failure) may favour its onset. Laboratory tests are not very informative; CPK values are frequently normal. Invasive investigations such as muscle biop-

sy to look for peculiar histological alterations (selective loss of thick myosin filaments, selective atrophy of type II fibres, acute necrotizing myopathy) are rarely feasible in ICU patients.

CIM types in the initial phase with purely functional alterations in the absence of structural changes have also been described [42].

In this context, EMG is essential to confirm the presence of neuromuscular disease and differential diagnosis with other causes of neuromuscular weakness.

ENG/EMG extended to the upper and lower limbs for the exploration of motor, sensory and mixed nerves is necessary: external popliteal sciatic nerve (EPS nerve), internal popliteal sciatic nerve (IPS nerve), sural nerve at the lower limbs, ulnar nerve, median motor and sensory nerve. Repetitive stimulation may be useful in doubtful cases of the persistence of the effect of neuromuscular blocking agents. Moreover, direct muscle stimulation (DMS) can be used, easily executable only for the derivation of the tibialis anterior muscle to identify primary impairment of the muscle [43]. The needle EMG examination must include the exploration of at least one muscle distal and proximal to a lower and upper limb.

Key findings for the diagnosis of CIPM. Conduction velocities are normal or only slightly reduced. The distal latencies are usually normal. The characteristic finding is a reduction in the compound muscle action potential (CMAP) amplitude with increased duration (Figure 11.11).

In addition, the increased duration of CMAP without changes in distal and proximal stimulation, defined as "synchronous dispersion", is considered a typical neurophysiological finding and is attributed to the decrease in conduction velocity of muscle fibres [44]. Unlike CMAP, the action potentials of sensory nerves may be of normal size [45].

This figure is considered a useful criterion for distinguishing types with motor involvement only (CIM) from motor and sensory types (CIP). However, the sensory nerve action potential may be reduced owing to tissue edema generally higher in the lower limbs (sural nerve). A reduction in sensory action potential (SAP) in the upper limbs (ulnar and median nerves) is, instead, a sure sign of sensory involvement.

Thus, CMAP is the most reliable finding, but its reduction can be due to axonal injury and primary muscle involvement. In view of the limitations of traditional neuronographic findings, the direct muscle stimulation technique has been proposed in order to distinguish between CIP and CIM. It assesses the ratio between the amplitude of CMAP after stimulation of the nerve (neCMAP) and that of CMAP after direct stimulation of the muscle (dmCMAP). In primitive muscle involvement, CMAP will be reduced by both stimulation of the nerve and direct stimulation of the muscle, with a ratio of 0.5 to 1 (Figure 11.12).

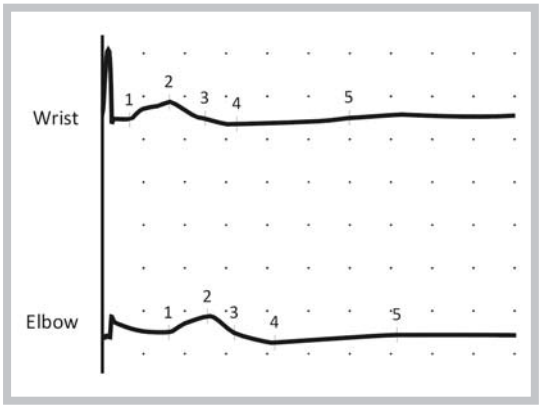

Figure 11.11. **CMAP derived from the abductor digiti minimi muscle (ADM muscle). Note the reduction in amplitude and the increase in duration. The increased duration of CMAP is of equal magnitude for distal and proximal stimulation.**

On EMG examination, spontaneous activity is a variable finding for magnitude and onset timing [46,47], so it isn't an essential criterion for diagnosis. In the CIPM individual, motor unit potential (MUP) can be short-lasting, with low amplitude and polyphasic morphology. But it is often impossible to obtain the patient's collaboration for the analysis of voluntary activity.

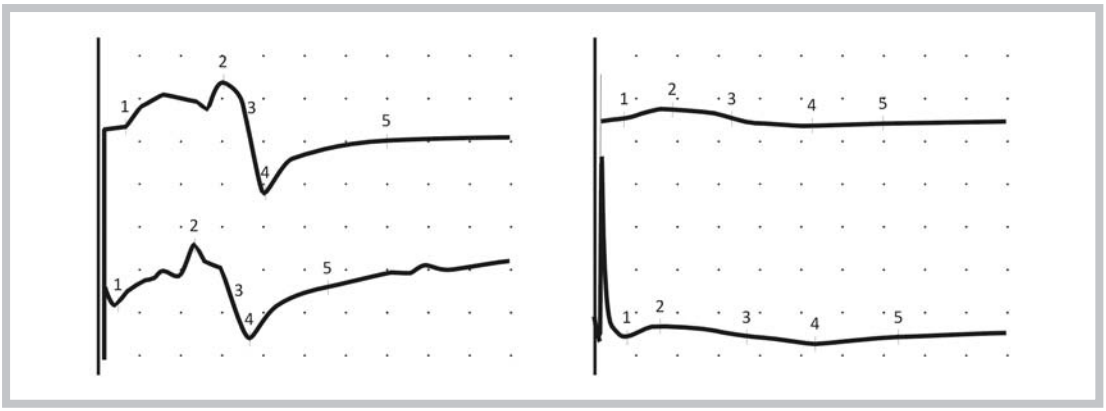

Figure 11.12. **Direct muscle stimulation in a normal subject (left panel) and in a patient with CIPM (right panel). Note the reduction in amplitude due to both nerve stimulation and stimulation of the muscle.**

Hence, the most reliable EMG parameters for diagnosis are essentially neuronographic, and in particular:

- Reduction in amplitude associated with increased duration of CMAP with synchronous dispersion pattern.
- Reduction in CMAP amplitude due to direct muscle stimulation with a neCMAP/dmCMAP ratio >0.5.

In our experience, "myopathic" involvement has been consistently detected, both with motor involvement only and with motor and sensory involvement. This myopathic component was confirmed by direct muscle stimulation.

In the alteration of muscle excitability, characteristic neuronographic findings of longer-lasting CMAPs are also present. This finding, typically impaired in patients with neuromyopathy, is also easier to obtain than DMS.

The above finding is attributed to hypoexcitability of the muscle responsible for weakness, and it is consistent with the inexcitability of the muscle membrane due to inactivation of Na^+ channels, according to data Rich and Pinter [48] obtained in an experimental animal model of acute myopathy.

The findings of reduced muscle excitability and increased duration of CMAP may have a common basis, supporting the pathogenic hypothesis that considers the neuromyopathy related to an alteration of transmembrane ion currents secondary to changes in the expression of isoforms of voltage-gated channels. These functional changes may also affect other tissues in septic patients (heart tissue, CNS), thus explaining the observed systemic abnormalities (ECG amplitude reduction, slowing down and reduction in the amplitude of EEG traces).

The neuromuscular impairment may be an additional "plug", being a part of a broader systemic framework of "multiple organ failure" secondary to the "syndrome of generalized loss of electrical excitability in septic patients" according to a term coined by Teener and Rich in 2006 [49], which would allow a common vision of changes detected in septic patients and would unify nerve, muscle, myocardium and cortical neuron involvement.

12 Monitoring Brain Chemistry by Microdialysis During Neurointensive Care

Urban Ungerstedt [1]

[1] Department of Physiology and Pharmacology, Karolinska institute, Stockholm, Sweden

12.1 Introduction

This chapter focuses on the use of microdialysis during neurointensive care. The emphasis is on the use and interpretation of bedside microdialysis in clinical practice. We apologize for leaving out several excellent articles on clinical findings not yet applicable in routine intensive care.

We have attempted to highlight those areas where there is unanimous agreement on findings and their interpretation. We hope to present knowledge that may be useful for preventing and relieving secondary insults, predicting outcome and guiding therapy during neurointensive care.

12.2 The Microdialysis Technique

Microdialysis, a technique for sampling the chemistry of the interstitial fluid of tissues and organs, started as an animal research technique but has gradually been applied to humans and animals [1]. Minimally invasive and simple to perform in a clinical setting, it has become a standard technique in physiological and pharmacological investigations on animals, with thousands of papers published to date. During the last 10 years it has developed into a clinically useful technique, with about 1000 papers published on its use in brain and peripheral tissues.

The idea of inserting a dialysis catheter into the tissue where a continuous flow of physiological fluid inside the catheter equilibrates with the interstitial fluid outside was conceived of more than 30 years ago by Delgado et al. and Ungerstedt et al. [2,3] using slightly different technical approaches. Today, the Ungerstedt approach of using a “hollow fibre” has become the standard technique. In its simplicity it forms a “biosensor”, where samples of the tissue chemistry are transported out of the body for analysis, in contrast to the traditional biosensor, where the analysis takes place inside the body. The availability of modern analytical techniques has made microdialysis a “universal” biosensor capable of monitoring essentially every small and medium sized molecular compound in the interstitial fluid of endogenous and exogenous origin. Today, there are CE-labelled and FDA-approved microdialysis catheters (Figure 12.1) and bedside chemical analyzers available for human use on the world market (CMA Microdialysis, Stockholm).

The dialysis membrane at the distal end of a microdialysis catheter functions like a blood capillary. Chemical substances from the interstitial fluid diffuse across the membrane

into the perfusion fluid inside the catheter. The recovery of a particular substance is defined as the concentration in the dialysate expressed as a percent of the concentration in the interstitial fluid.

A low perfusion flow and a long dialysis membrane yield a high recovery. If the membrane is long enough and the flow slow enough, the concentration in the dialysate will approach the concentration in the interstitial fluid, i.e., recovery will be close to 100%. In the human brain the perfusion flow is ordinarily 0.3 µl/min and the length of the membrane is usually 10 mm (allowing exact positioning in relation to a lesion). Under these conditions, the recovery has been estimated to be approximately 70% [4]. By using a longer membrane, e.g., 30 mm, and the same perfusion flow, it is possible to reach 100% recovery in the human brain.

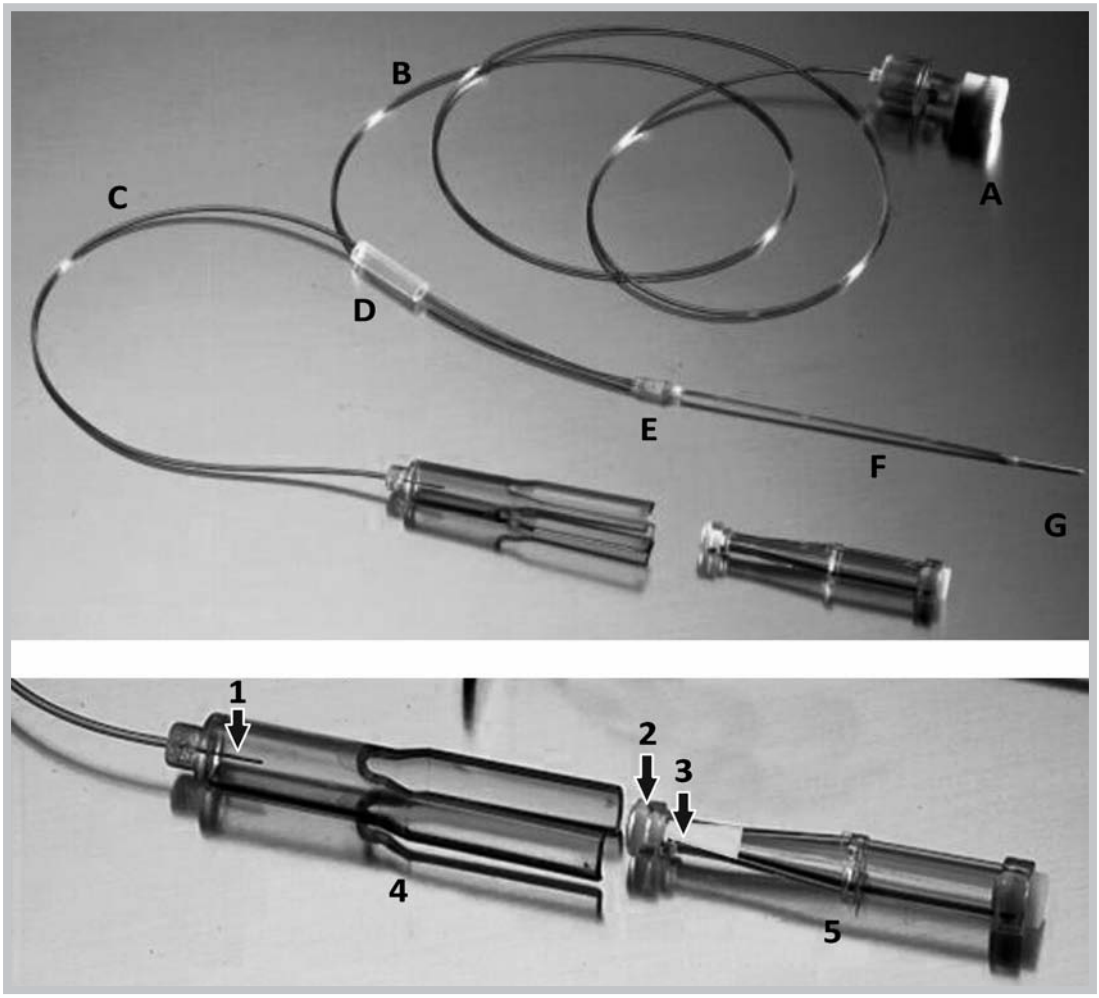

Figure 12.1. **The CMA70 brain catheter. The Luer (A) connects to the CMA106 syringe. The inflow (B) and outflow (C) tubes are surrounded by a sliding cuff (D) which is used to suture the catheter to the skin of the scalp. The two tubes join in the cylindrical "liquid cross" (E) which connects to the shaft (F) and the dialysis membrane (G) with a gold tip. The protective tube is not shown. The vial holder and the microvial are shown in the lower panel. The holder needle penetrates the membrane of the microvial when the vial is pushed into the holder. The sample is collected in the neck of the bottle just under the membrane.**

1 = Needle
2 = Membrane
3 = Sample
4 = Vial holder
5 = Microvial

It is important to realize that the concentration in the dialysate depends not only upon the flow and the length of the membrane but also upon the supply of substances from the blood capillaries, as well as from uptake and release from cells. For example, the supply of glucose to the microdialysis catheter may decrease due to a decrease in the capillary blood flow or due to an increase in the cellular uptake of glucose.

The high recovery of substances that can be achieved in the human brain makes it possible to analyze most neurotransmitters and energy metabolites but also cytokines [5] and small proteins by using catheters with a high cut off (100,000 Dalton). The priority of most investigators of the human brain has been to arrive at a clinically useful application of microdialysis. Therefore, the majority of studies have been done on patients with severe brain trauma or hemorrhage, where analysis of the brain energy state is of direct clinical importance and where such knowledge may improve patient outcome. In this chapter, we have concentrated on the use of microdialysis for the detection and monitoring of ischemia and energy breakdown.

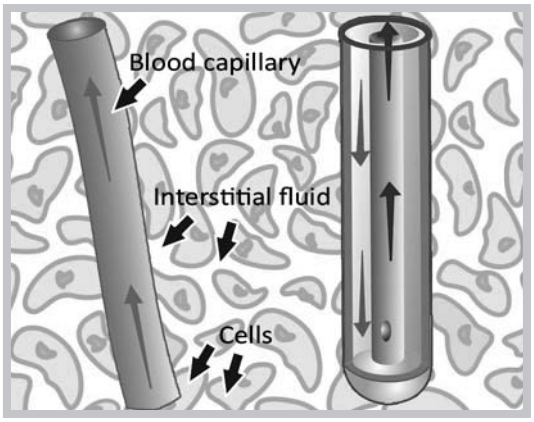

Figure 12.2. **The microdialysis catheter takes up substances delivered by the blood, e.g., glucose and drugs, but also substances released from the cells, e.g., cellular metabolism markers.**

12.3 Biochemical Markers of Ischemia and Cell Damage

The interstitial fluid is the "crossroads" of all substances passing between cells and blood capillaries. By monitoring this compartment in the brain, it is possible to obtain crucial information about the biochemistry of neurons and glia and how seriously the brain cells are affected by ischemia, hyperemia, trauma, hemorrhage, vasospasm, for example, as well as various physiological, pharmacological and surgical interventions during intensive care.

Although microdialysis samples essentially all small molecular substances present in the interstitial fluid, the use of microdialysis in neurointensive care has focused on markers of ischemia and cell damage. The reason is that they are of obvious importance for tissue survival, well understood from a biochemical point of view and easy to interpret in the clinical setting of intensive care.

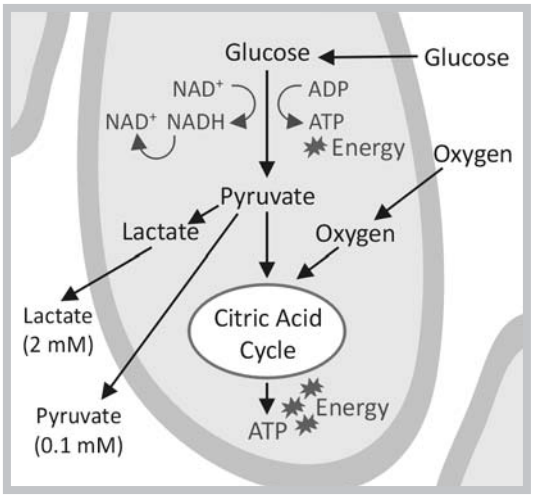

Figure 12.3. **A cell surrounded by interstitial fluid. Anaerobic glycolysis leads to the production of lactate and pyruvate that enter the surrounding fluid where they can be taken up by the microdialysis catheter. The aerobic part of glycolysis utilizes the citric acid cycle to produce the bulk of energy in the form of ATP.**

Microdialysis tells us how cells react to an increase or decrease in the supply of oxygen and glucose. However, while normal brain tissue may not suffer when exposed to a moderate decrease in oxygen and glucose, vulnerable cells in the pericontusional penumbra may simply not survive. Subsequently, severe secondary damage to brain tissue may pass unnoticed if microdialysis is not performed in the most vulnerable tissue of the brain (see below).

12.4 Lactate/Pyruvate Ratio

The lactate/pyruvate ratio is a well-known marker of changes in the redox state of cells caused by ischemia and mitochondrial dysfunction [6]. Pyruvate is formed from glucose in the anaerobic part of glycolysis to generate two molecules of ATP. It enters the citric acid cycle provided that oxygen is available. The citric acid cycle is the dominant producer of energy and yields 32 molecules of ATP. If the tissue is exposed to ischemia (a decrease in blood flow causing an inadequate supply of oxygen and glucose), the production of ATP from the citric acid cycle decreases.

The cells attempt to compensate for the decrease in ATP production by increasing the turnover of glucose in the anaerobic part of glycolysis. During this process it is necessary to regenerate NAD^+ from NADH by converting pyruvate to lactate, which causes an increase in lactate and the lactate/pyruvate ratio (Figure 12.3).

The decrease in glucose delivery from the blood capillaries causes a fall in glucose concentration in the interstitial fluid. This leads to a decreased production of pyruvate due to a lack of glucose. In the dialysate this is seen as a fall in pyruvate and a further increase in the lactate/pyruvate ratio, i.e., a worsening of the ischemia. In a recent study, Vespa et al. [7] compared the lactate/pyruvate ratio by means of positron emission tomography (PET) to investigate the metabolism of glucose and oxygen; they concluded that an increase in the lactate/pyruvate ratio is a sign of a metabolic crisis, which is not necessarily synonymous with ischemic cell damage. This emphasizes the importance of using glycerol as a marker of cell membrane decomposition and cell damage (see below) in addition to the lactate/pyruvate ratio.

The use of a ratio between the two analytes has the advantage of abolishing the influence of changes in catheter recovery, as such a change will similarly influence both lactate and pyruvate. Therefore, the lactate/pyruvate ratio may be used to compare the redox state of different tissues in one individual, as well as in different individuals. The ratio is essentially the same in all tissues, i.e., about 20. We consider a ratio >25 as a sign of beginning tissue ischemia.

Lactate alone is a less good marker of the redox state of cells, as an increase in lactate may be due to hypoxia, ischemia as well as hypermetabolism [8].

12.5 Glycerol

Glycerol is an integral component of the cell membrane. Loss of energy due to ischemia leads to an influx of calcium into the cells, activation of phospholipases, and eventually cell membrane decomposition which liberates glycerol into the interstitial fluid [9].

Considering the fast changes in glycerol concentration in vulnerable pericontusional brain tissue, which are often related to changes in the cerebral perfusion pressure (CPP),

it seems likely that the cells may react by "leaking" more or less glycerol according to the severity of the ischemia. The normal glycerol concentration in the dialysate from the brain when using a 10 mm dialysis membrane and a perfusion flow of 0.3 µl/min is approximately 50-100 µM [10].
In subcutaneous adipose tissue, on the other hand, glycerol originates from the splitting of fat (triglycerides) into free fatty acids and glycerol. This process is controlled mainly by the local sympathetic noradrenalin nerve terminals. Glycerol in the subcutaneous tissue is therefore an indirect marker of sympathetic tone in the dermatome where the catheter is inserted [11].
During intensive care a subcutaneous catheter may be inserted in the periumbilical region to monitor glycerol as an indicator of sympathetic "stress" and glucose as an indicator of systemic blood glucose levels [12]. The normal glycerol concentration in the dialysate from the subcutaneous tissue of a sedated patient when using a microdialysis catheter with a 30 mm dialysis membrane and a perfusion flow of 0.3 µl/min is approximately 200 µM.

12.6 Glutamate

During ischemia there is an increased release of glutamate, which may open neuronal calcium channels and initiate a pathological influx of calcium that causes cell damage. An increasing level of glutamate in the dialysate from the human brain is an indirect marker of cell damage. However, it is difficult to interpret changes in brain glutamate because glutamate release from neurons is mixed with a metabolic pool of glutamate.
The normal glutamate concentration in the dialysate from the brain of a sedated patient when using a 10 mm dialysis membrane and a perfusion flow of 0.3µl/min is approximately 10 µM and somewhat higher in a non-sedated patient [10].

12.7 Glucose

As the primary source of energy to the brain, glucose is an important marker of changes in brain metabolism. Glucose levels in the dialysate from the human brain may, however, change for several reasons:

- Ischemia – an insufficient capillary blood flow. Less glucose is delivered to the microdialysis catheter and the concentration in the dialysate **decreases**.
- Hyperemia – an increase in capillary blood flow. More glucose is delivered to the microdialysis catheter and the concentration in the dialysate **increases**.
- Hyperglycemia – increased blood glucose concentration due to metabolic stress, insulin resistance or intravenous infusion of glucose. More glucose is delivered to the microdialysis catheter and the concentration in the dialysate **increases**.
- Hypermetabolism or hypometabolism – increased or decreased uptake of glucose into the cells, e.g., a shift from aerobic to anaerobic metabolism. This will affect the amount of glucose in the tissue available to the microdialysis catheter, causing a **decreased** or **increased** concentration in the dialysate.

The fact that the glucose concentration in the dialysate may change for several reasons makes it difficult to interpret glucose levels unless glucose is compared to other markers. A subcutaneous microdialysis catheter implanted in the periumbilical region of the abdomen is of great value, as it will reveal changes in systemic blood glucose. If a change

in the brain is parallel to a change in subcutaneous glucose, the change is in all probability due to a variation in systemic blood glucose.
If the change in brain glucose is not parallel to a change in systemic blood glucose, it is probably due to altered brain capillary perfusion, e.g., hyperemia or hyper- or hypometabolism, which causes a simultaneous increase or decrease in both lactate and pyruvate.
On the other hand, if a decrease in brain dialysate glucose coincides with an increase in lactate and a decrease in pyruvate, it is in all probability due to ischemia. By observing the changes in lactate and pyruvate it is possible to interpret the changes in glucose.

12.8 Implanting and Positioning of Microdialysis Catheters

Microdialysis monitors the local chemistry of an area of the brain roughly corresponding to the length of the catheter membrane and a diameter of a few mm. The interpretation of microdialysis data will therefore depend upon the position of the catheter in relation to the existing pathology. The first clinical microdialysis catheters to appear on the market were not visible on computed tomography (CT) scans. Several clinical studies in the literature are difficult to interpret, as we do not know if the microdialysis catheters ended up in normal tissue or penumbra tissue surrounding a contusion or in damaged or dead tissue.
Today's catheters have a gold tip which renders them visible on CT scans. For the interpretation of bedside microdialysis data it is of great importance that the position of a catheter in the brain is can be visualized by CT [13]. Only then can microdialysis data be effectively used to provide an early warning of secondary insults and to evaluate the result of various clinical interventions aimed at improving the condition of brain tissue during neurointensive care.
It is important to adopt a consistent strategy of where to place catheters: in the penumbra surrounding a mass lesion; in the region most likely to be affected by vasospasm after subarachnoid hemorrhage; and/or in "normal" brain tissue. The general principles of where to place catheters in different categories of patients have been agreed upon

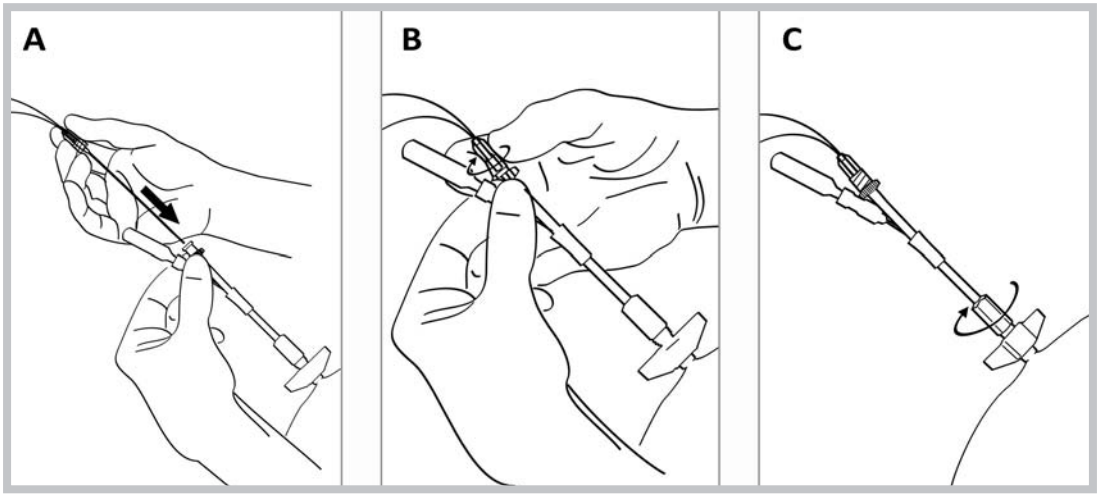

Figure 12.4. **(A). After fixing the bolt to the skull bone, the CMA 70 microdialysis bolt catheter is passed through the entrance tube. (B). The Luer lock connector of the catheter is fixed to the tube connector. (C). The tube channels are sealed by tightening the expansion nut.**

in a consensus paper authored by experienced users of microdialysis in neurointensive care [14].

In the intensive care unit (ICU) it is often convenient to place catheters through cranial bolts, thus obviating the need to bring the patient into the operating room. However, it is difficult to position the catheter in a selected region of the brain when using bolts, as there is no provision for changing catheter depth or angle. In the ICU, catheters are therefore often tunnellated and placed through burr holes to better aim for a predefined region of the brain [15].

In craniotomy, it is easy to place the catheter under visual inspection into the pericontusional penumbra of a lesion or in the territory of the parent vessel of an aneurysm. The catheter is tunnelated under the scalp and a small incision is made through the dura, subarachnoidea and pia. The dialysis membrane is positioned in the penumbra, usually 1 cm from the border of the lesion or in the region most likely to be affected by vasospasm after hemorrhage. In our experience, we have seen no consistent difference in the chemistry whether the catheter is placed in the white or the gray matter. However, it is to be expected that the levels of neurotransmitters may vary depending upon the

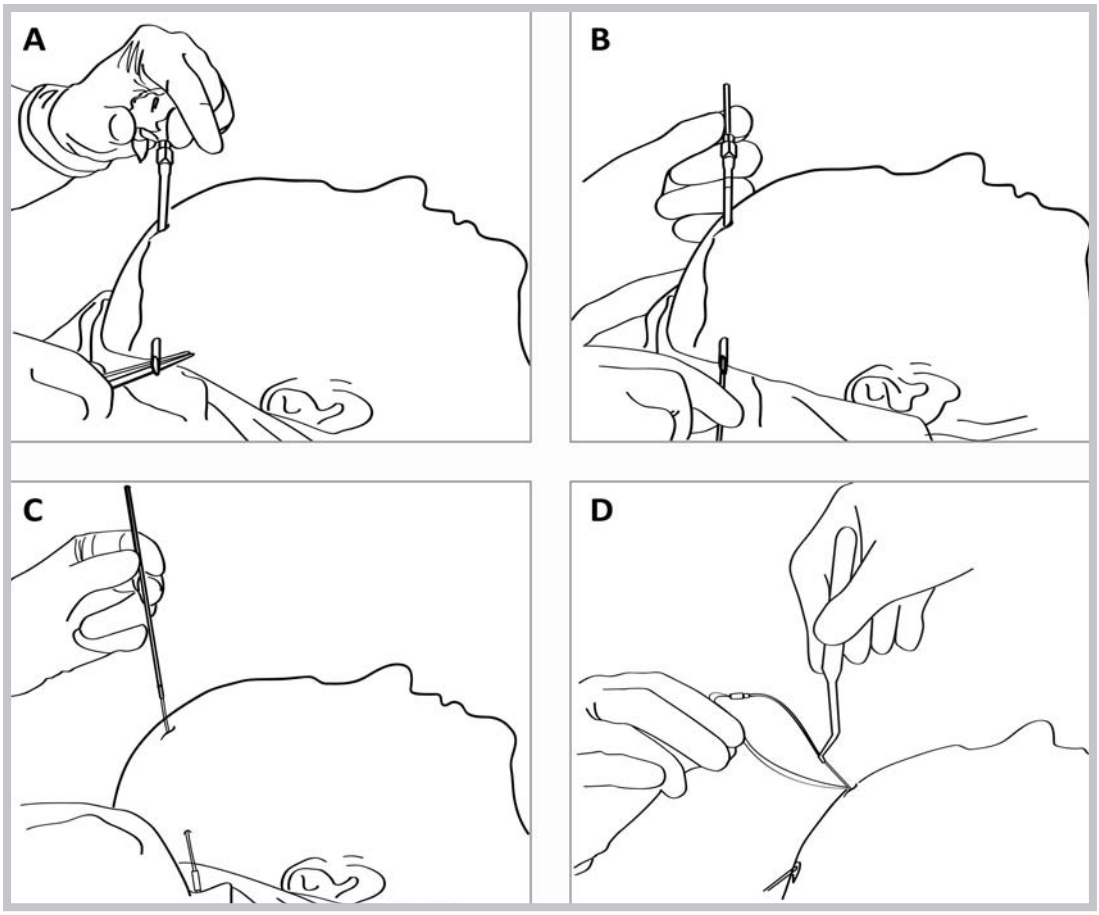

Figure 12.5. **(A). After drilling a hole in the skull bone and opening the dura, a tunnelator is passed under the scalp. (B). The CMA 70 microdialysis catheter is passed through the tunnelator and the tunnelator is then retracted. (C). The protection tube is removed from the catheter by turning it counter-clockwise. (D) The catheter is held firmly at the shaft (without touching the membrane) by a forceps or by hand and passed into the brain through the hole in the dura. The inlet and outlet tubings are stretched and the fixation cuff is sutured to the skin (see Figure 12.6).**

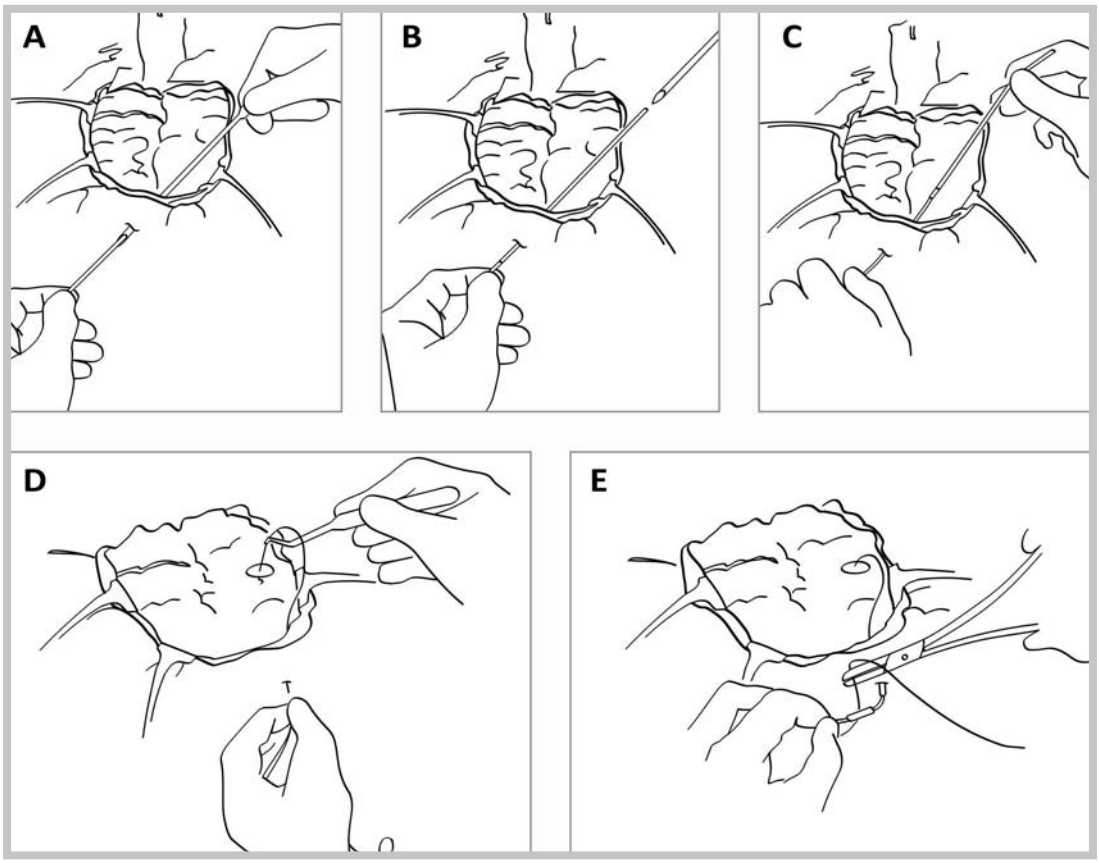

Figure 12.6. (A). During open surgery the dura is repositioned. A hole is cut in the dura where the catheter will be inserted. A tunnelator is passed under the scalp. The CMA 70 microdialysis catheter is passed through the tunnelator. (B). The tunnelator is retracted. (C). The protection tube is removed by turning it counter-clockwise. (D). The catheter is held firmly at the shaft (without touching the membrane) by a forceps or by hand and passed into the brain through the hole in the dura. (E). The inlet and outlet tubings are stretched and the fixation cuff is sutured to the skin.

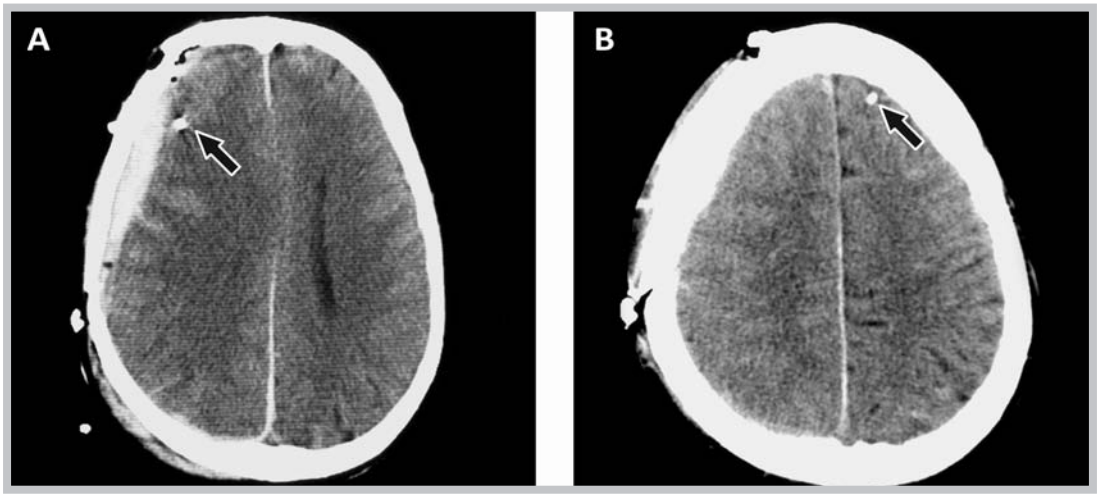

Figure 12.7. (A). Epidural hematoma. The arrow points to the gold tip which is easily seen on the CT scan. (B). Contralateral side showing the visible gold tip.

position. The cuff, which slides over the inflow and outflow tubing, is sutured tightly to the skin so that the catheter cannot be pulled out if, for example, the attached microdialysis pump drops out of the patient's bed.
Irrespective of how the catheter is introduced into the brain, it is important to locate the gold tip of the catheter on the first CT scan performed after implantation. The catheter location will determine how relevant the biochemical data are for the interpretation of brain pathology and the early warning of a secondary insult.

12.9 Selecting Perfusion Flow

The flow of a standard, commercially available microdialysis pump is 0.3 µl/min, which yields approximately 70% recovery when using a 10 mm dialysis membrane [16,17]. Catheters with a 20 or 30 mm membrane will give nearly 100% recovery in the brain. There may be situations where a higher perfusion flow is necessary, for example, when sampling is frequent and the 0.3 µl/min flow rate does not provide enough sample volume to permit analysis. Such may be the case during intraoperative microdialysis when samples are changed every minute in order to monitor ischemia during temporary clipping, for example. A flow rate of 1 µl/min will yield a recovery of approximately 30% using a 10 mm membrane [17].
Another reason to use a high perfusion flow is to reduce the time delay that occurs when the dialysate flows from the brain to the microvial. The delay is in the range of 20 min when the perfusion flow rate is 0.3 µl/min, but it can be reduced to close to 1 min if the flow is increased to 5 µl/min. In this way, it is possible to react to changes in brain chemistry during surgical procedures, for example, ischemia resulting from brain retraction [18]. During neurointensive care, however, because chemical changes usually take place over several hours, a 20-min delay is of minimal consequence.
During normal intensive care it is highly advisable to use the standard flow and standard catheter so that the data between patients in the same or different clinical departments can be compared over time.

12.10 Multimodal Monitoring

In order to make effective use of microdialysis data it is essential to relate them to other data collected at the bedside. This may be done using software which allows for integrating data from the microdialysis analyzer, the ICU monitor displaying intracranial pressure (ICP) and cerebral perfusion pressure (CPP), a tissue oxygen analyzer, the ventilator, the infusion pumps, or other machines.
This "multimodal monitoring" allows for the display of all data as trend curves on one computer screen. It creates the framework for individualizing therapy on the basis of clinical status, brain tissue chemistry and the effect of therapeutical interventions.

12.11 Interpreting Microdialysis Data

During intensive care, brain chemistry often changes profoundly in the patient. At our present state of knowledge, it is impossible to interpret every change; however, major

pathological states manifest themselves as dramatic increases or decreases in biochemical markers.
The first hours of microdialysis data give an indication of how severely the brain tissue is affected in the pericontusional penumbra. This information gives a reference value for determining whether tissue physiology is improving or deteriorating.
The implantation of a microdialysis catheter inflicts a certain amount of trauma to the brain tissue. This is well known from animal studies and it usually takes an hour or more before baseline values are reached after an implantation. In the human brain this is particularly evident for glutamate and sometimes for glycerol. In a clinical setting, however, the time between catheter implantation and the actual use of microdialysis data is often longer than 1 hour due to the various different procedures taking place around the patient.
The range from normal to pathological levels of different analytes are well known from normal brain tissue in patients with posterior fossa tumours [10] and from damaged as well as "normal" brain tissue in patients with traumatic brain injury (TBI) or subarachnoid hemorrhage (SAH). Normal levels differ strongly from pathological levels in severe brain trauma (see below).

12.12 Clinical Studies

The following is a brief account of studies where microdialysis was applied to neurosurgery and neurointensive care. The purpose is to present a selection of papers that describe biochemical findings of particular relevance for the early detection of secondary damage and the evaluation of therapeutic interventions during surgery and neurointensive care.
Microdialysis of the human brain was first performed in 1987 at the Karolinska Institute to alleviate tremor in a Parkinson patient with a thalamic lesion [19]. The catheter was introduced stereotaxically and samples were collected every 10 min and analyzed for a vast array of neurotransmitters and metabolites. We found that baseline levels of the various analytes in the dialysate were much higher than in animals due to the possibility of using a much larger dialysis membrane. Even more importantly, baseline levels were reached much faster probably due to the small implantation trauma in relation to the size of the human brain.
We performed the first study on brain ischemia in Uppsala by monitoring the brain chemistry in tissue which was resected during tumour surgery [20]. This led to a study of microdialysis during neurointensive care of TBI and SAH, in which changes especially in lactate, pyruvate and glutamate were described [21].
The experience from Karolinska and Uppsala prompted us, in cooperation with neurosurgery in Lund, to develop flexible catheters more suitable for implantation in the human brain and a microdialysis analyzer (CMA Microdialysis, Stockholm) designed for bedside use.

12.12.1 Subarachnoid Hemorrhage

Microdialysis has been used extensively for monitoring ischemia in SAH patients. Hamberger et al. and Runnerstam et al. found that the level of consciousness in the postoperative phase was inversely related to the total amino acid concentration in the neuronal environment adjacent to a SAH [22,23].

Persson et al. found that severe ischemia, e.g., temporary clipping, severe hypoxemia or infarct development within or close to the probe area resulted in a clearly detectable increase in the lactate/pyruvate ratio [8]. In many instances this was followed by an increase in glutamate when the lactate/pyruvate ratio reached values of approximately 25 or above. The lactate/pyruvate ratio appeared to be a more reliable marker compared to lactate alone. As opposed to lactate T, there was a statistically significant correlation between the lactate/pyruvate ratio and clinical outcome during days 0-4.

In a study combining microdialysis and PET, Enblad et al. concluded that the energy-related metabolites (lactate, lactate/pyruvate ratio and hypoxanthine) may be used as extracellular markers of ischemia [24].

Säveland et al. found that increased levels of glutamate correlate well with clinical course and neurological symptoms [25]. However, a rise of glutamate in one region did not necessarily parallel to the rise in the other regions. Nilsson et al. described the detailed biochemistry of vasospasm and concluded that lactate and glutamate may be the most sensitive and early markers for incipient ischemia, followed by the lactate/pyruvate ratio and glycerol, during manifest ischemia and cell degeneration [26]. They found that metabolic changes preceded the increase in blood flow velocity as recorded by transcranial Doppler (TCD).

In a series of studies, Unterberg and co-workers placed microdialysis catheters 25 to 35 mm into the parenchyma of the vascular territory most likely to be affected by vasospasm [27,28] concluded that microdialysis "can be carried out routinely in the ICU setting to detect and monitor patterns of metabolic impairment. Compared to TCD, it has a remarkable specificity, making it a well-suited method to monitor delayed ischemic neurological deficits following aneurysmal hemorrhage".

Sarrafzadeh et al. found that lactate and glutamate are early markers of clinical vasospasm, followed by lactate/pyruvate ratio and glycerol, during manifest vasospasm in patients with SAH [29] They stated that bedside cerebral microdialysis is a safe technique for the indication of acute and delayed ischemic neurological deficits in SAH patients when the catheter is inserted into the region of interest. They went on to suggest that "early detection of metabolic changes might also allow optimization of standard intensive care treatments, such as triple-H therapy". Skjøth-Rasmussen et al. found that the ischemic pattern after SAH preceded the occurrence of delayed ischemic neurological deficits by a mean interval of 11 hours [30].

12.12.2 Traumatic Brain Injury

Persson and Hillered (1992) conducted the first microdialysis studies of the human brain after traumatic brain injury (TBI). They found that microdialysis can be used for long-term studies of energy-related metabolites and amino acids, e.g., glutamate, and that the fluctuation of these substances corresponded to various clinical events "presumably involving hypoxia/ischemia". They used the lactate/pyruvate ratio as a marker for energy disturbance in the brain. This ratio is known to reflect the redox potential of the tissue and thereby the severity of ischemia.

They presented several arguments for the reliability of the lactate/pyruvate ratio in comparison to the use of the absolute concentration of other substances in the dialysate:

- Due to the structural similarity of lactate and pyruvate, any change in *in vivo* diffusion conditions during a pathological state could be expected to affect both metabolites similarly
- Being a ratio, it is independent of probe characteristics

- On the basis of a review of 13 papers in the literature describing the normal brain lactate/pyruvate ratio in different species, they concluded that the basal level of the lactate/pyruvate ratio is <20.

This fits with the basal lactate/pyruvate ratio of 23 that we found in the normal brains of patients operated for posterior fossa tumours [10].

Bullock, Zauner and co-workers made the important observation that when placing the microdialysis catheter next to a cerebral contusion, sustained cerebral blood flow reductions caused a massive release of excitatory amino acids, whereas in patients without secondary ischemic, complications or focal contusions, posttraumatic glutamate release appears to be only transient [31]. They conclude that sustained high ICP and poor outcome were significantly correlated with high levels of glutamate (>20 μM) [32].

In 1995 CE-labelled microdialysis catheters intended for human use and an instrument for bedside analysis of glucose, lactate, pyruvate, glycerol and glutamate came onto the market (CMA Microdialysis, Stockholm). This enabled us to start routine monitoring of all patients with severe head injuries in Lund and a few years later in Stockholm. In our first report on normal brain, we established baseline values for energy-related metabolites (see below) [10].

In view of previous findings, we routinely placed one catheter in the pericontusional, penumbra tissue and a second catheter in normal tissue, usually through a second burr hole in front of the intraventricular ICP catheter. We found that microdialysis could be performed on a routine basis by the regular staff in an ICU and that the data could be used for detecting global and local complications [33].

Our most important observations were:

- The metabolites measured give information that is of direct clinical importance regarding substrate availability (glucose), redox state of the tissue (lactate/pyruvate ratio), degradation of glycerophospholipids in cell membranes (glycerol), and extracellular concentration of excitatory amino acids (glutamate).
- There was a marked difference in the energy metabolism of the pericontusional tissue as compared to normal tissue in the same patients.
- The biochemical consequences of severe anaemic hypoxia were observed several hours before the deterioration was detected by conventional methods (ICP-CPP).

We were able to compare the mean levels of the various markers in the pericontusional area of a patient with a fatal traumatic lesion [33] versus the values obtained during wakefulness in the normal human brain [10]:

- Glucose: 0.1 (fatal); 1.7 (normal).
- Lactate: 8.9 (fatal); 2.9 (normal).
- Pyruvate: 31 (fatal); 166 (normal).
- Lactate/pyruvate ratio: 458 (fatal); 23 (normal).
- Glycerol: 573 (fatal); 82 (normal).
- Glutamate: 381 (fatal); 16 (normal).

In a study of 27 patients treated according to the Lund concept, we documented the brain chemistry in patients with favourable outcome [33] in contrast to the previous study of fatal outcome. Our intention was that such data may serve as reference data for bedside prediction of outcome in the individual patient.

The introduction of microdialysis catheters with a gold tip visible on CT marked a quantum leap in the use of microdialysis in routine monitoring during neurointensive care. It became possible to visualize the catheter position in relation to the contusion or hemorrhage and thereby determine the relevance of the microdialysis data. In our first study where the catheter position was verified, we received further proof of the pronounced difference in sensitivity to secondary insults between normal brain and the tissue of the pericontusional penumbra [13].

Several papers have substantiated the ability of intracerebral microdialysis to predict outcome after ischemia and metabolic crisis [34] and its usefulness in managing neurointensive care patients, e.g., the management of systemic glucose in relation to intracerebral glucose levels [35].

12.12.3 Intraoperative Microdialysis

Mendelowitsch, Landholt and co-workers introduced microdialysis as a technique of perioperative monitoring during neurosurgery [36]. In patients undergoing extra-intracranial bypass operations, they placed a catheter 1-1.5 cm from the bypass site immediately after craniotomy. pH was measured online by a flow-through sensor, while glucose and lactate were determined colourimetrically and fluorometrically, respectively. During the first four bypass operations there were no marked changes in any of the measured parameters, while in the fifth patient the last temporary clipping caused glucose to fall to unmeasurable values, with an increase in lactate and a slight reduction in pH over 20 min. In a subsequent study of 10 patients, they added the analysis of glutamate and found three patients with a significant increase in intraoperative glutamate, two of which awoke with hemiparesis [37].

They also monitored the brain during aneurysm surgery by means of a catheter inserted into the cortex frontally in the region where retractor compression was expected. Online pH was reduced and lactate increased during retraction and glucose was decreased in most but not all patients [36]. They concluded that microdialysis is a sensitive method for detecting intraoperative changes in cerebral metabolism and they emphasized that glutamate is an excellent marker of neuronal damage.

The tissue damage caused by brain retraction was also evaluated by Xu et al. in a study of patients operated on subfrontally for pituitary adenoma [18]. The catheters were placed in the cerebral cortex beneath the brain retractor. Glucose remained within the normal range, whereas the lactate/pyruvate ratio, glutamate and glycerol were all considerably above the normal range. This was interpreted as an incomplete ischemia which, however, seemed to cause tissue damage as indicated by the high glutamate and glycerol levels.

Hutchinson et al. demonstrated how combined microdialysis and tissue oxygen monitoring was able to assist in decision making in a patient undergoing aneurysm surgery where the level of oxygen, glucose and pyruvate decreased while lactate and glutamate increased during intraoperative ischemia, as well as postoperative hydrocephalus [16].

12.12.4 Middle Cerebral Artery Infarction

Severe hemispheric stroke carries a high mortality because of the formation of fatal brain edema. Berger et al. reported a case of fatal middle cerebral artery (MCA) infarction where the neurochemical alterations contralateral to the infarction preceded the clinical signs of herniation for several hours [38].

Schneweis et al. used ICP and microdialysis in the ipsilateral frontal lobe in an attempt to identify at-risk MCA patients and to aid in selecting invasive therapy, e.g., decompressive hemicraniectomy or hypothermia [39]. They found that chemical changes varied in accordance with clinical course, size of infarction and brain edema. Stable ICP and chemistry was found in patients without progressive space-occupying infarcts, whereas an increase in ICP, glutamate and the lactate/pyruvate ratio was followed by massive edema and large infarcts.

Berger et al. assessed the effect of therapeutic moderate hypothermia with microdialysis and were able to characterize three different brain regions with different reactions to hypothermia [40]:

- Noninfarcted tissue with stable chemistry and a moderate lowering of glutamate, lactate and pyruvate during hypothermia.
- Peri-infarct tissue where hypothermia caused a pronounced lowering of glutamate, glycerol, lactate and pyruvate.
- Irreversibly damaged tissue, with excessive increases of glutamate, glycerol and lactate and lowering of pyruvate.

They concluded that microdialysis is a safe and feasible neurochemical monitoring method to differentiate normal brain tissue, salvageable tissue and irreversibly damaged tissue and to estimate the effect of hypothermia on these different compartments. Therefore, future treatment strategies for life-threatening stroke should be guided by close neurochemical monitoring.

12.12.5 Drug Distribution

Microdialysis monitors the concentration of endogenous and exogenous substances in the interstitial fluid of the brain. This offers a unique window on the distribution and the free fraction of drugs in the brain and on the changes in endogenous substances that reflect a drug's effect on brain neurotransmission and metabolism.

In a neurointensive care setting it is clearly of interest to determine the penetration of anti-infective agents across the blood-brain barrier into the interstitial fluid where the drug becomes available to brain cells. Mindermann et al. published the first study on the penetration of antibiotics into the human brain [41]. They determined the absolute concentration of free rifampin in the interstitial fluid by equilibrium dialysis (no-net-flux method) in patients receiving a standard dose of rifampin before resection of primary brain tumours. Rifampin concentration was highest within tumours, followed by perifocal regions and normal brain tissue.

Another important aspect of drug penetration into the brain during neurointensive care is the possibility that drugs may penetrate more effectively into areas where the blood-brain barrier function is disrupted due trauma or stroke. Bouw et al. found that there was an increase in morphine levels near a trauma site, i.e., the pericontusional penumbra, when compared to uninjured brain tissue [42]. This is very likely because damage to the barrier in the penumbra region allows drugs to penetrate more freely. This also means that the vulnerable penumbra cells, which are most prone to suffer secondary damage, are exposed to unknown doses of drugs. While this may offer an opportunity to target drug treatment to the vulnerable cells, it carries the risk of unknowingly impairing their function, making them more susceptible to secondary damage.

12.13 Conclusions

Today, microdialysis is a well-established technique for monitoring brain tissue during neurointensive care. Numerous studies have described the chemistry of ischemia during SAH, TBI and stroke. These studies have identified markers to assess the extent of tissue pathology, its change over time. and its relationship with variables such as ICP and CPP monitored at the bedside.

The discovery that the pericontusional penumbra tissue has an increased sensitivity to secondary insults is well documented [12,43,44], providing the clinician with a unique opportunity to identify changes in chemistry which may develop into secondary damage before it has manifested itself in clinical signs. Most important, it gives the clinician the possibility to determine the effect of a therapeutic intervention aimed at correcting brain chemistry and avoiding secondary damage, e.g., by individualizing the CPP, provided that the catheters are located in the vulnerable pericontusional tissue [45]. The implications of microdialysis data obtained in clinical studies have been discussed in a recent consensus paper on microdialysis procedures in patients with SAH and TBI [14].

Section 3.
General Support

13 Fluid Therapy in Acute Brain Injury

Gustavo Piñero [1]

[1] Neurological Intensive Care Coordinator. Intensive Therapy Service for Acute Municipal Hospital "Dr.Leonidas Lucero", Bahía Blanca, Argentina

13.1 Introduction

The management of intravenous fluids in neurocritical patients plays an important role in the evolution and prognosis of acute brain injury. There is no clear consensus on what type of solution or at what stage of neurological disease fluid therapy should be initiated. Parameters extrapolated from studies on less neurocritical conditions provide only an approximation to the pathophysiology of acute brain injury.

This chapter develops general concepts in the management of water and electrolyte metabolism in the central nervous system, describes parenteral solutions commonly used in neurocritical care, and assesses their respective strengths and weaknesses.

The infusion of parenteral solutions may influence the development of cerebral edema [1], and the infusion of hypotonic fluids is reported to decrease plasma osmolarity, with the subsequent development of cerebral edema. Insofar as these observations may have been accurate, there was the widely held misconception that we should "restrict fluid intake" in the acute neurological patient to prevent intracranial hypertension [2]; however, fluid restriction also carries the risk of hypovolemia, hypotension and decreased cerebral perfusion pressure, a triad which favours the development of cerebral ischemia [3-6].

Water is the most abundant component of the body and accounts for 60-80% of body weight depending on age, sex, and body fat content. About half (50-60%) is distributed as intracellular water, the rest as extracellular water (38-45%), with the remaining small fraction as transcellular water.

With few exceptions, the cell membrane is permeable to the passage of water through an osmotic gradient. Osmolarity refers to the concentration of solutes in a solution; the osmotic gradient is the pressure difference between two solutions, wherein a solvent will move from a solution of lower to a solution of higher osmolar concentration, bringing it, the water in this example, to a higher osmolarity equal on both sides of the gradient.

Intracellular anions are macromolecules which do not diffuse across membranes; they attract large numbers of cations, the main one being potassium (K^+). Conversely, extracellular anions are small, and the major cation is sodium (Na^+). Cellular homeostasis is maintained by Na/K AT pumps that prevent cells from bursting. The other factor regulating cell volume is the osmolarity of the extracellular space [7].

The brain is highly sensitive to changes in homeostasis. A state of hyponatremia leads to an increase in cell volume, resulting in cerebral edema, whereas hypernatremia leads to cellular dehydration, with shrinkage of the brain parenchyma [8].

Importantly, some molecules are ineffective osmoles (ethanol, urea): they can increase the concentration of solutes in the extracellular space but do not cause water movement across a membrane. In contrast, effective osmoles such as hypertonic saline solutions attract water from the intracellular to the extracellular space by increasing the osmolarity [9]. For this reason, we use the term "tone" when referring to the effective osmolarity of a solution.

Tone is important in evaluating hyponatremic states which can be classified as: isotonic when the loss of Na^+ equals that of water; hypotonic when the loss of Na^+ is greater than that of water; and hypertonic when the loss of water is greater.
Control of osmoregulation is important because it involves the interaction between the kidney and the thirst mechanism through the antidiuretic hormone (ADH). This system is so sensitive that changes in serum osmolality of 1-2% can activate or inhibit it, while larger volume changes (8-10%) are required to activate the thirst mechanism and the release of ADH [10,11].
Fluid administration in neurocritical patients presents major challenges, including maintaining adequate cerebral perfusion pressure (CPP), while avoid hyperglycemia and controlling body temperature.
Preservation of CPP requires the maintenance of normovolemia without adversely affecting intracranial pressure [12]. Several physiological principles must be considered: in the peripheral tissues the capillaries of the membranes are highly permeable to water, ions and other low-molecular-weight molecules, but limit the movement of high-molecular-weight substances such as albumin. In these tissues, the distribution of fluid between plasma and interstitial fluid volume is regulated by oncotic pressure gradients. In contrast to the systemic capillary membranes, the brain capillary membranes constituting the brain blood-barrier (BBB) are impervious to most hydrophobic solutes, including sodium [13]. Acute changes in plasma sodium, however small, generate a significant osmotic pressure gradient of water movement that can bring about changes in the brain, with important clinical manifestations [14].

13.2 Fluids Commonly Used in Neurocritical Care

Fluids commonly used in neurocritical care can be grouped into crystalloids (isotonic crystalloids, and hypertonic crystalloids) and colloids (natural colloids (albumin), and artificial colloids (gelatins, dextrans and starches).

13.2.1 Crystalloids

Isotonic crystalloid solutions (0.9% saline solution, Lactated Ringer) are inexpensive, nontoxic, safe and non-reactive (Table 13.1). Usually, in conditions where vascular permeability is involved, only one third of the administered volume remains in the intravascular space, significantly increasing the interstitial fluid; therefore, large volumes are required to overcome a particular hemodynamic situation, which can lead to a state of shock or poor progression of resuscitation [15,16]. In patients with impaired capillary permeability, a volume ratio from 1/7 to 1/10 per liter can be administered (of which only 100 ml remain in the intravascular space). Other negative effects associated with isotonic crystalloids are the development of tissue edema, acute renal failure and abdominal compartment syndrome (ACS), as may occur with aggressive resuscitation with large volumes [17-19].
Large volumes of saline (0.9% saline) may cause hyperchloremic acidosis; large volumes of Lactated Ringer's solution can cause plasma hypotonicity, leading to hyperlactatemia without acidosis. Several studies have reported a pro-inflammatory effect of Lactated Ringer's solution (caused by the structure of the D-isomer) [20,21].
Hypertonic crystalloid solutions (3%, 7.5%, 23%) have a high sodium concentration and exert a great effect as volume expanders. They expand the extracellular space very effectively, reducing the tissue water; they also have a slightly positive inotropic effect and

Composition per liter	Plasma	Saline solution 0.9%	Lactated ringer	Observation
Osmolarity	290	308	273	Isotonic?
Sodium (mEq)	140	150	132	Physiological?
Chlorine (mEq)	100	150	109	
Potassium (mEq)	4	0	4	
Calcium (mEq)	4.6	0	3	
Lactate (mMol)	1	0	28	

Table 13.1. **Isotonic crystalloid solutions.**

decrease peripheral resistance [3,20,22,23]. The interest of these solutions in neurocritical care lies in their effects on cerebral hemodynamics by improving cerebral blood flow (CBF) and decreasing intracranial pressure (ICP). The mechanisms of action for these solutions are described in Table 13.2.

Their importance resides in their ability to expand with a small volume, but their effects are transient: increased diuresis and natriuresis, reduced cell swelling, including endothelial, and improved microcirculation [24].

However, their use can lead to hyperosmolarity, hyperchloremic acidosis, volume overload, renal failure, cerebral hemorrhage, pontine myelinolysis, hypernatremia and hypokalemia [25].

They can be given as a continuous infusion or bolus. A concentration of 2% can be given by the peripheral route; however, solutions with a concentration ≥3% may cause local irritation and local tissue damage.

Practical aspects in the administration of hypertonic crystalloids are the following:

- The rate of complications is low with close monitoring of serum sodium. (Keep Na^+ 145-155 mEq/l, serum osmolarity <320 mOsm/l).
- They are given with an infusion pump. Caution is warranted since they are not compatible with all medications, including some that are compatible with 0.9% saline. Avoid administering medications and transfusions with hypertonic saline (SSH).
- General care: control the hydration status and assess the infusion according to age (greater risk of complications in the elderly).
- Laboratory monitoring: Check serum sodium every 6 h. In patients with Na^+ levels <160 mmol/l there is a higher risk of renal failure, pulmonary edema and heart failure. The problem is greater if the levels remain elevated for

Mechanism of action	Effect
Osmotic	• Reduces brain water content • Reduces the mass effect • Prevents or treats elevated ICP
Hemodynamic	• Increases TAM and CPP • Improves organ perfusion
Vasoregulation	• Optimizes cerebral perfusion • Prevents or treats elevated ICP
Immunomodulation	• Modulates inflammatory response • Reduces secondary injury
Neurochemical	• Normalizes neuronal membrane potentials • Limits neurochemical changes secondary to injury
Hypernatremic	• Prevents and treats hyponatremia

Table 13.2. **Mechanisms of action of hypertonic crystalloid solutions.**

CPP = Cerebral perfusion pressure
ICP = Intracranial pressure

Composition per liter	Plasma	SSH 3%	SSH 7.5%	23%
Osmolarity	290	1016	**2586**	7790
Sodium (mEq)	140	513	1293	3933

Table 13.3. **Mechanisms of action of hypertonic crystalloid solutions.**

more than 48 h. Levels >160 mmol/l increase the risk of seizures. Monitor plasma osmolarity.

Discontinuation of therapy with SSH:

- It is difficult to establish the time when therapy should be discontinued. In general one must take into account the presence of intracranial hypertension and the risk of hyponatremia.
- When considering completion of SSH therapy, leakage can be reduced by half every 6 h as it takes <20 ml/h to complete. During discontinuation of SSH therapy, serum sodium should be monitored every 12 h. If levels increase or decrease more than expected, they should be checked more frequently.
- General management depends on the state of hydration, electrolyte levels and the patient's clinical condition. After completing SSH therapy, serum sodium monitoring should not be different than in other critically ill patients [26,27].

13.2.2 Colloids

Colloid solutions produce higher plasma expansion and remain in the intravascular space longer than crystalloids, with increased oncotic pressure and availability of oxygen to the tissues. Animal studies have shown that some of these solutions improve microcirculation rheology. The goals of resuscitation are achieved in less time and with less volume [28-30].

Albumin (natural colloid) is produced by the liver and is responsible for 80% of plasma oncotic pressure, but remains intravascular for 24 hours; the volemic effect should not last more than 4 hours. Albumin's ability to hold water is determined by both its quantity and the plasma volume loss that has occurred. One gram of albumin increases plasma volume approximately 18 ml, and 100 ml of 25% albumin increases plasma volume about 47 ml on average.

Undesirable effects have been described:

- Occurrence of hypocalcemia.
- Altered coagulation and inhibited platelet function.
- Presents pro-inflammatory properties.
- Facilitates the formation of edema if capillary leakage is present.
- Possibility of anaphylactic reactions (0.01%).

Its use in resuscitation is controversial and a large (SAFE) trial showed no differences with crystalloids in the resuscitation of critically ill patients [31]. In a post hoc analysis based on patients with severe traumatic brain injury who had entered into the SAFE study, resuscitation with albumin was associated with higher mortality than resuscitation with saline (41.8 versus 22.2%, respectively) [32].

Dextrans are monoquaternary polysaccharides which are seldom used because of their side effects: mainly altered coagulation (reduced factor VIII); altered blood group typing has been described; risk of obstructive nephropathy; possible anaphylactic reactions (0.27%) [29,30,33].

Gels (polygeline, modified oxypolygeline, melted gelatin). Derived from bovine collagen, they are iso-oncotic and have less expansion power, which is why they are being

	HES 70/0.5	HES 130/0.4	HES 200/0.5	HES 200/0.5 (Pentastarch)	HES 450/0.7 (Hetastarch)
Concentration (%)	6	6	6	10	6
Volemic effect (h)	1-2	3-4	3-4	3-4	5–6
MW (average) Daltons	70,000	130,000	200,000	200,000	450,000
Maximum dose (ml/kg)	33	30-50	33	20	20

Table 13.4. **Characteristics of hydroxyethyl starch (HES).**

abandoned. Brief expanding effect (2-3 h). Do not alter blood grouping or coagulation or platelet adhesiveness. Do not accumulate in the body and do not affect the kidney. Anaphylactic reactions (0.34%) [29].

Hydroxyethyl starch (HES) is currently the most widely used synthetic colloid. Derived from ethoxylated amylopectin from corn, this molecule is similar to glycogen, lending it interesting features since the body does not recognize it as foreign matter. According to their molecular weight and degree of hydroxiethylation, they vary in lifetime and volemic effect (Table 13.4). The most recent have minimal side effects. Large volumes can be used to achieve enhanced expandability; retention in the intravascular space is 4-6 hours. Improve blood rheology and microcirculation, do not have pro-inflammatory properties, and effects on coagulation are negligible. Low incidence of anaphylactic reactions (0.05%). Produce less edema than crystalloids and remain longer in the intravascular space [20,24,34,35].

The most important considerations when using a specific colloid are: the probability of anaphylactoid reactions; the tendency to increase bleeding; the development of tissue edema; renal involvement; and how the colloid affects immune response. Accordingly, starches between 100-200 MW would be the most suitable colloids [36].

13.2.3 Mannitol

Mannitol, a six-carbon sugar, has been used for over half a century and is a mainstay in medical treatment for cerebral edema and reducing intracranial pressure. Solutions are available in 20 and 25%, with an osmolarity of 1098 and 1375 mOsm/l, respectively. It is not metabolized and is excreted unchanged in urine [37]. Under normal conditions, mannitol cannot cross the intact BBB, but when the BBB is impaired or with repeated doses, it may accumulate in the interstitium and the normal blood-brain gradient is reversed, thus worsening cerebral edema [38]. Mannitol reduces ICP by the following mechanisms:

- Produces expansion of plasma, decreasing blood viscosity and hematocrit, thus increasing cerebral blood flow and delivery O_2. This action is more marked when the CPP is <60 mmHg [39-41].
- The osmotic effect facilitates the drainage of cerebral edema. This effect starts about 15-30 min after administration and lasts for at least 1.5-6 h depending on the clinical condition. This effect persists but needs an intact barrier.
- Improves cerebral perfusion by improving blood rheology [42].
- Normal cerebral blood flow is maintained despite the reduction in vessel diameter (reflex vasoconstriction). There is a decrease in cerebral blood volume and therefore ICP decreases. For this mechanism to work properly, the autoregulation mechanism must be intact.
- Mannitol also has antioxidant effects, but the contribution of this mechanism is not clear.

Side effects associated with the use of mannitol include pulmonary edema, cardiac failure, headache, nausea, vomiting, dehydration, rebound edema, electrolyte disorder and acute tubular necrosis [38,41].

13.3 Use of Fluids in Neurocritical Care

13.3.1 Hemodynamic Management

Initial Resuscitation

In the early care of neurocritical patients, a set of general measures should be initiated to achieve hemodynamic stability and an adequate oxygen supply with the aim to limit or prevent secondary brain injury. Cerebral ischemia is considered the central mechanism of secondary damage. Clinical studies have shown that hypoxia and hypotension are associated with poor prognosis [12,23,43,44]. The choice of fluid for maintaining normovolemia plays a role in the treatment of acute brain injury.

Normal blood pressure should be achieved or maintained as soon as possible, based on fluid administration and eventually with vasopressors. We recommend the administration of fluids to prevent or limit the time the patient is hypotensive [43]. Most prehospital crystalloid solutions are isotonic hypertonic solutions, which have been used in some smaller studies with or without the association of colloids [45].

The initial objectives of water management should be: maintenance of adequate circulating blood volume, a slightly decreased cerebral interstitial volume, and a tendency to serum hyperosmolarity [46].

The administration of glucose solutions in these patients is not recommended, unless there is a risk of hypoglycemia because hyperglycemia may exacerbate ischemic injury [47,48].

PPC Management

The reduction in ICP in patients with acute severe traumatic brain injury was originally the only parameter considered in the management of HEC and the prevention of secondary ischemia. Later, clinical observations focused on CPP, a variable derived by subtracting the value of ICP from mean arterial pressure [5,6,12]. While recent studies have shifted the focus to CPP management, it is clear that current clinical practice and guideline recommendations advise increasing blood pressure to maintain a CPP above a “critical threshold” in the treatment of patients with acute brain injury [49-51].

A CPP of 60 mmHg appears sufficient to limit secondary injury, but it is not devoid of the risk of regional cerebral ischemia. Hypo-osmolality and hypovolemia are harmful and patients should be kept normovolemic by avoiding the use of hypotonic fluids [52]. Initially saline 0.9% it can be used, but concentrations of SSH may vary according to each individual case.

Management of Vasospasm

Volume expansion in subarachnoid hemorrhage (SAH) has two major functions: to prevent clinical vasospasm and in acute intervention when clinical symptoms of vasospasm manifest [53]. The clinical effectiveness of volume expansion and improvement of hemodynamics in the treatment of cerebral vasospasm has been explained physiologically by increased CBF in response to increased CPP [54].

SSH	Mannitol
• Prehospital? • Patients with inadequate resuscitation, hypovolemia • Need to use small volumes • CPP/TAM low at the expense of low • hyponatremia • Need for continuous osmotic infusion therapy • Refractory to manitol	• Diffuse injury • Euvolemic patient with adequate volume resuscitation • Osmolarity <320 mOsm/l • CPP low at the expense of elevated ICP • Intact autoregulation • Bolus continuous infusion useful

Table 13.5. **Uses of SSH and mannitol.**

CPP = Cerebral perfusion pressure
ICP = Intracranial pressure
TAM = ?

Overload-induced hypertension was one of the first therapies used for treatment of vasospasm in patients with SAH. Subsequently, improved neurologic outcomes were reported in patients treated with volume expansion, hemodilution and induced hypertension (triple-H therapy) [55,56].

13.3.2 Osmolar Therapy in the Management of Cerebral Edema

The proper treatment of cerebral edema, and hence of increased ICP, improves cerebral perfusion and reduces mechanical damage caused by tissue compression. The goal of therapy is the reduction of osmolar brain water and limiting secondary brain injury. In the management of cerebral edema secondary to cerebral hypertension, the appropriate use of intravenous solutions and monitoring the internal environment are mainstays in the treatment and prognosis of brain injury, because it is important to know the benefits and likely side effects of the solutions commonly used in the treatment of this disease.

Initial water resuscitation with crystalloid solutions should be performed while strictly monitoring the plasma concentrations of sodium since hyponatremia is associated with worsening of brain edema. The use of hypotonic fluids is contraindicated, as is the use of dextrose solutions given the risk of hyperglycemia and its deleterious effects on the injured brain [47,48].

Many studies have compared mannitol with SSH. The reality is that we understand there are differences between the two substances that make them useful in different stages of brain injury. Table 13.5 compares the best use of both these substances [57-60].

13.3.3 Changes in Na^+ and Body Water

Patients usually present neurocritical water balance disorders; this is particularly but not exclusively the case in patients with SAH. The incidence of hyponatremia depends on the threshold for diagnosis (Na^+ <135 mmol/l) is common in neurological patients and is particularly associated with SAH, severe head trauma and meningitis. The causes of hyponatremia are numerous, but the syndrome of inappropriate of antidiuretic hormone (SIADH) secretion or the cerebral salt-wasting syndrome (CSW) occurs more frequently in neurocritical patients [61,62]. In addition, administration of hypotonic fluids is a common cause of iatrogenic hyponatremia [63]. The close monitoring of urine output, levels of nitric oxide in blood and urine and intravascular volume are of vital importance to the most appropriate choice of fluid for every situation.

Hypernatremia is defined as a serum sodium concentration >145 mmol/l; it is common in critically patients and is often an indicator of disease severity or underlying process. Hypernatremia is usually associated with water deficit, due to either inadequate fluid intake or excessive loss.

13.3.4 Therapeutic Hypothermia

The therapeutic use of hypothermia in neurocritical patients as a neuroprotective therapy has gained interest in recent years after the encouraging results found in post-cardiac arrest patients [64,65]. Owing to the complexities of neurocritical patients, the promising results obtained experimentally have not been seen in clinical practice; nonetheless, hypothermia is used by many neurological intensive care facilities.
Intravenous infusion of large cold volumes (4 °C) is one of the more conventional techniques for inducing hypothermia. This method has been successfully used in studies of patients with sudden death. Although it rapidly decreases body temperature, the method has several contraindications associated with the massive infusion of fluids [66]. The most commonly used fluids are 0.9% saline or lactated Ringer's solution, calculated at a dose of 30-40 ml/kg.

13.4 Conclusions

Proper patient care is based on neurocritical assessment of neurological symptoms and neuromonitoring findings coupled with close monitoring of hemodynamic status in order to minimize secondary neuronal injury.
Currently, there is no magic bullet in the management of fluids in the critically patient, and it seems unlikely that a protocol will meet all requirements for all patients and different levels of resuscitation.
Fluid resuscitation with either crystalloids or colloids is generally safe and effective in critically patients, but these agents may be potentially beneficial (e.g., sepsis) or potentially harmful (e.g., head injury) in certain patient populations. Modern fluid resuscitation protocols should be designed to minimize complications and secondary insults related to water therapy. Management of the neurological patient volume (as in all critically patients) should be based on a triad note:

- Fluid management.
- Type of patient.
- Goals and objectives.

14 The Metabolism of Sodium and Its Effect on the Brain

Francisco Javier Ruiz Miyares [1], **Dick Deleu** [1]

[1] Hamad General Hospital. Department of Neurology. Doha, State of Qatar

14.1 Introduction

The brain is a complex and delicate structure that is highly sensitive to abrupt changes in the internal environment, where the water-electrolyte balance plays a role in regulating body processes. In this context, sodium balance is essential for the proper functioning of nerve tissue, considering that nerve cell excitability depends largely on this cation. Its passage through the cell membrane can generate action potentials, which spread to adjacent neurons, and modulate activities in specific areas of the nervous system essential for its functioning.

Sodium is a cation predominantly found in the extracellular space, whereas the potassium cation is mainly concentrated inside the cells. The estimated percentage of sodium in the extracellular space is about 90%, or about 50 g in an adult weighing 70 kg.

Sodium channels are tubular structures that span the cell membrane. Under certain circumstances, they can open to allow sodium passage, thus changing the membrane voltage at a critical point that triggers action potentials, whose morphology, amplitude and duration depend essentially on its physical and chemical properties.

Physiologically, sodium plays an essential role in maintaining homeostasis. Imbalance in the sodium/water rate can lead to serious disorders which, unless corrected promptly, can be life-threatening for the patient.

To maintain this balance, the body has various mechanisms that interact to cope with different types of insults. Thirst, for example, is a central mechanism to counteract the increased concentration of sodium in the blood.

In the kidney, the renin-angiotensin system is highly efficient in detecting voltage drops. It reduces the concentration of sodium, indirectly stimulating the production of aldosterone, a hormone that acts in the reabsorption of sodium, which, in turn, in order to reach certain concentrations, stimulates the secretion of antidiuretic hormone (ADH) by the posterior pituitary (arginine vasopressin system). The most important function of the antidiuretic hormone is to inhibit the renal excretion of water, causing its retention and a subsequent decrease in sodium concentration. Another mechanism opposed to positive sodium balance and to an increase of volume caused by fluid retention, is the auricular receptors that are sensitive to distension caused by hypervolemia, resulting in the secretion of atrial natriuretic factor (ANF) which inhibits the renal uptake of sodium and water, restoring the osmotic balance in open antagonism to renin-angiotensin and ADH.

This complex of functionally juxtaposed systems moves in physiological oscillations within certain limits, ensuring an adequate water sodium balance in the body. However, several processes can concur to impair the body ability to maintain this balance, giving rise to natriuretic imbalances whose most common expression is hyponatremia.

14.2 Hyponatremia

14.2.1 Definition

Hyponatremia refers to a sodium concentration <135 mmol/l. The management of patients with hyponatremia depends on proper identification, including its possible etiologic causes, and timely treatment.

14.2.2 Clinical Aspects and Diagnostic Difficulties

Hyponatremia affects men and women equally. It is more prevalent in the elderly and children because of the difficulties of both infants and the elderly to express thirst and freely manage their demand for liquids. The clinical manifestations of hyponatremia depend on its onset. The chronic form is fairly well tolerated by patients and most are asymptomatic, given the body ability to prevent cerebral edema which, in rigid matter such as the skull, would imply a considerable insult. In this case, the output of solutes and other substances, including proteins from the intracellular space, averts this severe threat, and levels as low as 112 mmol/l are tolerated with minimal symptoms for long periods of time. In contrast, a decrease occurring within less than 48 hours would result in a constellation of symptoms from lethargy to seizures; these effects can be life-threatening and require prompt correction of the sodium deficit.
The severity of the disease is directly related to the degree of hyponatremia and the rapidity of its onset; with explicit symptoms starting from 120mm/l, starting from concen-

Hypovolemic hyponatremia	Simultaneous loss of fluid and sodium, the latter at a higher rate, and poor replacement infusion of hypotonic water: • Marathoners (ascites, intestinal obstruction, peritonitis, burns), diarrhea, CSW in patients with trauma, SAH • Post-resection intracranial tumour. Must be distinguished from SIADH secretion (different management) • Acute or chronic renal insufficiency, salt-losing nephritis • Diuretics: thiazides, carbonic anhydrase inhibitors
Euvolemic hyponatremia	Increased body fluid (no edema), with normal sodium reserve: • Psychogenic polydipsia • Infusion of hypotonic instead of isotonic solutions in postoperative and hospitalized children • SIADH. Differentiate from CSW (different management) • Hypothyroidism • Thiazides
Hypervolemic hyponatremia	Content of water and sodium increases simultaneously, but the water increases at a higher rate: hyponatremia and edema: • Renal impairment: inability to excrete ingested sodium • Nephrotic syndrome • Congestive heart failure • Hypothyroidism • Adrenal insufficiency • Recreational drugs (e.g., ecstasy) • Cirrhosis

Table 14.1. **Causes of hyponatremia.**
SAH = subarachnoidal hemorrhage
CSW = cerebral salt wasting
SIADH = syndrome of inappropriate antidiuretic hormone

trations of 120 mmol/l. In chronic cases, this level may be much lower, with almost imperceptible manifestations. Symptoms will depend on the type of hyponatremia and its underlying cause (Table 14.1).

Hyponatremia should not be confused with pseudohyponatremia, which is almost always due to sodium masking by certain substances such as triglycerides, proteins or excess glucose without altering plasma osmolarity, in which water from the body is redistributed into the extracellular space, creating false hyponatremia; therefore, one should try to correct these anomalies. Transureteral postresection prostatic syndrome should be considered in the differential diagnosis. This is caused by the absorption of litres of hypotonic solutions given during the procedure, causing a hyponatremia with normal plasma osmolarity.

Plasma osmolarity refers to the concentration of solids in a kilogram of plasma and is expressed in millimoles per litre. The formula for calculating plasmatic osmolarity is:

$$\text{mmol/l} = 2\,(\text{sodium}) + (\text{urea}) + (\text{glucose})$$

The normal range of plasma osmolarity is 280 to 300 mmol/l.

14.2.3 Types of Hyponatremia

There are three types of hyponatremia:

1. Hypovolemic.
2. Euvolemic.
3. Hypervolemic.

Hypovolemic hyponatremia manifests in patients as a simultaneous loss of fluid and sodium, but the latter at a higher rate. Among the most frequent causes are the use of diuretics, salt-losing nephritis, adrenal insufficiency, and salt-losing encephalopathies. Among the most important extrarenal causes are burns, diarrhea, excessive sweating (marathon runners), and the third space (bowel obstruction).

In euvolemic hyponatremia, body fluids increase (no edema), with normal sodium reserve, as occurs in psychogenic polydipsia, the administration of hypotonic solutions for isotonic maintenance in hospitalized patients, hypothyroidism and the syndrome of inappropriate antidiuretic hormone (SIADH). From a strictly clinical point of view, it can sometimes be very difficult to differentiate hypovolemic from euvolemic hyponatremia, so the most practical way would be to measure plasma osmolarity and urinary sodium concentration. The latter would help to more accurately identify patients with low plasma osmolarity.

In hypervolemic hyponatremia, water and sodium content increase simultaneously, but the water increases at a higher rate, thus causing hyponatremia and edema. This, in turn, can cause congestive heart failure, liver cirrhosis and various renal diseases such as the nephrotic syndrome that reduces plasma osmotic pressure by triggering the renin-angiotensin-aldosterone system involving the reabsorption of sodium and water.

There are other classifications of hyponatremia. One is based on plasma osmolarity and hyponatremia. It describes hypotonic, isotonic and hypertonic hyponatremia, thus creating some confusion with the one just described, which implicitly relates the volume with osmolarity. Hypotonic hyponatremia, which some incorrectly refer to as “true” hyponatremia, also known as dilutional hyponatremia, refers to an excess of water in the internal environment with normal or high osmolarity. Hypertonic hyponatremia involves an excess of solute in the extracellular space; in this case, the water moves from inside the cells to the extracellular space, as occurs with hyperglycemia or mannitol.

In isotonic hyponatremia there is normal osmolarity, the excess of certain triglycerides, normal or abnormal protein concentration, as in Waldeström's disease or multiple myeloma. Moreover, glucose itself can cause water to move from the intracellular space, which is known as pseudohyponatremia.

14.2.4 Clinical Management

As explained, it is essential to properly treat hyponatremia to establish whether it's acute or chronic, and also to identify the underlying condition or comorbidities that may facilitate its occurrence. Many drugs (Table 14.2) may cause it, such as diuretics, especially thiazides, but also acetazolamide, anticonvulsants such as carbamazepine, gabapentin, zonisamide, various immunomodulators (sirolimus), selective serotonin reuptake inhibitors (SSRIs) antidepressants, non-steroidal inflammatory drugs (NSAIDs) such as indomethacin, etc. The immediate suspension of such drugs helps to reverse the disorder, which is often chronic and should be corrected gradually with infusion of solutions never higher than 8 mmol/l over 24 hours. Sometimes, the mere suspension of the offending agent is sufficient.

Some recreational drugs such as ecstasy (MDMA) can also produce hyponatremia. It is obvious that they should be suspended immediately.

Many comorbidities may lead to hyponatremia, which are mostly chronic and oligosymptomatic, even at sodium levels as low as 110 mmol/l. However, there are sudden events that can lead to lower levels where compensatory mechanisms are insufficient and the symptoms can be noted in direct proportion to the amount of sodium reduction and the rapidity of the decline below critical levels. At this point, the clinician's expertise is critical because the disease should be differentiated from acute hyponatremia. This is less frequent and sometimes present with less extreme sodium levels and can be treated in postoperative patients who have recently received excessive volumes of hypotonic solutions, or people with mental disorders and compulsive polydipsia, or marathoners who, during a run, sweat profusely and ingest significant amounts of liquids, where osmolarity does not replace sodium losses, so quick replacement in such cases is an immediate urgency.

Antiepileptics	Carbamazepine, gabapentin, oxcarbazepine, levetiracetam, zonisamide
Others	Chlorpropamide, clofibrate, cyclophosphamide, indapamide, amiodarone, aripiprazole, amiloride, amphotericin B, basiliximab, sirolimus, thiazides, acetazolamide, NSAIDs, ARBs, bromocriptine, blockers of angiotensin II, desmopressin, interferon, SSRIs, mirtazipine, nicotine, tricyclic antidepressants, phenothiazines, prostaglandins, oxytocin, theophylline, opiates, sulfonylureas, vincristine

Table 14.2. **Drugs that can cause hyponatremia.**
ACE = angiotensin converting enzyme
ARBs = angiotensin II receptor blockers
NSAIDs = non-steroidal inflammotry drugs
SSRIs = selective serotonin reuptake inhibitors

The clinical manifestations of acute hyponatremia can vary from impaired mental status to coma and seizures. Therefore, it must be corrected immediately, as cerebral edema could lead to transtentorial herniation and distortion of the brainstem with catastrophic implications. The benefit of aggressive correction far outweighs the risk of extrapontine and pontine myelinolysis. Some authors recommend corrections of no more than 8 mmol/day, without achieving levels >125 mmol/l in such a short period of treatment, especially if starting at levels <105 mmol/l. It must be emphasized that when treating the underlying causes and in patients with endocrine diseases such as diabetes, excess glucose must be managed with insulin and infusion of isotonic solution because it is a

hypertonic hyponatremia. In adrenal insufficiency, hormone restoration is also the rule, and 120 mg of hydrocortisone administered over 24 to 48 hours is very beneficial. Sometimes it is difficult to demarcate the boundaries between acute and chronic hyponatrema. The context in which symptoms develop can help in decision making; in cases

	Syndrome of inappropriate antidiuretic hormone secretion	Cerebral salt-wasting syndrome
Causes	• CNS disorders: stroke, subdural hematoma, SAH, intracranial tumours, cerebral contusion, meningitis-encephalitis • Extracerebral: small cell lung carcinoma • Other cancers: colon adenocarcinoma, pancreatic cancer, lymphoma • Drugs: NSAIDs, thiazide diuretics, aminoglycosides	• CNS disorders: SAH, tuberculous meningitis with involvement of the base structure (hypothalamus), natriuretic peptides, concussion, meningitis carcinomatosis • Extracerebral: Exaggerated action of natriuretic peptides
Pathophysiology (Both disorders have low plasma sodium and urine osmolality increased. **Volume** is the fundamental difference)	Excessive ADH action: sodium retention, and to a lesser extent, euvolemic hyponatremia, urine osmolarity > serum osmolarity	Exaggerated action of natriuretic peptides in urine osmolarity hypovolemic hyponatremia > serum osmolarity
Main differences	• No signs of dehydration, no orthostatic hypotension (euvolemia) • Normal hematocrit, potassium, BUN • Normal or elevated pulmonary capillary wedge pressure and central venous pressure • Low urine volume + high sodium • Clinical presentation depends on the degree of hyponatremia and speed of onset	• Dry mucous membranes, lack of sweating, tachycardia • Orthostatic hypotension, negative fluid balance (hypovolemia) • High potassium, BUN, elevated hematocrit • Decreased pulmonary capillary wedge pressure (<8 mmHg) • Low central venous pressure (<5 mmHg) • Increased urine output + high sodium • Clinical measures depend on degree of hyponatremia and speed of onset
Treatment	• Try to remove the cause • Fluid restriction (≥1.5 l/24 h) • Thiazides have the advantage that they stimulate excretion of more water than sodium • Diet high in salt and protein • Infusion of hypertonic solutions if not resolved with hyponatremia • Correct hyponatremia with caution: no more than 0.5 mmol/l/h (<8 mmol/l/24h)	• Try to remove the cause • Volume replacement with hypertonic solutions to achieve a positive sodium balance, range no greater than 0.5 mmol/l (avoid myelinolysis) • Fludrocortisone 0.2 mg IV 10 days (check hypertension and hypocalcemia)

Table 14.3. **Differences between syndrome of inappropriate antidiuretic hormone secretion and cerebral salt-wasting syndrome.**

ADH = antidiuretic hormone
BUN = blood urea nitrogen
CNS = central nervous system
SAH = subarachnoid hemorrhage
NSAIDs = nonsteroidal anti-inflammatory drugs

with minimal symptoms, fluid restriction alone may be enough. However, this is very delicate and in some chronic cases has caused myelinolysis. The golden rule in the management of chronic hyponatremia is to eliminate the underlying cause. In the absence of hypovolemia, logic says that fluid restriction is the first step, with close monitoring of osmolarity. If, despite this, sodium does not reach normal levels and the patient is euvolemic, a malfunction of ADH should be suspected. In this case, the antibiotic demeclocycline (Declomycin(R)) should be administered, which, with its unique "nephrotoxic" effect (epiphenomenon), water reabsorption is decreased, thus achieving normal sodium concentration. Recommended doses are between 600 and 1200 mg daily.

The SIADH secretion is a common cause of hyponatremia and an expression of several diseases, of which the most important are meningitis, intracranial tumours, subdural hematoma, cerebral contusion, subarachnoid hemorrhage (SAH), as well as extracerebral diseases such as cancer, and small cell lung carcinoma in particular, along with infections such as pneumonia. In SIADH, the subsequent hyponatremia, if not identified and treated promptly, significantly worsens the evolution of processes such as SAH, and can lead to complications such as vasospasm, and refractory cerebral edema. Therefore, its diagnosis should be suspected in neurosurgical patients who develop hyponatremia.

The antidiuretic hormone vasopressin is a nonapeptide produced by the posterior pituitary or neurohypophysis, specifically in the gigantocellular area of the supraoptic nucleus. One of its functions is to inhibit the renal excretion of water and sodium, which means small and concentrated urine volumes, hence, the term "antidiuretic." In addition, it has a significant vasoconstrictor effect. It has several other important features and is involved in complex processes such as the maintenance of circadian rhythms and the development of adaptive responses based on learning processes mediated by multisynaptic reflexes involved mainly in short and medium-term memory formation.

In neurosurgical patients, it is essential to differentiate SIADH from cerebral salt-wasting (CSW), because the treatments are different and misdiagnosis can cause serious consequences (Table 14.3). One example of this problem is SAH, where hyponatremia is common and is related to CSW in most cases and to a lesser extent to SIADH.

In fact, vasopressin's mechanism of action is well described and its inhibitory action on renal excretion of water and on increasing osmolarity is universally accepted. However, its proposed mechanism in CSW is less clear and may involve the excessive action of natriuretic peptides in the eventual failure of the renin-angiotensin-aldosterone system, with consequent sodium loss and hyponatremia.

In SIADH there is fluid retention with fluid overload, the opposite of CSW, where there is loss of sodium and hypovolemia. Hematocrit, potassium, and plasma proteins have normal values in SIADH, whereas they are increased in CSW, except for potassium which is within normal limits in CSW. Central venous pressure and pulmonary capillary resistance tend to be normal or elevated in SIADH, whereas both are decreased in CSW. With these elements clearly specified, the differential diagnosis can be established, identifying each entity and initiating treatment accordingly.

Treatment of the Syndrome of Inappropriate Antidiuretic Hormone

The core management of SIADH entails fluid restriction and the use of hypertonic solutions. Because of the frequent inability of the kidney to absorb sodium in the same proportion of water, there is a negative balance of the cation in the extracellular fluid and increased in urine. In severe brain insults and severe symptoms such as coma and seizures, treatment should be individualized. Anticonvulsants should be administered, together with monitoring of vital signs, while maintaining oxygenation and check-

ing the sodium concentration in the blood: once minimum values are reached under which seizures are controlled, the infusion rate should be slowed, so that hypertonic status should not exceed 8 mmol/l in 24 h. It is worth noting that in SAH and other injuries, such as extensive infarctions or severe contusion, fluid restriction has resulted in worsening of symptoms, hence the importance of diagnostic accuracy.
An emerging and promising method for treating SIADH is with vasopresin receptor antagonists that inhibit vasopressin binding at the level of the nephron, with subsequent renal excretion of free water and decrease in extravascular fluid.

Management of the Cerebral Salt-wasting Syndrome

The most important thing to do is initiate fluid replacement, preferably with hypertonic solutions that have proven to be safe in non-controlled studies, where the index of cardiac, metabolic and myelinolytic complications was minimal. This requires strict control of infusions of no more than 0.5 mmol/l/time to avert the occurrence of myelinolysis. The administration of fludrocortisone at rate of 0.2 mg IV twice daily for 10 days, a mineralocorticoid with a not fully understood mechanism of action, diminishes the loss of salt by the kidney eliminate at a rate with very encouraging results.

14.2.5 Complications of Hyponatremia

We have explained that the symptoms resulting from hyponatremia depend on the speed of its onset and the levels of sodium. Its expression is variable and the range of symptoms includes subtle mood changes, poor concentration, irritability, drowsiness, anorexia, malaise, unexplained headache, deteriorating level of consciousness, coma and seizures. These symptoms are very difficult to manage if sodium levels are not increased reasonably.
Although it is quite uncommon, rhabdomyolysis should be suspected in hyponatramic patients with muscle aches and spasms. Hyponatremia alone can affect the integrity of the muscle membrane. The low concentration of extracellular sodium affects the sodium-calcium cation exchange, with a net increase in intracellular calcium that triggers the activation of apoptotic systems that involve the selective death of myocytes. The damaged membrane facilitates the discharge into the bloodstream of substances with a high toxic potential such as myoglobin, whose degradation products (globin and the iron pigment within it) precipitate in the renal tubules, significantly affecting their function, and the body homeostatic mechanisms. The presence of elevated creatinphosphokynase (CPK) levels is the most important indicator to confirm the diagnosis.
Myoglobin also has to be consistently high. Rhabdomyolysis, if not diagnosed promptly, can cause kidney damage and complicate patient management; therefore, controlling the patient's metabolic status is necessary. Treatment consists of two parts: correction of hyponatremia and relief of muscle spasms by the administration of baclofen, preferably in a continuous infusion pump, up to 200 mg IV daily in severe cases. If the desired improvement is not achieved, midazolam IV can also be administered, intermittently, as needed. Muscle enzymes should be tested routinely in patients with hyponatremia and some degree of hypertonia.
Extrapontine and pontine myelinolysis as a complication of hypercorrection of hyponatremia is a concern for those who have to deal with these patients. As we have repeated throughout this chapter, the aggressive correction of hyponatremia, especially in chronic cases, is the most important factor to trigger myelinolysis.
The gradual restructuring of the internal environment through the exchange of ions and other higher molecular weight substances that travel through the extracellular

space increase long-term tolerability. However, patients are more susceptible to complications such as myelinolysis related to the massive influx of sodium into the extracellular space. The subsequent exit of fluid from oligodendrocytes to the interstitial and intravascular compartments involved in their degradation is not inflammatory demyelination, which is often not confined to the pons, as was described in the first case, which is due to various causes such as alcoholism, malnutrition and cirrhosis. Diagnosis will be based on findings from neuroimaging studies because FLAIR and T2 sequences best identify demyelinating lesions that are displayed as hyperintensities, usually symmetrical, in the pons, striatum, thalamus, or even in the cortex brain (Figures 14.1 and 14.2). Symptoms are variable and often occur several days after osmotic insult. Virtually asymptomatic cases are described meanwhile others with delirium, locked-in syndrome, coma, and death. Pyramidal or extrapyramidal elements may also be present. There is no precise correlation between symptoms, the degree of extension of lesions and their intensity on magnetic resonance imaging scans. Unfortunately, there is no effective treatment once the injury occurs, hence the importance of correcting hyponatremia rationally.

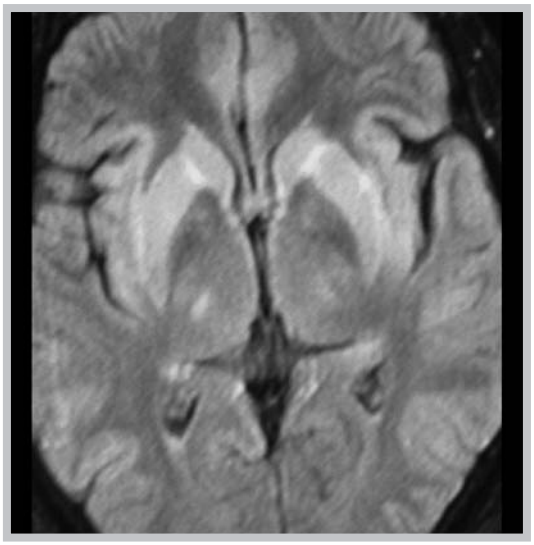

Figure 14.1. **Bilateral hyperintensity in the striatum, with FLAIR sequence, in a patient with chronic hyponatremia which worsened after 3 weeks, not promptly corrected, corresponding to extrapontine myelinolysis.**

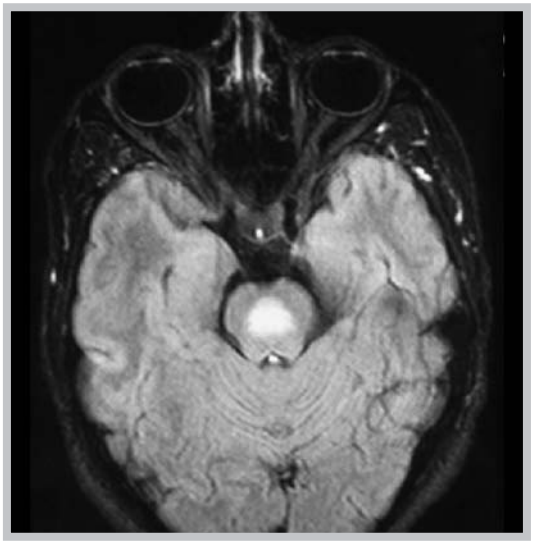

Figure 14.2. **Marked hyperintensity in the pons of the same patient, with FLAIR sequence, corresponding to pontine myelinolysis.**

14.2.6 Conclusions

Hyponatremia is a condition that can be identified and properly managed if the underlying causes are identified and possibly eliminated. On the basis of the patient's symptoms, hyponatremia should be corrected, taking into account whether it is acute or chronic and whether it constitutes an emergency or not.

In acute and life-threatening cases, the aggressive correction of sodium levels is beneficial, and the occurrence of myelinolysis is unlikely. In chronic cases, the suspension of the cause and the delicacy of the sodium correction are key to recovery without sequelae. The broad symptomatic spectrum and the presence of other comorbidities difficult to the management of hyponatremia which requires clinical expertise to finally beat it.

14.3 Hypernatremia

14.3.1 Definition, Epidemiology, and Risk factors

Hypernatremia is defined as a blood sodium concentration >145 mEq/l. It is the direct result of water loss or gain of sodium, so there is a positive balance of the cation in the extracellular space, resulting in a response to counter it by thirst, water outflow from the intracellular space or by increasing the renal sodium excretion. It is a less common alteration than hyponatremia (5% of total electrolyte disorders) and equally affects both sexes. It has a higher incidence in the elderly and children, because of the difficulty of these groups to have free access to liquids or because misaligned in the thirst mechanism in older people. Patients with psychogenic hypodipsia, children and elderly or those mismanaged with inappropriate infusions (iatrogenic) have an increased risk of hypernatremia.

The mechanisms that produce hypernatremia can be summarized as follows:

- **Loss of fluid** due to insufficient vasopressin function (decreased secretion or inadequate renal response to normal secretion). Extrarenal loss: diarrhea, profuse sweating. Decreased fluid intake (central or psychogenic adipsia, unavailability of water). The most serious consequence of this loss is cellular dehydration.
- **Increase of sodium in the extracellular space** caused by fluid losses, with positive balance of the cation, which also contributes to hormonal imbalances such as primary hyperaldosteronism and Cushing's syndrome. Further poor management of infusions (sodium bicarbonate, parenteral nutrition) and dialytic hypertonic solutions contribute to an iatrogenic increase in the sodium balance.

One of the major causes of hypernatremia is **diabetes insipidus (DI)**, both central and nephrogenic. The cardinal symptom is polyuria, which can reach more than 15 litres per day. Central DI is caused by the insufficient production and subsequent secretion of vasopressin or antidiuretic hormone by the neurohypophysis, which implies that the kidney is unable to concentrate urine. Consequently, blood sodium is increased, triggering the thirst mechanism. There are multiple root causes: ablation surgery, pituitary tumours, trauma (skull base fracture), intracranial infections, and congenital malformations. The cause is unknown in about 30% of cases. Renal or nephrogenic DI is clinically indistinguishable from central DI; however, the simple infusion of exogenous ADH (desmopressin) and the change in urine osmolarity can help in making the diagnosis: it is central if there is an increase in osmolarity and nephrogenic if urine is diluted.

In renal DI, the kidney is insensitive to adequate concentrations of ADH in the blood, and starts concentrating the urine, creating a noticeable increase of sodium in the extracellular fluid. The causes are the use of aminoglycosides, rifampicin, lithium salts, oral hypoglycemic agents, amphotericin B, demeclocycline, etc. Systemic inflammation such as amyloidosis may arise, as well as polycystic kidneys and electrolyte imbalances such as hypocalcemia and hypokalemia.

Hypernatremia has a variable clinical expression and depends on how quick its onset is and on the degree of nervous system involvement. In adults it usually remain asymptomatic until reaching levels as high as 160 mEq/l. Thirst can be a guiding symptom, especially in the beginning of the disease, and if the subject urinates significant quantities. The evolution of symptoms to coma and seizures depends on how quick the onset of hypernatremia is; high levels of sodium are tolerated with minimal symptoms, because of the balance maintained with the gradual exit of fluid from the extracellular space. This is impossible to achieve if there is a sudden (within <48 hours) increase in plasma osmolarity at the expense of sodium. Consequently, the intracellular fluid space rapidly de-

creases, contributing to neuronal dehydration, and leading to a series of symptoms proportional to the intensity of dehydration.

14.4 Clinical Management and Treatment

The best approach is to try to eliminate the cause, but sometimes, given the urgency of symptoms, rapid correction of hypernatremia is essential. The correct measurement of volume and urine osmolarity are critical to guide the diagnosis: if there are large volumes of not concentrated urine, the diagnosis will be DI, and the elective diagnostic test will be the desmopressin test to identify whether it is central or neurogenic. In the case of small volumes of urine and a higher concentration of sodium, the kidneys try to conserve water from the extracellular space and excreted sodium, as in hypernatremia of extrarenal origin and iatrogenic diseases, Cushing's syndrome or Cohn's disease. Normal renal osmolarity in children and adults is between 400 and 800 mOsm/kg. Under conditions of fluid restriction for more than 12 hours, levels of osmolarity of 400 mOsm/kg or less could be an index of severe kidney damage. Hypernatremia should be managed taking into account the volume of extracellular space to find out if it is euvolemic or hypovolemic hypernatremia. The amount of water needed by the body can be calculated using the following formula:

Free water deficit = Body weight (kg) x Total body water (%) x ([Serum Na/140] – 1)

Where the percentage of body water (TBW) accounts for approximately 60% by weight, hence, the constant 0.6 times the weight of the patient.
If hypernatremia is hypovolemic, infusion of normal saline (0.9%) is the treatment of choice, until the signs of dehydration decrease. Hypotonic solutions ("D5" - 5% dextrose; hypotonic saline fluids such as 0.45% sodium chloride solution) should then be administered to restore the volume and reverse the hypernatremia.
In cases of euvolemic hypernatremia, as occurs in elderly patients with poor thirst mechanism, oral rehydration therapy is indicated and effective.
In central DI, in addition to water restriction and low sodium diet, desmopressin administration (intranasally or subcutaneously) can help to alleviate the deficit of vasopressin.
In nephrogenic DI it is important to delete the trigger, usually a drug (phenytoin, lithium salts, acyclovir, demeclocycline, amphotericin B); this is sometimes enough to normalize serum sodium. Otherwise, a low-protein and low-sodium diet, supplemented with low doses of hydrochlorothiazide, is critical for relieving the kidney from solute overload.
Serum sodium should never decrease to <0.5 mEq/l/h because a rapid decline in serum sodium can cause cerebral edema. Do not administer more than 50% of the estimated deficit in the first 24 hours. The onset rhabdomyolysis and myelinolysis after aggressive correction of hypernatremia. Rhabdomyolysis and myelinolysis after aggressive correction of hypernatremia have been reported.

All science is measurement.
von Helmholtz

15.1 Introduction

The first step in evaluating a patient's hemodynamics is, without doubt, the clinical assessment. Bedside observation of the patient's general appearance, skin temperature, capillary refill, sensory status, diuresis, filling of the external jugular vein and so on, will give the physician an approximate idea of the hemodynamics. However, clinical data are often nonspecific and subjective and can be altered by the patient's concomitant conditions.
Invasive hemodynamic monitoring yields accurate, objective and reliable data about intracardiac and intravascular pressure, blood flow volume and distribution, oxygen supply to tissues and the use thereof by cells. Assessment of hemodynamic status should include measurement of tissue oxygenation (Figure 15.1). In the presence of oxygen, aerobic cellular metabolism produces a significant amount of energy (ATP) and non-toxic and easily removed waste product metabolites (CO_2). In the absence of oxygen, anaerobic cell metabolism produces little energy and toxic metabolites (lactic acid).

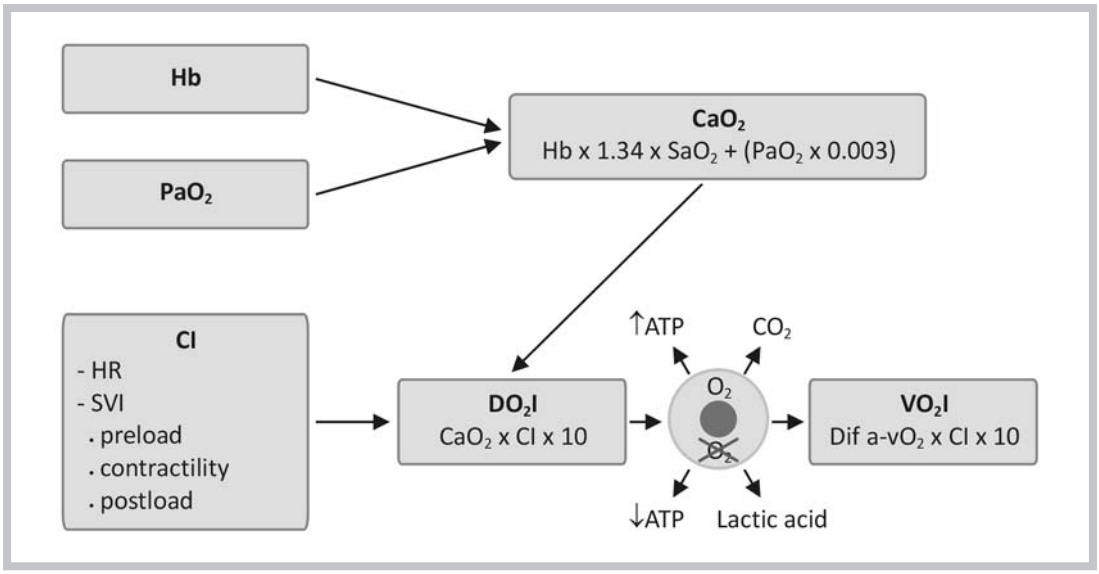

Figure 15.1. **Alveolar partial pressure of oxygen (PaO_2) and hemoglobin (Hb) are determinants of arterial oxygen content (CaO_2). Cardiac index (CI) is derived from the stroke volume index (SVI) and heart rate (HR), oxygen delivery index (DO_2I) and oxygen consumption index (VO_2I).**

15.2 Indications and Complexity of Hemodynamic Monitoring

Hemodynamic data are useful or even essential in proper patient management. As a general rule, the more severe the condition, the greater the complexity and depth of monitoring. A corollary to this is an appropriate risk/benefit ratio, since invasive monitoring is not devoid of complications, along with the cost/benefit ratio in the rational use of health resources, avoiding excessive spending wherever possible.

The information obtained should allow diagnosis, prognosis and effective treatment that will ensure the best outcome for the patient in terms of morbidity and mortality, minimizing risks through a more effective use of medical resources.

Noninvasive monitoring of heart rate, respiratory rate, and blood pressure, electrocardiography (ECG), pulse oximetry and exhaled CO_2 provide comprehensive information of the circulatory status.

Invasive monitoring involves the percutaneous introduction of catheters into the intravascular space to directly measure certain variables from which others can be calculated for more accurate and specific control of a particular hemodynamic situation.

Before a diagnosis can be established, hemodynamic monitoring data are necessary to obtain a quantitative basis which, together with the operator's clinical criteria, can aid in proper decision-making.

15.3 Definitions and Hemodynamic Parameters

15.3.1 Definitions

Preload. The load or volume that distends the left ventricular end-diastolic volume (Figure 15.2). It is determined by the volume of blood at the end of ventricular filling (left ventricular end-diastolic volume, LVEDV) [1]. The LVEDV correlates with left ventricular end-diastolic pressure (LVEDP) in ventricles with normal compliance. In restrictive ventricles (ischemic or hypertrophic) a higher filling pressure is needed to have an adequate volume at the end of diastole. Pulmonary capillary wedge pressure (PCWP) indicates left ventricular preload. The central venous pressure (CVP) is the practical expression of right ventricular preload.

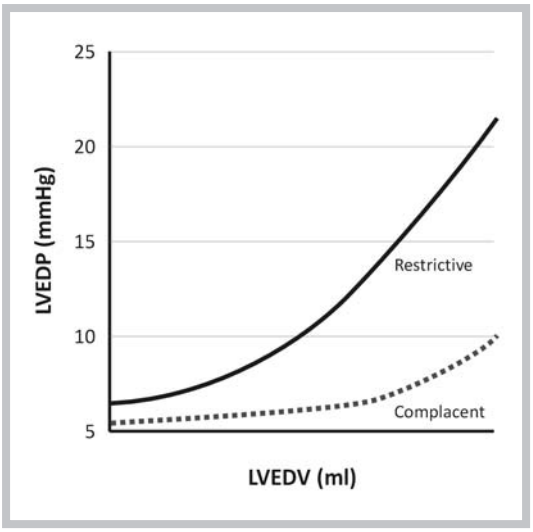

Figure 15.2. Preload: pressure/volume in complacent and restrictive ventricles.
LVEDV = left ventricular end-diastolic volume
LVEDP = left ventricular end-diastolic pressure

Contractility. The ability of cardiac muscle fibre to shorten after elongation. Prior knowledge of ventricular function through ventricular ejection fraction and fractional shortening provide useful baseline information in hemodynamic management. During monitoring the contractile capacity can be roughly related to the contractility index (CI) or the stroke volume index (SVI), although these parameters are also influenced by preload and afterload.

Measured variables	• Central venous pressure (CPV) • Systolic, diastolic, and mean pulmonary artery pressure (SPAP, DPAP, MPAP) • Pulmonary capillary wedge pressure (PW) • Mean arterial pressure (MAP) • Cardiac output (CO) (l/min) • Body surface area (BSA) in m^2
Calculated variables	• Cardiac index (CI) blood flow per minute per m^2 of BSA; normal value: 2.5 to 4.2 l/min/m^2 • Stroke volume (SV): CO/HR • Systolic volume index (SVI): CI/HR • Left ventricular systolic work (LVSW) = SV x MAP x 0.0144 • Left ventricular systolic work index (LVSWI) = SVI x MAP x 0.0144; normal value: 56±6 g/m^2/beat • Right ventricular systolic work (RVSW) = SV x MPAP x 0.0144 • Right ventricular systolic work index (RVSWI) = SVI x 0.0144 x MPAP; normal value: 8.8±0.9 g/m^2/beat • Systemic vascular resistance (SVR) = (MAP - CVP)/CO x 80 (dynes/s/cm^{-5}); normal value: 900-1400 dynes/sec/cm^{-5} • SVR index (SVRI) = (MAP – CVP)/CI x 80 (dynes/s/cm^{-5}) • Pulmonary vascular resistance (PVR) = (MPAP – PW)/CO x 80 (dynes/s/cm^{-5}); normal value: 150-250 dynes/sec/cm^{-5} • PVR index (PVRI) = (MPAP – PW)/CI x 80 (dynes/s/cm^{-5})
Metabolic variables	In addition to pressure and flow rate, tissue oxygenation parameters are also monitored: • Arterial oxygen content (CaO_2) = Hb × 1.34 × SaO_2 + (PaO_2 x 0.003): the amount of oxygen contained in 100 ml of blood • Oxygen delivery index (DO_2I) = CI x CaO_2 x 10: the amount of oxygen supplied to the tissues per m^2 of body surface per minute • Oxygen consumption index (VO_2I) = (C(a-v)O_2) x CO x 10: the amount of oxygen (ml) consumed globally per m^2 of body surface per minute
Hemodynamic parameters	• Heart rate (HR) • Mean arterial pressure (MAP) • Central venous pressure (CVP) • Mean pulmonary artery pressure (MPAP) • Wedge pressure or pulmonary artery wedge pressure (PW) • Cardiac output (CO) • Height and weight to calculate body surface area (BSA)
Calculated hemodynamic parameters	• Cardiac index (CI): CO/BSA (l/min/m^2); normal values: 2.5 to 4.2 l/min/m^2 • Stroke volume (SV): CO/HR • Systolic volume index: CI/HR • Left ventricular systolic work (LVSW) = SV x MAP x 0.0144 • Left ventricular stroke work index (LVSWI) = SVI x MAP x 0.0144; normal value: 56±6 g/m^2/beat • Right ventricular systolic work (RVSW) = SV x MPAP x 0.0144 • Right ventricular stroke work index (RVSW) = SVI x 0.0144 x MPAP • Normal value: 8.8±0.9 g/m^2/beat • Systemic vascular resistance (SVR) = (MAP - CVP)/CO x 80 (dynes/s/cm^{-5}); normal values: 900-1400 dynes/s/cm^{-5} • SVR index (SVRI) = (MAP – CVP)/CI x 80 (dynes/s/cm^{-5}) • Pulmonary vascular resistance (PVR) = (MPAP – PW)/CO x 80 (dynes/s/cm^{-5}); normal values: 150-250 dynes/s/cm^{-5} • PVR index (PVRI) = (MPAP – PW)/CI x 80 (dynes/s/cm^{-5})

Table 15.1 **Parameters in hemodynamic monitoring.**

A somewhat more specific parameter of contractility is the ventricular stroke work index.
Afterload. Determined by the resistance to ventricular ejection, which is opposed to ventricular emptying during systole [2,3]. Left ventricular afterload is expressed as systemic vascular resistance (SVR), which is directly proportional to the pressure difference between the two ends of systemic circulation (mean arterial pressure-central venous pressure, MAP-CPV) and inversely proportional to blood flow (cardiac output, CO). Right ventricular afterload is expressed as pulmonary vascular resistance (PVR), which is directly proportional to the pressure difference between the ends of pulmonary circulation (mean pulmonary artery pressure-pressure wedge, MPAP-PW) and inversely proportional to cardiac output.

15.3.2 Hemodynamic Parameters

Parameters in a hemodynamic profile include pressure and flow data, some measured directly and others calculated therefrom (Table 15.1).

15.4 Pressure Monitoring

Arterial blood pressure and central venous pressure are the most common parameters measured in the ICU patient.

15.4.1 Arterial Blood Pressure

Mean arterial pressure (MAP), the best parameter for assessing global perfusion pressure of all organs, should ideally be between 70 and 100 mmHg. The radial artery is most commonly used for intra-arterial catheter placement, but the brachial, femoral or pedal artery can also be used. In intra-aortic balloon counterpulsation, arterial blood pressure is measured with the same lumen of the balloon catheter.
Perfusion pressure requirements differ depending on the clinical situation and the organ in question. In the postoperative period after cardiac surgery, MAP must be >70 mmHg to ensure good perfusion of the bypass and good coronary blood flow (CBF), but it should be <100 mmHg to minimize postoperative bleeding. In a brain-injured patient with elevated intracranial pressure (ICP), however, MAP must be high enough to ensure adequate cerebral perfusion pressure (CPP). A patient in postoperative renal transplant requires good perfusion pressure to maintain adequate glomerular filtration rate of the graft.

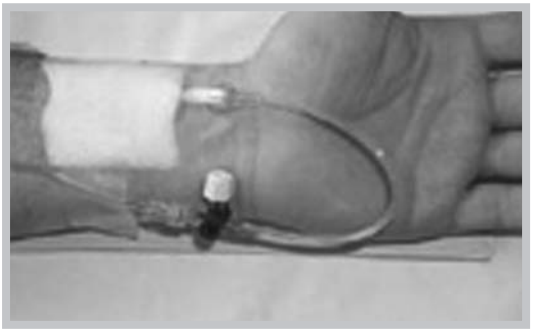

Figure 15.3. Radial artery catheter.

In addition to MAP, systolic blood pressure (SBP), diastolic blood pressure (DBP) and differential pressure (DP) allow us to infer a particular hemodynamic situation. A low diastolic pressure with a high differential may generate (besides aortic insufficiency) a pattern of vasodilatation and high cardiac output (sepsis). By contrast, a small differential pressure, with impingement of the SBP and DBP, can generate a pattern of low cardiac output (hypovolemia, cardiogenic shock).

Figure 15.4. Curve of arterial blood pressure (MAP).

The morphology of the curve offers additional information. Uneven and irregular arterial pressure waves can be seen in certain arrhythmias such as atrial fibrillation; unlike the ECG tracing, the monitor shows a higher pulse rate, i.e., the effective heartbeat is greater. And it also shows the variation in the amplitude of the pulse wave in relation to breathing [4], which is very evident in a patient with hypovolemia or cardiac tamponade (pulsus paradoxus: systolic pressure variation >12 mmHg between inspiration and expiration). This is magnified even more in patients on mechanical ventilation [5]. Pronounced respiratory variation of the pulse wave is also observed in patients with airflow obstruction. Therefore, bedside analysis of the arterial pressure wave is important in hemodynamic evaluation (Figures 15.3 and 15.4).

15.4.2 Central Venous Pressure

The introduction of central venous pressure monitoring in 1962 was the first step in bedside hemodynamic monitoring. The most common vascular access in ICU patients is via subclavian or internal jugular vein puncture. The distal end should be located in the distal part of the vena cava, without entering the right atrium or touching the tricuspid valve, as this can cause arrhythmias. The catheter serves for the infusion of solutions and drugs and to measure central venous pressure (CVP). This is an indicator of the balance between systemic venous return and right ventricular (RV) function. Its normal value is between 8 and 12 mmHg or, more widely, between 5 and 15 mmHg, although this "normal" value may differ depending on the patient's clinical situation. CVP is not correlated with right ventricular end-diastolic volume in critically ill patients, and it does not correlate with left ventricular preload in patients with right ventricular failure or pul-

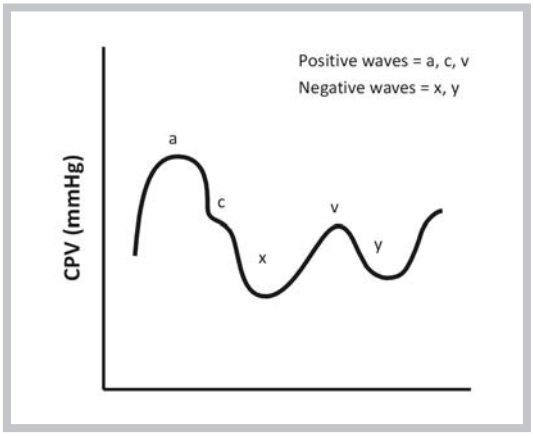

Figure 15.5. Morphology of the central venous pressure (CPV) curve.

monary vascular disease; however, in many cases when these values are extremely low or high, CVP can reflect a reduction or an increase in relative or absolute intravascular volume. The respiratory variation of CVP is due to a drop in CVP during inspiration, which is more marked in a setting of hypovolemia [6]. The greater the drop in CVP, the greater the need for volume replacement. Despite these limitations, CVP in the hands of an experienced operator is a useful parameter in the hemodynamic management of patients in intensive care. Figure 15.5 shows the standard morphology of the CPV curve.

15.5 Pulmonary Artery Pressure and the Swan-Ganz Catheter

The development and clinical application of a pulmonary artery catheter introduced by Swan and Ganz in 1970 provided a relatively simple, safe, fast and accurate way to measure pulmonary artery pressure and to estimate left ventricular end-diastolic pressure through the measurement of wedge pressure or pulmonary capillary wedge pressure.
Use of the Swan-Ganz catheter allows the calculation of cardiac output by the thermodilution method, as well as sampling of mixed venous blood from the pulmonary artery to assess systemic oxygenation.
The primary data are the measured variables; by applying mathematic formulas, other variables called secondary or calculated variables are obtained which complete the spectrum of hemodynamic information (Table 15.1) [7,8].
Later refinements to the original catheter have increased its usefulness, so that we can now continuously monitor cardiac output, determine the right ventricular ejection fraction, continuously measure right atrial pressure and oxygen saturation of mixed venous blood. There are also models that incorporate electrodes that can stimulate the right atrium or the right ventricle like a pacemaker.

15.5.1 Indications for Pulmonary Artery Catheterization

While there are no absolute rules that define the need for a Swan-Ganz catheter, there are clear recommendations for its use in certain contexts, such as acute myocardial infarction (AMI) with hemodynamic compromise. Its usefulness in other situations, such as routine use in cardiovascular surgery patients remains controversial. It can be useful in patients presenting with patterns of shock or severe hemodynamic instability or situations where the physician's experience suggests its use is warranted.

- Diagnosis or guide in the treatment of acute myocardial infarction:
  - Progressive heart failure, acute pulmonary edema.
  - Cardiogenic shock or progressive hypotension [9].
  - Mechanical complications (acute mitral insufficiency).
  - Doubt about the hemodynamic pattern: peripheral hypoperfusion or hypotension unresponsive to fluid administration without pulmonary congestion.
  - Patients with suspected AMI with hemodynamic compromise of the right ventricle.
- Determining the cause of dyspnea and hypoxemia:
  - Patients with coexisting cardiac and pulmonary disease (diagnostic difficulties and therapeutic dilemmas).
  - Patients with AMI and shock of unknown cause.
- Refractory heart failure:
  - Patients with dilated cardiomyopathy, hospitalized for decompensated heart failure, difficult to manage, requiring high doses of inotropes.

- Suspected pulmonary embolism with hemodynamic compromise.
- Septic shock [8,10,11], traumatic shock [12], vasoplegia.

Relative indications are:

- Assessment and management of patients with cardiac tamponade.
- Recurrent pulmonary embolism or pulmonary hypertension of unknown etiology [13].
- Perioperative monitoring in cardiovascular surgery patients.
- Acute Respiratory Distress Syndrome (ARDS).
- Assessment of pulmonary hypertension.
- Cardiac, pulmonary and cardiopulmonary pretransplant evaluation.

Most contraindications are relative and refer to an increased likelihood of complications during catheter placement. The technique is contraindicated in:

- Patients with severe coagulopathy or under thrombolytic therapy: high risk of bleeding.
- Patients with prosthetic tricuspid valve: the catheter can damage or cause valve dysfunction.
- Patients with implantable pacemakers: the catheter can become inadvertently displaced or knotted.
- Patients with pulmonary hypertension: high incidence of pulmonary artery rupture.
- Patients with right-sided endocarditis or vena cava system thrombosis.

15.5.2 Characteristics of Pulmonary Artery Catheters

Catheters can be used in children or adults. Catheters come in lengths between 60 and 110 cm and sizes from 4.0 to 8.0 F, balloon inflation volume 0.5 to 1.5 ml, and balloon diameter 8 to 13 mm. Made of polyvinyl chloride, they are flexible at room temperature and even at body temperature.

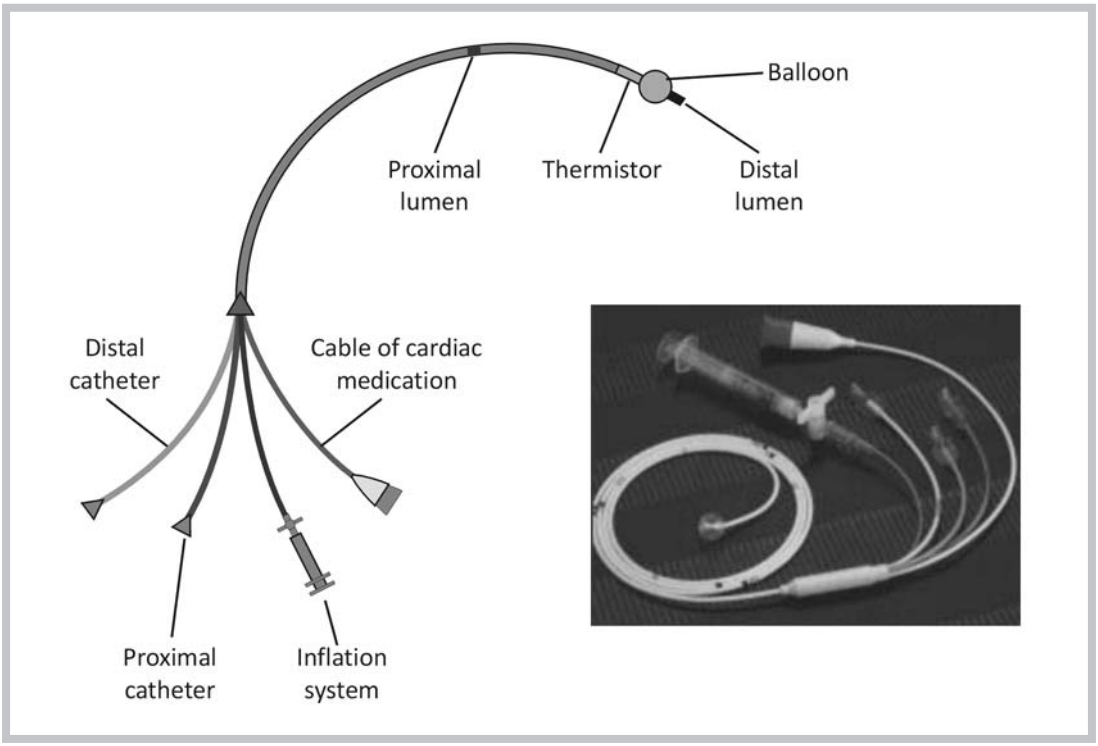

Figure 15.6. **Conventional Swan-Ganz catheter and optic fibre catheter.**

The catheter has markings every 10 cm consisting of black narrow bands from 1 to 4, at 10 to 40 cm, respectively. At the 50-cm mark the band is thicker than the others; the fine bands mark 60, 70, 80 and 90 cm. This helps to determine the location of the catheter tip during placement.
The most widely used conventional catheter is 4 lumens: distal (PA), proximal (RA), thermistor (thermodilution) and via inflation (balloon wedge) (Figure 15.6).
Other catheters incorporate various different features:

- 5 lumens (additional proximal lumen for fluid administration).
- Fibre optic catheter for continuously measuring mixed venous saturation in the pulmonary artery.
- Electrodes for use as a pacemaker.
- An additional lumen for the introduction of a temporary pacemaker catheter.
- A thermocouple to calculate right ventricular ejection fraction by measuring the end-systolic and end-diastolic volumes [14-16].
- A rapid-response thermocouple for continuous measurement of cardiac output by thermodilution.

15.5.3 Vascular Access for Swan-Ganz Catheter Placement

Operator experience dictates the vascular access site selected. In some patients, the depletion of vascular access or the presence of coagulation disorders, burns, or other conditions requires the use of alternative approaches.
Subclavian vein access has the advantage that it is easily accessible, allowing free movement of the arm and neck, with little risk of catheter displacement and reduced risk of thrombosis. The disadvantages are the increased risk of air embolism, puncture or laceration of the subclavian artery with hemorrhage because compression is difficult to apply. It may also cause pneumothorax, emphysema, especially in patients with mechanical ventilation with positive end-expiratory pressure (PEEP) and phrenic nerve or brachial plexus injury.
Internal jugular vein access has the advantage of direct access to the superior vena cava and right atrium, minor risk of catheter movement, low potential for thrombotic complications, lower incidence of arterial puncture and pneumothorax. The disadvantages are the increased risk of air embolism, puncture or laceration of the carotid artery and puncture of the trachea or the endotracheal tube cuff.
Femoral venous access is readily available but increases the chance of infection owing to its proximity to the inguinal area. It is contraindicated in patients with abdominal sepsis; it can impede optimum healing. The involved limb needs to be immobilized, increasing the risk of deep vein thrombosis and pulmonary embolism.
Peripheral venous access via the external jugular vein or basilic vein carries less risk of pneumothorax and can directly control hemostasis. However, it is associated with a higher incidence of infections, involves disabling a vein, and placement is more difficult because central venous access is not direct and there is greater risk of catheter malposition.

15.5.4 Placing the Swan-Ganz Catheter

First of all, explain the procedure to the family and the patient. Before arming the circuit, with 3-way keys and applying enough pressure, the transducer is attached to the patient's arm at the midaxillary line. It is important to proceed in a systematic fashion:
Before catheter placement:

- Verify that the ball is intact.
- Corroborate lumen patency.
- Check thermistor integrity.
- Prepare 2 bottles of saline solution (500 cc) plus 2500 U of heparin:
  - Bottle 1: high-pressure circuit (150-300 mmHg), with Intraflow Flush and Macrodrip. Venous extension connected to the distal lumen of the catheter (PA).
  - Bottle 2: venous extension connected to the proximal lumen of the catheter (RA).
- The transducer is placed at the level of the right atrium
- Calibrate the transducer with atmospheric pressure (zero).

Insert the catheter 40 cm into the brachial vein or 15 cm if using a subclavian or internal jugular puncture. Advance the catheter as guided under fluoroscopy to the pulmonary artery; alternatively, catheter introduction is guided by blood flow.

- Subclavian puncture: at 15 cm, should be the RA curve.
- Central venous pressure: check the RA curve and pressure.
- Inflate balloon with 0.5-1 ml of air.
- Withdraw 2-3 ml of blood with heparinized syringe.
- Scroll down until RV curve is obtained.
- Check the RV pressure curve.
- Normal RV pressure: 25/6 (15) mmHg.
- Blood samples for oximetry.
- Wash the catheter with the high-pressure circuit.
- Advance the catheter to the PA: there should be a sudden increase in pulmonary diastolic pressure.
- Check PA pressure curve.
- Normal pulmonary pressure: 25/10 (18) mmHg.
- Obtain samples for oximetry.
- Continue advancing the catheter balloon inflating it slowly.
- The flow is transported to a segmental branch of the pulmonary artery.
- Locking occurs and balloon pulmonary capillary wedge pressure (PW) is recorded.
- The balloon is deflated and PA pressure curve must be seen again.
- Verify proper catheter position with a chest X-ray.

15.5.5 Characteristic Curves

Figure 15.7 illustrates the typical evolution of the curve morphology.

Right atrium (RA). The curve shows waves (a, c and v) and troughs (y and x). In the absence of tricuspid valve disease, the average pressure of the RA is equal to right ventricular end-diastolic pressure, since both are connected at the time of valve opening.

During ventilation, positive pressure increases the pressure in the RA, whereas in spontaneous breathing, negative intrathoracic pressure decreases the pressure. Therefore, the pressure should be read to the end of expiration.

Right ventricle (RV). When the tip of the catheter enters into the right ventricle, there is a significant change in the structure of the pressure wave, becoming 3 to 4 times greater than that of the RA. Normal values are between 0 and 8 mmHg diastolic pressure, and 20 to 30 mmHg systolic pressure. At this time, there is the highest occurrence of arrhythmias.

Pulmonary artery (PA). When the catheter enters the PA, the curve changes again with a rise in diastolic pressure. The presence of a dicrotic notch on the descent of the curve indicates closure of the pulmonary valve. PA diastolic pressure is higher than RV pressure, which is isolated during valve closing. Normal diastolic pressure is approximately 10 mmHg and systolic pressure between 20 and 30 mmHg.

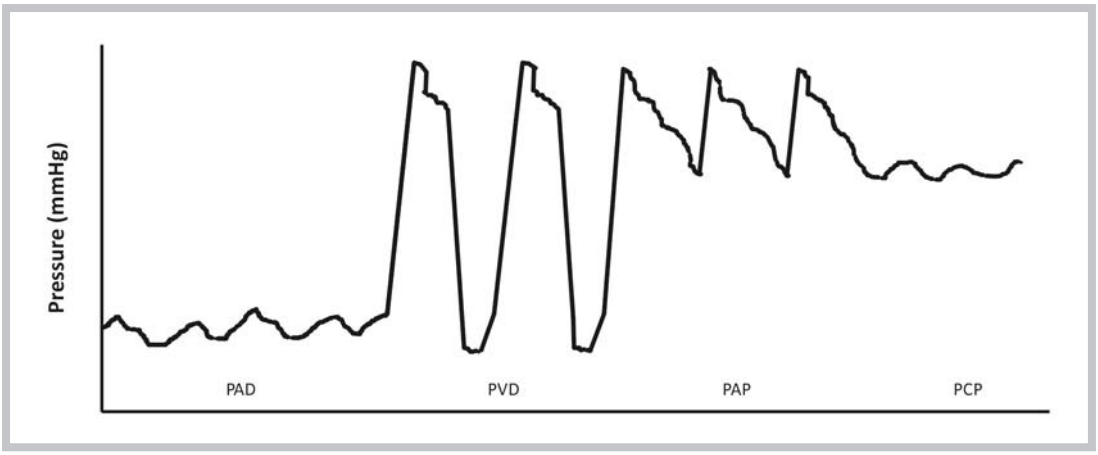

Figure 15.7. Typical pressure curves during Swan-Ganz catheter placement.

Pulmonary artery wedge pressure, pulmonary capillary wedge pressure (PW). With locking of the catheter, the curve flattens when it ceases to be pulsatile pressure. The blood flow is interrupted in a small portion of the pulmonary circulation and is thus connected to the lumen distally, reflecting the left atrial (LA) pressure, which is usually between 5 and 12 mmHg. The mitral valve opens during diastole. The catheter lumen is located in communication with a column of blood that reaches the left ventricle, thus indirectly measuring the left ventricular end-diastolic pressure (LVEDP). Therefore, there is a direct correlation between the PW, LA pressure and the LVEDP [17,18].

Causes damping of the curve. Any of the following may cause damping or defects in the curves:

- Bubbles in the system.
- Clots at the tip of the catheter.
- Transducer failure.
- Bad circuit connection.
- Catheter located distally.
- Lumen contact with vessel wall.

Guidelines for good results. The following items should be considered in pressure measuring:

- Remove air bubbles and blood clots.
- Discard bent or elongated catheters.
- Perform internal and external calibration with a mercury manometer.
- Check the calibration 3-4 times per day.
- Reset to zero before each measurement.
- Measure pressure at the end of expiration.

15.5.6 Measurement of Cardiac Output

The method currently used for cardiac output measurement is thermodilution [19,20]. For this, the computer records the patient's blood temperature from the thermistor incorporated in the catheter, and the temperature of the solution to be injected is recorded by an external thermistor near the solution, which is injected at room temperature (usually 25 °C). The difference between two temperatures should be >10 °C. The amount of solution (usually 10 cc) is entered into the computer, which subsequently determines a constant calculated from the preconditions and the catheter type entered into the program.

The solution is injected rapidly (3 to 5 seconds). The transient drop in blood temperature is recorded and transmitted by the thermistor, generating a thermodilution curve (time-temperature). The normal cardiac output curve has a rising portion, with a rapid increase reaching a peak followed by a gentle descent to return to baseline. The peak represents the lowest recorded temperature and also determines the temperature gradient between the venous blood and the injected solution. The downward slope of the curve represents the time of return to basal blood temperature. Thus, from the volume and temperature of the solution injected, the blood temperature and thermodilution curve, the software calculates the blood flow expressed as cardiac output (CO).
To obtain good results, the following guidelines should be followed:

- Adjust the constant of the computer according to the features used.
- Secure the position of the distal thermistor and the right atrium.
- Use 10 ml of water at room temperature, provided the temperature difference between the environment and the patient's core temperature is >10 °C.
- The solution should be injected rapidly and smoothly.
- The thermodilution curve should be harmonious.
- Rapid infusion of solution should not be performed during measurement.

15.5.7 Complications Associated With the Swan-Ganz Catheter

Atrial and ventricular arrhythmias due to mechanical stimulation of the endocardium may occur during placement, retention or removal of the catheter. The incidence of arrhythmias is higher in patients with myocardial ischemia, heart failure, shock, hypoxemia, hypocalcemia, hypocalcemia, hypomagnesemia and difficult placement of the catheter.
Right bundle branch block may occur due to mechanical irritation of the conduction tissue during catheter insertion. In general, this is not important, unless the patient has a history of left bundle branch block.
Balloon rupture. The absence of resistance to soft balloon inflation, the difficulty of enclaves and the aspiration of blood, all indicate balloon rupture. The average life of the ball decreases with excessive manipulation, averaging between 70 and 80 inflations.
The risks to the patient are air or balloon fragment embolism.
Catheter knotting occurs more frequently when there is enlargement of RA or RV, or the presence of another catheter. In some cases, the catheter can be cut and left in place or removed with a hemodynamic catheterization procedure or surgery.
Infections. Factors that increase the risk of infection include the location of an intracardiac catheter, excessive handling, the need for catheter repositioning, longer use, adherence of microorganisms to it, and severely critical patients. Since the risk of infection increase after 48 hours, the catheter must not remain for longer than necessary.
Thromboembolism. Thrombi can form in any part of the catheter, including the tip. The thrombi can directly occlude the PA branch, resulting in pulmonary ischemia or pulmonary embolism. Subclavian, internal jugular or vena cava thrombosis can also occur, with serious consequences.
Pneumothorax associated with venous access. The postinsertion chest X-ray should be carefully evaluated not only for correct catheter position but also to rule out pneumothorax.
Ischemia and pulmonary infarction result from catheter locking due to malposition or thrombus formation.
Pulmonary artery rupture may result in a small vascular injury or massive hemorrhage. It can be caused by catheter migration, tampering or balloon overinflation. It is more com-

Clinical situation	Hemodynamic pattern	Comments
Hypovolemic shock	↓PW, ↓CO, ↓MAP, ↑SVR	Peripheral vasoconstriction
Cardiogenic shock	↑PW, ↓CO, ↓MAP, ↑SVR	Severe heart disease
Septic shock	↓MAP, ↑MPAP, ↑PVR, ↑CO, ↓SVR	Warm skin, fast capillary refill
Cardiac tamponade	↑CVP, ↑PW, ↓CO, ↓MAP	Pulsus paradoxus, ↓y wave ↓x wave
RV dysfunction	↑CPV > 10, ↓CO, ↓PAP, CPV/PW >0.8	Deep y wave
Massive pulmonary thromboembolism	↓CO, ↓MAP, ↑PMAP, ↑PVR, normal PW	Normal PW, ↑SPAP, ↑DPAP
Chronic pulmonary hypertension	↑CVP, ↑RVSP,↑PMAP, ↑PVR, normal PW	Normal left-side pressures Elevated MPAP and RVSP
Constrictive pericarditis	↑CPV, ↑PW, dip-plateau in RV	Pulsus paradoxus, Kussmaul sign
Restrictive cardiomyopathy	PW > CVP	Echo Doppler for better diagnosis
Tricuspid regurgitation	↑CPV, ↑RVEDP	Prominent v wave
Septal defect	Increased PaO_2 of RA and RV to PA	RV CO >LV CO
Acute mitral regurgitation	PW, ↑v wave	Prominent v wave
Non cardiogenic pulmonary edema	Normal PW	Normal cardiac size

Table 15.2. Hemodinamic patterns.

mon in patients with pulmonary hypertension. It can manifest as intrapulmonary hematoma, mild hemoptysis, massive bleeding, and even shock and death.
The application of positive end-expiratory pressure (PEEP) can decrease bleeding. In extreme cases, emergency thoracotomy with resection of the affected lung lobe may be necessary.

15.5.8 Hemodynamic Patterns

From an analysis of hemodynamic monitoring variables and the clinical situation, we can distinguish different profiles or hemodynamic patterns. In this way, a particular diagnostic and prognostic category can be defined and treatment oriented accordingly. In some cases, such patterns can differentiate between hemodynamic variants of major syndromes, including shock, further subdivided into hypovolemic, septic, cardiogenic and mechanic shock.
In other cases, the patterns may allow us to identify different hemodynamic situations within the same disease, thus aiding in establishing prognosis and initiating a specific therapeutic approach.
Table 15.2 shows various different hemodynamic patterns.

15.5.9 Hypovolemic Shock

Hypovolemia refers to a reduction in intravascular volume due to hemorrhage or fluid and electrolyte loss from various causes. It implies a fall in CVP and PW, i.e., preload, with a consequent reduction in stroke volume. The compensatory response of sympathetic discharge (tachycardia, vasoconstriction) may initially maintain MAP and CO. Arterial hypotension (MAP <60 mmHg or drop >40 mmHg from baseline MAP), with impaired peripheral perfusion (pallor, slow capillary refill) and organ perfusion pressure

(oliguria, altered consciousness) form a hypovolemic shock pattern. Tissue hypoperfusion can cause lactic acidosis, indicating anaerobic tissue metabolism. The oxygen debt that is generated depends on shock duration and depth, and thus, the possibility of recovery, the degree of organ dysfunction or multiple organ failure and survival or death. The therapeutic response is high-flow infusing volume with an appropriate solution for the particular deficit (crystalloids, colloids, blood products), as well as life-sustaining treatment in shock.

15.5.10 Septic Shock

Septic shock is caused by a fall in SVR due to vasodilatation, with a loss in vasomotor tone and impaired microvascular blood flow (hypoperfusion, ischemia). The causes underlying vasodilatation are related to the action of inducible nitric oxide synthase and activation of cellular elements (leucocytes, platelets) which are part of the inflammatory response. It also produces an increase in cardiac output and an increase in mixed venous oxygen saturation in the pulmonary artery. PW may initially be low due to fluid loss which these patients manifest for various reasons, and it can be normalized in initial resuscitation. There is also impaired left ventricular contractility which is masked by the decrease in afterload. This phase, also called hyperdynamic shock, is followed in some cases by a hypodynamic phase, with a decrease in cardiac output and increased SVR, which is known as the cold-shock phase.

15.5.11 Cardiogenic Shock

In 1977 Forrester proposed a classification based on hemodynamic monitoring of patients after acute myocardial infarction (AMI) [21-23], which is still valid today. Different hemodynamic patterns (from I to IV) are generated according to Swan-Ganz catheter measurements. This classification scheme takes account the following parameters cardiac index (CI) (higher or lower than 2.2 l/min/m^2) and pulmonary capillary wedge pressure (PW) (more or less than 18 mmHg). The four hemodynamic patterns carry a different prognosis (mortality <5% in uncomplicated AMI and mortality >70% in cardiogenic shock) (Figure 15.8):

- Hemodynamic Pattern I. CI >2.2 l/min/m^2 and PW <18 mmHg. Normal hemodynamics. Mortality 2-5%. General treatment for AMI.
- Hemodynamic Pattern II. CI >2.2 l/min/m^2 and PW >18 mmHg. Heart Failure. Mortality 12%. Treatment with vasodilators and diuretics.
- Hemodynamic Pattern III. CI <2.2 l/min/m^2 and PW <18 mmHg. Hypovolemia, low cardiac output. Mortality 33%. Treatment with volume expansion, eventually with inotropics.
- Hemodynamic Pattern IV. CI <2.2 l/min/m^2 and PW >18 mmHg. Cardiogenic shock. Mortality 70%. Treatment with vasodilators if possible, diuret-

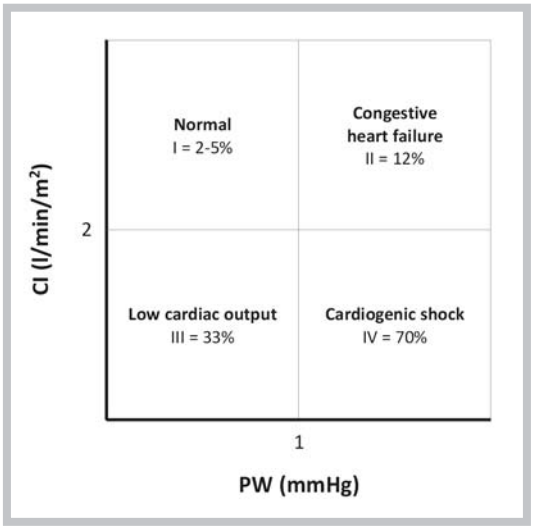

Figure 15.8. Hemodynamic Patterns in AMI (Forrester).

ics, eventually with inotropes, intra-aortic balloon counterpulsation as therapy or as support in revascularization (angioplasty or surgery).

Right ventricular infarction has a particular hemodynamic pattern [24].

15.5.12 Hemodynamic Monitoring in Heart Failure

The Evaluation Study of Congestive Heart Failure and Pulmonary Artery Catheterization Effectiveness (ESCAPE) trial [25,26] compared therapeutic management guided by clinical variables versus management guided by hemodynamic monitoring. There were no significant differences in the endpoints of death or hospitalization at 6 months follow-up. However, the results obtained in the monitored group may have been influenced by the heterogeneity of management.

There is a patient population with a clear indication of hemodynamic monitoring (advanced heart failure, unstable or refractory to treatment). Hemodynamic monitoring-adjusted therapy in these patients can achieve hemodynamic values associated with increased survival.

Building on Forrester's hemodynamic patterns, Stevenson devised a grid of patterns for clinical evaluation in patients with heart failure [27,28]:

Patients with normal perfusion (warm), types A and B, (Forrester I and II) and hypoperfused patients (cold) L and C (Forrester III and IV), above or below the cardiac index limit (2.2 l/min/m^2).

Also considered were patients without pulmonary congestion (dry), types A and L, and those with pulmonary congestion (wet), types B and C, according to PW below or above 18 mmHg.

Most patients hospitalized with decompensated heart failure were admitted with a humid/hot clinical profile (type B pattern) which correlates with a type II hemodynamic profile, i.e., a cardiac index >2.2 l/min/m^2 and pulmonary capillary pressure (PCP) >18 mmHg.

Patients with decompensated chronic heart failure can benefit from hemodynamic monitoring [29,30] since it does not increase mortality and significantly improves symptoms. The objective of improving quality of life is important in patients with advanced heart failure.

Figure 15.9 illustrates the correlation between hemodynamics and clinical characteristics in heart failure.

15.5.13 Hemodynamic Patterns in Critically Ill Patients

Based on the patterns developed from hemodynamic cardiology, we can define a set of hemodynamic profiles involving the global universe of critically ill patients. From a practical point of view, hemodynamic situations in intensive care can be divided using as benchmarks the cardiac index (CI) and pulmonary capillary wedge pressure (PW).

Cardiac index values between 2.0 and 3.5 l/min/m^2 are considered normal; pulmo-

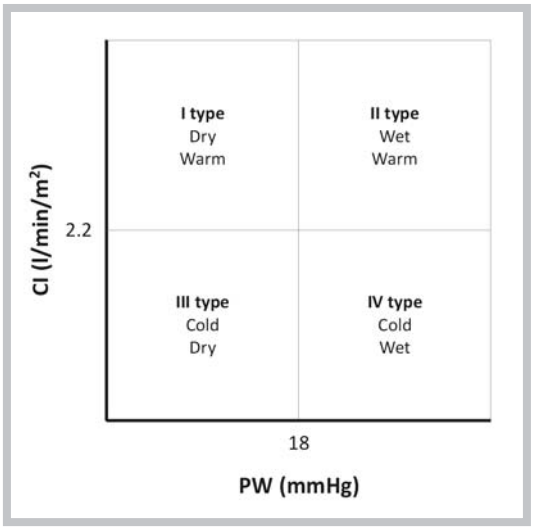

Figure 15.9. Correlation between hemodynamics and clinical characteristics in heart failure.

nary capillary pressure between 8 and 18 mmHg is considered normal.

The lower cut-off value of the cardiac index <2.0 l/min/m^2, as an indicator of circulatory hemodynamic patterns, is arbitrary in pathophysiological terms, and should be demonstrated by tissue hypoxia below this limit. The correlation of tissue perfusion factors such as gastric intramucosal pH or elevated lactic acid levels does not always hold in this situation [31]. The point is that we know many details of the oxygen supply to the tissues, but little about their metabolic oxygen need.

Another important indicator of global tissue oxygenation is the mixed venous oxygen saturation in the pulmonary artery measured continuously. However, it is difficult to measure this on a routine basis. In the postoperative period after cardiac surgery there is a correlation between the decrease in cardiac output and mortality, with a cardiac index <2 l/min/m^2, a point below which mortality significantly increases [32,33]. A cardiac index >3.5 l/min/m^2 is considered high, leading to hyperdynamic circulatory patterns.

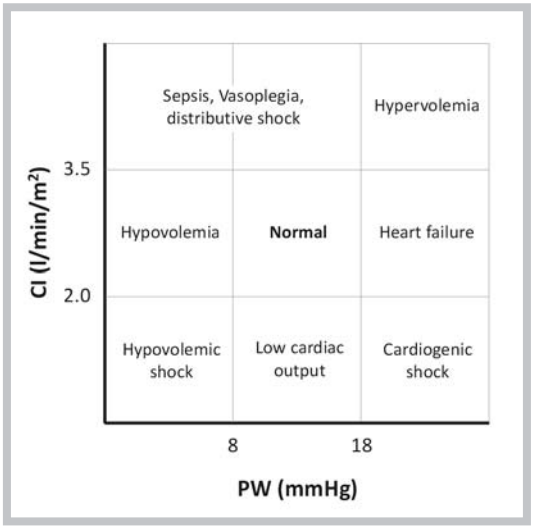

Figure 15.10. Hemodynamic patterns in ICU patients.

We consider pulmonary capillary wedge pressure (PW) values between 8 and 18 mmHg as normal. Patients with PW <8 mmHg and hemodynamic instability (hypotension) improve rapidly with intravascular volume expansion. Otherwise, patients with PW >18 mmHg are generally in volume overload.

Nine hemodynamic patterns are distinguished (Figure 15.10).

These nine patterns are defined by a parameter of preload (PW) and another that results from stroke volume and heart rate, but it can also be roughly considered as a parameter of contractility. Systemic vascular resistance is increased in the lower quadrants, usually increased in the middle lateral quadrants, and reduced in the upper quadrants.

The central quadrant is considered **normal**, with normal values of both CI and PW.

Patients with normal CI and low PW can be considered **hypovolemic**, but do not necessarily require volume expansion if the global perfusion parameters (peripheral perfusion and diuresis) are adequate. In some cases it is necessary to maintain a preload within the limits and to expansion with solutions, as in the maintenance of brain-dead potential organ donors who have polyuria and diabetes insipidus or in patients with postrenal transplant polyuria.

Patients with normal CI and high PW fall within the category of *congestive* **heart failure or pulmonary congestion** due to volume overload with impaired contractility. The proper treatment in these patients is with diuretics, vasodilators and eventually inotropics.

The upper quadrants include patterns of **hyperdynamic circulation** with increased CI. Patients with normal or low PW are generally vasodilated, with low SVR and increased CI, as in septic, distributive or traumatic shock. Vasoplegia also occurs in some patients in the postoperative period after cardiac surgery. In patients with low PW we must correct the hypovolemic component with volume expansion and then assess the response. The use of vasopressors such as norepinephrine, with its alpha dominant effect, is the treatment of choice to increase SVR in these patients, and thus avoid severe hypotension.

Patients with high CI and PW fall into the quadrant of **hypervolemia**, reflecting lung congestion. Usually, these patients are hypertensive and there is a decrease in SVR to compensate the increase in CI. As a typical example, here we can categorize patients with acute renal failure. Vasodilators may be used if the patient is hypertensive or presents with severe pulmonary congestion and dyspnoea. Diuretics and hemofiltration or eventually hemodialysis are necessary to remove the fluid overload.

The lower quadrants include low cardiac output states.

Patients with low CI and low PW can be categorized as having **hypovolemic shock** (shock involves clinical criteria for arterial hypotension and hypoperfusion). Volume expansion is the obvious therapeutic resource, in addition to treating the cause of volume loss.

Patients with low CI and high PW fall into the cardiogenic shock quadrant.

An interesting group comprises patients with low CI and normal PW. This pattern is called simply low cardiac output.

Low cardiac output (LCO) syndrome is well described in postoperative cardiac surgery [32,33] although it may be observed in other contexts as well. The reported prevalence (10-15%) varies widely according to the diagnostic criteria [32,34,35].

The development of LCO may be due to many causes that affect preload, contractility, afterload and heart rate. But the most likely mechanism is systolic and diastolic dysfunction associated with left ventricular ischemia and reperfusion phenomena which produce varying degrees of myocardial injury and stunning. The underlying conditions can be determined by the degree of previous ischemia, defects in intra-operative myocardial protection, incomplete revascularization, and prolonged cross-clamping time, which are closely related to peri-operative ischemic injury. However, other risk factors not strictly related to this may also be relevant to the development of LCO.

The low cardiac output syndrome is usually associated with hypotension and hypoperfusion signs (oliguria, cold extremities, acrocyanosis and metabolic acidosis).

The reported mortality is 10-40%, with a high rate of morbidity (renal failure, prolonged mechanical ventilation, prolonged hospitalization), and a consequent increase in costs.

While the strategies for myocardial protection and surgical technique, including off-pump surgery, have improved in recent years, the risk of patients undergoing heart surgery has also increased, so it is likely that the morbidity associated with this type of surgery has not changed or perhaps even increased.

Strategies to reduce the incidence and impact of low cardiac output include improved methods of myocardial protection in high-risk patients. Moreover, the early detection and aggressive management of patients who develop LCO are critical to minimize the disruption of tissue perfusion that generates the morbidity associated with this complication.

Management includes optimizing the preload by bringing the PW to a value high enough to achieve good pressure/volume for good filling of these ventricles, usually with restrictive diastolic dysfunction. It is also necessary to use inotropic drugs and inodilators (dobutamine, amrinone, milrinone) [36]. In general, vasodilators cannot be given to reduce afterload due to hypotension and vasopressors may even be required.

Usefulness and limitations of using the scheme of nine hemodynamics patterns

Patients with mechanical shock (cardiac tamponade, tension pneumothorax) and right ventricular failure are excluded from this scheme; these situations and should be taken into account when assessing a patient in shock.

While the limits for determining these hemodynamic patterns are somewhat arbitrary, they allow us to categorize patient populations with different degrees of risk and mortality.

These hemodynamic situations can evolve over time [37]. The therapeutic goal is to take the patient to a normal central quadrant, although this is not always possible or not convenient for the patient.

Remember, finally, we treat patients, not numbers. The purpose of hemodynamic monitoring is to provide a quantitative basis which, together with clinical criteria, upon which we can make the best decisions for patient's benefit.

16 Cardiac Arrhythmias in Nervous System Disorders

Guillermo Mazo [1]

[1] Medico Cardiologo, Electrofisiologo. Miembro adscripto SAC, Miembro titular SADEC, Presidente distrito Catamarca SAC, Argentina

16.1 Introduction

First described in detail by neurosurgeon Harvey Cushing in 1901, the discovery of the Cushing phenomenon led to the recognition of interactions between neurological events and their impact on the cardiovascular system. Central nervous system (CNS) insults can induce abnormalities in heart morphology and rhythm.

Neurological diseases can be detected directly at the heart, as a consequence of genetic and electrolytic changes, or indirectly through changes in the autonomous nervous system or the neurohormonal system. In addition, arrhythmias can cause neurological disease through the increase of thrombogenesis or the reduction of blood flow (cardiac arrest, bradycardia, etc.).

16.2 Stroke

Traumatic brain injury, acute ischemic stroke and hemorrhagic stroke have been associated with arrhythmias. They may be related to autonomous nervous system disorders affecting the cortical structures, particularly the insula (resulting in cardiovascular malfunction). This region may be involved in the control of heart rhythm and rate. Proarrhythmic changes in the cardiac sympathetic-vagal balance have been described after an event involving insula lesions. Cardiac function is modulated by the CNS in two ways: indirectly via humoral mediators such as adrenaline and noradrenaline and directly via the afferent effects of the sympathetic and parasympathetic system.

Hypothalamic lesions frequently result in an increase in catecholamine release and autonomic tone. These changes cause arterial hypertension, an increase in oxygen consumption and vessel spasm, leading to characteristic electrocardiographic (ECG), echocardiographic, enzymatic and histological changes, with subendocardial ischemia, microhemorrhage and focal necrotic lesions.

Hypokalemia is associated with prolongation of the QT interval. Subarachnoid hemorrhage is most often related to ECG changes (25-80%). Closed cranial trauma can produce ECG changes similar to subarachnoid hemorrhage. The ECG alterations most frequently associated with subarachnoid hemorrhage are: ST-T depression, T-wave inversion, U-wave prominence, and prolongation of the QT interval. A wide variety of arrhythmias have been described, such as sinus tachycardia, sinus bradycardia, auricular fibrillation, paroxysmal auricular tachycardia, ventricular extrasystolia, ventricular tachycardia, ventricular fibrillation and first, second and third-degree atrioventricular (AV) block.

Such changes have also been described for ischemic accidents, although in this group of patients the relationship is difficult to establish because of the major prevalence of coronary disease and arteriosclerosis. Typical changes are QT interval prolongation, ST disorders, and T- and U-wave abnormalities.

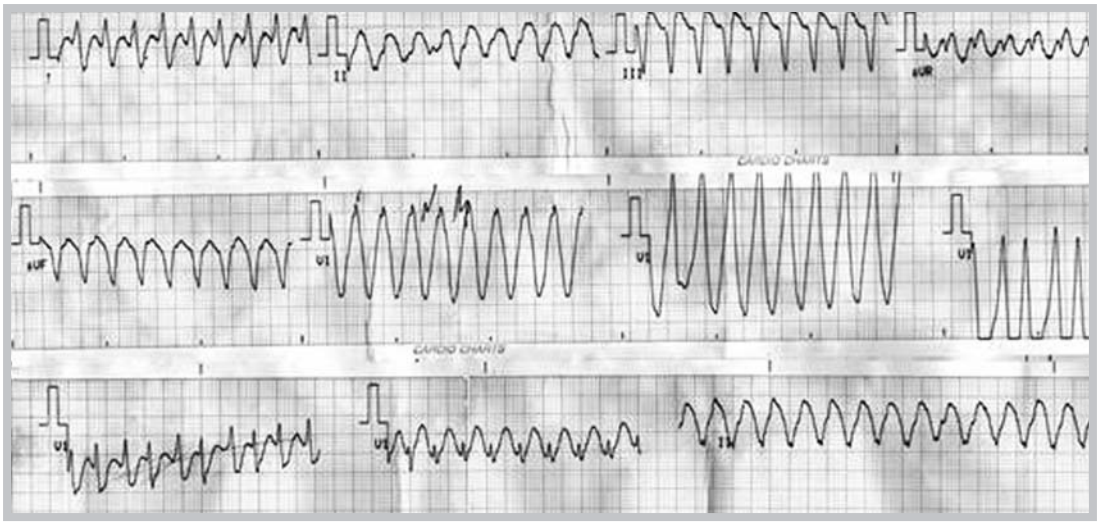

Figure 16.1. An episode of sustained monomorphic ventricular tachycardia.

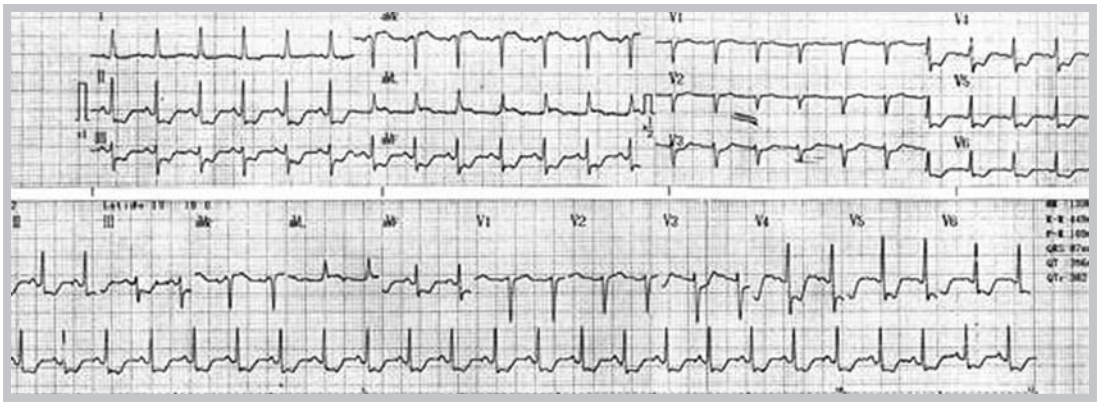

Figure 16.2. 36-year-old patient with traumatic brain injury and inferolateral ST-T depression without angiographically significant coronary lesions.

An increase in intracranial pressure can manifested with ECG changes and Cushing response: bradycardia, AHT and pulse pressure increase.

Treatment is mainly focused on monitoring heart rhythm and controlling electrolytic levels, particularly potassium. Therapy with beta blockers has proved effective in ventricular and supraventricular arrhythmias and in the reduction of myocardial damage related to subarachnoid hemorrhage and head trauma.

16.3 Paroxysmal Essential Hyper- and Hypopothassemia (Periodic Paralysis)

These kinds of paralysis are characterized by weakness episodes associated with increased potassium, though presenting normal K levels. Frequently, the attacks are induced by exercise and exposure to cold weather. Ventricular extrasystoles, ventricular tachycardia and ventricular bidirectional tachycardia are often observed.

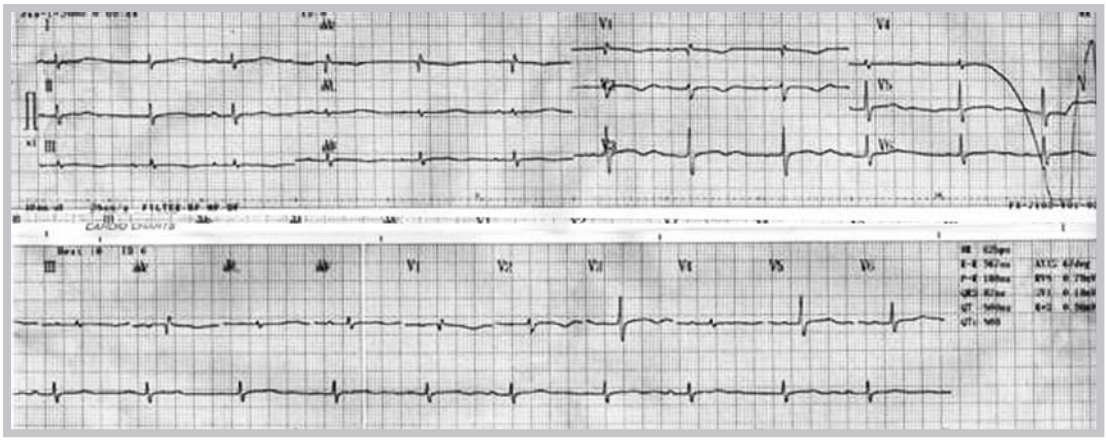

Figure 16.3. **Sinus rhythm with prolonged QT interval.**

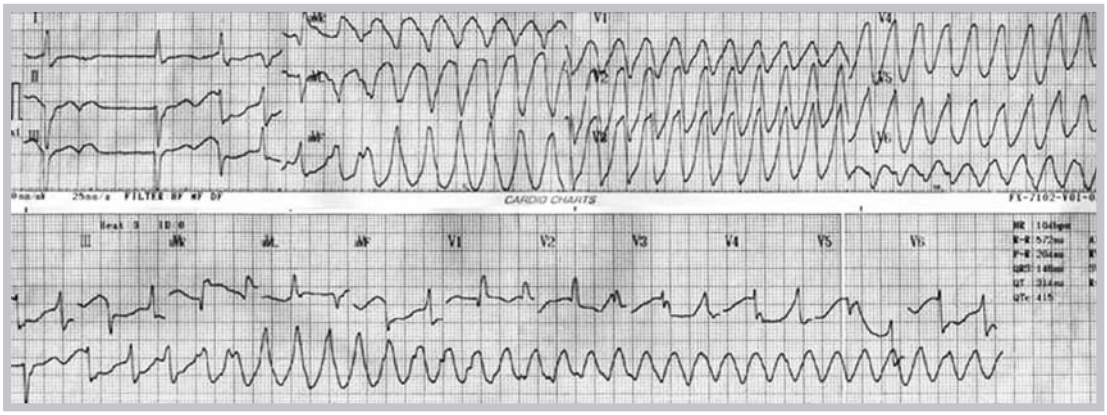

Figure 16.4. **Torsades de pointes. Patient with severe hypokalemia, 1.6 mEq/l paralysis. Strong ventricular arrhythmias, QT prolongation and ventricular extrasystoles are frequent.**

Weakness episodes and arrhythmias usually respond to measures initiated to normalize plasma potassium and mexiletine levels.

Paroxysmal essential hypopothassemia manifests as periodic paralysis attacks, with low potassium levels. Andersen's syndrome refers to periodic paralysis sensitive to potassium, associated with low implantation of the ears, clinodactyly, prolonged QT interval and ventricular arrhythmias. Weakness episodes are intense and prolonged, with attacks induced by exposure to cold weather and post-exercise rest. Carbohydrates can also cause episodes.

Correction of potassium levels usually improves the weakness, although arrhythmias tend to persist. Beta blocker therapy produces an improvement in non-sustained ventricular tachycardia. Anti-arrhythmia 1A-type medications should not be given because they exacerbate weakness and associated arrhythmias with prolongation of QT interval.

16.4 Dystrophy

Duchenne muscular dystrophy can present:

- Conduction disorders with an increase in conduction speed and short P-R (<120 msec.) or prolonged infranodular conduction in some patients.

- Rhythm disorders with sinus tachycardia secondary to alterations in the autonomic system, or due to fibrosis and fat infiltration of the sinus node, which develops a field for intranodal re-entrance; fibrillation and auricular flutter; ventricular extrasystole; ventricular tachycardia with late potential development. Heart death in 25% of patients, equally distributed between sudden death and progression to cardiac insufficiency.

Arrhythmia **treatment** with anti-arrhythmia drugs produces major respiratory insufficiency, besides a major risk of respiratory insufficiency associated with implantation of a heart defibrillator, without improvement in prognosis.

16.5 Myotonic Muscular Dystrophy

Cardiac alterations are mainly arrhythmias, with frequent ECG anomalies including AV blocks, branch blocks, and unspecified delays in intraventricular conduction. It manifests as pathological changes, with unknown mechanisms leading to conduction system degeneration (fibrosis and fat infiltration) of the sinus node, the AV node, the His and Purkinje fibres, and the auricular and ventricular fibres. It may progress to symptomatic myocardiopathy. Reduced conduction with positive late potentials is observed.

Conduction system disorders can progress to complete AV block, requiring a definitive pacemaker. Prophylactic implantation of a pacemaker must be evaluated. 2008 ACC/AHA/HRS guidelines suggest considering, in conduction disorders of myotonic muscular dystrophy patients, implantation of definitive pacemaker in patients with second or third degree symptomatic or asymptomatic AV block.

Auricular tachycardia, auricular flutter and auricular fibrillation are frequent arrhythmias (4%), often well-tolerated by controlled ventricular frequency due to concomitant conduction disorder.

Sudden death occurs in one third of patients and is believed to be caused by secondary asystole, although sudden deaths have been seen in pacemaker-bearing patients. Ventricular arrhythmias have been associated with branch-branch tachycardia.

16.6 Steinert Myotonic Dystrophy

This autosomal dominant disease is caused by a gene on the long arm of chromosome 19. It is clinically characterized by muscular weakness and myotony. Two forms are distinguished: a moderate, slowly progressive form with stationary periods, in which muscular weakness is limited to the forearms and dorsal foot flexors, scarce myotony without CNS disorders, while cataracts and cardiac conduction disorders are frequent; and the classical form characterized by more rapid progression and concomitant florid myotony. Muscular weakness has a characteristic distribution (facial, mandibular, cervical and peripheral flexor); there is usually palpebral ptosis and weakness in the masseter and orbicular muscles. Unlike scapular-humeral dystrophy, the scapular waist is affected late in the course of the disease; and unlike other myopathies, distal muscular weakness in the extremities is worse. Myotony tends to appear between the age of 5 and 25 years and it is characterized by involuntarily maintained muscle contraction when hit by a reflex hammer, for example, to the thenar musculature or when inviting the patient to contract a muscle. These patients tend to have low IQ, apathy, aggressiveness, hypersom-

nia, possibly due to an increase in gliosis, and decreased blood flow as detected by proton spectroscopy studies.
Cardiac alterations are caused by progressive fibrosis in the conduction ways, shown as arrhythmias (first degree AV-block, sinus bradycardia and branch blocks); there is a major risk of sudden death in the early phase of the illness.
Arrhythmias often prompt patients to seek medical attention. It is important to perform periodical evaluation with cardiac echo-Doppler and ECG.

16.7 Emery-Dreyfuss Muscular Dystrophy

This familiar disorder presents with mild weakness in skeletal musculature and frequent and lethal arrhythmogenic disorders. A recessive hereditary disease (less frequently dominant) related to chromosome X, it generates an alteration in the membrane protein emerin. This protein is located in the cardiac desmosomes and is associated with conduction disorders.
The dystrophy presents a triad of precocious contractures of the posterior cervical muscles, elbow muscles and the Achilles tendon, with weakness and slowly progressive muscular atrophy and cardiac alterations.
It is associated with dilated myocardiopathy and a high prevalence of conduction disorders. Conduction disorders, with AV blocks, auricular flutter, auricular fibrillation, sinus arrest, and union-rhythm bradycardia, start to appear in the third and fourth decades of life. Cardiac stimulation becomes necessary by the age of 40-50 years.
Sudden death has been described in association with ventricular tachycardia and auricular fibrillation.
Follow-up and surveillance of ECG disorders by means of Holter monitoring, ECG and echocardiography should be done. With progression of the disease, stimulation with a permanent pacemaker and/or an implantable automatic cardiac defibrillator is recommended.

16.8 Muscular Dystrophy of the Extremities and the Waist

This group of hereditary recessive (type 1) and dominant (type 2) disorders, including subgroups 1B, 2C, is associated with cardiac alterations such as dilated myocardiopathy. Other disorders manifest with the evolution towards progressive AV block, requiring pacemaker implantation. Episodes of sudden death have been described, even with the use of a permanent pacemaker, which suggests ventricular arrhythmias.
Follow-up with ECG, Holter monitoring and echocardiography is recommended, with special attention to at-risk subgroups, and eventual pacemaker implantation.

16.9 Friederich's Ataxia

This cerebrospinal degenerative recessive autonomic hereditary disease is characterized by ataxia of the extremities and torso, dysarthria, loss of deep tendon reflexes, sensorial anomalies, skeletal deformities and cardiac alterations. The genetic disorder is associated with chromosome 9, responsible for production of the protein frataxin.

The severity of the neurological symptoms and cardiac hypertrophy are related to alterations in this protein, which is a mitochondrial protein key to iron homeostasis and cell respiration.
Concentric ventricular hypertrophy is most frequently associated with Friederich's ataxia, although it has been observed with asymmetric septal hypertrophy and/or dilated myocardiopathy in some cases. Concentric ventricular hypertrophy signs are the most frequent ECG findings, with diffuse T-wave inversion. Auricular arrhythmias, as auricular flutter or auricular fibrillation, are generally associated with progression of the disease. Sudden death has been described, although its mechanism is not yet well known. Conduction disorders have not been described.

16.9.1 Treatment

Evolution to a severe dilated myocardiopathy requires treatment of cardiac insufficiency without any specific treatment.

16.10 Kearns-Sayre Syndrome

This encephalopathy results from anomalies in mitochondrial function. Histopathological studies of the skeleton and heart muscles show an abnormal proliferation of mitochondria.
Conduction alterations constitute the most typical cardiac abnormality, dilated myocardiopathy being less frequent. It presents with fibrosis and fat infiltration of the conduction system.

Figure 16.5. Preexcitation syndrome. Sinus rhythm, short PR and delta wave.

Diagnosis is based on the triad ophthalmoplegy, pigment retinopathy and cardiac block, with prolonged HV interval. Preexcitation leading to supraventricular paroxysmal tachycardia has been described. When there is a conduction disorder, prophylaxis with a definitive pacemaker is recommended.

16.11 Leber's Hereditary Optical Neuropathy

Another mitochondrial encephalopathy, characterized by a painless loss of bilateral vision, this pathology is associated with a short PR interval and preexcitation syndromes, with the development of supraventricular arrhythmias.
Preexcitation with paroxysmal tachycardia symptoms indicates treatment of the anomalous conduction.

16.12 Guillain-Barré Syndrome

This is an acute demyelinating inflammatory neuropathy, with malfunction of peripheral nerves, cranial pairs and the autonomous nervous system. Arrhythmias such as bradycardia, asystole, inappropriate sinus tachycardia, auricular fibrillation, tachycardia and ventricular fibrillation are related to the autonomous disorder. It may also be associated with hypertension and diaphoresis. These arrhythmias lead to an increase in mortality.
Intravenous administration of immune globulin or plasmapheresis improves prognosis. Monitoring is important. In patients with rhythm disorders, implantation of a temporary or permanent pacemaker is recommended. Infusion of atropine or isoproterenol before tracheal aspiration manoeuvres is recommended.

16.13 Myasthenia Gravis

This chronic autoimmune neuromuscular disease is caused by the production of antibodies directed against the nicotine receptor of acetylcholine. Producing weakness in voluntarily-controlled muscles, this weakness increases with activity and decreases with rest. The main symptom is fluctuating weakness, which usually starts with the ocular and facial muscles. It is generally associated with thymus gland hyperplasia.
Myocarditis is frequently associated, although arrhythmias such as auricular fibrillation, AV block, asystole, and sudden death have also been observed
Immunosuppressive medication and anti-cholinesterase are part of the typical treatment. These can diminish heart rate and hypotension. Administration of uinidine and propranolol can exacerbate weakness.

16.14 Epilepsy

The estimated annual incidence of epilepsy and sudden death varies between 1/370 and 1/1000 epileptic patients. The incidence is higher in the 20-to-40-year age group and higher still in very symptomatic epileptic patients. Unexpected sudden death is 3.8 to 9.3 times more frequent in epileptic patients than in the general population: 100% of

cases experience generalized tonic-clonic seizures alone or combined with another type of crisis, most complex partial crises having been deduced from what witnesses or doctors said or what the electroencephalogram showed.

Some 60% victims present with a structural cerebral lesion responsible for the attack. This percentage is much lower in non-selected epileptic patients. The types of lesion found were old frontal contusion, old penetrating lesion, chronic subdural hematoma, cortical arteriovenous malformation, tumour or old stroke.

Electrical events during an epileptic attack lead to centres involved in the heart's neurovegetative function, causing cardiac arrest or fatal arrhythmia. It seems that sympathetic, more than parasympathetic, activity reaches the heart, causing a fatal cardiac response associated with the crisis, but it is unclear why this occurs in certain patients. It could be because of a subtle myocardial lesion difficult to demonstrate following habitual autopsy techniques. Some authors have reportedly found small fibrotic areas in the terminal arteries, focal lesions of the myocarditis type and focal endocardiac fibrosis in conduction bundles. These can have their origin, as shown by experimental studies, by intense repeated sympathetic stimulation during the crisis.

According to Lathers et al., electrophysiological evidence of cerebral discharge due to arrhythmogenic potential was induced by generalized crises in anesthetized and mechanically-ventilated cats. Recording two separate branches of the sympathetic cardiac nerve and the vagus nerve, they proved that activity outbreaks occurred in the sympathetic cardiac nerves synchronized with ictal and interictal points of the EEG. With determined doses of the substance used to induce the crises (penthylentetrazol, [PTZ]), the degree of synchronization, variable between both branches of the sympathetic cardiac nerve, could be lost. Therefore, it was suggested that the different branches of the sympathetic cardiac nerve innervate different areas of the ventricular myocardium. The imbalance in the activities of the sympathetic and parasympathetic nervous system branches is thought to provoke a non-homogeneity in heart depolarization and repolarization which allows for the appearance of irritability places, re-entrance circuits and ventricular ectopias. Furthermore, the authors suggested that this mechanism can be activated in a normal crisis in the presence of subtherapeutic levels of anti-epilepsy medication, resulting in malignant arrhythmias and sudden death.

The most important data have been obtained, nevertheless, by stimulation of the hypothalamus, although there are changes in arterial pressure and respiration. However, it seems difficult to believe this to be the highest cerebral level of cardiac representation: there should be cortical mechanisms involved.

As to the type of arrhythmia observed, there were auricular fibrillation, multifocal premature ventricular contraction, ventricular tachycardia, sinus bradycardia, asystole periods and torsades de pointes. Interestingly, we have a patient with a right frontal glioma repeatedly suffering from supraventricular paroxysmal tachycardia which disappeared only after tumour removal. An alternative explanation to this is that the high levels of catecholamines have their role in the production of a neurogenic pulmonary edema observed after the appearance of different brain lesions. Hypoxia conditions could generate acidosis and, consequently, arrhythmias.

Systematic studies of cardiac rhythm alterations during a crisis indicate the appearance of:

- Sinus tachycardia in more than 90% of cases.
- Frequent auricular and ventricular ectopias in more than half of patients.
- Occasionally, periods of ventricular tachycardia, supraventricular paroxysmal tachycardia, bradycardia and even sinus arrest.

Changes in repolarization show up on the ECG tracing as a depression or elevation of the ST segment, T-wave inversion and altered morphology, variation in the R-R interval, increase or decrease of PR- and QT-intervals.

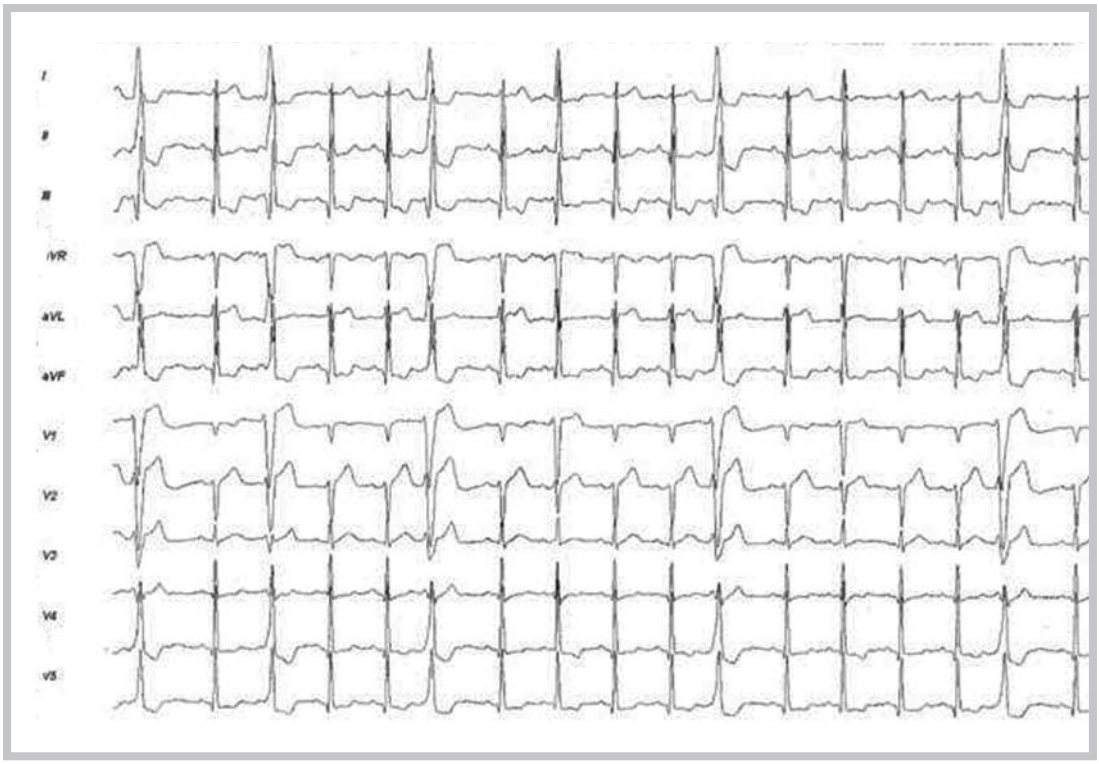

Figure 16.6. Patient with convulsive episodes, with sinus tachycardia and frequent ventricular extrasystole.

Figure 16.7. Sinus tachycardia with vibration of baseline ECG due to muscular tremor.

The induction of arrhythmias by photostimulation in cases of photosensitive epilepsy has also been observed: bradycardia or sinus tachycardia, and sinus arrest coinciding with the start of QRS.

There are patients who, investigated because of cardiac arrhythmias, are incidentally discovered to have epilepsy. Though they do not generally respond to conventional anti-arrhythmia drugs, they actually do respond to epileptic treatment.

Yearly assessment with ECG, 24-hour Holter monitoring and electrophysiological studies, as part of the diagnosis of arrhythmic patients, can help to determine etiology and guide treatment. Successful radiofrequency ablation of ventricular arrhythmias has been described. There is little experience with the use of implanted cardiac defibrillators.

17 Mechanical Ventilation in the Neurologic Critically Ill Patient

Guillermo Bugedo [1], **Jaime Retamal** [1]

[1] Intensive Medicine Department, Pontificia Universidad Católica de Chile, Santiago, Chile

17.1 Introduction

Acute brain injury, mainly head trauma or stroke, are devastating conditions with high morbidity, mortality and long-term sequelae, and huge economical and social costs. Respiratory depression, by itself or as a contributing factor, is one of the main causes of respiratory failure in the neurologic critically ill patient. Respiratory depression induces alveolar hypoventilation, airway obstruction, gastric content aspiration and hypoxemia, among others. The interaction between the respiratory system and the central nervous system (CNS) is so close, that the failure of one will necessarily affect the other, generating vicious circles (Figure 17.1). Therefore, aggressive airway management and ventilatory support are key to managing these patients.

In a large-scale epidemiological study on mechanical ventilation performed in 1998 and involving a cohort of 5,183 ventilated patients, "coma" was cited as the reason for ventilatory support in 17% of the study population, and the mortality rate was 36%. Similar findings were reported by a second study published in 2004, in which 19% of the ventilated patients received respiratory support because of neurologic reasons. The 28-day mortality rate was 48%, 35%, and 28% in patients with hemorrhagic stroke, ischemic stroke, and head trauma, respectively.

During acute head injury, 10 to 30% of patients will develop acute lung injury (ALI) or the acute respiratory distress syndrome (ARDS), jeopardizing vital and functional prognosis. The mortality rate among stroke patients is more than 50%.

There is strong evidence that hypoxia is one of the main causes of secondary neuronal injury after head trauma, nearly doubling mortality. Also, changes in PaO_2, $PaCO_2$, and pH may alter cerebral blood flow (CBF) and intracranial pressure (ICP), further hampering the outcome of neurologic critically ill patients.

This chapter gives an outline of the pathophysiologic interactions between the respiratory system and the CNS, some frequent ventilator-associated complications, and key issues in invasive ventilatory management which could improve outcome in the neurologic critically ill patient.

17.2 Breathing Control and Respiratory Depression

Ventilation relies on sensors and effectors which are closely regulated by the respiratory centre (Figure 17.2). This is composed of several groups of neurons located bilaterally in the medulla oblongata and pons of the brainstem, and is chiefly responsible for ventilatory activity. The respiratory centre is stimulated primarily by the hydrogen ion concentration in the cerebrospinal fluid (CSF) through sensors located in the medulla and carotid bodies. Carotid bodies also respond to changes in PaO_2. Awareness and no-

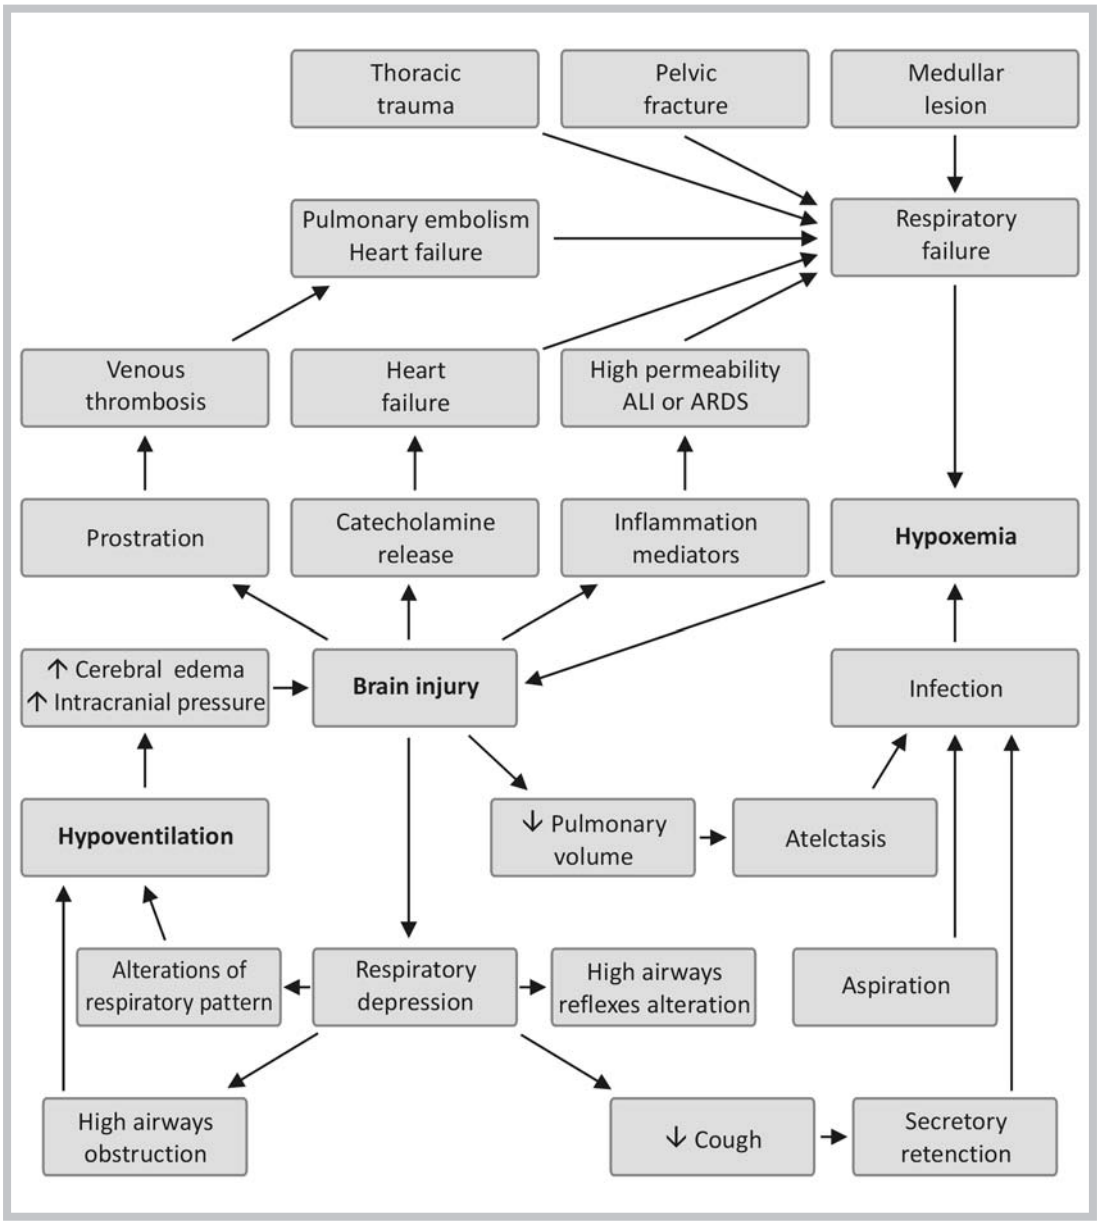

Figure 17.1. **Respiratory problems in brain-injured patients. Respiratory complications may produce secondary brain injury because of hypoxemia and hypoventilation, promoting vicious circles which jeopardize patient outcome.**

ALI = acute lung injury

ARDS = acute respiratory distress syndrome

ciceptive stimulation can also activate the respiratory centre through the reticular formation in the brainstem. Lung mechanoreceptors and cardiovascular baroceptors send information on functional residual capacity.

The respiratory system effectors are responsible for regulating the ventilatory cycle: airway (genioglossus and cricoarytenoideus muscles), and chest wall muscles (diaphragm, intercostal and accessories muscles). Each muscle group maintains a phasic activity for starting and coordinating inspiration, and a tonic activity in charge of maintaining a pat-

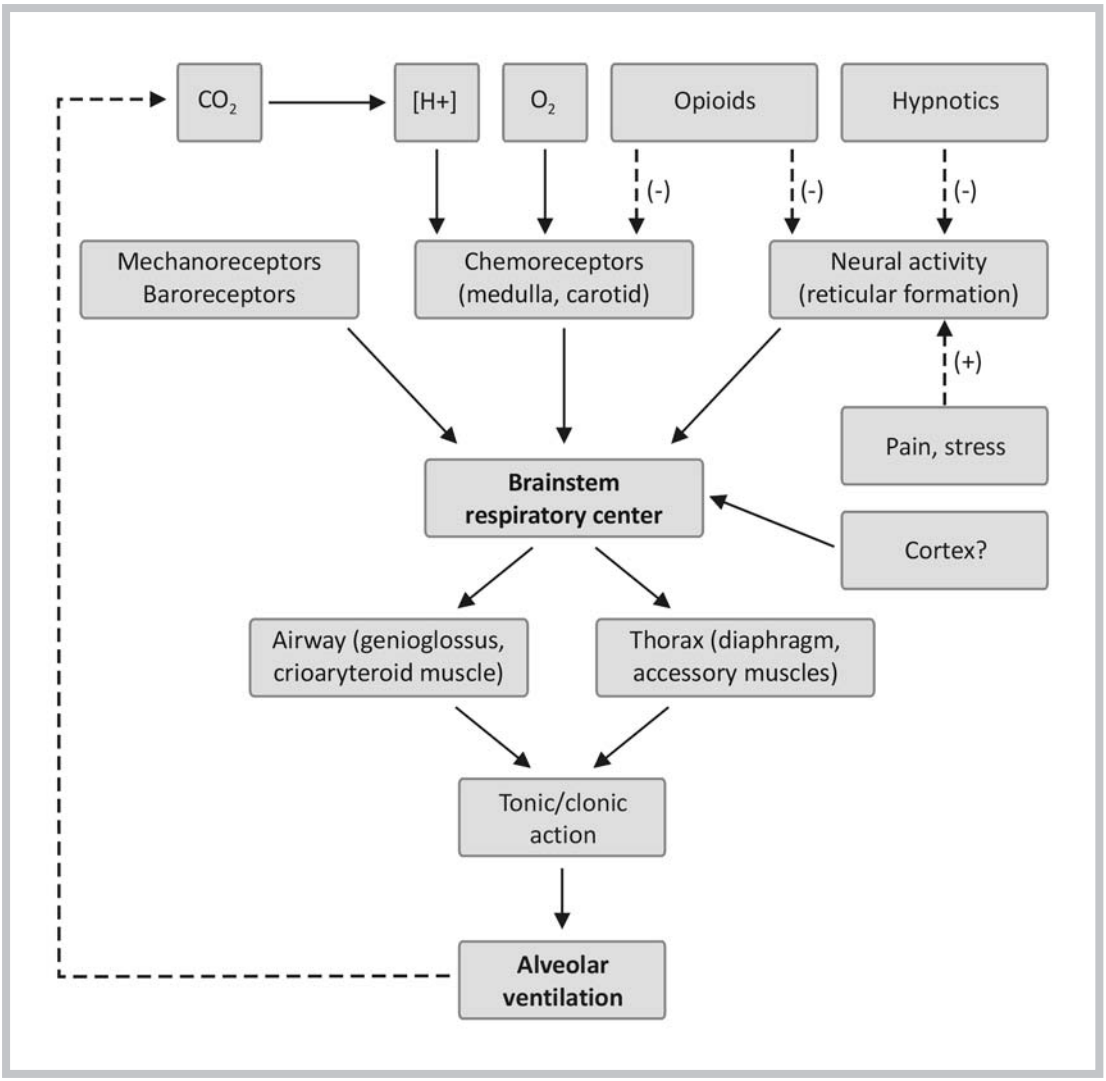

Figure 17.2. **Diagram illustrating respiratory centre function.**

ent airway, muscle tone and residual functional capacity. From these concepts, it is clear why one of the most common complications of brain-injured patients is respiratory depression and airway-related problems (Figure 17.1).

Respiratory depression is a clinical syndrome characterized by a dysfunction of the respiratory centre. Its diagnosis requires a variable but constant altered level of consciousness and breathing abnormalities (Table 17.1). The most common clinical consequences of respiratory depression are apnoea, bradypnoea or periodic breathing abnormalities, and the inability to maintain a patent airway (tongue falling backwards, retention of secretions and hypotonia of pharyngeal muscles), which may result in alveolar hypoventilation. Also, the decreased functional residual capacity may favour the development of atelectasis and hypoxemia (Figure 17.3).

Respiratory depression may be a serious complication in brain-injured patients because hypoxemia and hypercapnia may induce secondary injury (Figure 17.1). Therefore, airway management should be controlled early in patients with progressive drowsiness and coma. And since cyanosis and tachycardia develop late following hypoxemia, per-

manent observation of the patient's level of consciousness and breathing pattern are far more important than preventive measures.

Respiratory depression may also favour the aspiration of gastric contents (Figure 17.1). Patients with trauma and intracranial hypertension may present delayed gastric emptying. It follows that any patient with head trauma or stroke should be treated as a patient with a full stomach at high risk for aspiration. Any sign of vomiting in an unconscious patient is highly suspicious for gastric aspiration. Clinics of aspiration depend on the quality and amount of aspirated liquid, the aspiration of bilious contents or blood being less toxic than acid or food contents. In any case, the chance of secondary infection is high and should prompt antibiotic therapy.

Diagnosis	• Altered level of consciousness
	• Alteration in mechanics and abnormalities of breathing:
	  ▪ Apnea, bradypnea
	• Inability to maintain airway patency:
	  ▪ Hypotonia of pharyngeal muscles
	  ▪ Airway obstruction
	  ▪ Secretion retention

Clinical implications	• Alveolar hypoventilation:
	  ▪ Increased $PaCO_2$ and increased ICP
	• Decreased muscular tone:
	  ▪ Decreased FRC, atelectasis, hypoxemia
	• Aspiration of gastric contents:
	  ▪ Lung infection

Table 17.1. Diagnosis and clinical implications of respiratory depression.
FRC = functional residual capacity
ICP = intracranial pressure

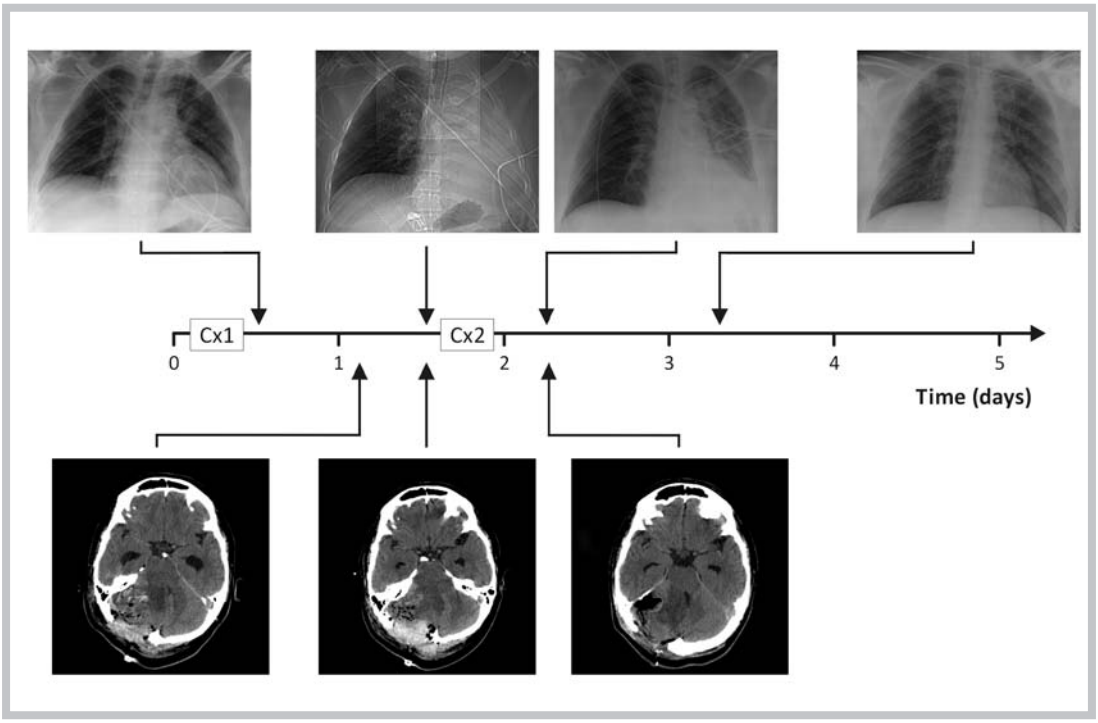

Figure 17.3. A clinical case of respiratory depression.A 29-year-old patient underwent surgery for removal of a tumour of the posterior fossa (Cx1). On the first postoperative day, the patient was drowsy and the CT scan showed edema and partial collapse of the IV ventricle. The patient was carefully observed, but later that day he had to be intubated because of coma. A new CT scan revealed greater collapse of the IV ventricle and postsurgical edema. Total atelectasis of the left lung because of loss of muscular tone, decreased residual lung capacity and decreased cough, was secondary to respiratory depression. The patient was returned to the OR for decompressive surgery (Cx2) and ventilated with positive pressure ventilation and PEEP. A postoperative CT scan showed an expanded IV ventricle. The clinical course was favourable and the patient was extubated two days later.

Figure 17.4. **A sedation scheme for brain-injured patients in use at the Centro de Pacientes Críticos, Universidad Católica de Chile [Riker, 1999].**
SAS = sedation agitation scale

17.3 Sedation

Sedation in brain-injured patients remains controversial because although it favours mechanical ventilation, it also hampers the evaluation of cognitive function, which is the basic and objective monitor of CNS functioning. However, beyond the objective of facil-

itating mechanical ventilation, sedation may decrease oxygen metabolism and intracranial hypertension, and control seizures.

There is no clinical study that evaluates the impact of mechanical ventilation, ventilatory modes or sedation in patients with acute neurologic diseases. Guidelines suggest sedative and analgesic drugs based on their pharmacologic effect on ICP, CBF, or $CMRO_2$, more than on data derived from prospective clinical studies. The choice of drugs and doses when ventilating patients with brain injury is extremely heterogeneous.

Sedation in patients with trauma or stroke should be based on: the necessity of clinical evaluation; oxygen metabolism; intracranial pressure; cerebral blood flow and perfusion pressure among others. The protocol for sedation and analgesia in patients with brain injury (Figure 17.4) at our intensive care unit (ICU) involves:

- Use of opioids as first-line agents.
- Use of an hypnotic agent, usually midazolam or propofol.
- Clinical evaluation of sedation according to the sedation against agitation scale (SAS) and the Glasgow motor scale.
- Intracranial pressure and CPP monitoring (if available).

Goal-oriented monitoring of depth of sedation and periodic adjustment are essential to prevent over- and undersedation, which may affect major outcomes and costs. Oversedation hampers neurologic clinical assessment, increases the risk of hypotension (especially when using propofol and barbiturates), increases mechanical ventilation and ICU and hospital length of stay, and may increase nosocomial infections. Undersedation may increase metabolism, oxygen consumption and intracranial hypertension.

The use of muscle relaxants, widely recommended for preventing fighting in patients with intracranial hypertension, is reserved for patients with severe forms of ARDS, with high sedative requirements or for non-conventional modes of mechanical ventilation.

In non-neurologic patients, sedation protocols have been shown to decrease ICU and hospital length of stay and costs. In neurological critically ill patients, a sedation protocol may also decrease infections and secondary hypoxemia and so improve such major outcomes as long-term cognitive functions.

17.4 Hyperventilation

Modulation of $PaCO_2$ has been used for more than 40 years to control intracranial pressure (ICP). The decrease in $PaCO_2$ levels induces a drop in hydrogen ion concentration (increased pH) in the cerebrospinal fluid (CSF), inducing cerebral vasoconstriction and decreasing cerebral blood volume and ICP.

Despite being highly effective to decrease ICP, hyperventilation is not widely accepted as it may induce a decrease in cerebral blood flow (CBF), a change that lasts longer than the decrease in ICP (Table 17.2). There is also evidence that hyperventilation may exacerbate ischemia in hypoperfused zones of the brain. The only randomized prospective study on hyperventilation

Regional	• Arterial vasoconstriction: decreased CBF • Transient decrease in ICP • Rebound increase in ICP, when normalizing $PaCO_2$
Systemic	• Increase in airway pressure: decreased cardiac output and oxygen delivery • Respiratory alcalosis: decreased oxygen release to tissues • Use of high tidal volume: ventilator-induced lung injury

Table 17.2. Adverse effects (real or potential) of hyperventilation.

CBF = cerebral blood flow
ICP = intracranial pressure
PbO_2 = brain tissue oxygenation
SjO_2 = oxygen jugular saturation

Level I (standard)	• There are insufficient data to support a level I recommendation
Level II (guideline)	• Prophylactic hyperventilation ($PaCO_2$ <25 mmHg) is not recommended
Level III (options)	• Hyperventilation is recommended as a temporizing measure for the reduction of elevated ICP • Hyperventilation should be avoided during the first 24 hours after injury when cerebral blood flow (CBF) is often critically reduced • If hyperventilation is used, SjO_2 or PbO_2 measurements are recommended to monitor oxygen delivery

Table 17.3. **Brain Trauma Foundation recommendations on hyperventilation in brain trauma. Modified from [1].**

Mode	• Volume-controlled ventilation
Tidal volume	• Vt 8 (6-9) ml/kg body weight index • Maintain plateau pressure <25 cmH_2O and airway driving pressure <15 cmH_2O
Respiratory rate	• RR 10-12 to maintain $PaCO_2$ 35-40 mmHg • Monitor $ETCO_2$ • Prevent hypoventilation ($PaCO_2$ >45 mmHg)
PEEP	• Low levels of PEEP: 5-10 cmH_2O • If thoracic trauma or lung aspiration: PEEP 8-15 cmH_2O
If refractory hypoxemia	• Consider high recruitment strategies, HFOV and/or prone positioning • Hypoxemia does more harm than hypercapnia
Hyperventilation	• Second tier therapy, transient

Table 17.4. **Initial ventilator programming in brain-injured patients.**
$ETCO_2$ = end-tidal CO_2
HFOV = high frequency oscillatory ventilation

was performed by Muizelaar et al. in 113 patients with head trauma. Patients ventilated with hypocapnia ($PaCO_2$ 25±2 mmHg) had a worse outcome at 3 and 6 months that those treated with eucapnia ($PaCO_2$ 35±2 mmHg). So far, there are no data to show that hyperventilation improves long-term outcome in patients with head trauma or stroke.

We usually try to maintain normo- or light hypocapnia ($PaCO_2$ 35-40 mmHg) in our patients, reserving hyperventilation as a second-line, transient therapy for patients with elevated ICP refractory to hypertonic therapy and with normal CPP (Table 17.4). If hyperventilation needs to be tried, brain tissue oxygen partial pressure (PbO_2) or jugular venous oxygen ($SjvO_2$) measurements are recommended to monitor the effect of ventilation on CBF and cerebral metabolic rate of oxygen ($CMRO_2$). Although CBF is not routinely measured at the bedside, $SjvO_2$ and PbO_2 may help tailor ventilation (Table 17.3). $SjvO_2$ <55% or PbO_2 <15 mmHg suggests increased oxygen extraction, decreased CBF or ischemia. In this setting, hyperventilation may be deleterious and treatment should be oriented to increase oxygen delivery (inotropes or vasopressors), decrease oxygen consumption (sedatives) or decrease brain edema (hypertonic therapy). $SjvO_2$ >65-70% suggests hyperemia, so hyperventilation may be tried as a temporary measure to decrease ICP.

When setting ventilation and $PaCO_2$ goals, they should be adjusted for geographic altitude and temperature, as arterial blood gases are referenced at sea level and at 37 ºC. This last correlation is especially important when applying therapeutic hypothermia.

Arterial $PaCO_2$ levels depend on CO_2 production (V_{CO2}) and are inversely proportional to alveolar ventilation (V_{Alv}), which is the difference between minute ventilation (V_{min}) and dead space (V_{DS}), wherein:

$$PaCO_2 = V_{CO2}/V_{Alv} = V_{CO2}/(V_{min} - V_{DS})$$

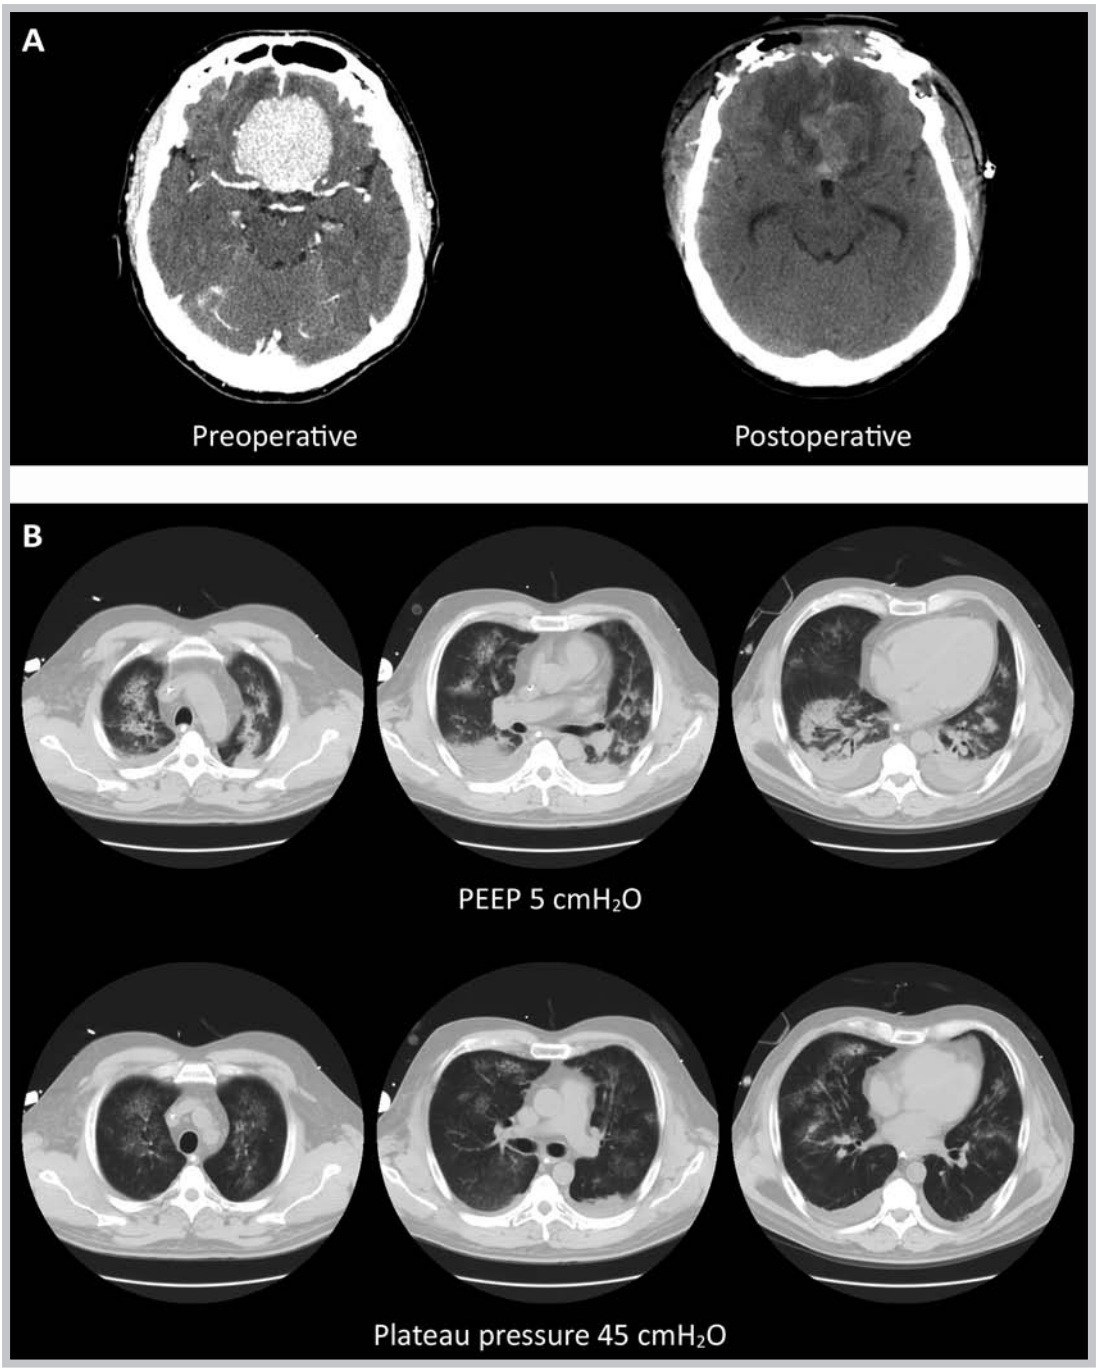

Figure 17.5. High potential for recruitment. A 54-year-old man underwent surgical removal of a large frontal brain tumour. During the postoperative period the patient developed severe agitation which required CNS depressants. At 48 hours, the patient required orotracheal intubation and mechanical ventilation due to respiratory failure secondary to aspiration of gastric contents. The figure shows the preoperative (left) and postoperative (right) head CT scan, and a lung CT scan during a recruitment manoeuvre. In the upper panel, CT slices at the upper, middle and lower zones of the lung during an expiratory pause at 5 cmH_2O PEEP. In the lower panel, the same slices at total lung capacity (TLC), taken during an inspiratory pause (plateau pressure) at 45 cmH_2O. Bilateral infiltrates decreased dramatically at TLC because of a high potential for recruitment. The patient was ventilated with high PEEP levels (12-15 cmH_2O). The clinical and neurologic course were good.

Hence, to decrease $PaCO_2$ levels we can increase minute ventilation (tidal volume or respiratory rate) or decrease dead space. Older textbooks and guidelines did suggest the use of high tidal volume (Vt >10 ml/kg) and low levels of positive end-expiratory pressure (PEEP). This latter concept was based on the idea that PEEP could decrease cephalic venous return and increase ICP.

If we use tidal volume >10 ml/kg, as frequently done in the last decades, there is an increased risk of ventilator-induced lung injury (VILI). Protective ventilation should be applied to all patients with brain injury, limiting Vt to 8 or 10 ml/kg, and further if ALI or ARDS develops. Also, PEEP levels should be tailored to decrease dead space and minimize shunt (Table 17.4).

Unfortunately, most clinical studies on hyperventilation do not describe how they set the ventilator, so it is difficult to make definitive conclusions on the role of ventilation or hyperventilation in patients with acute brain injury and intracranial hypertension.

17.5 Lung Recruitability and Use of PEEP

The use of PEEP (positive end-expiratory pressure) has been debated for more than 30 years. PEEP increases intrathoracic pressure and can decrease venous return, increasing cerebral blood volume and ICP. Although high PEEP levels may be detrimental, there are several reasons that support the routine use of low or moderate PEEP levels, even in patients with ALI.

First, most patients with acute brain injury may present hypoventilation, an increase in lung vascular permeability, a decrease in functional residual capacity, a tendency towards alveolar collapse and development of atelectasis (Figure 17.1). PEEP recruits previously collapsed alveoli, improves lung compliance, decreases shunt, and prevents and improves gas exchange.

Second, overdistention secondary to the use of high tidal volumes is the main cause of ventilator-induced lung injury (VILI). PEEP decreases dead space, allowing the use of lower tidal volumes for ventilatory and CO_2 management. Moreover, PEEP may also stabilize the alveoli, thus preventing the opening and closing of unstable alveoli, which may contribute to the development of VILI. This phenomenon may be specially relevant in patients with severe ARDS and high recruitability (Figure 17.5).

Recruitability, or the potential for recruitment, refers to the capacity of the lung parenchyma to incorporate previously closed alveolar units to gas exchange. Recruitability is highly heterogeneous in patients with acute brain injury, as it is related to impaired lung function (Figures 17.5 and 17.6). High PEEP levels (10-15 cmH_2O) in patients with high recruitability may improve gas exchange and prevent inflammatory response secondary to the opening and closing of a significant mass of unstable lung tissue. However, high PEEP levels in neurocritical patients with low recruitability may induce lung overdistention and increase ICP. Lung mechanics and dead space monitoring are key variables to set the most physiologic PEEP level (Figures 17.5 and 17.6).

The impact of PEEP on ICP depends mostly on its effect on mean airway pressure, as this is the one that best correlates with intrathoracic pressure, hemodynamic disturbances and oxygenation. However, ICP fluctuates more than PEEP after changes in $PaCO_2$, airway pressure or ventilatory mode. In a large-scale clinical study, Cooper et al. found a 1.3 mmHg increase in ICP after increasing the PEEP level by 10 cmH_2O in 33 patients with severe head trauma. Furthermore, the modest change in ICP was related to the effect of PEEP on hemodynamics and respiratory variables without major clinical consequences.

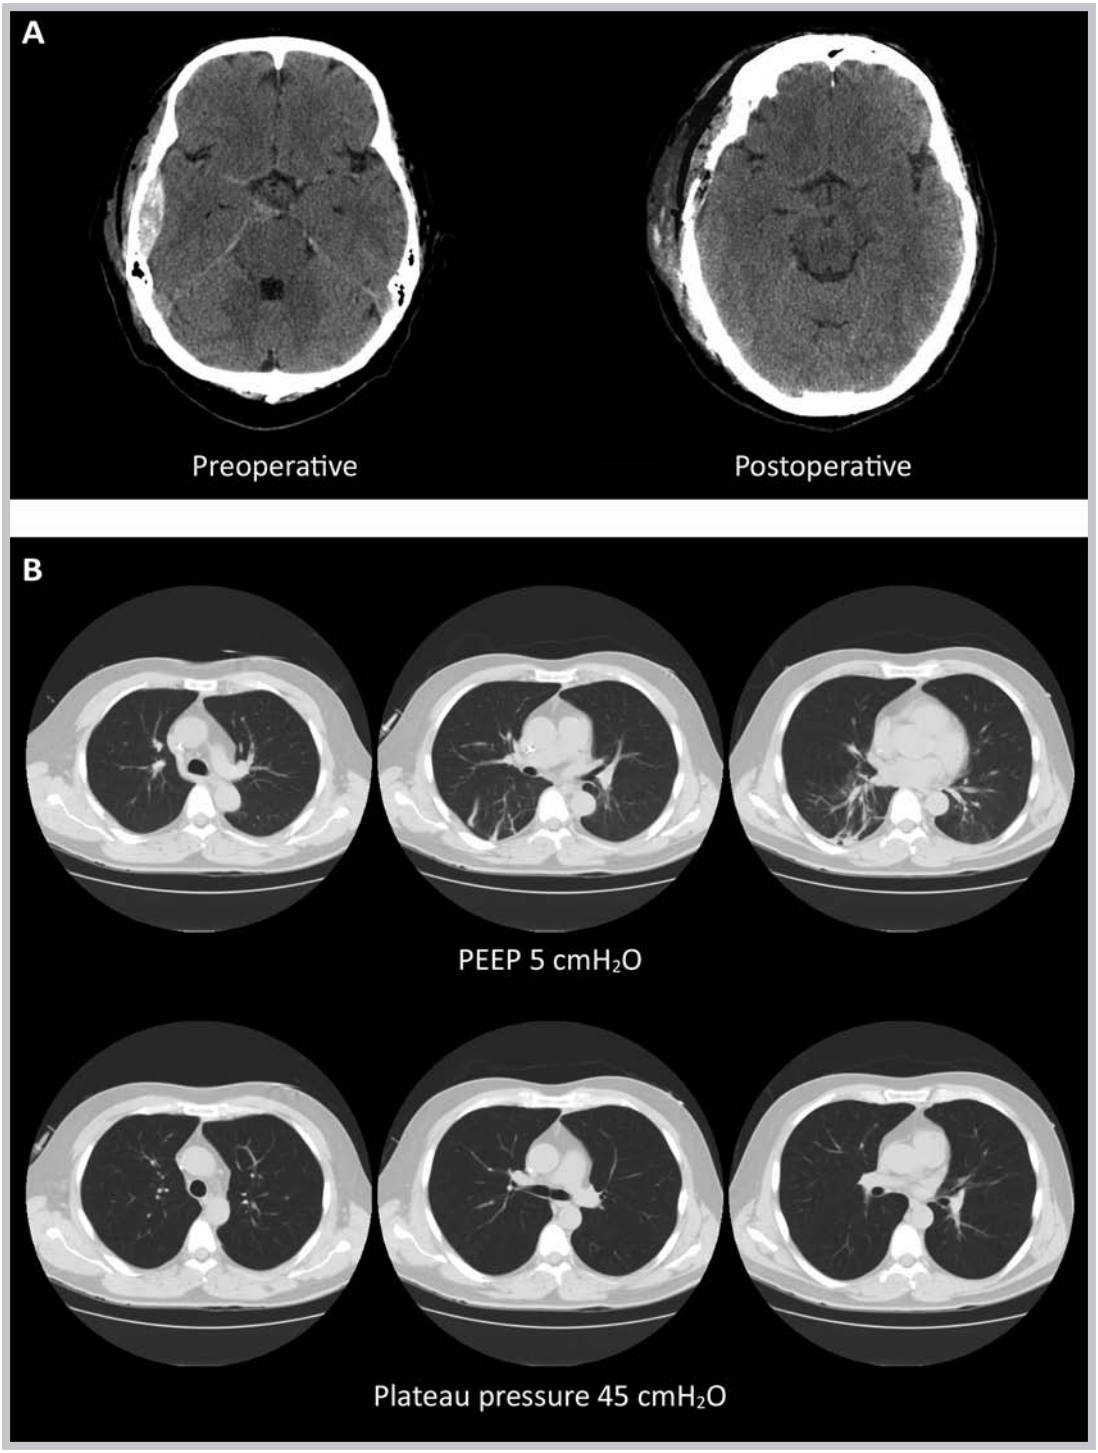

Figure 17.6. Low potential for recruitment. A 53-year-old man was admitted because of a right-sided traumatic epidural hematoma. The figure shows head CT scans before (left) and after (right) surgery (A), and a lung CT scan during a recruitment manoeuvre (B), as shown in the previous figure. At PEEP 5 cmH_2O, only lineal atelectasis are noted. Although these fully disappear at TLC, the benefit is scarce. Note compression and caudal displacement of the mediastinal structures. This patient did not benefit from high PEEP levels. He was extubated soon after surgery and the clinical course was good.

We ordinarily use low PEEP levels (5-8 cmH_2O) in most of our brain-injured patients, trying to decrease FiO_2 to below 0.6 (Table 17.4). This approach is also used by groups who focus on cerebral perfusion pressure (CPP) and ventilation management according to the patient's hemodynamic and respiratory status. Nevertheless, we are cautious in the use of high PEEP levels in patients with low recruitability, as this may overdistend the lung and increase mean airway pressure and ICP (Figure 17.6). In patients with severe brain injury and intracranial hypertension, close monitoring of CPP and ICP, as well as respiratory variables, is essential to titrate and optimize ventilatory management.
In neurocritically ill patients with severe respiratory failure, high PEEP levels or unconventional ventilatory modes may be necessary to prevent hypoxemia. In such patients with low respiratory compliance, changes in ICP after PEEP adjustments are subtle. Recruitment manoeuvres involving high airway pressure over short periods of time may open otherwise collapsed alveoli and have a diagnostic role in assessing recruitability in patients with severe hypoxemia. Their therapeutic role is limited, as several clinical studies in patients with ALI/ARDS have shown a transient increase in oxygenation along with hemodynamic derangement, but without an impact on major outcomes such as hospital mortality or length of stay. In brain-injured patients, especially those with low recruitability, recruitment manoeuvres may be harmful and increase ICP.

17.6 ALI/ARDS and Ventilator-induced Lung Injury

Previously, we mentioned that brain injury and unconsciousness produce hypoventilation, atelectasis, gastric content aspiration and/or an increase in permeability, all conditions which may produce or favour the development of ALI and ARDS. ALI/ARDS is observed in nearly 10 to 30% of patients with acute brain injury and jeopardizes outcome. Simmons et al. found in Vietnam war soldiers who had died of isolated head trauma that 85% of them presented evidence of significant lung injury, including hemorrhage, alveolar edema and congestion, which could not be explained by lung trauma. Bratton and Davis found a 20% incidence of ALI/ARDS in 100 coma patients, with a 2- or 3-fold increased probability of death or vegetative state. Similar data were reported by Holland et al. in 131 patients with head trauma, with a 31% incidence of ALI/ARDS associated with increased mortality (38 vs. 15%; p=0.004).
One of the most important changes in ALI/ARDS management comes from the recognition that mechanical ventilation may harm the lung through a series of mechanisms, collectively termed ventilator-induced lung injury (VILI). Initially, there is a mechanical injury to the lung parenchyma, followed by an inflammatory response which may further amplify damage in and beyond the lungs. Overdistention and the repetitive opening and closing of unstable alveoli generate mechanical stress and strain on the lung cytoskeleton, which may rupture the alveolocapillary membrane, activate endothelial and epithelial cells, and amplify the inflammatory response.
The main factor responsible for VILI is tidal volume (Vt). In a large multicenter, prospective study by the *ARDS network* involving over 800 patients with ALI/ARDS, a tidal volume of 12 ml/kg increased mortality from 31 to 39% when compared with low tidal volume. In patients without ALI/ARDS, a high tidal volume (Vt >10-12 ml/kg) may also induce lung injury. In an observational study involving 86 patients with severe head injury, Mascia et al. showed that 22% of patients developed ALI/ARDS within 72 hours after intubation, high Vt being an independent predictor of this complication. In a prospective, randomized study Determann et al. compared tidal volume of 6 or 10 ml/kg in 150 patients without ALI at the onset of mechanical ventilation (Pa/FiO_2 ≥300). Nearly 62%

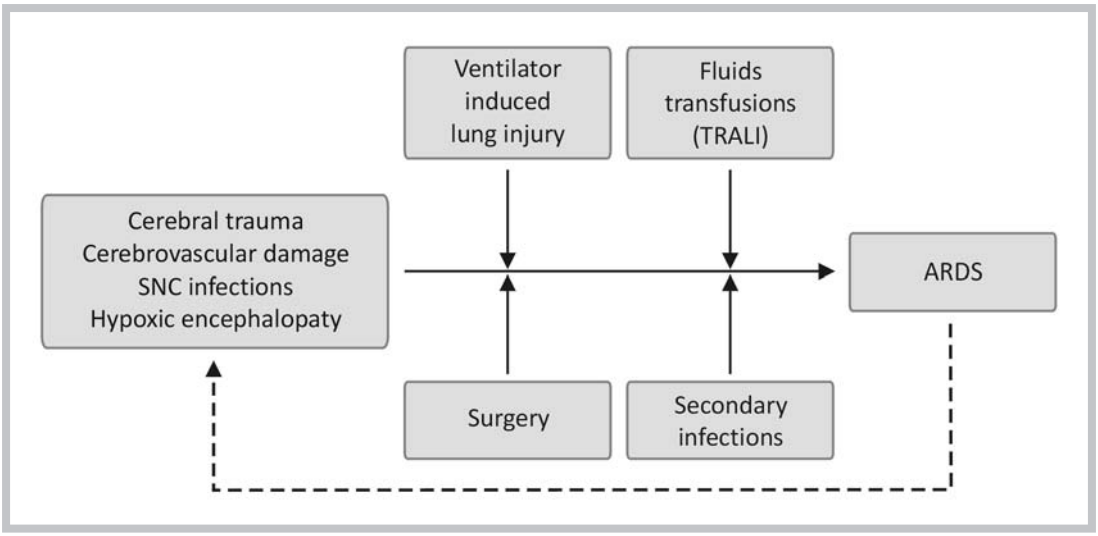

Figure 17.7. **Two-hit hypothesis.**
TRALI = transfusion-related acute lung injury

of the population were neurocritically ill patients (hospitalized for cardiac arrest or neurologic injury). The trial was stopped prematurely for safety reasons because the development of lung injury was higher in the Vt-10 ml/kg group (13.5 versus 2.6%; P=0.01). However, the was no difference in major outcomes as the patients developing ALI were promptly switched to ventilation with 6 ml/kg tidal volume.

More recently, in a prospective, randomized multicenter study involving 118 patients with brain death, the application of a protective strategy (Vt 6-8 ml/kg, PEEP 8-10 cmH_2O) vs. a conventional one (Vt 10-12 ml/kg, PEEP 3-5 cmH_2O) increased the number of patients who met lung donor eligibility criteria (54 to 95%; P=0.001). Lung donor eligibility criteria include a PaO_2: FiO_2 ratio >300 mmHg on FiO_2 1.0, a normal chest X-ray, and peak airway pressure <30 cmH_2O. Finally, the protective strategy doubled the number of patients from whom the lungs could be harvested (54 vs. 27%; P=0.004). This study underscores the importance of protective ventilation even in brain-injured patients with a poor prognosis.

All clinical evidence points to the fact that the lungs are always at risk of VILI, especially when high tidal volume is applied. This is especially relevant in the neurologic population, since high tidal volumes were frequently recommended in the past to induce hypocapnia. Similarly, ALI/ARDS is a complex entity which could be induced or triggered by multiple injuries in a "two-hit" hypothesis (Figure 17.7). Brain injury induces systemic inflammation which can affect distant organs, including the lungs. These lungs, "primed" by circulating cytokines, are exposed to successive inflammatory hits secondary to inadequate ventilation, transfusion (transfusion-related acute lung injury [TRALI]), hydric overload, nosocomial infections, among others, all of which may amplify the inflammatory response and favour the development of ALI/ARDS. In other words, high Vt will induce lung injury in previously injured or inflamed lungs but not in the healthy lung.

17.7 Weaning

Neurocritically ill patients are clearly distinct from the general ICU population: they cannot maintain a patent airway because of unconsciousness. This requirement is different

Main reason for mechanical ventilation in frank recovery	Normal ICP and brain compliance
Hemodynamics	Heart rate and arterial pressure stable
Oxygenation	PaO_2 >60 or $SatO_2$ >90% PaO_2/FiO_2 >250
Level of consciousness	Able to protect and maintain a patent airway

Spontaneous breathing trial	• Muscular strength
	  ▪ VC >20 ml/kg
	  ▪ MIP >-25 cmH_2O
	• Ventilatory drive (workload)
	  ▪ Minute ventilation <10-12 litres
	  ▪ Respiratory rate >10 and <35/min
	  ▪ Tidal volume 5-8 ml/kg
	  ▪ Ventilatory mechanics (cervical and abdominal muscles)
	  ▪ Adrenergic state (tachycardia, hypertension, sweat)

Table 17.5. **Clinical conditions for considering weaning from mechanical ventilation.**

ICP = intracranial pressure VC = vital capacity
MIP = maximal inspiratory pressure

from mechanical ventilation. With regard to weaning, we need to distinguish airway management from ventilatory support, evaluating both the capacity to protect and maintain a patent airway and to ventilate spontaneously (Table 17.5).

Before making the decision to discontinue ventilatory support, it is important to be clear that the reason that initially motivated support is improving and normal brain compliance has recovered. The switch from positive pressure ventilation to spontaneous ventilation may induce an hyperadrenergic state or cardiac failure, leading to hypoxemia and/or hypercarbia, which may increase CBF and ICP, thus jeopardizing neurologic recovery.

Spontaneous breathing trials, through a T-piece or at low levels of PEEP and pressure support, will allow us to evaluate respiratory drive and mechanics. If the patient shows good muscular strength and there is no sign of fatigue (Table 17.5) after 30 minutes to 2 hours, the trial is successful and the endotracheal tube can be withdrawn.

The level of consciousness is fundamental when evaluating the patient's capacity to maintain a patent airway. Salam et al. evaluated three simple clinical elements to discriminate whether the patient will tolerate extubation after having passed a trial of spontaneous breathing: level of consciousness, quantity of endotracheal secretions, and cough peak flows. The level of consciousness is evaluated on four simple tasks: open the eyes; follow with eyes; grasp the hand; and stick out the tongue. In that study, inability to complete the tasks, a cough peak flow <60 l/min or secretions >2.5 ml/h predicted extubation failure.

Delay in weaning in neurocritically ill patients is a risk factor for the development of pneumonia and other ventilator-related complications. However, failed extubation and tracheal reintubation may also favour complications. Early signs of extubation failure should prompt reintubation to avoid hypoxemia, hypoventilation, acidosis and lung aspiration, which could increase morbidity and mortality.

If a patient successfully passes a trial of spontaneous breathing but does not fulfil the criteria for extubation, or, if extubated, presents extubation failure, tracheostomy should be considered.

17.8 Tracheostomy

As mentioned, airway management is crucial in unconscious brain-injured patients. As a general rule, patients with head trauma and a GCS score <8 require invasive airway management (Figure 17.4). There is wide acceptance that laryngoscopy and endotracheal intubation have low morbidity and that a delay in intubation in the unconscious patient may increase morbidity; therefore, endotracheal intubation should be aggressively performed in such patients.

There is no definitive evidence that early tracheostomy (during the first week) improves major outcomes. However, there is a wide heterogeneity in definitions and outcomes in clinical studies and each centre had its own protocols for deciding when to perform tracheostomy. In general, patients with severe head injury, in which a prolonged ICU length of stay may be anticipated, an early tracheostomy may facilitate weaning from the ventilator. For periods shorter than 2 or 3 weeks, endotracheal intubation may be a good alternative. In patients with severe facial trauma, tracheostomy can be a good choice on admission to the emergency department.

In the last 20 years, percutaneous tracheostomy has greatly facilitated the decision-making process. It can be safely performed at the bedside, and it is now widely accepted as a first-choice technique. Tracheostomy in the ICU is an elective procedure, and should be deferred in patients with intracranial hypertension, hemodynamic instability, or infections.

17.9 Conclusions

Brain-injured patients present respiratory problems which, in turn, may affect the brain, inducing secondary neuronal injury and hampering recovery. Ventilatory support maintains ventilation and prevents hypoxemia and hypercapnia (Table 17.6). A judicious application of airway management, sedation, tidal volume and PEEP, based on the pathophysiology of the patient's condition is fundamental to hasten recovery and obtain a good long-term outcome.

Maintain ventilation	• Normocapnia or light hypocapnia ($PaCO_2$ 35-40) • Hyperventilation is second tier therapy
Optimize alveolar recruitment	• Routine use of PEEP (5-10 cmH_2O) • Higher PEEP levels (10-15 cmH_2O) if Pa: FiO_2 <200
Avoid lung injury	• Limit tidal volume (Vt ≤-9 ml/kg body weight index)

18 Surgical Airway Management in the Neurocritically Ill Patient: Timing, Technique, and Complications

Mario Raul Villalba [1], Mario Ramon Villalba [2]

[1] Attending Surgeon/Intensivist, Beaumont Health System, Royal Oak, Michigan, USA
[2] Director, Surgical Critical Care, Beaumont Health System, Royal Oak, Michigan, USA

18.1 Introduction

Neurocritically ill patients often require airway management in the emergency department and the intensive care unit (ICU). In most cases, the patient will be successfully intubated in a timely fashion. However, in a minority of patients, intubation may not be possible and a definitive surgical airway will be needed to maintain the patient and avoid additional morbidity. This chapter will describe the indications for establishing a surgical airway, both emergently and electively, the various different types of operation, and the potential risks and benefits of a surgical airway.

18.2 Surgical Airway Management

When head-injured or neurologically compromised patients arrive in the emergency room they should be evaluated in an expedited fashion. The patient's level of consciousness can be assessed according to the Glasgow Coma Scale (GCS), and the airway should be simultaneously inspected. Not infrequently, head-injured patients also have concomitant facial and cervical spine injuries which must alert the physician to potential difficulties in establishing an airway. A definitive airway should be secured in any patient deemed not to be able to protect their own airway. This includes all trauma patients with a GCS of 8 or below, or when other clinical factors are present, such as concomitant neck trauma. According to advanced trauma life support (ATLS) practice guidelines, establishment of the airway is of utmost importance. Loss of airway leading to hypoxia will quickly result in a lethal event or secondary injury in patients with a traumatic brain injury.

18.2.1 Endotracheal Intubation

Oral endotracheal intubation, generally performed with a rapid sequence induction, is the first-line intervention for establishing a secure airway. Care should be taken to maintain cervical spine precautions during intubation, as the majority of these patients have not had clearance of their cervical spine. An assistant can achieve this with in-line immobilization of the head and neck. The assistant can also facilitate intubation by performing a simultaneous jaw thrust. Pre-procedural preparation is of paramount importance for the successful intubation of trauma patients. Availability of multiple laryngoscopes, endotracheal tubes in different sizes, suction, and adequate is required prior to attempting oral endotracheal intubation.

When oral-tracheal intubation has failed, either because of anatomical factors or because of traumatic factors, multiple adjuncts are available to the physician, including laryngeal mask airway, use of gum elastic bougies, needle cricothyroidotomy, and retrograde intubation. The physician in charge of the airway should be adept and knowledgeable with these alternatives; however, they should be employed cautiously as not to prolong episodes of hypoxia or replace a necessary surgical airway. Most institutions have developed "airway carts" in both the emergency department and critical care units that store all the necessary equipment for airway management.

18.2.2 Cricothyroidotomy

A cricothyroidotomy is the only surgical airway that should be performed in an emergent basis on adult patients. This has been traditionally described as an open technique performed with little more than a scalpel and a small endotracheal tube (size, 5.0-7.0 mm). The non-dominant hand is used to immobilize the trachea and larynx. A generous vertical incision is made overlying the previously palpated cricothyroid membrane (Figure 18.1). The scalpel is used to divide the pretracheal tissue and fascia to the level of the membrane. Next, a shallow horizontal stab incision is made through the cricothyroid membrane and the blade is turned 90 degrees. This opening can be gently dilated if necessary with a hemostat, if available, or using one's digit. Finally, an appropriately selected endotracheal tube is placed through the opening and passed in a caudal direction. The tube should be advanced approximately to 5 cm, and the balloon inflated. It should be noted that significant hemorrhage might be encountered by inadvertent division of the branches of the anterior jugular vein, rendering the entire procedure essentially blind. It is because of this that the stabilizing hand becomes of utmost importance in maintaining an appropriate position and should not be moved until the airway has been secured. Bleeding can be controlled secondarily using either suture ligation or ties. Care should be taken to avoid electrocautery as this will likely be an oxygen-enriched field and a potential fire hazard.

Commercial cricothyroidotomy kits are readily available and generally involve a small vertical incision followed by placing a needle through the cricothyroid membrane, passing a guidewire through the needle into the trachea, employing the Seldinger technique to push a dilator and an airway simultaneously into the trachea. Either technique is suitable for an emergent surgical airway and should be performed based on the comfort level of the operator. It is generally advisable that any patient with a cricothyroidotomy be converted to a formal tracheostomy within 24 hours to avoid permanent damage to the larynx. This, however, can be delayed somewhat if the patient's clinical status is too unstable.

18.2.3 Tracheostomy

Tracheostomy should generally be regarded only as an elective procedure. Emergent awake tracheostomy performed under local anesthesia are beyond the scope of this chapter and unlikely to be employed in the neurocritically ill. The benefits of a tracheostomy compared to oral-tracheal intubation include enhanced patient comfort, improved access to the airway for suctioning and pulmonary toilet, improved patient communication, less need for sedation, and decreased vocal cord injuries. Tracheostomy should be reserved for neurocritically ill patients who fail ventilator weaning either due to respiratory function or because of decreased GCS and airway protection issues.

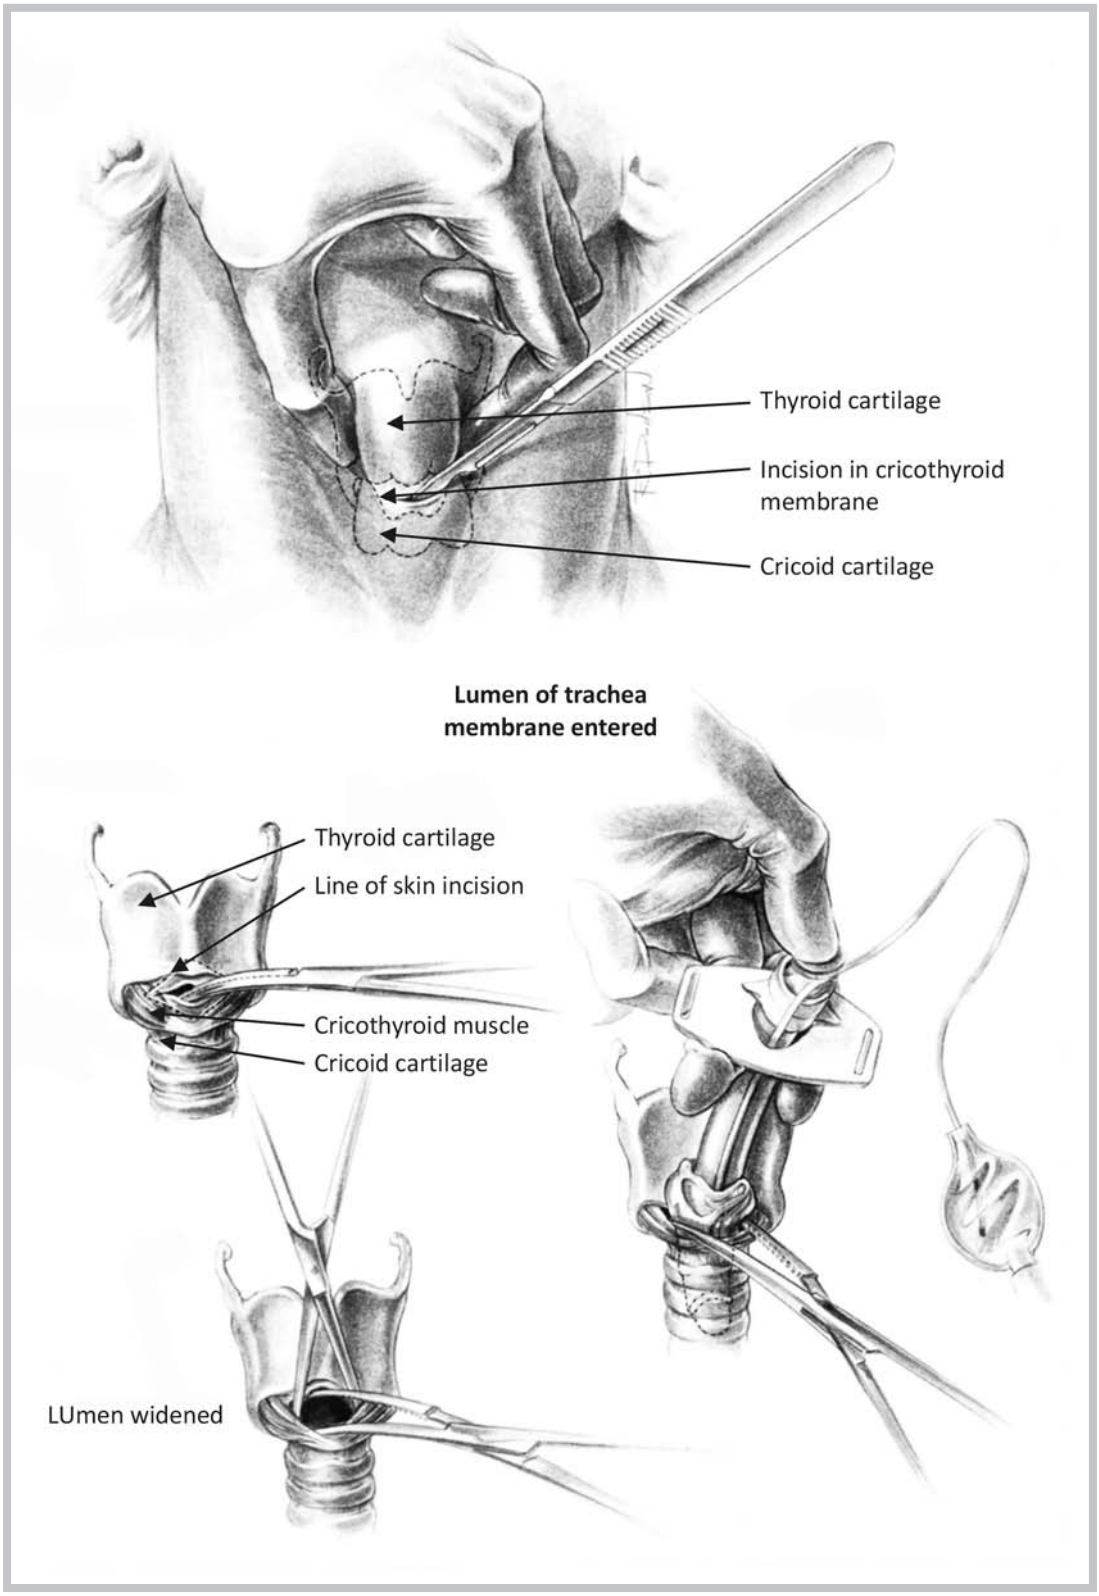

Figure 18.1. **Schematic representation of cricothyroidotomy [8].**

Timing of tracheostomy has changed over the past quarter century. Previously, patients were traditionally maintained intubated with endotracheal tubes for prolonged periods of time. Several studies have evaluated the effect of early tracheostomy. A recent prospective randomized trial in medically critically ill patients deemed to require long term ventilatory support found that those who underwent an early tracheostomy, i.e., within 48 hours, versus those receiving a tracheostomy at 14-16 days, had significantly reduced complications including ventilator-associated pneumonia, accidental extubation, and less damage to the oral cavity. Early tracheostomy was also associated with fewer days in the ICU, days on mechanical ventilation, and a significantly lower 30-day mortality. These findings have also been observed in retrospective studies and a recent meta-analysis [3]. It is the authors' opinion that any patient who is deemed to need prolonged mechanical ventilation be offered an early tracheostomy [2,4], within 72 hours, for all these reasons.

Tracheostomy can be performed safely either in the surgical suite or at the bedside in the intensive care unit (ICU). Our published experience with bedside tracheostomy revealed a 2.9% incidence of major complications and a 3.4% incidence of minor complications. These are comparable to rates reported in the literature for a surgical suite tracheostomy. A comparison of hospital charges shows that tracheostomy is less expensive when performed in the ICU rather than the surgical suite because it incurs no facility or anesthesia fees. Another advantage of bedside tracheostomy is that critically ill patients do not require being transported. While it is these authors' practice to perform virtually all tracheotomies in the surgical ICU [6], we recognize that patient safety takes precedent over financial considerations and suggest that the reader's practice be tailored as such.

Tracheostomy can be performed either open or with a percutaneous dilational technique. An open tracheostomy begins with appropriate patient positioning. This generally entails hyperextension of the neck over a blanket roll if possible, the neck is then prepped and a sterile field created; local anesthetic with epinephrine is given to anesthetize the skin and subcutaneous tissues. A transverse incision is made two fingerbreadths above the sternal notch. The platysma is divided with electrocautery. The midline fascia is incised and the strap muscles are separated. At this point, the thyroid can be gently retracted superiorly, exposing the second and third tracheal rings. This space is incised and widened with Metzenbaum scissors and an inferior tracheal flap is created by incising the lower tracheal ring bilaterally. The endotracheal tube is gradually withdrawn until it is out of the field, and the tracheostomy can then be gently inserted into the trachea and balloon inflated. Placement is confirmed with end-tidal carbon dioxide monitoring and return of appropriate tidal volumes on the ventilator. The tracheostomy is then secured with a tight cloth tied around the neck rather than sutures to the neck. Once the trachea is opened, cautery, because it is a potential fire hazard in an oxygen enriched environment, must never be used. It is our practice to postpone tracheostomy until the patient's oxygen requirement is <50% FiO_2 and there is no coagulopathy.

The percutaneous technique, as originally described by Ciaglia [1], employs a bronchoscope through the endotracheal tube to view the airway; the tube is gently withdrawn to the level of the cricothyroid cartilage. A small vertical incision is then made approximately 2 fingerbreadths above the sternal notch. Hemostats are used to dissect the tissues to the level of the trachea. Next, a large bore needle is introduced into the trachea under direct bronchoscopic visualization. A guidewire is then passed and serial enlarging dilations of the trachea are performed via the Seldinger technique. The tracheostomy can then be placed under direct visualization of the bronchoscope. As opposed to the open technique, these patients should be placed 100% FiO_2 prior and for the duration of the procedure as the bronchoscope limits both oxygenation and ventilation during the procedure.

The advantages of the open technique include no need for muscle relaxants, which are commonly used for percutaneous tracheotomies, and no need for bronchoscopy. Again, a review of hospital charges shows that the percutaneous technique is more expensive because it requires bronchoscopy during the procedure [5]. The advantages of the percutaneous technique are that the patient's neck is not hyperextended for exposure, which is useful in patients with concomitant cervical spine injuries or non-clearance, the minimal dissection causes less bleeding, which is an important consideration in patients who recently received anticoagulants or antiplatelet agents. Also, the percutaneous technique may be easier to perform in patients with a history of neck radiation. Again, we recommend that the practitioner be adept with both techniques and employ each on a selective basis.

Complications of tracheotomies can be divided into operative, postoperative, and late. The most common operative complication is hemorrhage, which occurs in 1-3% of cases, and is usually due to aberrant anatomy, i.e., a thyroidea ima artery. Less common operative complications include pneumothorax (0-4%) and recurrent laryngeal nerve injury. Such complications are generally due to technical error. Postoperative hemorrhage is rare and generally results from a missed bleeding vessel during dissection. Minor bleeding more than 48 hours after placement is generally associated with coagulopathy. Wound infections are rare and are generally averted by not closing the skin incision over an open tracheostomy. Most infections will be treated with a short course of antibiotics only.

Late complications are well described and include tracheal stenosis, tracheomalacia, and tracheoinnominate artery fistula. Fortunately, these complications are quite rare. We advocate the use of minimal leak techniques with high-volume low-pressure cuffs to to avoid the initial mucosal ischemic event precipitating these other complications. Tracheesophageal fistula is an extremely rare event following tracheostomy (1%). Tracheoinnominate artery fistula generally occurs approximately 1-3 weeks postoperatively due to the cuff pressing anteriorly on the innominate artery. Patients present with either a herald bleed event or massive hemoptysis. Control, prior to operative repair, can be obtained by either hyperinflation of the cuff or removing the tracheostomy and occluding it with a finger against the sternum through the stoma. In over 35 years of our ICU experience, a tracheotomy created high between the second and third tracheal rings has never led to the development of a tracheoinnominate fistula.

18.3 Conclusions

The patient with an acute traumatic brain injury will often need to be intubated for either respiratory distress or decreased mental status, raising concerns about their ability to protect their airway. When oral-tracheal intubation is not possible, it becomes imperative to establish an airway in an expedited fashion to avert secondary injury due to prolonged hypoxia. This can be performed in an emergent fashion with a cricothyroidotomy.

Once a patient is intubated and deemed to need prolonged mechanical ventilation or airway protection, an early tracheostomy should be strongly considered. The advantages include decreased sedative requirements, less infectious complications, fewer days on the ventilator, and shortened ICU length of stay. The type of tracheostomy technique and the location of the operation are both secondary considerations. While it is more cost effective to perform bedside open tracheotomies in the ICU, it is more important to perform the procedure safely with the most competent staff available.

19.1 Gastrointestinal Motility Disorders in the Neurocritical Patient

Gastrointestinal motility disorder (GIMD) is a frequent complication in the critically ill patient. It is estimated that 80% of patients with increased intracranial pressure after cranial trauma and 50% of ventilated patients have abnormalities in gastric emptying. GIMD manifests most frequently as an inhibition of gastrointestinal propulsion and less often as a hyperkinetic movement accompanied by diarrhea or vomiting. The inhibition of motility can affect the entire gastrointestinal (GI) tract or only a part of it. Added to discomfort is the increased risk of complications such as ventilator-associated pneumonia, bacterial translocation, the systemic inflammatory response syndrome (SIRS), sepsis and intolerance to enteral nutrition. Gastrointestinal motility is regulated by complex mechanisms involving the nervous and humoral pathways. The nerve path includes the nerve centres, the intrinsic nervous (intramural plexus) and the autonomic nervous system. Neurohumoral regulation is effected by neurotransmitters and GI peptides.
The causes of GIMD are multifactorial and include:

- Encephalic or spinal injury.
- Abdominal surgery.
- SIRS.
- Sepsis.
- Systemic or regional hypoperfusion and hypoxemia.
- Fluid and electrolyte imbalance.
- Acid-basic imbalance.
- Hyperglycemia.
- Neuroendocrine factors (catecholamines, nitric oxide, 5-hydroxytryptamine, liberating factor of corticotropin-releasing hormone, etc.).
- Drugs: anesthetics, opioids, sedatives, antihypertensives, antihistamines, anticholinergics, sympathomimetics.

Such disorders may be more frequent, more severe or persistent when they coexist with other diseases, including diabetes mellitus, neuropathies, Parkinson's disease, myopathies, amyloidosis, thyroid disease or connective tissue diseases, which themselves affect GI motility.

19.1.1 Gastroparesis

Gastroparesis results in intolerance to enteral feeding and limits delivering nourishment to the critically ill patient. This is particularly problematic when malnutrition is chronic or develops during hospitalisation. Furthermore, a lack of food in the intestinal lumen eliminates the major source of stimulus to maintain splanchnic flow and the integrity of the intestinal mucosae.

Enteral nutrients exert a cytoprotector effect on the GI tract and need to be taken into account in the critically ill patient. When the stomach fails to empty, the absorption of nutrients and medicines is slowed and bacterial colonization occurs. Other serious consequences are the risk of regurgitation and pulmonary aspiration.

Gastric retention is determined by measuring gastric waste, but the definition of excessive residue is vague as is the correlation between increased waste and its adverse consequences. By general consensus, a waste of ≥200 ml is considered excessive. A gastric reflux volume of 500 ml over 24 h indicates impaired gastric emptying.

Pharmacological treatment of impaired GI motility in critically ill patients is clinically challenging because the mechanisms underlying dysmotility are usually complex. The patient's pre-existing characteristics in terms of GI function are diverse and the availability of pharmacological tools is limited.

The beneficial effect of prokinetic drugs derives from their property to stimulate, directly or indirectly, contraction of the intestinal smooth muscle. In the only systematic review conducted to date (18 studies published in the last 20 years) on the effect of metoclopramide, erythromycin and cisapride on GIMD and tolerance showed contradictory results. The main problems with these studies are the small samples and heterogeneity of the populations studied, which makes it difficult to reach definitive conclusions.

Cisapride, a prokinetic drug, 5-HT_4 receptor agonist and 5-HT_3 receptor antagonist, is effective in stimulating motility throughout the GI tract. In 2000 cisapride was withdrawn from the U.S. market and most European countries because of its potential to induce serious and occasionally fatal cardiac arrhythmias, including ventricular tachycardia, ventricular fibrillation, and torsades de pointes. These arrhythmias result from prolongation of the QT interval through interaction with the pore-forming subunits of the HERG K^+ channel.

Cinitapride, another prokinetic drug, with a chemical structure and mechanism of action similar to that of cisapride, stimulates 5-HT_4 receptors; unlike cisapride, it is a dopamine D_2 antagonist, although less than metoclopramide. The recommended adult dosage is 1 mg every 8 h. It has not been evaluated in children and its use is not recommended.

The incidence of side effects of cinitapride, when given at therapeutic doses, is very low and does not differ much from that of placebo according to comparative studies. However the technical specifications of the drug warn that it can produce drowsiness or sedation and extrapyramidal reactions (dystonia, late dyskinesia), particularly in elderly patients. Cases of gynecomastia and hypersensitivity reactions have also been described.

The lack of serious cardiotoxic effects described with cisapride is apparently because the HERG channels of potassium concentration required/plasma-free drug concentration is 23,000 for cinitapride (much higher than the usual therapeutic doses) and 73 for cisapride. Although it appears to be safer than the cisapride, because the available information on cinitapride is scarce and studies to date present methodological limitations, its role in the treatment of gastroparesis and GI disorders is not clearly defined.

The prokinetic properties of **metoclopramide** are limited to the upper digestive tract. In critically ill patients it has been shown to produce beneficial effects on the GI tract and tolerance to feeding when administered by the intravenous route, but ineffective when

given via a nasogastric tube. Postoperative ileus is unaffected by metoclopramide. The main limitation of the drug is that it induces extrapyramidal reaction.

Erythromycin, a macrolide antibiotic that stimulates gastric and intestinal motility through direct action on motilin receptors on enteric neurons and smooth muscle cells, increases the pressure of the lower esophageal sphincter by stimulating the cholinergic nerves. Erythromycin administered intravenously is more potent in the relief of gastroparesis than following oral administration. The ability of erythromycin to facilitate gastric emptying and improve tolerance to enteral feeding has been confirmed in two double-blind, placebo-controlled studies in critically ill and mechanically ventilated patients. The impact of erythromycin on colonic transit remains controversial. A systematic meta-analysis of prokinetic drugs for treating gastroparesis reported that the effect of erythromycin on gastric emptying is greater than that of other prokinetic drugs.

The association of erythromycin with torsade de pointes and ventricular dysrhythmias and increased incidence of microbial resistance has motivated some authors to consider its use as a motility agent in critically ill patients to be problematic.

Domperidone acts primarily as an antagonist on peripheral dopamine D2 receptors. It increases esophageal peristalsis and facilitates gastric emptying by augmenting gastric peristalsis and improving antroduodenal coordination. Although domperidone is similar in efficacy to metoclopramide, it causes fewer extrapyramidal side effects because it does not cross the blood-brain barrier.

Neostigmine is a reversible acetylcholine esterase inhibitor that transiently increases the concentration of acetylcholine at its receptors and in this way facilitates parasympathetic and enteric stimulation of GI contractility. The effect of neostigmine injected intravenously to stimulate GI motility is controversial, although postoperative patients usually show a good response to the drug.

The combination of a drug that stimulates the release of acetylcholine from enteric neurons, like metoclopramide, with a drug that inhibits acetylcholine breakdown, like neostigmine, may be successful. Pharmacological options in the treatment of GIMD, the main drugs with prokinetic effects, their mechanism of action and recommended doses are summarized in Tables 19.1 and 19.2.

Therapeutic strategy	Therapeutic options	Individual drugs
Early use of supportive therapeutic options	Stimulant laxatives	Bisacodyl, sodium picosulphate
	Osmotic laxatives	Magnesium salts
	Polyethylene glycol plus electrolytes	Macrogol 3350
	Opioid receptor antagonists	Naloxone
	Reduce use of drugs with an inhibitory effect on GI motility	Anesthetics, sedatives, opioids and adrenergic agonists
Goal-directed specific therapies	Prokinetics for gastroparesis	Erythromycin Metoclopramide Domperidone
	Prokinetics for gastroparesis and intestinal motor inhibition	Erythromycin Metoclopramide plus neostigmine
	Prokinetics for intestinal motor inhibition without gastroparesis	Ceruletide Metoclopramide plus neostigmine

Table 19.1. **Pharmacological options in the treatment and prevention of gastrointestinal motility disorders.**

Drug	Mechanism of action	Site of action			Dose
		Stomach	Small intestine	Colon	
Metoclopramide	Dopamine D_2 receptor antagonist Partial 5-HT_4 receptor agonist Weak antagonist of vagal and central 5-HT_3 receptors	++	+	0	10-30 mg IV/day
Erythromycin	Stimulates gastric and intestinal motility through a direct action on motilin receptors on enteric neurons and smooth muscle cells Increases the pressure of the lower esophageal sphincter by stimulating cholinergic nerves	++	+	0	3x100 mg/day IV maximun use for 3 days
Neostigmine	Acetylcholine esterase inhibitor	0	(+)	+	0.5-1.5 mg once a day, IV, in 250 ml saline, over 1-2 h
Ceruletide	Contraction of the gallbladder and bile ducts by stimulating coordinated propulsive motility from the duodenum to the ileum and inducing segmenting activity of the colon	0/(--)	++	+	40 µg once a day IV, in 100 ml saline, over 30-60 min
Domperidone	Blocks peripheral dopamine receptors	+	(+)	0	30-40 mg, orally

Table 19.2. **Prokinetic drugs: dose, mechanism and site of action.**

0 = No effect
(-) = Effect negative possible
(+) = Effect positive possible
+ = Good positive effect
++ = Very good positive effect

19.1.2 Constipation

Motor dysfunction of the large intestine is common in seriously ill patients; motor function doesn't usually recover within 7-10 days of admission. There is no uniformly accepted definition for constipation in critical patients. As a result, its actual incidence is unknown. An applicable definition in clinical practice is to consider constipation when the patient has not passed stools for 3 consecutive days.

Constipation has not been well studied in critical patients, and its causes have not been clarified in controlled studies. It has been suggested that constipation may be due to alterations in bowel motility secondary to disease process, changes induced by routinely administered drugs (sedatives, opiates, etc.) and by a diet devoid of fibre.

In the evaluation of patients with constipation, we should follow the usual recommendations (clinical assessment of the abdomen, rectal examination and radiological investigations). In the prevention of constipation, the role of dietary fibre is fundamental in patients receiving prolonged enteral nutrition. Dietary fibre in the prevention or treatment of constipation associated with enteral nutrition has not been investigated by controlled studies in neurocritical patients.

The use of enemas for cleaning or laxatives is common. In drug treatment, however, agents of intermediate latency seem preferable to accelerator medications to stimulate intestinal transit as they increase the fecal bolus and act preferentially in the colon.

The lack of adequate bowel movement can lead to bacterial overgrowth and promote intestinal translocation and infectious complications in critical patients. This may be especially important when using digestive decontamination, given that the lack of deposition may counteract the purported effect (elimination of pathogenic intraluminal flora) and it can contribute to the development of secondary infectious complications.
In short, GIMD are common in the neurocritical patient and can lead to an increase in the incidence of complications and prolong stay in the intensive care unit (ICU). Therapeutic options for GIMD in the neurocritical patient include correction of water and electrolytic imbalance, early enteral nutrition, proper use of catecholamines and medications for sedation and analgesia, as well as prokinetic drugs. While the choice of the ideal prokinetic in the critically ill patient is not well established, metoclopramide may be the most reasonable drug. Bearing in mind that the treatment options are still limited for this type of disorder, it is important to identify the diagnostic and therapeutic approach in each case.

19.2 Common Gastroenterological Disorders in Severe Acute Neurological Illness

The severely ill neurosurgical patient tends to develop serious gastrointestinal complications which can be overcome with early diagnosis and appropriate treatment. The most important common gastrointestinal complications are: gastrointestinal bleeding, gastroparesis and diarrhea, which are encountered daily in the intensive care unit (ICU), but can be easily managed with prompt action by the interdisciplinary team.
The incidence of gastrointestinal bleeding is now fairly low due to the increasing use of gastric mucosal protective drugs, but this doesn't necessarily decrease its importance. Several causes have been associated with the presence of varices arising in the distal esophagus and proximal gastric regions and other acid-related causes, such as peptic ulcer and mucosal damage due to stress. Less common causes include the Mallory-Weiss syndrome and vascular lesions. Several risk factors for bleeding have been identified: mechanical ventilation for more than 48 hours, and ongoing coagulopathy.
Other causes, whose importance is variable, are: shock; liver and renal failure; sepsis; multiple trauma; burns over 35% of the body surface area; organ transplantation; spinal cord or head trauma; and a history of previous ulcer disease.
Many different causes of gastroparesis have been indentified, among which diabetes is one of the most common. Other causes include: infections; endocrine disorders; connective tissue disorders like scleroderma; neuromuscular diseases; idiopathic (unknown) causes; cancer; radiation treatment to the chest or abdomen; some forms of chemotherapy; and surgery of the upper intestinal tract.
The presence of gastrointestinal complications has a negative effect on the amount of diet that can be provided to the patient. This nutritional deficit can also adversely affect patient outcome, with an increase in infectious complications, hospital stay and mortality. The use of protocols for the identification and proper management of gastrointestinal complications in critically ill patients may be a beneficial factor in their evolution.
Nutrition in neurocritical patients plays an essential role, since their recovery depends also on it. Critically ill patients require early nutritional support to attenuate the physiological response to the illness, so the administration of adequate and early food decreases the progression of the multiple organ dysfunction syndrome (MODS). This will also result in reducing metabolic complications and infections.

19.2.1 Gastrointestinal bleeding

Introduction

Gastrointestinal (GI) bleeding is defined as the extravasation of blood in the GI tract from a bleeding site between the upper esophageal sphincter and the angle of Treitz or duodenojejunal flexure. Upper gastrointestinal bleeding (UGIB) is currently an uncommon complication (1-2%), although it is a cause of increased mortality. The two most common causes are gastrointestinal bleeding (GIB) due to peptic ulcer and secondary to portal hypertension.

Lower gastrointestinal bleeding (LGIB) is less common than UGIB, and tends to be self-limiting. Bleeding due to "stress ulcer" or acute gastric mucosal disease is the most common cause of bleeding in less severe cases and is closely related to the underlying disease and the degree of multiorgan dysfunction. Several factors, most notably mechanical ventilation in the strict sense and prolonged ICU length of stay, have been implicated in bleeding due to "stress ulcer". Improvement in hemodynamics and oxygenation, the use of enteral nutrition and the administration of gastric mucosal protective drugs are appropriate tools for the prevention and treatment of bleeding due to acute gastric mucosal injury in critically ill patients.

GI bleeding can have a significant effect on the nutritional management of patients. Often, GI bleeding, irrespective of its size or type, leads to the withdrawal of enteral nutrition or delays its start. However, this decision cannot be justified in all cases: the reason for withdrawing enteral diet in patients with bleeding due to "stress ulcer", peptic ulcer without risk of bleeding according to the endoscopic image, the Mallory-Weiss syndrome, angiodysplasia or LGIB should not be the risk that the diet increases bleeding, as there is no pathophysiological explanation for this. On the contrary, as indicated, there is evidence that enteral nutrition can protect the gastric mucosa and have a beneficial effect on both the prevention and treatment of mucosal injury.

Incidence

UGIB is one of the most common causes of emergency care, with an incidence of 100-150 cases per 100,000 inhabitants per year.

It is the main gastroenterological emergency and the leading cause of cancer death (10-14%), associated with co-morbidities and age.

UGIB is much more common in men than in women and increases with age; 75-100% of critically ill patients have mucosal damage within 24 hours after ICU admission.

Etiology

The most common causes of GI bleeding are primarily (each: 75% incidence in critically ill patients): hemorrhagic gastritis, gastric ulcer, duodenal ulcer (acid peptic disease).

As a secondary cause (each account for 5-15% of HVD causas): esophageal varices, duodenitis, esophagitis, mallory-Weiss syndrome.

The Mallory-Weiss syndrome refers to tears in the gastro-esophageal mucosa which are responsible for 5-10% of UGIB. The classic features are nausea, vomiting or gagging cough (arcadas de tos), and a previous history of hematemesis.

Three different types of bleeding due to stress-induced mucosal disease may occur in ICU patients: the first is occult bleeding, defined as a gastric aspirate or positive stool guaiac test, and is the most prevalent one. The second is obvious or overt bleeding: in most cases it is not clinically relevant and refers to the presence of hematemesis, melanemesis, hematochezia or melena. The incidence of obvious bleeding is only 5%. The third is clinically significant or relevant bleeding (1-4%) and is clinically evident with

hemodynamic instability and a hemoglobin decrease of 2 g/dl. ICU patients commonly develop problems in the proximal GI tract as a result of severe psychological stress.

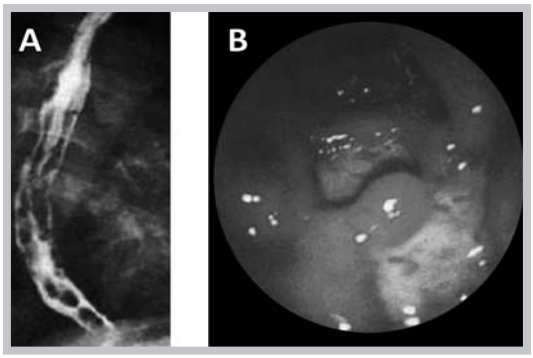

Figure 19.1. **Causes of gastrointestinal bleeding. A). Esophageal varices. B). Crohn's Disease.**

Prophylaxis

One of the leading causes of morbidity in patients hospitalized for any other cause is GI bleeding, although not all patients have the same risk of developing it as an intercurrent event. True prophylaxis is reserved for patients without underlying gastroduodenal pathology but with risk factors. Drugs should be administered before injury occurs.

Prophylaxis of this kind of bleeding must be established rationally and based on the risk factors of each case. Until recently, prophylactic treatment was indefinitely based on the use of antisecretory drugs because many bleeding ulcers progressed to hemorrhagic exacerbation within 2-3 years.

Different types of medications are used: traditional antacids (magnesium and/or aluminium hydroxide); sucralfate; histamine receptor antagonists (H_2 antagonists); proton pump inhibitors (PPIs); misoprostol and pirenzepine via oral and intravenous administration because they are dosed by bolus or infusion. The goal is to raise the pH over 4.0 and keep it there as long as possible to avoid renewed long-term bleeding.

19.2.2 Gastroparesis

Introduction

Literally, gastroparesis means "stomach paralysis". Gastroparesis is a syndrome defined by delayed gastric emptying essentially of solids, without evidence of mechanical obstruction. When the stomach works normally, gastric contraction helps to grind the ingested food and then propels the pulverized food into the small intestine, where digestion and absorption of nutrients continue.

The clinic of gastroparesis may range from mild forms, in which the patient reports dyspeptic symptoms such as early satiety, postprandial fullness or nausea, to severe forms with gastric retention that manifests as repeated vomiting, even with significant nutritional impairment.

Etiology

Although there are several causes leading to gastroparesis, one of the most common is diabetes, but there are also infections, endocrine disorders, connective tissue disorders like scleroderma, neuromuscular diseases, idiopathic causes (unknown) cancer, radiation treatment to the chest or abdomen, some forms of chemotherapy, and surgery of the upper intestinal tract.

Any surgery performed in the esophagus, stomach and duodenum may result in vagus nerve injury, which transmits sensory and motor responses (muscle) to the intestine: normally, the vagus nerve sends impulses through neurotransmitters to the stomach smooth muscle to produce contractions and propel gastric contents. If the vagus nerve is injured during surgery, gastric emptying may not occur. Symptoms of postoper-

- Narcotics for pain control
- Tricyclic antidepressants
- Calcium channel blockers
- Clonidine
- Dopamine agonists
- Lithium
- Nicotine
- Drugs containing progesterone

Table 19.3. **Drugs preventing gastric emptying.**

ative gastroparesis may develop immediately or years after surgery.

On the other hand, the use of some medications, especially narcotics for pain control with calcium channel blockers and some antidepressants, may delay gastric emptying and gastroparesis-like symptoms (Table 19.3). People suffering from eating disorders like anorexia and bulimia may also develop gastroparesis. Fortunately, gastric emptying can be restored and symptoms improve, while normalizing food intake and improving eating habits and feeding schedules.

19.2.3 Gastrokinetic-prokinetic Agents

In many patients with gastroparesis, prokinetic agents accelerate gastric emptying and improve nausea, vomiting and postprandial fullness sensation.

Metoclopramide

Metoclopramide was the first drug developed as a prokinetic and antiemetic agent. It has a D_2 antidopaminergic action and is also a serotonin 5-HT_4 receptor agonist. It acts on dopamine receptors in the stomach and intestine, as well as in the brain. By stimulating stomach contractions, it promotes better emptying. It can act on the part of the brain responsible for controlling the gag reflex, and therefore may reduce the sensation of nausea and the urge to vomit.

For some people, the use of this medication is limited owing to the side effects of agitation and facial spasms or tardive dyskinesia. Metoclopramide can also cause painful swelling of the breast and nipple discharge in both men and women. It is not recommended for long-term use. The recommended dose is 10 to 20 mg every 8 h orally, about 20 minutes before meals.

Domperidone

Domperidone also has an antidopaminergic action, but with the advantage that very little crosses the blood-brain barrier, so it has far less side effects at the central level. Chronic administration of domperidone can improve gastric dysrhythmia, which correlates with clinical improvement, but is not accompanied by significant changes in gastric emptying, thus suggesting the existence of an electromechanical dissociation. The recommended dose is 10 to 20 mg every 8 h orally, about 20 minutes before meals.

Erythromycin

Erythromycin, an antibiotic of the macrolide family, acts as a potent gastrokinetic agent and a motilin receptor agonist on intestinal smooth muscle. Intravenous erythromycin is followed by a normalization of gastric emptying of both solids and liquids; a beneficial effect persists with oral erythromycin but is much less than after parenteral administration.

The effectiveness of erythromycin in the long-term treatment of gastroparesis is controversial, since it seems to be accompanied by a progressive loss of efficiency, probably due to a tachyphylactic effect. Moreover, erythromycin has side effects such as ototoxicity in patients with renal failure or pseudomembranous colitis, which sometimes lead to discontinuation of its administration. Another fact to consider is that the use of this an-

tibiotic as a prokinetic agent carries the risk of inducing bacterial resistance. The recommended intravenous dose in acute cases is 3 mg/kg every 8 h. The oral dose is 250-500 mg every 8 hours, about 20 minutes before each meal.

Cisapride

Cisapride, a serotonin 5-HT_4 receptor agonist, and to a lesser extent, a serotonin 5-HT_3 receptor agonist, is another drug frequently used in the treatment of gastroparesis. Its administration, both oral and intravenous, enhances gastric emptying of digestible and indigestible solids.

It binds to serotonin receptors in the stomach wall, leading to contraction of the smooth muscle of the stomach and improvement in gastric emptying. At the end of 1990s, cisapride was withdrawn from the market due to reported complications of cardiac arrhythmias in patients with a history of arrhythmia or coronary artery disease who used this drug. Now, it is once again available, though its use is restricted. People who have underlying kidney or heart disease should not take cisapride.

19.2.4 Diarrhea

Diarrhea is a symptom typical to many pathological conditions, especially in diseases of the GI tract. It is a consequence of an alteration in GI mechanisms involved in the absorption and secretion of fluids, electrolytes and nutrients.

Etiology

Diarrhea is common in ICU patients, and its incidence is estimated between 20 and 60%. All medical staff associate diarrhea in the ICU with tube feeding, but not always does the cause reside in the process of feeding or schedule. The main factors associated with diarrhea in the ICU are drugs (antibiotics, antacids, with magnesium and others), intesti-

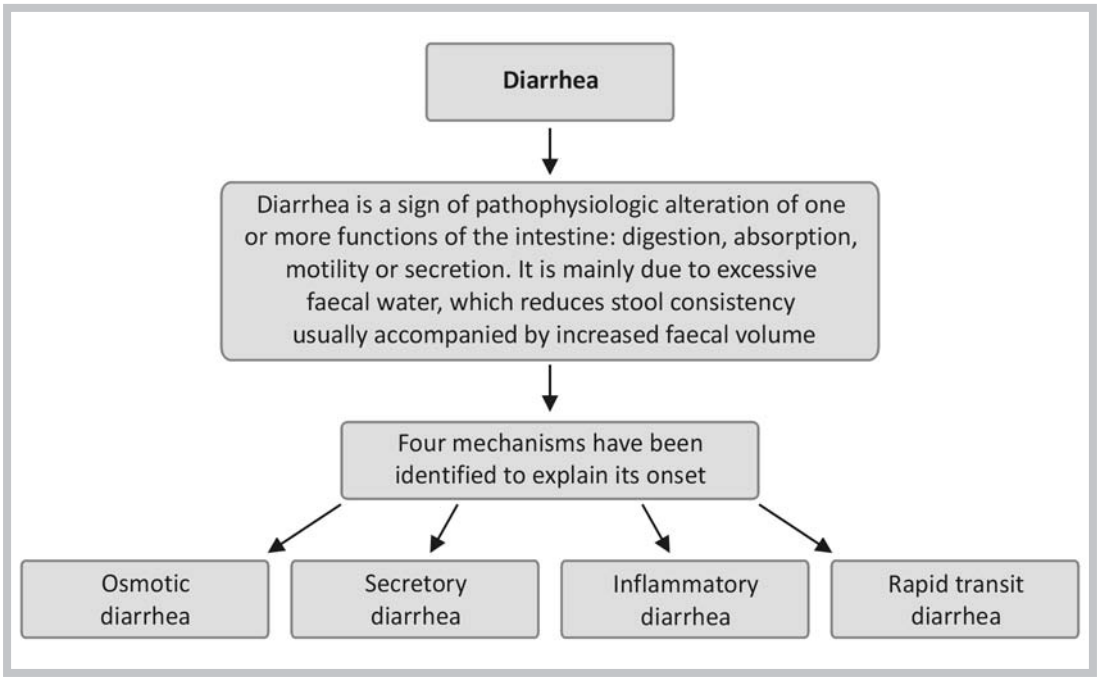

Figure 19.2. Types of diarrhea.

nal mucosal injury, bacterial or viral infection, and the administration of large volumes of hyperosmolar liquid preparations directly into the small intestine.

The causes of acute diarrhea are variable and can be classified in different ways, one of which is infectious (viral, bacterial, parasitic and fungal) and non-infectious.

The majority of enteric pathogens that cause acute diarrhea penetrate the body through the oral route and colonize the intestine before the onset of symptoms of diarrheal disease. A key step in the colonization process, in almost all cases, is bacterial adherence to the intestinal epithelium. Often, the mechanisms of adhesion of bacteria and protozoa are very specific and are mediated by interactions of receptor-ligand type. This process often uses lecithins or similar molecules (adhesins) which interact with hydrocarbon fractions of the membrane of the microvilli. The mechanisms by which enteropathogens cause diarrhea are various, but two broad categories are distinguished: those increasing intestinal secretion; and those reducing intestinal absorption.

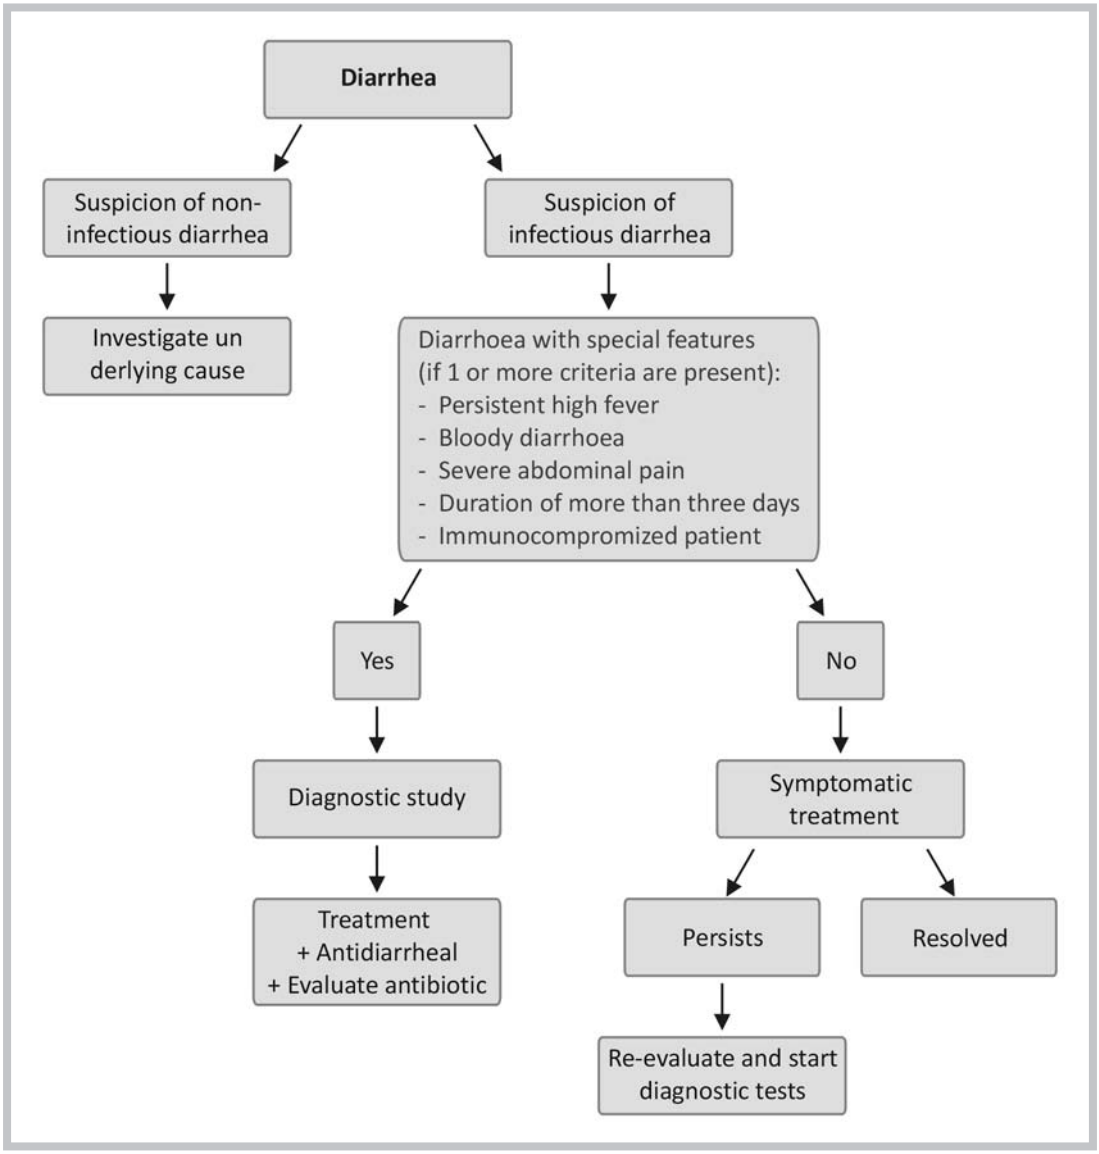

Figure 19.3. Flow chart of the management of acute diarrhea.

Diagnosis

For **acute diarrhea**, the most common diagnosis is established on the basis of the clinical history and features without recourse to other examinations. The latter may be indicated in severe processes or when the patient may be at increased risk (elderly, immunocompromised, etc.). In such cases, the most important diagnostic test in acute diarrhea is microbiological analysis of stool, usually culture for enteropathogenic bacteria and direct examination of the stool sample under optical microscopy to rule out the presence of parasites. It may be necessary to repeat this study to rule out with certainty the presence of pathogenic microorganisms (disease-producing pathogens). Figure 19.3 summarizes the management of acute diarrhea.

The study of a patient with **chronic diarrhea** can be daunting. Based on the multiple triggering causes, several laboratory tests could be described. However, the basis for establishing the diagnosis is a complete and thorough medical history, along with physical examination. At the beginning, even simple analytic studies such as blood testing can be ordered. With this information we can establish the mechanisms involved, direct causes, and nutritional and hydration status of the patient, the latter being key to treatment. At first, and depending on the suspected diagnosis, other investigations may be indicated, such as a fasting test (to demonstrate lactose intolerance), an examination of the large intestine by endoscopy (proctosigmoidoscopy in cases of suspected irritable bowel syndrome), colonoscopy, stool microbiology.

Other suitable tests include determining the fat (maldigestion or fat malabsorption), blood, leukocytes or laxative content of the stool. The presence of blood and leukocytes (inflammatory cells) suggests an inflammatory process, underlining the importance of microbiological examinations. Imaging studies such as upper GI endoscopy or radiological examination of the small intestine can also be useful.

19.2.5 Nutrition in Neurocritical Patients With Gastrointestinal Problems

The quality of nutrition plays an active role in everyday activities, emotional reactions, affectivity, as well as genesis of the cognitive substrate. Every year, thousands of people suffer serious head injuries with devastating effects on neurological function and the consequent deterioration in their quality of life. For four decades, advances in nutritional support in critically ill patients were not applied to severe neurosurgical patients, and, despite the predictability of the impact that these injuries have on body homeostasis and the profound metabolic effects on the hematopoietic, immune and muscular systems, treatment consisted of waiting, sometimes delaying for weeks the initiation of nutritional support.

Today, many studies on early nutritional support in severe neurosurgical patient suggest that early nutrition can lower the risk of infection and death of the neurologic patient.

Early or Late?

The critically ill patient requires early nutritional support which attenuates the physiological response to illness, so as to decrease the progression of multiple organ failure (MOF) with the adequate and early administration of food and to reduce metabolic complications and infections. Previous studies had shown that early nutrition lowers the risk of morbidity due to superinfection. However, while starting early enteral or parenteral support is not sufficient, it does provide an adequate supply of energy intake to cover the energy needs of these patients.

Enteral or Parenteral?

In any patient in critical condition, treatment will aim to reducing the risk of intestinal atrophy and bacterial translocation, for which enteral nutrition has become the main strategy to stimulate mucosal trophism. This principle is important and in most protocols enteral nutrition is included as an essential part of treatment. Sometimes, it is difficult to achieve caloric needs enterally early due to serious disorders in intestinal transit as a result of ECT and intracranial hypertension; therefore, the benefits of early nutrition are lost. This is especially true for gastric feeding, because gastroparesis is much longer than jejunal ileus.

Some studies, such as that by Young et al. suggest a better prognosis for patients fed with parenteral nutrition. The development of naso-esophageal probes, the early use of endoscopic gastrostomy, the use of new and improved prokinetic agents [Altmayer et al., 1996] and the basic formulas that favour absorption [Taylor et al., 1999] have improved the use of the enteral route, increasingly diminishing dependency on the parenteral route to supply the calories needed. Initially, it is recommended to start nutrition as soon as the patient has been revived and is hemodynamically stable.

Unless there are formal contraindications or an overt intolerance is documented, enteral nutrition is the technique of artificial nutrition of choice. This concept is applicable to any patient, even to gastroenterological patients. If a portion of the GI tract is functional, it must be used: enteral nutrition is more physiological, and brings more benefits to the patient's recovery, while aiming to quickly reach the resting energy expenditure. Parenteral support can be gradually decreased as enteral nutrition is increased.

Uncontrollable diarrhea with dehydration and/or electrolyte imbalance, or acute GI bleeding may preclude enteral nutrition. As a second step, parenteral nutrition can be initiated as soon as possible to prevent depletion.

In enteral nutrition, the route and the quantity of calories needed for the patient's energy expenditure should be determined. As the symptoms of diarrhea or bleeding decrease, the possibility of initiating enteral nutrition or mixed nutrition should be considered in order to gradually discontinue enteral nutrition.

In general, the frequency of potentially serious complications is greater with parenteral nutrition than with enteral nutrition. Until recently, the fundamental difference between them was the risk of catheter sepsis in parenteral nutrition. Although the risk is ultimately minimized, there are still differences in morbidity favouring enteral nutrition, especially with regard to metabolic disorders or liver problems related to artificial nutrition, which are more frequent and severe with parenteral nutrition.

Schedules

A naso-esophageal probe should be placed and an oligomeric formula started where the size of the macronutrient polymer is lower. Its use is indicated in cases of lower digestion or absorption capacity. Protein intake is provided as dipeptides and tripeptides and a very small portion of tetrapeptides and pentapeptides, keeping very limited the incorporation of amino acids, in addition to high osmolarity that they give to the formula, for the proper absorption of dipeptides and tripeptides.

These formulas contain a significant proportion of medium-chain triglycerides. Carbohydrates are supplied, as in the polymers, in the form of maltodextrin. In addition, the formula must be enriched with arginine, ribonucleotides and omega 3 fatty acids. Enteral nutrition should be started at low infusion volumes and then gradually increased, as tolerated, until all calorie supplements can be supplyied by this route.

Nutritional Monitoring

Once the nutritional regimen has been initiated, the physician will need to know the extent to which repletion of body behaviours considered strategic occurs to ensure the

success of pending medical-surgical action. Nutritional monitoring should serve as a feedback mechanism for changes in the scheme of nutritional support if the patient fails to respond as expected.

19.2.6 Conclusions

One of the most common problems in critically ill patients is GI complications during the stay in the ICU. The most clinically relevant complications include GI bleeding and complications associated with enteral feeding. Currently, GI bleeding is uncommon thanks to the use of mucosal protective agents and the increasingly widespread use of enteral nutrition. A common complication of enteral nutrition is diarrhea, which may result from improper use of formula or patient intolerance to the type of formula given. Furthermore, some medications such as sorbitol can cause diarrhea. GI complications have a negative effect on the amount of diet that can be provided to the patient. This nutritional deficiency can also adversely affect patient outcome, with an increase in infectious complications, hospital stay and mortality. The use of protocols for the identification and proper management of GI complications in critically ill patients may be a beneficial factor in their evolution.

20 Nutritional Support in Critically Ill Patients

Mario A. Domínguez Perera [1], Elias Béquer García [1]
[1] Arnaldo Milián Castro University Hospital, Santa Clara, Villa Clara, Cuba

20.1 Introduction

The critically ill patient presents with a metabolic picture in which a large amount of energy is needed in order to maintain hemostasis. The higher metabolic rate leads to a greater demand for calories, proteins, vitamins and electrolytes. If this situation is not taken into account, malnutrition will inevitably ensue. Malnutrition can develop quickly, with direct physiologic consequences for respiratory, cardiac, renal and gastrointestinal function, as well as a higher risk of infection, all of which increase complications and prolong intensive care stay. The incidence of death in trauma patients is higher when weight loss reaches 30%. This is why assessment and nutritional support are vitally important.

20.2 Metabolism During Injury

Glucose requirements are much higher following injury than during starvation. The stress response begins in the central nervous system (CNS) and includes the sympaticoadrenal axis, hormones, cytokines and acute phase proteins, all reactions which maintain high levels of circulating substrates.

In reaction to injury, nerve impulses are rapidly transmitted to the hypothalamus that responds by augmenting the release of corticotrophin-releasing factor, stimulating the pituitary gland to secrete ACTH, which augments the secretion of cortisol by the adrenal cortex. Corticotropin-releasing factor (CRF) stimulates the sympathetic system to release epinephrine by the adrenal medulla and norepinephrine in the sympathetic nerve endings.

Catecholamines, together with hypothalamic stimulation, increase the release of somatotrophic hormone (STH), which may be part of a feedback control system. These catecholamines produce hyperglycemia and increase glucagon secretion by stimulating pancreatic alpha cells. Insulin is also elevated in small amounts and the insulin: glucagon ratio is reduced, which stimulates glycogenolysis, gluconeogenesis and lipolysis (Figure 20.1).

Injury also stimulates the release of cytokines such as interleukin 1 (IL-1) and tumour necrosis factor alpha (TNF-α) which increase the synthesis of acute phase proteins, causing hyperinsulinemia and the release of counterregulatory hormones (cortisol, catecholamines and glucagon). Interleukin 6 (IL-6) induces hepatic synthesis of acute phase proteins. In patients under stress, especially in sepsis, hyperglycemia results from peripheral insulin resistance, increased levels of catecholamine hormones such as glucocorticoids and glucagon, increased hepatic and renal gluconeogenesis, as well as reduced intracellular glucose oxidation. Lipolysis is increased, with the release of fatty acids and glycerol, which is why fatty acids may constitute the main source of energy in the cells. Ketone production may be inhibited during injury as a result of various not well known mecha-

nisms. Muscle proteolysis during stress augments the release and production of alanine by branched-chain amino acids and their rapid uptake by the liver, with increased hepatic gluconeogenesis. Amino acids derived from muscle proteolysis are converted into

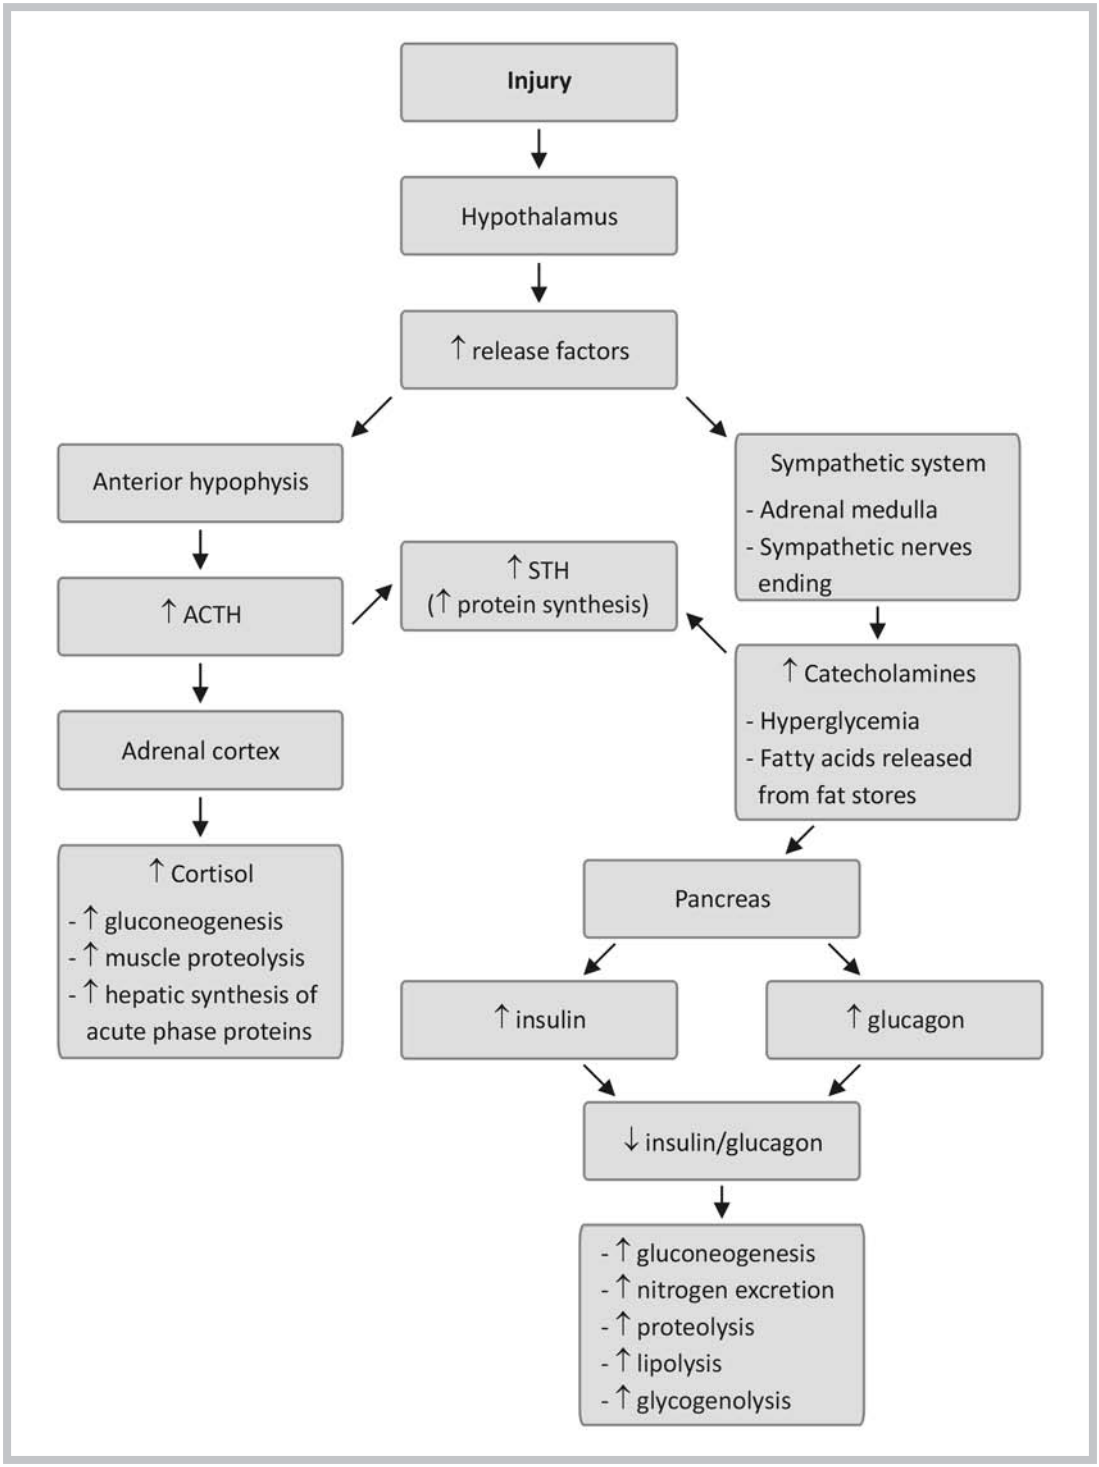

Figure 20.1. Schematic representation of the reactions to injury.

glucose and the rest goes into the synthesis of new liver protein, as evidenced by increased acute phase reactants.
When injury is not properly managed, the effective use of glucose is impaired, which will later affect fatty acid and ketone utilization and eventually the ability to use amino acids as an energy source. When muscle loss due to proteolysis is about 10% of body cell mass, the patient begins to deteriorate, and a loss of 30 to 50% of the body cell mass will end in death.
It should be noted that in patients with acute brain injury the metabolic control centre is damaged by the primary injury, so systemic response is more intense and prolonged than in other types of insults.

20.3 Assessment of Nutritional Status

The use of artificial nutrition has generated the need for an effective method to assess nutritional status in hospitalized patients. Because there is no simple method to define nutritional status, it is very important to have a comprehensive approach that includes careful medical history taking and anthropometric measurement, coupled with laboratory biochemical studies that can provide data about functional proteins and the patient's immune status as well.
The first step in assessing nutritional status is the clinical examination, as it will usually reveal elements that may indicate or suggest the presence of malnutrition. There are well-defined manifestations of a specific nutritional deficit; however, combined or partial clinical syndromes are most often observed. The classic malnutrition symptoms or signs are shown in Table 20.1. Other types of malnutrition are related to the lack of specific nutrients (electrolytes, minerals, oligoelements and vitamins). This lack can be isolated or combined and is often associated with the aforementioned disorders, which is why it may be masked by clinical manifestations.
A complete clinical examination includes evaluation of quantitative data obtained from objective and comparable studies which can be grouped as anthropometric and biochemical (biological indicators) measurement, immune status, and the nutritional prognostic index.

20.4 Anthropometric Measurement

Body weight is a simple guide to the patient's nutrition status, although it expresses the nature of tissue loss and may have errors of interpretation when there is dehydration

Malnutrition type	Marasmus (protein-energy malnutrition)	Kwashiorkor (protein malnutrition)	Mixed
Muscular mass	Very decreased	A little changes	Decreased
Visceral protein	A little changes	Very decreased	Decreased
Edema	Absent	Present	Present
Lymphocytes count	Decreased	Decreased	Decreased
Skin tests	Non-reactive	Non-reactive	Non-reactive

Table 20.1. Malnutrition. Classic types.

or edema. Because this parameter alone has relatively little value, other ways to assess body weight have been described.
Current weight as the **ideal weight percentage** can be calculated as follows:

% ideal body weight = actual weight x 100/ideal weight

Values are:
- Normal >90%.
- Mild malnutrition 80-89%.
- Moderate malnutrition 70-79%.
- Severe malnutrition <70%.

Current weight as **usual weight percentage** is equal to:

% usual weight = current weight x 100/usual weight

Values are:
- Normal >95%.
- Mild malnutrition 85-94%.
- Moderate malnutrition 75-84%.
- Severe malnutrition <75%.

Modified body weight or **recent weight change** is equal to:

% modified body weight = (usual weight – current weight) x 100/normal weight

Weight loss >10% indicates malnutrition, but even minor losses are reason for concern.

Triceps skinfold provides an estimate of subcutaneous fat which accounts for almost half of the body fat. It should be taken in the not-dominant arm (usually left) with the patient in the standing position or sitting with the arm hanging next to the body. If the patient is lying down, the arm should be placed with the forearm flexed over the chest. Measurement is taken at the midpoint between the acromion and the olecranon on the back of the arm. The fold thickness is measured with a Lange caliper or another type of instrument. A pressure of about 10 g/mm^3 should be applied, taking three measurements and then calculating the average value.
Standard values are 12.5 mm in men, and 16.5 mm in women. The obtained measurement is compared with the standard value using the formula:

% standard value = current measurement x 100/standard measurement

Values >80% indicate that adipose tissue is preserved; values <80% indicate loss of body fat. It is a useful index for assessing the degree of malnutrition, since changes in subcutaneous fat happen slowly.
Upper arm circumference is an indicator of muscle mass. Measurement should be taken in the half of the extended arm, at the midpoint between the spinous process of the acromion and the olecranon. The values can be compared using percentile tables or compared with the standard values using the formula:

% standard value = current measurement x 100/standard measurement

The reference values are 29.3 cm in men and 28.5 cm in women.
Values <85% indicate malnutrition.

Arm muscle mass is used to estimate body muscle mass, indicating protein reserves. The formula is:

Arm muscle mass = upper arm circumference (cm) – 0.31416 x triceps skinfold (mm)

The current measurement is compared with standard values (25.3 cm in men and 23.2 cm in women):

% standard value = current measurement x 100/ standard measurement

Values >80% indicate adequate muscle mass; values <80% indicate protein mass deficit.
Body height is obtained by dividing the height (cm) and the wrist circumference (cm) at the level of the styloid process.

Body height = height (cm)/wrist circumference (cm)

Values in men are:
- Normal <9.6.
- Light malnutrition 9.6-10.4.
- Moderate malnutrition >10.4.

Values in women are:
- Normal <9.9.
- Light malnutrition 9.9-10.9.
- Moderate malnutrition >10.9.

Creatinine-height index is an estimate of muscle mass because creatinine is formed from creatine only in the muscle. In patients with normal renal function this value is relatively constant for a given weight and height. This index is defined as the relationship between urinary creatinine excretion over 24 hours and the expected urinary excretion in a normal adult of the same size.

Men		Women	
Height (cm)	Creatinine (mg/dl)	Height (cm)	Creatinine (mg/dl)
157.5	1288	147.3	830
160.0	1325	149.9	851
162.6	1359	152.4	875
165.1	1386	154.9	900
167.6	1426	157.5	925
170.2	1467	160.0	949
172.7	1513	162.6	977
175.3	1555	165.1	1006
177.8	1596	167.6	1044
180.3	1642	170.2	1076
182.9	1691	172.7	1109
185.9	1739	175.3	1141
188.0	1785	177.8	1174
190.5	1831	180.3	1206
193.0	1891	182.9	1240

Table 20.2. **Urinary creatinine values according to sex and height.**

Creatinine-height index: = current urinary creatinine x 100/ideal urinary creatinine

The ideal urinary creatinine is obtained from tables (Table 20.2).
Creatinine-height index values <60% indicate a severe depletion of somatic proteins; values between 60 and 80% indicate a moderate depletion.
Errors in anthropometric measurement are due to methodological inaccuracies. Some authors argue that there is an insufficient correlation between these measurements and body nitrogen.

20.5 Biochemical Measures (Biological Indicators)

20.5.1 Estimated Somatic Protein Mass

Excretion of urinary 3-methylhistidine (3-me-his): 3-methylhistidine is formed from histidine methylation and is found only in the myofibre protein in the muscle. During muscle breakdown, actin and myosin proteins are released, but as they cannot be reused for protein synthesis, they are excreted with the urine, which provides an index of muscle catabolism. Each gram of muscle protein releases 4.2 micromoles of 3-methylhistidine.
Values depend on the pathological situation:

- Simple fasting <100 µmol/24 hours.
- Elective surgery 130±20 µmol/24 hours.
- Trauma 200±20 µmol/24 hours.
- Sepsis 450±50 µmol/24 hours.

20.5.2 Creatinine Urinary Excretion

Creatinine is produced by creatine metabolism. In patients with normal renal function, urinary excretion correlates with the total organic creatinine value.
Normal values: 23 mg/kg/day in men and 18 mg/kg/day in women.
These values vary according to renal function and nutritional intake of the patient.

20.5.3 Estimated Visceral Protein Mass

It refers to the measured plasma proteins synthesized by the liver.
Albumin, the main protein produced by the liver, maintains plasma oncotic pressure and is involved in the transport of various substances. It is not a good indicator of malnutrition, since it has a long half-life (16-21 days) and its concentrations are reduced and recovered very slowly during changes in nutritional status.
Values are:

- Normal 35 g/l.
- Mild depletion 30-34 g/l.
- Moderate depletion 25-29 g/l.
- Severe depletion <25 g/l.

Albumin levels <28 g/l lead to the development of edema because of the decrease in plasma oncotic pressure.
Prealbumin, a protein involved in the transport of thyroxine, has a half-life of 2 days and is present in a small pool in the body which decreases quickly with any sudden demand

for protein synthesis, as in trauma or acute infection. It is useful as a short-term nutritional index.
Values are:
- Normal 15-30 mg/dl.
- Mild depletion 10-14 mg/dl.
- Moderate depletion 5-9 mg/dl.
- Severe depletion <5 mg/dl.

Transferrin (TFN), a betaglobulin synthesized in the liver, conjugates the iron in plasma. Its half-life (t ½) is 8 to 10 days. It belongs to the group of acute phase reactive proteins and shows more precisely the changes in acute visceral proteins (depletion and repletion) due to its short half-life and small pool. It can be measured by radial immunodiffusion or calculated from total iron binding capacity (TIBC) with the following formula:

$$TFN = (0.8 \times TIBC) - 43$$

Values are:
- Normal 250-400 mg/dl.
- Mild depletion 150-250 mg/dl.
- Moderate depletion 100-150 mg/dl.
- Severe depletion <100 mg/dl.

Retinol binding protein, a specific protein that transports vitamin A alcohol is bound to prealbumin. Since it is filtered by the glomerulus and excreted by the kidney, it rises in renal disease. It is a sensitive index of subclinical malnutrition and a good responder to nutritional recovery because it breaks down within about 10 to 12 hours.
Normal range is 2.6-7 mg/dl.

Fibronectin is a protein with a half-life of less than 2 days. It has a very important relevance, more than other proteins, and is also used in monitoring the patient.
Values are:
- Normal range 320-360 mg/dl.
- Mild depletion 230-319 mg dl.
- Moderate depletion 200-229 mg/dl.
- Severe depletion <200 mg/dl.

Values <200 mg/dl are associated with increased mortality.
Techniques for measuring visceral proteins do not provide an accurate assessment of nutritional status, as they are influenced by factors other than malnutrition. There is a direct correlation between albumin, transferrin and fibronectin depletion with higher morbidity and mortality, delayed healing and decreased resistance to infection.

20.5.4 Measurement of Immune Response

Immune function is reduced in malnutrition, which is associated with higher morbidity and mortality from infectious diseases.
Decreased total lymphocyte count (TLC) is related to depressed cellular immunity, according to the following formula:

$$TLC = \% \text{ lymphocytes} \times \text{total white blood cells}/100$$

Values are:
- Normal >2000/mm^3.
- Mild immune deficiency 2000-1200/mm^3.

- Moderate immune deficiency 1200-800/mm^3.
- Severe immune deficiency <800/mm^3.

Skin tests indicate the cell-mediated immune state; to perform it are used antigens as the purified protein derivative antigens (PPD), Candida, mumps, histoplasma, and streptokinase-streptodornase and trichophytum. Intradermal hives appear on the anterior forearm when 0.1 ml of each of the antigens is given. Reading should be performed at 24 to 48 hours.

Values are:

- Positive or reactive: wheal >5 mm.
- Negative or non-reactive: wheal <5 mm.

A patient is considered immunocompetent when he has a good response (>5 mm) to two or more antigens. Anergy is defined as negative reaction to all antigens. These tests are less useful in patients with cancer, cirrhosis or in those under immunosuppressive therapy, because they may be incompetent due to the immunological condition itself, even when nutritional status is adequate.

20.5.5 Nutritional Prognostic Indexes (NPI)

These indices are very important to establish a relationship between nutritional status, as evaluated by objective parameters (anthropometric, biochemical or immune status) and morbidity and mortality. The index described by Buzby is derived by the formula:

$$NPI = 158 \text{ to } 16.6\ (Alb) – 0.78\ (TS) – 0.20\ (ST) – 5.8\ (DHR)$$

where: Alb = serum albumin (g/l); TS = triceps skinfold (mm); ST = serum transferrin (mg/dl); DHR = delayed hypersensitivity response.

Results are:

- No reaction = 0.
- Induration <5 mm = 1.
- Induration >5 mm = 2.

The result indicates the probability of occurrence of complications due to malnutrition, the most important of which is sepsis. Based on this index, several authors have applied multiple linear regression analysis using two or three variables which showed good correlation with severe complications and mortality, thereby generating various indexes, the most useful of which in our practice is:

$$NPI\ (Alb\text{-}DHR) = 55 \text{ to } 10.2\ (Alb) – 9\ (DHR)$$

DHR is used as the skin response to five antigens, scored as 1 when it is normal and 0 if there is anergy.

The values associated with a greater probability of complications are:

- NPI (Buzby) >40.
- NPI (Alb-DHR) >18.

20.5.6 Energy Expenditure

Living organisms need energy for all sorts of biological activities such as the synthesis of cellular material, transport of substances against a concentration gradient, muscle contraction, and production of heat to maintain body temperature constant. Nutrients (carbohydrates, fats and proteins) are transformed to provide the energy needed

for body functions. When energy intake exceeds consumption, the energy is stored, resulting in weight gain. Conversely, when energy expenditure exceeds intake, the deficit is made up for by the body's reserves, resulting in weight loss.

Basal energy expenditure (BEE), also known as basal metabolic rate (BMR) or basal metabolic index (BMI), refers to the production of energy per unit of time in basal conditions, defined as physical and mental rest, soon after awakening in the post-absorptive stage (about 12 hours after the last meal) and normal body temperature (18-26°C). This is the minimum energy consumption during physiological conditions. The liver, brain, heart and kidney consume 60% to 70% of BEE, although they account for only 5% to 6% of body weight, which reflects their high metabolic activity. In contrast, the muscles constitute 40% of body weight and use only 18% of BEE, depending on the activity of respiratory muscles and those required to maintain posture. BEE depends on cellular processes such as ion pump, synthesis and degradation of cellular constituents in which the protons cross the mitochondrial membrane, and also respiratory muscle and myocardial contraction. BEE is generally between 1500 and 1800 kcal/day and can be predicted by several methods (Table 20.3).

Body weight (kg)	BEE (kg Kcal/day)
50	1316
55	1411
60	1509
65	1602
70	1697
75	1784
80	1872

Table 20.3 Normograms.

Harris-Benedict formula:

$$\text{BEE (men)} = 66.5 + 13.75\ (W) + 5\ (H) - 6.75\ (A)$$

$$\text{BEE (women)} = 65.5 + 9.56\ (P) + 1.84\ (H) - 4.7\ (A)$$

where: W = weight (kg), H = height (cm), A = age (in years).

BEE is expressed in kcal/kg. This formula has the advantage that it can be rapidly calculated and is easy to apply, although errors of up to 30% of total calories have been reported.

Resting energy expenditure (REE) refers to the energy expenditure at basal conditions. The difference between BEE and REE derives from food-specific dynamic actions and thermogenic response, which is the increased energy expenditure caused by nutrition itself. REE is equal to BEE increased by 10%. It is reported that the REE of patients with traumatic brain injury is 140% on average. Barbiturates, propranolol and muscle relaxants can decrease hypermetabolism, although this has not proved to influence the prognosis.

Total energy expenditure (TEE) refers to the caloric intake to be administered to maintain body weight. It is usually obtained from BEE, and it takes into account the degree of catabolism associated with the disease or injury.

Different forms of production have been described:

$$\text{TEE (Rutten)} = \text{BEE} \times 1.75$$

This formula is unreliable because it does not adequately reflect the involvement of patient's physical activity or increased activity in situations of stress.

$$\text{TEE (Long)} = \text{BEE} \times \text{activity factor} \times \text{stress factor}$$

Clinical conditions	Correction factors
Prolonged fasten	0.85-1.00
Non complicated postoperatory period	1.00-1.05
Fever*	1.10-1.13
Peritonitis	1.05- 1.25
ARDS	1.20
Long bone fracture	1.15-1.30
Infection:	
Mild	1.20
Moderate	1.30
Severe	1.50-1.60
Head trauma	1.60
Burns	
10 to 30 % body mass	1.50
30 to 50 % body mass	1.75
More than 50 % body mass	2.00

Table 20.4. **Correction factors in different clinical conditions.**
* For each temperature grade above 37ºC or fever lasting more than 24 hours, increase occurs.

The activity factor (AF) corresponds to the degree of patient mobilization. In critically ill bedridden patients it is 1.20 (20% increase in BEE) and 1.30 in awake patients. Some authors use an average of 1.25 in all situations. This factor does not take into account paralyzed patients or ventilated patients under muscle relaxation. In mobile patients, one must use expenditure energy (EE) tables which link it with the type of activity. The stress or aggression factor (AF) corrects the EE for different conditions and is obtained from tables that have been created for this purpose. Table 20.4 describes the one used in our unit.

Another way to calculate TEE is by indirect calorimetry, which determines the amount of energy lost as body heat. This method measures the amount of energy expenditure of all metabolically active cells in the body, which is equal to TEE.

To calculate TEE by this method, one must know the concentration of inspired (FiO_2) and expired oxygen (FeO_2), inspired and expired CO_2 fractions ($FiCO_2$ and $FeCO_2$, respectively), inspired and expired minute volume (IMV and EMV), CO_2 production (VCO_2) and the respiratory quotient (RQ). This is done using the following formulas:

$$VO_2 \text{ (l/day)} = FiO_2 \times IMV - FeO_2 \times EMV$$

and

$$VCO_2 \text{ (l/day)} = FeCO_2 \times EMV - FiCO_2 \times IMV$$

Using these parameters, the Weir formula allows the calculation of TEE with three levels of accuracy.

Using only VO_2 in the formula $TEE = 4.83 \times VO_2$, the energy expenditure can be estimated with a minimum of accuracy. The combined use of VO_2 and VCO_2 increases the level of accuracy and allows the calculation of respiratory quotient (RQ):

$$RQ \text{ (TEE)} = 3.9 \times VO_2 + 1.1 \times VCO_2$$

Finally, the incorporation of protein metabolic factor into the evaluation of blood gas production and consumption allows for greater accuracy and to determine the oxidation of each nutrient separately.

$$TEE = 3.94 \times VO_2 + 1.1 \times VCO_2 - 2.17 \times No$$

Where No denotes urinary nitrogen.

Nutrient		Kcal/g	VCO_2 (l/g)	VO_2 (l/g)	RQ	Caloric value per liter of O_2
Carbohydrates	Monosaccharides	3.75	0.75	0.75	1	5
	Polysaccharides	4.30	0.83	0.83	1	5
Proteins		4.20	0.75	0.94	0.80	4.5
Fats		9.30	1.39	1.96	0.71	4.7
Ethanol		7.10	0.98	1.46	0.67	4.9
Ordinary diet		-	-	-	0.82	4.8

Table 20.5. **Energetic value for different nutrients.**
VO_2 = oxygen consumption
VCO_2= carbon dioxide production
RQ = respiratory quotient

It has been found that the exclusion of No generates an error of less than 25% in calculating TEE. Determining the respiratory quotient (RQ) is valuable for estimating the nutrients that are mainly oxidized. The nonproteic physiological RQ ranges from 0.71 to 1.2, which indicates the oxidation of fats and carbohydrates; when it is about 0.7, it depends only on the oxidation of fat; if around 1, it indicates that only carbohydrates are oxidized; and when greater than 1, this suggests that the carbohydrate supply is excessive and lipogenesis is occurring.
The difficulties with this method are that VO_2 and VCO_2 vary constantly; therefore, computers are used to process and analyze the data every minute to obtain a 24-hour average.
The combustion characteristics of each nutrient are related to its chemical structure. Table 20.5 presents the energy characteristics of different nutrients.

20.6 Nutritional Requirements

The energy requirements of different essential elements, as well as vitamins, minerals and water, vary in the hypercatabolic and critically ill patient in relation to the normal patient.
Energy requirements. The patient's energy needs are equivalent to TEE and determine the caloric intake to be provided to maintain body weight. If the objective is to achieve anabolism and weight gain, 1000 kcal should be added to the calculated value, which will increase a weight gain of approximately 1 kg or 2 pounds per week. Normometabolic patients must receive at least 25% of TEE as carbohydrates to save proteins. Since stressed patients have a higher need of carbohydrates to save proteins and maintain high-energy deposits in the tissues, at least 50% of TEE should be supplied as carbohydrates. When carbohydrates are used as the sole source of energy, the needs are around 500 up to 650 g/day. Total carbohydrates should be calculated at a rate of 2 g/kg/day in normal patients and 4-6 g/kg/day in hypercatabolic conditions.
The use of a high caloric intake based exclusively on carbohydrates can lead to essential fatty acid deficiency, liver dysfunction with elevated enzymes, inhibiting the synthesis of very low density lipoprotein (VLDL), increased hepatic triglyceride synthesis, decreased lung surfactant production and increased CO_2 production.
To avoid problems caused by the use of carbohydrates as the sole source of energy, it is recommended to associate them with fats, which have multiple functions, as well as

providing metabolic energy reserve in the adipocytes. Also, phospholipids are formed in the cell membrane and act as intracellular modulators (prostaglandins). Lipids can be used two times per week, with the aim of providing essential fatty acids (linoleic acid), or administered as an energy source, thus supplying some of the calories calculated. The daily fat requirement is 1 to 2 g/kg/day under basal metabolic conditions, which is higher in catabolic situations (3-5 g/kg/day).

The proportion of carbohydrates and fats to be administered varies according to different sets of criteria and the patient's illness. Some authors recommend using no more than 60% of nonprotein calories as fat, stating it should not exceed 100 g/day, although some set the limit as high as 75% of TEE.

Fat emulsions are not well tolerated in certain clinical situations, such as Gram-negative sepsis, neonatal hyperbilirubinemia and carbohydrate and lipid metabolic disorders.

Studies published in the 1960s reported on the need to differentiate long-chain triglycerides (LCT) from medium-chain triglycerides (MCT), highlighting the benefit of the latter because of their high caloric value, similar clearance and metabolism to glucose.

LCT emulsions of fatty acids containing 12 to 24 carbons undergo hydrolysis to fatty acids and glycerol in the intestinal lumen, which are esterified after being re-absorbed to form triglycerides that bind to proteins and phospholipids, forming chylomicrons. They then enter the lymphatic system and finally the blood, where they are distributed to the tissues.

MCT emulsions of fatty acids containing 6 to 12 carbons, mainly octanoic acid, esterified cholesterol are hydrolysed in the intestine five times faster than LCT (although some authors note that they do not need to be absorbed hydrolyzed) and their free fatty acids are absorbed twice faster. They then go directly to the portal vein and are transported to the liver and other tissues as free fatty acids or bound to albumin. They have the advantage of not being stored as fat in the body and are oxidized quickly and completely.

The use of LCT as the sole source of fat produces lipid deposition in the heart, kidneys and lungs, because less than 10% are oxidized and the rest is stored as neutral fat.

The use of MCT alone delivers more calories more rapidly than LCT. MCT are also associated with decreased fatty infiltration but do not prevent essential fatty acid deficiency. At present, the combined use of LCT and MCT is considered most advantageous; therefore, LCT solutions with 25 to 50% MCT are recommended.

In enteral nutrition, MCT should be introduced in small amounts, increasing them gradually to a daily intake of 50 to 100 g.

MCTs are ketogenic, so they are contraindicated in diabetic patients or in those with ketosis and acidosis, in which the capacity of extrahepatic tissues to use ketone bodies is saturated. They should not be used in patients with liver cirrhosis, as the medium-chain fatty acids are metabolized in the liver and liver function is reduced. Octanoic acid accumulates in these patients, so symptoms may appear similar to hepatic encephalopathy.

Protein requirements. In the body there is usually a loss of protein due to the synthesis and degradation of body proteins. The main protein losses occur through the urine and feces, the latter due to intestinal secretions and cell desquamation. In addition, there is minimal loss through the skin and during menstruation in women.

In healthy patients there is a positive nitrogen balance when nonprotein calories are provided for each gram of nitrogen (300-350/1) (7% of TEE). In hypercatabolic and critically ill patients, because urinary nitrogen elimination is increased, the patient needs more protein in relation to the total calories, as protein should comprise about 10 to 20% of TEE. In this particular situation, a ratio of nonprotein calories per gram of nitrogen (100 to 150/1) must be maintained. In septic patients this ratio should be 80 kcal of nonprotein nitrogen per gram of nitrogen.

In patients with acute brain injury, the estimated daily intake of nitrogen should be between 0.3 and 0.5 grams of nitrogen per kilogram of body weight per day.
Protein requirements can be calculated in the ways described below.
From 10 to 20% of TEE as proteins: it must be remembered that each gram of protein provides 4 kcal and that with each 6.25 g of protein 1 g of nitrogen is released (1g of protein is equivalent to 0.16 g of nitrogen).
Using tables that show the daily losses of nitrogen in different clinical situations (replacement must equal losses).
Measured urea in 24-hour urine: nitrogen excretion in urine is the final product of protein metabolism to obtain energy; therefore, the protein requirements can be determined by calculating the daily losses of nitrogen from the elimination of urea in 24-hour urine. For the proper calculation of nitrogen excretion, a steady diet should maintained for 24 to 48 hours beforehand.

Urea in 24 – hour urine (g/24 hours) = urine volume (l/24 hours) x urea in urine (g/l)

The urea molecule is not entirely composed of nitrogen. To obtain the real amount of nitrogen that it contains, it must be divided by 2.14.

UUN (g/24 hours) = urea in 24 – hour urine (g/24 hours) / 2.14

Where urinary ureic nitrogen (UUN) represents 80% of total urinary nitrogen losses (total urinary nitrogen or TUN). The latter can be calculated when 20% of UUN is added to itself.

TUN = UUN + 20% UUN

Added to the obtained value must be 2 to 4 g due to losses by the skin and feces, although these values may be higher in patients with diarrhea, burns, and extensive wounds or diffuse exfoliative dermatitis.
Calculation from TEE, using the desired ratio: nonprotein calories per gram of nitrogen.
When using amino acids as a nitrogen source, some measures should be taken into account:

1. Replacement of the total nitrogen lost.
2. Provide at least 20% of essential amino acids.
3. Provide a ratio of essential amino acids/total amino acid of 1/1 to 1/3.
4. Provide a ratio of essential amino acids per gram of nitrogen of 3.28.
5. The nutrient solution should include all the essential amino acids and traces of the nonessential ones.

Water requirements. Water requirements vary according to clinical status. In basal conditions the daily amount of water required is 25 to 35 ml/kg/day, and these needs increase in hypercatabolic states up to 50 to 70 ml/kg/day. Multiple factors modify water losses, such as high-protein diets, fever, polyuria, vomiting and kidney failure. It is advisable to deliver 1 ml water per kcal provided. It should be taken into account that before admonistering high volumes of fluids, cardiac and renal function and the patient's water balance should be evaluated.

Recommended doses	Nitrogen (g/kg/day)
Minimal daily doses	0.072
Recommended basal doses	0.128
Dosis for minimal stress	0.200
Dosis for moderate stress	0.240
Dosis for severe stress	0.280-0.320

Table 20.6. Nitrogen daily requirements.

Vitamin requirements. Vitamins are essential for nutrition; they are involved in protein metabolism, in extracting energy from carbohydrates and fats, as well as in tissue synthesis. Their needs are not well established, although various investigations have determined their baseline values, which can increase three- to fivefold in hypercatabolic states.

Vitamin requirements may be affected by changes in diet, use of some medications, diseases such as malnutrition, sepsis and trauma, and artificial nutrition, primarily parenteral nutrition. Inadequate or marginal intake in these situations can cause vitamin deficiency.

Vitamins are broadly classified into fat-soluble and water-soluble. The deficit of the water-soluble vitamins occurs more easily because the fat-soluble vitamins are stored in the body and have a slower turnover (Table 20.7).

Water-soluble vitamins should be supplied daily. Vitamin B12 should be taken 2 or 3 times a week and at very wide intervals thereafter.

Fat-soluble vitamins should be administered once a week and vitamin K twice a week.

Requirements of electrolytes, minerals and trace elements. These substances are involved in multiple cellular functions and various enzyme systems. Their needs in basal conditions are considered, and they are increased in hypercatabolic states (Table 20.8). When there are no solutions with trace elements, these can be provided by plasma transfusions given weekly or twice a week.

Vitamins	Daily requirements
Fat soluble	
A (retinol)	4000 UI
D (calciferol)	400 UI
E (tocopherol)	15 mg
K	200 µg
Water soluble	
B1 (thiamine)	3 mg
B2 (riboflavin)	3.6 mg
B3 (niacin)	15 mg
B6 (pyridoxine)	4 mg
Pantotenic acid	40 mg
Folate	0.4 mg
B12 (cyanocobalamin)	5 µg
Biotin	100-200 µg
C (ascorbic acid)	100 mg

Table 20.7. Vitamins daily requirements.

	Daily requirements
Electrolite	
Sodium (Na^+)	1-2 mEq/kg
Chlorus (Cl^-)	1-2 mEq/kg
Kalium (K^+)	0.9-1.2 mEq/kg
Calcium (Ca^{++})	5 mEq/kg
Phosphorus (P^-)	2 mmol/kg
Magnesium (Mg^{++})	0.3 mEq/kg
Nutritional trace	
Iron (Fe^{++})	10-100 mg
Zinc (Zn)	20 µg
Cobalt (Co)	70 µg
Iodine (I)	25 µg
Copper (Cu)	11 µg
Manganese (Mn)	20 µg
Fluorine (F)	1.5-4 mg
Chromium (Cr)	50-200 µg
Selenium (Se)	20-200 µg
Molybdenum (Mo)	150-500 µg

20.7 Artificial Nutrition

Artificial nutrition refers to that condition in which nutrients are not supplied by common dietary foods. It can be administered via different routes. A primary form of treatment, artificial nutrition plays an important role in the comprehensive care of critically ill patients since a nutritional deficit can interact with the disease and prolong the healing process or have devastating consequences.

The goals of artificial nutrition are to:
- Decrease catabolism and promote anabolism.
- Strengthen defence mechanisms.
- Hasten the healing process.
- Maintain or restore muscle mass and function.
- Maintain normal oncotic pressure to prevent edema formation.
- Promote recovery.
- Reduce recovery time, morbidity and mortality.

The routes of administration are enteral nutrition and parenteral nutrition, discussed below.

20.8 Enteral Nutrition

Enteral nutrition refers to the therapeutic delivery of nutrients to the gastrointestinal tract where they are absorbed and assimilated. It is an optimal way to provide nutrients as it is more physiological, maintains the integrity of the intestinal mucosa, and has fewer complications. During the course of critical illness, the gut almost always remains inactive because of ileus or other frequent problems that prevent feeding and require nasogastric aspiration.

Besides its role in the digestion and absorption of nutrients, the intestine also acts as an enteral flora barrier which prevents host invasion by microorganisms or their toxins. In patients who receive no food or nutrients into the digestive tract, the intestinal mucosa become more permeable to the passage of germs and their products into the bloodstream, leading to chronic hypermetabolism and multiple organ failure.

Enteral nutrition has the following advantages:
- Lower cost.
- Safe and effective for long periods.
- Lower incidence of complications (no central venous catheter complications).
- Positive physiological effects.
- Preserved integrity of the intestinal mucosa by intraluminal delivery of nutrients
- Maintenance of the sequence of intestinal and hepatic metabolism before the passage of nutrients into ystemic circulation (digestion, absorption, hormone-substrate interaction).
- Stimulation of the production of secretory IgA.
- Reduction of the metabolic response to stress.

20.8.1 Nutrient Management Methods

In **bolus administration** nutrients are deposited in the stomach which regulates the flow of the formula into the small intestine. The gastric emptying rate depends on the volume and osmolality of the formula. This method requires a small staff and special equipment. From the metabolic point of view, it is generally effective. Volumes of 200 to 400 ml 4 to 6 times a day can cause nausea, vomiting, diarrhea, cramps and bloating, with a high risk of aspiration.

Intermittent administration is given in small amounts of 80 to 160 ml from 20 to 30 minutes every hour; however, tolerance is poor in some patients and the technique is impractical since it occupies a lot of nursing staff time. An alternative way for use in patients requiring prolonged enteral nutrition involves continuous administration of enteral solutions at a rate of 160 ml/hour for 12 hours.

Continuous administration is better tolerated in patients with severe disease and is more useful for duodenal or jejunal nutrition, thus avoiding the arrival of large volumes of fluids to the jejunum. Isotonic solutions should be started at an infusion rate of 50 ml/hour, and then gradually increased, as tolerated, up to 80 ml/hour. The concentration and volume of nutrients should not be modified simultaneously, but the required volume and concentration should be obtained within 24 to 48 hours.
If intolerance develops, the volume or concentration of the diet should be reduced to the previous level of tolerance, and then increased after sufficient time for adaptation has elapsed. Wherever possible, regulators should be equipped with a flow or infusion pump to reduce the possibility of inadequate volumes, resulting in less bloating and diarrhea, lower residual volume and less risk of aspiration.

20.8.2 Routes of Administration

Intragastric nutrition is indicated when there is a good level of consciousness, normal cough reflex and adequate gastric emptying. This allows normal enzymatic activity on the nutrients. Due to the stomach's reservoir capacity and the dilution by gastric secretions, the osmotic load of the diet is not a problem; therefore, highly concentrated solutions can be initiated early.
The volume should be increased every 24 to 48 hours until it covers the total nutritional requirement with an intermittent bolus of 300 to 400 ml each, every 3 to 4 hours. If the nasogastric tube (NGT) has a suitable gauge, feeds can be administered by gravity for 20 or 30 minutes. Pumps are indicated if the patient is receiving viscous solutions.
The gastric residual should be controlled before each administration and administration discontinued if it is >150 ml. The patient should be rechecked after 2 hours and feeding can be restarted if the gastric residual is less than the stated value. If the NGT is in the duodenum, gastric residual can be up to 300 ml of fluid before deciding on temporary suspension. This route of administration of nutrients may not be used in neurocritical patients because of the risk of aspiration. In unconscious patients or in patients with deteriorated gag reflex, the NGT should be placed away from the pylorus to reduce the risk of aspiration.
Intestinal nutrition (duodenal or jejunal). The tube should be placed distal to the Treitz ligament to decrease the risk of aspiration. The technique for tube placement may be blind (high failure rate) or by endoscopy, fluoroscopy or ultrasound-guided. The use of prokinetic agents facilitates, at least in theory, the passage of the pylorus, regardless of the technique. Also, these tubes can be positioned by invasive methods such as endoscopic percutaneous jejunostomy, radiological percutaneous jejunostomy and traditional surgery or by laparoscopy.
Use of enteral nutrition, mainly jejunal nutrition, is suitable for early postoperative feeding, is safe and effective, as intestinal paralysis is predominant in the stomach and colon, and also it causes poor pancreatic stimulation.
Bolus administration of hyperosmolar solutions in the small intestine can cause bloating, diarrhea and electrolyte disturbances. To avoid these adverse effects, volumetric pumps can be used and solutions with half of the desired concentration should be started at infusion rate of 50 ml/hour.
If undesirable effects do not occur, then the gastrointestinal volume can be increased from 25 to 50 ml/hour every 24 hours until the daily volume is reached. The concentration of the solutions must be increased till the total osmolality of the nutritional formula is obtained.
The most important limiting factor in intolerance to the diet is the osmolar load (intake per unit time) received by the digestive tract, so a gradual increase in the infusion rate,

but not the concentration of the formula, is recommended, while maintaining a caloric density of 1 kcal/ml.
Accordingly, protocols has been devised under which the quantity should be 20 ml/hour for the first 6 hours and then incremented by 10 ml/hour every 6 hours until the desired volume is reached, or to start with 20 ml/hour for 8 hours with increments of 20 ml/hour every 8 hours until the infusion rate matches the requirements. If the patient develops diarrhea, and antidiarrhetic may be given, but if it persists or other adverse effects arise, feeding should be suspended for 48 hours.
In other nutrient administration methods, the location of the NGT should be verified before use, patients should be placed in the semisitting position, not less than 30 degrees elevation of the head. The presence of abdominal distention, diarrhea or other side effects have to be checked periodically. After feeding, the NGT should be washed and irrigated with 20 ml of water.

20.8.3 Classification of Enteral Diets

Nutritionally complete diets can provide adequate nutrition without the need for another source, are indicated in patients with normal proteolytic and lipolytic activity; they require normal motor ability, digestive and nearly normal absorption by the small intestine. These diets are composed of intact proteins, complex carbohydrates, varying amounts of fat, waste, vitamins and minerals and can be used as the patient's total nutritional support. There are several different types, described below.
Homogenized diets are prepared with natural foods under technical homogenization; they differ from normal food only in consistency and method of administration through a catheter. Other features are a high-fibre content, very viscous (requiring large calibre NGTs) and many contain lactose, which may be unsuitable for patients with lactase deficiency. The nutrient quantity is variable and there is a higher risk of aspiration. These diets are prepared from milk, yogurt and ice cream, and other nutrients are added. They are indicated in patients with normal intestinal function but requiring nutrition by NGT.
Milk-based diets use milk as the main protein source and other sources of protein like eggs are added; calories are provided as lactose, dextrins, milk fat and soybean or corn oil. They are poorly tolerated in patients with disaccharidase deficiency and can cause diarrhea.
Lactose-free diets use eggs and soybeans as the protein source. Nonproteic calories are provided as oligosaccharides from glucose, dextrin and fat derived from soybean or corn oil. These diets are useful in patients with lactase deficiency, have low viscosity, and can be administered via small-calibre tubes. In addition, they are sterile, because their preparation is commercial. Nutritionally complete diets can be normal in protein, with a protein intake <20% of total calories, or high in protein, which contain 20% or more protein in relation to the supply of calories. These diets also can be enriched with fibres, contain MCT, or high in caloric concentration.
Basic diets or formula-defined (monomeric or oligomeric) diets (also called chemically defined diets or peptides diets) are composed of nutrients that require minimal digestion, so they are easily absorbed by the duodenum and proximal jejunum. They consist of carbohydrates as oligosaccharides, sucrose and glucose, short-chain peptides (oligopeptides) or L-amino acids and medium-chain fatty acids, and small amounts of essential fatty acids and vegetable oils. These factors cause little gastric residue and small intestinal contents, which reduce the frequency of bowel movements and decrease colonic bacterial flora. Osmolality is high due to the low-molecular-weight nutrients; they are lactose-free and can be low in fat. They have a calorie density of 1 kcal/ml, reduce gastric acid secretion, but are expensive. They may be useful in patients with reduced inte-

stinal absorption surface and in those with impaired digestion or absorption ability. Prolonged use can cause essential fatty acid deficiencies.

Modular or nutritionally incomplete diets. Each module consists of one or more nutrients (proteins, fats and carbohydrates). The modules are combined to produce a complete diet. They have high molecular density and may be useful in patients who require fluid restriction.

Diets for special situations have been created to cover the nutritional needs in specific diseases. There are low-calorie diets for patients with respiratory failure, with the aim to reduce CO_2 output; there are formulas with essential amino acids for renal failure patients, and fortified formulas with branched-chain amino acids for patients with liver failure and high metabolic stress. In addition, there are immuno-enriched diets with arginine or omega 3 fatty acids and diets enriched with glutamine which is involved in intestinal barrier integrity.

Because of the vast variety of formulas for enteral nutrition, the diet composition and the proportion of different nutrients in the formulas should be reviewed before use.

20.8.4 Complications

Enteral nutrition is a simple and reliable technique, but complications can appear, which are described below.

Mechanical Complications

Mechanical complications are related to tube placement and maintenance, tube type and its anatomical position:

They can be related to **nasoenteral tubes**; for example:

- Misplacement of the tube in the pharynx, esophagus, airways and lungs increases the risk of aspiration. Intracranial insertion of the tube has been described in patients with skull fracture of the anterior fossa.
- Upper respiratory airway impairment during prolonged catheterization and use of rubber or plastics tubes can lead to: pharynx irritation, difficulty in salivation, increased airway secretions, dry mucous membranes, erosions or necrosis of the nasal mucosa and the posterior wall of the larynx, causing bleeding, infections (pharyngitis, sinusitis and otitis media).

These complications can be reduced with the use of flexible, small diameter tubes, changing the tube position and with the use of lubricants and topical decongestants.

Also **intestinal tract injuries** can uoccur, such as: gastresophageal reflux, esophagitis, esophageal stricture, tracheesophageal fistula, rupture of esophageal varices, and mumps.

Gastrostomy and jejunostomy include: technique-related complications, separation of the stomach or jejunum of the abdominal wall, surgical wound infections, cellulitis at the site of tube entry at the skin, abdominal wall abscess, necrotizing fasciitis, suture dehiscence and hernia, bleeding, gastric prolapse through the gastrostomy.

Complications related to stroma care may cause skin irritation if there is extravasation of digestive juices.

Catheter-related complications are:

- Movement or tube misplacement.
- Tube placement may occlude the pyloric antrum.
- Inadvertent output or external migration of the tube.
- Leakage of intestinal contents.
- Excessive granulation tissue around the exit of the tube.

- Gastrocutaneous, gastrocolic or enteroenteric fistula.
- Volvulus.
- Peritonitis.
- Intestinal obstruction.
- Gastric atony or delayed gastric emptying in the gastrostomy.

Other mechanical complications are: accidental tube displacement or migration, tube obstruction by foods or drugs (can be prevented by irrigating the catheter with 20 ml of water after use), and gastresophageal reflux due to lower esophageal sphincter insufficiency.

Metabolic Complications

Hypertonic dehydration is caused by hyperosmolar formulas that cause extracellular fluid leakage into the intestinal lumen resulting in intracellular dehydration. This can be averted by adding water to the body, orally or parenterally.

Hyperhydration is due to the administration of large amount of liquids with the nutritional solutions, especially in patients with heart, renal or liver diseases. Restriction of volume and fluid balance is necessary.

Hyperosmolality is a severe form of dehydration which occurs in elderly patients and situations of stress. Patients present as pseudodiabetics with sufficient reserves of insulin to prevent ketosis but inadequate to control hyperglycemia, resulting in polyuria, glycosuria, osmotic diuresis and nonketotic hyperosmolar coma. Tube feeding should be reduced or discontinued, and simple insulin and hypotonic fluids should be given.

Essential fatty acid deficiency is when fat intake is inadequate or poorly tolerated.

Hypoglycemia can occur in diabetic patientswho receive insulin or because of their disease (pancreatitis, stress, etc.) when normal diet is suppressed.

Electrolyte imbalances can occur, with sodium, potassium, magnesium or other electrolyte impairment.

Other possible complications are: hypoprothrombinemia, renal failure, and vitamin deficiency.

Gastrointestinal Complications

Increased gastric residue is caused by nutrition through a NGT or gastrostomy. Various factors are involved, such as inappropriate body position, gastric distension, formula consistency, osmolar load concentration, fat and amino acid concentration in the diet, as well as neuroendocrine imbalance or use of drugs that reduce gastric motility (anticholinergics, antacids, analgesics, sympathetic-mimetics, antihistamines, etc.). Gastric residue is increased when NGT aspiration is 200 ml or more, and 100 ml when there is a gastrostomy. When this complication appears, the diet should be temporarily suspended for 1 to 6 hours and prokinetic agents as metoclopramide or cisapride should be given. It is always necessary to find and control the cause.

Vomiting or regurgitation is caused by gastric intolerance and problems related to diet such as osmolality, fat and bacterial contamination. They are more common in intermittent nutrition regimes (bolus) and agitated patients. When it occurs, the diet should be temporarily suspended, the causes determined and corrected, and prokinetic drugs initiated.

Abdominal distension is caused by microbial contamination of the diet and an imbalance between nutrient supply and functional capacity of the intestinal tract, as well as intestinal diseases. To correct this situation, the diet must be suspended and the cause determined.

Constipation is caused by increased intestinal water absorption in patients with inadequate blood volume or on a low-residue diet. Prevention with the use of dietary fibre is discussed.

Diarrhea associated with enteral nutrition (DAEN) refers to an increase in the number of loose stools (stool volume >200 ml). Criteria to raise the diagnosis depend on stool frequency, consistency and volume (3 or more loose stools per day or >2000 ml/day).
The mechanisms of diarrhea associated with enteral nutrition are multiple and include:

- Use of hyperosmolar formulas during duodenal and jejunal nutrition.
- Lactose in the diet causes osmotic diarrhea in patients with disaccharidase deficiency (lactase), which can be congenital or acquired during severe malnutrition in critically ill patients.
- Diets rich in fats and vitamin A may cause diarrhea in patients with pancreatic insufficiency or other causes of malabsorption.
- Diets with a low quantity of sodium (<90 mEq/l) lead to an increased secretion of water and sodium in the jejunum.
- Volume infusion rate exceeding the absorptive capacity of the small intestine.
- Diet or NGT contamination can be a reservoir of germs and a cause of infectious diarrhea.
- Intestinal bacterial overgrowth and infection by *Clostridium difficile* causes infectious diarrhea.
- Several drugscause diarrhea, such as some antibiotics, antacids, laxatives, prokinetic agents, antiarrhythmics (quinidine), digoxin, sympathomimetic agents, antihypertensives, NSAIDs, bronchodilators and H_2 antagonists.
- Hypoalbuminemia due to decreased intestinal absorption.

Infectious Complications

Aspiration pneumonia is more common in patients with an altered level of consciousness, gastric retention, vomiting or regurgitation. The gastric content goes into the lungs and causes injuries aggravated by the hyperosmolality and acidity of the aspirated content. This can be prevented by keeping the patient in an appropriate position (head elevated 30° or more during feeding) and using volumetric pumps and small internal diameter NGTs. It is necessary to determine if gastric retention occurs and if so, then nutrition must be suspended.
Tracheal colonization is caused by gastric or nasopharyngeal flora that infect the lungs and cause nosocomial bronchopneumonia. It is controlled by using acidified enteral diet and intermittent nutrition.
Enteral NGT contamination occurs because the tube acts as a reservoir for germs that cause infectious diarrhea. This can be avoided by washing the tube after use; equipment and connections must also be changed daily, and the nutritional formula should not be retained for more than 4 to 6 hours at room temperature.
Contraindications are: vomiting and /or intractable diarrhea, gastrointestinal bleeding, high output intestinal fistulas, paralytic ileus, intestinal obstruction, diffuse peritonitis, and shock.

20.9 Parenteral Nutrition

In this intravenous technique all the necessary elements are brought together to meet the body's nutritional demands. It is Indicated in many clinical situations including: altered integrity of the intestinal tract, inability of oral intake for 5 days or more, negative caloric and nitrogen balance in patients whose digestive function is unable to improve the balance over a period of 7 days.

20.9.1 Routes of Administration

Parenteral nutrition can be given via a peripheral vein or a deep vein. It is classified in:

- **Central parenteral nutrition**. Nutrient intake via a central vein with a high calibre and high blood flow which facilitates rapid dilution of the hyperosmolar solutions and peripheral distribution in isotonic concentrations. The full nutritional requirements are provided to the patient in 12 to 24 hours and can be administered until the patient is able to tolerate enteral or oral nutrition.
- **Peripheral parenteral nutrition**. Nutrient intake is via the superficial venous system, using a formula with lower osmolality of about 800 mOsm/l. Its use is also limited to short periods. The venipuncture should be rotated daily, so the patient must have multiple veins available.

Before starting parenteral nutrition, the patient should meet the following requirements: stable hemodynamics, appropriate oxygenation, adequate blood volume, normal electrolyte concentrations, and pH close to normal.

20.9.2 Nutrient Characteristics

Central parenteral nutrition can be classified according to the proportion of nutrients:

- **Total parenteral nutrition** is based on the administration of amino acids and dextrose. Fat emulsions are used only to prevent deficiency of essential fatty acids.
- **Complete parenteral nutritio**n uses carbohydrates and fats as the main energy source, but amino acids also are used. Because of its composition, it is close to the normal diet. Different sources of nutrients have specific characteristics.

Sources of amino acids. Crystalline amino acid solutions containing mixtures of essential and nonessential amino acid L-shaped isomers are easily assimilated by the body. There are many products available. The one we most commonly use is Aminoplasmal, which is a mixture of amino acids with a pattern close to that of normal plasma, containing 8 essential amino acids, of which are 2 semi- and 10 non-essential, all in L form. Electrolytes can be added or not. Available in two concentrations:

Aminoplasmal L-5 provides 8 g of nitrogen with 50 g of protein and 200 kcal/l of solution. The osmolality is 595 mOsm/l, allowing its use via peripheral veins. The maximum recommended infusion rate is 120-180 ml/hour.

Aminoplasmal L-10 is an amino acid solution that provides 16 g of nitrogen, 100 g of protein, and 400 kcal/l. The osmolality is high (1040 mOsm/l), so it is given only through the central veins. The maximum infusion rate is 120 ml/hour.

There are other crystalline amino acid solutions similar to those described. Since the protein concentration, electrolyte content and carbohydrate combination depend on the manufacturer, it is advisable to check the characteristics of different products before use.

Human albumin has scant value as a source of amino acids because the proteins need to be broken down to allow the amino acids to be used. It is useful to maintain plasma oncotic pressure and prevent edema due to hypoalbuminemia.

Sources of carbohydrates. Hypertonic dextrose is a solution that provides a large number of calories with low volume and high hypertonicity. It is a source of physiological energy available in different concentrations (Table 20.9). When glucose concentrations >10% are used, they must be supplied by a central vein due to their high osmolality and low pH which cause phlebitis in peripheral veins. Use is optimal when administered at 4 to 5 mg/kg/min. The administration of >7mg/kg/min, even with the addition of insulin, increases the rate of glucose clearance, but not its oxidation, so glucosuria

Concentration (%)	Glucose (g)	Provide (kcal)
5	50	200
10	100	400
20	200	800
30	300	1200
50	500	2000

Table 20.9. Dextrose administration every 1000 ml.

and osmotic diuresis can occur. More than 300 to 400 g per day should not be provided. Carbohydrate tolerance decreases with stress.

Fructose is a caloric source independent of insulin and does not need insulin to be phosphorylated. It provides the same amount of calories as dextrose and has different strengths. It causes less hyperosmolality than glucose, is metabolized more rapidly and transformed into liver glycogen. It has the disadvantage that it can cause lactic acidosis and requires the administration of large volumes of liquid. It is useful in diabetic patients with insulin resistance, but it has shown no advantages over glucose.

Sorbitol provides the same amount of calories as dextrose and the use of insulin is not needed. It is oxidized in the liver and converted to fructose. It may cause melituria and osmotic diuresis because it is not absorbed by the renal tubule. It is available in 10% and 30% concentrations. It is useful in diabetics and in patients with liver damage because of its anticetogenic and protective liver function properties.

Xylitol is a five-carbon polyol derived from xylose; its metabolism and utilization depends little on insulin. It offers the same amount of calories as dextrose and is available in concentrations of 5% and 10%. Mixtures are used with 30% of calories as xylitol and 70% as glucose. Reported side effects include jaundice, hyperuricemia, severe acidosis, elevated liver enzymes, and deposits of calcium oxalate crystals in kidneys and other organs.

Ethanol provides 7 kcal/g but induces hepatic metabolism disorders.

Fat sources. Cottonseed oil derivatives were once used, but they cause overload syndrome. Currently, solutions derived from soybean oil are manufactured (<1 micron particles), similar to chylomicrons, so they are engulfed by the Kuppfer cells in the liver and degraded by the lipase enzyme. Fat emulsions provide a high number of calories (kcal/g) with a small volume of liquid. Since these solutions are very susceptible to bacterial contamination and proliferation, other substances should be added.

Long-chain triglycerides are polyunsaturated and are composed of soybean oil, egg yolk phospholipids, and glycerol; they have a high calorific value (kcal/g), with the contribu-

Product	Lipofundin			Lipovenous		
Composition (every 1000 ml)	S-10	S-20	MCT/ICT10 %	MCT/ICT20 %	10 %	20 %
Soy oil (g)	100	200	50	100	100	200

Osmolality (mosm/l)	345	380	-	-	310	360

Table 20.10. Composition and energetic value of lipids solutions.

tion of essential fatty acids and low osmolality (isotonic), so they can be given via peripheral veins. They are not eliminated with the urine or feces. Their administration in large amounts can lead to impaired function of neutrophils and the reticuloendothelial system (RES), with poor bacterial clearance.

Medium-chain triglycerides are esters of saturated fatty acids with chains of 6 to 12 carbon atoms; the source is coconut oil. They provide 8.1 kcal/g. Their use is advantageous because they do not require carnitine for metabolism (beta-oxidation), so that they oxidize quickly, do not block function of the RES and are never stored. They do not contain significant amounts of essential fatty acids.

Currently, there are recommended products that combine LCT and MCT to reap the benefits of both. The main products available are shown in Table 20.10.

In many centres, mixtures of nutrients are prepared in the pharmacy under sterile conditions in a laminar flow chamber. Emulsions of lipids are combined at 10% or 20%, amino acid solutions at 5% or 10% and 70% dextrose. Lipids should be mixed with amino acids before mixing with dextrose acid solutions, electrolytes, vitamins and trace elements may be added in sufficient quantity. Ethylene vinyl acetate bags must be used instead of polyvinyl chloride to prevent lipid-bag interaction.

Technical measures and care. The solutions used in parenteral nutrition are hypertonic, and they must enter into the bloodstream through a catheter positioned inside a large-calibre vessel with high blood flow. The superior vena cava is preferred since it can be canalized by any method and technique.

Besides the complications of deep vein catheterization, the main problems associated with this therapy are sepsis and metabolic complications. Preventive measures must be taken into account:

- Deep venous catheterization. Maintain good catheter insertion technique with very good skin preparation.
- Infusion systems. Avoid the use of central venous pressure (CVP) measuring equipment in the same line used for parenteral infusion. In addition, blood, plasma or other medicines should not be given through the line, nor should blood for lab studies be drawn from the infusion line. A 0.45 micron filter should be inserted in the infusion line, and the whole system, except for the catheter, should be changed every 12 to 24 hours.
- Solution care. Contamination of solutions should be avoided because nutrients facilitate growth and multiplication of microorganisms. Other products should not be added to these solutions, except insulin which is added to hypertonic dextrose.
- Administration of carbohydrates. Hypertonic dextrose should be administered slowly and progressively; the initial infusion rate should not exceed 50 ml/hour and can be incremented daily by 25 ml/hour up to 125-150 ml/hour, as needed. Metabolic status should be monitored by blood glucose and glucosuria every 12 hours every 4 to 6 hours. Serum glucose should be 200-250 mg/dl (11-14 mmol/l) and glycosuria should not exceed 2 g/dl (Benedict's solution turns orange). Hypertonic dextrose infusions should not be stopped abruptly, as rebound hypoglycemia may occur due to the large amount of circulating insulin as a result of pancreas stimulation. Insulin supplement must be supplied at the beginning of parenteral nutrition in patients with insufficient endogenous insulin production, while keeping in mind that on successive days these needs may decrease due to pancreas stimulation.
- Administration of amino acids. Amino acids must be supplied simultaneously with nonprotein calories for the synthesis of proteins and not as an energy source. The amino acid solutions do not maintain the plasma oncotic pressure, so colloids such as albumin should be added. We must remember that blood, plasma and albumin are ineffective as a nitrogen source, since hemoglobin has no isoleucine, globulins

take 10 days to break down into their amino acids, and albumin takes between 16 to 21 days.

- Management of lipids. When fats are not used, a deficiency in essential fatty acids appears with adverse symptoms and signs. The composition of the phospholipidic cell membrane is also altered. Abnormal serum lipid levels lead to the development of fatty liver disease. Fats should be administered progressively in a drip, starting from 0.5 to 1 ml/min, then gradually increasing them up to 2 ml/min or less. The total dose should not exceed 1000 -1500 g over a period of 10 to 14 days. Lipid infusions should be suspended 12 hours before any dialysis procedure so as to prevent lipid losses. Blood lipid levels are controlled by their appearance in refrigerated serum: a cloudy appearance indicates the presence of chylomicrons and the lipid infusion must be stopped. In this situation, some authors recommend the addition of heparin to clear the plasma, which is controversial, because although heparin increases the activity of lipoprotein lipase with increased clearance of triglycerides, it also raises the level of fatty acids and free glycerol, which can be harmful.
- Other measures. It is very important to maintain proper nitrogen, caloric and electrolyte balance. When parenteral nutrition lasts for several days, vitamins should be provided in higher doses than the usual requirements. After the first week of treatment, calcium, magnesium, phosphate and trace elements also must be provided.

Peripheral parenteral nutrition. Peripheral parenteral nutrition refers to the intake of essential nutrients (amino acids, carbohydrates, lipids, electrolytes, vitamins, trace elements and water) through a peripheral vein. The fragility of the peripheral veins limits the osmolality of the solutions that can be used and restricts the calories that can be given in the form of dextrose. The cornerstones of peripheral parenteral nutrition are fat emulsions with low osmolality, high caloric density, and protective effects on vascular endothelium (not accepted by some authors).

Among the advantages of peripheral parenteral nutrition is mainly that central venous catheter-related morbidity can be prevented, metabolic changes are fewer, and it does not require trained personnel to be inserted. This technique is recommended in patients with not very high energy requirements; good peripheral veins are required, and the site of venipuncture should be changed every 24 to 48 hours. It is mainly used in:

- Short-term nutritional support (up to 15 days).
- Patients with repeated septic episodes during central parenteral nutrition.
- Patients with subclavian vein thrombosis.
- Difficult or dangerous central venous catheterization technique.
- Surgical patients with marginal nutritional status.

20.9.3 Three Nutrient Management Systems Using the Peripheral Route

System One. Provides amino acids, electrolytes and water and preserves functional proteins. Energy needs are covered by lipolysis owing to low levels of insulin which occur when glucose has not been administered. It is used for 3 to 5 days in patients with moderate stress, well-nourished or obese patients.

System Two. The patient receives amino acids, carbohydrates, electrolytes and water. It conserves body protein and energy needs with exogenous glucose. It is used in the immediate postoperative period and may last from 5 to 10 days.

System Three. Provides amino acids, carbohydrates, fats, electrolytes, vitamins and water. It is used in situations of mild to moderate catabolism because it preserves body protein. Energy needs are covered with carbohydrates and fats which provide 30 to 60% of

caloric intake, since fats in the presence of amino acids save nitrogen as well as glucose. It can be used for 15 days.
The main complication of this technique is the damage to vessel intima caused by hypertonic solutions. To avoid this, the use of small doses of cortisol and heparin has been encouraged, which reduces the incidence of phlebitis. It is necessary to change the venipuncture site every 24 to 48 hours to avoid thrombophlebitis. The disadvantages of the method depend on the volume of liquid needed to provide the calories, and the instability of flow volume in the peripheral veins, so infusion pumps should be used.

20.9.4 Complications

Complications may arise frequently during parenteral nutrition. Complications related to central venous catheterization and infusion systems, metabolic complications related to the use of carbohydrates, lipids, amino acid or electrolyte imbalance (Table 20.11), and septic complications have all been described. Because of malnutrition, sepsis is common in patients receiving parenteral nutrition, as is the risk of concomitant infections in abdominal wounds, the urinary tract and respiratory system. The problem is compounded by the use of broad spectrum antibiotics, drugs or clinical situations that reduce immunity and the improper handling of venous catheters and infusion systems. In patients where prolonged parenteral nutrition is particularly long, there is a high prevalence of infection with Candida species that grow easily in nutrient solutions. Hyperglycemia also occurs frequently and is observed in 25% of patients receiving parenteral nutrition. The causes are several, including glucose overdose, high infusion rate of carbohydrates, inadequate secretion of endogenous insulin, insulin resistance, stress that increases the production of hyperglycemic hormones such as cortisol, catecholamines and glucagon to stimulate gluconeogenesis, hyperglycemic effects of drugs (e.g., corticosteroids, diuretics, phenytoin).
Monitoring and controlling blood glucose is very important in neurocritical patients as it has been suggested that hyperglycemia worsens hypoxic ischemic brain injury and worsens the prognosis. Glucose levels >150 mg/dl should be corrected quickly with insulin. Rebound hypoglycemia can be avoided with the gradual withdrawal of parenteral nutrition and achieving adequate energy intake with oral or enteral nutrition before discontinuing parenteral nutrition.

Dependent on carbohydrates	Dependent on amino acids	Dependent on lipids	Related to electrolites, minerals and vitamins
• Hyperglycemia • Hypoglycemia • Increased CO_2 production • Phosphates depletion syndrome • Liver dysfunction	• Metabolic acidosis • Increased urea serum level • Serum amino acids imbalance • Hyperamoniemia • Hyperuricemia	• Deficit of essentials fatty acids • Hyperlipidemia • Colloidal reaction • Overload syndrome • Ketoacidosis • Encephalopaty	• Overhydration • Dehydration • Hypernatremia • Hyponatremia • Hyperchloremia • Hypochloremia • Hypokaliemia • Hypocalcemia • Hypophosfatemia • Hypomagnesemia • Deficit of nutritional trace • Hypovitaminosis

Table 20.11. **Parenteral nutrition. Metabolic complications.**

Liver dysfunction and excess carbon dioxide production (harmful especially in patients with respiratory failure) can be avoided by providing 20 to 40% of total calories as fats. Complications related to the administration of amino acids are rare. The essential fatty acid deficiency is due to an inadequate management of lipids, with little contribution of essential fatty acids such as linoleic, linolenic and arachidonic acid. Of these, only linoleic acid is very important in the diet, as others can be synthesized from it. The clinical features of essential fatty acid deficiency include diarrhea and malabsorption due to epithelial changes in the intestinal mucosa. Dryness and peeling of the skin, hair loss and increased susceptibility to infections can also be found, as well as thrombocytopenia and decreased platelet aggregation, with a tendency to bleeding, increased fragility of red cells with hemolytic anemia and increased capillary permeability. Further noted are increased intracranial pressure, liver function abnormalities, osteoporosis and delayed wound healing. To avoid these complications, linoleic acid should be provided at minimum dose of 25 mg/kg/day, with 10% fat emulsion two or three times a week. Hyperlipidemia can appear during fat infusions or after their suspension; their magnitude and duration depends on the dose and disappears within 2 to 4 days after lipids have been suspended. It is diagnosed by the appearance of turbid, lipemic serum refrigerated in a sample taken 12 hours after cessation of the infusion. Adverse reactions to lipid emulsions (dyspnoea, allergic skin reactions, headache, sweating) are rare. A reduction in infusion rate or its discontinuation prevents or lessens these side effects. When patients require high daily energy intake, large amounts of volume are needed, which can lead to volume overload. Electrolyte disorders may be diverse and should be taken into account. Vitamin and mineral deficiencies are rare if nutrient preparations are properly managed. It has been suggested that with careful monitoring the rate of complications may be less than 5%.

20.9.5 Contraindications to Parenteral Nutrition

Contraindication are related to the nutrients used.

Contraindications to the use of carbohydrates. Glucose is not contraindicated. In diabetic patients, enough insulin should be supplied to prevent or control hyperglycemia. Fructose and sorbitol are contraindicated in patients with 1.6 diphosphatase lactase deficiency and in those with methyl alcohol poisoning.

Contraindications to the use of lipids are the following:

- Hypoperfusion syndrome: low cardiac output syndrome, heart failure, and shock.
- Vascular lesions: myocardial infarction, stroke, arteriosclerosis, thrombophlebitis.
- Other: pregnancy, active duodenal ulcer, metabolism of fats, severe anemia, severe liver failure, use of MCT – ketogenic conditions, and severe liver disease.

Contraindications to the use of amino acids are shock and liver failure.

20.10 Assessment and Monitoring of Artificial Nutrition

After the initiation of artificial nutrition it is necessary to make observations that allow us to know whether it is achieving its objectives and, on that basis, make necessary changes. Among the items we should consider:

- Body weight is actually a very general measure to be considered in the success of nutritional support, since it depends on the patient's water balance. It is most useful after long periods of nutrition to assess the progress of the patient.

- Nitrogen balance (BN) is the most practical way to evaluate the effectiveness of nutrition and it is also essential for calculating the daily needs of amino acids and other nutrients. It is obtained by calculating the difference between nitrogen input and output. Nitrogen balance should be between -5 and + 5 g/day and the optimal value is +1 to +5 g/day.
- Caloric balance (CB) controls input and caloric loss. Energy intake (EI) is calculated from the sum of the calories of all the nutrients provided. Caloric expenditure (CE) is similar to total energy expenditure (TEE); the result of caloric balance can be -5 to +5% of TEE, stated as an optimal value when it is between -100 and + 100 kcal.
- Other methods to assess the goals of artificial nutrition include: 1) Normalization of serum albumin, transferrin and fibronectin; 2) Reduction of urinary 3 methylhistidine; 3) Positive intradermal tests.

In artificial nutrition monitoring, acid-base and electrolyte balance should be evaluated, as well as metabolic status and the emergence of complications. The frequency of carrying out such determinations should not be guided by a fixed schedule, but rather as needed case by case. The following items are to be taken into account:

- Body weight: daily.
- Caloric, nitrogen and hydromineral balance: daily.
- Benedict and Imbert: initially, every 3-4 hours. If severe glucosuria appears, it may be necessary to perform these more often to obtain control (every 6 hours).
- Serum glucose: initially, every 12 hours to control the solution rate, then daily or every 2 days.
- CBC: daily at the beginning of nutrition, then every 3 or 4 days, especially if intravenous lipids are used, due to the possibility of hemolysis.
- Daily determination of urea in 24-hour urine.
- Urea and serum creatinine: daily during the first 3 days or if there is kidney damage; every 3 or 4 days in other clinical conditions.
- Serum electrolytes: every 12 hours the first 2 or 3 days, then daily when values have stabilized.
- Electrolytes in urine: daily for the first 2 or 3 days or if there is increased loss of electrolytes after 3 or 4 days.
- Urine and plasma osmolality: daily.
- Turbid, lipemic serum (Friderickson test): every day when using lipids as an energy source. Keep in mind that blood should be drawn 12 hours after the infusion of fat is finished.
- Other tests to be performed at the beginning of artificial nutrition and weekly thereafter include: calcium and phosphorus, lipids, serum iron, total and fractionated proteins, transaminases, bilirubin and alkaline phosphatase, Coombs test when using intravenous lipids, uric acid, transferrin, and fibronectin.

Blood gasses should also be evaluated when necessary and coagulation when initiating therapy, and then depending on the suspicion of abnormal clotting.

20.11 Is There a Specific Nutritional Formulation for Patients with Brain Injury?

At present writing, there is no published study comparing different formulations, whether enteral or parenteral, in patients with traumatic brain injury. It was recommended that protein intake should be about 15% of total energy expenditure, taking into account

the significant daily loss of nitrogen that appears in this kind of patient. Other formulations are based on reports from publications on nutrition in intensive care in general. Overall nutritional support is recommended to provide 1.5 to 2 g/kg protein, a ratio of 80 non-protein calories per gram of nitrogen added, and the total kcal for in a 24-hour period is about 25 kcal/kg.

There is some evidence that the use of branched-chain amino acids may improve the prognosis in septic patients, however, it has not been studied in this type of patient. The use of glutamine supplements and immunomodulatory diets containing glutamine, arginine, omega-3 fatty acids and nucleotides has not been investigated in patients with acute brain injury. A class II study showed increased scores on the Glasgow Coma Scale when zinc supplement was given.

20.11.1 When to Start Nutrition in Neurocritical Patients

Nutritional support should begin without delay because catabolism begins quickly. Usually, it should not be delayed more than 72 hours, with total replacement on the seventh day because 2 or 3 days of gradual increase in nutrients are needed for the total replacement of caloric and protein needs, whether via the stomach or jejunum. It should be similar in cases where parenteral nutrition needs to be started: during the first 72 hours after injury and with a caloric intake below the calculated total energy, which must be achieved by the seventh day. A review of randomized controlled studies investigating the time or route of administration of nutritional support in patients with head trauma found that early nutrition may be associated with a tendency to better prognosis in terms of survival and disabilities.

20.11.2 Enteral Nutrition vs. Parenteral Nutrition

Some authors prefer to start feeding through the stomach, but it has been estimated that 80% of patients with increased intracranial pressure after head trauma and 50% of ventilated patients (a common situation in patients with severe brain injury) have abnormal gastric emptying with the risk of aspiration and pneumonia. Better tolerance of nutrient can be obtained by starting at 25 ml per hour and then increasing the volume every 12 hours to achieve the desired objective. Continuous feeding is better tolerated than bolus feedings. The jejunal or postpyloric route of nutrition through a tube, placed by endoscopy or fluoroscopy, is preferred by most authors because of better tolerance, lower risk of aspiration, and greater nitrogen retention than with gastric feeding. In our service, either for technical reasons and/or resources, postpyloric tube placement is not a common procedure, or there is more experience in the last years with early gastrostomy or gastrojejunostomy in patients who rarely recover consciousness during the first week. This method of nutrient management via a NGT is better tolerated. There is also a low incidence of pneumonia and fewer indications for intravenous feeding. Parenteral nutrition, as stated above, is not recommended in patients with severe brain injury. Although studies on laboratory animals have shown that parenteral nutrition can worsen cerebral edema, the available evidence in humans suggests that this is not a clinical problem.

The 2007 Brain Trauma Foundation guidelines state that has no method has been clearly demonstrated superior to another with regard to complications or discharge status.

21 Acute Renal Injury in the Neurocritical Patient

Daniel Agustín Godoy [1], José Luis do Pico [2]

[1] Neurointensive Care Unit. Sanatorio Pasteur, Catamarca, Argentina
[2] Head Intensive Care Unit. Hospital Municipal. Necochea. Buenos Aires, Argentina.

21.1 Introduction

Acute kidney injury (AKI), also known as acute renal failure, refers to a sudden decline in renal function, with disorders in fluid balance, electrolytes and acid base status due to loss of small solute clearance and decrease in the glomerular filtration rate (GFR). The term AKI reflects more accurately the spectrum of diseases from subclinical injury to complete organ failure.

21.2 Epidemiology of Acute Kidney Injury

The incidence of AKI has risen. Depending on how defined, between 35 and 66% of critically ill patients develop AKI, with a substantial increase in morbidity and mortality. On average, between 5 and 6% of critically ill patients with AKI in the critical care unit (CCU) require renal replacement therapy (RRT). The reported mortality due to AKI varies considerably, depending on the definition of AKI and the patient population evaluated (e.g., sepsis, trauma, cardiovascular surgery or contrast-induced nephropathy). Most studies found that mortality increases proportionally with increasing severity of AKI. In patients with severe AKI requiring RRT, mortality is about 50 to 70%. AKI requiring RRT is an independent factor of hospital mortality: even small changes in plasma creatinine (PCr) are associated with increased mortality.
The morbidity associated with AKI in the CCU is a less appreciated consequence, but it is associated with prolonged hospital stay, higher risk of chronic kidney disease (CKD) and end-stage renal disease (ESRD).

21.3 Definition of AKI in Critically Ill Patients

There are more than 35 definitions of AKI in the literature. In 2002, a group of experts formed the Acute Dialysis Quality Initiative (ADQI) and proposed the RIFLE classification scheme (R: risk, I: injury, F: failure, L: Loss, E: end-stage) specifically for AKI in critically ill or terminal patients (Table 21.1). Using the parameters of PCr and/or GFR and urine output, they defined three levels of severity and two prognostic classes.
Changes in serum creatinine as measured with the RIFLE method are applied in relation to a baseline serum creatinine value (BSCV). But since this is unknown in most patients, the modification of diet in renal disease (MDRD) formula (Table 21.2) was devised to estimate the BSCV, according to gender, race and age group, assuming a normal GFR (75 to 100 ml/min/1.73 m^2).

Risk	One or more of the following: • 1.5 fold increase in serum creatinine • decrease (>25%) in GFR • urine output <0.5 ml/kg/h for 6 hours
Injury	One or more of the following: • 2-fold increase in serum creatinine • decrease (>50%) in GFR • urine output <0.5 ml/kg/h for 12 hours
Failure	One or more of the following: • 3-fold increase in serum creatinine • decrease (>75%) in GFR • serum creatinine ≥4 mg/dl when acute increase ≥0.5 mg/dl • urine output <0.3 ml/kg/h for 24 hours • anuria for 12 hours
Loss	Persistent AKI or complete loss of renal function: presence of AKI >4 weeks
End	End-stage renal disease: requirement of renal replacement therapy >3 months

Table 21.1. **RIFLE criteria for AKI diagnosis and staging (2004).**

$$GFR = 186 \times SC^{-1.154} \times Y^{-0.203} \times 0.742^{\circ} \times 1.21^{*}$$

$$186 \times SC^{-1.154} = (Y^{-0.203} \times 0.742^{\circ} \times 1.21^{*})/\text{normal GFR}$$

$$SC^{-1.154} = (Y^{-0.203} \times 0.742^{\circ} \times 1.21^{*} \times 186)/\text{normal GFR}$$

where:
SC = serum creatinine; Y = years of age; ° in females; * in blacks

The RIFLE method's validity and predictive ability for mortality have been evaluated in critically ill patients in several trials. In their review of studies which used this system between 2004 and 2007, Ricci et al. examined 24 studies involving a total of 71,000 patients. They noted that the studies had several weaknesses: small cohorts; selected subpopulations of critically ill patients; lack of "urine output" criterion; and single-centre design. What the studies did show, however, was the first mortality rates of AKI (31.2%) diagnosed according to a uniform definition. A striking finding was that the relative risk of death was higher when renal dysfunction was more severe (18.9%, 36.1% and 46.5% for mortality as risk, injury and failure, respectively).
In 2008, Bagshaw et al. published a multicentre evaluation of AKI diagnosed according to the RIFLE classification within the first 24 hours after admission (120,123 patients in

Age (years)	Black male (mg/dl)	White male (mg/dl)	Black female (mg/dl)	White female (mg/dl)
20-24	1.5	1.3	1.2	1.0
25-29	1.5	1.2	1.1	1.0
30-39	1.4	1.2	1.1	0.9
40-54	1.3	1.1	1.0	0.9
55-65	1.3	1.1	1.0	0.8
≥65	1.2	1.0	0.9	0.8

Table 21.2. **Estimated baseline creatinine value.**

57 Australian CCUs from 2000 to 2005). They reported an AKI incidence of 36.1% (Risk = 16.2%, Injury = 13.6%, Failure = 6.3%), being more common in patients over 65 years of age, female gender, with comorbidities and admitted for medical causes, mainly cardiac, septic or liver diseases. Worsening in RIFLE category was correlated with an increased length of stay in hospital and the CCU and, as Ricci et al. had found, with higher mortality.
Recently, the ADQI group and representatives of the American Society of Nephrology (ASN), the International Society of Nephrology (ISN), the National Kidney Foundation (NKF) and the European Society of Intensive Care Medicine Acute Kidney Injury Network (AKIN) proposed a new diagnosis and classification system (Table 21.3) modified from the RIFLE scheme:

- The Risk, Injury and Failure categories were replaced with three numerical stages of severity (1, 2 and 3), while retaining similar cut-off points for PCr and urine output.
- The method's sensitivity was enhanced by including in Stage 1 increases in PCr ≥0.3 mg/dl, based on studies showing that this small change was associated with higher risk of mortality.
- Implementation of RRT was eliminated as a severity criterion because patients classified in the Failure category who received RRT could be included in Stage 3, given that the starting time of RRT varies across different populations and countries due to variability of resources and criteria.
- An "acute" change in serum creatinine was specified as occuring within 48 hours, based on evidence that the worst prognosis observed with these small increases occurs during this period. Unlike RIFLE, the AKIN system considers increases in PCr in relation to the value recorded at admission rather than in relation to a theoretical baseline creatinine.
- It was noted that these criteria should be applied only after having achieved an optimal state of hydration because the blood volume status can modify PCr values.

In 2008, Bagshaw et al. carried out a retrospective comparison between the RIFLE and AKIN schemes on the same 120,123 patients evaluated the same year, and reported similar sensitivity, robustness and predictive ability of both methods. The study revealed several weaknesses, however: assessment of AKI was performed only within 24 hours of the patient's admission to the CCU; detailed urine output and weight of patients were unknown; and there was no record of the proportion of cases undergoing RRT.
Except for the use of diuretics or the presence of urinary obstruction, diuresis is still considered a more sensitive parameter of intrarenal hemodynamic changes than biochemical markers or solute clearance. It is also more likely to be used in CCUs and general care wards owing to its easy identification.

AKIN stage 1	One or more of the following: • Acute increase* in serum creatinine ≥0.3 mg/dl (≥26.4 µmol/l) or 1.5 to 2-fold • Urine output <0.5 ml/kg/h for more than 6 hours
AKIN stage 2	One or more of the following: • Acute increase* in serum creatinine (>2 to 3-fold) • Urine output <0.5 ml/kg/h for more than 12 hours
AKIN stage 3**	One or more of the following: • Acute increase in serum creatinine >3-fold • Serum creatinine ≥4 mg/dl when acute increase* ≥0.5 mg/dl • Urine output <0.3 ml/kg/h for 24 hours • Anuria for 12 hours

Table 21.3. **AKIN criteria for AKI diagnosis and staging (2007).**
* "Acute" changes in serum creatinine refer to those which occur within 48 hours of the last recorded value
** Includes patients receiving RRT

The RIFLE system assumes that the use of this parameter enhances the method's sensitivity. The AKIN scheme also recognizes that this marker of renal dysfunction becomes impaired before PCr values increase, thus offering a sensitive and easy tool to identify patients with AKI. Recently, Bagshaw et al. demonstrated that the use of urine output in the RIFLE scheme has prognostic and predictive value for length of CCU and hospital stay and for mortality.

Both the RIFLE and AKIN schemes set an arbitrary urine output value derived from the initial definitions of Kellum, which state that a patient with a urine output <800 ml in 24 hours can be defined as an AKI patient, or the equivalent of 30 ml/h, i.e., 0.5 ml/kg/h for a 70-kg patient. Although these figures are theoretical, neither the RIFLE nor the AKIN scheme specifies how often measurement should be taken, and it is unknown whether they are applicable to catheterized patients in whom measurements are taken every 2, 4 or even 6 hours, or in those with spontaneous urination.

21.4 Diagnosis of AKI in Critically Ill Patients

Procedures and parameters for diagnosing AKI (PCr) and determining its etiology (clinical history, physical examination, renal ultrasound, fractional excretion of sodium [FENa], fractional excretion of urea [FEU], plasma urea and urine sediment) are available in the CCU. However, no single marker may be accurate enough to estimate GFR and to indicate injury. A simple analogy of this problem is the use of cardiac enzymes (troponin specific to cardiac muscle) as a "surrogate marker" of cardiac muscle injury in acute myocardial infarction. This marker of cardiac injury does not provide information on changes in global cardiac function and myocardial performance. To evaluate cardiac performance, more examinations are needed. Extending this analogy to critical care nephrology, the surrogate markers for GFR (e.g., urea and creatinine), however, are not sufficiently specific for detecting acute kidney injury. What we urgently need are markers that incorporate function and injury in critical care nephrology.

The diagnosis and etiological classification of ARI depend largely on the detection of changes in endogenous conventional markers of renal function: serum levels of plasma creatinine and urea, and, less frequently, other urine tests. Although conventionally used, these markers have their limitations as none reflect dynamic changes in GFR nor do they reflect kidney injury. Moreover, these endogenous markers require time to accumulate before they can be detected as abnormal levels in serum, thus potentially delaying the diagnosis of AKI.

Serum creatinine is an amino acid compound derived from the non-enzymatic conversion of creatine in skeletal muscle and subsequent hepatic metabolism of creatine through the methylation of amino acetic acid to form creatinine. Creatinine clearance is the most common tool to estimate GFR, and serum creatinine levels typically show an inverse relationship to GFR (in stable situations). Like urea, there is no evidence of toxicity caused by creatinine accumulation in the blood. However, there are limitations in the use of serum creatinine as a marker of renal function:

- The production and release of creatinine in serum may be highly variable. Differences in age, gender, food intake (e.g., vegetarian or creatine supplements) and muscle mass (e.g., neuromuscular disease, malnutrition) can cause baseline serum creatinine values to vary significantly. Similarly, certain diseases can predispose to a variable release of muscle creatinine. For example, serum creatinine may rise more rapidly during rhabdomyolysis due to the release of preformed creatinine from damaged muscle or peripheral metabolism of creatine phosphate to creatinine in ex-

tracellular tissue. Critically ill patients may present abnormal liver function and a dramatic reduction in muscle mass, both of which can significantly alter creatinine metabolism. Other factors contributing to increased creatinine production include muscle catabolism in trauma patients, fever, and immobilization. Its production can be reduced in liver disease, in patients with reduced muscle mass and in the elderly. The volume of creatinine distribution (total body water) influences plasma creatinine and can increase dramatically in critically ill patients. However, like creatinine clearance, plasma creatinine does not accurately reflect GFR in non-equilibrium conditions such as AKI. Creatinine clearance overestimates GFR in patients with AKI because, as GFR decreases, tubular secretion of creatinine increases; therefore, urinary excretion is much greater than the filtered load, resulting in a potentially gross overestimation of GFR. During the evolution of AKI, plasma creatinine levels may underestimate the degree of dysfunction, while the opposite is true as far as kidney function will recover.

- About 10 to 40% of serum creatinine is cleared by tubular secretion into the urine. This effect has the potential to "hide" a substantial initial decline in GFR.
- Many drugs (e.g., trimethoprim, cimetidine) may alter creatinine secretion, leading to transient and reversible increases in serum creatinine levels.
- Although less frequent, the accuracy of serum creatinine assays may be reduced, leading to artificial increases in serum creatinine levels in diabetic ketoacidosis; increased serum concentration of acetoacetate may interfere with selected tests (e.g., with the alkaline picrate method) and cause false elevations in serum creatinine regarding Jaffe's reaction. Similarly, some drugs may have similar effects (e.g., cefoxitin).
- Various equations to evaluate kidney function can be applied to predict creatinine clearance or GFR. They are based on demographics and biochemical indices (e.g., gender, age, race, weight, blood creatinine and albumin) but they have not been validated in patients with AKI. All equations use serum creatinine and, therefore, have the same limitations as serum creatinine for the assessment of GFR in patients with AKI. There are few data on the use of equations to estimate GFR in patients with AKI.

Changes in serum creatinine are aspecific, do not discriminate between the nature and the type of renal insult (ischemic, nephrotoxic) or the site and extent of tubular or glomerular injury, and serum creatinine levels are relatively insensitive to small changes in GFR. Moreover, changes in serum creatinine "may fall behind" the changes in GFR, both its increase and its decline, for several days. Finally, because serum creatinine is influenced by potential interventions in AKI (creatinine removed by RRT), its specificity to assess renal recovery is even more problematic.

Plasma urea, a by-product derived from the metabolism of water soluble low-molecular-weight proteins is used as serum marker of retention and removal of nitrogenous solutes. The accumulation of urea per se is thought to predispose to metabolic biochemical and physiological side effects such as increased oxidative stress and impaired function of Na-K-Cl co-transporters, which are critical in regulating intracellular water and potassium, and alterations in immune function. In addition, retention of uremic toxins may contribute to such secondary organ dysfunctions as acute lung injury.

Similarly to serum creatinine, urea levels exhibit a non-linear and inverse relationship to GFR. However, measuring urea levels to estimate GFR is a problem due to extra-renal factors which influence its endogenous production and renal clearance, regardless of the GFR.

The urea production rate is not constant. Urea values can be modified by high protein intake, critical illness (sepsis, burns, trauma), gastrointestinal bleeding, or drugs such as steroids or tetracycline. The use of steroids in the CCU is a fairly common practice and may increase protein catabolism. Critically ill patients with chronic liver disease may

have almost normal urea levels due to reduced protein production and restriction and, at the same time, normal serum creatinine levels due to either decreased hepatic production of creatinine or loss of muscle mass, despite significant reductions in GFR and impaired renal function.

The rate of renal clearance of urea is not constant. Approximately 40-50% of filtered urea is passively reabsorbed by the proximal and distal tubule cells. In states of volume depletion with low cardiac output, there is an increased reabsorption of sodium and water in the proximal tubule cells, with a corresponding increase in urea reabsorption. The urea concentration can increase far beyond the rate of change in serum creatinine and doesn't represent a reduction in GFR.

Overall, urea concentration is a poor marker of GFR. It doesn't represent real-time changes in GFR and requires time to accumulate. In addition, urea doesn't really reflect "acute" kidney injury. Relying on serum levels of urea leads to delays in the diagnosis of AKI.

Urine output can be used as a "crude" dynamic measurement of renal function. It may be a more sensitive marker of changes in renal hemodynamics than biochemical markers for the clearance of solutes. The importance of dynamic changes in urine output has been recognized because such changes are integrated into the RIFLE and AKIN classifications. Generally, however, urine output lacks sensitivity and specificity as a marker of renal function or AKI in critically ill patients in whom the excretion of free water and solutes is altered. At times, critically ill patients with severe AKI, characterized by elevated serum creatinine or retention of nitrogenous solutes, can maintain normal or even high urine output.

The term AKI spans the whole spectrum from prerenal azotemia to acute tubular necrosis (ATN), and from functional impairment to structural injury. Numerous tests have been described as a "replacement" for tubule cell function and have been and still are used for the detection and classification of AKI, particularly in the diagnosis of prerenal azotemia and ATN. Although easy to perform, they lack sensitivity and specificity for the early characterization of AKI, particularly in critically ill patients. In addition, the causes of prerenal azotemia and structural injury commonly coexist in critically ill patients. Until we have other diagnostic tools, different from the current ones, and in the absence of validated new biomarkers, prerenal azotemia is often a retrospective diagnosis made only after fluids challenge.

Fractional excretion of sodium (FENa) is based on the fact that filtered sodium is avidly reabsorbed in the renal tubules of the glomerular filtrate in prerenal azotemia, in which tubular function remains intact, resulting in FENa <1%, while FENa is >1% in tubular injury, as in ATN. Although physiologically sensitive, in clinical practice the diagnostic accuracy of FENa is poor and its value has been questioned.

FENa is often >1% in patients receiving diuretics and has been found to be <1% in various settings, including sepsis, rhabdomyolysis, and exposure to contrast media. Carvounis et al. suggested that the fractional excretion of urea (FEU) is more sensitive and specific for discriminating between prerenal azotemia and ATN, especially if diuretics have been administrated. However, this study had important methodological errors.

Not all tests have been tested and questions remain whether they are useful for the diagnosis and classification of AKI in critically ill patients. Also, they don't quantitatively measure kidney injury nor do they provide any information about prognosis. We must remember that the classification of AKI in prerenal azotemia and ATN is arbitrary and that both probably exist as a continuum of injury and that their separation in terms of diagnosis also has its clinical and prognostic limitations.

Proteinuria is frequently detected in critically ill patients. Microalbuminuria is defined as <300 mg/g of creatinine or proteinuria >300 mg/g of creatinine. Proteinuria is more

commonly encountered in the elderly, patients with diabetes, chronic kidney disease, or shock. A high albumin/creatinine ratio (>100 mg/g) is associated with increased mortality.

The detection of microalbuminuria is suggestive of increased capillary permeability to proteins, with a predictive and prognostic value of disease severity and mortality. However, no studies have assessed the value of microalbuminuria in predicting the course of AKI in patients admitted to the CCU. The detection of low-molecular-weight proteins of tubular origin has been described in critically ill patients with AKI and sepsis. No study has evaluated *a priori* urinary protein excretion as a marker of AKI or as a predictor of decline in renal function or recovery in critically ill patients.

The classic urinary profile of ATN is represented by tubular epithelial cells with large casts, brown casts or casts with mixed cells, whereas fine granular casts can sometimes be detected in prerenal azotemia.

Few studies have assessed urinary sediment in AKI in critically ill patients. Moreover, the value of urine sediment to classify AKI pathogenesis and severity is imperfect and often fails to correlate with traditional urinary biochemical markers or derived indices. There are no clinical studies to date that have evaluated *a priori* the value of urine sediment and microscopy as a marker of renal function or AKI. Urine microscopy should be performed when systemic vasculitis, rapidly progressive glomerulonephritis or a pulmonary-renal syndrome is suspected.

In conclusion, these conventional markers are familiar to the CCU team though they are not ideal, have limitations, and none reflect real-time changes in GFR or genuine injurious processes in the kidney. Moreover, they may lead to delayed recognition of AKI and delay proper support and therapeutic interventions.

Fortunately, the application of innovative technologies such as functional genomics and proteomics in humans and animal models of AKI has discovered new genes and gene products that have emerged as biomarkers. Biomarkers are required to:

- Identify the primary site of injury (proximal tubule, distal tubule, interstitium, or vasculature).
- Indicate the duration of renal failure (AKI, chronic renal disease or re-exacerbation of chronic renal failure).
- Identify the pathogenesis of AKI (ischemia, toxins, sepsis, or a combination thereof).
- Stage risk and prognosis (AKI duration and severity, need for renal replacement, hospital stay, mortality).
- Define the course of AKI.
- Monitor the response of AKI to various interventions.

New and promising markers of AKI have been proposed and are currently under evaluation. These include a plasma panel (neutrophil gelatinase-associated lipocalin [NGAL] and cystatin C) and a urine panel (NGAL, IL-18 and KIM-1). Because they are sequential biomarkers, it is likely that panels for the diagnosis of AKI may be useful at the time of initial insult and to assess the duration of AKI (analogous to the diagnostic panel in chest pain) and to predict global prognosis regarding RRT and mortality. What is likely is that diagnostic panels will allow us to distinguish between different types and pathogenesis of AKI.

21.5 Common Causes of AKI in Critically Ill Patients

The causes of AKI in critically ill patients are multifactorial and often result from a combination of hypovolemia, sepsis, pharmacological therapy, and hemodynamic alterations.

Often, a single cause cannot be isolated, further complicating the search for effective therapeutic interventions in this complex disease.
Sepsis is the most common cause of AKI in critically ill patients, accounting for up to 50% of cases. AKI is common after cardiac surgery, occurring in up to 40% of patients without pre-existing renal disease and associated with increased morbidity and mortality with an elevated PCr of only 0.3 mg%. AKI in trauma patients is multifactorial (e.g., hemorrhagic shock, abdominal compartment syndrome, rhabdomyolysis) and occurs in up to 31% of adult trauma patients.
The kidneys are very sensitive to intra-abdominal hypertension and intra-abdominal pressure over 12 mmHg associated with AKI. A sustained intra-abdominal pressure of 20 mmHg in association with a new organ dysfunction may be associated with AKI in more than 30% of cases. Rhabdomyolysis occurs in 28% of trauma patients with AKI requiring RRT.
Pharmacological therapy is a common cause of AKI, accounting for about 20% of all causes of AKI in critically ill patients. The mechanisms inducing AKI are multiple, including acute interstitial nephritis (AIN), direct tubular toxicity (e.g., aminoglycosides) and hemodynamic abnormalities (e.g., nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors). AIN is an underrecognized cause of AKI in the CCU and is associated with pharmacological therapy. Because of the relative paucity of clinical findings, however, a high index of suspicionis needed for diagnosis.

21.6 Prevention and Management of AKI in Critically Ill Patients

The primary prevention of AKI in the CCU is limited to those conditions in which the time of injury is foreseeable, such as exposure to contrast media, cardiac surgery, and chemotherapy. Unlike most cases of community-acquired AKI, almost all cases of AKI in critically ill patients originate from more than one insult (Tables 21.4 and 21.5). In critically ill patients the first insult is often unpredictable. Therefore, prevention of AKI in the CCU relies on the prevention of secondary injury in a patient at high risk of AKI, as the patient is critical. In a retrospective study of over 5000 critically ill patients (6), AKI developed in 67% and occurred after CCU admission in 45%.
The general principles of secondary prevention of AKI include:

- Recognition of underlying risk factors which predispose patients to AKI (e.g., diabetes, arterial hypertension, chronic renal disease, age, cardiac and hepatic dysfunction);
- Maintenance of renal perfusion, prevention of hyperglycemia and nephrotoxin exposure to these high-risk patients.
- Primary prevention of contrast-induced nephropathy (CIN) includes hydration, N-acetylcysteine (NAC) and the use of low hypo-osmolar or iso-osmolar nonionic contrast volumes. No strategy has been completely effective in preventing CIN. Risk factors for its development include diabetes, chronic kidney disease, arterial hypotension, absolute or relative depletion of intravascular volume.

- Sepsis
- Major surgery
- Low cardiac output
- Hypovolemia
- Nephrotoxic medications
- Trauma
- Abdominal Compartment Syndrome
- Rhabdomyolysis
- Obstruction of urinary flow

Table 21.4. **Common causes of AKI in critically ill patients.**

Intuitively, critically ill patients constitute a population at high risk for CIN owing to frequent hemodynamic abnormalities, multiorgan dysfunction, routine use of nephrotoxic medications, and concomitant co-morbidities. Of the many randomized controlled trials (RCTs) on the prevention of CIN, only one was specifically carried out in critically ill patients.

Exogenous	• NSAIDs • Aminoglycosides • Amphotericin B • Penicillins • Acyclovir • Chemotherapy • Contrast media
Endogenous	• Rhabdomyolysis • Hemolysis • Tumour lysis syndrome

Table 21.5. **Nephrotoxins causing AKI in critically ill patients.**

Adequate fluid resuscitation is a well-established measure to reduce the risk of CIN, while the choice of fluid remains controversial. Five meta-analyses of sodium bicarbonate suggested a beneficial effect of saline solution. However, there is considerable heterogeneity across studies. The latest RCT did not demonstrate superiority between the two fluids in relation to the primary objective of a reduction >25% in GFR within 4 days of exposure to contrast material.

NAC (N-acetyl cysteine) is an antioxidant which reduces the risk of CIN as compared with placebo. Since 2003 more than 10 meta-analyses have been published on the role of NAC in the prevention of CIN. The conflicting results may be attributable to the heterogeneity of the study populations. There are conflicting data on the possibility that NAC itself can reduce PCr without affecting GFR. The use of nonionic hypo-osmolar or iso-osmolar contrast media is clearly associated with a reduction in CIN when compared with high osmolarity agents.

Due to the absence of sufficient data on critically ill patients, we are forced to extrapolate the best available evidence obtained in other patient populations. Therefore, the generally accepted recommendations in relation to the prevention of CIN are:

- Avoid the use of endovascular contrast media if other imaging techniques are available.
- Use either saline or sodium bicarbonate as volume expanders.
- Although its use is questionable, NAC is a safe, inexpensive agent and can reduce the risk of AKI.
- Whenever possible, avoid the use of other nephrotoxic drugs in the patient.
- Use low volumes of hypo- or iso- osmolar contrast media. More studies are needed to determine the true role of these preventive measures in critically ill patients.

The management of critically ill patients with AKI revolves around optimizing hemodynamics and renal perfusion, correcting metabolic abnormalities, and providing adequate nutrition in the attempt to mitigate the progression of injury. Volume resuscitation, vasopressor and/or inotropes are required to optimize renal perfusion.

Extrapolating from experimental data, it appears that the human kidney is less able to self-regulate (maintain blood flow and GFR within a wide range of perfusion pressure) in AKI. Therefore, a priority in the prevention and management of AKI is to maintain normal hemodynamics and avoid volume depletion. A mean arterial pressure >65 mmHg is a generally accepted goal, however, available data are limited.

The paradigm of renal blood flow (RBF) in AKI with sepsis is based on experimental observations and in humans with hypovolemic shock; it states that renal hypoperfusion occurs during AKI. This reasoning implies that restoration of adequate RBF should be our initial objective to protect the kidney in critically ill patients (septic or not). However, we don't know the RBF in septic patients because it cannot be measured continuously in humans beings, and its intermittent assessment can be done only with highly invasive means.

In experimental trials of AKI in the context of sepsis it was observed that RBF is reduced globally after the induction of sepsis or endotoxemia. This not only reduce glomerular filtration but also, if hypoperfusion is severe and prolonged, metabolic deterioration as well, with a reduction of high-energy phosphates, possibly resulting in cell death, acute tubular necrosis and severe AKI.

Other studies have shown that the renal circulation is involved in the systemic vasodilation seen during severe sepsis and septic shock; therefore, RBF is not reduced and the development of AKI in the context of sepsis occurs in the absence of hypoperfusion and in the presence of adequate and even increased renal perfusion.

Brenner et al. developed a percutaneously placed catheter for the measurement of RBF by thermodilution in eight critically ill patients with AKI. They demonstrated that sepsis-induced AKI occurred despite normal RBF values. During sepsis, patients in the CCU typically show features of hyperdynamic circulation.

The reason for the discrepancy between experimental and clinical studies in terms of RBF may be entirely related to the experimental model (including the animal used and the kind of insult practiced), different measurement methods, frequency of measurement and, most importantly, the state of systemic circulation (hypodynamic or hyperdynamic). Indeed, it is consistantly observed that, once a hyperdynamic state exists, hypoperfusion/global renal ischemia may not necesssarily be present.

In a recent review of the literature on experimental models of sepsis and AKI, Langenberg et al. reviewed 160 experimental studies on induced sepsis and aspects of renal function or dysfunction and measurement of RBF by one or more available techniques. In almost one third of the studies, RBF remained preserved or increased in experimental sepsis. At multivariate logistic regression analysis, cardiac output was the only predictor of RBF, i.e., sepsis with elevated cardiac output was associated with preserved or increased RBF, and sepsis with low cardiac output was associated with reduced RBF. As mentioned, most patients seen in the CCU with sepsis have an elevated cardiac output.

Using a sepsis model in sheep, Langenberg et al. continuously measured cardiac output and RBF while inducing a septic circulatory state of high cardiac output with the infusion of *Escherichia coli*. According to this model, the researchers were able to show that in hyperdynamic sepsis in an aware mammal of considerable size, RBF is markedly increased and renal vascular resistance decreased.

In this context, GFR is markedly reduced, with a three-fold increase in serum creatinine and an equivalent reduction in creatinine clearance. Consistent with these findings, renal recovery from AKI in sepsis is associated with reduced cardiac output, increased renal vascular resistance, and reduced RBF. These observations suggest that changes in renal vascular activity (vasodilation) may be important in the loss of glomerular filtration pressure during the first 24-48 hours of sepsis. The findings also provide “proof of concept” that glomerular filtration pressure can be lost in AKI in the context of sepsis, with a marked increase in RBF. On the other hand, it could be argued that AKI in the context of sepsis may represent a “hyperemic form of AKI.”

Glomerular filtration pressure, in turn, is determined by the relationship between the afferent and efferent arterioles. When the afferent arteriole contracts, the filtration pressure falls and GFR and urine output decrease. Conversely, when the afferent arteriole expands and the efferent arteriole expands further, RBF increases markedly, however, the pressure in the glomerular capillary falls. In this sense, GFR also decreases. This could be the scenario in human sepsis. Unfortunately, little is known about RBF during severe sepsis and septic shock.

In conclusion, renal hypoperfusion may be important in AKI in the context of sepsis associated with hypodynamic states (a rare finding in patients in the CCU) but it may not

play a role in the development of AKI during hyperdynamic sepsis (observed in most patients in the CCU with sepsis and severe AKI).

The degree to which RBF is dependent on systemic arterial pressure varies significantly according to age, underlying disease and acute illness or underlying conditions. We could say that the threshold of mean arterial pressure where RBF is dependent is not static varies according to each patient and each patient varies according to the changing conditions of their clinical status.

In septic shock,the most common cause of AKI in critically ill patients, vasopressor therapy is instituted to raise arterial pressure during resuscitation. The standard is to infuse the volume to improve hemodynamic parameters rather then to achieve adequate values. It is very difficult to define “adequate hemodynamic parameters”; and if vasopressors are administered in conjunction with fluid resuscitation, over-resuscitation with fluids and its well-documented side effects could be avoided. As there are no RCTs to date comparing vasopressors, there is no evidence that a vasopressor improves the prognosis of AKI.

While the infusion of dopamine may temporarily improve urinary flow, the renal dose of dopamine does not reduce the incidence of AKI, the need for RRT nor improve the prognosis of AKI. Besides, low-dose dopamine may worsen renal perfusion in critically ill patients with AKI and is associated with increased oxygen demand by the myocardium, with increased incidence of atrial fibrillation. In addition, we must take into account the extra-renal effects of dopamine, including negative immunomodulator effects. There is wide consensus on the potential dangers of dopamine, with no evidence of its beneficial effects for the prevention and treatment of AKI.

Fenoldopam is a dopamine D-1 receptor agonist administered for treating hypertensive crisis (5). Paradoxically, low-dose fenoldopam increases RBF without systemic effects. Studies validating the observations reported in a meta-analysis on fenoldopam could provide evidence that the drug might supplant the need for RRT.

Our primary goal in volume resuscitation is to restore circulating volume to prevent or alleviate organ injury. The kidneys receive 25% of cardiac output and are highly sensitive to hypoperfusion due to a true or relative hypovolemia. That is why the choice of fluid in AKI is a major question. While crystalloid solutions are still preferred in routine care, the debate over the use of colloidal solutions continues.

The SAFE study involved nearly 7000 patients who received either crystalloids or colloids as resuscitation solutions. The study showed no difference in survival between the two treatment groups. In a post hoc analysis performed on a patient subset, resuscitation with albumin was associated with increased mortality in critically ill patients after head injury. In contrast, there was a trend toward improved survival in patients with septic shock who had received albumin. There is no evidence supporting the use of albumin over crystalloids for improved survival in a heterogeneous population of critically ill patients.

Synthetic colloids, hydroxyethyl starch (HES) and dextrans are widely used, despite multiple reports that warned of undesirable effects on renal function. Small studies have shown an increased risk of AKI while using HES; and more recently a systematic review of 12 randomized trials showed an increased risk of AKI with the use of HES in patients with sepsis. In contrast, the largest retrospective analysis to date (SOAP study) exploring the effects of HES on renal function did not find HES to be an independent risk factor of AKI or need for RRT. Dose and preparation vary across the studies. Adverse effects have been related to molecular weight, the lower-molecular-weight compounds being the less involved in AKI.

The question of fluid management isn’t limited to the type of fluid administered; the amount of fluid administered is also very important as well. Critical illness is a dynamic

process requiring frequent evaluation and integrated monitoring to assess the status of blood volume and fluid requirement.

In a RCT of patients with the acute respiratory distress syndrome (ARDS), conservative strategy with fluids reduced the days on mechanical ventilation and did not increase the need for RRT. Furthermore, in an observational study involving over 3000 patients, an association between a positive fluid balance and increased mortality in patients with AKI was demonstrated. However, the question remains whether positive fluid balance is a marker of disease severity or is really a true cause of poor prognosis: these observations deserve further investigation.

Although the beneficial effects of intensive insulin therapy on mortality in critically ill patients remains controversial, two large RCTs showed that with strict glycemic control there was a reduction in the incidence of AKI and in the need for RRT. However, a more detailed secondary analysis strongly suggested that strict glycemic control may have a "renoprotective" effect in critically ill patients.

In contrast, in a recent prospective RCT assessing the effects of strict or intensive vs. conventional control of blood glucose in more than 6000 critically ill patients, no difference was found in the number of patients requiring RRT. However, the overall incidence of AKI was not reported in this study. Therefore, it is unclear whether strict glycemic control has a renoprotective effect and whether this is attributable to the toxic effect of blood glucose or a beneficial effect of insulin. These findings require further evaluation, particularly because strict glycemic control may be associated with a high frequency of episodes of hypoglycemia.

The nephrotoxic medication is a contributing factor in up to 25% of cases of AKI in critically ill patients. Identifying high-risk patients is key. Aminoglycosides are associated with significant nephrotoxicity. Although the daily dose of aminoglycosides has been shown by some studies to reduce the incidence of AKI, later meta-analyses found comparable efficacy but did not show a significant reduction in nephrotoxicity. Standard amphotericin B has been associated with AKI in 25 to 30% of patients. The lipid formulations of amphotericin B are preferred due to the reduction of nephrotoxicity.

The use of diuretics in the prevention and treatment of AKI is not based on any prospective clinical study. Diuretics can increase urine flow but do not have a decisive impact on mortality. Mehta et al. demonstrated that the lack of response to diuretics was associated with an increased risk of death and lack of recovery of renal function. In hindsight, in a large prospective, multicentre, international study Uchino et al. Found no increase in mortality, leaving the question unanswered about the use of diuretics in the prevention and treatment of AKI. Although oliguric AKI has been associated with a worse prognosis than non-oliguric AKI, there is no evidence to support measures to "convert" an oliguric in a non-oliguric AKI by using diuretics. The use of diuretics has not been demonstrated to shorten the duration of the AKI, reduce the need for RRT or improve the patient's global prognosis. In a recent RCT the use of furosemide was compared vs. placebo in the recovery phase of AKI requiring continuous renal replacement therapies (CRRT). Furosemide increased urine output and the fractional excretion of sodium (FENa) but did not improve renal recovery. In a study of epidemiological surveillance worldwide, nephrologists and intensivists reported their uncertainty regarding the use of furosemide in the prevention and treatment of AKI, supporting any initiative to undertake a definitive RCT. Probably, furosemide is indicated in cases of volume overload, but we must not delay the indication of RRT in patients with AKI and fluid overload.

Malnutrition in hospitalized patients is associated with increased mortality. The assessment of nutritional status in critically ill patients is limited by the lack of reliability of conventional markers. For example, prealbumin is excreted mainly by the kidneys and therefore may be "falsely elevated" in patients with AKI. AKI patients are hypercatabolic

patients with a negative nitrogen balance due to increased catabolism and altered protein synthesis.
Unfortunately, the recommended amount of protein is still controversial and current recommendations are based on expert opinions owing to lack of evidence from RCTs. The consensus recommends 20 to 30 kcal/kg/day and 1.5 grams of protein/kg/day. However, several studies have demonstrated a reduction in the negative nitrogen balance with up to 2.5 grams of protein/kg/day.

21.7 Indications and Initiation of Renal Replacement Therapy in AKI

The conventional indications for initiating RRT in AKI include volume overload, hyperkalemia, metabolic acidosis and manifestations of the uremic syndrome such as encephalopathy and pericarditis. RRT is also indicated in cases of poisoning where the toxin or drug can be dialyzed. These indications are well accepted, but subject to interpretation. How do we assess the degree of volume overload, hyperkalemia or metabolic acidosis? If diuretic therapy was initiated before RRT, which dose causes resistance to diuretics?
In many patients, however, RRT is initiated in the absence of specific indications in response to a persistent oliguria unresponsive to fluid therapy or progressive azotemia without uremic manifestations. There are different patterns of implementing RRT and no uniform standard of care: wide variations prevail in daily practice.
In the past, the paradigm of management of severe AKI was that patients died of uremic complications rather than renal injury. The corollary of this view was that the management of RRT was merely circumscribed to ensure that patients do not succumb to hyperkalemia, metabolic acidosis or volume overload, preventing overt complications of uremia such as encephalopathy and/or pericarditis. During the last decade, this paradigm has been challenged by data from different studies showing that AKI is an independent risk factor for mortality. It has been recognized that the specific management of RRT can impact on the prognosis of AKI and that optimizing renal support can reduce the high mortality.
The experience of the wars in Korea and Vietnam led to the concept of “prophylactic hemodialysis”, a term coined by Teschan and colleagues almost 50 years ago. Teschan and colleagues described their experience using “prophylactic hemodialysis” in 15 patients with oliguric AKI treated at the Renal Branch of the U.S. Army. The aim was to prevent uremic symptoms and their complications, for which dialysis should be started early with urea levels <200 mg/dl, with the aim of maintaining urea <150 mg%, with even daily frequency.
Although there was no control group, the authors argued that the results contrasted dramatically with the past experience of the same group when they began dialysis in the conventional manner. A posteriori multiple retrospective and observational studies carried out in the 1960s and 1970s compared early initiation of hemodialysis vs. late initiation of therapy, using blood urea nitrogen (BUN) values as the parameter. All studies demonstrated improved survival with early initiation of hemodialysis.
The first prospective trial of prophylactic dialysis in AKI was reported by Conger et al.: 18 patients with post-traumatic AKI were assigned to an intensive hemodialysis regimen that maintained the predialysis BUN <70 mg% and creatinine <5 mg/dl or to a non-intensive regimen in which hemodialysis was not initiated until BUN and serum creatinine reached 150 mg/dl and 10 mg/dl, respectively, or there were other indications

for initiating therapy (hyperkalemia, volume overload or uremic encephalopathy). Survival was 64% (five out of eight patients) in the intensive group as compared with 20% (two out of ten patients) in the non-intensive group (p=0.14). Gastrointestinal bleeding and Gram-negative sepsis were less frequent in the arm of the intensive hemodialysis group.

Ten years later, Conger et al. reexamined the intensity of hemodialysis in 34 patients. Matched patients were randomly assigned to the intensive regimen designed to maintain predialysis BUN <60 mg/dl and serum creatinine ≤5 mg/dl when plasma creatinine reached 8 mg% or to an intensive regimen in which BUN and plasma creatinine were allowed to reach 100 mg/dl and 9 mg%, respectively. While the therapeutic strategies were not designed to strictly assess the time of initiation of therapy, the average time from the start of AKI to the initiation of hemodialysis was 5±2 days in the intensive regimen group compared with 7±3 days in the non-intensive regimen. Mortality was higher in the intensive treatment group; however, because of the small sample, the difference was not statistically significant (p=0.73).

On the basis of these data, it has been suggested that in the absence of specific symptoms, hemodialysis is to be started when BUN reaches approximately 100 mg%, but there is no additional benefit associated with earlier or more intensive initiation of therapy.

Several studies published in the late 1990s re-examined the topic, focusing only on the time of initiation of continuous renal replacement therapy (CRRT). In their retrospective analysis, Gettings et al. related time of initiation of CRRT and prognosis of 100 consecutive patients with post-traumatic AKI. Patients were classified according to early or late initiation of therapy and according to baseline BUN, using a cut-off value of 60 mg% to separate the two groups. In the early initiation group, CRRT was begun on day 10±15 after admission (average BUN, 43±13 mg/dl) as compared with the start of therapy after 19±27 days (average BUN, 94±28 mg/dl) in the late group. Survival was 39% in the early initiation group compared to 20% in the late group (p=0.041). The patient demographics, disease severity, and disease severity scores in the two groups were comparable, but a higher percentage of patients in the late initiation group had multiple organ failure or sepsis. Although the timing of initiation of therapy may reflect the variable randomization in medical behavior, it is more likely that the patients' individual characteristics contributed to decisions not to randomize regardless of time of initiation of therapy. For example, 56% of patients in the early initiation group were oliguric on the first day of CRRT compared to 39% in the late initiation group. Therefore, the observed differences in prognosis may have been due to unreported differences underlying the decision to initiate early versus late therapy. Similar results have been reported in two retrospective analyses of time onset of CRRT in patients after cardiac surgery.

Piccinni et al. described the use of early isovolemic hemofiltration in oliguric patients with sepsis. They compared the prognosis in 40 patients with sepsis and oliguria in which high-volume hemofiltration was started (45 ml/kg/h) without net removal of fluid within 12 hours after CCU admission compared with 40 historical controls in which replacement therapy was initiated according to conventional indications. In patients treated with isovolemic hemofiltration, survival at 28 days was 55% compared with 27.5% in the historical control group. Although the authors described isovolemic hemofiltration in terms of early therapy, the comparison of the interval between the onset of renal dysfunction and initiation of therapy was not provided by biochemical indices of renal function and the initiation of renal support was similar, with a trend toward higher concentration in BUN and serum creatinine in the isovolemic hemofiltration group (110±38 mg/dl vs. 120±30 mg/dl and 1.7±2 vs. 1.8±2, respectively), suggesting that the time of initiation was not significantly different between the two groups.

Liu et al. analyzed data from the beginning of RRT (continuous and intermittent) of the Program to Improve Care in Acute Kidney Injury, a multicentre observational study of AKI. They evaluated 243 patients who received RRT in the early group and a late initiation group based on BUN (76 mg/dl) at initiation of RRT. Although the patients in the late group (BUN >76 mg/dl) had a reduced burden of organ failure, the survival rate at 14 and 28 days in this group was 75% and 59%, respectively, being somewhat lower than in the early initiation group (BUN >76 mg/dl) in which the survival rate was 8% and 65%, respectively.
After adjusting for age and clinical factors and staging for the site and initial modality of RRT in multivariate analysis, the relative risk of death associated with the initiation of dialysis with more severe azotemia (using the early initiation group as a comparator) was 1.85 (95% confidence interval [CI], 1.16-2.96). We also found an increase in relative risk of death in the high BUN group (2.07; 95% CI 1.30-3.29).
We should consider several limitations when analyzing the results of these retrospective studies. First, the use of BUN as a "replacement" for the measurement of the duration of AKI is problematic. Urea production is not constant, with a wide range among patients and even in the same patient, as is the degree of stress.
Similarly, the volume of distribution of urea in critically ill patients is highly variable and inconstant. Therefore, the rate of increase in BUN may vary among patients and may even vary in an individual patient over time. Second, there is a bias due to indications. Renal support was initiated because of oliguria in the early groups and due to azotemia and hyperkalemia in the late groups in both studies of AKI in post-operative cardiac patients. Although the reasons for early and late initiation in the studies by Gettings and Liu were not specified, it is likely that early initiation was due to volume overload and electrolyte disturbances, whilst the late initiation was indicated most likely because of progressive azotemia. We do not know if there is a relationship between the indication of therapy and prognosis.
In all four studies there were limited analyses in patients who received RRT, ignoring the subgroup of patients with AKI who recovered or died without RRT.
A recent study by Bouman et al. randomly grouped 106 critically ill patients with AKI into three groups:

- Early initiation with high-volume CVVHD (n=35).
- Early initiation with low-volume CVVHD (n=35).
- Late initiation with low volume CVVHD (n=36).

where CVVHD: continuous venovenous hemodiafiltration.
Treatment was initiated early within 12 hours to meet the requirements to be included in the study (presence of oliguria >6 h despite hemodynamic optimization or measured creatinine clearance <20 ml/min in urine collection of 3 hours), whereas in the late initiation group, RRT was initiated when BUN was >112 mg/dl, hyperkalemia >6.5 mEq/l or in the presence of pulmonary edema.
There were no significant differences in survival among the three groups. However, mortality at 28 days for these patients was only 27%, substantially lower than the mortality rates reported in other studies of critically ill patients with AKI, suggesting a lesser degree of severity in this patient group.
Current data do not allow us to know what the right time is for initiating RRT in AKI. We do not know if starting early or conservatively improves survival: the question remains unanswered. Although observational studies suggest a better outcome with early initiation, this can only reflect the inclusion of patients with less organic injury, in whom the prognosis is better regardless of the therapeutic strategy.
All observational studies focus on the problem of patients with AKI who require RRT. However, most patients with AKI do not require RRT. To answer this question, research should include all patients in whom the initiation of RRT is considered.

The timing of initiation of RRT in AKI patients remains uncertain. Conventionally, its initiation is accepted in case of volume overload, hyperkalemia, metabolic acidosis, progressive increase in uremia even without specific symptoms. However, there are no precise definitions of these indications in patients with AKI. In addition, observational studies and retrospective analyses have suggested that early initiation may improve survival. Nonetheless, the lack of inclusion of patients with AKI who met the inclusion criteria for early therapy but never received RRT limits the validity of these analyses. In order to carry out well-designed studies, we need more reliable biomarkers of renal injury, which are predictors of the clinical course of AKI.

21.8 Dose of Renal Replacement Therapy in Acute Kidney Injury

Three of the six prospective RCTs on RRT dose in critically ill patients have suggested that high doses of dialysis improve prognosis, especially by reducing mortality. In 2000, Ronco et al. published the first RCT investigating the results of three different ultrafiltration rates (20, 35 and 40 ml/kg/h). While mortality was high in all three groups, it was significantly lower in the two groups that received dialysis at the higher ulrafitration rates, with no difference in complications among the three groups. The single centre trial took years to complete and the percentage of sepsis-related AKI was lower than those usually observed in the CCU.

In 2002, Shifft et al. in a prospective, randomized study found that daily dialysis was superior to dialysis on alternate days. There were significantly fewer episodes of hypotension in the daily dialysis group (5 vs. 25%). Mortality was lower in the daily dialysis group (28 vs. 46%). An important limitation of this study was that the dose of dialysis delivered was significantly lower than that prescribed; therefore, the daily dialysis group received only an “adequate dialysis dose” compared to contemporary standards of treatment. In essence, the study compared “adequate” therapy vs. “inadequate” therapy.

Saudan et al. demonstrated that adding dialysis to continuous venovenous hemofiltration (CVVH) improved survival at 28 and 90 days when compared to CVVH alone in 206 critically ill patients (39 vs. 59% and 34 vs. 59%, respectively), suggesting that clearance of small solutes is important.

In contrast, three prospective RCTs found no difference in mortality. Bouman et al. found no difference in mortality when comparing early hemofiltration at high ultrafiltration rate, early hemofiltration at low ultrafiltration rate vs. late hemofiltration at low ultrafiltration rate, with an average ultrafiltration dose of 48, 20 and 19 ml/kg/h, respectively.

More recently, Tolwani compared two different doses of ultrafiltration (20 vs. 35 ml/kg/h of CVVH) and found no differences in mortality at 30 days between the two groups. Of note is that the dose delivered in the two groups was 17 and 29 ml/kg/h, respectively.

In 2008, the Acute Renal Failure Network published a multicentre study comparing the results of two RRTs, an intensive therapy vs. another conservative therapy. The intensive care group received daily dialysis, CVVHD or sustained low-efficiency dialysis (SLED) at an ultrafiltration rate of 35 ml/kg/h while the conservative therapy group received dialysis on alternate days (three times per week) with CVVHD or SLED at an ultrafiltration rate of 20 ml/kg/h. The patients were allowed to switch between intermittent and continuous regimens according to their hemodynamic stability, but they remained in the therapeutic group initially assigned. AKI was considered multifactorial in 59% of patients. No benefit was found with the use of intensive RRT compared to the conventional, less in-

tensive therapy. There were no significant differences in mortality, rate of renal function recovery, duration of replacement therapy or progression of non-renal organ failure. In our opinion, this study has some limitations: definition of AKI (referred to ATN); time of initiation of RRT (not standardized in the study); unclear transition from unstable to stable over time.

In 2009, the DO.RE.MI. group led by Ronco published a study comparing CVVHD at a rate >35 ml/kg/h or intermittent hemodialysis (IHD) six times per week vs. CVVHD at an ultrafiltration rate >35 ml/kg/h or IHD less than six times per week. In this multicentre, international trial involving 15,200 patients, no benefit in survival was observed between the two treatment modalities. The intensive regimen was associated with a shorter stay in the CCU and duration of mechanical ventilation.

Finally, the RENAL study involving 1508 patients compared two therapeutic modalities of CVVHD (25 vs. 40 ml/kg/h) and reported no differences after 90 days in mortality between the two groups.

Important factors to consider when evaluating the results from the available evidence are the differences between the patient populations studied, the use of convective techniques alone or the combination of convective and diffusive modalities and, in particular, the difference between the indicated dose and that actually delivered to patients.

Findings of negative assays should not be interpreted as “the dose is unimportant.” As the work of the Acute Dialysis Quality Initiative (ADQI) concludes, the clearance given to the patient should be monitored throughout the whole renal supportive therapy. No specific recommendations can be made about dialysis dose for patients with specific diseases at this time. A minimum dose of RRT, however, needs to be delivered in AKI. The best evidence supports the use of an ultrafiltration rate ≥35 ml/kg/h for CVVH and CVVHD. Also recommended is that the prescription should exceed the dose calculated as “adequate” because of the known gap between the prescribed dose and the real one delivered to the patient.

A systematics based on solute removal in relation to the dose appears to be too restrictive, albeit operationally relatively simple, and, by analogy to terminal chronic renal failure, it could be linked to prognosis.

We might initially start from a hypothetical point with “zero dose” or “no therapy”, which would have a negative prognosis of 100%. From there we would enter a “dose-dependent” zone, where any dose increase, however small, would result in improved prognosis. This may be true until a point where further dose increments do not improve the prognosis and the dose-prognosis relationship begins to enter a plateau or plateau phase. This area can be called “dose-independent” or “dependent on the practice or art” or “dependent on the severity.” Beyond this point, survival is not affected by an increase in treatment but rather by the level of severity of the patient’s conditions.

Currently, the cutoff for CRRT is 35 ml/kg/h; in a septic population, however, the cutoff could be raised to 45 ml/kg/h or even more. The current recommendation based on available data is to ensure a dose of Kt/V of 1.2 to 1.4 for the intermittent modality. In our opinion, the use of Kt/V to adjust the dose of intermittent modalities involves extrapolating the results obtained in patients with chronic renal disease on a regular hemodialysis schedule of three times a week, while it doesn’t seem appropriate to do so in critically ill patients with AKI. The plateau level can be defined by other factors beyond the treatment dose. In critically ill patients with AKI, these conditions of adequacy of RRT have not yet been explored, but may be important in the final prognosis. Further studies should focus on other aspects beyond the dosage (e.g., volume control, acid-base status, toxicity, etc.) and evaluate their relationship with the prognosis.

21.9 Methods of Renal Replacement Therapy in Acute Kidney Injury

Treatment options for replacing renal function in critically ill patients are intermittent hemodialysis (IHD) and various continuous techniques of renal replacement: continuous venovenous hemofiltration (CVVH); continuous venovenous hemodialysis (CVVHD); continuous venovenous hemodiafiltration (CVVHD); sustained low-efficiency dialysis (SLED); and extended daily dialysis (EDD). The suitability of one over another, particularly in critically ill patients, has been the subject of heated controversy.

Continuous techniques and SLED are better tolerated by patients with abnormal hemodynamics. From the point of view of efficacy in the extraction of solutes, a better control of homeostasis has been attributed to CRRT, due to its prolonged effect, absence of a "rebound effect" (post-procedure increase in blood solutes, such as urea), and potential clearance of inflammation-related molecules, sepsis and the multiple organ dysfunction syndrome (MODS) in critically ill patients with AKI.

Several studies have compared the results of IHD with CRRT in the evolution of AKI. Since most studies are retrospective and not randomized in design, it is difficult to draw valid conclusions owing to the differences in the severity index. A higher mortality for patients undergoing CRRT has been reported, but when adjusted for the severity index, no differences can be attributable to the type of therapy.

In a large, randomized prospective trial, Mehta et al. sought to compare both techniques. Mortality was higher in the CRRT-treated group than the IHD-treated group in both the CCU (59.5 vs. 41.5%) and the hospital (65.5 vs. 47.6%). But despite randomization, the CRRT patients had a higher APACHE III score and more patients had liver failure. The many uncontrolled factors in this study preclude definitive conclusions. In a meta-analysis, Kellum et al. found no differences in mortality between intermittent hemodialysis and CRRT. However, the quality of the reviewed studies was poor and only three of them were prospective. In a subanalysis, after adjusting for study quality and severity index, a beneficial effect of CRRT on survival was found (RR = 0.72, 95% CI 0.60-0.87; $p < 0.01$). In six studies involving patients with similar severity, mortality was lower with CRRT (RR = 0.48, 95% CI 0.34-0.69; $p < 0.0005$). Despite the secondary analysis, the meta-analysis concluded that there was insufficient evidence to support a specific therapy in AKI. Moreover, Tonelli et al. in another meta-analysis also found no survival benefit with one technique compared to another.

Recently, a program to improve care in AKI carried out a retrospective study comparing the results of different RRT modalities in 368 patients (CRRT, n=206 vs. IHD, n=192). As compared with IHD, CRRT was associated with an increased relative risk of mortality. The authors acknowledged that the patients in the CRRT arm were more severely ill and that the results might have been influenced by that.

In a recent paper, Vinsonneau et al. reported a prospective, randomized trial in 21 CCUs over a period of three and a half years. The primary endpoint was mortality at 60 days after having randomized 360 patients with AKI to receive CVVHD or IHD in centres that were familiar with both technologies. The election criterion was changed after eight months because the inclusion rate was too low. There was no difference in mortality in either group, concluding that patients with AKI as part of MODS can be treated with IHD. The trial was well designed and performed; to date, it is the best example of a randomized controlled study comparing the two techniques. However, the study began more than seven years ago: the practice of different purification techniques has changed considerably since then. One change is related to the dose delivered in renal support vs.

prescribed treatment. But because there was no information about the dose in either arm, no definitive conclusions can be drawn.

The question of which treatment is best is influenced by the nature of a study. CRRT may be better in terms of total water and solute removal in a 24-hour-period and hemodynamic tolerance, but IHD can remove much more water and solute per hour and does not require continuous anticoagulation or complete patient immobilization. The problem, however, is not to achieve high efficiency within a short period of time; instead, our goal is to achieve the best blood purification and restoration of homeostasis with the lowest possible rate of complications. If it is true that all patients with AKI as part of MODS can be treated with IHD, it follows then they can be safely treated with CRRT.

In patients with cerebral edema, intermittent treatment could worsen the patient's clinical condition due to the influx of fluid into the brain tissue after dialysis. After a hemodialysis session, the cerebral density decreases due to deviations of osmotic fluid. These alterations induced by intermittent therapy would not occur with CRRT, which could be used in patients at risk for cerebral edema.

In the last two decades, technological advances in IHD have dramatically reduced the incidence of IHD-induced intradialytic hypotension. These advances include the introduction of machines that control volume, the use of biocompatible synthetic membranes, and the use of dialysate containing bicarbonate, and the delivery of higher doses of dialysis.

Schortgen et al. reported a lower rate of hemodynamic instability during IHD with the implementation of an algorithm designed to improve hemodynamic tolerance of IHD, which consists of priming the circuit with saline, sodium in the dialysis solution >145 mEq/l, discontinuing therapy with vasodilators, and setting the solution temperature to <37°C.

There have also been improvements in CRRT. The use of bicarbonate in replacement fluid is available today.

Ideally, CRRT and IHD coexist according to the needs of each patient, which we call an "à la carte menu." Whether one technique may be superior to another is a fruitless artificial discussion.

As designed in Vinsonneau's protocol, a change from one treatment to another seems reasonable when clinical status changes. Although this routine seems to make sense, it has never been validated.

The random selection of patients for one dialysis method or another, regardless of their clinical, can produce results that will be difficult to generalize in daily practice. A decade ago, debate raged about the best systematic disconnection of the patient from the mechanical ventilator. Perhaps electing one method rather than another is difficult, and the way in which the disconnection technique is performed may have a greater effect on the possibility of disconnection than the method itself. The design of future studies should include other prognostic parameters besides mortality.

Recently Uchino et al. reported the results of an observational, prospective trial involving 54 international centres with 1258 patients treated with RRT for AKI. CRRT was the most common initial treatment modality (80%) followed by intermittent therapies (16.6%). Patients who were initially treated with CRRT required vasopressors and mechanical ventilation more often than those requiring intermittent renal replacement therapy (IRRT). The "unadjusted" raw hospital survival rate was lower (35.8 vs. 51.9%; $p < 0.001$). However, the absence of dialysis dependence at hospital discharge was higher for CRRT (85.5 vs. 66.2%; $p < 0.0001$). The multivariate logistic regression analysis showed that the choice of CRRT was not an independent predictor of hospital survival or hospital days without dialysis. However, the choice of CRRT was a predictor of a lack of dialysis dependence at hospital discharge among survivors. Other studies found similar results.

Hybrid therapies developed in the last decade provide a feasible compromise solution in this eternal dispute. Depending on variations in the selection and removal of solutes (convection or diffusion), they such therapies are known under a variety of names: sustained low-efficiency dialysis (SLED), (Marshall et al.); prolonged daily intermittent therapy (Nakay et al.); extended daily dialysis (Kumar et al.). In theory, the intent is to maximize the benefits of each therapy, continuous and intermittent, including the efficient removal of solutes with a minimum solute disequilibrium, reduction of the ultrafiltration rate with hemodynamic stability, optimizing the delivery of the prescribed dose, low need for anticoagulation, and enhancement of patient mobilization.

Initial studies have shown the feasibility and potentially high clearance associated with such treatments. Recently, Baldwing et al. randomly assigned 16 patients to treatment with CVVH or extended daily dialysis with filtration (EDD) for three consecutive days and compared the control of small solutes, acid-base status and electrolytes. No significant differences were found between the two therapies in relation to urea and creatinine levels during the three days. All electrolyte abnormalities before treatment were corrected as a result of treatment, except in one patient in the CVVH group who developed hypophosphatemia at 72 hours. After three days of treatment, a mild metabolic acidosis remained in the EED group compared with the CVVH group.

It is now possible to generate ultrapure replacement fluid and to administer it in the CCU at a lower cost than CRRT in large quantities and for shorter periods of time. Hemofiltration may be combined with diffusion. It is possible to perform three to four hours of standard IHD or CRRT at 35 ml/kg/h of ultrafiltration. SLED is performed with a dialysate and blood flow rate of 150 ml/min for eight hours during the day or, as an alternative, for 12 hours at night. It is also possible to combine an initial therapy with CRRT in the first two or three days when the patient is in the hyperacute phase, followed by SLED when recovery begins.

If we consider the teaching of ventilatory modalities, the RRT modalities are similar to those of ventilation, and can be changed according to therapeutic objectives, patient's needs and stages of disease.

Restricting the management of critically ill patients with AKI to one therapy or another is a simplistic approach. So far, there is no prospective, randomized trial with sufficient power to provide solid evidence for electing any one type of treatment. Given that this would require 660 patients in each of the two study arms, it is arguable whether a study of this kind can be carried out. The different clinical situations and variables to consider support the view to individualize treatment according to need. Various different techniques can be complementary, even in the same patient.

21.10 Conclusions

AKI-realted morbidity and mortality of in the critically ill patient requiring dialysis are high. Dialytic strategies that can reduce their impact are not universally accepted. The lack of sensitive markers of uremic toxicity and of fully assessed indices of dialysis in AKI hinders the determination of well-defined therapeutic goals. Another problem is the underestimation of the volume of urea distribution by anthropometric methods, which can lead to prescribing an inadequate dialysis dose. The high burden of comorbidity in AKI patients in the CCU is another obstacle when it comes to elucidating the potential benefit of dialysis in its evolution. Adequate dialysis dose in AKI is not consensual. Some practices seem to be more effective, but there is no sufficient scientific evidence. Replacement treatment in AKI patients needs to be flexible, adapting the technique (IHD SLED

or CRRT) to the patient's clinical status, as measured by urine output, hemodynamic status, and the number of affected organs. Treatment should be adjusted to the needs of the individual patient and not the other way round. Furthermore, we should consider an "à la carte" dialysis therapy, according to the suitability of each patient, individualizing the starting time, dose and time of initiation of RRT for each patient when we meet them. As we go forward we will need define new disease groups that may benefit from the effects of purification and determine the appropriate treatment necessary to ensure optimal performance.

Currently, renal replacement is intended as a replacement for purification, but the first steps have already been taken to realize a concept of renal substitution in which not only the elimination functions are controlled but the synthesis mechanisms specific to the native kidney are also applied.

In light of the above, we can say that RRTs are continuous evolving in terms of basic concepts (patient characteristics, definition of new indications), current definitions (a good marker of treatment intensity or proper dose), technical aspects (appropriate material), or consensus on the most suitable type of RRT from among the many available.

22 The Brain and the Abdomen: Closer Than You Think

Inneke De Iaet [1], **Manu Malbrain** [1]

[1] ZiekenhuisNetwerk Antwerpen, Campus Stuivenberg, Intensive Care Unit, Antwerp, Belgium

22.1 Introduction

Intra-abdominal hypertension (IAH) and abdominal compartment syndrome (ACS) are a relatively common occurrence in ICU patients, as was demonstrated by Malbrain et al. [1,2]. Interest in this topic has increased dramatically over the last few years leading to a rapidly growing body of evidence regarding all aspects of IAH. The deleterious effect of IAH on organ function has been well documented [3,4]. Especially the organs lying within or adjacent to the abdominal cavity (e.g. the kidney) are at risk due to decreased blood supply and direct pressure on the organ involved [5]. However, also distant organs, such as the heart and the brain, are influenced by IAH in ways that are not yet completely understood [6,7]. Several animal studies and human clinical studies have described the relationship between intra-abdominal pressure (IAP) and intracranial pressure (ICP) [8-13] and some have offered insights into the mechanisms involved [7,14-19]. Some small series describing successful treatment for patients with IAH and intracranial hypertension (ICH) have also been published [10,20].
In this chapter we will summarize all research findings concerning the relationship between the abdomen and the brain, offer an overview of current knowledge on this fascinating topic and make a few clinical recommendations based on the findings described.

22.2 The Relationship Between IAP and ICP

22.2.1 Animal Studies

The first report describing a relationship between IAP and ICP was published in 1994 by Josephs et al. of the Boston University School of Medicine who induced IAH in a porcine model (by installing a pneumoperitoneum) and observed a concomitant increase in ICP but no significant decrease in cerebral perfusion pressure (CPP) [11]. The same effect could be observed when the added insult of brain injury (by inflating a balloon in the epidural space) was induced. The authors explained this phenomenon by formulating a hypothesis based on the modified Monro-Kellie doctrine. The Monro-Kellie doctrine recognizes three main contents in the cranial space: vascular, cerebrospinal fluid (CSF) and parenchyma. The doctrine states that, in adults, changes in one or more of these contents result in reciprocal changes in the remaining compartments. The imbalance of the contents produces an ICP increase when buffer mechanisms are exhausted. In other words, ICP reflects the relationship between the volume of intracranial contents (vascular, CSF, and parenchyma) and the volume of the cranial vault. In their brain injury model, Josephs et al. increased the intracranial volume directly by inflating an epidural balloon [11]. At the same time they indirectly increased the vas-

cular contents by inducing a pneumoperitoneum which decreases thoraco-abdominal compliance and reduces venous outflow from the brain, thus producing an ICP rise. A combined effect of pneumoperitoneum and endotoxemia on cerebral perfusion has been observed in pigs [21].

The confirmation of Josephs' hypothesis came a few years later. Using a porcine model of acutely elevated IAP, Bloomfield et al. clarified the mechanisms by which IAH increases ICP and decreases CPP, evaluated the effect of intravascular volume expansion upon ICP and CPP and studied the relationship between IAP, pleural pressure (PP), CVP and ICP [8,9]. They measured the effects of elevated IAP upon ICP and CPP before and after intravascular volume resuscitation [8]. IAP was increased in 5 anesthetized swine by inflating an intraperitoneal balloon until 25 mmHg above baseline. Intravascular volume was then expanded and, finally, abdominal decompression was performed.

Bloomfield demonstrated that elevated IAP increases CVP, PP, ICP and decreases cardiac index (CI), mean arterial pressure (MAP) and CPP. Moreover, volume expansion, in the presence of elevated IAP, further raised the ICP and CPP (because of a larger increase in MAP). An interesting finding was that an IAP greater than or equal to 25 mmHg produced a statistically significant decrease in CPP, even in animals without head injuries.

The results of this study confirmed that the mechanism of increment of ICP is mechanical. In accordance with the Monro-Kellie doctrine, the authors demonstrated that cerebral venous outflow via the jugular venous system was impeded by a significant rise in the CVP. This phenomenon was amplified by volume expansion, due to the additional rise in CVP. The authors suggested that the functional obstruction of the jugular venous system and the ensuing obligatory increase in the volume of the cerebral vascular space, are the mechanisms responsible for the increased ICP caused by elevated IAP.

One year later, the same group published a new study with a similar setup, only this time the pigs were divided into two groups [9]. The first group was treated as mentioned before, the second group underwent sternotomy and pleuropericardotomy before increasing IAP. Interestingly, in the second group, sternotomy and pleuropericardotomy abolished all effects of increased IAP, except the decrease in CI, which supports the hypothesis formulated in the first study (Figure 22.1).

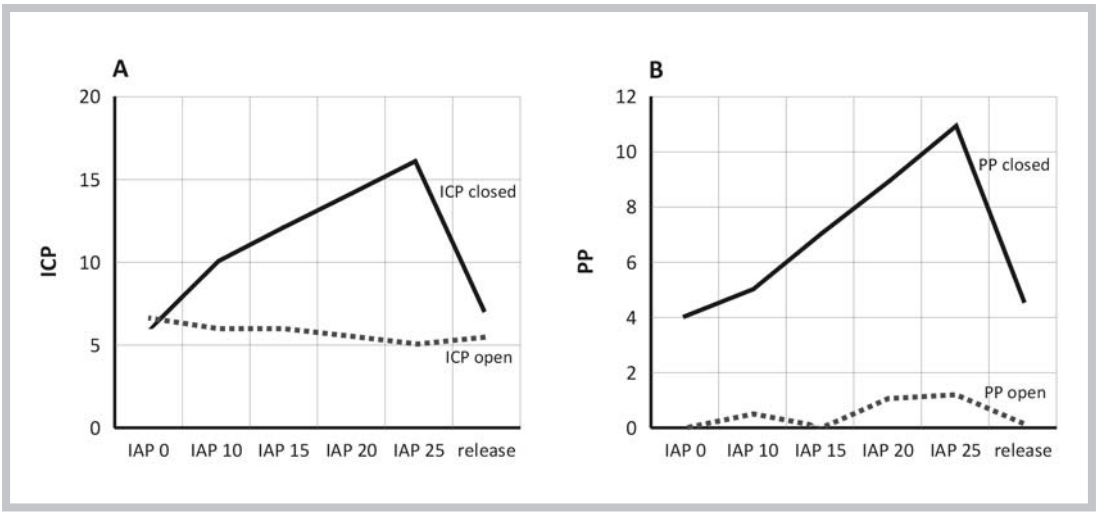

Figure 22.1. **Effect of increasing intra-abdominal pressure (IAP) in closed and open-chest animals on intracranial pressure (ICP) and pleural pressure (PP). A. ICP: solid line closed chest, dotted line animals with thoracotomy. B. PP: solid line animals without sternotomy, dotted line animals with sternotomy. Modified from Bloomfield [9].**

In a similar study in 5 pigs, Rosin et al. found no significant change from baseline in ICP when the IAP was 5 mmHg [22]. However, ICP and CPP were affected by increasing the IAP to 15 and 25 mmHg ($p = 0.035$ and 0.04 for ICP respectively). They concluded that low-pressure laparoscopy may reduce the adverse effects of pneumoperitoneum on ICP and CPP. It may therefore be advisable to use low pressures in laparoscopic surgery, especially when changes in ICP or renal perfusion may have significant clinical implications [22,23].

Hanel et al. measured cerebral hemodynamics in 10 pigs during laparoscopic insufflation to 12 mmHg [24]. Pneumoperitoneum significantly ($p < 0.05$) increased CVP from 6.3 ± 2.1 to 11.1 ± 3.0 mmHg and sagittal sinus pressure from 8.0 ± 2.8 to 11.9 ± 3.0 mmHg. However, bilateral internal carotid artery blood flow (46.0 ± 7.4 vs. 47.7 ± 7.1 ml/100 g per minute), cortical cerebral blood flow, CBF (263 ± 115 vs. 259 ± 158 tissue perfusion units), and subcortical CBF (131 ± 145 vs. 133 ± 149 tissue perfusion units) did not change during CO_2 pneumoperitoneum. The increases in sagittal sinus pressure are likely related to decreases in cerebral venous drainage caused by increases in IAP.

Other studies looked at the effect of combined abdominal and thoracic binding (ATB) on neurologic function during CPR: mean ICP was higher during ATB (46 ± 2 mmHg) than conventional CPR (20 ± 2 mmHg) [25]. However, the net brain perfusion pressure gradient (carotid artery pressure – ICP) was greater with ATB (14 ± 3 mmHg) than with conventional CPR (5 ± 0.4 mmHg). Cerebral blood flow was significantly greater during ATB CPR (32 ± 7% of pre-arrest cerebral flow) than during conventional CPR (3 ± 2%). They conclude that ATB CPR substantially improved brain perfusion by enhancing CPP in this experimental dog model. The same results were found by Ratjen et al. in lambs [26].

Palafox et al. looked at the effect of MAST suit on ICP in dogs [27]. During MAST inflation, they found a rise in ICP that mirrored the rise in CVP and never reached potentially harmful levels in the hemorrhaged animals and animals with a mass intracranial lesion. In the animals with cardiac tamponade and tension pneumothorax, inflation of the abdominal portion of the MAST suit produced a marked rise in CVP and ICP. This was altered by either relieving the lesion or reducing the pressure of the abdominal portion of the MAST suit.

Schob et al. compared the pathophysiological neurologic effects of carbon dioxide, helium and nitrous oxide pneumoperitoneum in 24 pigs [28]. The mean ICP increased significantly in all groups during peritoneal insufflation compared with the control group ($p < 0.005$). The CO_2-insufflated animals also showed a significant increase in $PaCO_2$ ($p < 0.05$) and $ETCO_2$ ($p < 0.05$), as well as a decrease in pH ($p < 0.05$). After inflating the epidural balloon the ICP remained significantly higher in animals inflated with CO_2 as compared with the He and N_2O groups ($p < 0.05$). They concluded that peritoneal insufflation with He and N_2O resulted in a significantly less increase in ICP as compared with CO_2. That difference was most likely due to a metabolically mediated increase in CPP. Further studies need to be conducted to determine the safety and efficacy of using He and N2O as inflation agents prior to attempting diagnostic or therapeutic laparoscopy in patients with potential closed head injuries.

In conclusion, these laboratory studies clearly showed that an IAP rise decreases the thoracic-abdominal compliance and increases intrathoracic pressures. This in turn reduces cerebral venous outflow, causing an ICP elevation.

22.2.2 Clinical Studies

Despite the convincing results of the previously mentioned animal studies, interest in this subject in human clinical research is very recent. In 1995, two early case reports

were published that confirmed the results of the animal studies [29-31], but the first well conducted clinical study evaluating the relationship between IAP and ICP was published by Citerio et al. in 2001 [15]. They conducted a prospective non-randomised observational study to systematically measure the effect of increased IAP in 15 patients with traumatic brain injury. IAP was increased by positioning a soft 15-l bag of water on the patient's abdomen. Naturally, patients could only be included in this study after the acute phase of their injury, when no intracranial hypertension was present. All patients

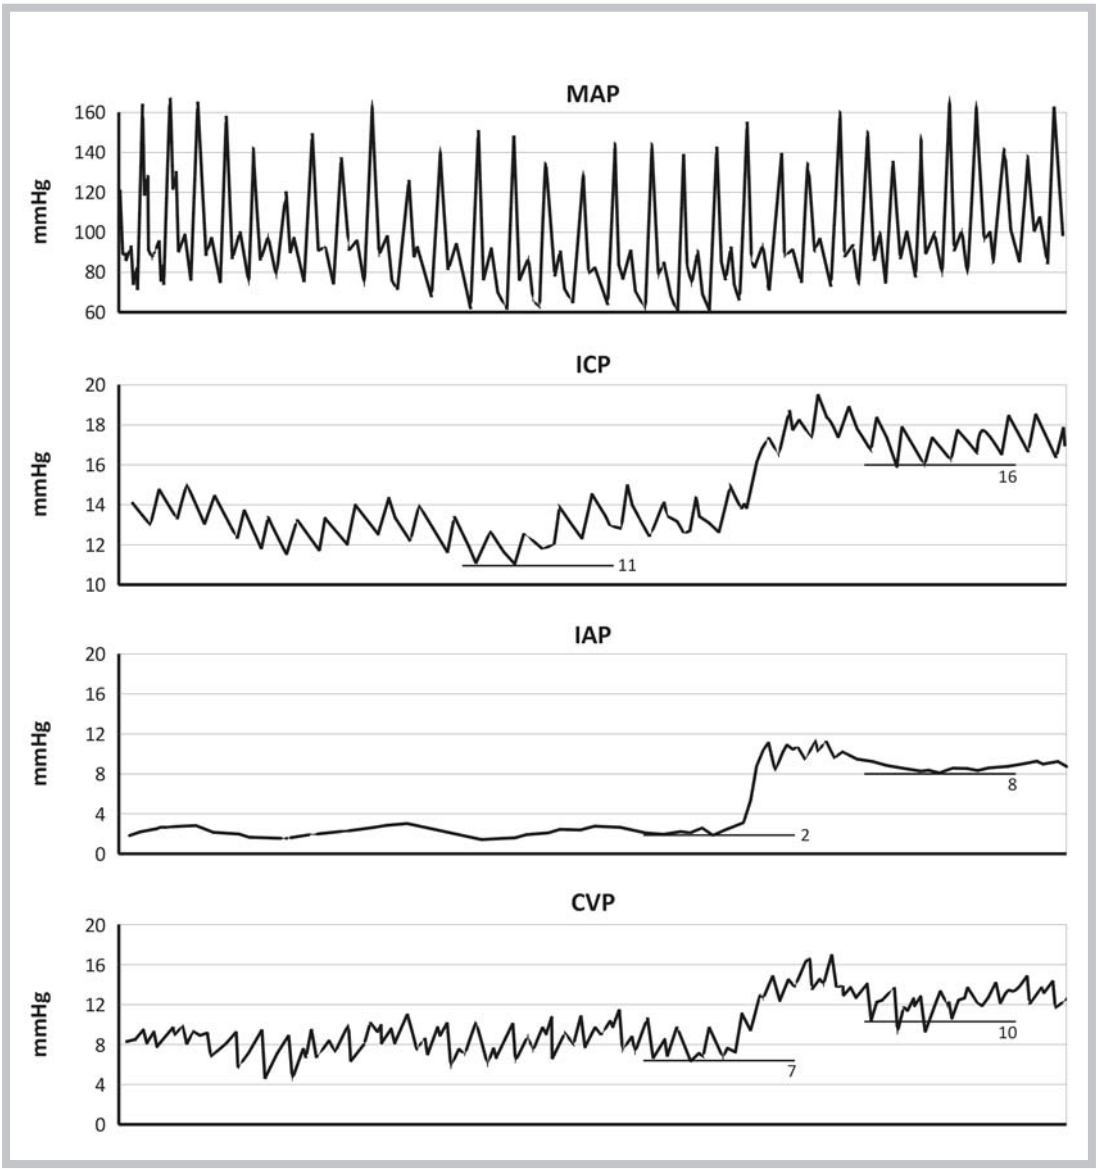

Figure 22.2. **Effect of increased IAP, obtained with a weight application in a single patient. Computerized tracings are from top to bottom: MAP = mean arterial pressure; ICP = intracranial pressure; IAP = intra-abdominal pressure; CVP = central venous pressure. The IAP increased from 2 to 8 mmHg, this resulted in an increase in CVP from 7 to 10 mmHg and an increase in ICP from 11 to 16 mmHg. Hence the transmission from the abdomen to the thorax compartment can be calculated as ΔCVP (= 10 – 7) divided by ΔIAP (= 8 – 2) or thus 50%, and the transmission from the abdomen to the cranial compartment can be calculated as ΔICP (= 16 – 11) divided by ΔIAP (= 8 – 2) or thus 83%. Modified from [7,15].**

were intubated and mechanically ventilated. Many parameters were measured: IAP, MAP, CVP, ICP, CPP, jugular bulb pressure (IJP), jugular bulb oxygen saturation and compliance of the respiratory system, divided into pulmonary and chest wall components. The authors found that placing a weight on the patient's abdomen generated a significant increase in IAP and a concomitant and rapid increase in CVP, IJP and ICP. All these changes required only seconds to reach a plateau and remained stably increased until the IAP returned to baseline after the weight removal (Figure 22.2).

Curiously, in this study a rise in MAP was observed, allowing for maintenance of a constant CPP in spite of increased ICP. This is not in concordance with the animal studies. This may be due to the lower levels of IAP generated in this human study compared to the animal studies and the use of different sedatives in animal and human studies or it may represent a true physiologic mechanism where increased intrathoracic pressure facilitates systolic ejection (although venous return is decreased). A second interesting finding from this study is that respiratory system compliance decreased significantly in all patients and this decrease was exclusively due to decreased compliance of the thoracic wall. Lung compliance did not change at all.

These findings confirm the hypothesis that IAH displaces the diaphragm upward, reducing the chest wall compliance and therefore respiratory system compliance. The pressure in the abdominal compartment (IAP) is directly transmitted to the thoracic compartment, where it increases intrathoracic pressures (CVP, esophageal pressure), and thereafter to the cerebral compartment (causing an increase in IJP and ICP). In other words, the ICP rise appears to be the result of an obstruction to the cerebral venous drainage, causing elevation of pressure in the intracranial compartment.

Deeren et al. found similar results in 11 patients with nontraumatic brain injury [20]. They found tight associations between IAP and ICP, ΔIAP and ΔICP, and ΔIAP and ΔCPP even at only slightly increased levels of IAP (Figure 22.3). In total eleven patients were studied with simultaneous IAP and ICP-monitoring because of ischemic (in four), hem-

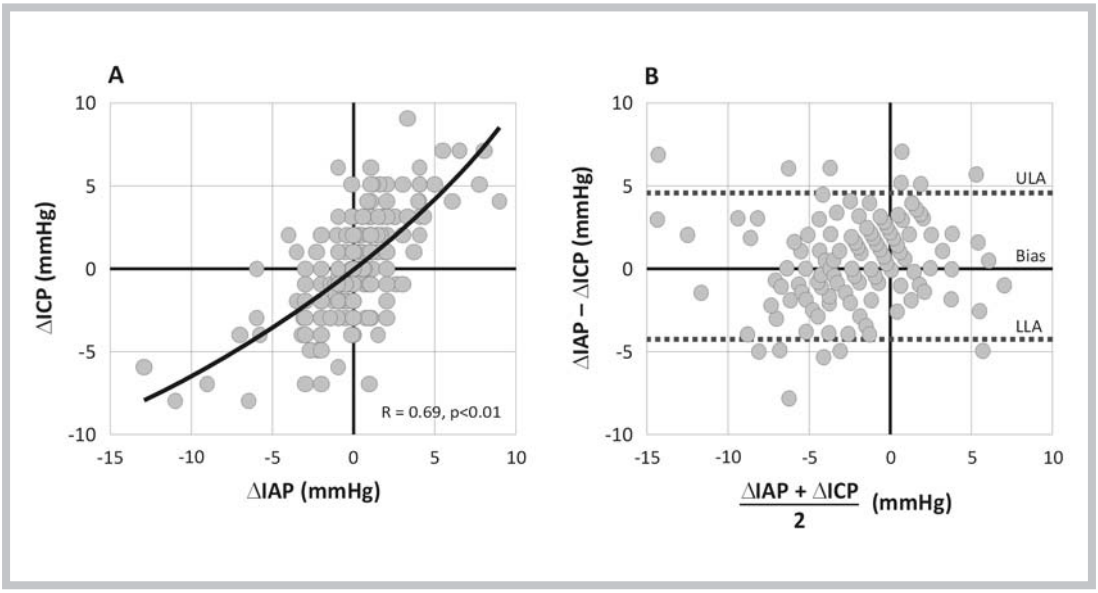

Figure 22.3. **(A). Regression analysis between ΔIAP versus ΔICP (positive correlation). (B). Bland-Altman plot of ΔIAP and ΔICP.**

LLA = lower limit of agreement
ULA = upper limit of agreement

orrhagic (in five) and metabolic (in two) encephalopathy. Two hundred fourteen consecutive paired data sets were compared. The mean IAP of each patient ranged from 3.8 to 11.8 mmHg, with a mean ICP from 6.7 to 15 mmHg and mean CPP from 70.8 to 123 mmHg. For ICP, the regression coefficient associated with IAP was 0.64 (standard error = 0.05; 95% confidence interval = 0.56 to 0.73; $p < 0.001$, partial correlation = 0.70). For CPP, the regression coefficient associated with IAP was -1.36 (standard error = 0.3; 95% confidence interval = -1.94 to -0.78; $p < 0.001$; partial correlation = -0.30). Cooke investigated key symptoms and signs of raised ICP in 39 patients after laparoscopic abdominal surgery and compared them with a control group of 33 patients after open operations [32]. They found that the incidence of headache and nausea was significantly higher in the laparoscopic group than in the control subjects and they concluded that these results could be explained by raised intracranial pressure exacerbated by the CO_2 pneumoperitoneum, and that this effect is not mediated by raised expiratory CO_2 levels intraoperatively.

In an ophtamologic journal, Neville et al. have published a study in which 15 patients with normal opening pressures on lumbar puncture who were referred for CSF analysis, were asked to artificially increase their IAP through a Valsalva maneuver [33]. All patients were able to elevate their CSF pressure to values above 25 cmH_2O and one patient achieved a value of 47 cmH_2O! The authors were prompted to perform this study after the observation that patients were referred for fundoscopy due to increased CSF pressure while they had no symptoms of intracranial hypertension.

Recently several reports have been published alluding to neurologic deterioration related to increased IAP in patients with ventriculoperitoneal shunt (VPS) dysfunction [34-36]. These reports provide anecdotal evidence that transient and easily reversible increases in the IAP of adults with VPS can result in dysfunction. Although it may not be practical to delay shunt revision while attempting to correct constipation, meteorism, ileus, or small bowel obstruction, clinicians treating patients with these abdominal conditions should be aware that they could cause transient VPS failure [37]. Martinez-Lage et al. describe constipation as an under-appreciated cause of VPS malfunction in children and advise pediatric neurosurgeons to investigate the abdomen first before considering surgical valve revision of the VPS [38]. In a similar way colonoscopy can increase ICP [39]. Several reports also pointed towards obesity as a cause of increased IAP leading to idiopathic ICH and pseudotumor cerebri [40-43]. Interestingly, negative abdominal pressure, weight loss and bariatric surgery have been demonstrated to reduce the clinical signs of ICH (headache, blurred vision, etc.) and ICP [44-48]. Furthermore recent weight gain may be associated with relapses of idiopathic ICH [49]. Obesity associated sleep apnea may also be associated with idiopathic ICH [50, 51]. Sahuquillo et al. performed a study in 60 patients requiring a VPS for hydrocephalus [52]. They recorded BMI and measured IAP during the shunt surgery and found that there was a linear relationship between IAP and BMI. They conclude that the assumption that IAP is close to 0 mmHg does not apply in obese or overweight patients and neurosurgeons should take IAP into account when selecting both the most adequate differential pressure valve to be implanted and in which distal cavity to place the distal catheter to avoid shunt underdrainage induced by high IAP.

22.3 Clinical Importance of IAH in Patients at Risk for ICH

According to the previously mentioned modified Monro-Kellie doctrine, ICP remains constant over a relatively wide range of intracranial volume. In this plateau phase, an in-

crease in intracranial volume due to e.g. cerebral edema, hematoma or mass lesion, will be compensated by the evacuation of cerebrospinal fluid through the foramen magnum at the base of the skull. However, when these compensation mechanisms are exhausted at higher intracranial volumes, any small increase in volume produces a marked increase in ICP rapidly leading to ICH (Figure 22.4).

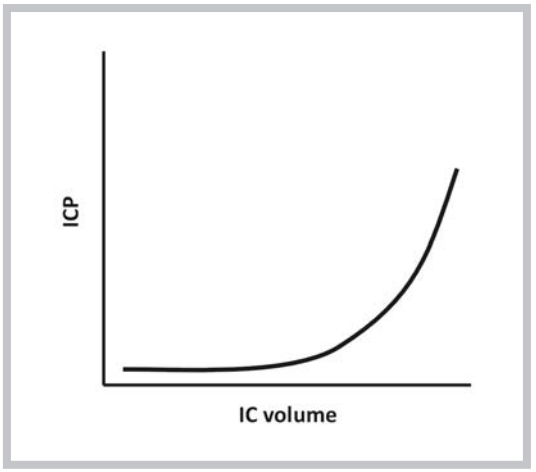

Figure 22.4. **Relationship between intracranial volume (IC volume) and intracranial pressure (ICP) according to the Monro-Kellie doctrine.**

When we combine this concept with the findings of the previously mentioned experimental and clinical studies we can speculate that in the presence of ICH the effect of increased IAP probably induces a more profound and harmful increase in ICP due to a different starting ICP position on the intracranial PV curve and different strain on the compensatory capacity. Therefore, it is crucial to measure IAP in patients with ICH at risk for IAH (or *vice versa*). These findings are of great importance for patient care, for example in trauma patients, since abdominal trauma is commonly associated with head trauma and therefore patients with combined ICH and IAH may be more common in the ICU population than previously thought. Scalea et al. recently published a study describing 102 consecutive patients with severe TBI who underwent decompressive craniectomy (DC) for intractable intracranial hypertension [53]. Twenty-four patients in this series also had decompressive laparotomy (DL) due to what the authors describe as multiple compartment syndrome (MCS). The found that both DC and DL reduce ICP and can be used in sequence and conclude that MCS should be considered in multiply injured patients with increased ICP that does not respond to therapy. Joseph et al. performed a retrospective study and found that in their institution 17 patients in a period of 3 ½ years underwent DL for refractory intracranial hypertension [10]. All had failed maximal therapy including 14 who had had DC. Mean ICP was 30 ± 8.1 mmHg (range 20-40 mmHg) before decompression. No patients had evidence of abdominal compartment syndrome (ACS). Before decompression mean IAP was 27.5 ± 5.2 mmHg (range 21-35 mmHg). After abdominal decompression ICP dropped precipitously by at least 10 mmHg to a mean of 17.5 ± 3.2 mmHg (range 10-25 mmHg). The authors conclude that decompressive laparotomy can be a useful adjunct in the treatment of ICH failing maximal therapy following TBI.

Another obvious risk population are patients with existing VPS [52]. In the event of neurologic deterioration in these patients during critical illness, IAP should be monitored and IAH should be treated promptly. IAP should also be monitored in critically ill, sedated and mechanically ventilated patients with VPS since neurologic examination is unreliable in these circumstances. Table 22.1 summarizes the neurologic effects of increased IAP.

- Intracranial pressure ↑
- Cerebral perfusion pressure ↓
- Cerebral blood flow ↓
- Jugular bulb saturation ↓
- Cerebral venous outflow ↓
- Cerebrovascular resistance ↑
- Idiopathic intracranial hypertension in morbid obesity
- Pseudotumor cerebri in morbid obesity
- Neurologic effects reversed after bariatric surgery or weight loss
- Neurologic deterioration during laparoscopy

Table 22.1. **Neurologic effects related to IAP.**

Case reports and small series applying these concepts in clinical settings are beginning to appear in literature with an increasing frequency. For example, in a review on cough, exertional and sex headaches Cutrer et al. find that these symptoms are triggered by increased IAP and that they may be the manifestation of an underlying, potentially serious cause [54]. They advocate the elimination of intracranial structural or vascular abnormalities in the presence of these headaches. Eberhart et al. have published a review on the prevention of postoperative nausea and vomiting in post-craniotomy patients and discuss the importance of avoiding sudden increases in IAP due to vomiting in this risk population [55].

22.4 Treatment Options

A few studies have addressed the issue of treatment of ICH in the presence of IAH. A group of the Adams Cowley Shock Trauma Center of Maryland published a paper on the use of decompressive laparotomy for the treatment of intractable ICH after traumatic brain injury [10]. This technique was used in 17 patients whose intracranial hypertension was unresponsive to maximal therapy. The decompression resulted in a marked decrease in both ICP and IAP. In 6 patients the decrease in ICP was transient and all patients died. The remaining 11 had sustained decreases in ICP and IAP and survived, made neurologic recovery and were discharged to a rehabilitation facility. The same remarks were posted in a letter by Lyons [56]. Bloomfield also described the successful management of a patient with severe multisystem injury in whom abdominal decompression dramatically reduced high ICP unresponsive to medical measures [31].
Deeren et al. published a clinical study in 2005 describing the relationship between IAP and ICP in patients with nontraumatic brain injury (Figure 22.5). In four of these patients IAP and ICP measurements were obtained before and after administration of a neuromuscular blocker [20]. Both IAP and ICP decreased and CPP and abdominal perfusion pressure (APP) increased significantly after administration of a 10 mg bolus of cisatracu-

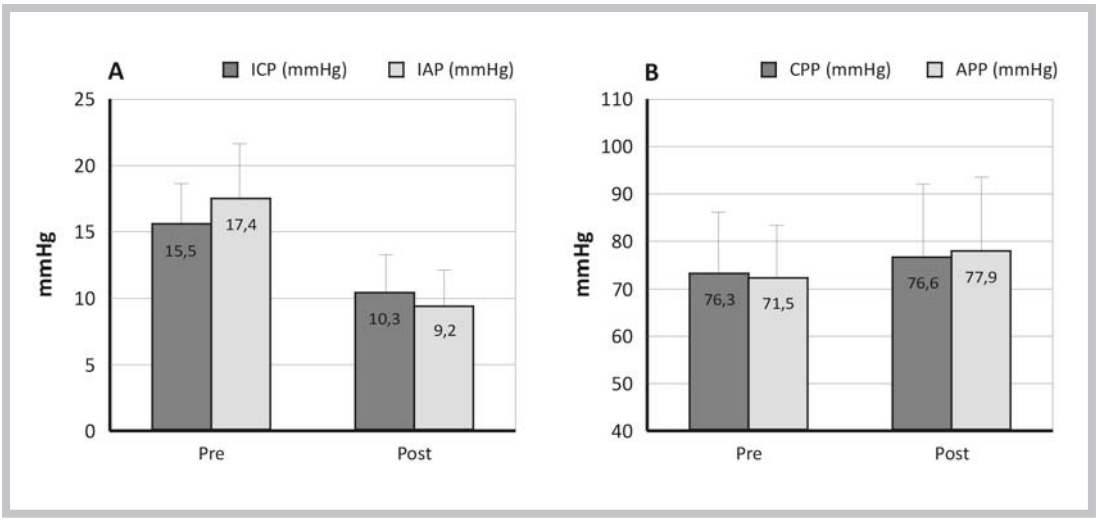

Figure 22.5. **Bar graphs showing IAP and ICP (A) and APP and CPP (B) before (pre) and after (post) neuromuscular blockade (10 mg cisatracurium) bolus administration. Modified from [20].**

APP = abdominal perfusion pressure
CPP = cerebral perfusion pressure
IAP = intraabdominal pressure
ICP = intracranial pressure

rium. Both IAP and ICP also dropped towards levels that are generally accepted to be safe. These results not only suggest that ICH in patients with IAH can be treated by administration of neuromuscular blockers, they also lend more support to the notion that there is a causal, rather than circumstantial, relationship between IAH and ICH. While neuromuscular blockers exert their effect on IAP through improved compliance of the abdominal wall, it is highly unlikely that they have any direct effect on ICP since the skull is a closed box lined by bony structures that are not responsive to neuromuscular blockers. Some other treatment options have been described, such as continuously applied negative abdominal pressure or nonsurgical abdominal decompression [44,57]. Both techniques will not be described here in detail. The findings of Deeren et al. suggest that ICH can be treated in the presence of IAH by reducing IAH [20]. The treatment of IAH as such lies beyond the scope of this text.

Preventive measures to avoid increase in ICP in patients who need to undergo abdominal surgery include the avoidance of induced pneumoperitoneum or if needed changing the type of insufflation gas [28,58].

22.5 Clinical Recommendations

Naturally, all patients with intracranial hypertension need to be treated according to all accepted international standards and guidelines regarding ICH in their specific clinical situation. Although no randomized clinical trials have been conducted on any aspect of treatment of IAH, let alone the specific situation of ICH combined with IAH, we feel it is possible to make a few clinical recommendations based on the results of the previously mentioned animal and human studies.

- IAP monitoring is essential for all traumatic or nontraumatic patients at risk for ICH or IAH (according to the risk factors published by the World Society for the Abdominal Compartment Syndrome) [59].
- The presence of increased IAP can be an additional “extracranial” cause of intracranial hypertension in patients with abdominal trauma without overt craniocerebral lesions.
- In all patients with ICH and in patients with VPS, preventive measures should be undertaken to avoid increase in IAP (the specific techniques involved lie outside the scope of this text).
- In all patients with IAH, a possible association with ICH should be considered and preventive measures should be taken (head of bed elevation, avoid constipation, avoid hypervolemia, hypernatremia and hyperthermia, etc.) [60].
- Neurologic status should be frequently monitored in patients with IAH
- Avoid hypervolemia in patients with IAH to prevent further increase in ICP. This may be difficult to achieve in a clinical setting, however, since volume management of these patients is complicated by the lack of reliable hemodynamic monitoring parameters. The use of routinely measured cardiac filling pressures is not reliable in the presence of IAH. This problem can be mediated by using (estimated) transmural filling pressures or by using volumetric hemodynamic monitoring parameters with PiCCO (Pulsion Medical Systems, Munich, Germany) [6].
- Consider using APP (abdominal perfusion pressure; APP = MAP – IAP) as a resuscitation target in patients where ICP is not available and CPP can not be used as a target.
- Provide adequate treatment for IAH, especially if ICH or a VPS is also present.
- Avoid laparoscopy in patients at risk for ICH. The pneumoperitoneum used for laparoscopy creates a situation analogous to experimental settings of IAH and ICH in

which detrimental effects on ICP have been observed. This is especially important in trauma patients with associated brain and abdominal injuries.

- In patients with refractory ICH, decompressive laparotomy may be considered as a rescue therapy in the presence of IAH [56]. Although promising results have been published, further research is necessary to appropriately define indications for this practice.

22.6 Conclusions

A close relationship between IAP and ICP has been observed in several animal and human studies. The clinical impact of this association is dependent on the baseline ICP and the compensatory reserve of the patient. Some studies have reported good results in treating refractory ICH by abdominal decompression in patients with concomitant IAH. Clinicians should be aware of the different interactions between intra-abdominal, intrathoracic and intracranial pressures and be able to intervene adequately in the complex situation of combined intra-abdominal and intracranial hypertension. Monitoring of IAP and ICP in risk patients is essential.

In this review we summarized the current state of knowledge on this fascinating topic and formulated some clinical recommendations for management. It remains clear, however, that the complex phenomenon of IAH is still not completely understood and recommendations may change in the future as more clinical research is conducted.

23.1 Basic Anatomy, Physiology and Changes in Acute Brain Injuries

23.1.1 Introduction

Endocrine changes during critical illness have attracted growing attention from clinicians and the importance of an intact hypothalamo-pituitary-adrenal (HPA) axis for metabolic and immunological homeostasis during stress is now well recognized. Pituitary function is an essential regulator of a variety of adaptive responses that allow survival during critical states of any cause. Because the mechanisms regulating pituitary hormone secretion are mainly located in the hypothalamus and brainstem, acute brain injury might be expected to modify the neuroendocrine responses more than any other type of critical illness.

Traumatic brain injury (TBI) is a worldwide health problem, a major cause of disability and death among young adults, and a cause of neuroendocrine dysfunction. The prevalence of hypopituitarism in the chronic phase after TBI is nearly 25%, with growth hormone (GH) and follicle-stimulating hormone/luteinizing hormone (FSH/LH) deficiencies more common than other pituitary hormone deficiencies. Studies on acute TBI are too few to determine the prevalence of pituitary dysfunction; however, despite some controversial results, most show that all hormonal axes may be affected to different extent during the period of critical illness after TBI (Table 23.1).

Currently available published data are heterogeneous due to differences in patient selection, injury severity, study design, ethnicity of the population, methodology and timing of assessment. Moreover, earlier studies were not specifically designed to determine the frequency of acute hypopituitarism after TBI; instead, they tried to correlate neuroendocrine changes with the severity of head trauma. More recently, the type and frequency of pituitary hormone deficiencies have been investigated in more detail in brain-injured patients during the critical period (Table 23.1).

Nontraumatic brain injury includes ischemic stroke, intracerebral hemorrhage and aneurysmal subarachnoid hemorrhage. Although few studies to date have described acute neuroendocrine changes in nontraumatic brain-injured patients, what they do suggest is that there are substantial hormonal changes in nontraumatic brain injury as occur in TBI (Table 23.1).

Although the physiological changes during critical illness and the neuroendocrine sequelae of brain injury are slightly different in pediatric patients, the studies including adult patients (over age 14 years) are widely used as reference. Therefore, the management and treatment recommendations outlined in this chapter cannot be applied to pediatric patients.

Study	Number/Type of brain injury	Time to testing	Axes tested	Main findings
Fleischer, 1978	15/TBI	10-25 days	TH, GT	Central hypothyroidism and hypogonadism
King, 1981	6/TBI	72 h	TH, GT, ST, LT	No trends in hormone levels
Feibel, 1983	14/TBI, 9/ICH	12-36 h	HPA	High cortisol level despite high-dose dexamethasone
Hackl, 1991	21/TBI	Acute phase	TH, HPA, ST, LT	High cortisol and T4 levels; low prolactin level; impaired GH response to arginine stimulation
Della Corte, 1998	22/TBI	1-5 days, days 15 and 16	TH, HPA, ST, LT	Low cortisol (days 2-7); high IGF-I (days 7 and 15); exaggerated GH response to GHRH; low T3; normal TSH; prolactin unchanged
Cernak, 1999	31/TBI	7 days	TH, HPA, GT	High cortisol (days1+2); high TSH (days 1-3); low testosterone
Agha, 2004	50/TBI	Median 12 days	TH, HPA, ST, GT, LT	16% ACTH, 18% GH, 2% TSH and 80% with FSH/LH deficiencies; 52% with high prolactin
Dimopoulou, 2004	34/TBI	Median 21 days	TH, HPA, ST, GT, LT	53% of patients with abnormal result in at least 1 hormonal axis; cortisol hyporesponsiveness and hypogonadism most common abnormalities
Cohan, 2005	80/TBI	1-9 days	HPA	53% of patients with acute secondary adrenal insufficiency
Tanriverdi, 2006	52/TBI	24 h	TH, HPA, ST, GT, LT	10% ACTH, 20% GH, 6% TSH and 42% with FSH/LH deficiencies; 12% with high prolactin
Klose, 2007	46/TBI	0-12 days	TH, HPA, ST, GT, LT	76% of patients with central hypogonadism or hypothyroidism
Tanriverdi-Ulutabanca, 2007	104/TBI	24 h	TH, HPA, ST, GT, LT	9% ACTH, 20% GH, 4% TSH and 40% with FSH/LH deficiencies; 18% with high prolactin
Schwarz, 2003	22/IS	On admission, days 3, 5, 7, 9	TH, HPA, LT	Abnormally low plasma ACTH and cortisol levels; low TRH stimulation of plasma TSH and prolactin
Dimopoulou-Kouyialis, 2005	21/ ICH, 12/IS	72 h postextubation	TH, HPA, ST, GT	33% ACTH, 45% GH, 36% TSH and 39% with FSH/LH deficiencies
Tanriverdi-Dagli, 2007	22/SAH	24 h	TH, HPA, ST, GT, LT	23% ACTH, 23% GH, and 32% with FSH/LH deficiencies; 22% with high prolactin

Table 23.1. **Studies on anterior pituitary function in patients with traumatic brain injury (TBI) and nontraumatic brain injury (BI) during the period of critical illness.**

GT = gonadotropic
HPA = hypothalamo-pituitary-adrenal
ICH = intracerebral hemorrhage
IS = ischemic stroke
LT = lactotropic
SAH = aneurysmal subarachnoid hemorrhage
ST = somatotropic
TH = thyroid

The principal aims of this chapter are: 1) to review the anatomy of the HPA axis and the physiologic hormonal changes after acute stress; 2) to describe and differentiate adaptive and pathological hormonal changes after acute brain injury; 3) as informed by current evidence-based data, to define the diagnosis and management of pituitary hormone deficiencies, and adrenal insufficiency and diabetes insipidus in particular; and 4) to alert clinicians to situations in which interventions and treatment may be unnecessary.

23.1.2 Anatomy of the Hypothalamo-pituitary-adrenal Axis and Endocrinology of Normal Stress Response

Functional Anatomy of the Hypothalamo-pituitary-adrenal Axis

Figure 23.1 illustrates the functional anatomy of the HPA axis and Table 23.2 summarizes the physiologic effects of pituitary hormones.

The hypothalamus is formed by the anterior and inferior parts of the walls of the third ventricle. It is interrelated to the pituitary gland via the stalk, which is derived from the median eminence, a region of the floor of the third ventricle. The median eminence receives endings from the hypothalamic neurons that produce releasing and inhibiting factors which regulate the function of the anterior pituitary hormones. The pituitary gland weighs about 0.5 to 1 grams and is divided into an anterior (adenohypophysis) and a posterior lobe (neurohypophysis). It sits in the sella turcica immediately behind the sphenoid sinus.

Anterior pituitary hormones are regulated by hypothalamic releasing and inhibitory hormones and the negative feedback action of the target glandular hormones at both the pituitary and hypothalamic levels. Among the pituitary hormones, only prolactin secretion is increased in the absence of hypothalamic influence, since it is mainly under tonic suppression through prolactin inhibitory factor (dopamine) (Table 23.2).

All anterior pituitary hormones are secreted in a pulsatile fashion and tend to follow a diurnal pattern. Antidiuretic hormone (ADH; vasopressin) is produced by the supraoptic and paraventricular nuclei of hypothalamus and travels in the axons through the pituitary stalk to the posterior pituitary gland. The chief physiologic stimulus of ADH secretion is an increase in serum osmolality and a decrease in plasma volume, resulting in water reabsorption at the level of the distal and collecting ducts of the kidney. Small increments in serum osmolality >290 mOsm/kg induce prompt secretion of ADH.

The blood supply of the hypothalamus is provided by the small branches of the arteries of the circle of Willis. Arterial supply to the anterior pituitary gland, median eminence, and stalk is derived from the superior hypophyseal arteries. These arteries form the primary vascular plexus and converge into venules to form the long and short hypophyseal portal veins. These veins descend to the pars tuberalis and pars distalis of the anterior lobe, where a secondary plexus of sinusoidal capillaries is formed. The long portal veins pass through the diaphragma sella, thus being vulnerable to mechanical compression from brain or pituitary swelling or direct stalk injury. In contrast, the short portal veins originate below the diaphragma sella.

The anterior pituitary lobe, particularly its lateral aspects, receives its blood supply indirectly after passage through the median eminence and portal vessels. Any interruption of the portal vessels may result in anterior pituitary dysfunction. In contrast, the neurohypophysis receives its direct arterial blood supply from the inferior hypophyseal arteries.

	Hypothalamic regulatory hormone	Target gland/ secreted feedback hormone	Major physiologic effects of pituitary hormones	Clinical findings of pituitary hormone deficiency
Anterior pituitary hormone				
ACTH	CRH, ADH	Adrenal/cortisol	Several vital functions via cortisol such as vascular integrity and blood pressure maintenance, response to stress, immunomodulatory effects	Weight loss, weakness, dizziness, vomiting, circulatory collapse, fever, shock, hypoglycemia, hypotension, hyponatremia
GH	GHRH, somatostatin	Multiorgan/IGF-I from liver	Direct effects or via IGF-I. Promote growth, control protein, lipid and carbohydrate metabolism, control memory function	Adults: visceral obesity, fatigue, impairment of attention and memory, premature atherosclerosis
TSH	TRH	Thyroid/T4,T3	Control energy metabolism and vital functions	Tiredness, cold intolerance, dry skin, cognitive slowing, bradycardia, hypotension
Gonadotropins (FSH/LH)	GnRH	Ovary and testis/ E2, T	Control reproductive function	Infertility, decreased libido, deceased muscle mass, osteoporosis
Prolactin	PIF (Dopamine)	Breast	Milk production, immunomodulatory effects?	Agalactia
Posterior pituitary hormone				
ADH	-	Kidney	Conservation of body water and plasma osmolality	Polyuria, polydipsia, hypernatremia
Oxytocin	-	Breast and uterine	Stimulates milk ejection and uterine contraction	?

Table 23.2. Components of the hypothalamic-pituitary-adrenal axis: hormones secreted by the pituitary gland, hypothalamus and target organs. Major physiologic effects of pituitary hormones and the clinical findings of pituitary hormone deficiencies.

ACTH = adrenocorticotropin hormone
ADH = antidiuretic hormone
CRH = corticotropin-releasing hormone
E2 = estradiol
FSH = follicle-stimulating hormone
GH = growth hormone
GHRH = growth hormone-releasing hormone
GnRH = gonadotropin-releasing hormone
IGF = insulin-like growth factorLH = luteinizing hormone
PIF = prolactin release-inhibitory factor
T = testosterone
T3=triiodothyronine
T4 = thyroxine
TRH = thyrotropin-releasing hormone
TSH = thyroid-stimulating hormone

23.1.3 Endocrinology of Normal Stress Response

The physiologic response to stress involves the activation of the stress regulatory centres in the central nervous system, which, in turn, activates the HPA axis and the auto-

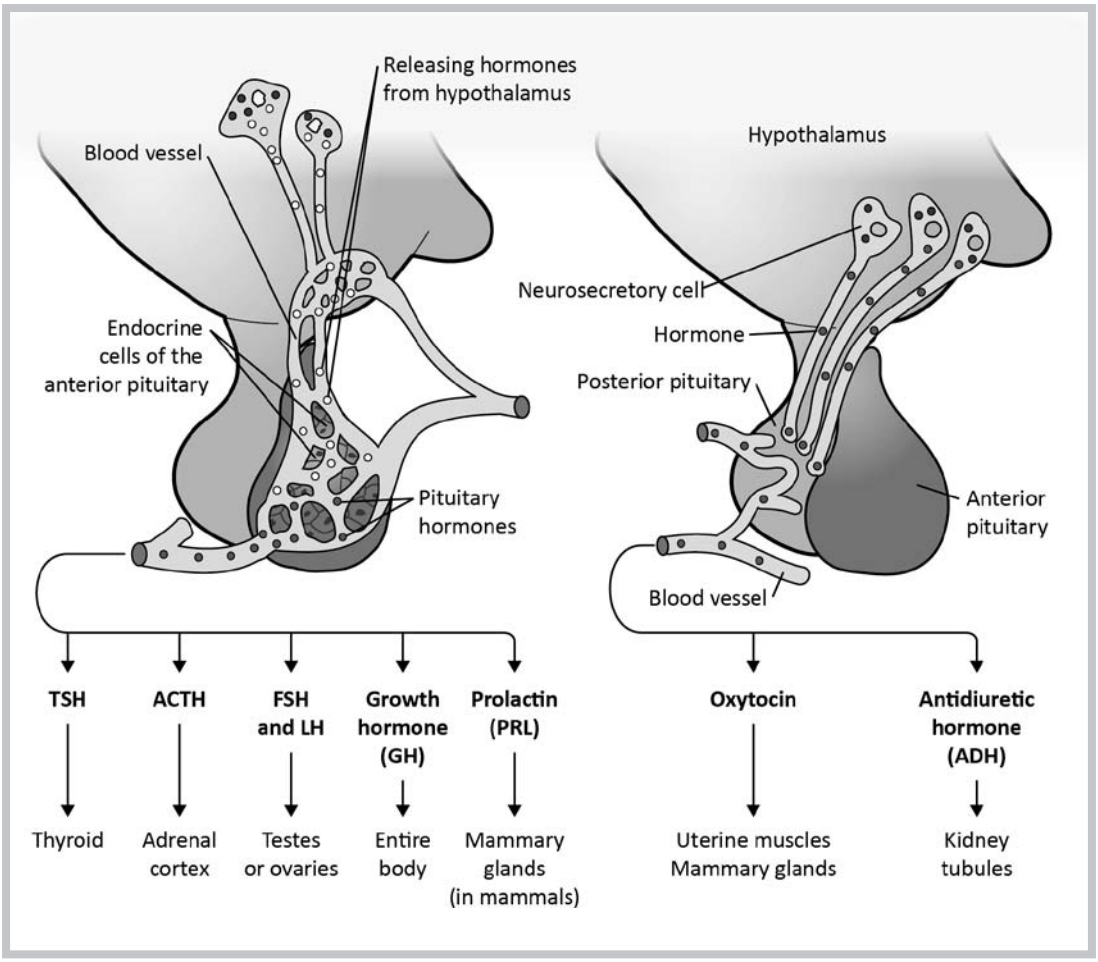

Figure 23.1. **Functional anatomy of the hypothalamic-pituitary-adrenal axis.**
* The target gland hormones also work as feedback hormones (negative feedback) at the hypothalamic and pituitary levels

nomic nervous system. The brain, hippocampus and amygdala in particular, are closely involved in the stress response. The stress response is predominantly regulated by the sympathoadrenal system, which includes the sympathetic nervous system and the adrenal medulla, and by the HPA axis. The stress system also influences other hypothalamo-pituitary axes (those controlling gonadal, thyroidal, and growth functions) and exerts complex effects on immune/inflammatory reactions. The end hormones of the neuroendocrine system, particularly glucocorticoids and catecholamines, act to maintain behavioural, cardiovascular, metabolic, and immune homeostasis during stress.

Severe acute stress, as occurs in critically ill patients, leads to strong activation of the HPA axis. Activation of the HPA axis involves increased secretion of corticotropin-releasing hormone (CRH) and antidiuretic hormone (ADH), also called arginine vasopressin, which enhances CRH activity. CRH stimulates the production of adrenocorticotropin hormone (ACTH), causing the adrenal cortex to produce more cortisol and dehydroepiandrosterone. Additionally, CRH activates the sympathoadrenal system at the same time. Following road accidents or during major surgery or sepsis, the human body can increase its glucocorticoid production by 5- to 10-fold. An adequate increase in glucocorticoid production is therefore crucial for survival and is required to cope with the severe stress during critical illness.

23.1.4 General Principles of Pituitary Hormone Changes During the Acute Phase of Brain Injury

Alterations in pituitary function during the acute phase of brain injury result in a temporary increase or decrease in pituitary hormone concentrations in blood circulation. Recent data revealed differences between alterations in hypothalamic-pituitary function in the acute phase (the first hours to days) and those in the prolonged phase or chronic phase (from 10 to 15 days beyond) of critical illness. During the acute phase, the secretory pattern of pituitary hormones inactivates anabolic target hormones. This response has been suggested to be beneficial and adaptive. In prolonged critical illness when the patient continues under intensive medical care, the pulsatile secretion of the anterior pituitary hormones generally decreases because of decreased hypothalamic stimulation, and this underlies the impaired anabolism in critical care patients.

The normal pituitary gland responds to acute brain injury with two sorts of secretory patterns: increased production of ACTH, prolactin (PRL) and growth hormone (GH), and decreased or unchanged production of gonadotropins (FSH and LH), and thyroid-stimulating hormone (TSH), associated with a decreased activity of their target organ. Changes in circulating hormone levels become apparent during the first hours or days after trauma and may persist for the duration of the acute critical illness. These hormonal alterations reflect the acute adaptive response to the injury and may be influenced by the type of injury and pharmacological therapy given to treat the critical illness (glucocorticoids, narcotic analgesics or dopaminergic agents). The basic philosophy of the neuroendocrine response after acute brain injury may be summarized as follows: these adaptations are initially protective for the human body; however, if they are inadequate, as in pituitary dysfunction or excessive, they may be harmful and cause endocrine, metabolic and immune disturbances. Therefore, the most important target for intensive care should be to differentiate adaptive response from pathological hormonal changes and to avoid unnecessary interventions.

23.1.5 Anterior Pituitary Dysfunction in the Acute Phase of Brain Injury

The Hypothalamo-pituitary-adrenal Axis

The HPA axis status is the most extensively investigated endocrine function in critically ill brain-injured patients (Table 23.1). Patients normally present with increased cortisol levels. These changes may persist up to 10 to 15 days after brain injury and are essential for maintaining vascular tone and endothelial integrity. Initially, cortisol increase is mediated by ACTH. Later, other substances, mainly cytokines and catecholamines, act as mediators. The diurnal variation of cortisol may be preserved or abolished.

TBI studies investigating the association between cortisol dynamics, severity of TBI (assessed by the Glasgow Coma Scale, GCS) and outcome prediction have yielded controversial results. Some investigators concluded that higher cortisol values are associated with more severe head trauma and with a worse clinical outcome, whereas others found lower cortisol values in the most severely injured patients with brainstem dysfunction or in brain-dead victims. Still other studies found no correlations between baseline cortisol and TBI severity. Acute adrenal failure after TBI may occur as a consequence of ischemia or direct trauma to components of the HPA axis, a secondary form of adrenal insufficiency. In addition, primary failure of the adrenal gland due to a systemic inflammatory response after the release of pro-inflammatory mediators may complicate recovery from

TBI. The only difference between primary adrenal failure and secondary adrenal failure is the presence of mineralocorticoid deficiency. However, because the common clinical problem is due to hypocortisolism, it is not practical to differentiate primary from secondary adrenal failure in routine clinical management, commonly called adrenal failure. Throughout the text, HPA axis insufficiency and adrenal failure are used interchangeably. According to clinical studies, the incidence of adrenal failure after acute TBI is 10-50% (Table 23.1). The incidence of HPA axis insufficiency during the acute phase is generally 20-25%, which signals a high risk. Although the data are heterogeneous, critically ill patients with nontraumatic brain injury may also experience adrenal failure. Recent studies suggest that around 25-30% of patients with ischemic stroke or aneurysmal subarachnoid hemorrhage have HPA axis insufficiency during the acute phase (Table 23.1). Current evidence suggests that HPA axis insufficiency immediately after brain injury is associated with poor neurological outcome, greater need for vasoactive drug therapy, hyponatremia, relative or absolute hypocalcemia, hemodynamic instability, and rapidly progressive hypotension, all of which may increase the risk of death. Therefore, such clinical signs/symptoms should prompt their urgent investigation as a possible cause of adrenal insufficiency during acute care.

Algorithm for Diagnostic Testing and Management

The adequacy of cortisol secretion in critical illness, including brain injury, remains a diagnostic challenge because the normal range for baseline or stimulated cortisol levels in critically ill patients is inadequately defined. Recent published guidelines recommend acute anterior pituitary hormone evaluation in all patients with moderate-to-severe TBI, but those with documented baseline skull fracture, increased intracranial pressure or diabetes insipidus require specific attention. There are no defined selection criteria for patients with nontraumatic brain injury; however, in all brain-injured patients the best selection criteria for endocrine evaluation, particularly of the HPA axis, are clinical findings (Table 23.2) and high clinician suspicion.

Serum basal cortisol measurement is the primary test to evaluate the HPA axis. Although a morning cortisol test is recommended by some authors, stress will decrease the normal diurnal variation in cortisol release, making random values acceptable. Cortisol will be low in most cases of both primary and secondary adrenal failure. The actual concentration that defines a low value is somewhat controversial because of the expected increase in cortisol in response to brain-injury-induced stress. The amount of cortisol required cannot be predicted from the severity of injury and it may change as the clinical status changes. Although some authors suggest random basal cortisol levels <25 μg/dl or 36 μg/dl, a cortisol concentration <15 μg/dl (410 nmol/l) are acceptable as a diagnostic value for adrenal insufficiency in critically ill brain-injured patients. In patients lower values and clinical findings consistent with adrenal insufficiency, there is no need for further stimulation testing in routine clinical practice.

ACTH may also be directly measured to differentiate primary from secondary adrenal failure. As mentioned, differentiation between primary and secondary adrenal failure is not warranted in critically ill brain-injured patients in routine clinical practice. Additionally, because ACTH measurement is not routinely available in most hospital laboratories, urgent measurement is not recommended.

In patients with basal cortisol levels between 15 and 25 μg/dl and suspicious clinical findings, then ACTH stimulation testing is warranted. Standard-dose ACTH stimulation test (after blood sampling for baseline cortisol measurement, 250 μg ACTH is administered intravenously and cortisol measured at 30 and/or 60 minutes after stimulation) is routinely used in the diagnosis of primary or secondary adrenal insufficiency. In normal

conditions, peak cortisol response after ACTH stimulation >20 μg/dl is defined as adequate cortisol response. In critically ill brain-injured patients, however, the best cut-off value after standard ACTH stimulation test is yet to be defined. The recommended value of 25 μg/dl (690 nmol/l) seems more realistic as a cut-off higher than that used in an outpatient setting because the peaks achieved during this test are, on average, higher than in patients without stress or severe illness.

In some studies, low-dose (1 μg) ACTH stimulation was used for the diagnosis of adrenal insufficiency during acute brain injury. More sensitive than standard testing, its main advantage in mild HPA axis insufficiency is early diagnosis, because the higher pharmacological amount used in standard-dose ACTH testing may allow a partially dysfunctional gland to release a sufficient amount of hormone to appear falsely normal. However, low-dose ACTH testing is not routinely used or recommended in critically ill brain-injured patients because there is no diagnostic cut off value for intensive care unit settings. Low-

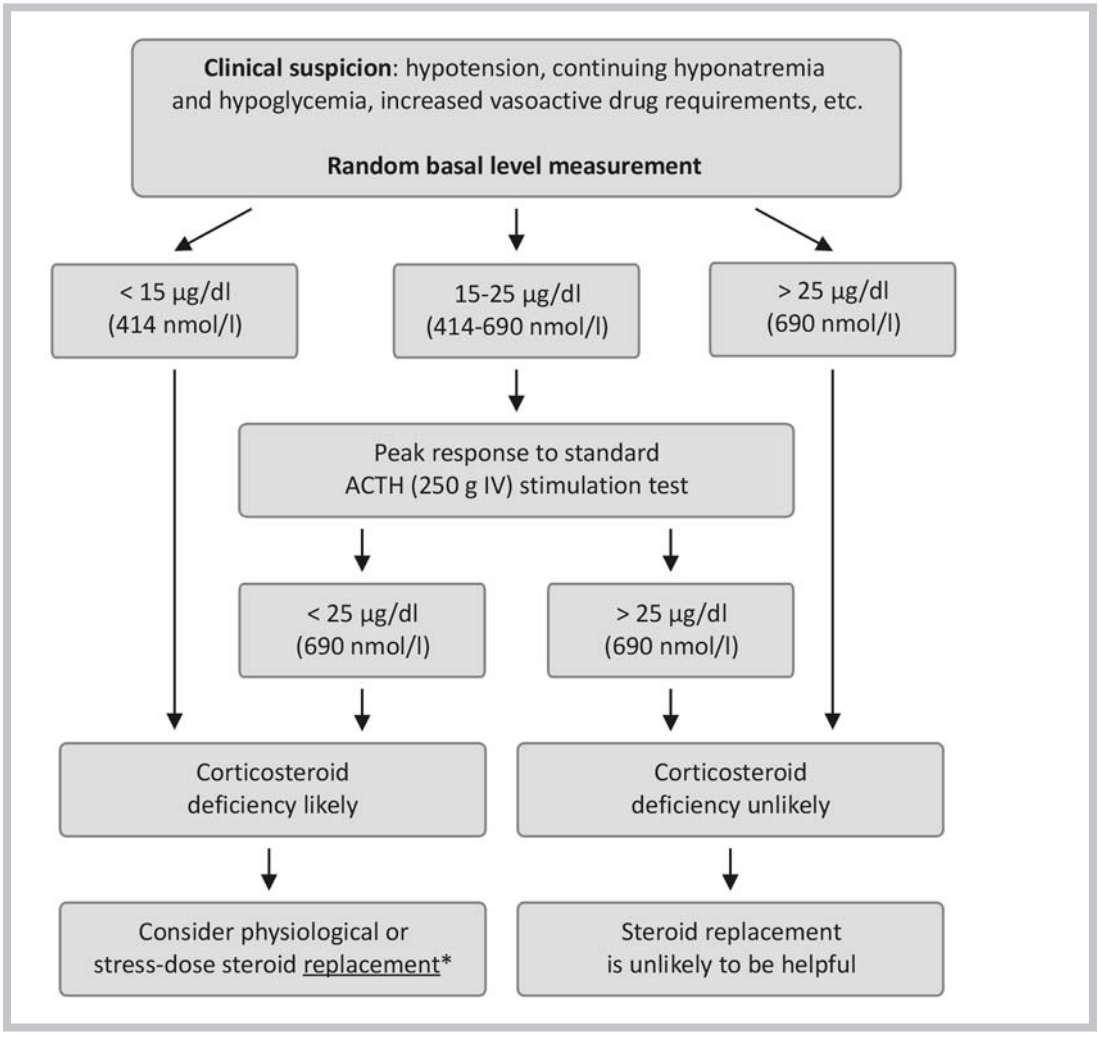

Figure 23.2. **Algorithm for the management of adrenal insufficiency in brain-injured patients in the acute phase.**

*It is proved that a pharmacological dose of corticosteroid replacement is not useful and may be harmful. In stable patients, physiological dose (hydrocortisone 10 mg IV every 8 h), in unstable patients with severe clinical findings, stress dose (hydrocortisone 50-100 mg IV every 8 h or an IV infusion of about 15 mg/h) steroid replacement is recommended

dose ACTH testing may gain a place in the workup of HPA axis evaluation in critically ill patients and may be used routinely in the near future.

Because serum cortisol concentrations may vary, the magnitude of serum cortisol response to ACTH stimulation was also considered critical in the diagnosis of adrenal failure and the identification of a patient's status as a responder (change from baseline cortisol of at least 9 μg/dl) or non-responder to stimulation. But a recent study showed no positive correlation between this criterion and survival. Current guidelines recommend this classification only in septic shock. Therefore, we do not recommend using this criterion in the diagnosis of adrenal insufficiency in patients with acute brain injury.

Finally, cortisol is measured in the blood as both an unbound ("free") form, which is the biologically active hormone, and as cortisol bound with corticosteroid-binding globulin (CBG). CBG is commonly low in critical illness/injury, especially when serum albumin is <2.5 g/dl and it may be one of the causes of an apparent low cortisol serum concentration. Measurement of free cortisol has been suggested as a more accurate assessment of adrenal output. Testing methods for CBG and free cortisol are rarely available, however. Several research groups have recently investigated the use of salivary cortisol concentration as a surrogate marker for serum free cortisol levels. Salivary cortisol measurement is simple to obtain and easy to measure in most laboratories. The data on the utility of salivary cortisol in critically ill brain-injured patients are currently insufficient.

The diagnosis and the management of adrenal insufficiency are briefly summarized in Figure 23.2.

Treatment

Large scale clinical studies such as the Corticosteroid Randomization After Significant Head Injury (CRASH) trial and literature reviews have indicated that routine corticosteroid administration at high doses or pharmacological doses (30 mg/kg methylprednisolone) to all patients with moderate/severe TBI is not indicated or may be harmful.

It is generally agreed, however, that therapy should be provided for patients with confirmed hypoadrenalism in whom clinical circumstances, such as hypotension, hyponatremia and hypoglycemia, warrant intervention. The steroid replacement dose should be titrated based on the critically ill patient's clinical status and requirements. In patients with adrenal insufficiency as determined according to previously discussed criteria (Fig. 23.2) and stable, replacement with hydrocortisone (10 mg IV every 8 h) could be sufficient initially. When severe stress is present and the patient is not stable 50-100 mg of hydrocortisone IV every 8 h or an IV infusion of about 15 mg/h is recommended (Fig. 23.2). Dexamethasone or methylprednisolone at equivalent hydrocortisone doses could be used as alternatives. It is important to note that dexamethasone does not have any mineralocorticoid activity. Addition of a mineralocorticoid is not usually required, but may be considered when hyponatremia is significant and the patient has proven primary adrenal failure.

The optimal duration of corticosteroid supplementation is unknown, but it should be continued until the patient's clinical situation has improved and when there is no need for vasopressor therapy.

The Thyroid Axis

Several changes in circulating thyroid hormone concentrations occur in acute critical illnesses including brain injury. The conversion of T4 (thyroxine) to T3 (triiodothyronine) in peripheral tissues is dramatically reduced and an altered form of T3, reverse T3 (rT3), is generated. Serum measurement will characteristically show a low T3; normal or low T4 and normal TSH have been synonymously referenced as the euthyroid-sick syndrome or low T3 and/or low T4 syndrome. These changes appear immediately after brain injury,

can persist for at least 2 weeks and may normalize after the acute illness has resolved. True "central" hypothyroidism occurs in 4 to 15% of patients following brain injury. The presence of low free T4 and low TSH level is diagnostic for central or secondary hypothyroidism; except for academic purposes, stimulation testing for diagnosis is not warranted in clinical practice. Impaired thyroid axis, however, should be confirmed in the absence of other medications known to reduce TSH production/release (e.g., dopamine, high-dose glucocorticoids). Although the evidence is not strong, some studies demonstrated that central hypothyroidism was associated with prolonged coma following TBI, poor neurological outcome, and higher mortality as compared to patients in whom TSH did respond to TRH stimulation.

Thyroid hormone replacement during the acute treatment of TBI or nontraumatic brain injury has not been reported previously. Prospective studies demonstrated that TSH deficiency (central hypothyroidism) is generally transient and that most of the changes resolve after 3 months. In critically ill burn or medical patients, acute thyroid hormone replacement therapy was not shown to produce short-term improvement.

Therefore, based on current evidence we do not recommend thyroid hormone replacement in the acute phase of brain injury. If TSH deficiency persists for more than 2 weeks and the clinical findings are compatible with hypothyroidism, the patient could be treated after steroid replacement if adrenal insufficiency is present.

The Somatotropic Axis

A reduced GH response to GHRH or other stimulation soon after severe TBI occurs in approximately 18% of patients. Early after TBI, basal plasma GH is within normal limits or high, and insulin-like growth factor (IGF-I) is normal or low. Peripheral resistance to GH action (probably due to decreased GH-receptor expression), manifested by high basal GH concentrations with low IGF-I, has been reported in patients with critical illness including brain injury. This seems to be an adaptive response because GH is an anabolic hormone: in the acute phase of critical illness, catabolism is the initial response to provide fuel for vital organs. Based on basal hormone levels and dynamic tests, current studies (Table 23.1) demonstrate that 20 to 50% of brain-injured patients have GH deficiency. Prospective data confirm that most patients with GH deficiency during acute phase recover within 3 to 12 months after brain injury.

GH and IGF-I levels in the acute phase are not generally correlated with trauma severity. Some studies investigating the correlation between GH response to provocative tests and prognosis or clinical outcome in the early post-TBI period have reported conflicting results.

To date, no studies have investigated the effects of GH replacement therapy in the acute phase of brain injury in patients with GH deficiency. In a recent randomized, prospective, double blind, placebo controlled study by Hatton et al., IGF-I and GH therapy within 72 hours of TBI produced sustained improvement in metabolic and nutritional endpoints. But the GH status of the TBI patients in this study was not defined. A large multicenter study by Takala et al. showed that the administration of high doses of GH in critically ill patients doubled the mortality instead of improving the outcome.

Therefore, GH supplementation is not currently recommended during the acute phase of brain injury. Future confirmatory data are needed to determine the effects of physiological dose GH replacement in GH-deficient patients with prolonged critical illness at the catabolic state.

The Gonadotropic-lactotropic Axis

After brain injury, and after TBI in particular, a substantial decrease in testosterone and low gonadotropin (FSH/LH) levels develop shortly after injury and deteriorate over the

ensuing days. The magnitude of the decline in testosterone was correlated with head trauma severity in some studies but not in others. The pituitary-ovarian axis is comparably depressed.
The incidence of hypogonadism in critically ill TBI patients varies between 20 and 80%. In most patients, hypogonadism improves within 3-6 months after injury. The current data suggest that these changes in the gonadotropic axis in the acute phase of brain injury are adaptive and transient; therefore, gonadotropin replacement is not recommended in the acute phase.
Prolactin (PRL) may increase, remain normal, or decrease in acute brain injury. Baseline PRL is negatively correlated with head trauma severity, as expressed by the Glasgow Coma Scale score. Hyperprolactinemia is reported in 20 to 50% of patients with acute brain injury. Although the mechanism and the effects are not known, this response is thought to be adaptive.

23.1.6 Posterior Pituitary Dysfunction in the Acute Phase of Brain Injury

Inadequate ADH secretion due to posterior pituitary dysfunction results in central diabetes insipidus (DI). DI following TBI is less common than anterior lobe injury, occurring acutely in around 20-25% of patients. Most patients recover from DI, but rarely (6-7%) persistent DI may occur. While DI is a well-recognized complication of TBI, the data one patients with other causes of brain injury are scarce.
The primary symptoms of DI are thirst and polyuria in conscious patients. In critically ill patients, the main clinical findings are increased daily urinary volume (>3 litres) and hypernatremia. If volume is significantly reduced, hypernatremia may cause weakness, altered mental status, seizures and coma. The diagnosis of DI in brain-injured patients with clinical suspicion is confirmed by measuring plasma and urine osmolality. The urine is inappropriately diluted for the degree of serum osmolality, usually urine osmolality < 200 mOsm/kg and specific gravity < 1005 with plasma osmolalite >295 mOsm/kg. The most commonly used agent to treat central DI is the ADH analogue desmopressin, which has a longer half-life and almost no pressor activity. It may be administered intranasally at a dose of 5-20 µg once or twice daily. In critically ill patients, desmopressin is more commonly given IV, IM or subcutaneously (2-4 µg once or twice daily), which is 5-10 times more potent than via intranasal route. The effectiveness of the treatment is established by measuring urinary volume and plasma sodium concentration.
Despite the hypernatremic dehydration induced by ADH deficiency, hyponatremia also develops in many patients during the acute period of brain injury due to an inappropriate release of ADH (syndrome of inappropriate antidiuretic hormone, [SIADH]). The reported prevalence of this abnormality is 2.3-36%. As a rule, TBI-induced SIADH is transient.
Symptoms of SIADH vary depending on the degree of hyponatremia (serum sodium levels < 130 mEq/l and < 125 mEq/l in severe cases) and rapidity at which it develops. SIADH is a diagnosis of exclusion of other hyponatremia causes. Renal, adrenal and thyroid function must be normal to establish the diagnosis. In BI patients with HPA axis dysfunction, SIADH can only be diagnosed after appropriate corticosteroid replacement. A low (280 mOsm/kg) serum osmolality is consistent with SIADH. An inappropriately elevated urine osmolality (>100 mOsm/kg) and urine sodium (>40 mEq/l) concentration are consistent with SIADH. Most cases are self-limiting and the cornerstone treatment is fluid restriction. Early diagnosis and treatment of posterior pituitary dysfunction after brain injury is important for maintaining water homeostasis and electrolyte balance in critically ill patients.

23.1.7 Pathophysiology of Pituitary Dysfunction Following Acute Brain Injury and Predictive Value of Hormonal Changes

There are several mechanisms underlying hypothalamo-pituitary dysfunction due to TBI including hypoxic insult or direct mechanical injury to the hypothalamus, the pituitary stalk, or the pituitary gland; compression from hemorrhage, edema, or increased intracranial pressure; and vascular injury to the hypothalamus or the pituitary gland. Autopsy findings in patients who died of TBI showed evidence of injury to the hypothalamus, the pituitary gland or the pituitary stalk in 26-86% of cases. Rotational acceleration-deceleration can cause shearing injury of axons, as commonly seen in the midline structures of the brain. This may represent a possible mechanism of hypothalamic pituitary dysfunction after TBI. In nontraumatic brain injury, evidence for the possible mechanisms of pituitary dysfunction is lacking; however, vascular injury seems to be the most possible cause in the pathogenesis of nontraumatic brain injury. The exact mechanisms of acute hormonal response and pituitary dysfunction due to brain injury remain to be elucidated and further clinical and experimental studies are warranted.
Recent prospective studies in patients with TBI and SAH revealed that most of the acute phase hormonal changes are transient and do not predict pituitary dysfunction at 6 months and 12 months after brain injury. Current guideline recommendations advise evaluation of pituitary function in all TBI patients with moderate and severe injury at 3 to 6 months and again at 12 months after trauma, regardless of acute hormone deficiencies.

23.1.8 Conclusions and Key Concepts

- Alterations in pituitary function may occur during the acute phase of brain injury and most of these hormonal changes are adaptive responses to acute stress.
- These adaptations are initially protective for the human body; however, if inadequate as in pituitary dysfunction or excessive, they may damage health.
- Differentiating adaptive responses from pathological hormonal changes and avoiding unnecessary interventions are important goals.
- Except for clinically significant adrenal insufficiency and DI, other endocrine alterations do not seem to require any therapeutic intervention in brain-injured patients during the acute phase.
- Serum basal cortisol measurement is the primary test to evaluate the HPA axis. Clinical findings consistent with a cortisol concentration < 15 µg/dl (410 nmol/l) are accepted as a diagnostic value for adrenal insufficiency.
- In stable patients, physiological dose replacement with hydrocortisone (10 mg IV every 8 h) could be sufficient. When severe stress is present and the patient is not stable, 50-100 mg of stress-dose hydrocortisone IV every 8 h or an IV infusion of about 15 mg/h is recommended. Steroid replacement is not recommended unless adrenal dysfunction is confirmed. The pharmacological steroid dose should be avoided in all brain-injured patients.
- The main clinical findings of DI in critically ill patients are increased daily urinary volume (>3 litres) and hypernatremia.
- For the diagnosis of DI, urine is inappropriately diluted for the degree of serum osmolality, usually urine osmolality < 200 mOsm/kg and specific gravity < 1005 with plasma osmolalite >295 mOsm/kg.
- The most commonly used agent to treat central DI is desmopressin; it may be administered intranasally at a dose of 5-20 µg once or twice daily. In critically ill patients,

desmopressin is more commonly given IV, IM or subcutaneously (2-4 μg once or twice daily), which is 5-10 times more potent than via the intranasal route.
- Most acute phase hormonal changes are transient and do not predict pituitary dysfunction at 6 months and 12 months after brain injury.

23.2 Endocrinology of Acute Brain Injury Secondary to Traumatic Brain Injury (TBI) and Subarachnoid Hemorrhage (SAH)

23.2.1 Introduction

The hypothalamus and anterior pituitary gland are critical in the higher co-ordination of a number of hormonal axes including the hypothalamic-pituitary-adrenal (HPA), hypothalamic-pituitary-thyroid (HPThyroid), hypothalamic-pituitary-gonadal axis (HPGonadal), the synthesis and secretion of prolactin and growth hormone. The posterior pituitary along with the osmoregulatory centre in the supraoptic and paraventricular nuclei of the anterior hypothalamus controls salt and water balance via the hormone arginine vasopressin (AVP, also known as anti-diuretic hormone) and the thirst response.
HPaxis dysfunction (hypopituitarism) can occur due to a spectrum of pathologies including pituitary and sellar tumours and their treatment, cranial radiotherapy, vascular insults (SAH, pituitary apoplexy and hypotensive pituitary infarct), TBI, inflammatory, infiltrative and autoimmune disorders. These insults can lead to defects in one or more of the HPaxes.
The recognition of HPaxis dysfunction is important as it is associated with increased morbidity and mortality in the acute (particularly due to ACTH deficiency) and chronic phase. Tomlinson et al. have reported a Standardized Mortality Ratio of 1.87 in a cohort of 1,014 patients with longstanding, treated hypopituitarism so one might hypothesize that the mortality may be higher in an undiagnosed cohort.

23.2.2 Hypopituitarism in Acute Cerebral Injury

In recent years two important new causes of hypopituitarism have been recognized and widely studied, TBI and SAH. Over the past seven years ten studies of endocrine function have been performed in the chronic phase after TBI which included a total of 749 patients and revealed a prevalence rate of 35% for some degree of HPaxis dysfunction. Five studies have systematically assessed HPaxis function in the recovery phase following subarachnoid hemorrhage in a total of 122 patients and have reported some degree of HPaxis dysfunction in 48%.
The incidence of TBI is between 80 and 235 cases per 100,000 and the incidence of SAH is 10 cases per 100,000, however South America may have even higher incidences, particularly of TBI. Therefore when combining these figures, conservatively, it would lead to an incidence of 31 cases of HPaxis dysfunction attributable to TBI and SAH per 100,000 population per year. Therefore a large number of patients with HPaxis dysfunction may remain undiagnosed. This failure to diagnose hypopituitarism and the associated increased morbidity also has economic consequences; in the USA it is estimated that five million persons are living with the sequelae of TBI at a lifetime cost of $600,000 to $1.9 million per person.

HPaxis dysfunction may occur very early after acute cerebral injury or may take weeks and months to develop. At the early stage the most important deficiency not to miss is that of the HPA axis where the resulting hypoadrenalism can be fatal, and deficiency of AVP that results in diabetes insipidus and severe hypernatremia. At a later stage deficiency of any and multiple anterior pituitary hormones can occur, a problem that can be difficult to recognize and may only be identified with specific endocrine testing. These axes will be discussed in turn focussing on the prevalence and consequences of dysfunction both early and later in the course of acute cerebral injury.

23.2.3 The Hypothalamic-pituitary-adrenal Axis

During stress there is normally a dramatic activation of the HPA axis leading to increased cortisol levels in the circulation. This increase in cortisol is primarily due to increased production of corticotrophin-releasing hormone (CRH) from the hypothalamus which in turn causes the release of adrenocorticotrophin (ACTH) from the anterior pituitary. ACTH acutely stimulates the adrenal to synthesize and release cortisol but there is also a trophic action on the adrenal cortex. This increases the future capacity of the adrenal to release cortisol in response to ACTH. Outpatient testing for adrenal insufficiency is predominantly by ACTH stimulation tests (short Synacthen/Cosyntropin tests). In conditions that directly damage the adrenal, the response to this test is poor due to direct impairment of cortisol production. In conditions where ACTH production is impaired, the loss of the trophic action of ACTH leads to an atrophied adrenal cortex that responds poorly to an acute ACTH stimulation.

After acute cerebral injury the appropriate response of the HPA axis is to substantially increase cortisol production. Unfortunately there are a number of factors that can impair this response. Direct damage to either the hypothalamus or pituitary can impair ACTH release. Anesthetics can impair these responses even if the pathways are anatomically intact. The use of etomidate as an induction agent during anesthesia has been linked to impaired responsiveness of the adrenal cortex to ACTH. This effect is marked when etomidate use is prolonged and was associated with a dramatic increase in mortality of critically ill patients. Fortunately etomidate use is of less importance when used for short duration in patients without severe sepsis.

The adequacy of the HPA response to acute cerebral injury is also very difficult to test. Most importantly outpatient tests for adrenal insufficiency are dangerously unreliable in this setting. Acute ACTH deficiency is the likely cause of adrenal insufficiency in this setting but the adrenal gland will still maintain responsiveness to exogenous ACTH. Thus an increase or a high peak value on an ACTH stimulation test will be falsely reassuring. Other tests that examine the whole of the axis such as the insulin tolerance test (ITT) or metyrapone test are contraindicated in the setting of acute cerebral injury. The only reliable measure is thus a basal measure of serum cortisol. Even this is a complex measure in critical illness. The rise in cortisol level with trauma is roughly proportional to the underlying severity of injury but there is no easy way of determining in an individual whether a serum cortisol is appropriate. Most of the cortisol in the circulation is heavily bound to corticosteroid-binding globulin (CBG), with only a small percentage available as “free” hormone. During severe illness however the synthesis of CBG decreases and its clearance increases. This leads to an increase in the proportion of “free” cortisol. Currently we cannot reliably measure “free” cortisol in an individual patient. There are also changes in the tissue binding of cortisol during severe illness, especially sepsis that might reduce the effectiveness of cortisol in counteracting inflammatory pathways. This has led to the concept of relative or functional adrenal insufficiency where the level of cortisol,

although normal or high by some measures, is still inappropriately low for the clinical situation. No test has been developed to date that can accurately diagnose these states. As mentioned before, currently the only reliable test of the HPA axis in the first few weeks after acute cerebral injury is a serum cortisol, ideally taken early in the morning (e.g. 0800). A level of less than 400 nmol/l (15 µg/dl) in a sick patient strongly indicates HPA axis dysfunction. A level in excess of 700 nmol/l (25 µg/dl) indicates that HPA axis dysfunction is unlikely. Between these two values there will be uncertainty and the decision whether to treat with replacement glucocorticoids will depend on the severity of injury in association with any potential clinical features of adrenal insufficiency. In patients where deficiency is likely, the standard procedure is to use hydrocortisone at a dose of 50 mg tds until the patient's condition is improving. The hydrocortisone dose can then be gradually reduced down to a replacement of 20 mg am and 10 mg pm until the patient becomes fit for endocrine testing (e.g. ACTH stimulation test), to determine whether this treatment is needed long-term.

HPA axis dysfunction has been reported to occur acutely in ~ 12% of patients with TBI. In about 50% of patients this subsequently improves. Some patients without preexisting dysfunction subsequently develop HPA dysfunction and thus the prevalence of abnormalities at 12 months is again about 12%. Patients with delayed onset adrenal dysfunction can be identified by standard outpatient tests for adrenal insufficiency such as the ACTH stimulation test or ITT.

23.2.4 Hypothalamic-pituitary-gonadal Axis

In the healthy individual, the gonadal axis is controlled by pulsatile release of gonadotrophin releasing hormone (GnRH) from the hypothalamus, which in turn stimulates secretion of the gonadotrophins luteinizing hormone (LH) and follicular stimulating hormone (FSH) from the pituitary, which acts on the testes/ovary to control germ cell synthesis and sex hormone secretion.

During critical illness, in males, testosterone levels decrease significantly in the acute phase (first few days), despite maintenance of circulating gonadotrophin concentrations. It has been postulated that high levels of cytokines seen in critical illness are responsible, and that the acute reduction in testosterone levels reduces unnecessary anabolism, thus possibly conferring a survival advantage.

If the patient survives the acute phase, but does not immediately recover, a period of prolonged critical illness may follow, during which a decrease in gonadotrophin secretion superimposes itself upon the pre-existing testosterone deficiency. This produces a state of central and peripheral impairment of the gonadal axis. Although hyperprolactinemia can occur during critical illness as a stress response and hyperprolactinemia can cause hypogonadotrophic hypogonadism, the high prolactin levels seen in critical illness do not appear to contribute significantly to depressed gonadotrophins in males.

The changes in sex steroids that occur with critical illness in women have not been as extensively studied, and studies are in general confined to post-menopausal populations.

After recovering from critical illness, gonadotrophins and sex steroid levels typically normalize. However if the initial insult was one that may have compromised the hypothalamic-pituitary gonadal axis, such as TBI or SAH, chronic deficiencies may occur (HPGonadal axis dysfunction develops in 12.5% and 5.9% of patients respectively). This can be diagnosed in men as a low testosterone with inappropriately low or normal gonadotrophins and in women it often presents as amenorrhea and low estrogen with inappropriately low or normal gonadotrophins. Thus far, attempts at restoring the gonadal axis with agents such as GnRH have produced a partial and transient response only. Addi-

tionally, it remains to be seen whether successful reactivation of this axis will have beneficial or deleterious effects for the acutely critically ill patient and therefore it is not recommended at present.

23.2.5 Thyroid Axis

Thyroid hormone synthesis is tightly regulated by a negative feedback loop including thyrotrophin releasing hormone (TRH) from the hypothalamus and thyrotrophin (TSH) from the anterior pituitary. TSH stimulates the production and release of T4 and T3 from the thyroid gland.

There are multiple changes which occur within the HPThyroid axis in critical illness, these changes described below give rise to "sick euthyroid syndrome". Within two hours of the initial insult during critical illness, circulating T3 levels decrease, and rT3 levels increase. Two mechanisms underpin the increase in rT3; a marked reduction in deiodinase 1 activity (leading to decreased clearance of rT3) and an increase in deiodinase 3 activity (increasing conversion of T3 to rT3).

Given prolonged states of critical illness, a central impairment superimposes itself upon these peripheral changes, manifesting as a significant and sustained reduction in pulsatile TSH secretion and T4/T3 levels. With recovery of the thyroid axis, transient increases in TSH are often seen. To date no trials have demonstrated significant improvements in mortality following any form of thyroid hormone replacement therapy, and therefore its use is not recommended in this scenario. For this reason thyroid function tests should be avoided in the critical care setting unless specific signs and symptoms of thyrotoxicosis or hypothyroidism are present as they can often be misleading and may lead to inappropriate therapy.

As before, in critical care following TBI or SAH there is a specific neuroendocrine insult and these patients are at increased risk of developing longstanding secondary hypothyroidism. Deficiencies in TSH have been observed in 4.1% of patients in the recovery phase following TBI, and 5.9% following SAH.

23.2.6 Growth Hormone/IGF-I Axis

GH is a polypeptide released from the anterior pituitary whose main physiological control is by growth hormone releasing hormone (stimulatory) and somatostatin (inhibitory) along with inputs from other hormones, peptides and cytokines. Insulin growth factor-I is synthesised in response to GH predominantly in the liver but also in the kidney, muscle and bone/cartilage. Several changes occur in GH and IGF-I concentrations in critical illness. In post operative patients GH concentrations are increased, whereas they can be normal in sepsis patients, and normal to low, with low secretory pulse amplitude in polytrauma patients. As mentioned before, the question whether GH therapy in an ICU setting will improve outcome was addressed by Takala et al. This study investigated the effect of high dose GH (0.07-0.13mg/kg/ body weight) in patients who had been in ICU for 5-7 days and were expected to stay in ICU for 10 days or more. This study reported a negative effect of high dose GH in this patient population with an increased length of ICU stay and in-hospital mortality rate (39-44% in patients who received GH compared to18-20% in the patients who received placebo). The authors concluded that in patients with prolonged critical illness, high doses of GH are associated with increased morbidity and mortality. There have been a number of criticisms since regarding this study particularly related to the high dose of GH which lead to elevated IGF-I levels which could have lead to insulin resistance and aggravated concealed hypoadrenalism and hypothyroidism. GH therapy therefore is not advocated in this setting.

23.2.7 Neurohypohyseal Dysfunction in Traumatic Brain Injury

Disorders of salt and water balance are common in the neuro-intensive care setting. In this setting hyponatremia may be due to a number of pathophysiologies including SIADH, Cerebral Salt Wasting Syndrome (CSWS), glucocorticoid deficiency, hypovolemia and injudicious intravenous fluid use. Disorders of salt and water balance are particularly common following TBI and SAH. Most available information regarding the occurrence of disorders in water balance following TBI has been derived from retrospective case note studies. Agha et al. have reported that in 50 patients prospectively studied following TBI, cranial diabetes insipidus (CDI) occurred in 13 patients (26%) in the acute phase; of these, 9 had recovered by 6 months and a further 1 by a year follow up, therefore 3 (6%) patients developed permanent CDI following TBI. The development of CDI was associated with lower initial GCS ($r = -0.39$, $P = 0.005$) indicating a more severe initial insult and a poorer outcome as measured by the Glasgow outcome score at 1 year ($r = -0.45$, $P = 0.001$). Also in this study 7 patients (14%) had acute hyponatremia which was attributed to SIADH and this had resolved in all patients at 6 months.

It is essential that the correct pathophysiology of hyponatremia be diagnosed as treatment of hyponatremia due to SIADH is fluid restriction and hypovolemic hyponatremia and CSWS is fluid resuscitation with 0.9% saline (Table 23.3). CDI is diagnosed in the presence of polyuria associated with hypotonic urine and hypertonic plasma and if left unchecked will lead to the development of hypernatremia. Many patients with traumatic brain injury will develop CDI which is only transient, however some may develop permanent CDI. The treatment of acute CDI depends greatly on the patients GCS. In the conscious patient treatment should be a combination of SC desmopressin and allowing the patient to drink according to their thirst (as in the vast majority of patients the thirst response to plasma hyperosmolality is intact and will allow the patient to drink until normo-osmolar). However, if there are neurological sequelae of brain injury/hypernatremia these patients may need monitored infusion of hypotonic solutions. In the unconscious patient treatment should be a combination of SC desmopressin and hypotonic solutions to normalize plasma sodium. The use of stat doses of SC desmopressin in response to polyuria (>500 mls of urine in 2 hours) allows one to assess recovery of the neurohypophysis. If there is no recovery of CDI then the patient should be transferred onto oral or nasal DDAVP (Desmopressin Acetate Tablets). Importantly some patients may develop a classic Triple Phase Response in which they get initial CDI, which is followed a couple of days later by SIADH but ultimately end up with permanent CDI.

Importantly, patients with CDI or any abnormality of sodium need regular assessments of plasma sodium (may need multiple assessments per day in the acute phase of treatment to prevent to rapid correction which can lead to significant sequelae such as central pontine myelinolysis, particularly when treating hyponatremia).

	SIADH	CSWS
Plasma Na^+	Low	Low
Blood urea	Normal/low	Elevated
Blood pressure	Normal	Normal/ postural drop
Urine volume	Low	High
Urinary Na^+	High	High
CVP	Normal	Low

Table 23.3. **Syndrome of inappropriate antidiuretic hormone secretion (SIADH) vs. Cerebral Salt Wasting Syndrome (CSWS).**

23.2.8 Natural History of TBI and Implications for Testing

It is well recognized that many posterior and anterior pituitary abnormalities following TBI are transient. Agha et al. assessed the natural history of TBI in 50 consecutive patients with TBI. This study revealed that

many of the deficiencies diagnosed in the acute phase had recovered by 6 months. Hyperprolactinemia and gonadotrophin deficiencies were particularly likely to recover. ACTH deficiency recovered in half and GH recovered in two-thirds. Conversely, some patients who were not deemed to have a deficiency in the acute phase developed deficiencies at retesting 6 months following TBI (no more new deficiencies were encountered when retested at 1 year post TBI). This data, along with the data from other studies, illustrate that there are dynamic changes in hypothalamic pituitary function in the acute phase post TBI but also up until 6 months following insult. These data have implications for the assessment of the GH, gonadal and thyroid axes in patients following TBI. Assessment of the GH, gonadal and thyroid axes is not necessary in the acute phase because there is currently no evidence that acute phase replacement of these hormones in the deficient patient improves outcome. All patients with moderate or severe TBI should have anterior pituitary assessment performed in the post-acute phase, which will vary considerably between patients but is usually between 3 and 6 months after injury. The choice of the stimulation test(s) for GH and ACTH reserves will depend on the preference and experience of the unit and normal responses will need to be defined locally. At that point, if no abnormalities are found, no further assessment will be necessary (Figure 23.3). However, if hypopituitarism is detected, replacement therapy with glucocorticoids, sex steroids and T4 should be given, as appropriate. Although no study has yet examined the impact of GH treatment on rehabilitation in patients with post-traumatic GHD, a trial of GH replacement in such patients during the rehabilitation phase may be considered. In patients with documented anterior hypopituitarism at 3-6 months post-TBI, repeat anterior pituitary assessment at 1 year may be considered if the clinical or biochemical parameters raise the possibility of delayed recovery.

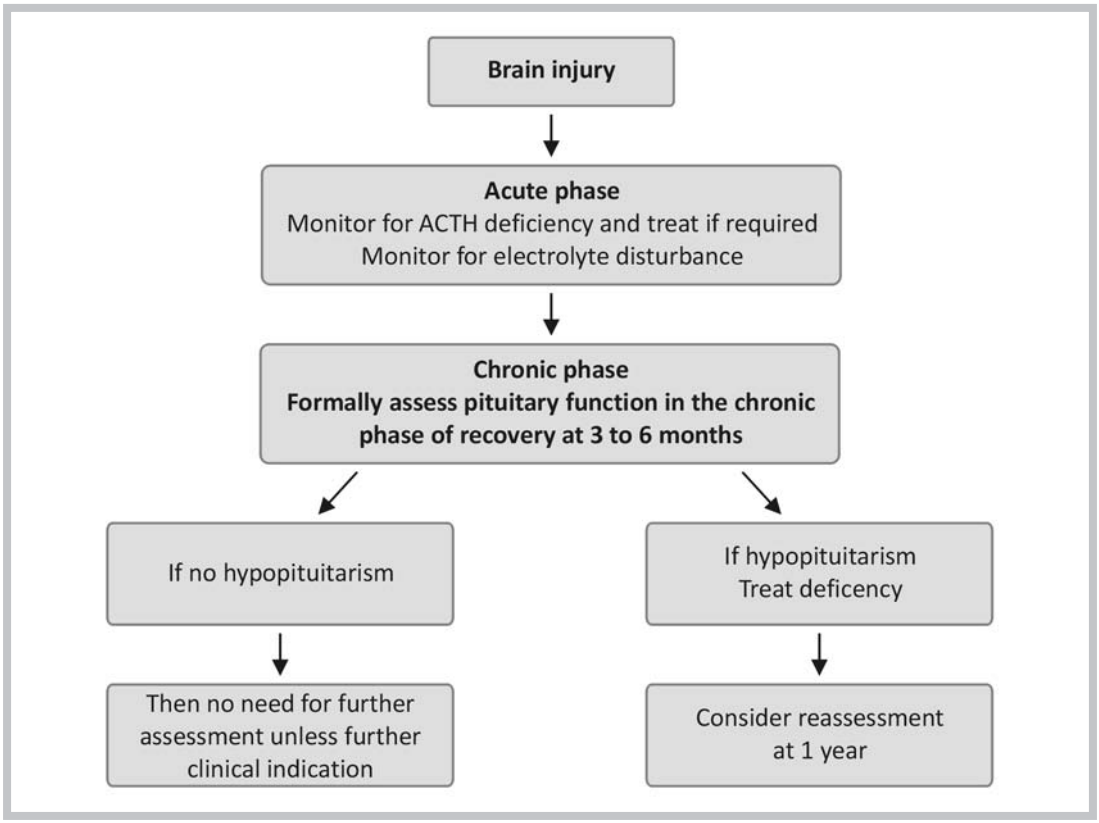

Figure 23.3. Timing of investigation for pituitary dysfunction following traumatic brain injury.

23.2.9 Key Concepts

- Hypothalamic pituitary axis dysfunction is common after acute cerebral injury and many associated features may be protective in nature by redirecting metabolic focus to critical organs.
- "Relative" and "functional adrenal insufficiency" may have important clinical implications. Diagnoses of these conditions can be difficult given the lack of any widely accepted diagnostic criteria. ACTH stimulation tests cannot be used in the early phase of acute cerebral injury to identify adrenal insufficiency.
- In certain subsets of critically ill patients glucocorticoid therapy may be of benefit however treatment of the endocrine dysfunction with GH, sex steroids, thyroxine and DHEA are not recommended at present.
- Increasingly, there is a role for endocrine testing in the recovery phase of acute cerebral injury since new deficiencies can develop months after the initial injury.

[2] Sub-Director of Intensive Care Unit, Hospital Interzonal General de Agudos "Prof. Dr. Luis Güemes", Haedo, Buenos Aires State, Argentina

24.1 Introduction

Coagulation disorders in neurocritical or neurosurgical patients is a matter of significant importance. Hypercoagulability states in which intravascular thrombotic activity is increased, as well as deficits in hemostatic mechanisms leading to increased fibrinolysis and bleeding, compromise the evolution of these patients, overshadow the prognosis and worsen the results.
Clotting disorders may be the underlying cause of the neurocritical disease, as in spontaneous bleeding in patients with pre-existing coagulation disorders or in those under anticoagulation treatment. Also, an hypercoagulability state could be the etiology of an ischemic stroke. These disorders can increase secondary insult, promoting both the extent of intracranial bleeding or the development of intravascular thrombosis leading to brain ischemia. The frequency of the association between coagulation disturbances and neurocritical pathologies varies: the highest incidence (60%) is in patients with traumatic brain injury (TBI); 8-12% of cases of spontaneous intracranial hemorrhage (sICH) are related to anticoagulation treatment or coagulopathies; and <5% of patients with ischemic stroke are noted to have an hypercoagulability state.

24.2 Pathophysiology

In healthy individuals, a delicate balance is maintained between coagulation and fibrinolysis mechanisms to counteract excessive bleeding in the context of vascular lesion and inadequate thrombosis activity leading to vascular occlusion. These mechanisms, which include the activation of plasma and tissue factors, are closely regulated and activate only small proportions of clotting factors, since their concentration in a single millilitre of blood is sufficient to clot all the intravascular content within seconds.
In neurocritical patients, these mechanisms are often imbalanced, leading to inappropriate or excessive activation of the coagulation cascade, which results in complications of varying degrees of severity. In this chapter, we will describe the current state of knowledge of disturbances in coagulation-fibrinolysis mechanisms in neurocritical disease.

24.3 Traumatic Brain Injury

In TBI (traumatic brain injury) patients, clotting disorders are described as a combination of hypercoagulability and deficit in hemostasis, occurring simultaneously or successively.

It has been observed that, after the primary insult, tissue factors are released from platelets, white blood cells and endothelial tissue. This is the main trigger of the extrinsic mechanism of coagulation in which, through the triggering of the coagulation cascades, prothrombin is converted into thrombin, culminating in the formation of fibrin with the expected risk of thrombosis. While this "excessive" release of the tissue factor occurs in all trauma patients, the magnitude of this release is related more closely to brain injury than to shock, tissue hypoxia, or other extracranial injuries. It has also been reported that the degree of increase in tissue factor release is directly proportional to the extent of the brain injury. This trend to hypercoagulability triggers the activation of fibrinolysis mechanisms (increase in tissue factor inhibitor, protein C, protein S, antithrombin III, etc.). When fibrin production exceeds the capacity of these physiological mechanisms, an intravascular coagulation ensues in the small and medium-sized blood vessels. This intravascular coagulation can be generalized (disseminated intravascular coagulation leading to the development of extracranial organ failure), as well as localized. In necropsies of animals and patients, the latter has been observed in pericontusional and contusional areas where it leads to an increase in brain damage by extending tissue ischemia. Trauma patients may have a marked reduction in antithrombin III, protein C and S, resulting in thromboembolic or thrombotic complications rather than bleeding.

In TBI patients, coagulopathy may occur parallel with and/or secondary to the depletion of platelets and clotting factors due to hemorrhage, multiple transfusions and/or consumption by disseminated intravascular coagulation (DIC) in a setting of acidosis, hypothermia or hemodilution. Some studies have drawn attention to the occurrence of platelet dysfunction after TBI, more common than in trauma patients without TBI, and that it could have an impact on mortality. Whatever the mechanism involved, the presence of coagulopathy may extend the secondary injury by increasing bleeding in the intracranial lesions.

The incidence of coagulation disorders in TBI patients is related to the severity of the TBI, as categorized by the Glasgow Coma Score (GCS), and is correlated with evolution and prognosis. Various series have described an increase of up to 10 times in the risk of death in patients with coagulation disorders compared with those without such disorders and a greater risk of poor performance in the survivors with such disorders.

With regard to diagnosis, a good practice during the acute phase of TBI is daily assessment of activation partial thromboplastin time, platelet count and prothrombin time to precociously detect these disorders. Under clinical manifestations suggestive of DIC it is good practice to dose plasma concentrations of fibrinogen and fibrinogen degradation products. Specific determinations of clotting factors are not always available in all units, but evaluation is necessary in situations in which standard treatment does not control the coagulopathy state and a more precise assessment is needed.

24.3.1 Treatment

The therapeutic indication for a coagulation disorder in TBI patients should be aimed at controlling the predisposing factors that may have triggered it (hypothermia, acidosis or hypoxemia) and it also should be aimed at replacing the clotting factors. The administration of fresh frozen plasma (FFP) associated with cryoprecipitate solution is used for replacing clotting factors. The latter contains factor VIII and fibrinogen, both absent or at very low concentration in FFP, thus the desirability of their association. Platelets must be simultaneously reinstated, if necessary, according to the analytical.

24.4 Spontaneous Intracranial Hemorrhage

The main relationship between coagulation disorders and sICH is when it is secondary to anticoagulant therapy. This is the most serious and often fatal complication of such treatment. Much less frequently, the etiology of sICH is related to primary hematologic diseases: hereditary coagulation disorders and lymphoproliferative diseases.

The estimated incidence of sICH associated with the use of oral anticoagulants is 1.8% of patients treated with these drugs per year. This association raises the mortality of sICH by more than 10% compared to patients not under oral anticoagulant therapy. According to the 1999 SPIRIT study, those patients with a prior brain pathology and receiving oral anticoagulants have a higher risk of developing sICH. It has also been reported (Smith, 2002) that the presence of leucoaraiosis on brain images was an independent predictive factor for the development of sICH in patients treated with oral anticoagulants.

Gradient echo magnetic resonance imaging (MRI) studies have reported a high incidence of asymptomatic microhemorrhages in aged and/or hypertensive patients. It has been proposed that the use of oral anticoagulants could increase such bleeding events, making them symptomatic. This could be related to the finding that the majority of episodes of sICH, associated with the use of oral anticoagulants, occur within normal international normalized ratio (INR) therapeutic ranges, while higher values increase the risk.

The progression of bleeding of a sICH with expansion of the hematoma within 48 hours of the primary bleeding is seen in about 40% of patients with sICH. In cases associated with the use of oral anticoagulants or coagulopathies, this expansion could be more frequent, larger and extend beyond 48 hours, as has been observed in different published series.

Studies investigating the activation of hemostatic mechanisms in patients with intracranial bleeding have reported that such mechanisms are activated when there is subarachnoid or intraventricular blood. In these cases, there were significant increases in the thrombin-antithrombin and plasmin-antiplasmin complexes as compared to patients without subarachnoid blood and normal controls. According to these findings, there could be an increased risk, at least theoretically, of thrombotic events.

24.4.1 Treatment of Patients With sICH Associated With the Use of Oral Anticoagulants or Associated With Coagulopathy of Other Etiology

In addition to routine therapeutic measures in patients with sICH, in those cases in which it occurs in patients receiving oral anticoagulants or in those with clotting disorders, the treatment should include specific measures to reverse the anticoagulation state. These include the administration of vitamin K and clotting factors. This association is necessary, since the transfused factors have a median life of 5 to 60 hours, depending on each factor; therefore, they exert a rapid but transient effect. To ensure the reversal of anticoagulation over time, concomitant administration of vitamin K is required. Vitamin K begins to exert its effect on K dependent factor synthesis from 6 to more than 24 hours after intravenous infusion (doses of 5 to 20 mg). The intravenous administration of vitamin K solutions can potentially produce allergic reactions of varying magnitude. A slow infusion rate, not exceeding 1 mg per minute, is recommended. The risk of allergic and anaphylactic reactions is 3 in 10,000. Vitamin K given in either subcutaneous or intramuscular form will need longer to take effect.

There are two options in the administration of clotting factor solutions: fresh frozen plasma (FFP) or concentrate of prothrombinic complex (CPC). We will also consider the place of the cryoprecipitates (CP).

Since FFP has a low concentration of factors by volume, it must be administered in high volumes, which may be a limitation in some particular cases. One published study found that the infused volume needed to raise the INR 1.4 points ranged from 800 to 3500 ml. Of note is that the content and concentration of factors in such solutions are highly variable and depend also on storage time. Factor X has the greatest variability. This feature could normalize INR measurements, but it is associated with persistently low plasma levels of factor X and the risk of bleeding. Although this solution does not require compatibilization tests, it is advisable to infuse FFP obtained from donor blood of the same isotype as the recipient. The side effects associated with the use of these solutions include volume overload, allergic reactions, lung injury secondary to transfusion of blood products, and citrate toxicity. The recommend dose is 15-20 ml/kg body weight, but it may be necessary to increase this dose in cases of massive bleeding.

CPC contains K-dependent factors and proteins C, S and Z. It does not require compatibilization tests and, having a high concentration of clotting factors, it allows the infusion of smaller volumes than those needed for FFP.

Cryoprecipitates are solutions which contain factor VIII and fibrinogen, both factors scarce or absent in FFP. They are indicated in treating the specific deficits of these factors and also in cases of massive bleeding in anticoagulated patients, linking them to FFP.

As a recommendation and taking four clinical guidelines as reference, we suggest: vitamin K 5 to 10 mg IV + CPC 30-50 U/kg or FFP 15 ml/kg.

INR measurements are used for the follow-up, always taking into account prevention with respect to the X factor and the use of FFP alone.

Another more recent therapeutic option in the treatment of sICH is the use of recombinant activated VII factor (rVIIa), a potent trigger of the hemostasis cascade. It has been used in patients with hemophilia in intracranial or extracranial bleeding events. Experimental studies have shown that it has a rapid onset of action, mainly at the site of vascular injury. Also, it requires very low infusion volumes and it has good effectiveness and safety profiles. Because of these properties, it has been proposed and tested in patients with sICH to limit persistent bleeding and the growth of the hematoma, both features closely related to poorer outcomes. In a 2005 phase IIB study, rVIIa administration within 4 hours of the primary bleeding correlated with limiting the growth of the hematoma, lower mortality and improved outcome, assessed within 90 days after primary bleeding. But an increase in arterial embolic complications was also observed. According to this study, and the results of the FAST study, a Consensus Committee of experts concluded that the use of rVIIa in sICH limits the growth of the hematoma, but it has no beneficial effects on the survival rate at 90 days. So, rVIIa treatment remains confined to research studies and is not to be used in general practice.

There are few studies on the use of rVIIa in patients with sICH associated with oral anticoagulant therapy; mostly are retrospective with a small series of patients. It was warned that INR values might normalize after rVIIa administration, but, regardless of the persistently low values of other clotting factors, the risk of bleeding remains.

Some published clinical data, which might be confirmed by new studies, showed that reversal of the oral anticoagulant effect with the infusion of FFC or CPC could exacerbate perilesional edema by inducing the release of endothelial growth factor from “leakage” platelets, with an increase in capillary permeability. However, this phenomenon was not observed with the use of rVIIa in experimental studies.

24.5 Ischemic Stroke

A relationship between coagulation disorders and hemorrhagic complications in ischemic stroke is associated with the use of fibrinolytic therapy, but this issue is beyond the scope of this chapter.

Ischemic stroke might result from an hypercoagulability state. Several metabolic diseases or autoimmune disturbances may cause transient ischemic attack (TIA) or venous sinus thrombosis. Numbering among these disorders are: deficit of protein S, antithrombin III, protein C or plasminogen; prothrombin gene mutation; presence in the plasma of anticardiolipin antibodies or lupic anticoagulant factor; high plasma levels of homocysteine or lipoprotein a; and resistance of factor V to protein C. Specific laboratory studies for the detection of each of these disorders are needed when there is some degree of certainty that these mechanisms are involved in certain patients, according to the history and characteristics of the thrombotic event. Younger or pediatric patients with recurrent TIA events, or patients with recurrent venous thrombosis, or those with a family history of venous thrombosis, are likely to be considered affected by some kind of hypercoagulability disorder. Many of these disorders may be treated. A detailed discussion of these pathologies lies outside the scope of this chapter. An interesting and comprehensive review of these aspects was published by Rahemtullah and Van Cott in 2007.

24.6 Subarachnoid Hemorrhage

An increase in the activation of coagulation and fibrinolysis mechanisms has been described in patients with subarachnoid hemorrhage (SAH). It has been observed that the intensity of this activation (reflected in the increase in thrombin-antithrombin complexes, D dimer and fibrinogen concentrations) has a directly proportional relationship with the clinical severity of the bleeding, the amount of subarachnoid blood, the presence of intraparenquimatose hematoma or intraventricular blood. It is likely that these findings may explain what is observed in other studies which found a significant relationship between the magnitude in the elevation of these markers and a poor outcome. Therapeutic approaches to these disorders in patients with SAH have not been proposed.

24.7 Prophylaxis of Pulmonary Thromboembolism in Neurocritical Patients

Among the complications of critical care patients admitted to critical care units, thromboembolic disease and deep venous thrombosis (DVT) should be highlighted because of their high incidence and because they may result in severe consequences. The prophylactic therapy of DVT of the lower limbs is a routine issue in the basic care of all critical patients. Pharmacological therapy has shown greater efficiency for this purpose than mechanical methods such as elastic stockings, bandages or periodical/sequential compression pneumatic boots.

Critical patients with an acute neurological or neurosurgical disease constitute a special category. First, most of them have major risk factors for DVT such as prolonged immobility, coma, old age or associated injuries in the pelvis or lower limbs in trauma patients. On the other hand, pharmacological prophylactic therapy in these patients is reasonable

thought as dangerous because it may impair intracranial bleeding, whether spontaneous or traumatic, and there is a risk of bleeding inside an ischemic stroke lesion.
We will summarize the current state of knowledge about the prevention of thromboembolic disease in neurocritical patients.

24.7.1 Ischemic Stroke and Spontaneous Intracranial Hemorrhage

The reported incidence of symptomatic DVT and/or pulmonary thromboembolism (PTE) in patients with ischemic stroke and sICH is 5-6%. However, the detection of asymptomatic DVT has been found to occur more frequently (from 5 to nearly 50%), depending on the method used for its diagnosis. In 2004, Kelly et al. published a study on 102 ischemic stroke patients who received prophylaxis with aspirin and compression stockings. They reported an incidence of DVT and symptomatic PTE of 3 and 5%, respectively, as diagnosed by MRI. But the incidence of DVT and PTE (symptomatic and more often asymptomatic) was 17.7 and 11.8%, respectively. At multivariate analysis, there was a significantly higher incidence in patients with a Barthel index ≤9 and an increased trend in patients over 70 years of age.
These findings, and those from other studies, underscore that we have to apply measures to prevent such serious complications. In recently published large series of patients, half of them who suffered a PTE event died as a consequence of it.

Prophylaxis

A Cochrane review, which included two randomized trials on the efficacy of compression stockings and pneumatic boots in the prevention of DVT in stroke patients, concluded that their use reduced the incidence of DVT, but the reduction was statistically non-significant. Furthermore, a randomized multicenter European study involving 2518 patients published in 2009 (The CLOTS trial collaboration) reported no significant reduction in the incidence of DVT with the use of elastic compression stockings, but it also reported a 4-fold higher incidence of cutaneous complications, including skin necrosis.
With regard to pharmacological prophylactic therapy, a systematic review assessing the efficacy of the use of antiplatelet drugs for the prevention of DVT/PTE concluded that their use reduces the risk of PTE but not the incidence of DVT.
Studies designed to assess the effectiveness of heparin administration in the acute phase of stroke to prevent stroke recurrence revealed that the incidence of PTE was reduced but with a concomitant significant increase in the risk of intra- and extracranial bleeding. In 2007, Kamphuisen et al. published a systematic review of 17 studies involving 23,043 patients, in which low and high doses of low-molecular-weight heparin (LMWH) were compared with unfractionated heparin. They concluded that the use of low-dose LMWH was the therapeutic strategy that showed the best risk/benefit relationship in reducing DVT and PTE, without an increase in extracranial or intracranial hemorrhage complications.
In 2007 Sherman published the results of the PREVAIL study which included 1762 ischemic stroke patients unable to walk. Patients were randomized to receive, within 48 hours of the primary event, 40 mg of enoxaparin once daily versus 5000 IU of unfractionated heparin twice a day. The enoxaparin-treated group showed a significantly lower incidence of DVT and PTE, with no difference in the incidence of intracerebral bleeding between the two groups (1% in both groups). However, in those who received enoxaparin there was a significantly higher incidence of major extracranial bleeding (0.8 vs. 0%).
Sandercock, in a 2008 Cochrane review (9 studies involving a total of 3137 patients) compared different heparinoids versus unfractionated heparin administered within the first 14 days of an ischemic stroke event. LMWH was associated with a significant reduc-

tion in the incidence of DVT compared to standard heparin; however, Sandercock concluded that the data are insufficient to determine whether the use of this heparinoid reduces the risk of PTE or does not increase the risk of intra- or extracranial bleeding.
The 2007 American Heart Association and American Stroke Association (AHA-ASA) guidelines for the early management of adult stroke patients are based on published levels of evidence. The guidelines recommend: mobilize patients as early as possible; use subcutaneous LMWH in immobilized patients, but the ideal time for initiating therapy is unknown; aspirin is an alternative therapy but it is less effective than heparin; use mechanical compression methods when anticoagulants are contraindicated.
In 2008 Tetri et al. published a retrospective study involving 407 patients with sICH who survived 48 hours after the primary bleeding. They compared those who received 20 mg of enoxaparin once daily with those who did not receive prophylaxis during the acute stage. There were no differences in mortality at 3 months and there were no differences in the degree of growth of the hematoma between the two groups.
The update of the 2007 AHA-ASA guidelines for the management of adults with sICH based on the few articles published about this issue recommends the use of mechanical methods of intermittent compression. In those patients who remain immobilized or with motor deficit in the lower limbs within 3-4 days of the primary bleeding, low-dose LMWH may be used if there is no evidence of ongoing bleeding on the follow-up CT scans.

24.7.2 Traumatic Brain Injury

The incidence of asymptomatic DVT in patients with severe TBI is between 25 and 54%. The use of removable filters in the lower vena cava has been studied in a few trials. The analysis of these studies suggests that its use might be reserved only for those patients with known DVT and in which anticoagulation therapy is contraindicated.
With regard to mechanical or pharmacological prophylaxis, the published data on TBI patients are scarce.
A randomized study of patients with TBI and traumatic spinal cord injury (SCI) compared the use of intermittent pneumatic compression boots versus 40 mg enoxaparin once daily. The study found no significant differences in the incidence of DVT and PTE between the groups. Another retrospective study found that the use of LMWH, initiated within 72 hours of the primary injury, was not related to an increase in the size of intracranial hemorrhagic lesions.
In 2007 Cothren, published an observational study involving 6247 trauma patients (174 of which with TBI), who received 5000 IU dalteparine once a day. Dalteparine administration was begun when the patients showed hemodynamic stabilization and, in those patients with TBI, when the second CT scan at 12-24 hours after the primary injury showed no worsening in intracranial bleeding. The intracranial injury worsened in none of the patients and no death related to PTE or bleeding was recorded.
The 2007 Brain Trauma Foundation Guidelines based on published evidence recommend: use graduated compression stockings; the use of pharmacological therapy is known to potentially increase the risk of intracranial bleeding; there is not enough evidence to recommend any specific agent, doses or time after the primary injury to begin its administration.

24.7.3 Spinal Cord Injury

The incidence of DVT in SCI patients who not receive prophylaxis ranges between 7 and 100%, depending on injury severity, patient age, and the method to diagnosis DVT. Be-

cause of this high incidence, it is an accepted practice to use early prophylaxis in all of these patients. It was stated as a standard, with class I evidence, in the American Association of Neurological Surgeons Guidelines for the Management of Spinal Cord Injury. The guidelines also recommend extending prophylactic measures for 3 months after the primary injury, being reasonable to suspend them before such time if the patient has recovered motor function of the lower limbs.

With regard to which therapy is better, prolonged use of removable lower vena cava filters has been associated with some complications. A 2009 retrospective study suggests that the use of filters could increase the incidence of DVT. They are also indicated in patients under pharmacological prophylaxis who, despite this, underwent a thromboembolic event.

With regard to mechanical devices (graduated stockings, pneumatic boots), the results in some published studies suggest that they could be as effective as pharmacological measures. Others suggest that when associated with pharmacological therapy, their use can enhance its effectiveness. The above-mentioned guidelines recommend the combined use of mechanical devices and low-dose unfractionated heparin. We could add that, in those patients in whom anticoagulation therapy is contraindicated, it might be an indication for its use.

Finally, with regard to LMWH, several studies have found equal effectiveness by comparing the different products available. A 2009 systematic review including 30 studies concluded that LMWH is the best alternative because of its effectiveness and safety, whereas the use of unfractionated heparin has been associated with major bleeding complications.

24.7.4 Elective Neurosurgery

Published series of patients undergoing elective neurosurgical procedures (most of which affected by brain tumour) report an incidence of DVT between 19 and 54% and an incidence of PTE of around 5%. Despite these figures, there is reluctance to use pharmacological prophylaxis therapy in these patients because of the fear of an increased risk of bleeding. Two recently published surveys reported that only 32 to 33% of such patients receive pharmacological prophylaxis, although it is not definitively established whether therapy actually increases the risk of intracranial hemorrhage to any significant degree. Comparing study results is difficult because most studies are non-randomized and because spontaneous re-bleeding after elective neurosurgery has been reported to occur in more than 25% of cases. Also, the rate of reoperation because of post-operative re-bleeding ranges between 1 and 10%, even in patient series in which pharmacological prophylaxis for DVT was not administered.

In 2003, Gerlach published a study of a series of 2823 neurosurgical patients who received 0.3 ml of nadroparine in a single dose within 24 hours of surgery. The incidence of post-operative bleeding associated with clinical deterioration or which required a new operation was 1.5%. Also, Chibaro, in a 2008 study involving a series of 746 neurosurgical patients who received Tinzaparine, reported post-surgical intracranial bleeding in less than 1% of cases.

In 1998 Agnelli published a randomized study of 307 patients undergoing elective neurosurgery (90% involving the brain, 97% of which brain tumours) who received 40 mg enoxaparin once daily + graduated compression stockings versus graduated compression stockings + placebo. Enoxaparin was initiated within 24 hours of surgery and was continued for 1 week. The incidence of DVT and PTE was significantly lower in the enoxaparin group, and there was no increased incidence of major or minor bleeding between the groups.

Coincidentally with this last study, two meta-analyses (Iorio 2000 and Collen 2008), which included 7 and 30 studies, respectively, agreed that the use of LMWH proved effective in preventing DVT, without an excessive increase in the risk of bleeding. According to this evidence, the greatest benefits might be obtained by combining the use of mechanical compression devices with LMWH therapy, but the ideal time when these drugs should be initiated remains unknown.

25.1 General Concepts

Intracranial pressure (ICP) is one of the key parameters of acute head injury pathophysiology; its knowledge and management are essential to improve the outcome of neurocritically ill patients.

Some basic concepts in intracranial dynamics need to be kept in mind to understand the events that occur during intracranial hypertension (ICH). ICP is classically described as the pressure exerted by the cerebrospinal fluid (CSF). Its normal range in adults in supine position is 5-10 mmHg, measured in the lateral ventricle and taking as zero the foramen of Monro. The normal range in children is 1.5-6 mmHg. ICP results as the interaction between the cranium (inextensible compartment) and its content, which is what will determine ICP variations.

The content is composed of three compartments: the brain (neurons and glia) accounts for 80% (1200 cc); the brain-blood volume (arterial and venous vessels) for 10% (150 cc); and the CSF and interstitial fluid for 10% (150 cc). Although there is no ideal theoretical model that explains every phenomenon in relation to intracranial dynamics, very useful clinical accepted models do exist. Two which play a key role in its understanding are the Monro-Kellie equation and Marmarou's mathematic model.

According to the Monro-Kellie equaltion, intracranial volume is constant as it finds itself in a rigid compartment (uncompressible, but displaceable); therefore, any increase in one of these components or the apparition of a new volume must be necessarily compensated by a decrease in one of the others, otherwise ICP will rise.

$$V_K = V_{CBV} + V_{CSF} + V_{parenchyma}$$

$$1500 = 150 + 150 + 1200$$

It is important to highlight that the Monro-Kellie equation describes volume and not pressure; therefore, even if volume remains constant, this doesn't mean that the system pressure will remain constant. This concept to understand ICH also works in situations where only one of the system's components decreases, as occurs in ICH related to CSF fistula. In such cases, one component of the system must increase its volume to maintain the K, usually the intracranial veins and/or the cerebral blood flow (CBF), which ultimately produces the diagnostic elements of this condition.

Current discussion on defining ICP in measured units from a mathematical point of view has focused on: a scalar magnitude, where there is no direction of the vector that generates the magnitude; a vectorial magnitude, where there's clearly a direction and a sense of the magnitude, or a tensor, and where this magnitude operates in all tridimensional planes. This concept derives from biophysics, given the brain's biomechanical complex characteristics, as a semi solid with complex visco-elastic properties, where ICP must be

defined in the strict sense as a tensor and not as a liquid according to the classical clinical definition (personal communication, Dr. Alonso Peña).
Marmorou's model explains the dynamics of the intracranial system and differentiates: normal conditions (basal state or balanced state); and pathologic conditions, phasic or transitory state.

25.1.1 Normal Conditions (Basal State or Balanced State)

ICP is determined by several factors including the CSF production index, its absorption, venous sinus pressure, and arterial blood flow, as described in the formula:

$$\text{Basal state ICP} = f \times R + Pd$$

where: f (flow) of formation = f (flow) of absorption; f stored (capacitance) = 0; R= flow resistance; Pd = dural sinus pressure
In this situation, CSF formation flow is equal to absorption flow and storage. In other words, a capacitance system where the liquid at any given moment doesn't change and remains at 0. R is the flow resistance and is the sum of all small resistances (r, r′, r′′ …) which the flow encounters. Therefore, the flow resistance (absorption flow or formation flow) plus dural sinus pressure are what maintain the ICP normal or balanced. The dural sinus pressure is the outlet pressure and must be the lowest pressure of the system. Clearly then, the balance between the formation and storage of CSF is critical. If absorption is exceeded, for example, as a result of an elevation in the CSF flow resistance, this will determine, once the CSF storage capacity is exhausted, an elevation in ICP.

25.1.2 Pathologic Conditions, Phasic or Transitory State

This state is produced when the system is subject to an abnormal overload which alters the volume of one or more compartments. To understand this state, we will describe the volume tolerance curve, formerly called the compliance curve. Marmorou showed that the relationship between volume and cranial spinal pressure could be described as a straight line derived from the logarithm of the pressure/volume, which implies a single exponential curve of the volume/pressure ratio that depends on the intracranial compliance grade (Figure 25.1).
The compliance curve was used to describe volume variation over pressure variation; as the curve is exponential, the compliance varies along it.
Three sectors are distinguished:

- Initial: almost horizontal. This is the compensating phase because increasing volume produces minimal changes in ICP, showing the effectiveness of compensating mechanisms.
- Intermediate: (decompensating phase) is the inflection and shows the transition between the two sectors. It corresponds to variable values of ICP (depending on the speed of onset) between 20 and 25 mmHg. This value must be considered as a warning sign because ICP will increase dramatically at higher values.
- Final: almost vertical (cerebral tamponing phase). The increasing volume generates rapid ICP increments because the compensation mechanisms can no longer counteract it. This phase corresponds to ICP values of around 50-60 mmHg, where only systolic flow (ICP=DAP) remains.

These variations in pressure and volume behaviour are determined by intracranial compliance, which is defined as the relationship between volume variations and pressure

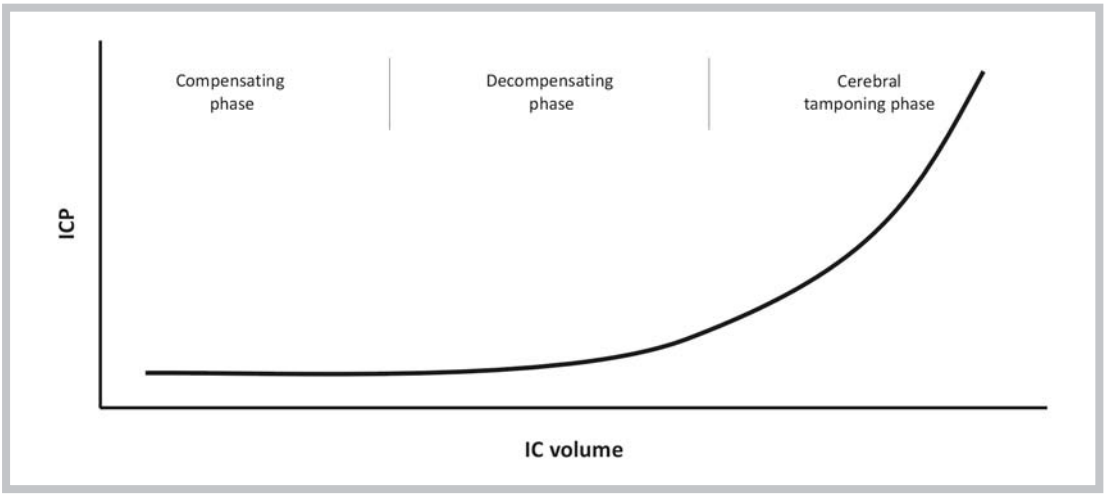

Figure 25.1. **The volume tolerance curve, formerly called the compliance curve.**

variations ((ΔV/ΔP). It is high initially and frankly decreases above 20 mmHg. Its normal range is 0.15 to 0.5 ml/mmHg. Many authors argue that compliance should be referred to as "pseudocompliance" because the intracranial volume is constant. They prefer to refer to it as a volume tolerance curve, referring to the displaced volume more than to the volume variation. Compliance is not homogeneous: it is greater in the supratentorium compartment (80%) than in the infratentorium (20%), in which the compliance curve is displaced to the left, indicating its lower tolerance to volume increments. Some authors prefer to refer to this property as as elastance and not compliance, which would be a more physiological definition, because the brain has a constant volume. Elastance is the opposite of the compliance, i.e., the pressure variations that must be generated to displace a certain volume.

The other important concept is that the compensating system is time-dependent. This means that the slower the volume load, the greater the system's tolerance, ensuing in a lower pressure to a higher volume. This explains why slow-growing tumours can occupy intracranial space, whereas even a slight, sudden increase in ICP with a much smaller volume will generate a much higher pressure. Between this two extremes lie all kinds of intermediate situations, and the physician will need to consider the time factor when making decisions.

So, in short, **the phasic state or transitory state of the intracranial system**, according to Marmorou's model, is described by the compliance curve or elastance. The system works with a non-ideal response with a variable compliance, the pressure/volume ratio is exponential and time-dependent.

25.2 Compliance

There are two ways to measure compliance with the compliance test:

- PVR (Miller): when injecting 1 ml/second it's known that the ICP should be <4 mmHg.
- PVI: it's index of pressure/volume of Marmorou.

This is the volume (normally >20 ml) needed to increase ICP 10 fold.

Commonly used in the 1980s, these indices are now rarely applied but serve to understand the logarithmic relationship between pressure and volume: the higher the volume, the better the compliance and therefore the more tolerant the system to volume loads.

25.3 ICP Waves

ICP waves refer to the study of cerebral pulse curve and periodic waves.

25.3.1 Cerebral Pulse Curve

Another way to understand the compliance curve is to study the cerebral pulse curve, i.e., the ICP instantaneous curve. It normally presents three consecutive peaks, (P1, P2 and P3). The first positive deflection, P1 (percussion wave), corresponds to the arterial pulse wave and represents the arrival of blood to the intracranial cavity. The second wave, P2 (volume wave), is considered a reflex of intracranial elastance. The meaning of the third wave, P3 (dicrotic wave), is still unknown. Normally, the amplitude of P1 is higher than that of P2; however, in situations of greater elastance or decreased compliance, P2 increases in relation to P1. The magnitude of this change is a measure of intracranial compliance, constituting the so-called compliance auto-test.
When we have a space occupying lesion, the arterial pulse constitutes a real volume load. From cerebral pulse wave analysis we can infer in what sector of the compliance curve we are. The normal pulse wave amplitude is 3 mmHg. A high amplitude (10 or 15 mmHg) pulse wave indicates a volume load in the ascending slope of the compliance curve.

25.3.2 Periodic Waves

In the classic description, following Lundberg who described ICP waves (A, B, C) which bear his name, Lundberg A waves, or plateau waves, are the most important from a pathologic point of view. According to its description they were ominous, with duration between 5 and 20 minutes, with an amplitude >50 mmHg, reaching values of 100 mmHg. B Lundberg waves last between 2 and 5 minutes, with an amplitude >20 mmHg, reaching 50 mmHg. Their clinical meaning is less accurate than A waves, but are warning signs that show a decrease in intracranial compliance. Type C waves, (Hering Traube), are of short duration, with low amplitude (<20 mmHg) and show arterial curves; their clinical meaning is unknown. Our current notion about ICP periodic waves follows the concept of Lemaire, which introduced the globalized concept of periodic events separated according to frequency range and taking the B waves as the centre, then subdividing them into infra B, B and ultra B, according to how it's established (Table 25.1).
To detect this type of waves it is important to count with slow ICP recordings. The usual display on most monitors, although they provide a good recording and visualization of the cerebral pulse curve, don't permit these events to be observed. In these conditions, the existence of periodic waves may be sometimes suspected from spontaneous changes in ICP values above the treatment threshold and should prompt doubt about its treatment. What must be emphasized is that as long as the elevation in ICP is not excessive, we must always wait 15 to 20 minutes before starting to treat an increase in ICP so as to avoid unnecessary treatment of reversible ICP elevation caused by these periodic waves.
The phenomenon of periodic waves is essentially a physiological event, as has been demonstrated by transfontanel recording in normal neonates. It is generally of vasogenic origin, emerging from the normal vasomotricity of normal circulation and that of the brain circulation in particular. The most pathological forms would be given by the higher amplitude and slower frequency waves (infra B), which typically show: 1) a sharp drop compliance in all cases; and 2) conservation, but not always, of the autoregulating pres-

Classification	Wave	Oscillation (waves/min)	Aplitude (mmHg)	Frequency band (mHz)
Janny	Type 1	6 to 12	1.5-2.2 (healthy subjects)	66.3-200
	Type 2 or slow cycle "Coup d'hypertension"	0.5 to 3 (dominant 1w/min) Variable occurrence	10.3 (current)	8.33-50
Lundberg	C wave	4 to 8	From discernible to 20	66.3-133.3
	B wave	Variable occurrence (current duration 5-20 min)	From discernible to 50	-
	A wave or plateau wave		50-100 (current)	8.33-33.3
Frequency	UB			>50-200
	B			8-50
	IB			<8

Table 25.1. **Periodic wave classification.**

sure. Detailed study of the chronobiology that initiates a wave of this type is essential for determining its mechanisms. With simultaneous multimodal monitoring and multichannel recording it is possible to determine whether it corresponds to cerebral autoregulating events that normally originate the wave or to a phenomenon of autoregulation loss.

25.4 Factors Which the ICP Depends on

In summary, ICP depends on the following factors: CSF production; CSF flow resistance; venous sinus pressure; and compliance. The first three are balance factors and determine basal ICP. The fourth is the compliance factor. Its behaviour shows with the other variables the volume, i.e., the change magnitude and the time variable, determining ICP by volume load.

For example, head-injured patients with normal ICP have alterations in the balance factors, mainly in the intravascular compartment. At the same time, subarachnoid hemorrhage with normal ICP also has great alterations in balance factors, but mainly the resistance to CSF flow.

25.5 Intracranial Hypertension Compensating Mechanisms

Due to the inextensibility of the cranial enclosure, compensations before elevation of ICP imply displacement of the intracranial structures to tolerate volume loads.

- CSF constitutes the main initial compensatory mechanism. The CSF moves to the subarachnoid space which is distensible and also increases its absorption. Importantly, the spinal fluid accounts for more than 50% of the total CSF and it is the main buffer before ICP starts to rise. Its magnitude is higher in patients with cerebral atrophy and increased subarachnoid space. It can be quantified by computed tomography (CT) to evidence the remaining buffer according to the size of the subarachnoid space, mainly in the basal cisterns and peri-brainstem. The ICP-CT correlation is accurate when both are normal, but an abnormal CT finding could suggest or not

an increased ICP. At the same time, a normal CT finding doesn't necessarily guarantee a normal ICP. Nevertheless, indirect tomographic signs (not pathognomonic) of increased ICP are:
  - Basal cistern and peri-brainstem compression.
  - Unilateral lateral ventricle system compression.
  - Midline deviation.
- Cerebral blood volume (CBV). The decrease in CBV is one of the initial compensatory mechanisms. It involves venous collapse (earliest mechanism) and arteriolar vasoconstriction, which could also be stimulated by hyperventilation, temperature decrease or osmotic agents, besides maintaining adequate cerebral perfusion pressure (CPP). The venous vessels are collapsible structures that displace a considerable volume, decrease their volume, and transfer their pressure to the dural sinus. These two systems, venous and CSF, are very economical for the brain, with fewer clinical repercussions on the patient's final outcome. When these two systems are overwhelmed, however, the ensuing structural changes lead to a major alteration in intracranial physiology: the arteries produce ischemia and the parenchyma is displaced.
- The encephalic mass accommodates ICP elevations at the expense of displacement and distortion of encephalic structures, which constitutes more a second cerebral aggression mechanism than a compensatory mechanism. Likewise, as the compensatory mechanisms depend on the three types of intracranial structures, themselves compromised, ICP ensues:
  - Increased CSF: hydrocephalus (CSF blockage).
  - Increased CBV due to vasodilatation (hyperemia) or hypertension when autoregulation limit is surpassed.
  - Increased encephalic volume due to expansive processes or cerebral edema.

Elevation of ICP depends on:
- Speed of onset of increase.
- Factors concomitant with the initial process caused by increased CBV or cerebral edema, secondary ICP elevation (secondary mechanisms), e.g., seizures, hyperthermia, hyponatremia.

25.6 Effects of Intracranial Hypertension

Intracranial hypertension *per se* is not a structural or functional deteriorative element; instead, it works through two main mechanisms (ischemia and encephalic displacement) to produce brain ischemia by vascular compression. An ICP >20 mmHg generates ischemia initially through venous capillary compression and later by arterial compression. Values of 35 mmHg generate arterial compression; this value is considered as severe ICP. A prolonged ICP of 40 mmHg is correlated with 70% mortality. When ICP equals mean arterial pressure (MAP), CBF ceases. This is called critical cerebral perfusion pressure (CPP) to CPP = 40 mmHg, because CPP <40 mmHg for 2 hours is correlated with a mortality of 100%.

Increased ICP generates severe distortion of anatomic structures. It is this distortion or displacement that determines hernia with occlusion of the compartments. Its clinical manifestation is late and corresponds to the herniary syndrome. When a hernia is accompanied by a compartment occlusion, the total system volume is suddenly reduced, with a significant reduction in compliance and, in general, a pronounced increase in ICP. So we move from an initial exponential curve to its most vertical phase of cerebral tamponing. From the point of view of pressure and flow, this situation occurs when diastolic

pressure equals ICP (ICP = DAP). In such cases, there is only systolic flow to the brain. Later, when ICP equals systolic pressure (ICP = SAP) cerebral fugue flow can occur, i.e., the injected blood returns. We have a detained cerebral circulation which will rapidly lead to brain death. Each of these situations can be clearly identified with a transcranial Doppler study. When ICP >DAP, during the diastolic phase a return of blood after the systole is produced, determining a reverberating diastolic flow, a sign of cerebral tamponing and an indirect sign of brain death.

Displacement occurs earlier than the herniation syndrome, as magnetic resonance imaging studies have shown. Early displacements were found to have a close correlation with neurologic deterioration and deepening coma. The main consequences of displacement are brainstem angulation and distortion, which ultimately define the severity. Also, displacement can cause ischemia by direct vascular compression in diverse topographies, as occurs in transtentorium hernia or in occipital infarction, by compromising the posterior cerebral artery. There's also the notion that several tentorium anatomic variation, 25% of which could be the variations that restrict brainstem displacement, and these patients would have a higher risk of early onset of a herniary syndrome.

25.7 Intracranial Pressure Gradients

The classic concept of ICP measurement based on the system's liquid nature cannot explain the phenomenology of intracranial and cranial-spinal gradients because pressure gradients don't naturally occur inside a liquid. The modern concept that encompasses the system's viscoelastic properties and the conceptualization of ICP as a tensor is the key to understanding the relationship between ICP and deviation of the cerebral parenchyma. Deviation or displacement of the cerebral parenchyma is produced by intracranial pressure gradients. The existence of gradients between the supratentorium and the infratentorium and between the posterior cranial fossa and the subarachnoid spinal space have been observed and confirmed in both experimental models and by clinical assays. There are also gradients inside the supratentorium compartment, between both hemispheres (interhemispheric gradients) and inside each hemisphere (transhemispheric gradients). The gradients originate mainly when there is a space-occupying lesion and depend mainly on its growth rate and they tend to disappear with time. In such cases, the intracranial space acts like two-chamber system in which ICP is unequally distributed for a variable period of time and the higher ICP is always found on the side of the lesion and close to it. That's why ICP monitoring should always be performed ispilateral to the lesion. The reduction and disappearance of the gradients over time could be related to brain relaxation and accommodation to this new volume. (Sahuquillo et al.). In patients with diffuse lesions (midline deviation <3 mm and lesion volume <25 mm) it can be assumed that the intracranial compartment acts like a single-chamber space, with ICP practically equal in both hemispheres (Sahuquillo et al.), so that even a very slight increase in ICP will produce more cerebral distortion, more ischemia and herniation. This occurs because of focal pressure elevations, which possess intracerebral gradients, in the dura mater, which is inextensible, distends inwards. Because the volume change is negligible, ICP doesn't increase greatly. That's why it is important to understand that ICP isn't the panacea in the management of patients with head injury and some other lesions, especially in temporal lobe lesions. In such cases, CT is more reliable for measuring the midline deviation using planimetry as a main factor when taking decisions.

25.8 Herniaton Syndrome

Magnetic resonance imaging (MRI) has revealed that is not necessary that distortions in one compartment lead to changes inside others to produce the herniation syndrome. The herniation syndrome is produced only by cerebral distortions in the horizontal plane or distortions in the vertical plane, without a part of one compartment moving to other to cause hernia, which would be a final event. A close relationship has been identified between consciousness level and midline distortions. Acute distortion >1 cm at the pineal gland and 1.5 cm at the pellucid septum causes coma.

25.9 Elevated ICP

The main events leading to elevated ICP are given below. It must be kept in mind that in many cases more than one process is active in the genesis of ICH, such as: brain edema (congestion or brain edema), hematomas, and hemorrhages.
The difference between hematoma and hemorrhage is that a hematoma arises where there is no pre-formed cavity. Hemorrhage refers to bleeding in a cistern or a ventricle, i.e.: Arteriovenous malformations – giant aneurysms, any kind of collections, tumors, hydrocephalus, osseous causes.
Hydrocephalus results from two mechanisms. At point 1) brain edema and at point 7) hydrocephalus. When hydrocephalus is severe as in hydrocephalic edema which is periependimary edema, then there is a double mechanism through which ICP increases. In hydrocephalus of osseous causes, bone thickening occurs in some hereditary forms of anemia which reduce compliance.

25.10 Hydrocephalus

Before talking about hydrocephalus, we will refer to some basic concepts about CSF physiology and its functions.
Three stages of CSF physiology are distinguished:

- Secretion from the choroid plexus.
- Downstream circulation through the III ventricle, aqueduct of Sylvius, IV ventricle, peri-brainstem cisterns, and from there to the convexity and spinal subarachnoid spaces, ascending up through them to the interhemispheric fissure. This circulation is pulsatile, because that's how CSF is secreted by the choroid plexus, which beats with arterial pulse.
- Absorption by the arachnoid villi in the venous sinus, and extra-villi absorption.

The amount of CSF is about 150 cc (70% from choroid plexus secretion and 30% from interstitial liquid that passes to the ependymal space). The secretion rate is around 20 ml/h, which amounts to a total of 500 cc/day, therefore CSF refill about every 8 hours.
Authors who advocate treatment of ICH by CSF drainage sustain their position by citing two facts: it is the most physiological mechanism and the mechanism through which the clearance is done in interstitial edema and vasogenic edema (due to the communication between the interstitial fluid and the CSF).
CSF functions are many: cushioning of cerebral structures against movement and trauma; transport of neurohormones and neuropeptides; maintenance of the interstitial microhabitat and lymphatic-like effects, elimination of cellular waste through the CSF, which is greater than via the venous sector.

Hydrocephalus is variously defined and no consensus on its definition has been reached. Rekate [Rekate, 2008] proposed a definition to take as a starting point for future debates. He describes it as an active distension of the ventricular cerebral system resulting from an inadequate passage of CSF from its production point in the cerebral ventricles to its absorption point in the systemic circulation. He also poses the existence of a common underlying cause for its different manifestations and for an imbalance between CSF production and absorption.

This definition implies an active process, which excludes cerebral atrophy and hydrocephalus ex-vacuo, and in general implies ventriculomegaly. It can be suspected from the presence of ventriculomegaly but ventriculomegaly isn't synonymous with hydrocephalus. Hydrocephalus can exist without ventriculomegaly and ventriculomegaly without hydrocephalus, as occurs in cerebral atrophy. This form is seen in older patients, in which the spaces where the liquid circulates are dilated. Such patients present a reduction in parenchyma volume and there is no resistance to circulation or liquid absorption. Sometimes it is hard to rule out a hydrocephalus in these situations. A wider definition would be that hydrocephalus represents resistance to the circulation of CSF or a difficulty in its absorption.

Normal resistance is the pressure difference between the CSF pressure and the pressure of the venous sector, i.e. in the venous sinus. The value of the pressure difference between the cortical subarachnoid space and the superior sagittal venous sinus (last CSF absorption point) is approximately between 5-7 mmHg [Rekate, 2008].

25.10.1 Brain Edema

Brain edema is a main factor in most cases of ICH. It constitutes a brain tissue monomorph and a self-response or stereotyped response to multiple forms of acute injury, both structural and metabolic.

Edema refers to an increase of the volume of one or more the tissue components. Strictly defined, it is an increase of water content in the extravascular tissue due to an increase of water in either the extracellular space or the intracellular space alone or both. Clinically, however, brain edema usually refers to an increase in cerebral volume. Therefore, to employ the same terminology, we will use the term brain swelling (or brain bulk enlargement in the English language literature) to describe increased brain volume or brain mass due to:

- Augmented vascular volume: arteriolar dilation or venous obstruction.
- Cellular swelling of intracellular neurons or glia usually caused by cytotoxic edema.
- Extracellular edema or interstitial edema:
  - Vasogenic (altered blood-brain barrier).
  - Osmotic (decreased plasmatic osmolarity).
  - Interstitial, hydrocephalus or peri- ependimary (altered CSF circulation).

Edema may be a focal or a diffuse disturbance.

At the cellular level, several different patterns reflect different etiopathogenic mechanisms.

Vasogenic edema refers to the presence of liquid in the extracellular space caused by loss of blood-brain barrier (BBB) integrity. The BBB is composed of elements between the capillary and the neuron (endothelium, basal membrane, pericytic, astrocytic prolongations). The BBB is less permeable than other capillary membranes of an organism (pores of 6 Ångström vs. 60 Ångström of the general circulation), due to tight endothelial intercellular unions, configuring the so-called continuous capillary type, unlike the other types of capillaries (fenestrated as in the choroid plexus and renal glomerulus, and sinu-

soidal as in organs where cellular passage occurs as in the liver and spleen). Therefore, it is said that systemic circulation is an "oncometer" (it does not allow the passage of proteins but easily allows low-molecular-weight solutes to cross it), while the BBB would be an "osmometer" (the liquid passes through channels according to osmotic pressure differences and the ions by finely regulated transport channels). The movement of liquid is determined by the factors accounted for by Starling's law, wherein: there must be an adequate level between the hydrostatic and osmotic forces to produce edema that tend to move the liquid to the interstitial space. In normal conditions, the BBB is impermeable to the liquid due to tight endothelial unions; however, under pathological conditions, endothelial hydraulic conductivity rises, allowing the passage of liquid through the vascular wall. This increase in vascular permeability also produces plasmatic extravasation, rich in proteins which end up collecting mainly in the extracellular space of the white matter and subsequently in the glia. Vasogenic edema tends to be peri-focal, circumscribed to the initial lesion, but progresses towards unharmed white matter by diffusion and tissue pressure gradient. Although vasogenic edema depends on the permeability of the BBB, the main force is the hydrostatic capillary pressure, which depends on systemic arterial pressure and the RVC. This holds therapeutic importance because increments in the main arterial pressure, even more so when associated with disturbed autoregulation, increase vasogenic edema. However, we think that the hydrostatic pressure by itself is very unlikely to generate vasogenic edema in patients with an intact BBB.
Cytotoxic edema is related to direct neuroglial injury. It's characterized by augmented cerebral cellular volume at the expense of the intracellular space. It mainly affects the gray matter. The underlying mechanisms are complex and include cellular metabolic disturbances, with the accumulation of intracellular sodium due to a dysfunction of the ionic pumps which bring liquid from the extracellular space.
The main causes are: brain ischemia, brain hypoxia, neurotrauma, meningitis, hyperosmolar states.
Osmotic edema is a cellular and interstitial edema linked to a rapid and sharp decrease in serum osmolarity, as occurs in hyponatremia. This results in an important osmotic gradient through the BBB. Normally, the BBB inhibits the passage of liquid excess, but under pathological conditions, its integrity could be affected. In addition, a positive regulation for water channels, aquaporines, could favour its passage through the BBB.
Interstitial-peri-ependimary edema is linked to CSF obstruction as in hydrocephalus, usually with CSF deviation from the ventricles to the interstitial space. It accumulates around the peri-ventricular white matter, assuming a crest form from the frontal and occipital horns.

25.10.2 Classification of Hydrocephalus

The classification of hydrocephalus is controversial. Classically, and since Dandy and Blackfan's work in the early 20th century (1914), hydrocephalus is classified as "obstructive" or non-communicant and "communicant". Later, with the advent of imaging techniques, first CT and then MRI, the exact location of obstruction points to CSF flow was determined with greater precision, leading from the notion of two types of hydrocephalus to multiple types according to the point where CSF is obstructed, with specific treatment techniques for each one [Rekate, 2008]. Non-communicant or obstructive hydrocephalus is produced by an alteration in CSF circulation in the foramen of Monro (passage from the lateral ventricle to the III ventricle), aqueduct of Sylvius (between the III and IV ventricle), the IV ventricle, the basal cisterns (between the spinal subarachnoid space and the cortical space) or between the cortical subarachnoid space and

the venous sinus (final absorption points) [Rekate, 2008]. Communicant hydrocephalus manifests with all cavities dilated, indicating a problem with CSF absorption. Ransohoff described this type of hydrocephalus as "extra-ventricular obstructive hydrocephalus", resulting from obstruction involving the cortical subarachnoid space. The current tendency is to think that most forms of hydrocephalus are obstructive and that the only real communicant hydrocephalus is the one due to CSF overproduction caused by choroid plexus papilloma, which is a rare condition. Another condition considered as hydrocephalus is external hydrocephalus, in which a new space is created, usually in the subdural space, where liquid is secreted and is in communication with the arachnoid space. Several hygromas resemble a real external hydrocephalus.

Hygroma refers to the collection of CSF in the subdural space, between the dura matter and the arachnoid space. Hygroma forms from a lesion in the arachnoid space, where CSF flows from the subarachnoid space to the subdural space. It may or may not be in communication with the CSF circulating system. In the latter case, the hygroma is drained to resolve the problem.

Sometimes an evacuated hygroma will recur; this implies that it is in total communication with the CSF circulation system and is called external hydrocephalus.

25.10.3 Effects of Hydrocephalus

Applying Laplace's law for a liquid inside a recipient:

$$T = 2 (P \times D)$$

where: T = tension; P = pressure; D = diameter.

The tension that produces hydrocephalus depends on pressure and diameter. Therefore, diversion of CFS to treat the hydrocephalus will reduce both pressure and tension. In many situations, however, even if we reduce the pressure, but the diameter is large, the tension will not drop. Therefore, we must wait for the tension to decrease before a proper effect can be obtained. It's the later one that affects the long pyramidal fibres, with the consequent march disorder.

In normotensive hydrocephalus, the pressure is already adjusted at the expense of a larger diameter (larger space) and a subsequently higher tension. Normotensive hydrocephalus was at some point hypertensive. The hydrocephalus must therefore be drained. And this is done by decreasing the pressure while waiting for the tension to fall and the diameter to adjust. Oftentimes the pressure must be reduced to subnormal values or even to negative values to reduce tension and ventricle diameter. When the resistance rises, the ventricle diameter increases, so that it's easy to suspect a hydrocephalus from a ventricle enlargement.

Another effect of hydrocephalus is hypertensive and has a certain evolution in the apparition of a white matter peri-ependimary edema due to an interstitial absorption deficit which is observed as crests around the frontal and occipital horns.

Pseudonormal pattern syndrome with hydrocephalus + cerebral edema: in this case, there are two concomitant processes: cerebral edema (of different etiology) and an alteration in liquid circulation. Therefore, we will have two forces, the centripetal force caused by the brain edema and the centrifugal force caused by the hydrocephalus. And we will have an enormous pressure within the balance state but with normal ventricles because they are two similar forces with different signs, i.e., forces which add up arithmetically but subtract geometrically. This generates a pseudonormal pattern, as shown

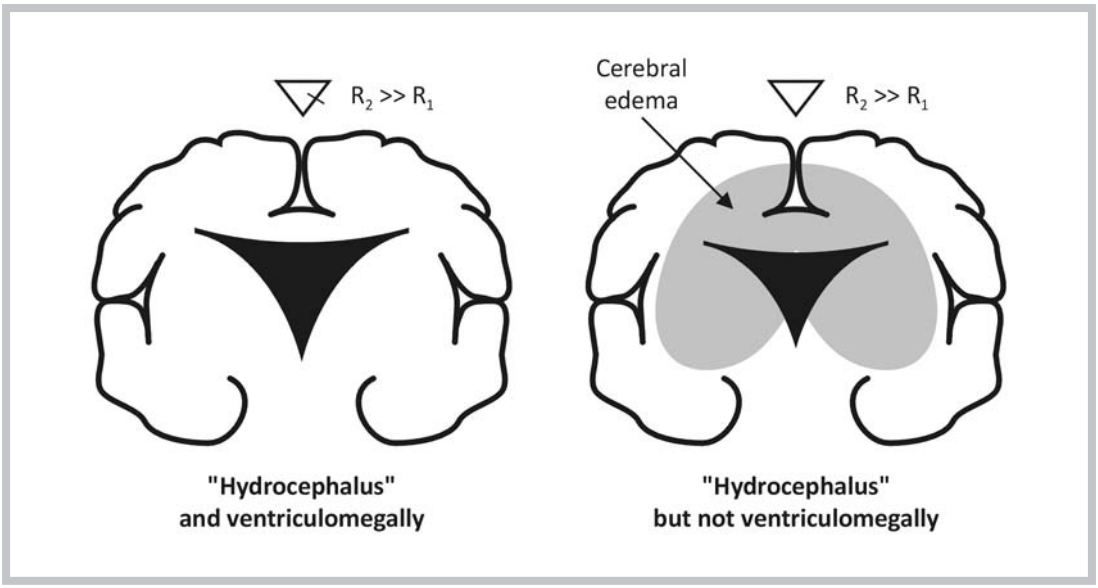

Figure 25.2. Representation of hydrocephalus with and without ventriculomegally.

in the diagram. This phenomenon was described by Levy and Rekate in post-trauma children, but we have observed it in subarachnoid hemorrhage (SAH), post-trauma meningitis, and cerebral cryptococcosis in neuroAIDS.

26.1 Introduction

While the pathologies that lead to an admission to a neurocritical care are varied, most have in common a natural history of secondary injury. Frequently, the process that leads to secondary injury is cerebral edema, the ubiquitous alteration of normal intracranial fluid and electrolyte balance. In addition to contending with respiratory failure, infection, anemia, and venous thrombosis, the routine treatment of cerebral edema is a common and essential intervention in a specialized neurologic ICU. The focus of this chapter will be to delineate the mechanisms that lead to cerebral edema as well as how it is measured, and its various treatments. Edema can be categorized by the anatomic and physiologic failure that leads to the accumulation of fluid; however, these distinctions may over simplify the reality of the pathology. The understanding of the biochemistry of cerebral fluid balance is in its infancy, but recent investigations into neural water channels have advanced our understanding and will hopefully lead to new interventions. Traditionally, mannitol was the mainstay of osmotic treatment, but now hypertonic salt solutions and renal ADH receptor antagonists have provided new tools for the neurointensivist in modulating cerebral edema by altering water and sodium homeostasis.

The first step in understanding cerebral edema is to explore why its effects are so detrimental. Certainly edema is not a foreign concept to other organ systems. For example, pulmonary edema occurs with impaired cardiac function. Interstitial accumulation of fluid or “third-spacing” is common in liver failure or with sepsis. With these other organ systems, edema can lead to a reversible impairment of normal function which may require intervention; however, in general, the accumulation of fluid does not lead to further injury. Cerebral edema is of an even greater concern in comparison to systemic edema due to the rigid design of the skull. The brain is maintained in a rigid container with minimal compliance. This has obvious survival advantages from traumatic insults; however, it limits expansion of tissue making the brain susceptible to the effects of compression and herniation. Each system has a method to try to compensate for edema. In the case of pulmonary edema, the lungs hyperventilate and the heart increases its output. The brain attempts to compensate for edema by removal of the fluid components of the skull: CSF (cerebro-spinal fluid) and blood.

The limitations of skull chamber compliance were first described in the late 18th and early 19th century and donned the “Monro-Kellie doctrine” or the “Monro-Kellie hypothesis.” The brain is composed of three components: cerebral spinal fluid (approximately 150 ml), blood (both venous and arterial, approximately 150 ml), and brain (parenchyma as well as dura madre and connective tissue, approximately 1400 ml). If there is an intracranial lesion increasing the contents of the skull it must be at the expense of one of its components or an increase in intracranial pressure will occur. Usually this means the entering of CSF or blood. As the intracranial pressure increases, brain perfusion may be compromised leading to global ischemia. Furthermore, the dura and tentorium form

Herniation syndrome	Manifestations
Subfalcine	Cingulate gyus herniates under falx cerebri; may compress anterior cerebral artery and cause contralateral lower extremity paresis
Transtentorial (uncal)	Herniation of mesial temporal lobe/uncus causing ipsilateral third nerve palsy and contralateral hemiparesis
Cerebeller (tonsilar)	Herniation of cerebellar tonsils through foramen magnum, with compression of medulla oblongata
Central herniation	Downward herniation of prosencephalon compressing diencephalon and mesencephalon

Table 26.1. **Manifestations of herniation syndrome.**

functionally separate compartments and pressure differentials caused by mass or edema between these compartments causes herniation of brain tissue and injury. Herniation is described in a set of classic syndromes: subfalcine, transtentorial (uncal), cerebellar (tonsilar), and central herniation (Table 26.1).

26.2 Causes of Edema

Edema is categorized by the dysfunction leading to its formation. Depending on the pathology, the edema may be diffuse (e.g. traumatic brain injury, TBI) or focal (e.g. tumor). While diffuse edema will more often increase global intracranial pressure (ICP) potentially impeding cerebral perfusion, focal edema will cause unopposed pressure differentials, leading to herniation. Edema is an unfortunate companion to most intracranial pathologies, and as disparate are the types of insult as are the ways they may disturb fluid balance. The various etiologies do have in common a similar scheme of inflammatory mediators such as glutamate, free oxygen radicals, kinins, lactate and simple ions exacerbating the edema. Previously, each type of lesion was categorized under a single mechanism; for example, vasogenic edema in tumor and cytotoxic edema in stroke. As can be seen in Table 26.2, recent investigations show that there are elements of both types of edema in both pathologies. Clearly, edema is not as simple as previously thought. As you read the following sections, keep in mind that all of these distinctions are artificial designations for a disease process that we still do not fully understand.

The first category of edema is **vasogenic**. The blood-brain barrier (BBB) is composed of tight endothelial junctions, the zona occludens that preclude the free movement of fluids and solutes. This creates an isolated environment with its own water and electrolyte balance providing protection from systemic disturbances and invading pathogens. If the barrier is disturbed, solute and water can enter the brain parenchyma leading to edema. Exudate is then formed containing plasma proteins and albumin. Often the extent of the barrier disruption is proportional to the amount of edema it causes. Pathologies related to BBB and vascular integrity compromise includes tumor, hemorrhage, trauma, hypertension and cerebral infarction (to a certain extent) and PRES (posterior reversible encephalopathy syndrome). The BBB may be open for weeks after infarction. While traditionally thought to close in a biphasic pattern corresponding with ischemia and reperfusion, the barrier disruption may be monophasic and open for more than a month [1]. With tumor, direct mechanical disruption of the barrier can occur, or production of vasoactive and endothelial factors can lead to edema. With excessive blood pressure, the autoregulatory mechanism of the cerebral vasculature may be overwhelmed and fluid

will leak into the parenchyma due to Starling forces. In posterior reversible encephalopathy syndrome (PRES), also called reversible posterior leukoencephalopathy syndrome (RPLE), cerebral edema occurs with a predilection for occipital and parietal lobes in the setting of uncontrolled blood pressure and leads to headache and visual disturbances. Also included in the vasogenic category is cerebral venous thrombosis associated with hypercoagulable states (including pregnancy and oral contraceptive use as well as intrinsic coagulopathies) leading to a vascular back pressure causing intraparenchymal hemorrhage as well as edema. At high altitudes a special condition can occur as part of acute mountain sickness. As the oxygen partial pressure decreases, hypoxia leads to a decrease in oxidative metabolism of the BBB causing a vasogenic type edema called high altitude cerebral edema (HACE).

The second major category is **cytotoxic edema**. In this category, the sodium/potassium ion exchanger fails leading to an alteration of the normal osmotic balance between the intracellular and extracellular compartments. As cell components degrade and free proteins accumulate, a further increase in intracellular osmolality occurs leading to a water shift termed cytotoxic edema. Diseases usually included under this heading are: cerebral infarction, global hypoxia (such as with cardiac arrest and strangulation), traumatic brain injury as well as tumor and abscess. These pathologies not only cause the direct destruction of parenchyma, but also disrupt the cellular structure or surrounding tissue as they expand and infiltrate worsening the edema.

A third category is **interstitial edema** that occurs with alteration of CSF physiology. CSF is created in choroid plexus, circulates through the ventricular system across the foramen of Monro, Magendie and Lushka and then exudes into the venous circulation via arachnoid villi. If this system is disrupted by an ependymal tumor creating too much CSF or any limitation of its outflow (such as a colloid cyst obstructing the Foramen of Monro or communicating hydrocephalus caused by subarachnoid hemorrhage) hydrostatic pressure will build causing hydrocephalus and flow of fluid into the interstitial space surrounding the ventricles. Traditional therapies for edema can only ameliorate the edema if the underlying cause of the hydrocephalus are not adequately managed.

Toxin exposure, hyperthermia, and systemic disturbances in osmotic balance can also lead to cerebral edema, such as occurs in case of decreased albumin production with liver failure, SIADH (syndrome of inappropriate anti diuretic hormone), psychogenic water intoxication, and beer potamania. Two-thirds of patients develop hyponatremia during hospitalization, but certainly it can occur in non-hospitalized or even in healthy patients, such as long-distance runners who excessively consume water beyond the body capacity to regulate it [2]. SIADH deserves special attention as it is such a frequently encountered problem in a neuro ICU and has been associated with signifi-

Type of edema	Associated pathologies
Vasogenic	• Tumor • Stroke (hemorrhagic/infarct) • Hypertension/PRES • Trauma • HACE
Cytotoxic	• Stroke (hemorrhagic/infarct) • Tumor • Global hypoxia/anoxia • Trauma • Infectious/abscess
Interstitial	• Subarachnoid hemorrhage • Tumor (obstructing outflow) • Tumor (CSF producing)
Systemic/ osmotic	• Liver failure • SIADH (syndrome of inappropriate antidiuretic hormone secretion) • Psychogenic water intoxication • Beer potomania • Overcorrection of hyperosmotic states: hyperglycemia, uremia

Table 26.2. **Type of edema and associated pathologies.**

cant increases in mortality [2]. Common causes of SIADH include drugs, cancer, pulmonary dysfunction, or most of CNS insults. High levels of opiates, angiotensin, endothelian, cytokines, and neurotransmitters can all lead to abnormal production of anti-diuretic hormone (ADH, vasopressin) from the posterior pituitary gland. Even without any CNS pathology, an acute change in ECF osmolality will alter the osmotic balance causing fluid to shift to the intracellular compartment which represents more than the 80% of the brain parenchyma. Excessive hemodialysis of urea can cause an acute decrease in extracellular osmolality leading to marked cerebral edema. Similarly, over rapid correction of hyperglycemia in non-ketotic hyperosmolar hyperglycemia can lead to edema. Regardless of the etiology, a systemic decreased osmolality will cause a shift of fluid from the ECF to the ICF likely leading to cerebral edema.

Cerebral edema was identified early in neurocritical care as a frequent complication of brain insults, but our knowledge about the pathophysiology or even the normal physiology was very limited. While it can be observed macroscopically, it wasn't until this decade that science began to unlock the molecular mechanisms that regulate brain water homeostasis. Clearly diffusion alone is not responsible for fluid management; the brain has very specific mechanisms for maintaining homeostasis creating a privileged, isolated environment. Why would water and salt balance be any different? Indeed, specific molecules controlling the movement of water have been discovered: aquaporins. Peter Agre is credited with beginning an exploration into these transmembrane molecules that are responsible for selective water transport. While working in his lab at Johns Hopkins in the early 1990's on red blood cells and the Rh factor, he identified a molecule responsible for water transport for which he won the Nobel Prize in 2003. This became known as aquaporin-1 or AQP1 and since then 11 different aquaporins have been discovered. The molecule is a small transmembrane protein selective for water with tandem repeats of membrane spanning helices with carboxyl and amino terminals towards the cytoplasmic side containing an aspargine-praline-alanine (APA) motif. Two subtypes are described, the traditional one, transporting water (AQP0, 1, 2, 4, 5, 8) and the aquaglycerolporin, transporting also glycerol (AQP3, 7, 9, 10) [3]. While AQP 1 predominates in the kidney, AQP4 predominates in the brain. It is a 32 kDa protein found in astrocyte end-feet processes close to capillaries. AQP1 is also found in choroid plexus and AQP9 is found in tanycytes [4].

Perivascular astrocytes can increase their volume two to three times in the presence of edema while those not located next to vessels show little change when challenged by free water. As the aquaporins are located mainly in the astrocytes, it is postulated that they are responsible for the change in astrocyte volume [5]. The relationship between aquaporins and cerebral edema has been supported experimentally in transgenic mice that are APQ4 null. Interestingly, The AQP null mice have less edema in cytotoxic edema models while they have more edema in vasogenic models [6,7]. This apparent contradiction may be due to multiple subtypes of AQP4 as well as their role not only in water transport but also in causing astrocyte migration in cerebral edema.

Aquaporin expression likely varies with the current physiologic state. The neural environment has rapid turnover of neurotransmitters and peptides requiring a dynamic system to maintain fluid and electrolyte balance. A growing body of evidence shows upregulation in AQP4 expression associated with edema in cerebral infarction models [8], and interestingly, the upregulation is increased more significantly in the presence of exogenous hypertonic saline [9]. Aquaporin expression is likely not just regulated by local factors but is influenced by systemic signals. For example, liver failure is thought to cause cerebral edema through elevated levels of ammonia and manganese. Astrocytes have been shown to swell in vitro in the presence of ammonia and alteration of aquaporins may be responsible for these changes [3].

26.3 Methods to Measure Edema

When treating cerebral edema it is important to have some way to measure its severity in order to determine whether it is being adequately treated or if a different intervention is needed. Three different methods are usually used: clinical exam, radiographic findings, and invasive monitoring. The choice of a specific exam depends on the location of the insult and the neurologic function of the affected tissue. If the patient has a frontal lobe tumor and shows progression of abulia, impulsiveness, somnolence or language deficit, then the edema may be getting worse. In a temporal subdural with uncal herniation, a pupil becoming fixed and dilated or worsening of hemiparesis may indicate that the cerebral edema is progressing leading to compression of the third cranial nerve.

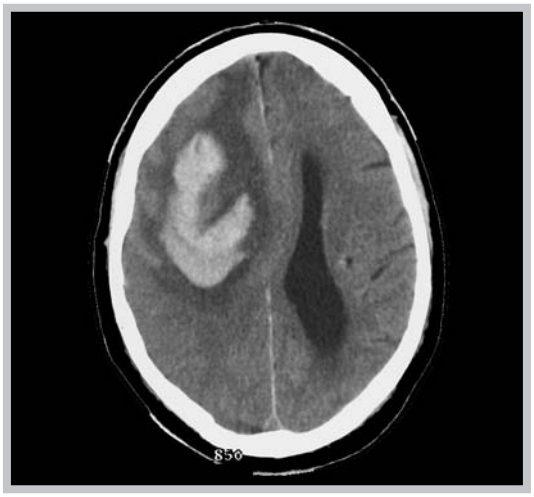

Figure 26.1. Hemorrhagic stroke with cytotoxic edema as indicated by hypodensity surrounding the hemorrhage.

While clinical changes are the most important endpoint of cerebral edema, they indicate an advanced stage and therefore should be coupled with other methods such as radiography. Cerebral edema can be identified by computed tomography (CT) observing low density attenuation around the primary CNS insult (Figure 26.1) causing mass effect. Examining its location and dimension, one can estimate the time of the lesion progression and its effects on the surrounding tissue. The effects of the edema can be identified by the amount of sulcal and cisternal effacement or shifting of tissue out of its normal location (Figure 26.2) such as midline shift or temporal lobe herniation through the tentorum cerebelli. MRI can provide further detail of the location and extent of edema with T2 or FLAIR imaging.

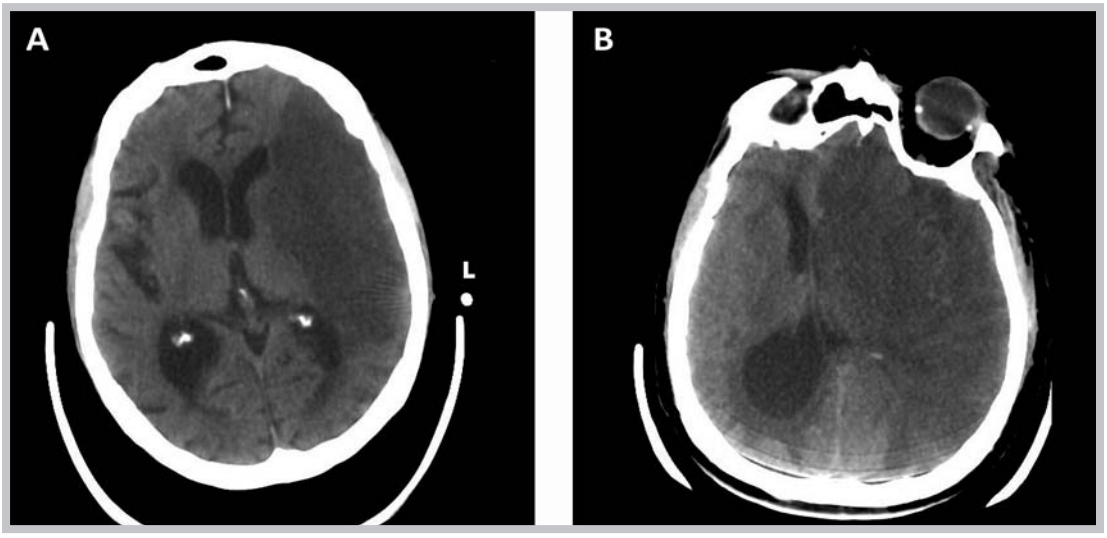

Figure 26.2. Cerebral infarction with edema causing effacement of sulci and ventricles as well as herniation and midline shift of the left hemisphere towards the right.

Cerebral edema can also be measured indirectly by quantifying changes in ICP measured invasively. While the primary insult will have a certain degree of effect in ICP, subsequent changes are more likely due to changes in edema. The intraventricular catheter (ventriculostomy) is a soft tube placed through a burr hole into the lateral ventricle. This not only allows measurement of ICP, but also allows removal of CSF which can relieve pressure caused by edema. The implantable transducer is drilled through the skull with a probe that extends into the parenchyma allowing it to measure ICP but not allowing the removal of fluid. ICP measurement is often the method of choice in diffuse injury such as TBI or global hyponatremia/hyposmolarity caused by metabolic derangements or liver failure, as the CT scan may not show any focal changes. These changes can be followed radiographically in order to determine if an intervention is needed, as well as the response to it.

26.4 Treatment

Now that the causes and methods to measure edema have been explored, we will discuss the treatment of cerebral edema. Several strategies have been developed to treat cerebral edema, both medically and surgically. We'll focus on medical therapies to remove the excess of fluid related to edema. Surgery can effectively treat edema not only by removing the primary insult, but also by removing a large bone flap allowing decompression of edematous tissue. Alternatively, metabolic suppression through induction of hypothermia or drug induced coma can reduce metabolic activity providing protection from edema.

Osmotic therapy has long been the mainstay of medical therapy of cerebral edema. The use of osmotic therapy is based on water diffusion; two solutions separated by a semipermeable membrane will allow the flow of solvent from the compartment with lower solute concentration to the one with the higher concentration. In addition to the barrier created by the vascular endothelium, the BBB will prevent solute from following solvent. The same principle that leads to edema can guide its treatment. Accumulation of osmotically active particles from cell death or leakage caused by membrane breakdown creates an abnormal osmotic gradient which is treated with mannitol to create a new one.

Mannitol is the most commonly used osmotic agent for the treatment of cerebral edema. It is a sugar alcohol with the chemical formula $C_6H_8(OH)_6$. Other examples of sugar alcohols include xylitol and sorbitol. Its properties were first described by Weed and McKibben in 1919 but its use to treat cerebral edema wasn't common until the 1960s. Its role as the ideal osmotic agent is based on the fact that it has a high reflection coefficient, a measurement of how much a substance is excluded by a membrane. The higher the coefficient, the more likely it is to be excluded by the BBB. Sodium chloride has an approximate coefficient of 0.95 (rated 0 to 1) while mannitol coefficient is 0.90. Because it is largely excluded and is not metabolized by the brain or liver, it is an osmotically active particle as long as the cell membrane and BBB are intact. After administrating a dose, it distributes within a few minutes through the extracellular compartment [10]. The effects of mannitol occur in multiple phases. First, it removes excess fluid by creating an osmotic gradient in favor of the ECF over the ICF. Secondly, mannitol acts as osmotic diuretic: as it is excreted by the kidney, it removes free water and thereby reduces overall volume status. Additional postulated effects of mannitol include increasing RBC rheology, thus reducing blood viscosity. As this leads to increased blood flow, cerebral vascular autoregulation may decrease blood volume, potentially assisting in decreasing

ICP. Furthermore, it is postulated that mannitol acts as a free radical scavenger reducing the inflammatory cascade present in cytotoxic edema.

The first question concerning mannitol is, is it effective? The literature clearly shows that it can decrease ICP in TBI [10]. This effect seems to be dose-dependent and higher doses show a more durable ICP control [11]. In respect of cerebral infarction, some animal models show a decrease in peri-infarct edema with mannitol as well as residual deficit, but other models do not show efficacy. The Cochrane review of mannitol in stroke does not find evidence for improvement in outcomes [12]; but the American Heart Association Guidelines still recommends it as a potential therapy based on expert opinion. While osmotic therapy clearly can alter ICP, whether it can cause an improvement in outcome is much harder to demonstrate. In many patients mannitol doesn't seem to affect a patient's sodium level: in one series of 167 patients, 73 (44%) didn't have an increase of sodium greater than 5 mEq/l while 37 patients (22%) didn't have a rise greater than 1 mEq/l [10].

Typical doses of mannitol are 0.5 to 1.5 g/kg given in four to six hour increments. The main limitations of its use are excessive diuresis causing volume depletion which may lead to renal insufficiency, rebound cerebral edema, and renal failure if it obstructs the renal tubules. Within hours to days of mannitol administration, the brain adapts to the higher osmolality by accumulating yet to be described organic osmoles called "idiogenic osmoles" in an attempt to restore normal cell size. This might explain why its effects seem time and dose limited; however, it is likely that this same phenomenon happens with hypertonic saline or other osmotic therapies.

A possible limitation to mannitol therapy is that as it creates an osmotic gradient most effectively across an intact BBB, it may preferentially extract water from the intact brain and not be as effective in the damaged brain. Consequently, it could theoretically exacerbate the intracranial pressure differential and actually aggravate tissue shifts. This complication may be prevented, however, if mannitol is fully eliminated before administering another dose. The complete clearance of mannitol by the kidneys given sufficient time has been well documented, including MRI spectroscopy showing end stage renal patients treated with mannitol that has leaked into the brain parenchyma who demonstrates absence of mannitol after dialysis [13].

In order to ensure proper clearance and prevention of rebound of cerebral edema, mannitol levels need to be monitored. The goal is to ensure proper clearance between doses. Mannitol cannot be routinely measured in a clinical setting. As a surrogate, serum osmolality is directly measured and compared to the calculated osmolality. The calculated osmolality is simplified to the dominate serum solutes sodium, urea, and glucose. The difference between the measured and calculated osmolality will then be composed of the unmeasured osmoles including mannitol and called the "osmotic gap" (OG).

Osmolality is calculated using the following euation:

$$2Na^{+} + (BUN / 2.8) + (glucose / 18)$$

where BUN = bllod urea nitrogen.

This osmotic gap has been validated by studies as an indicator for mannitol levels with a high correlation of OG to mannitol [14]. Historically, some authors recommended to follow a safety level of osmolarity equal to 320 mOsm/l, but such practice is not well founded as it relies on studies where mannitol was given as a continuous infusion, which is not common in clinical practice. It is important that the osmolality and gap are measured before the mannitol is administered as the gap is used to measure the trough of the drug and not its peak. Gap is not used to measure efficacy but to prevent toxicity by ensuring

mannitol is cleared from the blood after each dose. If the current dose is not obtaining the desired effect on the cerebral edema, it can be increased depending on the change of the osmotic gap from its baseline.

The next issue to address is the potential adverse effects caused by inducing a hypernatremic state. To show the extent of the concern, some authors report a mortality of 40% to 60% in those with elevated sodium but this might be do their admitting diagnosis and not the sodium perturberance itself. Hypernatremia can occasionally be found in dehydrated and cognitively impaired patients, but it usually occurs in hospitalized patients. Certainly in a neurologic and neurosurgical ICU hypernatremia is common even in subjects not on osmotic therapies, due to the fact that these patients are obtunded, having central insults causing diabetes insipidus, and central fevers causing insensible fluid loss. Hypernatremia can cause renal failure, gastrointestinal dysfunction, cardiac dysfunction, and worsening delirium. Mannitol itself can be nephrotoxic if it accumulates in the kidneys and shouldn't be used in people with significant renal impairment. Furthermore, patients with poor renal function caused by such things as hypertension and diabetes require careful monitoring. Typically, in our ICU we use a maxiumum sodium level of 160 mEq/l. In a 6.5 year retrospective analysis of more than four thousand patients, sodium over 160 mEq/l was found to have independent increased mortality on multivariative analysis [15]. Once a patient recovers from their primary insult, it is safe to correct the sodium at a rate no faster than 5-10 mEq/l/day to avoid rebound edema. Additionally, magnesium and phosphorous should be followed on a daily basis to monitor for depletion associated with osmotic dieresis.

Hypertonic saline (HS) has become increasing popular as an alternative to mannitol to treat cerebral edema. Skeptics of HS would point out that mannitol might not be solely effective because of the osmotic effects but because of its other actions as described above, but still consider it a reasonable alternative in patients with renal impairment or refractory to mannitol therapy. It certainly has the advantages of being a volume expander, and therefore might be superior in trauma. In addition, patients with subarachnoid hemorrhage may have edema but also be at risk for developing vasospasm if their volume is depleted by mannitol. Insufficient head to head comparison studies have been done, which are largely limited by varying doses used (how much hypertonic saline is clinically equivalent to how much mannitol?) and the heterogenicity of the patient population treated for cerebral edema. Hypertonic saline does have a slightly higher reflection coefficient than mannitol, and therefore less risk of rebound, but it also has other higher risks. For example, more rapid sodium alterations increase the risk of central pontine myelinolysis. Hypertonic saline leads to significant volume expansion which may lead to heart failure and pulmonary edema if not taken into consideration. The excessive chloride with HS increases the risk of hyperchloremic metabolic acidosis. While it does lack of free radical scavenger properties, it has been correlated with decreased ICP in both adults and children [10]. While mannitol is still the first line drug for cerebral edema, there are patient populations for which HS may be an appropriate alternative.

While mannitol is by far the most commonly used osmotic agent, others have been used. **Glycerol** is a sugar occasionally used with the theoretical advantage of being metabolized after crossing the BBB making the likelihood of rebound unlikely. It is hard to comment on glycerol efficacy, because of lack of substantial studies or common clinical experience.

Furosemide is commonly used for control of patient's overall volume status, and its efficacy is certainly well established. **Steroids** such as dexamethasone are the mainstay of vasogenic cerebral edema as they are well established in stabilizing the integrity of the BBB and thereby reducing fluid influx. Pathologies such as tumor-associated edema are commonly treated with steroids, but they have not proven effective in other patholo-

gies such as stroke. Peritumoral brain edema (PTBE) is related to inflammatory mediators secreted by the tumor such as interleukin [16] and growth factors such as vascular endothelial growth factor (VEGF) causing abnormal vascularization with impaired capillary endothelial tight junctions that leads to vasogenic edema [17]. Steroids have not been shown to be effective in cytotoxic edema probably because the integrity of the BBB is not necessarily compromised in these conditions.

As stated previously, SIADH is a common phenomenon in patients with CNS insults. Hyponatremia can worsen cerebral edema; therefore, it's worthwhile to discuss its treatment. A relatively new therapy is the **V1A/V2 (arginine vasopressor) receptor antagonists** such as conivaptan and tolvaptan. They treat SIADH by directly blocking the supraphysiologic ADH at the renal tubule allowing an aquaresis. Previously SIADH was treated with limiting free water intake, hypertonic solutions, and furosemide. Its use requires a careful distinction between cerebral salt wasting and SIADH because in the case of salt wasting syndrome, the further volume depletion with V1A/V2 antagonists would lead to a more severe hypovolemia. Furthermore, its use in subarachnoid hemorrhage patients must be carefully monitored because of the risk of volume depletion contributing to vasospasm. ADH antagonists will cause an aquaresis even in normotremic patients and thereby could be used to treat cerebral edema. Generally speaking, it is better to use ADH antagonists in hyponatremia associated with SIADH, rather than in cerebral edema, but future studies may highlight their role in inducing hypernatremia.

26.5 Conclusions

While cerebral edema seems a relatively simple concept, developments in both clinical medicine and basic science have shown that its causes are as diverse as the disease associated with it and its physiology has complex regulation. We are used to distinguish different types of edema (cytotoxic, vasogenic, hydrostatic, and osmotic); however, most of the diseases encountered in a neurologic ICU show combinations of these types of edema. While many osmotic therapies have been used, mannitol is still the mainstay of treatment, and if used and monitored appropriately it has little risk. The growing use of hypertonic saline will likely continue to increase and in some cases may be a better choice than mannitol. The most exciting development in the science and treatment of cerebral edema is a growing understanding of the role and regulation of aquaporins, whose modulation is already being tested [18] in animal studies and may lead to novel therapies to alter not just the location of fluid by osmotic gradient but augment the brains ability to compensate for edema.

It is quite possible that the phrase "primum non nocere" is more applicable to the treatment of traumatic brain injury in the acute stage than any other pathology. Maintaining an optimal cerebral environment and correctly treating intracranial hypertension are fundamental in avoiding added injury to our patients and achieving the continual decrease in mortality and poor results.

27.1 Introduction

Traumatic brain injury (TBI) continues to be the leading cause of death and disability in people under 45 years of age. Furthermore, incidence is on the increase; at present this disease is considered pandemic, with particular repercussions for less developed countries. However, this pessimistic finding contrasts with a clear, objectively positive observation in recent years: although high-energy injuries involving the severest acceleration/deceleration mechanisms have increased, mortality rates and poor results have decreased significantly. In 1991 the information gathered by the American Traumatic Coma Data Bank (TCDB) indicated that mortality rates were situated at 36%, with an overall percentage of poor outcome (death, vegetative state or severe disability) reaching nearly 60% of patients with severe TBI [1]. Recent analysis indicates that this figure has been reduced very significantly to 40% in centers with extensive experience in the management of brain injured patients [2].

The main explanation for this decrease should be sought in the significant changes in treatment applied to these patients. However, drugs and therapeutic maneuvers used on patients with TBI (mannitol, hyperventilation, barbiturates, etc.) are unchanged in the last 20 years and all attempts to introduce new neuroprotective drugs (glutamate inhibitors, calcium channel blockers, or oxygen-free radical inhibitors, among others) have failed. The causes of this decline in poor outcome may be explained by a combination of factors, including the following: 1) improved understanding of the pathophysiology

of TBI, 2) the multidisciplinary management applied to this condition, 3) the creation of units specialized in the management of these types of neurocritical patients, and 4) the development and following of clinical practice guidelines (CPG) that have advocated the use of standardized and systematic treatment protocols for the treatment of intracranial hypertension (ICH) [3,4]. Nevertheless, the treatment of TBI is still prone to excessive variability in the numerous hospitals that receive and treat such patients. This variability, while justified in some cases, can be a reflection of reluctance on the part of the various medical groups implicated to accept that the systematic treatment of these cases brings about a clear benefit, not only for patients but also for the social environment in which they live.

In the last decade, our center has observed a progressive reduction in mortality and an increase in good outcome in patients with severe TBI. We are convinced that this change is due to the fact that our center was able to carry out the 4 measures described above, especially the systematic, stepwise protocol for the management of these patients optimized on the basis of a multimodal neuromonitoring protocol. This chapter summarizes the series of general measures and the systematic approach used by our hospital for TBI patients admitted to the Neurotraumatology Intensive Care Unit (ICU).

In this chapter, the general measures and specific treatment for ICH given to in-hospital patients with severe traumatic brain injury are outlined. We assume that the foundations of "evidence-based medicine" and other aspects, including multimodal neuromonitoring or the management of specific aspects, such as fluid therapy or nutrition, have been covered extensively in other chapters of this work. In this chapter we focus on general measures and first level measures in the treatment of ICH based mainly on recommendations of the Brain Trauma Foundation (BTF) without ruling out additional sources of evidence, such as the Cochrane Collaboration.

We aim at providing information that is above all practical and concise by supplementing the text with a series of useful tables and algorithms. In addition to theoretical information, we have included an illustrative case report in which we describe the maneuvers used and identify the controversial points or inadequate aspects of patient management.

27.2 Neurotraumatic Patient Treatment in the Hospital

In this section we refer to the treatment of patients once they have arrived at the final hospital. Treatment at the receiving hospital should begin in the emergency department. The therapeutic conduct and the type and number of complementary testing to be carried out must be individualized in all cases. As a general rule, however, once the airway and hemodynamic status is stable, patients should be evaluated according to the Glasgow Coma Scale (GCS), noting whether there are differences at the initial assessment made after resuscitation, during transport of the patient, or at the first reference center. In addition to the GCS score, breathing pattern and the size and shape of the pupils, pupil reactivity to light and the presence of corneal reflexes should all be noted during the neurological examination. In paralyzed patients undergoing mechanical ventilation, prehospital evaluation using the GCS will guide the therapeutic management. In cases where this assessment is unreliable and the CT brain scan shows no obvious injuries, it is advisable to reverse paralysis and re-examine the patient before proceeding to monitoring and aggressive, and possibly unjustified, treatment.

Any associated systemic injuries (pulmonary, genitourinary, abdominal, etc.) should be evaluated and treated in order of priority. At the same time, external craniofacial inju-

ries are evaluated (otorrhagia, head contusions, etc.) and the possible existence of cervical injuries are determined before transferring the patient to the neuroradiology unit for tomography scanning. It is important that the transfer to the CT area is under optimal conditions, which includes ensuring flow of the airway, adequate ventilation and proper functioning of the fluid delivery pathways. Too often, these patients suffer significant deterioration in their neurological status during the periods spent in the hospital corridors waiting for various complementary examinations.

Tomography scans should be performed in a quick and technically correct manner because this first exploration allows existing brain injury to be assessed and classify the patient according to the different groups of pathologies described by Marshall et al. [5]. Based on the volume of the lesions, the status of cistern compression and the degree of deviation from the midline, this classification consists of 4 types of diffuse lesions and the presence of intra- or extra-axial focal lesions requiring surgical evacuation. The Marshall classification also provides initial prognostic information because each of the injury categories is associated with an increased risk of ICH and a poor outcome (Figure 27.1) [6].

Early surgical treatment of space-occupying lesions is essential for the correct treatment of patients with severe TBI. At our center, all space-occupying accesible lesions with a volume exceeding 25 ml are evacuated surgically. In our opinion, the use of the initial levels of intracranial pressure (ICP) in making surgical decisions, while controversial, is helpful in doubtful cases. In general, we can say that regardless of their level of consciousness, patients with focal lesions whose ICP levels are moderately elevated will

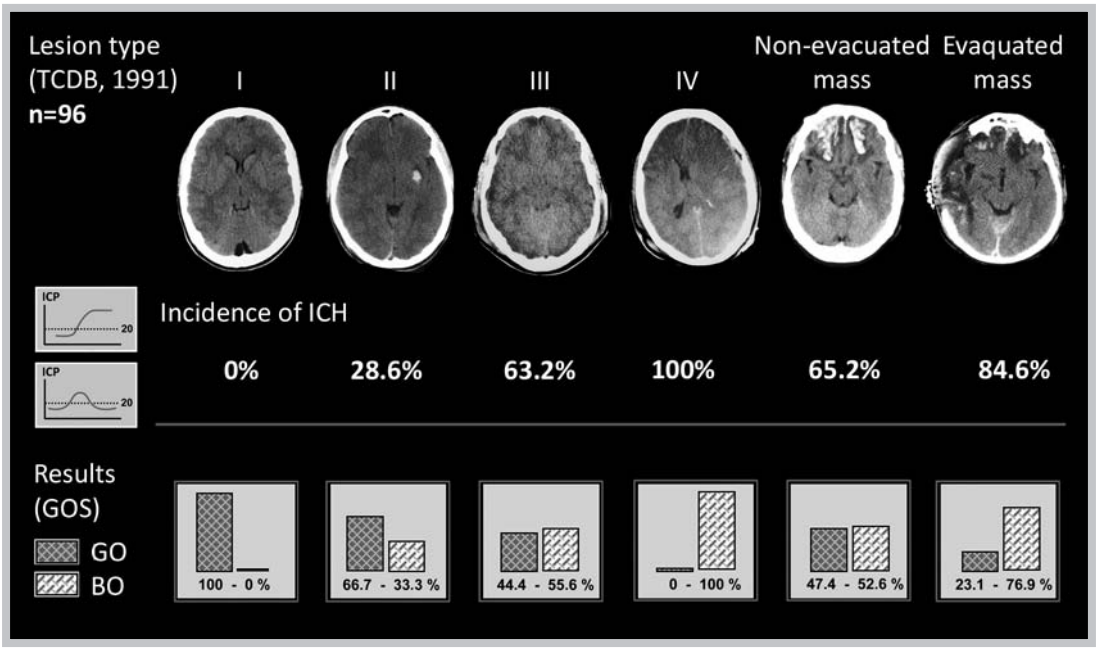

Figure 27.1. **Traumatic brain injury according to the classification system of the American Traumatic Coma Data Bank. (I) Diffuse type I injury (comatose patient with normal CT). (II) Diffuse type II injury (permeable cisterns, midline centered with small lesions). (III) Diffuse type III injury (bilateral brain swelling). (IV) Diffuse type IV injury (midline shift >5 mm with no focal lesions to account for this distortion in the brain). Non-evacuated mass is any intra- or extracerebral lesions with a volume >25 ml that were not evacuated. Evacuated mass is any evacuated focal lesion. The image shows the different percentages of intracranial hypertension incidence and associated poor outcome in the 96 patients included in the study [6].**

GO = Good Outcome

BO = Bad Outcome

present late neurologic deterioration, the result of uncontrolled ICP elevations in a large percentage of cases [7,8]. We feel this point justifies an aggressive therapeutic approach aimed at preventing these situations. The wait-and-see approach in these types of patients, especially those presenting concussions, often has catastrophic results. Although the predominant type of lesion may vary depending on the damaging mechanism, it is generally estimated that 25-45% of patients with severe TBI, 3-12% of those with moderate TBI, and 1 in 500 mild TBI patients present a focal lesion requiring intervention.

27.3 Multimodal Monitoring in Patients With Severe Traumatic Brain Injury

Once the CT scan is performed and any space-occupying lesions are evacuated, patients are transferred to the ICU, where the therapeutic approach should be aimed at creating a means favorable to the recovery from primary lesions and the early treatment and prevention of secondary injuries. The difficulty in carrying out appropriate clinical monitoring in these patients requires the use of a multimodal monitoring protocol that includes neurological and systemic parameters. It is well established that a score less than or equal to 8 on the GCS reflects a risk of ICH. In studies performed by the Traumatic Coma Data Bank during the 1990s, it was shown that between 50-75% of these patients had ICH at some point during the evolution of the injury [9]. At present, we know that this incidence can be adjusted according to the type of brain injury[6] and that it decreases dramatically with an aggressive surgical approach to focal lesions.

The high risk of ICH in severe TBI explains why continuous monitoring of ICP has been implemented almost routinely in the management of these patients, especially since the 1995 publication of the CPG for TBI management developed by the BTF. These guidelines have been updated and endorsed by most international scientific societies. The latest version, published in 2007, reaffirmed with level II evidence that ICP monitoring should be applied in all severe TBI patients with an abnormal CT scan upon admission [10]. The implementation of an ICP sensor is also indicated in TBI patients with an initial CT scan that is normal if a GCS score of less than 8 can be confirmed. This is based on the fact that 1 of every 3 of these patients show new brain lesions in the subsequent CT scan [11]. In recent years, however, we have found that the value of ICP as a parameter alone is insufficient for decision making in complex cases. In addition to the ICP sensor in the latest edition of the BTF guidelines, it is also recommended that additional monitoring systems be included to provide overall or specific information regarding cerebral oxygen availability, such as oxygen saturation in the jugular bulb (SjO_2) or catheters for direct measurement of oxygen pressure at the tissue level ($PtiO_2$) [12].

In our center, all patients with TBI who present a diffuse lesion, or those in whom a focal lesion was evacuated, undergo implantation of an intracranial pressure (ICP), intraventricular, or intraparenchymal sensor. When using an intraparenchymal sensor, the more damaged brain hemisphere is selected [13]. In addition to the ICP sensor, TBI patients are implanted with a retrograde catheter in the predominant jugular vein and/or a catheter for tissue oximetry in the less injured hemisphere. In selected cases, 1 or 2 cerebral microdialysis catheters are also placed in the patient. These new monitoring techniques allow continuous information on various aspects of blood flow and cerebral metabolism to be obtained. At the systemic level, multimonitoring of patients is also recommended. This basically involves the control of diuresis, heart rate, blood pressure (with the transducer leveled at the foramen of Monro), and central venous pressure, in addition to measuring the pressure in the pulmonary artery in cases of hemodynamic instability.

27.4 General Measures for Treating Brain Injured Patients

While in the ICU, severe TBI patients undergo monitoring of both ICP and cerebral and systemic hemodynamics. This is what guides the course of treatment for these patients. Although many of these cases involve associated systemic injuries, we generally refer to the patient with "pure" severe TBI or with associated lesions that do not significantly modify treatment. To simplify, we could define the key therapeutic targets in patients with intracranial hypertension as reducing ICP and maintaining a mean arterial pressure (MAP) sufficient to maintain adecuate cerebral perfusion pressure (CPP). In severe TBI patients, a series of general measures, regardless of the initial value of the ICP, should be taken early on to achieve a correct hemodynamic stability and an adequate supply of nutrients, and to avoid any factors that increase ICP. The latter may include maladaptive breathing, improper positioning of the patient (Figure 27.2), hypoxia, hypercapnia, high fever, seizures, hypo- or hypertension, and hyponatremia.

Maintaining normovolemia and making a correct selection of serums to administer play an essential role in the treatment of these patients. Electrolyte management includes maintaining an adequate circulating blood volume (which helps maintain the correct CPP and availability of O_2), a volume in the brain interstitium that is somewhat lowered, and a discrete serum hyperosmolality. It is recommended that isotonic solutions are administered in TBI patients. A NaCl solution at 0.9% is considered the crystalloid of choice. A 5% albumin or hydroxy-ethyl starch of low molecular weight are the more widely accepted colloids. The administration of glucose solutions is not advised unless there is a risk of hypoglycemia because this condition may exacerbate ischemic injury. In addition, glucose causes an osmotic drag of water in the transport, which may contribute to the formation of cerebral edema.

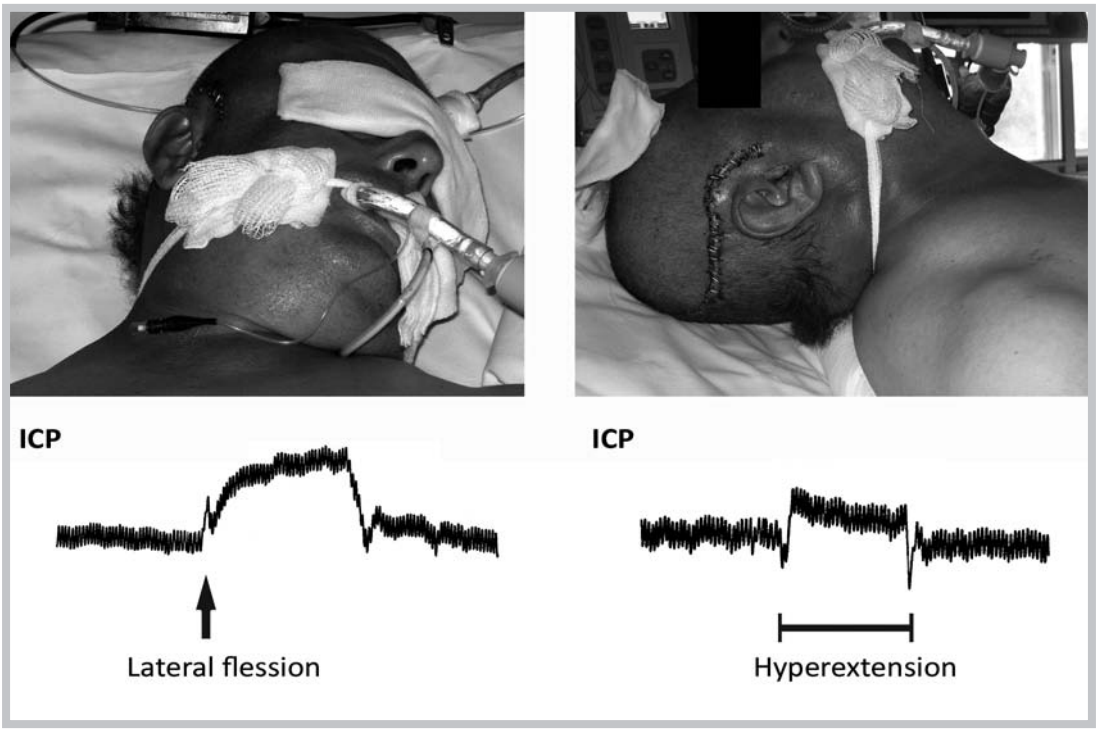

Figure 27.2. **Image showing the effect of cranial position on intracranial pressure (ICP). Both hyperextension (right) and lateral flexion (left) in moderate amounts cause evident increases in ICP.**

Ideally, the objectives of this set of comprehensive measures are aimed at: 1) evacuating lesions with a volume >25 ml occupying intra- or extracerebral space, 2) maintaining normothermia, with a core temperature (rectal, esophageal or bladder) <37 °C, 3) maintaining an ICP below 20 mmHg, 4) maintaining levels of MAP >90 mmHg that allow CPP values ≥ 60 mmHg [14], 5) maintaining a total content of hemoglobin and a level of PaO_2 to ensure proper transport of oxygen to the brain (recommended: hemoglobin >10 g/dl and PaO_2 of 100-110 mmHg), 6) maintaining values of SaO_2 >95% associated, if possible, with normocapnia and 7) maintaining values for SjO_2 above 60% [15].
General measures also include proper analgesia and sedation of the patient. Analgesics and sedatives should be used in combination to enhance their effects and thereby reduce the individual doses. Given the depressant effect of these drugs on the respiratory system, mechanical ventilation should be used. To address their cardiovascular impact, doses may be adjusted according to the patient's hemodynamic status. At present, **midazolam** is considered the sedative of choice due to its short half-life in comparison to other benzodiazepines. Other sedatives, such as **propofol**, may cause arterial hypotension, an important drawback. **Morphine hydrochloride** and **fentanyl** are the more adequate analgesics because a conventional dose not increase cerebral blood flow (CBF) or ICP.

27.5 Specific Treatment of Intracranial Hypertension

In cases where ICP >20 mmHg and the abovementioned maneuvers have been carried out correctly while ensuring that there are no new space-occupying lesions requiring surgical evacuation, a stepwise, additive treatment for ICH should be initiated. From the

Measurement	Recommendation	Level of evidence
Muscle relaxants	There are no specific recommendations	-
Evacuation of CSF	There are no specific recommendations	-
Mannitol	Without monitoring ICP, mannitol may only be given if signs of transtentorial herniation or progressive neurological deterioration are observed	III
	Mannitol is effective in controlling ICH when used at doses of 0.25-1 g/kg. When used, decreases in systolic arterial pressure (SAP) to below 90 mmHg should be avoided	II
Hypertonic saline solution	There are no specific recommendations	-
Hyperventilation (HV)	HV should not be used prophylactically ($PaCO_2$ <25 mmHg)	II
	HV should be used intermittently for ICH	III
	HV should be avoided during the first 24 hours of injury, when CBF is reduced	III
	If using HV, monitoring the availability of brain oxygen using SjO_2 or $PtiO_2$ is recommended	III

SAP = systolic arterial pressure
SjO_2 = jugular bulb oxygen saturation

time of the publication of the first version of CPG (1995) by the BTF, our center designed a treatment algorithm largely adapted to the recommendations of these guidelines. After almost 15 years, this algorithm remains essentially unchanged because the latest versions of these guides have not produced significant changes in most of the therapeutic measures used. However, this algorithm included, and includes, differential aspects, such as a less frequent use of barbiturates (this is discussed extensively in the chapter on second level measures in the treatment of ICH), additional maneuvers, such as hypertonic saline, as well as specific considerations for certain injuries obtained from other sources of evidence.

For patients with persistent intracranial hypertension, first level measures for the treatment of ICH, as outlined in the first 2 editions of the BTF CPG, will be initiated in addition to reviewing previous general measures. These measures include muscle relaxation, the evacuation of cerebrospinal fluid (CSF), the administration of hyperosmolar solutions, and hyperventilation. Almost all are based on type I or II levels of evidence (Table 27.1). In the sequence of application for treating ICH, the administration of muscle relaxants follows the evacuation of CSF, if possible. This therapeutic maneuver is only possible in cases in which ICP monitoring is done using an intraventricular catheter. Hyperventilation and/or the administration of hyperosmolar solutions are the subsequent therapeutic stages. When all these measures are insufficient, the BTF recommends the administration of barbiturates at doses sufficient to induce a burst-suppression pattern [16]. However, based on the controversies generated by the dissemination of the results of the Cochrane Collaboration on the real effectiveness of this drug [17], our center does not routinely consider using this therapeutic measure.

27.6 Muscle Relaxation

Despite the controversy that still exists in the literature on the use of muscle relaxants in the treatment of patients with severe TBI, it is generally accepted that the first specific maneuver to treat ICH should be muscle relaxation [18-21]. The periodic tracheal aspirations performed on these patients may incur significant elevations in ICP despite the additional administration of sedatives and analgesics. When the patient is given muscle relaxants continuously, these changes in ICP are reduced significantly. As an additional advantage, muscle relaxants reduce elevations in ICP that may occur during habitual movements of the patients (daily hygiene, postural changes, clapping, etc.), and facilitate mechanical ventilation. Despite the fact that the BTF do not include a specific chapter on muscle relaxants in its CPG, in its previous version and in the chapter on the early management of patients, the panel recognized that muscle relaxants facilitate the ventilation and treatment of ICH, although they do not address its use on specific patients [22]. For children, there are no specific recommendations for these drugs [23].

While the use of muscle relaxants during the prehospital phase or hypothermia treatment is unquestionable [24], a continuous infusion of muscle relaxants during hospital treatment has been associated with longer stays in the ICU and a greater dependence on the ventilator, both of which increase rates of septic complication in the patient [19,25]. Other problems associated with the prolonged administration of relaxants are the impossibility of making an appropriate neurological assessment, drug accumulation and the appearance, in some cases, of secondary myopathy [26]. The latter is enhanced by the co-administration of aminoglycosides and corticosteroids [26]. Despite these drawbacks, recent studies have not associated the use of muscle relaxants with a worse patient outcome [24].

Response*	Cause	Recommendation
TOF=0	Excessive muscle relaxation	Dose reduction or temporary suspension of relaxant administration
TOF=1	Appropriate level of muscular block	None
TOF=2-4	Inadequate level or absence of muscular block	Increase dosage of the drug

Table 27.2. **Monitoring the effectiveness of muscle relaxants using the "Train of Four" (TOF).**
TOF = 0: no muscle response by electrical stimulus
TOF = 1: muscular contraction by electrical stimulus
TOF = 2-4: two to four muscular contractions by electrical stimulus

Current recommendations on the use of muscle relaxants indicate that they should always be administered simultaneously with sedatives and analgesics. The dose should be the lowest possible amount, with monitoring of its effect using the train of four (TOF – peripheral nerve stimulator), and should be stopped at an early stage [22]. Adequate relaxation should cause a contraction by electrical stimulation. The administration of relaxants should be optimized according to the responses obtained in the TOF [15] (Table 27.2). Of the drugs emerging on the market, vecuronium at a dose of 0.01 to 0.05 mg/kg/hour is recommended because it allows for more hemodynamic stability [15]. Other alternatives continue to be pancuronium or cisatracurium. In the absence of contraindications, preventative measures for deep vein thrombosis and bedsores should be taken [22].

27.7 Evacuation of Cerebrospinal Fluid

When ICP increases, there is a physiological tendency toward the displacement of CSF from the cranial cavity to the spinal canal and an increase in elimination, mainly via the venous compartment. This phenomenon is one of the main mechanisms for compensating for increased volumes in a "closed" system like the cranial cavity and explains why patient ICP initially remains stable despite this increase (the "flat" area of the pressure-volume curve). In contrast, CSF formation is relatively constant and independent of ICP values. A slight but noticeable decrease in CSF production is observed only at very high levels of ICP. From a therapeutic standpoint, we can enhance the elimination of CSF by diverting it to outside of the cranio-spinal system using a ventricular or lumbar catheter. The implantation of a ventricular catheter is a routine maneuver in neurocritical patients, but the placement of a lumbar drain should be reserved as an alternative measure in the treatment of ICH, only applicable to certain patients and never in the initial phase of trauma.

Intracranial pressure monitoring via ventricular catheter permits not only the evacuation of CSF but also access to the CSF for sampling and/or drug administration. It is recommended that the catheter is open intermittently if needed, limiting the evacuation to 2-5 ml without exceeding 20 ml/h [15]. The ventricular catheter reservoir should be located about 20 cm from the external auditory canal (EAC), an anatomical reference for locating the foramen of Monro. In this position, CSF drains against a pressure of 20 cm of H_2O (15 mmHg). The need to evacuate CSF volumes >20 ml/h should be regarded as a treatment failure and requires an additional therapeutic measure, such as hyperosmolar solutions and/or moderate hyperventilation. Taking into account that the treatment of ICH is additive and not a substitutive, CSF drainage in these patients should not be dispensed with *a priori*, unless the ventricular system collapses. Ventricular drainage should

not be left open permanently because it distorts the ICP readings [27] (Figure 27.3) and subjects the patient to unnecessary risks. The only exception to this rule is in patients who present a dilated ventricular system secondary to trauma. In these cases, post-traumatic hydrocephalus plays a key role in ICH and requires a continuous opening in the system. In this subgroup of patients, it is advisable to measure ICP with a device separate from the ventricular catheter.

The implementation of a ventricular catheter is a relatively simple maneuver and is associated with a reduced complication rate, even when placed in a TBI patient with nor-

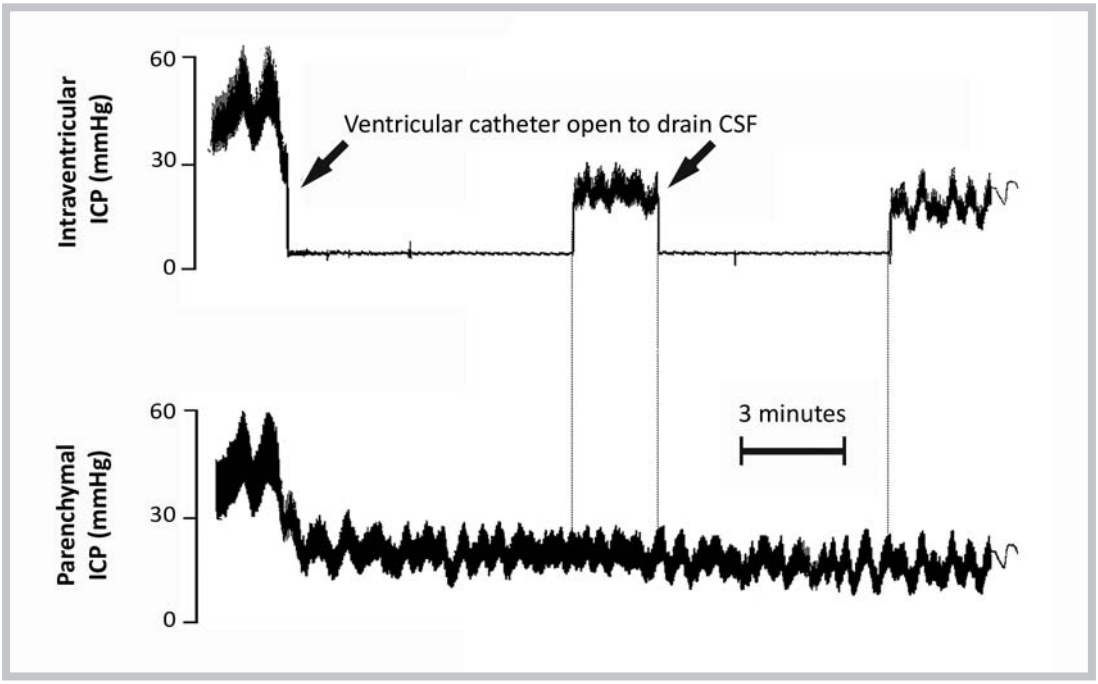

Figure 27.3. **Recording of simultaneous intracranial pressure (ICP) monitoring in parenchymal and intraventricular compartments. Observe how when the ventricular catheter remains closed the recordings match. However, when the ventricular catheter is opened to drain CSF, the intraventricular ICP recording is lost.**

A) Insertion of the catheter	• Avoid hyperextended cervical positions for prolonged periods of time • Avoid the sudden loss of large quantities of CSF • When using a fluid-coupled system, the ventricular catheter should be tunneled through the subcutaneous brain tissue (this maneuver is avoided if the ventricular catheter is inserted through a screw implanted in the cranial vault) • Initial position of the space 20 cm above the foramen of Monro (EAC)
B) Maintenance of the catheter	• Protect direct access to the ventricular catheter (silicone element) • Protect and prevent tampering of the 3-step keys • Biochemical and microbiological analysis of CSF every 48-72 hours • Intermittent opening of the system through the clamp (Figure 27.3) • Regular control of the volume of CSF being drained
C) Removal of catheter	• Suture the catheter exit point to prevent leakage of CSF • Send the removed catheter tip to the microbiology lab

Table 27.3. **Methodological recommendations to consider during the implementation, maintenance, and removal of ventricular catheters.**

CSF = cerebrospinal fluid

EAC = external auditory canal

mal or reduced ventricles [28]. Despite the advantages offered by new intraparenchymal devices, the BTF continues to recommend the use of a ventricular catheter to measure ICP because of the therapeutic potential and cost-benefit ratio [29]. However, the use of these devices increases the workload for nurses and exposes the patient to a series of potential complications, including: 1) infection, 2) catheter obstruction, usually by hematic content, 3) migration of the catheter, 4) CSF leakage through the space surrounding the catheter or from the residual hole after removal, and 5) over-drainage due to poor handling of the system. All these complications have been reported variably in the literature, although frequency is reduced with experience and rigorous protocols for the insertion and maintenance of ventricular catheters (Table 27.3). In patients with a collapsed ventricular system in the initial stage or those with a deviated midline, a ventricular catheter to measure ICP should not be inserted. In these patients, the sensor of choice is intraparenchymal and the treatment of ICH should be started with the administration of hyperosmolar solutions and/or moderate hyperventilation.

27.8 Hyperosmolar Solutions

For over 30 years hyperosmolar solutions have been central in the treatment of ICH. Mannitol has replaced other osmotic diuretics, which in some cases had increased side effects or were less effective in reducing ICP (urea, glycerol or sorbitol). Mannitol is considered one of the most useful drugs in the neurosurgical therapy arsenal and is the only hyperosmolar solution currently recommended by the BTF for the treatment of ICH [30]. However, there is evidence that hypertonic saline solutions are more useful than mannitol in some patients, therefore these solutions are also used in certain patients with TBI and ICH. To understand the fundamental mechanism of hyperosmolar solutions, the pathophysiology of the blood-brain barrier (BBB) must be recalled.

Under physiological conditions, the BBB limits the flow of substances from brain capillaries into the brain parenchyma. This consists of a moderately water-permeable membrane that is relatively impermeable to small solutes and proteins, and thus it maintains a balance between the transcapillary hydrostatic pressure gradient and the osmotic pressure gradient, which determines the flow. However, in areas with a disrupted BBB this balance does not exist and thus the passage of proteins and electrolytes through the membrane is permitted. The hydrostatic pressure in this case becomes the dominant force and favors the movement of fluid from the intravascular space to the brain tissue. This movement of solutes and fluid produces cerebral edema, increases ICP, and decreases CPP, favoring the development of secondary brain injury.

Initially, it was thought that the beneficial effect of osmolar substances on ICP was exclusively due to the dehydration produced at the brain tissue level. It has now been confirmed in animal models that osmolar substances cause a reduction in brain volume, although this occurs only in the non-injured areas of tissue with the BBB intact. At the same time, the decrease in ICP persists for some time after the plasma concentration of the osmotic substance has declined to below the level considered osmotically active. These findings suggest that hyperosmolar solutions act by additional mechanisms of action other than mere tissue dehydration.

At present, we know of two distinct mechanisms of action of mannitol: rheological effects and osmotic action [31]. Mannitol, given in bolus form, produces an expansion of circulating blood volume, decreases hematocrit levels, reduces blood viscosity (hemodilution), and increases CBF [32]. Secondary to the hemodynamic effects, a reflex vasoconstriction of cerebral vessels is produced, with a consequent drop in cerebral blood

volume and therefore a reduction in ICP [33]. These mechanisms of action may explain the rapid effect of mannitol on ICP (mere minutes) and the demonstrated fact that this drug is particularly effective in patients with a CPP under 70 mmHg.

The best known mechanism of action of mannitol is osmotic activity. This effect occurs between 15 and 30 minutes after administration, when an osmotic gradient between plasma and cells is established [32]. In the brain, mannitol does not cross the normal BBB, but remains in the cerebral vascular bed. In this situation there is a "pull" of water from the interstitial compartment to the intravascular compartment. When the BBB is injured, mannitol can penetrate the brain tissue, worsening the edema. Regarding additional mechanisms of action, it has also been found that mannitol reduces CSF production and the rigidity of red blood cells, facilitating their passage through small vessels and tissue areas with precarious perfusion.

It has been shown that the response to mannitol depends on the type of lesion, the values of the ICP, and the state of cerebral autoregulation [33,34]. Muizelaar et al. [33] showed that mannitol reduced ICP by 27% in patients with TBI and intact autoregulation, without changing CBF. However, when autoregulation was impaired, ICP decreased by only 4.7% and CBF increased. This suggests an individualized response to mannitol for each patient. In the treatment of ICH, mannitol should be the therapeutic measure of choice in situations of normal or reduced CBF.

Despite numerous studies, there are no defined protocols in relation to how this drug should be administered [35]. The dosage of mannitol required for the treatment of ICH differs depending on the author. In terms of its effect on ICP, the rate of infusion plays as important a role as the dose administered. At a higher rate of infusion, the decrease in ICP is more significant, but the duration of this effect is also shorter [36]. Doses of 0.5 g/kg of mannitol at 20% in 60 minutes is recommended in non-emergency situations or when prolonged treatment is expected. In emergency situations, a dose of 1 g/kg at a faster rate (30 minutes) can be administered. The decrease in ICP starts at 5-10 minutes, with a maximum effect at 60 minutes and a duration of 3-4 hours.

The association of mannitol and furosemide in the treatment of ICH is controversial. Clinical and experimental studies show that when combining the 2 drugs, the osmotic gradient induced by mannitol is prolonged [37]. In this partnership, furosemide inhibits the reabsorption of H_2O and electrolytes at the ascending limb of Henle's loop, delaying the restoration of the normal osmotic gradient across the BBB [37]. However, for some authors there is no clear evidence that the mannitol-furosemide association is more effective than the administration of mannitol alone. The addition of furosemide should be reserved for cases of fluid overload or pre-existing heart disease in which it is necessary to use mannitol.

Following administration of mannitol, diuresis must be replaced to prevent dehydration, volume depletion and hemoconcentration, factors that tend to create a situation of low cerebral perfusion because they act as vasodilator stimuli that produce secondary increases in ICP. Electrolyte replacement should aim to keep osmolality below 320 mOsm/kg, maintaining a normal circulating volume and cardiac output. At the same time, the maximum daily dose of 6 g/kg mannitol ahould not be exceeded because higher amounts increase the risk of hyperosmolality.

Side effects of mannitol have been reported to include acute volemic overload (hypervolemia) followed by volume depletion and dehydration, a rebound effect on ICP, hyperosmolality, and electrolyte disturbances (hyponatremia, hypokalemia, hypocalcemia). The use of mannitol is contraindicated in cases of severe dehydration, anuric renal failure, heart failure, hepatic decompensation and osmolality exceeding 320 mOsm/kg.

Several authors have demonstrated the efficacy of hypertonic saline solutions (HSS) as a therapeutic alternative to mannitol in the treatment of ICH. Vialet compared 20% man-

nitol with HSS at 7.5% in patients with severe TBI and ICH despite sedation, CSF drainage and optimal systemic management [38]. The objective was to reduce ICP to below 25 mmHg or increase CPP to above 70 mmHg. The authors found an increased mortality in the group treated with mannitol. However, equimolar doses of either drug were not used and the study was not designed to test the effect of osmotic agents on mortality or the functional outcome of patients [38].

Administering HSS produces a rapid expansion of intravascular volume due to the high osmotic gradient established between this compartment and the extravascular space [39]. Volume expansion depends on the concentration of sodium administered. These solutions have been shown to be ideal in the resuscitation of hypovolemic patients, with the administration of small volumes achieving rapid hemodynamic stabilization. Furthermore, they also produce a decrease in peripheral vascular resistance, which improves perfusion in various organs. HSS also improve myocardial contractility in patients with shock and promote lung and kidney function. When the BBB is intact, the infusion of HSS creates an osmotic gradient that decreases cerebral edema. In the context of TBI, these solutions have proved particularly effective in patients unresponsive to mannitol or furosemide.

The action of HSS is short-lived and can be extended with the addition of a hyperoncotic agent such as dextran 70 at 6%. Continued use requires comprehensive monitoring of the hemodynamic state, the osmolality and the serum electrolytes. Regarding adverse effects, administering large doses HSS can result in states of severe hyperosmolality and hypernatremia. Rapid volemic expansion can also cause hypokalemia and arrhythmias. In addition, the significant administered concentrations of chlorine can cause hyperchloremic metabolic acidosis [40]. However, a prospective study of 106 patients, designed to detect potential risks for the administration of NaCl at 7.5%, showed no notable adverse effects [40]. Due to potential side effects, its use is contraindicated in patients with hypervolemia or heart, liver or kidney disease, as well as those patients in states of hyperosmolality and hypernatremia.

According to the latest revision of the BTF, there is currently insufficient evidence to recommend the use, concentration and method of administration of HSS in patients with TBI (Table 27.1). In our center, the hyperosmolar solution of choice is mannitol. However, in situations of serum sodium <135 mEq/l, CPP <60 mmHg or hemodynamic instability, the hyperosmolar solution of choice is HSS at 7.2%.

27.9 Hyperventilation

For years, moderate hyperventilation (HV) (pCO_2 at 31-35 mmHg) or severe HV (pCO_2 <30 mmHg) has been one of the main pillars of treatment of endocranial hypertension. It is a therapeutic measure that is easy to apply and fast acting, producing a significant influence on ICP (Figure 27.4). Although the mechanism of action of hyperventilation is not well known, one of the most accepted theories is that the decrease in pCO_2 causes a decrease in the concentration of hydrogen ions in the extracellular medium, which produces an arteriolar vasoconstriction. Vasoconstriction that provokes hypocapnia decreases cerebral blood flow and volume and, consequently, ICP. Furthermore, studies have shown that most severe TBI patients maintain cerebral reactivity to CO_2 until very advanced stages of neurological deterioration. This allows therapeutic HV to be used throughout the evolution of the brain injured patient.

In contrast, the vasoconstrictor effect induced by HV, apart from reducing ICP, may also contribute to the development or aggravation of ischemic lesions (findings common in

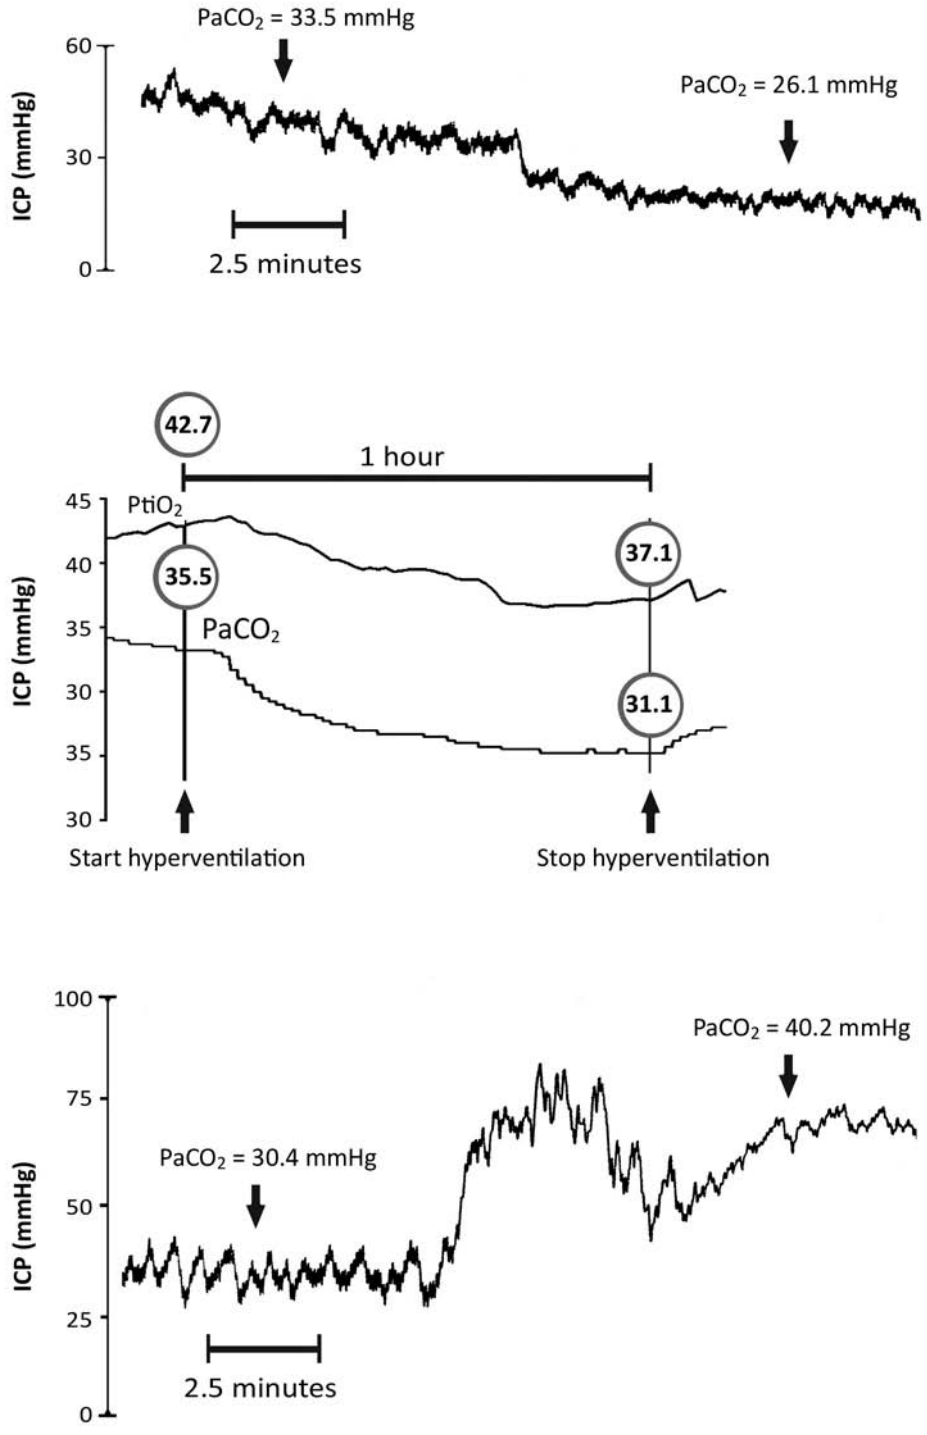

Figure 27.4. **The effect of hyperventilation ($PaCO_2$ reduction) on intracranial pressure (ICP) and tissue oxygen pressure ($PtiO_2$). Note below the "rebound" in ICP when the values of CO_2 normalize after a change in ventilatory parameters.**

the evolution of these patients). This has been the source of considerable controversy in recent years. Several authors have shown that TBI generally involves a situation of low CBF in the acute phase of trauma [41,42]. In some cases, CBF is found to be below the threshold of irreversible ischemia or tissue infarction [43]. In patients with focal lesions, HV leads to precarious metabolic situations that affect the injured brain and the surrounding areas (the "traumatic penumbra") in particular ways [44]. Figure 27.4 shows the parallel decline, caused by the drop in CO_2, in the brain tissue oxygen pressure. These findings demonstrate that the indiscriminate use of HV in certain patients could cause or exacerbate underlying ischemic lesions [45], making this a contraindicated therapeutic maneuver.

An additional problem or difficulty in the use of HV that should be taken into account, given that changes in interstitial pH tend to cancel in time, is the potential loss of efficacy of maintined HV affirmed by some authors [46]. In healthy volunteers, Raichle showed that the maximum decrease of CBF (40%) occurred within 30 minutes from the start of HV. After 4 hours of maintaining HV, CBF had reached 90% of the baseline value [47]. When restoring the initial arterial level of $PaCO_2$, an increase in CBF occured that exceeded the baseline value by 31% [47]. Figure 27.4 shows the rebound effect on ICP produced by normalizing $PaCO_2$ after a period of marked hyperventilation. At the same time, Muizelaar showed in a prospective study of randomized patients that the prophylactic use of HV for severe TBI worsened neurological outcome when assessed at 3 and 6 months after injury [48].

Because of these potential adverse effects, the recommendations of the BTF in 2000 clearly indicated (level I recommendation) that this therapeutic measure should be avoided within the first 24 hours of injury, and as a level II recommendation that moderate HV ($PaCO_2$ at 31-35 mmHg) should not be used prophylactically. In cases in which levels of $PaCO_2$ need to be maintained below 30 mmHg (intense HV) to control ICP, this maneuver should be used under the control of parameters that provide information on blood flow or cerebral oxygen availability (level III recommendation) [49]. In the most recent guidelines (2007) all of these recommendations remain, albeit with a lower level of evidence (Table 27.1) given the absence of randomized studies that demonstrate the relationship between HV used to treat ICH and patient outcome [12]. The BTF guidelines [12] recommend the use of SjO_2 or $PtiO_2$, as instruments for cerebral oximetry monitoring to detect potential adverse effects from using HV, and the avoidance or suspension of this measure if the values fall below 50% or 15 mmHg, respectively ("optimized hyperventilation," a term defined in 1992 by J. Cruz [50]).

Despite the drawbacks mentioned and the very specific recommendations on the use of this therapeutic measure published before 2000, the use of HV today is still very liberal and does not follow the BTF recommendations. In a recent study, Neumann et al. [51] described how 22 European BrainIT member centers (http://www.brainit.org) routinely used this therapeutic measure in tertiary hospitals known for their extensive experience in treating brain injured patients. Information collected on the use of HV in 202 patients with TBI treated in these centers between 2003 and 2005 showed alarming data:

- There is a tendency to use HV indiscriminately. Prophylactic HV (for patients without ICH) was used during 40% of the ventilation time. Intense HV ($PaCO_2$ <30 mmHg) was used in a high percentage of patients during and after the first 24 hours of injury, even with ICP values <20 mmHg. At some centers severe TBI patients were never normoventilated.
- In situations of ICH, intense HV was frequently administered before mannitol.
- Monitoring SjO_2 or $PtiO_2$ was carried out with a frequency of only 4 or 5%, respectively, in the cases involving ventilation analyzed by the authors.

Based on the above, the following recommendations for use of HV have been made [12]: 1) HV should not be used prophylactically and HV within the first 24 hours of injury should be carried out with caution; 2) HV can be used in a timely manner in cases of persistent ICH despite the previous and adequate use of sedation/analgesia, muscle paralysis, CSF drainage, and the administration of hyperosmolar solutions; 3) HV use should be "optimized" through the simultaneous monitoring of CBF or tissue oximetry, especially when $PaCO_2$ levels <30 mmHg are required. In cases in which ICH persists and the measures described have been carried out properly, the intensity of HV may be increased based on the values of SjO_2 or $PtiO_2$.

27.10 Therapeutic Alternatives in the Treatment of Intracranial Hypertension. Second Level Measures: How Often do We Use Them?

The high morbidity and mortality associated with ICH refractory to treatment (>90% of these patients die, are left in a persistent vegetative stage or are severely disabled), has prompted the search for alternative therapeutic options. The BTF refer to second level therapies for ICH as a series of measures to be used as rescue therapy in these patients. Among the measures most commonly used today are barbiturates, more intense hyperventilation ($PaCO_2$ <30 mmHg), decompressive cranial surgery and moderate hypothermia (32-33 ºC). These measures are considered second line therapies because there is less support from evidence-based medicine. At present their use is based on small series of patients, case reports or expert opinion (level III recommendation). Depending on the clinical and radiological characteristics of each patient, our center tends to opt for more intense hyperventilation, decompression techniques or moderate hypothermia when first level measures are exhausted. Regarding alternative drugs to the abovementioned measures, some authors recommend the use of lidocaine, indomethacin, THAM, or dihydroergotamine, among others. However, none of these measures are widely accepted at the moment. Today, this set of therapeutic options should be considered experimental treatments. The practice of controlled clinical studies with randomized patients is essential for determining if they constitute real therapeutic alternatives for ICH refractory to standard measures.

An important aspect to consider is when and in what percentage of TBI patients is it necessary to implement second level measures to treat ICH. Figure 27.5 summarizes the general algorithm for treatment of ICH in our center and includes the criteria for starting the use of second level measures in the treatment of refractory ICH. In centers with extensive experience in treating brain injured patients, there has recently been a clear reduction in the percentage of patients requiring second level therapeutic measures to treat ICH, no doubt due to the rigorous application of stepwise therapeutic protocols and a greater tendency to remove focal lesions early. In 2000, the European multicenter study published by Citerio et al. indicated that at that time the percentage of patients in whom any second line therapy was used was around 19%, with severe hyperventilation or barbiturates being the most commonly used therapeutic measures [52]. In 2008, the same study was carried out and found that the percentage of second line measures used for refractory ICH was reduced from 19 to 13% [53]. This percentage coincides with our center (13.1%), with decompressive craniectomy as a second line therapy currently being most frequently used treatment for our patients.

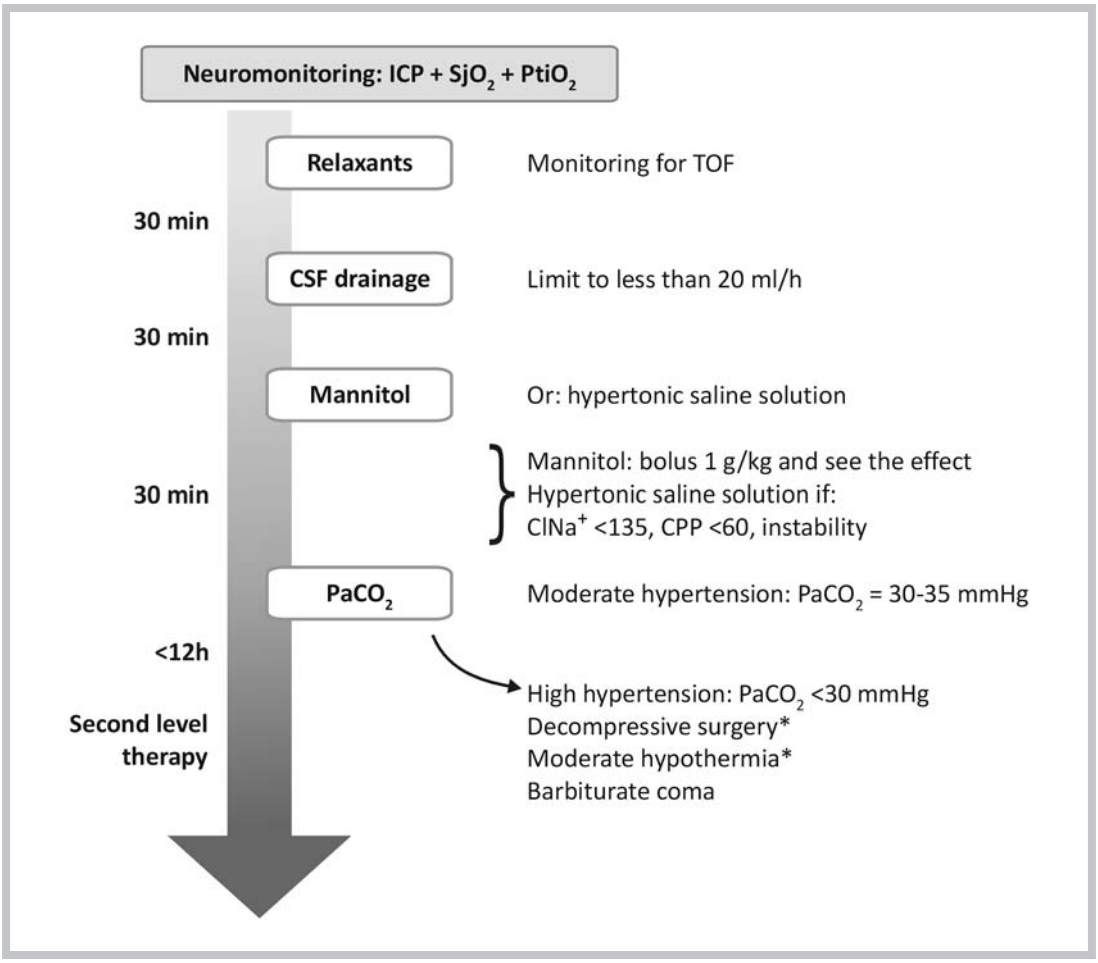

Figure 27.5. **Algorithm for hospital treatment of intracranial hypertension in patients with severe traumatic brain injury admitted to the neurotrauma ICU at Vall d'Hebron University Hospital. The image shows the minimum monitoring required for these patients, the time period allowed between the different therapeutic measures, and the criteria used for the practice of decompression craniectomy.**

* Inclusion criteria: ICP >25 mmHg, refractory to level I measures; age = 1-60 years; Glasgow = 4-8, reactive pupils; absence of focal lesions >25 ml, multiple or devastating trunk injuries

27.11 Quantification of Intensity of Treatment Applied to Control Intracranial Pressure: The Extended Therapy Intensity Level Scale

Two patients with similar injuries as seen in the brain CT scan and similar ICP values may involve difficulties in management and very different outcomes if only the maintenance of basic sedation and analgesia were required, or if the administration of all drugs and therapeutic measures previously mentioned were needed, in order to maintain ICP levels. In order to quantify the intensity of treatment required for these patients, we propose the use of a scale that addresses each therapeutic measure. The scale we propose is a modification of a version presented in 1987 by Maset et al. (TIL: Therapy Intensity Level Scale) [54] and includes the various possibilities that we use today in the treat-

ment of the ICH: the E-TIL scale (Extended Therapy Intensity Level Scale) [55].

For the use of this scale of treatment, one must remember that the general management of these patients in the acute stage of trauma always includes the maintenance of sedation and analgesia, usually through a continuous administration of midazolam and morphine. Specific treatment of ICH includes muscle relaxation, CSF drainage, moderate hyperventilation, and the intermittent administration of a bolus of mannitol or hypertonic saline solution. When these measures do not sufficiently control ICH, second line treatments, such as greater hyperventilation, moderate hypothermia (32-33 °C), or surgical decompression techniques, are used. In our center, barbiturates are used only when all of the above measures fail.

In the E-TIL scale, a minimum score of 1 is given if the patient only receives sedation and analgesia. A maximum score of 62 corresponds to a maximal therapeutic application (Table 27.4). When the patient is not hyperventilated ($PaCO_2$ >45 mmHg) or does not require muscle relaxants, CSF drainage, or the administration of hyperosmolar agents, a score of 0 is given for these items. Regarding the application of level II therapies, 15 points are assigned to moderate hypothermia and the administration of barbiturates at doses sufficient to achieve burst-suppression, and 20 points to decompression craniectomy. Included in hyperosmolar treatment is the administration of mannitol or hypertonic saline. In CSF drainage, no difference in score is obtained if a ventricular catheter (standard technique) or a lumbar drain is used. The latter is indicated only in selected patients in a subacute phase of injury.

Therapeutic measure	Score
Decompressive craniectomy	20
Moderate hypothermia (32-33°C)	15
Barbiturates	15
Mannitol	
• >1g/kg/h	6
• ≤1g/kg/h	3
• Do not administer	0
Hypertonic saline solution (7.2%)	
• >140 ml/h	6
• 1-140 ml/h	3
• Do not administer	0
Drainage of CSF	
• >10 ml/h	2
• 1-10 ml/h	1
• Do not perform drainage	0
Hyperventilation	
• Intense ($PaCO_2$ <30 mmHg)	2
• Moderate ($PaCO_2$ 30-44 mmHg)	1
• $PaCO_2$ <45 mmHg	0
Muscle paralysis	
Yes	1
No	0
Sedatives and analgesics	
Yes	1

Table 27.4. Extended Therapy Intensity Level Scale (E-TIL) for treatment of ICH. The minimum score on this scale is 1 (patient sedation and analgesia) and the maximum score 62, which corresponds to the application of all therapeutic measures described to maximal intensity.

ICH = intracranial hypertension

$PaCO_2$ = partial pressure of carbon dioxide.

27.12 The Withdrawal of Treatment: A Reverse Stepwise Process

One of the aspects with fewer protocols in the treatment of severe TBI patients is the withdrawal of therapeutic measures. In patients with severe TBI, the withdrawal of treatment should be gradual and should not be initiated until the patient maintains ICP values <20 mmHg for at least 24 hours (48 hours is recommended). Withdrawal follows

the reverse order of therapeutic measures implemented, meaning the withdrawal of the second level measures takes place first while first level measures are continued. If ICP remains below 20 mmHg, the phasing out of first level measures can begin, followed by a withdrawal of sedation and analgesia if the patient's condition allows it.

McKinley et al. propose a period of 6 hours between removing each of the therapeutic measures administered to the patient, provided that this withdrawal is not followed by a further increase in ICP [56]. The increase, or "rebound", of ICP after removing one of the measures justifies the immediate reinstatement of the measures that were effective in their control.

After the first week of injury, the decision to treat ICP values >20 mmHg should be done case by case based on the control CT scan findings and clinical variables. It must be taken into account that in the final phase of waking, nociceptive stimuli generated by intubation, nasogastric tubes/probes or other elements may cause increased ICP. However, the compliance of the craniospinal system in this period should already be improved enough so that the patient adapts to these transient increases in ICP. During this process, maintaining the sensor and treating periodic increases in ICP will prolong the process of extubation and may lead to iatrogenia from unnecessary "overtreatment".

27.13 Case Report

The following is a didactic description of the evolution and treatment of a patient with severe TBI. The description begins at the scene of the accident and includes the acute phase after admission to the ICU. The purpose of this case report is to highlight some of the aspects mentioned in this chapter and to analyze controversial issues in the management of this patient.

A 33-year-old woman with no known prior pathologies was involved in a traffic accident (2-car collision) at 5 p.m. on a Tuesday in December (temperature 10 °C) and became trapped in the vehicle. Forty-five minutes after the onset of injury she was assisted by firefighters and evaluated at the scene. A GCS score of 4 (EO 1 + VR 1 + MR 2) was assigned and anisocoria (right pupil: 6 mm; left pupil: 4 mm) with both pupils non-reactive was observed, along with arterial hypotension (70/36 mmHg) and a heart rate of 68 bpm. After cervical stabilization and oral-tracheal intubation, the patient was sedated and myorelaxed. She was then taken to the nearest hospital, which in this case was a level II hospital. Due to pupillary changes during transfer, the patient was administered a bolus of mannitol and underwent hyperventilation. Following a 20-minute trip by ambulance, the patient arrived at the destination hospital, where the following tests were performed: general blood analysis, electrocardiogram, chest radiography, and arterial blood gas analysis. Thirty minutes after arrival at the hospital, the patient presented bradycardia (<35 bpm) and hypertension (220/110 mmHg), which required her transfer to a Trauma Center (arrival time: 11 p.m.).

Upon arrival at the level III hospital, the patient was re-evaluated and given a GCS score of 6 (EO 1 + VR: intubated + MR 5). Normoreactive and isochoric pupils, normal blood pressure and heart rate, and normal cardiopulmonary examination results were observed. A few minutes after admission, the patient was transferred to the neuroradiology unit to undergo a cerebral CT scan. During this exploration, an absence of basal cisterns, a midline deviation to the right measuring 12 mm, and diffuse hemorrhagic spots (petechiae) in both brain hemispheres were detected (Figure 27.6). The total volume of these lesions was <5 ml, corresponding to a diffuse injury type IV according to the Marshall's classification [5]. With these findings in mind, the patient was admitted to the

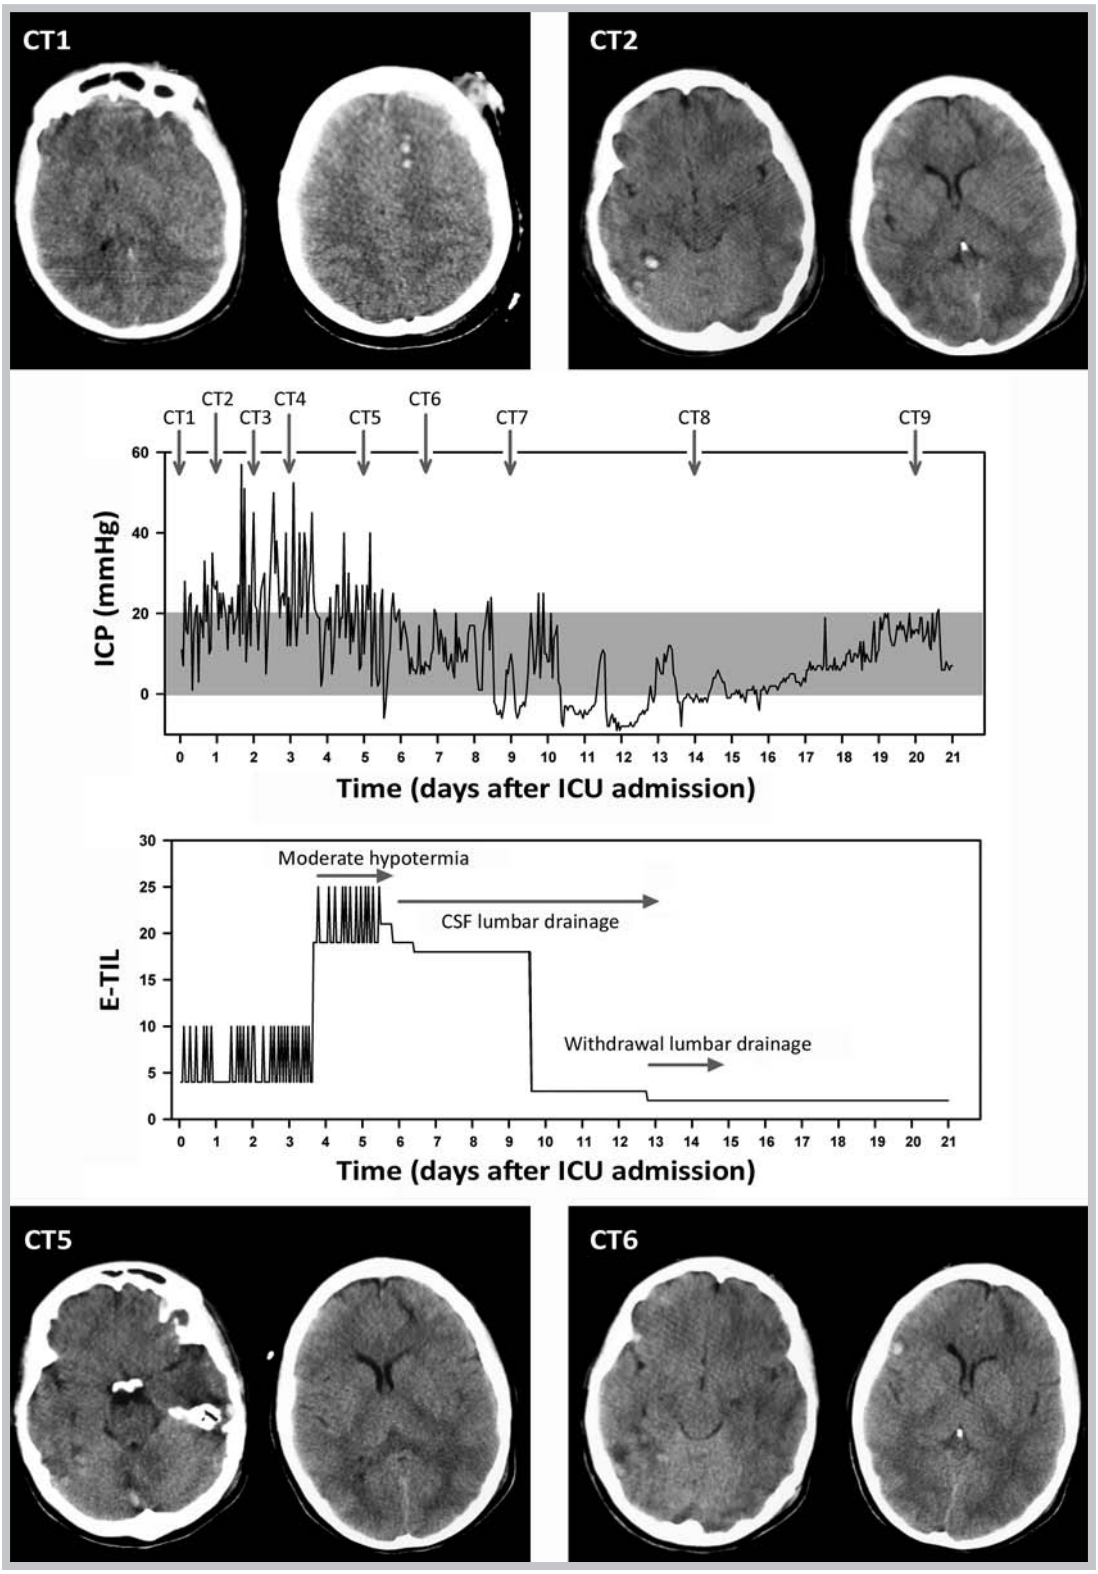

Figure 27.6. CT brain scan, intracranial pressure values, and a recording of the intensity of treatment required for this patient (E-TIL) to control ICP. For detailed explanations, see text (case report).

ICU and administered multimodal neuromonitoring, which included an intraparenchymal ICP sensor implanted in the left hemisphere, a retrograde jugular catheter placed in the right side, and a $PtiO_2$ sensor and a microdialysis catheter implanted in the right hemisphere.

At 24 hours from the time of injury, and 14 hours after ICU admission, a new CT scan was taken that showed an improvement in the parameters when compared to the initial CT (visible basal cisterns, midline displaced <5 mm and no increase in the volume of the hemorrhagic lesions, corresponding to a Marshall type II injury). Despite the radiological improvement (Figure 27.6) during the first 24 hours of admission and the correct maintenance of myorelaxation, sedation, and $PaCO_2$ values of approximately 27 mmHg, the patient required 5 boluses of mannitol and hypertonic saline solution in order to keep ICP at <20 mmHg and CPP at >60 mmHg. Over the next 72 hours, the patient continued to present slightly elevated ICP values, requiring the periodic administration of hypertonic saline and mannitol, despite the results of control brain CT scans performed at 48 and 72 hours that did not show significant changes (diffuse injury type II) (Figure 27.6). During this period SjO_2 levels were always >60%.

On the fourth day of admission, ICP was refractory to first level measures. After performing a new brain CT scan that showed no changes compared to the previous scans, the decision to apply a second level therapeutic measure was taken. In this case, moderate hypothermia (32 °C) was the chosen technique. With this maneuver, ICP values initially improved. However, these levels increased once more after a few hours. On the sixth day of ICU admission, ICP returned to a refractory state despite first level measures and hypothermia therapy. This led to the addition of a new bailout measure. After a new control brain CT scan was taken, a lumbar drain was implanted in the patient in order to drain CSF. This maneuver controlled ICP almost immediately and allowed the patient to begin gradual warming (0.5 °C/24 h). All other therapeutic measures were also withdrawn one by one, with the exception of lumbar CSF drainage, which remained in place for 7 days (removed on day 13 of ICU admission) (Figure 27.6).

27.13.1 Points to Consider

- The level of consciousness presented by the patient at the accident site could have been an artifact produced by the hypothermia and hemodynamic instability that occured at the time of evaluation. The GCS score and pupillary examination were more reliable when recorded on arrival at the definitive medical center.
- In this patient, the left hemisphere was selected for the implementation of an ICP sensor because it corresponded to the more swollen hemisphere, where ICP values were most likely to be higher. Based on the characteristics of the initial injury, an intraparenchymal ICP sensor was selected. A retrograde jugular catheter was inserted into the dominant jugular vein. The remaining cranial monitoring devices were implanted in the less-injured brain hemisphere.
- During the evolution of the injury, the patient required several control brain CT scans to rule out the emergence of new space-occupying lesions. These scans also showed how the patient went from presenting a type IV diffuse injury to a type II, illustrating the dynamic nature of neurotraumatic injuries.
- After the poor response to moderate hypothermia in order to control ICH, the decision to place a lumbar drain was taken at 7 days post-injury based on the following: 1) the patient presented cerebellar tonsils in an intracranial position, 2) the basal cisterns were visible, and 3) no deviation from the midline was observed. The existence of apparently benign radiological images in this period contrasted with the difficul-

ty in controlling ICP, suggesting an alteration in CSF dynamics. This was confirmed after inserting a lumbar drain, CSF drainage being the most effective therapeutic measure in this patient.
- The figures illustrating the evolution of the ICP levels and the intensity of treatment required to control ICP (E-TIL) show how both the application and withdrawal of treatment were stepwise.

27.13.2 Points of Controversy and Inadequate Therapeutic Maneuvers

- At present, there is sufficient evidence to conclude that this patient should have been transferred directly to a Trauma Center, defined as a center equipped with CT scanning, a neurosurgeon on duty, and all human and technological resources required by patients with severe TBI. The intermediate transfers and "superfluous" exploratory tests in the early stages of injury adversely affected the outcome of the patient.
- In patients with TBI and clinical signs of ICH before ICP monitoring (in our patient, anisocoria and pupillary reactivity failure), initial hyperventilation should be administered. Mannitol should be administered in cases of hemodynamic stability only, and was contraindicated in this patient.
- The CPG of the BTF indicate that first level measures to control ICH should include moderate hyperventilation ($PaCO_2$ >30 mmHg). In this patient, it was administered prematurely before exhausting other first level therapeutic measures.
- The effectiveness of lumbar drainage of CSF in this patient suggests that more aggressive therapeutic techniques, such as hypothermia, could have been avoided. The adequate moment for this maneuver occurs after the third control brain CT scan showing a non-deviated midline and normal ventricular size.

27.14 Key Concepts

Resuscitation and treatment carried out in the acute phase of trauma are vital to the outcome of TBI patients. Arterial hypotension and hypoxia, in addition to intracranial hypertension, should be avoided throughout the evolution of injury in these patients.
Action algorithms for these patients should be standardized as much as possible, in addition to being well-directed and started early on post-injury.
Because TBI is highly dynamic, periodic exploration using cerebral CT scans are required before initiating specific therapeutic measures for intracranial hypertension.
The early evacuation of focal cerebral lesions of sufficient volume further facilitates the clinical management of patients with TBI.
Correctly applying the general measures indicated for patients with TBI reduces the percentage of patients requiring specific treatment for ICH. At the same time, applying first level measures correctly would allow an incidence of only 10-15% for TBI patients who require second level measures to treat refractory ICH.
The use of a ventricular catheter for ICP monitoring also permits the drainage of CSF, which can reduce the number of additional therapeutic maneuvers needed for such patients.
Hyperventilation should be used in moderation in accordance with BTF recommendations and, if possible, optimized in combination with the monitoring of parameters that are used to estimate CBF or cerebral oxygen availability.

Quantifying the intensity of treatment required provides additional information about the level of severity and the management difficulties of these patients.
Although the general treatment algorithm outlined in this chapter is designed for most cases of TBI, it should be noted that there are specific therapeutic maneuvers that should be reserved for specific injuries or select patients (e.g. anticonvulsants, steroids). The treatment of these patients concludes with the withdrawal of the administered drugs or maneuvers, which should be carried out in the reverse order in which these therapies were administered.

27.15 Acknowledgements

We thank the nursing personnel for the implementation of monitoring and treatment protocols in TBI patients admitted to the neurotrauma ICU at Vall d'Hebron University Hospital. This chapter has been partially supported by grants FISS 08/0480, FISS 10/00302 and FISS 11/00700 from the *Fondo de Investigación Sanitaria del Instituto de Salud Carlos III* (fondos FEDER) and funding from the *Fundación Mutua Madrileña* (FMM-2010-10), given to J. Sahuquillo and M.A. Poca.

28 Second Level Measures for the Treatment of Intracranial Hypertension in Traumatic Brain Injury

J. Sahuquillo [1], M. Vidal-Jorge [2], MA. Poca [1]

I have yet to see any problem, however complicated, which, when you looked at it in the right way, did not become still more complicated.
Poul Anderson (1926-2001)

28.1 Introduction

Intracranial hypertension (ICH) is still the leading cause of death in patients with acute brain damage and especially in those with severe traumatic brain injury (TBI) (Glasgow Coma Scale [GCS] score ≤8).

The normal range of intracranial pressure (ICP) measured in any compartment (intraventricular, in the brain parenchyma, subdural space, etc.) does not exceed 10-12 mmHg in the supine position. However, high ICP or intracranial hypertension (ICH) is defined when the absolute values of ICP exceed 20 mmHg during a defined period of time (5-10 minutes) and all those causes that can increase it have been ruled out (poor patient adaptation to the ventilator, inadequate sedation or analgesia, postural changes, nadequate head and neck position, high blood pressure, hyponatremia, fever, etc.). However, this threshold should always be considered relative, and it can vary depending on the etiological factors responsible for ICH, the location of the injury, and other circumstances such as when the skull is partially open in patients with decompressive craniectomy or semiclosed as in infants and children. There is now widespread agreement, endorsed by the Clinical Practice Guidelines of the Brain Trauma Foundation (BTF), that the threshold of 20 mmHg is acceptable, with a level II recommendation to initiate therapeutic measures [1]. However, ICP values should be individualized for each patient and for each clinical situation in particular [2].

Traditionally, it was claimed that between 50-75% of patients with severe TBI developed ICH during the first week after injury. This incidence has been verified in nearly all studies since the publication of the results of the Traumatic Coma Data Bank (TCDB) published in 1991 [3,4]. In this study, 72% of patients had an episode of ICH (>20 mmHg) during their stay in intensive care [3]. Since then, we know that in the natural evolution of patients with severe TBI the risk of ICH is highly variable and will depend on the type of injury according to the classification proposed by Marshall et al. [5]. However, the

analysis of recent multicentre studies questions this widely-accepted premise. The results of a phase III controlled study to demonstrate the neuroprotective efficacy of dexanabinol (synthetic cannabinoid), showed that in both the treated and the control group the percentage of time in which ICP remained above the 25 mmHg threshold was only 10% [6].

The results of this study are striking and may be explained by the following reasons: 1) the 861 patients included were treated in highly specialized neurotrauma centres with a standardized and homogeneous medical and surgical treatment; 2) half of the patients (48% in the placebo group and 49% in those treated with dexanabinol) had type II lesions on the Marshall classification while in the TCDB study only 24% of the patients were included in this category, and 3) in most participating centres the Brain Trauma Foundation recommendations were followed (to evacuate the space-occupying lesions with a volume >25 cc).

In our opinion, the significant reduction of ICH reported in this study was mainly due to an early management of systemic complications and a more proactive behaviour in the evacuation of focal lesions with a relevant volume in most of the participating centres.

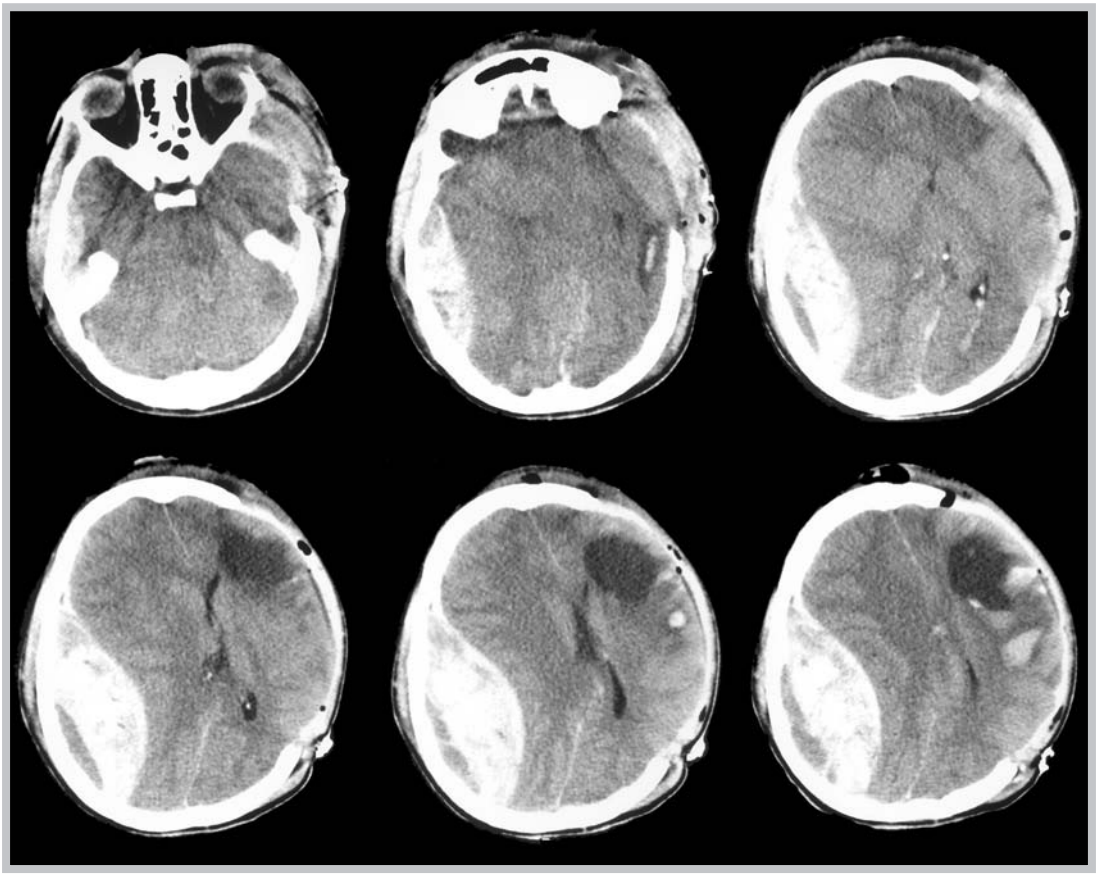

Figure 28.1. **CT scan of a 19-year-old woman who underwent evacuation of an acute left subdural hematoma. In the immediate postoperative period she developed a contralateral anisocoria with a mydriatic right pupil. A new control CT scan showed the appearance of an extensive right epidural hematoma which caused severe brain herniations (subfalcial, uncal and tonsillar), with the complete absence of the basal cisterns. Although the latter hematoma was also evacuated, the patient remained in a vegetative state for several months after injury. She then regained a minimally conscious state; 3 years after trauma, she remained in a state of severe disability, with total dependence for activities of daily living and very limited communication.**

28.2 Etiology of Intracranial Hypertension

To better understand the implementation of the second level measures, it is useful to recall the traumatic lesion classification introduced by Gennarelli et al. in the 1980s [7-9]. Pragmatically, these authors differentiated between two types of lesions: focal and diffuse. The inclusion of a patient in one of these two groups is determined from the findings observed in the computed tomography (CT). This classification, although apparently simple, allows to differentiate groups of patients with different mechanisms of injury, clinical presentation and outcome. Focal lesions (cerebral contusions, lacerations and hematoma) cause neurological deficits due to tissue destruction and perilesional ischemia and cause coma when they reach a size big enough to cause brain herniation and secondary compression of the brainstem (Figure 28.1).
Diffuse injuries are those that do not occupy a well-defined volume within the intracranial compartment (axonal injury, brain swelling, etc.). This latter group of patients is clinically and neuroradiologically heterogeneous, and in most cases coma is a consequence of the diffuse involvement of axons in the cerebral hemispheres and deafferentation of subcortical structures and the brainstem. In these cases, anatomopathological study fairly consistently demonstrates diffuse axonal injury of variable severity [10].

28.3 Intracranial Pressure Monitoring

The only reliable way to confirm whether or not a patient has ICH is with the continuous monitoring of ICP. Estimates from neuroradiological signs have a high margin of error. Continuous ICP monitoring has become routine in the management of severe TBI since the publication of the Brain Trauma Foundation's Clinical Practice Guidelines for the management of severe TBI in adults in 1995 [11]. These Guidelines have been updated and endorsed by most international scientific societies. The latest version, published in 2007, reaffirms with level II evidence, that ICP monitoring should be conducted in all patients with severe TBI who have an abnormal CT scan on admission [1]. However, in recent years we have learned that the absolute value of ICP, although the mainstay in the management of severe TBI, as an isolated parameter is not sufficient for decision making in complex patients. Monitors for recording ICP, signal processing, its value as a diagnostic method and its importance in the clinical management of many patients with acute neurological diseases have been substantially modified over the last two decades. There are two main reasons for this change: first, a much better understanding of the pathophysiological factors that regulate the response of the craniospinal axis in situations of volume increases, and second, advances in the technology available for recording and analyzing the ICP signal and other physiological variables associated with it (cerebral perfusion pressure, cerebral blood flow, etc.).
The introduction in the last two decades of global and regional methods to monitor cerebral metabolism and oxygen supply (jugular bulb oxyhemoglobin saturation, brain tissue pressure of oxygen and microdialysis) has provided valuable information that allows us to better understand the complex pathophysiology of high ICP.

28.4 Clinical Significance of the Pressure-Volume Curve

Often, new technologies let people forget basic pathophysiological fundamentals. In the late 19th century, Monro and Kellie were the first to define the relationship between

pressure and volume in the intracranial space. In the neurosurgical arena, Burrows and Cushing introduced their theories, which remain valid today with almost no significant changes.

According to the Monro-Kellie theory, in the adult – in whom the fontanelles and cranial sutures are completely closed – the volume of intracranial space must remain constant due to the physical characteristics of its components. These characteristics are: the incompressibility of the three intracranial components – brain parenchyma, blood and cerebrospinal fluid (CSF) – and the indeformability and inextensibility of the intracranial space in the adult. For these reasons, a volume increase at the expense of any of the three intracranial components or adding a new volume (tumour, hematoma, etc.) must necessarily be accompanied by a simultaneous decrease in one or all of the other components can be distingusihed. The mathematical equation which relates the variables pressure and volume in the intracranial space is not comparable to that of a perfect elastic body, but two distinct components. In a first phase, the volumetric increases do not change the absolute value of ICP, suggesting an intracranial compartment with high compliance (low elastance) [12]. However, when the physiological buffers of the intracranial space (circulating blood volume and CSF, mainly) are depleted, even a minimal increase in volume causes large increases in ICP (low compliance or high elastance phase). The pressure-volume curve is mathematically described by an exponential function and its mathematical description is based on both clinical and experimental studies. The pressure increase is always more pronounced as the patient moves to the right part of the curve. This right part of the curve, which draws an almost vertical segment, is called the space decompensation phase and is associated with a higher risk of neurological deterioration (Figure 28.2).

The mathematical relationships between pressure and volume allow to assess by means of injecting a known volume in the intracranial space, the patient's tolerance to the ad-

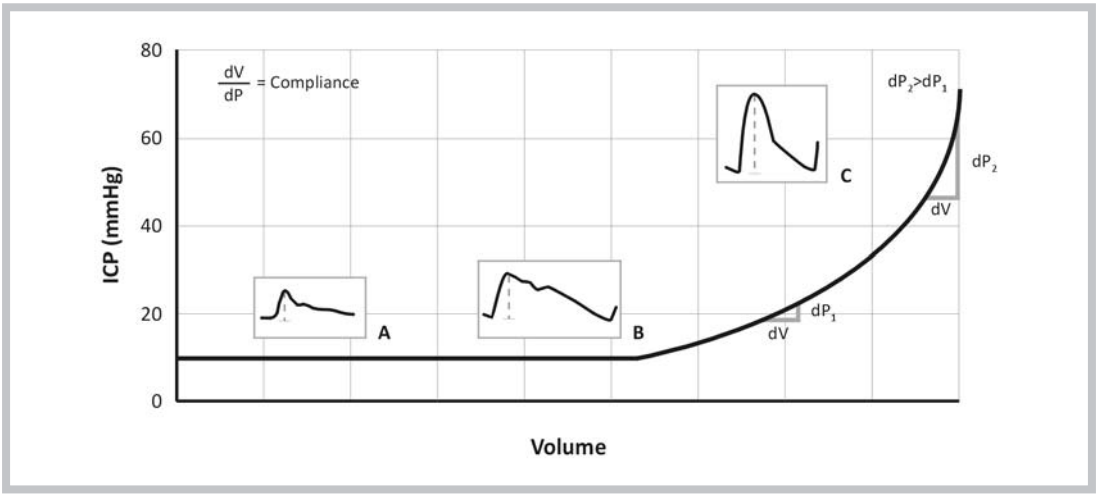

Figure 28.2. **Pressure-volume curve. The horizontal segment of this curve (A) corresponds to the compensation phase. In this phase, the physiological compensatory mechanisms (venous drainage, displacement and increased absorption of CSF, etc.) allow, despite the progressive increase in volume, the maintenance of intracranial pressure (ICP) within the normal limits. As compensatory mechanisms are exhausted, i.e., the more we move to the right of the pressure-volume curve, small increases in volume generate significant increases in ICP. From the point of inflection (B), we enter what is called the decompensation period of the curve or period of high elastance (low compliance) (C). This figure also shows how, as we move to the right the curve, there is a progressive increase in the amplitude of the cardiac component of the ICP. This increase can be used as an indirect information on the intracranial compliance.**

dition of new volumes into the cranial cavity or the elastance of the craniospinal axis. Czosnyka proposed, as a noninvasive method for continuous monitoring of the elastance, the use of a computerized system to assess continuously the Pearson's correlation coefficient (R) between the amplitude of the arterial wave and the intracranial pressure wave. The periodic increase in the blood volume entering the intracranial space with each cardiac cycle induces a synchronous change in the amplitude of ICP, which allows to estimate the intracranial volume reserve [12].

An R value close to zero between the amplitude of the arterial wave and the amplitude of the cardiac component reflects the lack of synchronization between the pulse wave and ICP and therefore indicates an adequate reserve volume. A high index close to 1 indicates an almost linear transmission of the pulse wave to the intracranial space and therefore a low volume reserve (low compliance or high elastance status) [12].

The volumetric compensatory mechanisms in the intracranial space require a variable period of time to be effective. Therefore, slow increases in volume (brain tumours) are always compensated for much more effectively than the abrupt increases that occur in acute situations, such as in spontaneous intracerebral hematoma or acute hydrocephalus.

28.5 Where to Monitor ICP? The Problem of Intracranial Pressure Gradients

The traditional concept assumes that the intracranial space behaves as a single chamber where the pressure is distributed evenly and is, therefore, identical at all points. The immediate consequence that follows from this premise is that ICP monitoring in any compartment (epidural, subdural, etc.) should reflect similar results both in absolute values and in its evolution. The existence of gradients between the supra- and infratentorial space and between the subarachnoid space of the spinal cord and the posterior fossa has been confirmed in different animal species. However, the existence of gradients between the two cerebral hemispheres has always been questioned. Experimental studies have objectified the presence of significant interhemispheric gradients in space-occupying lesions. However, the few clinical studies on interhemispheric gradients in head-injured patients ended with conflicting conclusions.

Our group studied this subject in 50 patients with moderate or severe TBI in whom ICP was monitored in both cerebral hemispheres [13]. The monitoring results were stratified according to the predominant type of lesion into two groups: focal or diffuse lesions. Within the diffuse injury category, patients were included in whom the focal lesion volume was <25 ml and the midline shif was ≤3 mm. In the focal lesion cathegory we included patients in whom the sum of the lesion volumes of a hemisphere was >25 ml and/or the midline shif was greater than 3 mm.

Our study showed that in 25% of patients with a focal injury there were clinically significant differences in ICP (>5 mmHg) and hence in cerebral perfusion pressure (CPP) calculated in the two hemispheres. However, in none of the patients with a diffuse injury the differences observed were clinically relevant. It is therefore possible to assume that in patients with a diffuse injury the intracranial space behaves as a single unicameral chamber without a compartmentalized space and, therefore, the pressure transducer can be implanted interchangeably in either of the cerebral hemispheres. However, since volumetric increases may occur in initially small focal lesions, it is always advisable to monitor ICP on the side where lesion volume is greater. In focal lesions with or without

midline shift, monitoring must always be performed on the side with the greater lesional volume. If ICP is monitored on the side contralateral to the lesion, treatment will be inappropriate and calculation of CPP inaccurate and overestimated.
The clinical management of patients with increased ICP is complex and often differentiated into several stages. The Brain Trauma Foundation Guidelines (1995) proposed a staged protocol wherein a distinction was made between first and second level therapeutic measures. Many clinical protocols have been based on this scheme. In the first Guidelines version, the classes of evidence (Class I, II and III) defined recommendations called standards, guidelines and options. In the latest Guidelines version published in 2007, the same classification of the evidence is followed, but the initial terminology is replaced with the most commonly used in other clinical guidelines: Level I, Level II and Level III [14]. Class I evidence is a result of controlled studies of high methodological quality. Controlled but methodologically questionable studies (systematic biases, significant losses, etc.) may give support to a lower level of evidence (II or III).
Class II evidence usually derives from well-designed prospective or retrospective studies where two or more treatment options are compared. The lowest level of evidence (Class III) corresponds to retrospective studies, case series or expert opinion, among others [14]. In the new 2007 Guidelines, although the standard terms and options are abandoned, its meaning remains.

28.6 Stepped Versus Individualized Treatment

In the 1990s many units, including ours, attempted to use individualized treatment of high ICP based on CT sacn criteria and parameters obtained from the monitoring of hemodynamics and cerebral oxygenation. At present, we believe that this kind of management is not successful, since it is difficult to systematize and is subject to great variability in both its application and its effectiveness. Moreover, the success of these personalized treatments often depends on uncontrollable factors such as the physician's experience, protocols which are difficult to implement and the availability of complex and not widely-available neuromonitoring methods. Therefore, since the early 2000s, the use of structured and uniform protocols applied systematically to all patients with severe TBI and ICH has become general. These protocols tend to be minor modifications from the recommendations published by the different versions of the BTF Guidelines. There is no need to stress that these protocols should not be rigid, but flexible enough to allow their adaptation to specific clinical situations [15].

28.7 Types of the Therapeutic Measures

The original version of the Guidelines for the clinical management of patients with severe TBI defined three main levels to manage ICP: 1) general measures which should be applied to all patients, with and without ICH, 2) first-level measures for the treatment of high ICP and 3) second-level measures for the management of patients who do not respond to the first-level measures.
General and first-level measures have already been discussed in previous chapters of this book. This chapter will discuss the second-level measures. Note that the 2007 Guidelines present no treatment algorithm, so in this section we have followed the systematics of the initial BTF guidelines release updated in 2000. It is essential to empha-

size that evacuation of volumetrically significant (>25 ml) space-occupying lesions or those with a lower volume but located in high-risk anatomic locations, as in the temporal lobe, should be included within the general or first-level measures. When there is a focal lesion, extending medical measures to extremes without evacuating the lesion is the wong way to go. This premise is especially important in the treatment of brain contusions, a field traditionally abandoned by the neurosurgeon and where early surgery allows to obtain excellent results in patients with high GCS scores. Recently Servadei et al. have completed a comprehensive review on the role of surgery in the management of TBI [16].

In all patients with severe TBI, a set of general measures should be initiated early in order to achieve hemodynamic stability, adequate nutritional support, and to avoid any factors that can increase ICP [15]. Among the last are the mismatch between the patient and the ventilator, improper patient position, hypoxia, hypercapnia, fever, seizures, arterial hypo-or hypertension and hyponatremia. Maintaining normovolemia and the proper choice of replacement solutions play a vital role in the management of the neurotrauma patient.

28.7.1 First-level Measures

These are initiated when the ICP values are >20 mmHg. The first version of the BTF Guidelines recommended treating thresholds above 20-25 mmHg, but it should be underlined that this recommendation was based on expert consensus rather than in any strong evidence. In a previous work, we emphasize that, in our opinion, the lower threshold suggested by the Guidelines (20 mmHg) is preferable because in this way treatment is started earlier improving the chances of achieving a correct control of ICP [2]. The last version recommends a threshold of 20 mmHg (level II evidence) although the text mentions the threshold of 20-25 mmHg as proposed in the 1995 version [17] makin this issue misleading. In patients with a bone decompression greatet than 5 cm and with an open duramater, it is recommended to lower the treatment threshold to 15 mmHg [4]. Also, this threshold should be also reduced in patients with focal lesions in one or both temporal lobes.

28.7.2 Second-level Measures

In the first version of the BTF guidelines these measures were defined as treatments which should be initiated when the first level measures (muscle paralysis, hyperosmolar solutions, moderate hyperventilation, etc.) were unable to control ICP below the established thresholds. In the 2007 update, this term and the whole algorithsm of treatment has disappeared. As a result of the collaboration between the Brain Trauma Foundation and a group of methodology experts, the methodology on the latest release has changed significantly compared to the first two editions. However, the lack of a clear proposal as to when and how to apply the various measures has generated some confusion. The latest version lacks a common thread and loses clarity. At the time of writing this chapter, the Brain Trauma Foundation has appointed an expert committee to update the algorithm proposed in the first version of the guidelines that should be upgraded in 2013.

In the earlier editions, the “second-level” measures formed a broad category which included many therapeutic manoeuvres considered strictly first-level or even general manoeuvres such as the use of the Lund therapy or a CPP increase above accepted thresholds (Rosner therapy).

To avoid misunderstandings, we have selected for discussion three therapeutic options: 1) barbiturates, 2) moderate hypothermia and 3) decompressive craniectomy.
These second-level measures should be introduced early after the threshold of 20 mmHg has been passed and under a stepwise treatment protocol. Some authors have suggested modifications in the indication and timing to introduce these measures, using other monitoring parameters such as the CPP, tissue oximetry and/or the jugular bulb oxyhemoglobin saturation. It should be emphasized that there is no evidence that any of these alternatives is superior to the classical thresholds of ICP. In addition, it must be emphasized that high ICP itself is harmful and that brain herniations may occur at relatively low ICP thresholds. Our recommendation is to apply these measures following a set of pre-established rules agreed between neurosurgeons and intensivists. The degree of collaboration between different specialists in the multidisciplinary management of these patients is probably the "non-measurable" and hidden factor which more strongly modifies the outcome of the patient with severe TBI.
Our recommendatios is second-level measures implementation shloud be based on the evolution of the ICP and serial neuroimaging tests. A new CT must always be obtained before instituting any of these measures and to rule out evacuable space-occupying lesions. Once the decission has taken, these measures should be implemented quickly applied in a complementary and not exclusive way. The association of barbiturates and hypothermia has been reported, as has the association of hypothermia and decompressive craniectomy. It is important to empasize that the use of these rescue measures makes sense only if the patient is considered neurologically viable.

28.8 Barbiturates

Barbituric acid was first synthesized in 1864 by von Bayer and is obtained from the condensation of malonic acid with urea [18]. From the chemical substitution of this primordial molecule a series of barbiturates are obtained which have a depressant action on multiple cellular functions in all organs, including the central nervous system (CNS).
The first barbiturates introduced into clinical practice were barbital in 1903 and phenobarbital in 1912 [18]. Since then, numerous derivatives has been introduced in the therapeutic armamentarium as sedatives, hypnotics, anticonvulsants or anesthetics. The most important ones from a neurological point of view are phenobarbital, pentobarbital and thiopental. At high doses, these drugs diffuse across all cell membranes and concentrate preferentially in certain tissues depending on their blood supply and the lipid solubility of the molecule, its affinity for plasma proteins and its degree of ionization [19]. Barbiturates are highly lipid soluble substances with a relatively uniform distribution in the CNS, are metabolized in the liver by oxidation, and are mostly eliminated with the urine [20]. However, there are pharmacokinetic differences depending on the type of barbiturate and its lipid solubility [20]. Moreover, individual factors such as body weight, fat compartment volume, muscle mass and other variables modify their pharmacokinetic characteristics. The main mechanism of action of barbiturates on the CNS is through the GABAergic system, the major inhibitory system in the mammalian CNS, mediated by GABA and its receptors (GABAA and GABAB). Barbiturates block GABAA receptors, a receptor involved in the mechanisms of action of benzodiazepines and substances with convulsive capacity such as picrotoxin [21]. In addition, barbiturates also inhibit AMPA glutamate receptors. This dual mechanism explains the deep depression that these drugs cause on the CNS metabolism.

28.8.1 Effects of Barbiturates on ICP: Recommendations

The effect on ICP of barbiturates was first reported by Horsley in 1937 [22]. However, it was Shapiro et al. in 1973 who first introduced barbiturate coma as treatment for patients with severe TBI and increased ICP [23,24]. In the beginning, this therapy created, as often happens with new treatments, excessive optimism owing to its potential neuroprotective effect. Over time, the use of these drugs has raised significant controversy and has also shown that their use requires considerable pathophysiological knowledge for their precise and individualized application [25]. In the 1995 Guidelines version, barbiturates were covered in a single paragraph [11]. In the last update of 2007, barbiturates are included in a larger section called "Anesthetics, analgesics and sedatives" [26]. In this section, two drugs are considered for the treatment of ICH, barbiturates and propofol. In our view, the inclusion of barbiturates in this broad section blurs the issue, because both analgesia and sedation are part of the general management of severe TBI, while high-dose barbiturates are used only as a second-level measure in the treatment of refractory ICP.

The 2007 Guidelines state that "High-dose barbiturates are recommended (level II evidence) to treat ICH refractory to medical or surgical measures. Hemodynamic stability is essential before and during the administration of barbiturates".

Propofol is recommended with a level II evidence for ICP control but its efficacy in improving mortality or functional outcomes has not been proved. In addition,

high doses of propofol (>5 mg/kg/h) can cause serious side effects and the so-called "propofol infusion syndrome" [26].

In reviewing the evidence on the use of barbiturates there are only three controlled studies. The first multicentre study on the use of barbiturates in the treatment of TBI was published by Schwartz et al. in 1984 [27]. However, its design left unanswered the most important questions because it compared barbiturates versus mannitol in patients with severe TBI [27].

In a study by Ward et al. pentobarbital was administered prophylactically to a group of patients with intradural hematoma or diffuse lesions and a GCS score ≤5 [28]. In the analysis of the results there were no significant differences in the group assigned to pentobarbital compared with the control group or in the incidence of increased ICP, in the duration of these elevations or in its response to treatment [28]. Only the study published by Eisenberg et al. in 1988 studied the effect of pentobarbital in patients with refractory ICP [29]. In this prospective, multicentre controlled trial, barbiturates were used as a last resort to control refractory ICP. It included 73 patients aged between 15 and 50 years and with GCS score ≤7 [29]. The treatment protocol started early when ICP was above 15 mmHg, using hyperventilation, mannitol, muscle relaxation and other first-level options. When ICP was not controlled according to preset criteria – 25 mmHg in patients without bone defect and 15 mmHg in those with a bone defect >25 cm2 –, patients were randomized to treatment with pentobarbital or continuation with conventional measures. The success or failure of treatment was evaluated by assessing the control of ICP but not the patient's functional outcome. The findings showed that the probability of controlling ICP in the group treated with pentobarbital was twice that in the control group. This probability remained after controlling for prognostic variables (GCS score, accident-inclusion period, etc.). In those cases without cardiovascular complications before inclusion into the study, the effectiveness of barbiturates was four times higher in controlling ICP than in the control group.

This study is the one which supports the Brain Trauma Foundation recommendation to assign a level II evidence to these drugs. However, this study presents some problems that prevent its analysis. Among others, 11 patients who did not respond to conven-

tional therapy were allowed to cross over. When the "intention to treat" methodology was applied to the analysis of the results, the effect of barbiturates on mortality was lost [26]. In the latest Guidelines version, the results match those of the systematic review conducted by the Cochrane Collaboration that concluded that even though barbiturates may be useful to reduce ICP, their effect is moderate. In Eisenberg's study the relative risk (RR) for the control of ICP was 0.81 (95% CI, 0.6-1.06)[30]. In addition, there was no evidence that barbiturates improve either mortality or functional outcome and in one out of four patients treated with pentobarbital hypotension was a clinically relevant adverse effect.

28.8.2 Thiopental or Pentobarbital?

The effects of barbiturates on ICP are attributed to their ability to reduce the brain functional metabolism and the consequent coupled reduction of cerebral blood volume (CBV). This CBV reduction causes decreased ICP. An important issue for clinical practice is which barbiturate is preferred to treat refractory high ICP. The most commonly used barbiturates have been pentobarbital in the United States and thiopental in Europe. In a pilot study Pérez-Barcena et al. have suggested that thiopental may be better than pentobarbital [31]. However, because of its design, this study does not allow draw any definitive conclusions. As a general recommedation, barbiturates should be selected based on pharmacokinetic considerations and the lower frequency of their side effects. Although thiopental is more widely used in Europe, pentobarbital theoretically offers some advantages that facilitate its use.

The metabolism and pharmacokinetics of thiopental are more complex than those of pentobarbital [20,32]. Part of thiopental administered parenterally becomes pentobarbital [20,32], making it difficult to control plasma levels and their correlation with therapeutic effects. Thiopental is more lipid soluble than pentobarbital and its action faster, although its half-life is shorter due to rapid redistribution into fat, muscle and other tissues [20,32]. The extracerebral distribution of pentobarbital is lower and its excretion slower, as it is eliminated mainly by metabolism. In obese patients or those with a large volume of adipose tissue, thiopental accumulates more than pentobarbital and after prolonged treatment, thiopental is eliminated more slowly than pentobarbital [20,33]. Moreover, thiopental has a significant depressant effect on the immune system by inhibiting the phagocytic activity of lymphocytes. This effect has not been observed with pentobarbital [20,34].

For these reasons, and in the absence of controlled studies on the subject, our recommendation is to use pentobarbital when treating patients with increased ICP.

28.8.3 Dosage and Controls in Barbiturate Coma

The main problem with the use of barbiturates is that they make the patient completely inaccessible to neurological examination. Continuous ICP monitoring and sequential CTs are the primary methods for controlling the clinical of the patients in induced coma. The last version of the BTF guidelines recommend starting with a loading dose of 10 mg/kg pentobarbital administered over half an hour followed by three consecutive doses of 5 mg/kg/h [26]. The load should be continued with a continuous infusion of 1 mg/kg/hr [26]. The frequently observed hemodynamic instability should be treated with colloids and/or vasoactive drugs (dobutamine, dopamine or phenylephrine). It has been shown, however, that when intravascular volume is properly preserved and drug administration is slow, the hemodynamic effects are significantly reduced [19]. Daily barbituremias

should be performed, trying to maintain plasma pentobarbital levels between 35 and 45 µg/ml. It has been shown, however, that there is often a dissociation between the degree of suppression observed on the electroencephalogram (EEG) and plasma barbiturate levels [20]. EEG is the best way to monitor barbiturate coma and the "burst suppression" EEG pattern is the best indicator of the maximum metabolic reduction achievable with barbiturates. The usefulness of the BIS or entropy in monitoring the depth of induced coma is still poorly defined.

28.9 Moderate Hypothermia

Moderate hypothermia, defined as a core temperature of 32-33.9°C [35], has been used sporadically since the 1940s in both experimental models of TBI and in non-controlled clinical studies for its potential neuroprotective efficacy [36,37]. The neuroprotective effects of hypothermia are manifold and some still poorly understood. Traditionally, it is assumed that its effect is closely linked to its ability to reduce cerebral metabolism, especially the basal metabolism. It is clear that brain metabolism, and cerebral oxygen and glucose consumption ($CMRO_2$, CMRgl), are temperature-dependent and that hypothermia reduces both. However, experimental studies show that this effect is only one of the many mechanisms by which hypothermia modulates the abnormal neurochemical cascades triggered by TBI [38,39,40].
In healthy subjects, moderate hypothermia induces a linear reduction of CBF in a temperature range between 18 and 37°C. An interesting phenomenon is that physiological metabolic coupling is preserved intact across this temperature range [41].

28.9.1 Basal Metabolism and Functional Metabolism

To understand the beneficial effects of hypothermia on the CNS, it is important to remember some basic physiological concepts. Basal metabolism of an organism is the basic metabolic requirements below which the body is unable to survive [42]. Howerver, certain animals are able to reduce their metabolism for prolonged periods of time and enter in a self-induced state of prolonged reduction of their metabolism to protect themselves against adverse environmental conditions such as lack of heat, water or oxygen [42].
In the cerberal metabolic rate of oxygen ($CMRO_2$), we must distinguish two compartments: functional metabolism and basal metabolism. Functional metabolism is the fraction of $CMRO_2$ dedicated to maintaining electrical brain function, an the electrical activity reflected in the electroencephalogram (EEG) [43]. Basal metabolism is dedicated almost exclusively to sustain the functions necessary to maintain cell structure [43]. The basal metabolism in mammals is organ-dependent, so that each organ contributes differently to the total basal oxygen consumption. Skeletal muscle, abdominal organs and the brain are the three organs which, in this order, consume most of the basal oxygen. However, when $CMRO_2$ is considered in relation to weight, the brain has the highest basal metabolism of any organ in the body.
Vise, using the comparison with a computer defined functional metabolism simply as the metabolic requirements needed to give support to the "brain software", while basal metabolism is responsible for maintaining the "hardware" [44]. Michenfelder reported that 50-60% of $CMRO_2$ is dedicated to maintaining the brain's electrical activity [45,46]. This functional metabolism is the one that decreases when barbiturates are adminis-

tered at doses sufficient to induce the so-called “burst suppression”. An important fact to consider is that hypothermia is only able to cause an isoelectric EEG when reaching 17 to 18°C core temperature.

28.9.2 Therapeutic Use of Hypothermia

In the early 1990s several researchers reported encouraging results in phase II and III clinical trials in which moderate hypothermia was used—prophylactically or to treat patients with increased ICP— in patients with severe TBI [47-51]. The turning point that rekindled interest in hypothermia was the study of Marion et al. published in 1997 where moderate hypothermia was used prophylactically [50]. The excitement caused by this study was largely due to the substantial media coverage that it received outside the medical field. However, the hopes that moderate hypothermia was able to improve the outcome of patients with severe TBI were aborted prematurely and probably hastily, after reports of the results of two large multicentre trials conducted in the United States and Japan [52-55]. In these two studies, early induced moderate hypothermia was not effective in improving mortality and functional outcome of patients with severe TBI. The two studies were questioned for various reasons but we will not discuss them in detail in this chapter. However, it must be emphasized that these results put a moratorium on further research into this powerful but complex treatment.
A few years later, a controlled single-centre study published by Zhi et al. involving 396 patients showed that hypothermia was able to significantly reduce mortality and increase the percentage of patients with a favourable neurological outcome [56]. Due to the uncertainty of its effectiveness, the complexity of its use and its side effects, hypothermia has been virtually abandoned in recent years in the management of patients with TBI. However, in the opinion of many, hypothermia deserves a second chance in the management of neurotrauma patients. At present, a European multicentre study is being designed, aimed at demonstrating the effectiveness of moderate hypothermia in patients with severe TBI.
In a recent systematic review, Sydenham et al. [57] found 22 randomized clinical trials on hypothermia in severe TBI. These studies included 1409 patients. The study showed that mortality was significantly lower in the group treated with hypothermia than in the control group (odds ratio [OR] = 0.76, 95%CI, 0.60-0.97).However, the eight studies considered methodologically the most robust showed no significant differences in mortality (OR 0.96, 95%CI, 0.68-1.35) or in the probability of a favourable functional outcome [57]. The review also reported a greater tendency to pneumonia, but with a narrow odds ratio and a wide confidence interval (OR 1.06, 95%CI, 0.38-2.97).
Recently, Sahuquillo et al. in a pilot study have demonstrated the feasibility, speed and effectiveness of this measure, induced by intravascular cooling in reducing increased ICP refractory to first-level therapeutic measures [58]. These results are consistent with those of other authors who demonstrated in open and non-controlled studies that hypothermia is effective in reducing ICP.
In addition, the results of the six systematic reviews carried out to date do not allow to definitively exclude the neuroprotective efficacy of prophylactic hypothermia. For this reason, moderate hypothermia can be considered a reasonable alternative to barbiturates in a selected group of patients when first-level measures have failed to control ICP. However, we recommend that moderate hypothermia be used only in centres with experience in its management and a sufficient number of patients to maintain a minimum level of expertise, without which the complications of moderate hypothermia can mask its clinical utility [58].

Traditionally, methods to induce moderate hypothermia in patients with severe TBI were surface methods (by convection or conduction) associated or not with adjuvant measures such as gastric lavage with cold saline, infusion of cold intravenous fluids, ice applied to the skin surface, and so on. The main disadvantage of these methods is that they require skilled nursing staff to reach the target temperature within a reasonable time, which is almost always more than 6-8 hours. On the other hand, after reaching the target temperature with these methods, the stability of the core temperature is highly variable and can range from 0.5 to 1.5°C in either direction. These temperature variations result in a suboptimal temperature management. Another additional disadvantage of the surface methods is the significant workload it posses to nurses.

Moderate hypothermia may have some complications which can be grouped into four broad categories [59]:

- Cardiac, including bradycardia, arrhythmias, reduced myocardial contractility and hypotension;
- Immune, mainly immunosuppression with consequent increased infectious complications, especially nosocomial pneumonia and bacteremia;
- Hematologic, primarily thrombocytopenia and coagulopathies; and
- Metabolic.

The last include metabolic stress induced by shivering , hyperglycemia, hypokalemia, paralytic ileus and cold-induced polyuria and their associated electrolyte disturbances.

We can conclude that although the role of moderate hypothermia is not yet well established, the variability in clinical outcomes may be the result of the different methods and protocols used to reach the target temperature. Further studies are clearly needed to establish the criteria for selecting patients with severe TBI who may benefit from this treatment, the optimal time for moderate hypothermia induction, the optimal target temperature with a better risk-benefit ratio, the optimal duration of treatment, and the best way to avoid complications. The new European multicentre study funded by the European Society of Intensive Care Medicine (EuroTherm3235) may help in the near future to better define the indications for moderate hypothermia in TBI [60].

28.10 Decompressive Craniectomy

A rescue alternative to medical treatment when ICP is not controlled is decompressive craniectomy. In essence, this technique seeks to increase the cranial volume by removal of a more or less large part of the cranial vault and by opening the dura mater (Figure 28.3).

Decompressive has been reinstated for the treatment of severe TBI after many years of almost complete abandonment. Despite the lack of Class I evidence to justify its routine use in adults, decompressive craniectomy is often used in many specialized neurotrauma centres. In the last decade, both neurosurgeons and intensive care physicians have shown a renewed interest in decompressive craniectomy for the management of high ICP refractory to first- and second-level measures. These patients have a catastrophic result if ICP is not controlled. We recently updated a systematic review for the Cochrane Collaboration, upon which we base much of the content of this section [61].

Even if it remains unclear who was the first neurosurgeon to practice decompressive craniectomy, the first known publication was by Annandale in 1894. For an excellent historical review of the initial stages of this technique, we recommend the work by Spiller and Frazier, 1906 [62]. Nearly all pioneers in neurosurgery occasionally performed this surgical procedure as a palliative measure in inoperable tumours, although it was Kocher in

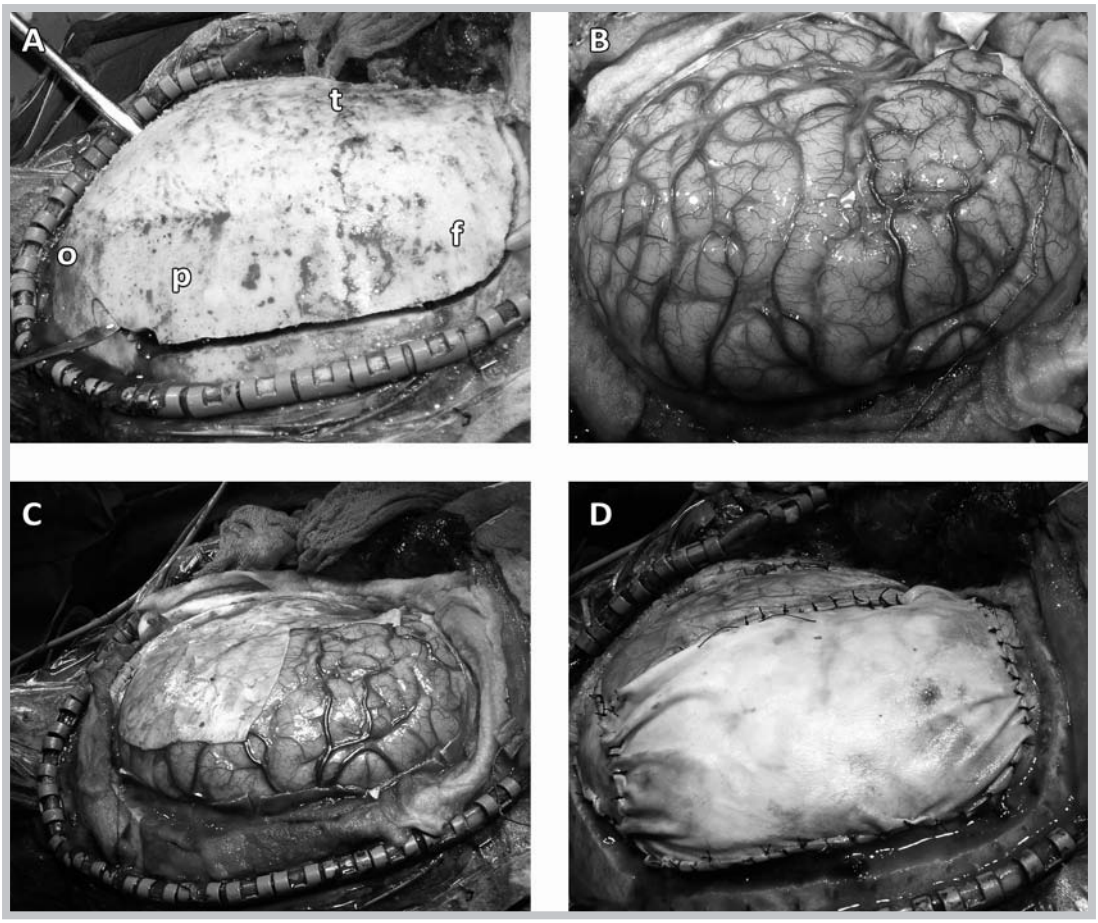

Figure 28.3. **Decompressive hemicraniectomy in a patient with unilateral brain swelling. The image (A) shows the bony limits of the craniectomy, which includes part of the frontal (f), temporal (t), parietal (P) and occipital (o) bones. The decompression is not effective until wide dural opening has been done (image B and C). Although the duramater of the patient can be used for duraplasty, there is need to augment it with a duraplasty which allows better tissue closure in the acute phase and facilitates reimplantation of the bone graft or cranioplasty in a later period (D).**

1901 who first proposed decompressive craniectomy as a technique for the treatment of high ICP. In 1905, Cushing made the first detailed description of subtemporal craniectomy to relieve ICP in patients with brain herniation secondary to inoperable brain tumours [63].

Historically, resection of a bone area of the cranial vault with or without opening of the dura mater has been used sporadically by many neurosurgeons. The first formal publications on this technique dates back to the late 1960s. It must be emphasized that in TBI, decompressive craniectomy does not change the primary lesion – established at the time of impact – but it can be very useful to reduce secondary injuries caused by ICH.

28.10.1 Types of Decompressive Craniectomy

In our systematic review, we distinguished between two types of decompressive craniectomy: prophylactic or primary decompressive craniectomy and secondary decompressive craniectomy [61]. We defined primary decompressive craniectomy the decom-

pression technique which is practiced in patients undergoing any intervention for the removal of an intradural lesion and in whom the purpose of removing the bone flap is to prevent postoperative increases in ICP. In these procedures, the decision is made during the surgical procedure and it is usually based on neuroimaging tests and/or intraoperative findings (brain swelling or difficulty with replacement of the bone flap). "Secondary" decompressive craniectomy is the one practiced in patients in whom ICP control is not achieved with maximum medical treatment. This therapeutic option is generally used when the first- or second-level measures have failed to control ICP.

A systematic review was performed with the objective of assessing the effectiveness of secondary DC in patients with severe TBI and ICP refractory to maximum medical treatment and the functional outcome at 6 and 12 months after injury. For this, randomized or quasi-randomized studies published in any language were included which included patients aged over 12 months, a GCS score ≤8, and ICP refractory to medical treatment (analgesia, sedation, muscle relaxants, hyperosmolar solutions, hyperventilation, barbiturates, etc.) [61].

The review detected only one Australian study aimed to test the effectiveness of DC in increased ICP refractory to medical treatment in the pediatric population (<18 years). The study by Taylor et al. included a total of 27 patients over a period of 7 years and was suspended by the authors because they thought it was unethical to continue enrolling patients after having demonstrated the effectiveness of this technique in an interim analysis. The quality and design of the study were high and the lack of blinding of patients was compensated by evaluation of outcome by an independent evaluator [64]. In this study the relative risk (RR) of death in the DC group was significantly lower than in those treated with medical therapy (RR = 0.54, 95%CI 0.17-1.72). The risk of an unfavourable outcome (death, permanent vegetative state or severe disability) was also lower than in the control group (RR 0.54, 95%CI 0.29-1.01).

Despite the numerous publications on this technique in the last decade (retrospective, prospective nonrandomized studies, etc.) suggesting the effectiveness of secondary DC, no studies were found in adults that met the criteria set by the review. Therefore, in adults, we must strictly conclude that there is insufficient evidence to substantiate the efficacy of decompressive craniectomy in reducing mortality or improving neurological outcome in patients with severe TBI and high ICP. It should also be emphasized that DC may have potential adverse effects, such as increased edema, the appearance of subdural collections, hydrocephalus or stroke.

28.10.2 Indications for Decompressive Craniectomy

Despite the lack of robust evidence, many small series consistently indicate the potential benefit of DC in reducing mortality and improving functional outcome in adults with severe TBI and increased ICP refractory to medical treatment. However, these studies have important methodological limitations, so it is difficult to extract any conclusion because of the heterogeneity of patients and the wide variability in the surgical techniques. Therefore, and although decompressive craniectomy cannot be strictly recommended as routine treatment in patients over 18 years of age, in our opinion it is reasonable to include this procedure as a rescue therapy in patients in whom maximal medical treatment has failed to control ICP.

In pediatric patients, the only study carried out so far showed that decompressive craniectomy—even without the opening of the duramater— is effective in reducing ICP, mortality and improving functional outcome. We would like to emphasize that leaving the duramater closed should be considered a suboptimal procedure in children and not indicated

in adults. Currently, there are two randomized controlled trials (RESCUEicp and DECRA) which will set the indications of decompressive craniectomy in adult patients. In fact, evidence-based guidelines, protocols and recommendations from both European and North American societies consider DC acceptable as a rescue procedure when medical treatment fails to control ICP and intracranial lesions surgically evacuable are ruled out.

28.11 Acknowledgements

We'd like to thank the nursing staff of the Intensive Care Unit of Hospital of Traumatology for their collaboration in this study. This work was supported in part by a grant from the Fondo de Investigaciones Sanitarias (FIS PI080480 and PI11/00700) and Fundación Mutua Madrileña Grant (FMM2010-10) awarded to Dr. J. Sahuquillo.

29 Non-conventional Therapeutics for the Treatment of Elevated Intracranial Pressure: Indomethacin and THAM

Madds Rasmussen [1], Alberto Biestro [2]

[1] Department of Neuroanesthesia, Århus University Hospital, Nørrebrogade 44, 8000 Århus C., Denmark
[2] Professor alone de Medicina a Intensiva, Intensive Care Center Hospital de Clinicas Montevideo, Uruguay

29.1 Indomethacin

Indomethacin, a non-selective fatty acid cyclo-oxygenase inhibitor, is a potent cerebral vasoconstrictor and decreases cerebral blood flow (CBF) without affecting cerebral oxygen metabolism in experimental and clinical studies. Indomethacin's action on cerebrovascular physiology is unique and does not appear to be shared by other cyclo-oxygenase inhibitors.
Published clinical experience with indomethacin in the management of elevated intracranial pressure (ICP) in head-injured patients is limited to six small uncontrolled studies. In order to provide the clinician with sufficient information on the use of indomethacin as a treatment option, the following section presents a short review of the literature on clinical experience with indomethacin in controlling ICP.

29.1.1 Literature Review

Jensen et al. treated five patients with severe head injury and elevated ICP. Indomethacin was administered as bolus of 30 mg IV, followed by infusion of 30 mg/h for 7 hours when ICP was >20 mmHg despite treatment with hyperventilation, pentobarbitone and mannitol [1]. Intracranial pressure decreased within 5-10 seconds after administration and reached a minimum 1-5 minutes after indomethacin administration; and within 15 minutes, the mean ICP decreased from 28 to 17 mmHg. This decrease in ICP lasted about 4 hours and was followed by an increase in ICP after 7 hours. The reduction in ICP was accompanied by a non-significant increase in cerebral perfusion pressure (CPP) and an average decrease in CBF from 34 to 29 ml/100 g/min, measured 15 minutes after initiation of treatment. The pronounced effect of indomethacin in lowering ICP was later confirmed in an uncontrolled study by Biestro et al. who treated 10 patients with severe head injury and elevated ICP refractory to treatment with mannitol, hyperventilation and barbiturates [2]. Indomethacin was administered as a bolus dose of 50 mg IV over 20 minutes, followed by continuous infusion of 21.5±11 mg/h over 30±9 hours. Mean ICP was reduced from 34.4 to 16.4 mmHg and associated with an increase in CPP. Intracranial pressure (average, 23.1 mmHg) remained decreased during the infusion. Subsequent discontinuation of indomethacin treatment resulted in a significant rebound of ICP to pre-treatment levels. The authors did not measure CBF or cerebral metabolic rate of oxygen ($CMRO_2$) [2].

In another study of patients with severe head injury, Dahl et al. found that the decrease in ICP following an indomethacin bolus dose of 30 mg was comparable to the ICP decrease observed during a 0.88 kPa decrease in partial pressure of carbon dioxide in arterial blood ($paCO_2$) [3]. However, as compared to hyperventilation, the authors reported that indomethacin administration was accompanied by a more pronounced decrease in CBF and a significant increase in both mean arterial blood pressure (MABP) and CPP.
Imberti et al. demonstrated in 9 patients with severe head injury or intraparenchymal hemorrhage that indomethacin (bolus of 15-20 mg) is effective in extinguishing plateau waves (sudden and steep increases in ICP due to cerebral injury) [4]. They found that ICP decreased from an initial average of 58 to 21.2 and 25.8 mmHg after 5 and 10 minutes, respectively. Also, they found an increase in brain tissue oxygen partial pressure (PO_2), CPP and arteriojugular venous difference of oxygen ($AVDO_2$) without changes in MABP.
Recently, Puppo et al. demonstrated in 16 patients with severe head injury that indomethacin significantly reduced ICP and CBF and increased CPP. Their study also suggested that indomethacin may improve dynamic cerebral autoregulation [5].

29.1.2 Dose Considerations

The bolus dose of indomethacin used in clinical studies ranges from 0.1 to 0.5 mg/kg. Infusion rates range from 22 over 30 hours to 30/h mg over 7 hours.

29.1.3 Adverse Effects

The vasoconstrictive effect of indomethacin may increase the risk of cerebral ischemia in head-injured patients with compromised CBF. No studies have evaluated the risk of indomethacin-induced cerebral ischemia in patients with head injury. Currently, no adverse effects have been reported. However, reductions in CBF after indomethacin administration were reported in the above-mentioned studies and it is possible that some of these patients suffered from cerebral hypoperfusion.
Indomethacin does extend bleeding time but not beyond the normal range in healthy volunteers. It is possible that indomethacin may increase the risk of bleeding in coagulapathic patients.
Care should be taken with the use of indomethacin in patients with compromised renal function, and the drug may also have an adverse effect on renal function in hypovolemic patients.

29.1.4 Summary and Recommendations for the Use of Indomethacin

Evidence for the use of indomethacin in the treatment of elevated ICP is scarce. In a small number of uncontrolled studies, indomethacin has been demonstrated to effectively reduce ICP and improve CPP in patients with severe head injury. Therefore, we only recommend it as a therapeutic option to reduce increases in ICP when conventional therapy has failed. We suggest the following treatment protocol in the sedated, mechanically ventilated patient with severe head injury (Glasgow Coma Scale [GCS] <8):

- Elevated ICP >20 mmHg for 1-2 hours despite conventional ICP-reducing therapy. Surgical explanations for persistent high ICP should be eliminated.
- Administer indomethacin as a bolus dose of 0.1 mg/kg followed by infusion of 0.1 mg/kg/h. Monitor ICP if possible and repeatedly re-evaluate the patient and reconsider the need for indomethacin. We suggest that indomethacin infusion be terminated after a maximum of 30 hours.

- A central venous catheter should be placed in the jugular bulb to monitor the effect of indomethacin on CBF. Jugular bulb oxygen saturation ($SjVO_2$) <50 % may indicate cerebral hypoperfusion and increase the risk of cerebral ischemia.

29.2 Tromethamine (THAM or TRIS)

In our experience, THAM is a alternative option for the treatment of refractory intracranial hypertension (ICH). The drug acts on the main mechanisms of ICH: 1) derangement in cerebrovascular reactivity; and 2) lowering of spatial buffering.
Like indomethacin, it is a low-cost, easily managed drug with a good benefit/risk ratio.

29.2.1 Pharmacological Properties

THAM is a stable, hydrophilic alcohol amine that behaves as a weak base and can buffer metabolic and respiratory acidosis (formulas 1 and 2, respectively). Along with carbicarb, it is the only compound in clinical use with the property to reduce carbon dioxide content in the blood.

$$\text{THAM-R-NH}_2 + H^+ + La^- \leftrightarrow \text{THAM-R-NH}_3^+ + La^- \text{ (Formula 1)}$$

$$\text{THAM-R-NH}_2 + H_2O + CO_2 \leftrightarrow \text{THAM-R-NH}_3^+ + HCO_3 \text{ (Formula 2)}$$

The formulation currently used is a 0.3 molar solution of THAM acetate (mol/l) with the following properties:

- Molecular weight = 121 Da.
- Osmolarity = 380 mOsm/kg of H_2O.
- pH = 8.6.
- Both properties (osmolarity and pH) make peripheral venous administration safe.
- pK 7.82 very close to the plasma pH range, which is why THAM is a more efficient buffer than sodium bicarbonate, which has 6.1 pK. THAM also maintains unchanged its buffering capacity in hypothermia, which is why it is also preferred in this condition.

THAM is rapidly distributed in the approximate volume of the extracellular space. Very little penetrates into the cells and its passage across the intact blood-brain barrier (BBB) is negligible [8,9] unless the BBB is injured.
THAM is eliminated renally in a protonated form, with a clearance similar to creatinine. In healthy subjects, 25% of the intravenously administered drug is excreted in 30 minutes and over 80% after 24 hours.

29.2.2 Mechanism of Action

The mechanisms of action of THAM in lowering ICP in the brain are not fully elucidated. Some explanations have been postulated:

- Reduction of cerebral blood volume (CBV). Despite its poor passage across the BBB, THAM alkalizes the brain interstitium and the intracellular fluid at a distance from the capillaries. At this level, THAM induces a decrease in CO_2, with a CO_2 offsetting increase, highly diffusible from the cell into the extracellular medium, to form HCO_3. The resulting alkalinisation of the extracellular medium induces vasoconstriction and reduces CBV, improving cerebral hemodynamics and the pressure-volume ratio, and lowering ICP. This is thought to be the drug's mechanism of immediate action in controlling specific rises in ICH.

- Effect on intracellular brain edema. Alkalinisation of the intracellular fluid gives rise to "saving" of sodium entry into the glia where the ion is accumulated in order to expel protons (generated in abundance during injury) and maintain electroneutrality thanks to the membrane H^+/Na^+ exchanger. This sodium "drags" water and consequently swelling is the price the cell pays to maintain intracellular acid-base balance. Thus, THAM operates as a "proton vacuum pump" from the capillaries, as confirmed by animal models of acute brain injury which showed a decrease in sodium and water content (edema) of both cerebral hemispheres in the THAM-treated group [10]. This drug-mediated action would provide the rationale for THAM's prophylactic use in continuous infusion.
- Recently, a differential action on cerebral microvascular reactivity between hypocapnia and THAM has been reported. While both produce alkalinisation of the brain interstitium, only THAM activates the extracellular signal-regulated kinase (ERK) pathway of the interstitium, which is believed responsible for a further increase in

Study design	Nr. of patients	ABI type	Dose	Initial ICP	ICP	Other effects

vascular resistance and inhibition of endothelial-related relaxation [11]. This could impair cerebral autoregulation due to the action of THAM, an event not demonstrated in our own studies, however [12].

29.2.3 Clinical Studies

Several clinical studies (Table 29.1) have demonstrated the efficacy of THAM in lowering ICP. The results of randomized prospective trials conducted by Muizelaar [13], Rosner [14] and Wolf [15] provide a higher level of evidence and should be considered. These studies reported a decrease in ICP in the THAM-treated groups and a decrease in therapeutic intensity as evaluated by the need for cerebrospinal fluid (CSF) drainage, mannitol doses and use of barbiturate. ICP decreased as reliably as with osmotherapy, and its effect was more durable. In Muizelaar's study [13] it was observed that THAM offset the negative effect on the outcome obtained with intense hyperventilation alone (<30 mmHg $paCO_2$), even better than in the control group (moderate hyperventilation). The THAM group also showed more stable ICP. Although this was confirmed by Wolf's study [15], no final improvement in patient outcome was evident because a type alpha or II error may have had an impact owing to the small sample in this study.

29.2.4 Practical Aspects

THAM [8] can be administered in two ways:

- 500 cc to 1000 cc bolus of 0.3 molar solution over 30-60 minutes, followed by 0.3-0.6 mmol/kg/h.
- Bolus similar to the first one, on demand, according to ICP values.

The recommended daily maximum dose is 15 mmol/kg.

In prolonged infusion, arterial pH should be monitored, without exceeding pH 7.5. Otherwise, infusion should be reduced.

There are three recommended specific indications for the use of THAM in neurocritical patients with ICH:

- When $paCO_2$ can't be manipulated by mechanical ventilation because of severe respiratory impairment, THAM can be given to reduce capnia and thus reduce secondary ICH.
- Sequential alternation of osmotherapy with hypertonic saline (synergistic effects on ICP while regulating the acid-base status, theoretically counteracting the effect of hyperchloremic acidosis) to control refractory ICH.
- Correction of accidental severe hyperventilation ($paCO_2$ <30 mmHg). Dose (150-300 ml/h over 3-6 hours) can be repeated after achieving moderate hyperventilation. THAM should be given during prolonged intense hyperventilation, as it improves clinical outcomes, as Muizelaar's study showed.

During its use, the plasma K level and daily intake of the ion should be monitored, because of the possibility of THAM causing hyperkalemia.

Contraindications:

- Renal failure.
- Spontaneous breathing (THAM requires mechanical ventilation); and c) pH >7.5.

29.2.5 Conclusions

This is a very interesting drug, with unique actions not shared by other therapies (complementary). Its use is common, especially in Europe; however, the most relevant stud-

ies are from the United States, though it is not cited in the more widespread guidelines. We have gained experience in its use over the past ten years and believe that has been studied insufficiently, so that new studies are needed to identify its right place in the management of neurocritical patients.

30 A Different Point of View in Intracranial Hypertension Management: the Lund Therapy

Per-Olof Grände [1], Peter Reinstrup [1]

[1] Department of Anaesthesiology and Intensive Care, University Hospital of Lund, Lund, Sweden. Address: Department of Anaesthesiology and Intensive Care, Lund University Hospital, SE-221 85 Lund, Sweden

30.1 Introduction

Traditional treatments of severe head injury have mainly followed the protocols formulated by the U.S. Brain Trauma Foundation [1], the European Brain Consortium (EBIC) [2] and some local protocols such as the Addenbrook algorithm from Cambridge [3]. These protocols are based on meta-analytic overviews, combined with consensus and expert opinions. The protocols have been variously modified since their introduction, but they all comprise essentially the same components and have informed the dominating guidelines worldwide during the last 10 to 15 years.

An essential goal in the treatment of severe brain injury is to minimize the secondary injuries that develop soon after trauma. For this purpose, traditional treatments have advocated the maintenance of cerebral perfusion pressure (CPP) above a certain level in an attempt to squeeze enough oxygenated blood through the swollen brain. Vasopressors such as noradrenalin have been used more or less routinely and often in relatively high doses. Traditional treatment can therefore be characterized as a mainly "CPP-targeted" therapy. Mortality rate and poor outcome after severe head injury remain high. Two recent British database surveys showed that overall outcome after severe head injury has not improved during the decade after 1995 in spite of significant advances in general intensive care [4,5]. This and the lack of convincing scientific support for most measures in the treatment of severe head injury have cast doubt on the effectiveness of traditional treatments. The introduction of a different point of view in the management of intracranial hypertension, such as the Lund therapy, is therefore warranted.

The Lund therapy [6] was introduced about 20 years ago at the Lund University Hospital, Sweden. The Lund therapy was controversial from start as it differed considerably from traditional protocols, both in theory and in clinical approach. Its main characteristics are based on hypotheses derived from basic physiological principles of the control of brain volume and cerebral perfusion. The Lund therapy can be characterized as a combined "ICP-targeted" and "perfusion-targeted" therapy. In the normal brain there is a wide margin for cerebral perfusion before adverse hypoxia will occur, as in the less injured areas of the injured brain. Accordingly, the perfusion-targeted part of the therapy aims to optimize perfusion of the pericontusional areas, normally denoted the penumbra zone. As with traditional treatments, we still lack randomized clinical studies proving the effectiveness of the Lund protocol. However, its principles rest on a strong physiological basis and are supported by experimental studies and non-randomized clinical outcome studies from five different neurotrauma centres [6]. Most of the hospitals that have adopted the Lund concept have shown a marked reduction in mortality compared to historical control data [6,7].

This chapter will present the main principles of the Lund therapy and its use in clinical practice. A more detailed overview of the basic principles of the Lund therapy and its clinical application has been presented previously [6].

30.2 Pathophysiology After Brain Trauma

There is a general view that not only primary injury but also secondary injuries, developing over a period of hours and days and ensuing in a further loss of potentially salvageable cells, is of importance for outcome. Secondary injuries may be triggered by the release of neurotoxic factors such as excitatory amino acids and free radicals. Cell apoptosis is further aggravated by hypoxia around the hemorrhagic and ischemic contusions. Hypoxic pericontusional areas (penumbra) may expand due to further compromised microcirculation resulting from vasoconstriction, endothelial cell swelling, blood cell aggregation and wall adhesion. This may cause the release of inflammatory and neurotoxic substances and trigger more cell damage, including opening of the blood-brain barrier (BBB) and more brain edema.

Brain edema after head trauma may be intracellular due to energy failure (cytotoxic edema). It may also be interstitial due to increased hydrostatic and decreased plasma oncotic pressure, combined with disruption of the BBB (vasogenic edema), in addition to increased interstitial osmotic pressure from cellular and molecular disintegration. As we still lack any neuroprotective substance shown to improve outcome, we have to focus our therapy on reducing the secondary insults by improving microcirculation around the contusions and by reducing brain edema. Vasogenic edema can be counteracted by modulating transcapillary hydrostatic and oncotic pressures. Modulating the transcapillary Starling forces (hydrostatic and oncotic transcapillary pressures) and improving microcirculation around contusions are keystones in the Lund therapy, as will be described below. Improved microcirculation will not only spare brain cells from hypoxia but also counteract the vasogenic edema by reducing the breakdown of the BBB and ultimately save hypoxic brain cells.

30.3 Measures to Reduce Vasogenic Brain Edema

Normal control of brain volume is based on an intact BBB. This means that passive transport of even the smallest solutes – sodium and chloride ions – across the cerebral capillaries is highly restricted and only water passes the capillary membrane passively. At steady state, the transcapillary hydrostatic pressure of 20-25 mmHg is balanced by an equal plasma oncotic pressure. Any imbalance between these pressures favours filtration, however, it will not induce transcapillary fluid exchange because fluid filtration of pure water will be immediately counteracted by dilution of the high interstitial crystalloid osmotic pressure of about 5500 mmHg. In the normal brain, these mechanisms protect it against variations in brain volume following alterations in intracapillary hydrostatic and oncotic pressures.

In the injured brain with a BBB permeable to small solutes, the normal dilution mechanism counteracting filtration will be much weaker, as the filtrate will contain small solutes owing to an imbalance between the hydrostatic and the oncotic pressure. The filtration will continue until it reaches a new steady state at a higher ICP. It can be calculated that, in the worst case, the increase in intracranial pressure (ICP) may be up to 8 times higher than the imbalance between the hydrostatic and the oncotic pressures triggering the fil-

tration [8]. The hypothesis that ICP is highly dependent on arterial pressure at a state of increased cerebral capillary permeability has been confirmed experimentally in the cat [9]. The gaining relation between the Starling forces and ICP is a consequence of the fact that the brain is enclosed in a rigid shell, allowing ICP to be higher than extradural venous pressure. This is in contrast to other body tissues where tissue pressure is close to atmospheric pressure or even negative. The supra-atmospheric intracranial pressure is created by a sophisticated balance between the production and absorption rates of cerebrospinal fluid (CSF) and the fact that the brain lacks a lymphatic draining system. The hemodynamic principles for the brain being enclosed in a rigid dura/cranium are presented in Figure 30.1.

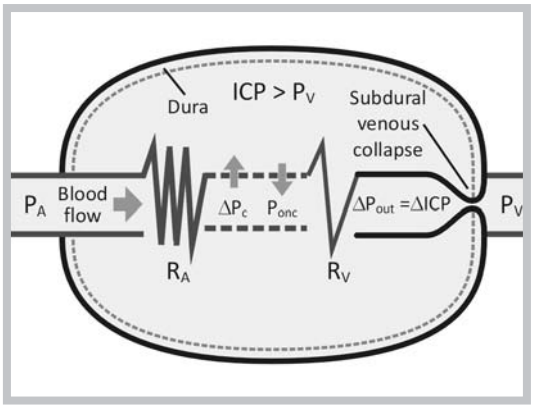

Figure 30.1. **A schematic illustration of the brain enclosed inside the dura/cranium. ΔP_c denotes transcapillary hydrostatic pressure; P_{onc} plasma oncotic pressure; P_A arterial inflow pressure; R_A arterial resistance; R_V venular resistance; P_{out} pressure just retrogade to the venous collapse; and ICP intracranial pressure. The magnitude of subdural venous collapse depends on the difference between ICP and P_V. The existence of a venous collapse means that the change in ICP in any direction is greater than the imbalance between P_c and P_{onc} creating the change in ICP, and that the brain is protected hemodynamically from P_V variations (see text for details).**

According to these principles, vasogenic brain edema can be counteracted by reducing hydrostatic capillary pressure and by normalizing the lowered plasma oncotic pressure. The first can be accomplished by reducing arterial pressure from the commonly raised levels towards normal values (see below) and, the second, by increasing the plasma oncotic pressure by colloid infusions. Note that the limit for adequate arterial pressure is lower in the sedated patient in a horizontal position than in the awake mobile patient. The hydrostatic capillary pressure will vary more with the arterial pressure in the injured brain with depressed autoregulation than in the normal brain.

Reducing arterial pressure with antihypertensive treatment should only be initiated from a normovolemic state (see below) and only with drugs which do not induce cerebral vasodilation, which *per se* will increase intracranial blood volume and ICP. Drugs with $beta_1$-selective antagonistic, $alpha_2$-agonistic and angiotensin II antagonistic effects are therefore recommended. Moderate head elevation can be used, if necessary, to reduce the hydrostatic capillary pressure from the arterial side. Plasma oncotic pressure can be normalized with albumin infusions (see below). In contrast to the hydrostatic transcapillary filtration effect, the oncotic absorbing effect is independent of the brain's autoregulatory capacity. Note that the reduction in brain edema following a shift in the balance between the hydrostatic and the oncotic pressure towards absorption is slow, and it may take several hours before any signs of ICP reduction will appear.

As mentioned above, normal ICP (about 10 mmHg) is always higher than extradural venous pressure, creating a passive venous collapse just inside the dura (venous outflow resistance, Figure 30.1). The magnitude of the collapse depends on the difference between ICP and the extradural venous pressure. By an automatic passive adaptation of the degree of venous collapse to the difference between ICP and extradural pressure, the brain is protected hemodynamically against venous pressure variations [6,8]. For example, it is because of this passive mechanism that brain circulation is not influenced on the venous side by head elevation or the use of positive end-expiratory pressures (PEEP) in the ventilator. Therefore, PEEP has no side effects on venous drainage and should always be used

in head-injured patients to prevent atelectasis. The initial reduction in ICP following head elevation can be explained by a blood volume reduction on the arterial side and to some extent from the gravitational force in the spinal canal, but not by an increase in venous drainage. A more long-term ICP-reducing effect of head elevation can be explained by the reduction in hydrostatic capillary pressure when arterial inflow pressure to the brain is reduced, analogous to the effect of antihypertensive treatment.Osmotherapy given in a single bolus dose of hypertonic saline can be used as a life-saving means to prevent an incipient brainstem herniation, while awaiting the effect of other ICP-reducing measures. Mannitol should not be used due to its adverse rebound effect on brain edema.

30.4 Decompressive Craniotomy and Other Surgical Measures

Evacuation of hematomas and focal lesions may reduce the release of inflammatory substances and result in less edema. Decompressive craniotomy will offer extra space to the brain, reducing the risk of herniation. Decompressive craniotomy, however, also causes a loss of transcapillary counterpressure when ICP is reduced which, in the injured brain with a disrupted BBB, will result in transcapillary filtration with the risk of herniation through the cranial opening. Transcapillary filtration may also explain the slow recovery in ICP from the lowered value often seen soon after the operation. These adverse effects can be counteracted by preventing unnecessarily high arterial pressure and by maintaining normal plasma oncotic pressure. Also, the ventricular collapse sometimes seen after CSF drainage can be explained by the induced imbalance between transcapillary hydrostatic and oncotic pressures, and the loss of CSF will be replaced by brain edema with an increased risk of brainstem herniation. Continuous CSF drainage, therefore, must be done with great caution and, when performed, done under computed tomography (CT) control of the ventricular volumes.

30.5 Microcirculation Around Contusions

According to the analogy to Ohm´s law, tissue perfusion relies on perfusion pressure and vascular resistance. The vascular resistance of the penumbra zone depends on several factors, such as the vasoconstrictor state of vessels, degree of micro-occlusion and wall adherence of various blood cells. This means that blood flow to the penumbra zone can be improved by increasing CPP and by decreasing its vascular resistance. According to the fourth power relationship between radius and resistance as formulated in Poiseuille's law, even small variations in vessel radius may result in large variations in vascular resistance in areas with increased resistance, such as the penumbra zone. It follows then that a relatively small decrease in the radius of a vessel or an increase in the degree of micro-occlusion/adherence in the penumbra zone will result in a large decrease in perfusion. Therefore, it is much more important for the perfusion of the penumbra zone to minimize vascular resistance than to maintain a high CPP. The paragraphs below deal with different measures to improve penumbra zone perfusion.

30.6 Maintenance of Normovolemia to Improve Cerebral Microcirculation

Hypovolemia compromises cerebral circulation via an alpha-mediated effect secondary to activation of the baroreceptor reflex. As shown experimentally in piglets, hypovole-

mia has a great adverse impact especially on the traumatized brain [10]. Prevention of excessive baroreceptor reflex activation, and the concomitant catecholamine release by keeping the patient normovolemic, is probably the most important measure to preserve microcirculation of the penumbra zone. Preservation of normovolemia under a generally increased permeability is, however, a sophisticated task, as explained below.

Unless adequately treated with intravascular volume substitution, head trauma patients will develop hypovolemia due to increased permeability in most body organs and a reduced recirculating capacity of the lymphatic system in the unconscious immobile patient. The transcapillary escape rate (normal, 5-7% of total plasma volume per h) may increase significantly above the level of the lymphatic capacity, which will increase the interstitial protein concentration in combination with tissue edema.

When using a crystalloid solution as plasma volume expander, the infused volume must be much greater than that when using a colloid solution, as crystalloids are distributed quickly throughout the whole extravascular space, resulting in general tissue edema. More importantly, the crystalloid solution will also be distributed to the interstitial space of the injured brain with a disrupted BBB, aggravating the brain edema. Furthermore, plasma oncotic pressure cannot be maintained when crystalloid solution is used as plasma volume expander.

Normal endogenous plasma protein albumin has become the dominating colloid in severe head injury because of the potential risk with synthetic colloids of coagulation disturbances and increased intracranial bleedings, and because albumin is the only colloid that allows measurement of its plasma concentration. Plasma concentration also gives a measure of plasma oncotic pressure. Like other colloids, albumin also improves a compromised microcirculation. As will be described below, albumin has side effects mainly related to transcapillary leakage. But when used in combination with an otherwise proper therapy, protein leakage can be limited to the extent that normovolemia can be maintained with the use of moderate volumes of albumin without inducing severe side effects.

30.7 Arterial Pressure and Plasma Volume Expanders

A crucial component in the Lund therapy is to avoid hypertension with the use of antihypertensive drugs and the avoidance of vasopressors, so as to prevent or counteract brain edema. According to the 2-pore theory for transvascular fluid exchange [11], the magnitude of transcapillary leakage at increased microvascular permeability in the rest of the body depends on the hydrostatic capillary pressure – the larger the hydrostatic capillary pressure, the larger the leakage of plasma to the interstitium and vice versa. The principles of the 2-pore theory are illustrated in Figure 30.2 and will be described below. The capillary membrane has small pores permeable only to small solutes, while there are a few (about 20,000 times fewer) large pores also permeable to proteins at the venous side of the capillary network and in the venules. This means that the hydrostatic filtration force is the only force inside the large pore. In brief, the higher the hydrostatic pressure, the greater the loss of plasma fluid to the interstitium. Accordingly, the need for plasma volume substitution to maintain normovolemia will be lower in situations of low than of high arterial pressure, also resulting in less interstitial edema. It is known that vasopressor-induced increases in arterial pressure will increase the transcapillary loss of plasma fluid and proteins. This effect was confirmed in a recent study on the rat which showed a drastic increase in plasma volume loss following treatment with noradrenalin at a state of increased permeability [12].

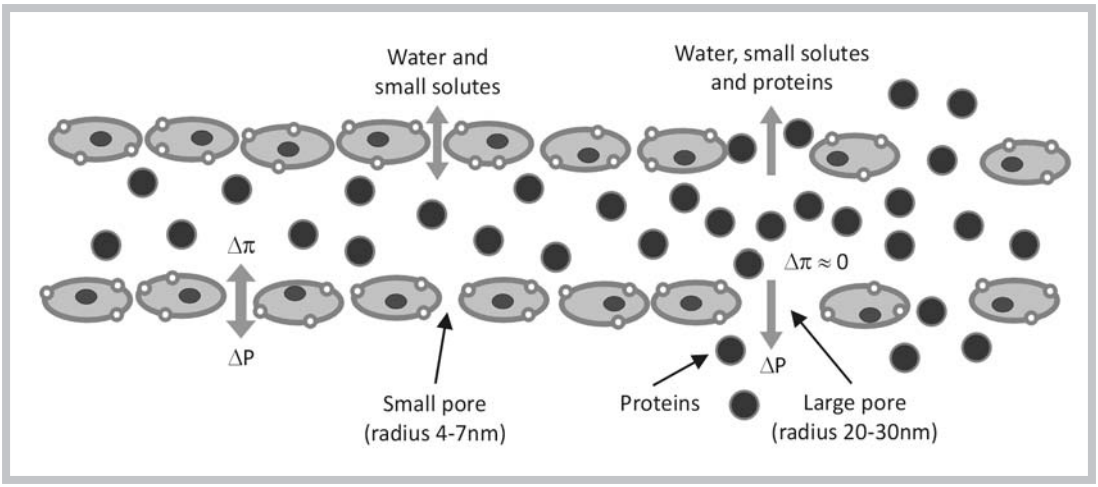

Figure 30.2. **The principles of the 2-pore theory for transcapillary fluid exchange in the body (not the brain). The capillary membrane with its numerous small pores and its few large pores at the venous side of the capillary network. While the transcapillary hydrostatic and the oncotic pressure balance each other across the small pores according to the Starling fluid equilibrium, the hydrostatic filtration force is the only force acting across the large pore, as the oncotic pressure is equal on both sides of the membrane for the large pore. Plasma proteins are lost mainly via convection following the fluid stream through the large pore. This means that an increase in hydrostatic capillary pressure will increase the loss of plasma proteins (see text for details).**

Most likely, due to its effect on hydrostatic capillary pressure, overtransfusion will increase the loss of plasma fluid to the interstitium, as shown experimentally in the rat, and should therefore be avoided [13]. The need for albumin transfusions can also be reduced by increasing the recirculating lymphatic capacity of proteins with a more effective physiotherapy and by keeping a relatively normal hemoglobin concentration (see below).

30.8 Albumin and Erythrocytes as Blood Volume Expanders

There are no studies evaluating the effect of blood transfusion to maintain normovolemia in patients with severe head injury. The need for plasma substitution, however, will be lower when the hemoglobin concentration is normal than when it is low, because a low hemoglobin concentration indicates that the loss of red blood cells must be replaced by a similar large volume of plasma to avoid hypovolemia. A low hemoglobin concentration raises the risk of larger transcapillary leakage of plasma to the interstitium. It has also been shown in the dog [14] and the rat that the loss of plasma volume to the interstitium is larger at a low than at a normal hemoglobin concentration. This is in accordance with our clinical experience where we noted less need for albumin at normal than at low hemoglobin concentrations and that the frequency of undesired hypotensive periods were markedly reduced. Modern research has also shown that optimal oxygenation of the brain occurs when the hemoglobin concentration is close to normal [15]. Most likely, net oxygen delivery to the brain is higher at a normal than at a low hemoglobin concentration in spite of the higher blood viscosity. There are arguments for the use of red blood cell transfusions to achieve normal hemoglobin values, and the Lund therapy recommends erythrocyte transfusions up to a lowest hemoglobin concentration of 12 g/dl. To reduce the side effects associated with blood transfusion, leukocyte-depleted blood and a short storage time of the blood are strongly recommended.

According to the principles described above, normovolemia cannot be achieved in spite of large volumes of albumin infused under acceptance of low hemoglobin concentrations and acceptance of a high arterial pressure, and especially when using vasopressors. Large volumes of albumin infusion do have side effects, which most likely can be related to an increased loss of plasma to the interstitium as a result of vasopressor therapy. This may explain, at least partly, why outcome with albumin was not better than with 0.9% saline [16]. However, when used correctly as a part of the Lund therapy, albumin is most likely the best plasma volume expander available today for severely head-injured patients. This is not only because of its endogenous nature or that the volumes of albumin needed are relatively small to maintain normovolemia, but also because it preserves a relatively normal oncotic pressure. Serum albumin levels were recently shown to be a favourable predictor of outcome after severe head injury [17]. Therefore, albumin is recommended as the main plasma volume expander in the Lund therapy. Higher concentrations of albumin (20-25%) are to be preferred, as higher concentrations have a relatively better plasma volume expanding effect and smaller transcapillary leakage. Furthermore, the peak concentration of albumin following a fast infusion will cause a larger transcapillary leakage of albumin than when albumin is given more slowly over a longer period of time.

30.9 How to Determine Whether Intravascular Volume is Adequate

No doubt, the probability of maintaining normovolemia is much higher with normal hemoglobin and albumin values than with low values – in fact, there are great difficulties to maintain a normovolemic condition with low hemoglobin/albumin concentrations. It is no guarantee, however, that the patient is normovolemic even when hemoglobin and plasma albumin (protein) concentrations are normal. A blood pressure below acceptable values in spite of relatively normal hemoglobin and albumin concentrations indicates that the patient is still hypovolemic. In an isolated head injury, this rarely indicates the need for vasopressors. In such a situation, normalization of blood pressure with further infusion of erythrocytes, perhaps in combination with albumin infusion, will confirm whether the patient is hypovolemic or not. Hypovolemia is the main cause of hypotension in most head-injured previously healthy patients. It must be stated from the principles described above, however, that we cannot fully normalize the intravascular volume whatever the blood volume expander given without inducing side effects such as interstitial accumulation of fluid and proteins, but the side effects will be minimized with use of the therapeutic principles of the Lund therapy. In this respect, avoidance of vasopressors and the use of antihypertensive therapy and transfusion to a relatively normal hemoglobin concentration hold special importance.

30.10 Other Measures to Improve Cerebral Microcirculation

Vasoconstrictors may compromise perfusion of the penumbra zone in analogy with baroreceptor reflex activation during hypovolemia, and they may also compromise microcirculation in other body organs such as the intestine, the kidney and the lung, triggering the development of the acute respiratory distress syndrome (ARDS). The use of noradrenalin, a proinflammatory drug, to increase arterial blood pressure under a hy-

povolemic condition may have severe adverse effects not only on brain circulation, but also on the perfusion of other body organs. Unless otherwise motivated by specific reasons, as in patients with paraplegia or those with severe sepsis, the Lund therapy does not include vasopressor therapy, vasoconstrictors or inotropic support. Beta-stimulating inotropic drugs may increase ICP through their cerebral vasodilating effects and their hydrostatic capillary pressure-increasing effect. The veno-vasoconstrictor drug dihydroergotamin was previously a component of the Lund therapy to reduce intracranial blood vlolume and ICP, but is no longer recommended due to its potential peripheral circulatory side-effects [6].

Stress-induced increases in sympathetic discharge and concomitant catecholamine release may compromise cerebral circulation of the penumbra zone. Antistress therapy is therefore an important part of the Lund therapy. Antistress therapy can include the use of sedatives and analgetics and the avoidance of awakening tests. Also, recommended antihypertensive treatments with $beta_1$-antagonists and $alpha_2$-agonists may have antistress properties, and $beta_1$-antagonists may protect the heart against stress-induced microinfarctions.

Besides its metabolically-induced vasoconstriction and ICP-reducing effects, barbiturate treatment is also effective as antistress therapy. However, the traditional use of barbiturate therapy in high doses up to a burst suppression electroencephalographic (EEG) pattern and over several days leads to severe cardiovascular, electrolyte and pulmonary complications. High fever is also a common sequela of this therapy perhaps due to pulmonary complications. Barbiturates given in lower doses and over a limited period of time, however, are safe and are accepted in the Lund therapy as antistress and ICP-reducing therapy.

It is a well-established recommendation that hyperventilation should be avoided in order to avert hyperventilator-induced vasoconstriction. Short-term hyperventilation can still be of value to break a persistent ICP plateau wave or an incipient brainstem herniation while waiting for other ICP-reducing measures to take effect.

30.11 Arterial, Plasma Oncotic and Cerebral Perfusion Pressure

The optimal arterial pressure is the pressure at which transcapillary hydrostatic and oncotic forces are balanced (no transcapillary filtration). But, simultaneously, there must be an acceptable perfusion of the brain. The higher the plasma oncotic pressure, the higher the arterial pressure (CPP) can be used without transcapillary filtration. A normalized plasma oncotic pressure will allow a higher arterial pressure without filtration, resulting in better perfusion of the penumbra zone compared to a low plasma oncotic pressure.

The lower the vascular resistance of the penumbra zone, the better the perfusion and the oxygenation at a specific CPP. Therefore, a lower arterial pressure can be accepted for preventing the development of vasogenic brain edema under normovolemia and normal hemoglobin concentrations than under hypovolemia and low hemoglobin concentrations. The coupling between ICP, arterial pressure and CPP (CPP = mean arterial pressure – ICP) means that a low arterial pressure does not necessarily imply a low CPP, as a lower arterial pressure means a lower ICP.

The Lund protocol is not a CPP-targeted therapy. In principle, any CPP values in the range of 50-75 mmHg in an adult are acceptable, providing the principles of the Lund therapy are followed. Our experience is that CPP stays in the range of 60-70 mmHg in most adult patients treated according to the principles described in this chapter. CPP values

in the range of 50-60 mmHg may appear and it may be necessary to reduce a markedly raised ICP; such values are acceptable only if cerebral perfusion is optimized as described above. In children, CPP is lower since arterial pressure is lower in children, and CPP values as low as 38-40 mmHg can be accepted in small children but, once again, only with use of the ICP and perfusion-targeted therapy presented in this chapter. A significantly raised ICP in a state of high CPP values despite antihypertensive treatment can be reduced by intensifying antihypertensive treatment and/or by head elevation.
In a large series of adult head-injured patients treated according to the Lund protocol, the interstitial milieu of the penumbra zone was analyzed with the microdialysis technique [18]. The study showed that the interstitial lactate/pyruvate ratio and the glycerol and glutamate concentrations decreased after initiation of the Lund therapy, and this in spite of a simultaneous reduction in CPP following antihypertensive therapy. A reduction in the lactate/pyruvate ratio reflects improved oxygenation, a reduction in glycerol and glutamate reflects less cell damage. In this study, CPP was reduced to 60-70 mmHg in the majority of patients, and the microdialysis results strongly indicated that perfusion of the penumbra zone was improved in spite of the lowered CPP.

30.12 Body Temperature Control

There is a general consensus that fever worsens outcome after severe head injury and that active cooling has neuroprotective effects. This has resulted in the marketing of equipment for active cooling. However, we still lack any randomized studies showing beneficial effects of active cooling after severe head injury. The two randomized studies performed so far, one in adults and one in children, instead showed a trend toward worse outcome in the patient groups treated with active cooling [19,20]. It may be that active cooling has adverse effects in addition to beneficial neuroprotective effect and that the net effect is not predictable.
Lowering of body temperature via active cooling below the thermostat level in the brain induces increased stress and shivering, with increased sympathetic discharge and release of catecholamines to restore the temperature back to its previous level. This may further compromise penumbra zone perfusion. Active cooling to temperatures below normal will also induce coagulation disturbances, with the risk of aggravating contusional and other intracranial bleedings. It has been suggested that the adverse effects of active cooling can be referred to the warming period. The reasons may be related to an increase in intracranial blood volume and an increase in hydrostatic capillary pressure due to a vasodilator effect induced by the increase in temperature. Unlike the situation after cardiac arrest, there are potential negative effects of active cooling after severe head injury, and especially cooling to temperatures below normal, which may explain the lack of improved outcome in the studies performed so far. Physiologically, a better alternative than active cooling would be to normalize a persistently raised body temperature by acting on the thermostat pharmacologically. A bolus dose of steroids can be used for this purpose. Due to the documented side effects of long-term treatment of severe head injury with steroids (the MRC CRASH study), steroid treatment should be limited to a single dose. Paracetamol can also be used, but its temperature-reducing effect is small, and it may have adverse prostacyclin-inhibiting effects.
The best way to prevent fever is to counteract its causes. Fever can be avoided or reduced by lowering the risk of pneumonia by minimizing atelectasis with general lung support and recruitment, the use of PEEP, inhalation and bagging. Furthermore, avoidance of proinflammatory vasocontrictors and high-dose barbiturate therapy are impor-

tant measures to prevent fever in head-injured patients. Fever can also be reduced with the use of enteral instead of parenteral nutrition and by avoidance of overnutrition.

30.13 Nutrition

Nutrition should be adapted to provide the basal energy need without overnutrition, as too much energy supply cannot be utilized in these highly catabolic patients and results in an adverse increase in body temperature. From measurements of the metabolic rate in deeply sedated head-injured patients we have estimated an energy demand of 15-20 kcal/kg/day in the adult. The nutritional requirement per kg body weight in head-injured patients varies with age: it is higher in children than in adults; therefore, it should be adapted to age.

30.14 Clinical Application

A short summary of the main guideline principles is given in Table 30.1.

A more detailed summary of the clinical application of the principles presented in this chapter to reduce brain edema and improve microcirculation of the brain are summarized in the Appendix following this chapter. The treatment components are applicable to all ages, but drug doses must be adapted to the age of the patient. The Lund therapy has no adverse effects – in fact, its principles are beneficial to both less injured patients with normal ICP and to more severely injured patients with elevated ICP. It can be used in both patients with depressed and those with more normal autoregulation. The Lund therapy should start as early as possible after the trauma to prevent ICP from rising to dangerous levels. ICP measurement is of great value in such patients. The Lund therapy can still be used even if ICP cannot be measured. The Lund therapy also seems to be beneficial for other body organs. Almost no severe ARDS, intestinal ischemia or renal insufficiency with the need for dialysis has occurred in patients with an isolated head injury treated at our neurointensive care unit since the introduction of the therapy. This in spite of the fact that the Lund therapy includes antihypertensive therapy. Most likely, this can be explained by better general perfusion obtained with optimal volume therapy, including erythrocytes to normal hemoglobin concentrations, avoiding vasoconstrictors and stress, and with the use of effective lung recruitment including PEEP. When treating a severe head injury according to the Lund therapy, all components presented in the Appendix should be considered. The Lund therapy can also be used to reduce elevated ICP in meningitis.

- Surgical evacuation of contusions and hematomas
- Normoventilation using mechanical ventilation and effective lung recruitment including PEEP
- Maintenance of normovolemia and a normal plasma oncotic pressure with albumin and erythrocytes
- Antihypertensive therapy ($beta_1$-blockade, $alpha_2$ agonist, angiotensin II inhibitor
- Antistress therapy
- Low energy, preferably enteral nutrition
- Avoid vasopressors (neither vasoconstrictors nor substances for positive inotropic support)
- Craniotomy may be life-saving in refractory high ICP
- A single bolus dose of hypertonic saline (not mannitol) can be used to prevent incipient brainstem herniation

Table 30.1. **Short summary of the most important guiding principles of the Lund therapy. See the Box in the following page for details on its clinical application.**

Clinical Guidelines for the Lund Therapy in Severe Head Trauma

- Surgical evacuation of available hematomas and contusions. Placement of an ICP device.
- Mechanical ventilation to normal $paCO_2$ (4.6-5.2 kPa, 35-39 mmHg) and normal paO_2 (12-14 kPa, 90-105 mmHg). Use PEEP (6-8 cmH_2O), intermittent moderate bagging under ICP control, and inhalation to prevent atelectasis. Reduce doses of β-stimulating inhalation drugs (e.g., salbutamol) if they increase ICP and decrease blood pressure (vasodilation). Short-term moderate hyperventilation (<2 min) can break intermittent ICP peaks. Do not extubate until ICP has been stabilized to a normal level.
- In persistent high fever (>38.5°C), the temperature can be reduced with paracetamol or one bolus dose of Solu-Medrol IV (5-7 mg/kg). Do not use active cooling.
- Use low-energy, preferably enteral, nutrition (15-20 kcal/kg/24 h in adults, relatively more energy in children). Enteral nutrition can be complemented with intravenous glucose 5% with electrolytes 1000-1500 ml/24h in the adult. Keep blood glucose levels normal (5-8 mmol/l) with insulin, if necessary. Avoid hyponatremia.
- Effective sedation and stress reduction can be achieved with sedatives (midazolam, thiopental, propofol) combined with α_2-agonist and β_1-blockade (see below). Thiopental should only be used in low doses (2-3 mg/kg in bolus + 0.5-3 mg/kg/h IV), and for 2 days at most to avoid the side effects of barbiturates (e.g., pneumonia, ARDS, fever). Due to uncertainty about long-term treatment with propofol, this drug should be limited to the weaning period.
- Normovolemia is mandatory and is achieved with erythrocyte infusions (leukocyte-depleted blood) to normal S-Hb (120-140 g/l) and albumin transfusions to normal S-alb (33-40 g/l), also normalizing plasma oncotic pressure. High concentrations of albumin solution (20-25%) are to be preferred. Limit the use of crystalloids as plasma volume expanders. Physiotherapy may reduce the need for albumin infusions by activating the lymphatic system. The need for plasma volume expanders is lower in normal than in raised arterial blood pressure (see below), and may be lower when given at a slow than at a fast infusion rate. Avoid overtransfusion. Diuretics can be used (not mannitol). Low doses of an ADH analogue can be used in marked polyuria.
- ICP can be controlled by normalizing plasma oncotic pressure (see above) and blood pressure, the latter with antihypertensive and catecholamine-reducing therapy with β_1-antagonists (e.g., metoprolol 0.04-0.08 mg/kg x 6-8 IV, or corresponding doses continuously, or 50-100 mg x 2 per os) and α_2-agonists (e.g., clonidine 0.3-1.0 μg/kg x 4-6 IV, or corresponding doses continuously or per os) and angiotensin II inhibitor (e.g., losartan 50 mg x 1-2 per os). Clonidine may have adverse α_1-agonistic vasoconstrictor effects at higher doses.
- Optimal CPP is individual. In most cases, it is 60-70 mmHg in the adult and, depending on age, 38-55 mmHg in children and adolescents. Transient, relatively low CPP values (50 mmHg in the adult) may be necessary in selected cases to reduce a critically elevated ICP. Such low CPP values can only be accepted if the perfusion-targeted therapy recommended here is used. Too low a CPP may be corrected by: (a) correcting latent hypovolemia; (b) no extra head elevation; (c) discontinuing thiopental; and (d) reducing antihypertensive therapy. Vasopressors should not be used.
- Moderate head elevation (max 20°) can be used to reduce ICP and provide an acceptable CPP. Additional head elevation may have the adverse effect of reducing venous return to the heart.
- CSF drainage should not be used routinely. It may be used intermittently via a ventricular catheter in small volumes to break an incipient Cushing reflex or a critically high ICP. Drainage at a fairly high level may help to control ICP at a later phase of therapy if CSF absorption is insufficient.
- If ICP increases to higher persistent values despite the interventions described above, a large uni- or bilateral craniotomy may be a life-saving measure to reduce ICP, break a Cushing reflex, and reduce arterial pressure. Optimal ICP-reducing pharmacological and fluid therapy (points 1-9 above) must be continued to reduce strangulation and herniation in the craniotomy. A bolus dose of hypertonic saline (not mannitol) can be used as osmotherapy to break an incipient brainstem herniation.

31 A Critical Point of View in the Management of Intracranial Hypertension: Are All Therapeutic Tools Evidence Based?

Thomas Lescot [1], Lamine Abdennour [1], Louis Puybasset [1]

[1] Neurosurgical Unit, Department of Anesthesiology and Critical Care Pitié-Salpêtrière Hospital, Assistance Publique, Hôpitaux de Paris, Université Pierre et Marie Curie, Paris, France

31.1 Introduction

Most TBI patients with cerebral lesions on cerebral computed tomography (CT), such as hematomas, swelling, contusions or herniation, will develop ICH in the days ensuing injury. A recent observational study showed that the mean intracranial pressure (ICP) will peak within the first 3 days after injury in half of such patients and after 5 days in 25% [1]. An uncontrolled rise in ICP is probably the most common cause of death in TBI patients. For these reasons, ICP monitoring is strongly recommended in TBI associated with abnormal cerebral CT findings. Intracranial pressure monitoring allows to continuously monitor ICP, manage cerebral perfusion pressure (CPP), and withdraw cerebrospinal fluid if an external ventricular drainage is inserted. Elevated ICH is strongly associated with poor outcome in patients with severe TBI. Indeed, elevated ICP may lead to decreased CPP, cerebral ischemia and/or herniation. The ICP threshold above which treatment should be initiated is still debated. A large, prospectively collected database study published in 1991 by Marmarou et al. [2] reported a strong correlation between the number of hours with an ICP >20 mmHg and outcome. Similar results have been recently reported by Balesteri et al. in a retrospective analysis involving 429 TBI patients [3].

Does treatment to decrease ICP improve outcome in TBI? Few data exist regarding this question, and no controlled randomised trial is available, but it seems that patients in whom ICP could be controlled have a much better outcome than those with in whom ICP remained uncontrolled [4,5]. More recently, two retrospective studies showed similar results, suggesting an improved outcome with aggressive ICP therapy [6,7].

In the treatment of ICH, one of the key issues to consider is that TBI is more likely a syndrome than a disease. After trauma, the traumatised brain is characterised by a marked pathophysiological heterogeneity: ischemic areas (cytotoxic edema) coexists with areas with blood-brain barrier disruptions (vasogenic edema), contusions, and normal brain parenchyma. The proportion of each of these areas likely depends on the etiology of TBI. Intracranial pressure-lowering therapies may have some systemic or cerebral differential effect according to the TBI presentation. For example, one can consider that in blood-brain barrier disruption, treatment such as hypertension-induced high CPP and osmotherapy could worsen contusional areas of the traumatised brain.

31.2 Sedation as a Therapy

Sedatives and anesthetics are commonly given to prevent agitation, minimize noxious stimuli, and adapt TBI patients to mechanical ventilation. Benzodiazepines, especially midazolam, are administered in combination with morphine or derivatives such as sufentanil. While they are particularly suitable in the neurological intensive care unit, they are unable to depress brain electrical activity even at high doses, present a long duration of action and a plateau effect.

Propofol administration has been proposed as an alternative in TBI patients. Propofol decreases ICP by reducing brain metabolism [8], which explains its potential neuroprotective effect. Only one double-blind controlled randomised trial was conducted to compare propofol infusion with another sedative regimen in TBI patients. Kelly et al. [9] evaluated the clinical safety and multiple clinical and radiological endpoints in 23 patients in the propofol-morphine group and 19 patients in the morphine sulphate group. The authors found a lower incidence of ICH at day 3 in the propofol group, without any difference in adverse effects between groups. The combined use of midazolam and propofol allows the control of ICH and the possibility to obtain burst-suppression at high doses. Such a combined strategy reduces the use of barbiturates. However, the potential risk with using propofol is the feared propofol infusion syndrome. This syndrome, characterized by multiorgan failure, has a high incidence in sepsis or septic shock, which are therefore contraindications to propofol administration. It is mandatory to stop propofol in case of metabolic acidosis (with or without lactates), hyperkalemia, renal insufficiency, rhabdomyolysis or triglyceride level >5 mmol/l [10]. A daily dosage of blood triglycerides is a common practice in our unit. Hypertriglyceridemia is a warning symptom in this context.

The occurrence of refractory brain hypertension during the first days following the onset of head trauma often requires therapeutic escalation with such therapeutics as neuromuscular blockers, hypothermia and thiopental, all of which have a high potential to deteriorate lung status further through mechanical effects or direct immunosuppressive effects. Barbiturate therapy reduces cerebral blood flow (CBF) and cerebral metabolic rate of oxygen ($CMRO_2$) and it increases cerebral vascular resistance in patients with severe head injury [11]. Barbiturates, particularly pentobarbital and thiopental sodium, have been used effectively in brain-injured patients with increased ICP refractory to sodium management, cerebrospinal fluid drainage, and moderate hyperventilation. The first published series of head-injured patients receiving this therapy in 1979 [12] found that high-dose barbiturate administration reduced elevated ICP in most patients refractory to a rigorous regimen of ICP management. Several studies in the 1970s suggested that barbiturate therapy had a major impact on the prognosis of patients with intractable ICH. Marshall et al. [12], for example, found that 19 of 25 (76%) patients with severe, intractable ICH responded to treatment with high-dose pentobarbitone therapy and that 10 of the 19 responders made a good functional recovery. The authors concluded that barbiturate therapy significantly improved clinical outcome on the assumption that their patients would have otherwise died.

Other studies showed that high-dose barbiturate, when added to a routine of conventional management, could be useful for the reversal of ICP. Barbiturates seem to provide the brain with some protection against anoxia, ischemia, and cerebral edema by decreasing the brain's oxygen consumption, reducing CBF, and stabilizing the membranes. However, barbiturates have a number of serious adverse effects. Cordato et al. [13] reported that prolonged barbiturate infusion induces respiratory complications in 76%, lung infection in 55%, arterial hypotension in 58%, hypokalemia in 82%, hepatic dys-

function in 87%, and renal dysfunction in 47% of the treated patients. Continuous barbiturate infusion is also known to produce immunosuppression by inhibiting lymphocyte function [14], affecting neutrophil function and depressing humoral immune response through a decrease in immunoglobulin production [15]. The use of barbiturates is, by itself, a statistical predictor of an increased risk of pneumonia [11].

31.3 Hyperventilation

The simplest way to decrease ICP is to reduce arterial partial pressure of carbon dioxide ($PaCO_2$). Reduction in ICP is secondary to a decrease in cerebral blood volume. The impact of a sudden change in blood volume on ICP depends on brain compliance and the position of the patient on the Langfitt curve. Accordingly, a given change in $PaCO_2$ and cerebral blood volume will markedly decrease ICP in a non-compliant brain and induce nearly no change in pressure in a compliant brain. Such a decrease in cerebral blood volume also occurs when the mean arterial pressure is increased. However, both therapies have opposite effects on CBF.

Cerebral arteries respond to highly localized perivascular alterations of $PaCO_2$ and pH. During chronic hypocapnia, the CBF remains constant, suggesting that carbon dioxide itself does not control cerebral vascular cerebral tone. It is likely that local pH rather than local carbon dioxide is the mediator of tone regulation. The mediator cascade that links extracellular pH to cerebral vascular tone is complex and interrelated, the final mediator being intracellular calcium. Most studies report a change in global CBF of 1 to 2 ml/100 g^{-1} min^{-1} for each mmHg change in $PaCO_2$. Acutely reducing $PaCO_2$ to 25-30 mmHg decreases the global CBF by 40 to 50%.

Payen et al. [16] studied by contrast-enhanced magnetic resonance imaging the relationship between the change in ventilation and CBF in rats. The authors demonstrated that hypercapnia results in a significant increase in CBF in the brain-studied regions, although there was no direct correlation between the change in cerebral blood volume and flow. Carmona Suazo et al. [17] investigated the effect of hyperventilation on cerebral oxygenation by means of continuous monitoring of brain tissue oxygen pressure ($PbrO_2$). Acute hypocapnia significantly decreased $PbrO_2$, indicating the risk of secondary ischemic damage during hyperventilation in severely head-injured patients. These conclusions agreed with those of Imberti et al. [18] who observed similar results, clearly suggesting that hyperventilation can compromise cerebral oxygenation. The most recent guidelines of the Joint Committee on Trauma and Critical Care of the American Association of Neurologic Surgeons indicate that aggressive or prophylactic hyperventilation must be avoided in patients with severe head trauma [19].

31.4 Drainage of Cerebrospinal Fluid

Drainage of cerebrospinal fluid (CSF) is frequently performed in TBI patients. The external ventricular drain (EVD) connected to an external strain gauge allows to continuously measure ICP and to calculate CPP (when the drainage line is externally clamped), or to withdraw CSF (when the drainage line is open). In low cerebral compliance due to cerebral edema, the evacuation of a few ml of CSF may be sufficient to decrease ICP dramatically. Kerr et al. showed that a 3-ml withdrawal of CSF resulted, on average, in a 10% decrease in ICP and a 2% increase in CPP, which were sustained for 10 minutes [20]. This

therapy is simple, cost effective and overrides the often serious systemic complications related to drug or physical therapies, especially those induced by barbiturates and hypothermia. Drain placement might be technically difficult, and can be complicated by cerebral contusion or ventriculitis [21]. Two studies have shown that the difference in pressure gradient induced by intracranial CSF drainage facilitates the transfer of cerebral edema to the ventricles, thus improving its clearance [22]. Continuous drainage of CSF against a zero pressure via an EVD, combined with continuous ICP monitoring with an intra-parenchymal catheter, is a common practice in our unit. This technique likely increases the volume of drained CSF as compared to discontinuous drainage, although there are no hard data to support this clinical observation.

31.5 Osmotherapy

In TBI, increased ICP is most often due to cerebral edema. Hyperosmolar agents are widely used to control edema formation after TBI. There is abundant literature supporting the use of mannitol to decrease ICP, increase CPP, and enhance CBF (23) without affecting cerebral oxygenation [24]. Hypertonic saline used at various concentrations (from 3% to 23.4 %) has been consistently shown to decrease ICP and cerebral water content in TBI patients [25]. Hyperosmolar agents were shown to decrease water content in non-traumatised brain tissue by osmotic mobilisation of water across an intact blood-brain barrier (BBB). However, there is the possibility of an opposite effect of the osmotic agent in the areas of a disrupted BBB. This was observed by Saltarini et al. [26] using magnetic resonance spectroscopy to assess cerebral water content in a patient with refractory ICH. One recent CT-based analysis showed an increase in contusion volume after hypertonic saline infusion, suggesting a leak of electrolyte and plasma from the extracellular compartment into the contused area through a disrupted BBB [27]. These results argue for the differential effects of hypertonic saline according to the state of the BBB in various brain areas. As a result, it could be proposed to reserve the use of osmotic agents for patients presenting a small volume of contusion.

31.6 Cerebral Perfusion Pressure

Management of cerebral perfusion pressure (CPP) in TBI is still debated. In 1995, Rosner et al. developed a management paradigm that focused on maintaining CPP >70 mmHg. This strategy, based on BBB integrity and preserved cerebral autoregulation, seemed to improve outcome in an uncontrolled series of TBI patients [28]. An alternate approach has been described and popularized by the Lund group [29]. The Lund theory hypothesises that the BBB is mainly disrupted after head trauma and that cerebral autoregulation is lost. Increasing CPP or using osmotic agents is therefore regarded as a potentially dangerous therapy which can increase edema formation. The Lund protocol therapy has two main goals: 1) to reduce or prevent an increase in ICP (ICP-targeted goal); and 2) to improve perfusion and oxygenation around contusions (perfusion-targeted goal). There is current evidence to support the concept that hypotension is deleterious for the traumatised brain. In contrast, increasing CPP up to 70 mmHg was associated with an increased incidence of pulmonary failure [30].

A recent prospective observational study compared the 6-month outcome of two groups of TBI patients: one group (n=67) treated in Sweden with the aim of keeping

ICP <20 mmHg and CPP >60 mmHg, and a second group (n=64) treated in Scotland with a Rosner-derived strategy protocol in which the goal was to reach a CPP of at least 70 mmHg while keeping ICP <25 mmHg [31]. The authors noted that CPP management therapy seemed to be more efficacious in the patients with intact cerebral autoregulation. In contrast, patients with loss of cerebral autoregulation appeared to benefit from Lund CPP management. This discrepancy could be linked to the presence of contusions: preserved autoregulation is more frequently observed in patients with few contusions [32]. Taken together, the results suggest that patients with numerous contusions (BBB mainly disrupted and loss of autoregulation) would benefit from a Lund-based therapy. Conversely, in patients with only a few contused areas, a CPP-targeted therapy associated with osmotherapy would be logical from a pathophysiological point of view.

31.7 Hypothermia

Prophylactic hypothermia is effective in improving outcome in cardiac arrest [33]; however, it remains controversial in other indications such as brain injury. Nevertheless, the results of different studies, and meta-analyses in particular [34-37], did not demonstrate that hypothermia was associated with a reduction of mortality in TBI. However, the systematic use of hypothermia, independently of ICP, may have underestimated its usefulness. Polderman et al. assessed the efficacy of hypothermia therapy (32-34°C) as part of a step-up protocol to detect and treat side effects [35]. They found that artificial cooling could improve survival and neurological outcome, especially in the patient group with low Glasgow Coma Scale (GCS) scores (GCS=5-6). According to these results, it seems logical to reserve hypothermia for patients with increased ICP. Outcome after hypothermia can be optimised when proper indications, techniques for implementation, as well as management procedures and their enforcement are followed. A rigorous and effective application cannot be conceived outside specialized units with experienced teams. After a minimum duration of 24 hours and after controlled ICP, very gradual warming can be started with the possibility to interrupt it when ICP increases [38]. A decrease in brain metabolism associated with anti-inflammatory effects is the main mechanism of action attributed to hypothermia treatment. Kalemia must be strictly controlled during the ascending and descending changes in body temperature. Of note is that the implementation of hypothermia has been recently facilitated with the availability of automatic cooling blankets and specially designed catheters.

31.8 Steroids

Steroids are particularly effective to treat ICH secondary to cerebral tumoral processes and bacterial meningitis. The bulk of available evidence indicates that steroids do not improve outcome or decrease ICP in TBI patients. The randomised controlled CRASH trial [39] involving 10,008 patients showed no effect of corticosteroids on ICP and a higher mortality was observed in the steroid-treated groups. The study demonstrates that systemic corticosteroids are detrimental to TBI patients. However, the inclusion criteria were very broad and the population of TBI patients was extremely heterogeneous.
The use of steroids in TBI patients with severe contusions could be effective in managing ICH owing to their acting on pericontusional edema, which usually markedly increases ICP between 24 and 72 hours after trauma (clinical experience). Their use under these

Emergency care	**1. Mannitol 20% (0.7 to 1.4 g/kg) or hypertonic saline (20%, 40 ml) if pulsatility index >1.4 and/or mydriasis** **2. Immediate correction of hemostasis disorders** • Fresh frozen plasma if prothrombin time <70 % and platelets if <70,000/mm^3 • Prothrombin concentrate complex (PPSB) if patient chronically treated with oral anti-coagulant therapy **3. Surgical treatment** *3.1 Categorical indications* • Extradural hematoma >10 mm on CT • Temporal polar hematoma with ipsilateral anisocory and disappearance of the basal cistern on the same side • Open skull fractures *3.2 To be discussed on an individual basis* • Subdural hematoma with a midline shift >5 mm if: ▪ Mydriasis duration <30 min or reversible with mannitol whatever its duration, ▪ Parenchymal lesions compatible with short-term survival and long-term relational life • Closed skull fractures • Drainage of an intraparenchymal hematoma • Contusectomy **4. Delay non-vital surgery** • Contraindication to volatile anesthetics • Surgery performed only after stabilization and under strict monitoring of ICP
LEVEL 1 **Mandatory in all patients**	**Homeostasis control (all items must be controlled)** • Head 30°, neutral neck alignment without impeding venous return • CPP between 65 and 75 mmHg • Normovolemia • Normalization of left ventricular function • Sedation for adaptation to mechanical ventilation (combining sufentanil + midazolam) • $PaCO_2$ between 35 and 40 mmHg • SaO_2 >97 % • Temperature between 36.5 and 37.5°C with paracetamol and/or automatic cooling blanket • 5.5 <glycemia <7.5 mmol/l • Maintain natremia between 140 and 155 mmol/l • Diagnostic and treatment of cerebral salt wasting • Prevention of seizure (levetiracetam 500 mg every 8 h) • Transfusion to maintain hemoglobin level >8 g/dl **External ventricular drainage for cerebrospinal fluid drainage and ICP measurement**
LEVEL 2 **if ICP >20-25 mmHg and/or IP >1.4 after level 1 completion** **Go to the next item if ICP is not controlled with the previous one** **Cerebral CT scan obtained to exclude new surgical lesion**	**1. Nursing without mobilisation** **2. Intraparenchymal catheter for ICP monitoring and continuous CSF drainage via EVD** **3. Increase sedation and add propofol** (measure pH daily and serum triglycerides every 48 h – stop propofol infusion if metabolic acidosis, hyperkalemia, renal insufficiency, rhabdomyolysis or triglyceride level >5 mmol/l). **4. Contusion volume** *4.1. Contusion volume <20 ml* • hypertonic saline • and/or increase CPP >70 mmHg *4.2. Contusion volume >20 ml* • Methylprednisolone 120 mg every 12 h (3 days) • Consider albumin administration **5. Hypothermia between** 35°C and 36.5°C **6. Transfusion** to maintain hemoglobin level >10 g/dl
LEVEL 3 **If ICP not controlled at level 2**	• Decrease temperature step by step according to ICP response (control kalemia every 6 h) • Pharmacologic coma with barbiturates (EEG monitoring) • Consider surgical therapy (lobectomy, decompressive hemicraniectomy)

Table 31.1. **Algorithm for the treatment of intracranial hypertension. Neurosurgery-neurointensive care, Pitié-Salpêtrière Hospital, Paris France.**

conditions is possible should all other conventional therapies fail to reduce ICP. A treatment duration of 2 to 4 days is often enough in these circumstances. In our unit, methylprednisolone is administered (dose of 120 mg twice a day for 3 days) if ICP increases in a patient with major brain contusions despite maximal medical therapy and temperature control.

31.9 Albumin

There are some experimental findings showing that albumin reduces pericontusional edema. In a model of ischemia-reperfusion in an isolated guinea pig heart model, albumin more effectively prevented fluid extravasation than crystalloid or artificial colloid. This effect may be attributable to an interaction of albumin with the endothelial glycocalyx also present on the endothelial layer of the BBB. In humans, the results of systemic albumin administration are disappointing. A post-hoc analysis of the SAFE study showed deleterious effects of systemic albumin administration [40]. The main flaws of this study were the *a posteriori* analysis and the slight imbalance between the two groups. Albumin use should be restricted to this sub-population of patients with severe TBI.

31.10 Conclusions

One of the key issues to consider is that TBI is more likely a syndrome than a disease. After trauma, the traumatised brain is characterised by pathophysiological heterogeneity. One and the same therapy for the various different types of brain trauma is not efficient. This could partly explain why systematic use of an increased CPP approach, hypothermia, corticosteroids or albumin failed to demonstrate any positive effect in large multicentre trials. Indeed, the volume of contused brain seems to reflect the state of the BBB and the preservation of cerebral autoregulation, which are the determinants in the choice of therapies. The algorithm in Table 31.1, used in our institution, illustrates therapeutic strategies delineated according to both the side effects of the therapies and the presence or not of a high contusional volume.

32.1 Introduction

Traumatic brain injury (TBI) is a major health problem and a leading cause of death or disability in persons aged under 45 years. TBI has social and economic implications with a direct impact on healthcare resource utilization. Despite decisive changes in the diagnosis and management of head-injured patients in the last 25 years, prevention remains the most effective treatment. In reference to a disease, the term "mild" implies "not severe or dangerous; benign" (*Webster's Third New International Dictionary*). But within the context of TBI this definition falls short of describing the totality of cases, since the initial condition may worsen in some and will require further diagnostic procedures and therapeutics. Over the medium and long term, the adjective "mild" loses relevance in such cases, given that physical and neurocognitive sequelae after an acute "mild" traumatic event have been variously reported.

We find often ourselves attending head-injured patients, either intoxicated or with a previous pathology, in whom the initial management must be appropriate. Although very few will need therapeutic manoeuvres and still fewer will require surgery, an error in the initial diagnosis can lead to lengthy – and worst of all, unnecessary – hospitalization, as well as dilatory interventions that can be fatal in the prognosis of the disease.

Various different strategies for the management of mild traumatic brain injury (MTBI) are based on the availability and/or accessibility of resources for its diagnosis and treatment. Any approach adopted, however, requires a working algorithm adapted to the complexity and diversity of the local or regional healthcare system. The objective in case management thus consists in identifying those brain injuries involving greater risk and then selecting the appropriate therapy or intervention. the focus of this chapter is the management of mild traumatic brain injury.

32.2 Epidemiology

The incidence of TBI varies between 229 and 2000 cases per 100,000 inhabitants per year in Europe, constituting the primary cause of death in persons aged under 45, with the highest occurrence in the 15-to-25-year age group. About 95% are MTBI, 6.3 to 21% of which can exhibit abnormalities on computed tomography (CT), while injuries possibly needing surgery account for between 0.2 and 3.1% of cases.

In the United States, the incidence of MTBI is 128 cases per 100,000 inhabitants per year, with similar age-group distributions, CT findings, and frequency of surgical interventions as reported for Europe.

In Argentina, Marchio et al. (2006) reported, based on a series of 1540 patients hospitalised in a trauma hospital in Buenos Aires, an incidence of 300 cases of MTBI per 100,000 inhabitants, with a trimodal distribution according to age group from 20 to 24, 40 to 44, and more than 75 years. Of a total of 108 CT scan, only 3 (2.7%) showed hemorrhagic lesions that required surgical drainage.

32.3 Classification

32.3.1 Risk categorization

The risk for neurologic deterioration or the presence of potentially surgical intracranial lesions is predicted on the basis of the Glasgow Coma Scale (GCS) score after the patient has been resuscitated, the presence of neurologic symptoms and risk factors, together with neuroimaging evaluation for deciding a possible hospitalization.

Glasgow Coma Scale

The GCS, devised by Teasdale and Jennet in 1974, is a physiological scale that evaluates the level of consciousness according to three components: motor, ocular, and verbal. While easy and quick to use, interobserver variability and difficulties in recording certain of the scale's components have documented, e.g., the ocular in facial injury, the motor in injury of the extremities, discrepancies between pre-hospital services and in-hospital emergency departments in recording GCS components.
GCS upon hospital admission after TBI has great prognostic value for outcome. But since the time elapsed between the moment of injury and arrival at hospital can influence categorization, various authors have established that the measurements are valid for 24 hours after the injury. Alterations in the state of consciousness exponentially increase the possibility of encountering lesions on CT. For example, patients with 14 points on the GCS have double the risk of developing intracranial hemorrhage than those with 15 points, while those with 13 points are at four times the risk of having CT abnormalities.
Continuous evaluation of the state of consciousness is of utmost importance for noting clinical improvement in cases with favourable evolution or clinical deterioration which requires more aggressive therapeutic interventions. This approach is necessary above all in a medical centre where the diagnostic resources (e.g., neuroimaging services) or treatment facilities (e.g., emergency neurosurgery and/or a critical care unit) are limited.

Neurologic Alarm Symptoms

Loss of consciousness. In a patient who has suffered a TBI, it be must established whether or not loss of consciousness (LOC) has occurred, and if so, its duration. The occurrence of LOC represents a ten-fold increase in the risk of cranial fracture and brain lesions, although the absolute risk of the latter still remains low.
Establishing the duration of LOC is difficult if no witness of the event is available for questioning. Although different time limits can be cited for determining the relevance of LOC, the clearest interval applies to pediatric patients in whom LOC longer than 15 minutes necessitates CT in order to discard the possibility of an intracranial lesion. In adults, a LOC for 15 to 30 minutes is believed valid by some authors, while others hold that the occurrence of LOC is sufficient for ordering a CT scan.
Posttraumatic amnesia. Posttraumatic amnesia (PTA) is defined as the difficulty in acquiring and/or recalling new |sensory or cognitive information after the moment of injury, i.e., a lack of remembering daily activities. PTA is a functional expression of focal anatomical damage in the frontal and/or temporal lobe secondary to diffuse axonal injury or contusions. PTA may be associated with spatiotemporal disorientation – especially in persons with attention disorder, retrograde amnesia, confabulation, agitation and uninhibited behaviour – depending on the extent of injury. The duration of PTA is one of the most useful prognostic factors for the eventual recovery of cognitive functions in TBI patients. According to the American Academy of Neurology guidelines, a lesion is considered mild when PTA lasts for less than 30 minutes.

Risk Factors

Risk factors include predictive variables independent of the presence of an intracranial hemorrhagic lesion such as age over 60 years, coagulopathy or antithrombotic treatment, very recent use of illicit drugs or alcohol, previous neurochemical treatment, history of epilepsy, a high-energy trauma mechanism, or evidence of injury above the clavicle. Depending on the literature consulted, the principal causes of traumatic injury are vehicle collisions, falls, and physical aggression. Stiell (2001) reported that the most frequent situations involved a pedestrian run over by a car, a driver or a passenger thrown out of a moving vehicle or off a motorcycle, and a fall from a height of 1 meter or 5 steps.

32.3.2 Definitions

The World Health Organization (WHO) classification distinguishes three categories of brain trauma: mild, moderate, and severe, according to the severity of the alteration. In accordance with this scheme, we can clearly determine what we consider to be MTBI.
In 1981 Rimel applied the term **light** to designate head-injured patients with a score between 13 and 15 on the GCS. In 1996 Culotta published a paper illustrating a pronounced difference between patients with a GCS score of 13 and those with score of 14 or 15 with respect to CT findings, cranial fractures, and the need of |neurosurgery. On the basis of these observations, along with the differences in the extent of brain damage and the risk of death, a distinct differentiation among patients with MTBI must be made.
Certain authors define **concussion** as being that form of cranial trauma where the victim exhibits LOC or amnesia, but the skull is not fractured and no lesions are radiolographically demonstrable. This definition, however, we regard as rather broad and risks blurring the initial categorization.
In accordance with the Neurotraumatology Committee of the World Federation of Neurosurgical Societies classification, we prefer to define MTBI as the presentation of a patient with a GCS score of 14 to 15. Within this classification and according to the incidence of hemorrhagic lesions, we would define three risk levels.

- **Low risk:** GCS of 15 with no history of LOC, amnesia, vomiting or diffuse headaches; the risk of presenting with a hematoma requiring neurosurgery is <0.1%.
- **Moderate risk**: GCS of 15 with one or more of the above-mentioned symptoms, including recovery from concussion; the risk of presenting with a hematoma requiring neurosurgery is between 1 and 3%.
- **High risk**: GCS of 14 or 15 along with cranial fracture or a neurologic deficit**;** the risk of a finding that requires neurosurgery is from 6 to 10%.

To finalize this classification we must determine whether or not the patient presentation includes the associated risk factors cited above. These risk factors include elements from the patient's medical history that increase the incidence of lesions potentially requiring surgery. The inclusion of any one of these risk factors would place the patient in the high-risk group with respect to the occurrence of surgically relevant findings.

32.3.3 Initial Management

All patients with a traumatic injury to the brain or the cranium must be admitted to the emergency service for evaluation. According to the severity of the injury, the symptoms, and the associated lesions, a decision is made following a treatment algorithm.
The first step in the treatment plan is to document the means of trauma, the nature of the presenting symptoms, the risk factors involved, and the extensiveness of the objective data. Finally, the evaluation on the basis of the norms for all trauma patients – in

Group	Clinical condition	Skull radiography	Brain CT without contrast with bone window	Management
0 Low-risk	GCS 15/15 Without neurologic deficit With or without pain at the point of impact or temporary vertigo	No	No	Discharge with instructions about warning symptoms
1 Moderate-risk	GCS 15/15 No neurologic deficit Headache, vomiting, loss of consciousness, amnesia, or major trauma [ATLS]	Yes	No fracture on skull radiography Optional (availability)	Clinical observation for 24 h (if CT unavailable)
			No intracranial lesion or fracture	Observation for 6 h
			Intracranial lesion or fracture	Hospitalization for at least 24 h Neurosurgical consultation
2 High-risk	GCS 14/15 Confusion, stupor, or disorientation With or without neurologic deficit With or without headache, vomiting, loss of consciousness, amnesia, or major trauma [ATLS]	No	No intracranial lesion or fracture	Hospitalization until symptoms resolve Repeat CT at 24 h with coagulopathy or use of anticoagulants
			Intracranial lesion or fracture	Hospitalization until symptoms resolve Neurosurgical consultation
0, 1, 2 Plus risk factors	GCS 14/15 GCS 15/15 + risk factors	No	No intracranial lesion or fracture	Hospitalization until symptoms resolve Repeat CT at 24 h with coagulopathy or use of anticoagulants
			Intracranial lesion or fracture	Hospitalization until symptoms resolve Neurosurgical consultation

Table 32.1. **Algorithm for the management of mild traumatic brain injury. Risk factors: coagulopathy or antithrombotic or anticoagulant treatment, alcoholism, drug addiction, epilepsy, previous neurosurgical treatments, age >60 or risk factor, advanced age with some degree of disability.**

addition to an assessment of the state of consciousness, pupil diameter, and neurologic foci – will assist in making an initial categorization of the patient's condition, including a definition of that victim's risk situation.

Table 32.1 illustrates our proposed systematic approach to decision-making in patients with MTBI. This table is based on 1996 Italian guidelines and on the 2001 Neurotraumatology Committee classification.

32.3.4 Special Situations

MTBI in Patients Under the Effect of Depressants or Toxicants

Alcohol intoxication is involved in 35-50% of head-injured patients. The effect of alcohol is dose-dependent, with a minimal effect at blood concentrations <80 mg/dl, but caus-

ing coma at concentrations >200 mg/dl. The authors of a recent study were unable to find a linear relationship between the level of alcohol intoxication and the initial GCS score (unintoxicated, 10.1±4.8 *vs*. intoxicated, 10.3±4.7; p=0.5). This would imply| that a lower GCS should not be attributed to alcohol intoxication alone and that the attending physician should not wait until a patient has metabolized the ethanol load before making a diagnostic decision.

MTBI in Patients With Coagulopathy

Since TBI patients are part of the general population, a certain proportion may be under medication with warfarin or acenocumarol or may harbour hepatic lesions or hematologic alterations. Accordingly, this patient subset will constitute a group at higher risk for bleeding and with larger and more rapidly growing hematomas.

Cohen et al. found that in patients with a GCS <8 the International Normalized Ratio (INR) in more than 50% was >5.0 and that the mortality rate was 91.5%. In this group the most frequent brain CT finding was subdural hematoma, and progression was furthermore documented by CT for up to 18 hours after the first scan. The combination of coagulopathy, age >65 years, and TBI should be regarded as a potentially lethal circumstance. Working with this patient group requires caution in admitting a patient; CT studies in accordance with established criteria; and if surgical treatment has been elected, the provision of vitamin K, freshly obtained frozen plasma, and concentrated coagulation factors in order to ensure proper homeostasis during the intervention.

MTBI in Sports

The incidence of MTBI during a sports event – and especially contact sports such as boxing, rugby or American football – is an interesting subject for discussion. Athletes presenting after a high-contact sports accident should be examined with the same criteria in mind as for MTBI under any other circumstance regardless of the trauma's having occurred during competitive event. The pressure to "get back into the game" should in no way jeopardize the patient's health by influencing the decision-making process; and the persistence of symptoms should be carefully evaluated, if necessary, advising the athlete against returning to competition or practice in the days to weeks after the accident. Another point to stress is that although more than twenty sets of guidelines have been issued on this subject in recent decades, the level of available evidence for definitive recommendations for the timing of resumption of physical activity is low.

The U.S. Academy of Neurology defines **sports-related concussion** as an alteration in mental state following an injury that may or may not be accompanied by a change in the level of consciousness and further emphasizes that the state of confusion that characterizes this circumstance can appear either immediately or some minutes afterwards. The Academy classifies concussion into three grades: **grade 1**, where symptoms persist for <15 minutes; **grade 2**, where the symptoms persist for >15 minutes; and **grade 3**, where LOC occurs. In the initial evaluation (at the place of competition), the state of consciousness (orientation, concentration, and memory); response to external stimuli; and degree of| motor ability, acuteness of sensation, and pupillary reflexes are all assessed. Individuals presenting with grade 1 are fit to return to competition if no further symptoms persist after 15 minutes. Those with grade 2 are recommended to discontinue the sport for at least 24 hours, provided that the symptoms (headache or others) resolve; but if the latter continue or worsen during the first 7 days, neuroimaging evaluation and neurologist consultation are recommended. In LOC (grade 3) the patient should be taken immediately to the emergency department of the nearest hospital for appropriate evaluation and a brain CT with a bone window to rule out possible spinal cord injury. The patient must refrain from participation in sport for 7 to 14 days, during which he/she will undergo sequential monitoring by a specialized neurologic team.

32.4 Radiological Diagnosis

32.4.1 Skull Radiography

Between 3 and 18% of radiographed MTBI patients exhibit a cranial fracture with an ample margin owing to the heterogeneity of the indication. The risk of harbouring a lesion requiring surgical drainage after skull fracture is 4%; and if accompanied by a deterioration in consciousness, it increases to 25%. Conversely, some 95% of patients with epidural hematoma will also be found to have an associated skull fracture. Skull radiography, however, is not sufficiently sensitive or specific to warrant its recommendation as a routine procedure, especially since the reading of radiograms is difficult and on occasion incorrect.
Nevertheless, the technique can play a role in centres lacking brain CT services. The recommendation is that skull radiography be reserved for the moderate-risk group. The absence of fractures on skull radiography will still require clinical observation of the patient for 24 hours, while the presence of skull fractures will necessitate a CT in order to discard the possibility of lesions requiring surgical drainage.

32.4.2 Brain CT Without Contrast Material

Neither the clinical history nor the neurological findings – and not even the GCS – can predict with certainty the presence of lesions within the cranial cavity. A CT with normal findings can indeed ensure that a discharged patient has no dangerous lesions; but the volume of patients with MTBI makes this generalization difficult to apply to the general population, especially in countries without optimal resources.
Not all tomographic findings require neurosurgery; nevertheless, the physician must not rule out the possibility that skull fracture on an early initial CT will not necessarily eliminate the possibility of the later development of epidural hematoma [Poons, 1992; Riesgo, 1997; Matsuda, 2008].
On the basis of the proposed algorithm, CT would be appropriate in patients with a GCS score of 14, a GCS of 15 with a skull fracture, or a GCS of 15 with a high-risk factor.
Whether or not the availability of a resource or device should influence management guidelines is a subject of debate. The norm should perhaps be to improve the use of the technical resource through the application of algorithms or clinical guidelines before using the technology either in a defensive manner or excessively. More specifically, the question is whether or not to carry out a series of CT studies in such patients. The literature proposes as a good option the assessment of the severity of the initial CT and clinical findings as a criterion for deciding upon the necessity for ordering a second image.
A routine second CT in patients whose primary lesions are considered to have no risk of progression is not recommended. Nevertheless, in patients with associated risk factors such as coagulopathy or coagulant use, clinically observed neurologic deterioration, or hemodynamic alterations, a second image would aid in ruling outing the possibility of late lesions that would compromise the evolution.

32.4.3 New Radiologic Modalities

The evaluation of the brain structures by magnetic resonance imaging (MRI) in the acute stage of MTBI has disadvantages compared to CT. For example, MRI is less useful for identifying bone lesions, needs patient cooperation in order to minimize movement-associated artifacts, requires lengthy time periods for image acquisition (less so with last

generation machines), involves the cost of the imaging study, and is hampered by the irregular availability of MRI machines and trained personnel for correct image interpretation. This would relegate the use of MRI to situations where CT services are unavailable and the degree of patient risk be such that the potential presence of surgically operable lesions or the need for hospitalization be discarded. The imaging sequences of spin-spin relaxation time (T2) and fast-fluid inversion-attenuated recovery (FLAIR) have greater sensitivity than CT for the detection of contusions, diffuse axonal lesions or edema and also enable differentiation between acute hemorrhagic and other types of subacute or chronic lesions. The technique termed susceptibility-weighted imaging (SWI) shows higher sensitivity in detecting hemosiderin deposition in the acute stage of TBI; but although this modality is highly promising, the technique is not widely available for use.
In the post-concussion syndrome, MRI during the follow-up period exhibits a good correlation with neuropsychological-testing results – for which reason we consider the technique as a support modality in such patients – and is able to detect minimal frontal and temporal lobe lesions at up to 3 months after injury.
Very recent studies have shown ever-increasing accuracy between image findings and clinical findings, as, for example in MRI and the modality called diffusion-tensor technique or tractography. The latter is an extension of the sequence employed by diffusion and allows reconstruction of the white matter tracts; in so doing, it constitutes an assessment of axonal integrity. In acute TBI, tractography can identify small alterations in the white matter that are consistent with a diffuse axonal lesion of the corpus callosum and the internal capsule not evident on CT. In chronic lesions, generally those associated with high-contact sports such as boxing, the degree of alteration in the diffusion of water within the white matter is related to motor sequelae and long-term neurocognitive alterations.
In a 2008 paper published by a group from Baylor University, abnormalities in the tractography of patients with mood changes or the post-concussion syndrome indicating cytotoxic edema were readily visualized. These findings can now serve to redefine the long-term management of this patient group in order to select different, more appropriate modalities of therapy and neuropsychological support.
Single-photon-emission computed tomography (SPECT) employs a tracer to indicate by indirect means changes in cerebral metabolism by measuring blood flow through the brain. In MTBI or moderate TBI, the authors found alterations in 40-70% of patients followed for up to 3 months after the injury – the affected zones being areas local of hyperperfusion within the frontal and temporal lobes and the gray basal nuclei. The persistence of these findings was correlated with the duration of the post-concussion syndrome. An initial SPECT study is a reliable indicator of good functioning at the end of 3 months. Despite these characteristics, SPECT application remains limited because of its low resolution, high radiation dosage, and difficulties in obtaining quantitative data, in addition to its higher cost.
Perfusion CT enables the quantification of cerebral blood volume, the transit time for the clearance of a contrast marker, and the cerebral blood flow rate, though only within a limited area of the brain. Nevertheless, perfusion CT reveals hemodynamic alterations within the regions near a hemorrhagic lesion which, because undetectable by CT without the use of contrast material, would constitute a potential target for treatment.

32.5 Timing of Hospital Discharge

Patients with a normal neurologic examination and without associated symptoms can be discharged if accompanied by another person and given an instructions sheet informing

them about warning symptoms which, if they occur, the patient must return to the hospital immediately. An analysis by Servadei and colleagues indicated that, among 1480 patients discharged in this way to home care, no new lesions were detected. On the basis of this evidence, a hospital discharge policy under such criteria can be considered safe. Table 32.2 illustrates a hospital discharge instructions sheet for the caregiver or the patient. These instructions would be adequate for any healthcare facility or institution utilizing them.

By contrast, if a patient does present symptoms, the following patterns of timing must be borne in mind. Clinical deterioration associated with an epidural hematoma occurs within the first 6 hours, while a delayed hematoma may have its onset up to 24 hours after the injury. Therefore, in the moderate-risk group if only a fracture without hematoma is demonstrated on skull radiography or CT or some risk factor is determined, in-hospital observation should continue for at least 24 hours.

In high-risk patients, i.e., with a GCS score of 14 or 15 and neurologic findings, the timing of discharge should be determined by resolution of the symptoms.

- You were examined for a mild head injury for which at the present time no findings suggest neurologic effects or that the injury was severe. If you show any of the following symptoms over the next hours or days, you should return to the hospital for a follow-up examination (We strongly recommend that you be watched by someone for the next 48 hours):
  - Sleepiness or difficulty in waking up
  - Nausea or vomiting
  - Dizziness
  - Severe or persistent headaches
  - Confusion
  - Convulsions
  - Changes in your normal behavior
  - Loss of strength or numbness in any part of your body
  - Visual alterations such as double vision or blurred vision
  - Buzzing in your ears
- Do not drink alcoholic beverages or take any medications for going to sleep

Table 32.2. **Hospital discharge instructions for mild traumatic brain injury.**

32.6 Post-traumatic Sequelae

Although MTBI has a low probability of poor functional outcome or death – with the incidence of such sequelae in patients with GCS of 1 and 2 being 1.0 and 0.5%, respectively – the occurrence of PTA, memory lapses or headache are frequent reasons for a follow-up visit and sick leave from work.

Unfortunately, the prognostic usefulness of biochemical markers for neural damage (e.g., the glia-specific protein S100B and other S100 regulatory proteins) utilized in severe TBI has not yet been established for MTBI, though such markers are, in fact, present but at insignificant levels. Certain laboratories have attempted to determine a relationship between the presence of APOEe4 after initial injury and the possibility of substantial neurocognitive deterioration. Basic research, however, has not established the significance of the presence of the allele in the short- and long-term outcome of MTBI.

Post-concussion or Post-MTBI Syndrome

The post-MTBI syndrome refers to a constellation of common symptoms in MTBI patients, e.g., headache, irritability, neurocognitive deficit, depression, insomnia, and that persist for 60 days or more in >50% of such patients. Although a systematic follow-up is not felt to improve the development of their case, the communication of information forewarning the patient of the possibility, or even likelihood, of experiencing these symptoms does improve their acceptance of such an eventuality. The persistence of symptoms, however, would necessitate re-examination using orientation and neuropsychological tests.

32.7 Key Concepts

A classification system and management algorithm should be established for patients with MTBI since such an approach would avoid misdiagnosis and excessive costs, and the availability of technology *per se* provides no guarantee for the proper management of MTBI.

Even with accurate classification, however, careful initial management is essential to determine whether or not a patient will require further observation for the detection of lesions that might require surgery.

33 Moderate Traumatic Brain Injury

Silvia Lujan [1], Carlos Rondina [1], Gustavo Petroni [1]

[1] Intensive Care Unit, Dr. Clemente Alvarez Emergency Hospital, Rosario, Argentina

33.1 Introduction

Traumatic brain injury (TBI) may be rated as severe, moderate or mild according to the Glasgow Coma Scale (GCS). Severe and mild TBI have been extensively reviewed in the last few decades and international consensus documents, management guidelines and papers supported by various degrees of scientific evidence have been published. Moderate TBI positions somewhere between the two, probably because this patient category is much more heterogeneous, with ends-of-range bordering on mild and severe TBI where far different management guidelines apply. Such variability within the same category may carry a higher risk of inadequate medical procedures, through medical actions or lack thereof, in the ends-of-range of severity in patients with GCS scores 13 and 9, respectively.

33.2 Epidemiology

The incidence of TBI is between 250 and 600 new cases per 100,000 people/year, depending on the geographical area considered. It has been estimated that about 12.5% of TBI cases are severe and 75% are mild. Though no confirmatory data are available, we could very well estimate that about 12.5% of cases are moderate TBI, or roughly 10,000 cases per annum in our country.

Between October 1997 and October 2000, 412 TBI patients were admitted to our service (Intensive Care Unit, Dr. Clemente Alvarez Emergency Hospital [HECA], Rosario, Argentina) (HECA ICU Database), 137 (33.2%) of which were moderate and mostly involved young men.

33.3 Baseline Evaluation

TBI severity is evaluated on the basis of neurological response according to the GCS criteria: severe TBI (GCS ≤8); moderate (GCS 9-13); and mild (GCS ≥14). Even when patients with GCS 13 are initially evaluated as having mild TBI, we rate them as moderate, in line with other authors. This practice is partly based on prognostic considerations and partly on the higher risk of negative progression.

Concomitant conditions such as alcohol or drug intoxication that hinder the outcome need to be ruled out. Respiratory or circulatory instability must be monitored to determine the TBI score (GCS score after non-surgical life support).

Moderate TBI patients may deteriorate while under observation. Deterioration may be defined as a reduction in GCS of 2 or more points and/or understood from the onset of focal neurological deficits. Such patients will eventually be rated as severe (10-20%).

A major problem is predicting which patients will require early intervention and how to identify them. But what are the clinical or prognostic variables (age, mechanism of injury, temporary loss of consciousness, focal neurological deficit, GCS, computed tomography [CT] lesions, etc.) that have the sensitivity and specificity sufficient to help pinpoint the risk of neurological impairment or the need for early intervention? Perhaps the lack of clear responses explains the paucity of reliable data that describe the evolution of TBI in this patient subset. Therefore management recommendations will ultimately depend on data extrapolated from other groups.
In brief, moderate TBI patients need to be approached as a heterogeneous group having different, identifiable variables which evolve over time, where medical intervention needs to anticipate the natural history of head injury.

33.4 Management Issues

All moderate TBI patients will require medical care, hospitalization and full life support provided according to the Advanced Trauma Life Support (ATLS) guidelines. Also the mechanism of trauma, the time since the injury, and the clinical events that occurred before hospital admission (hypotension, hypoxia) will need to be taken into account.

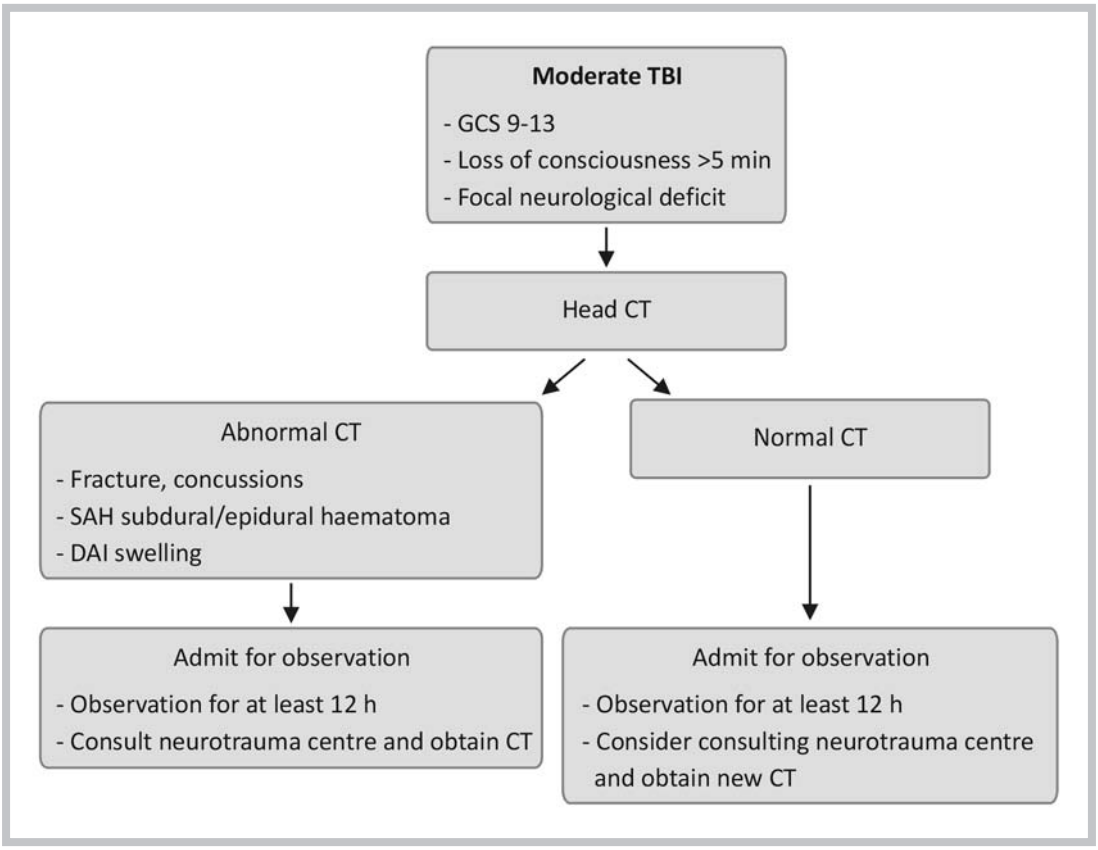

Figure 33.1. **Algorithm for the management of moderate TBI patients recommended by the Scandinavian Neurotrauma Committee**.
DAI = diffuse axonal injury
SAH = subarachnoid hemorrhage

Added to these are the assessment of extracranial lesions (chest, abdomen, limbs, etc.) and a "mini-neurological examination" including the GCS, motor focal deficit, pupils (symmetry and reactivity), difficulty breathing, and loss of consciousness.
Since focal neurological deterioration is the most powerful predictor of poor outcome, patient management should be carried out in a facility that can ensure continuous clinical surveillance.

33.5 Computerized Tomography

A head CT scan without contrast material is recommended in all moderate TBI patients due to the high incidence of acute intracranial lesions (Figure 33.1). Some 40% of patients have CT scan abnormalities and 4-8% of these will require a surgical procedure.
There is an exponential relationship between a GCS score from 13 to 15 and the frequency of CT abnormalities: the frequency of CT abnormalities is four-fold higher in patients with a GCS score 13. The frequency of surgical injuries shows the same trend (5% for GCS-13 patients).
Head CT should be repeated in patients where recovery is less or slower than anticipated and in those with evidence of worsening neurological status.
Skull fractures, cerebral concussions, history of loss of consciousness and worsening consciousness level on admission are major risk factors. A small decrease in the consciousness level on admission increases the risk of an abnormal head CT as well as the risk of a surgical lesion. Cerebral concussion or subarachnoid bleeding following trauma increases the risk four-fold of a hematoma or swelling. Other additional risk factors to be considered are: anticoagulant or hemophilia therapy; alcohol abuse; posttraumatic seizures; multiple injuries; and skull-base fracture.
Many patients have an altered state of consciousness after TBI, as well as secondary neurological sequelae with relevant CT findings throughout their evolution. Cranial magnetic resonance imaging (MRI) is a sensitive test for detecting non-hemorrhagic lesions in the posterior fossa and could therefore play a major role in evaluating these patients. MRI detects diffuse axonal lesions with a much greater sensitivity and should thus provide a higher prognostic capacity.

33.6 Intracranial Pressure Monitoring

Intracranial pressure (ICP) monitoring is not indicated on a routine basis in moderate TBI. The physician, however, may opt to monitor ICP in certain patients with mass lesions.

33.7 Results

This heterogeneous patient group is remarkably variable in relation to long-term neurological recovery and outcomes. Early predictive factors of poor outcome include: GCS score, CT findings, coagulopathy, subarachnoid bleeding, and skull-base fracture.
While technological progress has improved patient survival in the last two decades, it has also lead to multiple disabilities in survivors. The Glasgow Outcome Scale (GOS) is

widely used to globally assess TBI patient outcomes. Some limitations (wide categories, scarce sensitivity to subtle recovery changes, excessive worth attached to physical disability *vis-à-vis* cognitive and behavioural alterations, etc.), however, have been described. Several authors recommend the Disability Rating Scale (DRS) or the Extended Glasgow Outcome Scale (GOS-E) to assess delayed (6-month) outcomes in moderate TBI patients because of the higher sensitivity these tools have.

Many moderate TBI patients show some degree of neuropsychological impairment, memory, fine coordination or speech alterations. Even when cognitive functions improve in the first few years, memory deficits can persist.

33.8 Final Considerations

Moderate TBI patients are a heterogeneous group whose evolution and outcomes are almost impossible to predict, making it difficult to set up clear intervention guidelines. Hospitalization and baseline life support are universally accepted procedures, as is CT on admission. Predicting which patients will require intervention (ICP monitoring, neurosurgery, or both), however, has not been possible, except in the event of deterioration. A large multicentre trial is needed to improve the management of this group of patients.

34 Medical Treatment of Severe Traumatic Brain Injury

Francisco Murillo Cabezas [1], **Ángeles Muñoz Sánchez** [2]

[1] Professor of Medicine. University of Seville. Head of Emergency and Critical Care Department Hospital Universitario Virgen del Rocio. Seville, Spain
[2] Associate Professor Medicine. University of Seville. Chief of Trauma Center Emergency Department Hospital Universitario Virgen del Rocio. Seville, Spain

34.1 Introduction

Traumatic brain injury (TBI) is a serious public health problem in both developed and developing countries. In the developed countries it is the leading cause of death and permanent disability in young people. Globally, it is one of the main reasons for hospital admission, with a high mortality rate and an aftermath of enormous social and economic impact. TBI patients are most often the victims of traffic, sports and workplace accidents, unexpected falls, and violent assaults. The distribution of TBI incidence varies across different world regions. While prevention measures and strict enforcement of traffic laws have notably reduced the occurrence of TBI in the developed countries, its incidence in the developing countries has increased because of the greater use of motor vehicles and more frequent workplace accidents associated with growing industrialization and building construction. Conversely, increased longevity in the richer nations has led to a rise in the number of high falls and road accidents involving the elderly. TBI secondary to violent assault, however, continues to rise worldwide in connection with terrorist or criminal attacks.
The mechanisms underlying TBI produce a wide variety of brain injuries which, together with the possible association of extracranial lesions, make it a heterogeneous entity in pathology, pathophysiology, classification, and probably in its therapeutic approach as well, despite the development of clinical treatment guidelines to improve its management. In this chapter we outline current knowledge and methods in the evaluation and treatment of the acute phase of TBI.

34.2 Epidemiology

The annual incidence of TBI ranges between 200 and 500 new cases per 100,000 inhabitants. As in the rest of the European Union, the incidence in Spain is estimated at around 200/100,000 inhabitants, a rate below that observed in other parts of the world, including Argentina (323/100,000) and the United States (403/100,000). Fairly uniformly throughout the world, TBI patients are predominantly male (male-to-female ratio 3-4:1). About 80-85% of the total are considered mild TBI, and only about 15% require hospitalization for the treatment of severe or moderate TBI. In spite of advances in evaluation and treatment, the 6-month mortality rate for severe and moderate TBI is 24% and 15% of TBI patients remain severely disabled. However, there is wide geographic variability in outcome, being worse in low-income countries where mortality is twice that of rich countries.
Added to these discouraging figures is the ensuing psychological impairment: 10% of patients will suffer memory deficits, inattention, disorganized thinking, disinhibition, irri-

tability, depression, hyperkinesia, impulsivity, and 25% will be unfit to resume work or maintain social or family life. Measured against a country's level of medical development and income, mortality associated with severe TBI may reach around 50%. While the impact of TBI on personal and family relationships is unquantifiable, its social and economic burden is enormous. The United States spends more than $60 billion per year; in Spain the economic cost of hospital stay alone was estimated at 180 million euros in 2002. Added to healthcare expenditures is the loss in years of productive work and revenue from taxable income.

34.3 Classification

The difficulty in defining objective criteria for classifying TBI has been a major obstacle to comparing different series or therapeutic approaches, evaluating the real benefit of new drugs in clinical trials, and designing benchmarking programs in health care quality. TBI has been variously classified: mechanism of injury; presence (or not) of associated traumatic injuries; clinical severity according to level of consciousness; age; and magnitude of structural damage on head computed tomography (CT). Each of these factors weighs differently on outcome and should therefore be taken into account to describe an individual patient or to categorise them. For example, age ≥40 years in a patient with the same clinical severity or anatomic lesion as a younger one may influence decisions on whether or not to monitor intracranial pressure (ICP).

Traditionally, the level of consciousness as assessed by the Glasgow Coma Scale (GCS) score has been the keystone of classification. According to the GCS (Table 34.1), TBI is considered severe in patients with a score ≤8 and moderate in those with a score between 9 and 13. Higher scores indicate TBI will be mild. The widespread use of the GCS as a primary classification in the initial phase of TBI has not been questioned. The GCS debate centres on its subjective criteria, artifacted at the most acute stage by intoxication (alcohol or illegal drugs), drugs (analgesics, sedatives or relaxants) or associated medical complications (hypotension, hypoxemia) or difficulties in evaluation due to eyelid injury, endotracheal intubation, etc. And because the final score is the sum of three components, these must be scored independently, since it has been shown that the motor scale is best classified and related to prognosis. TBI is considered severe in all patients with a GCS score ≤5 on the motor component.

Response	Score
Verbal response (V)	
Orientated	5
Confused	4
Inappropriate	3
Incomprehensible	2
None	1
Eye opening (E)	
Spontaneously	4
To speech	3
To pain	2
None	1
Motor response (M)	
Obeys commands	6
Localizes to pain	5
Withdraws to pain	4
Flexion to pain	3
Extension to pain	2
None	1

Table 34.1. Glasgow Coma Scale.

Unless influenced by other factors, the head CT scan can fairly accurately assess the extent of structural damage, which is related to TBI severity. Thus, CT allows for a more objective categorization of patients than the level of consciousness. The

Injury type	Features
Diffuse injury type I	No visible lesions on CT
Diffuse injury type II	Cisterns are present with shift <0-5 mm; no high or mixed density lesions >25 ml; may include bone fragments and foreign bodies
Diffuse injury type III	Cisterns compressed or absent; shift 0-5 mm; no high or mixed density lesions >25 ml
Diffuse injury type IV	Shift >5 mm; no high or mixed density lesions >25 ml
Evacuated mass lesion	Any lesion surgically evacuated
Non-evacuated mass lesion	High or mixed density lesions >25 ml; non-surgically evacuated

Table 34.2. **CT Marshall classification categories.**

classification proposed by Marshall et al. (Table 34.2) has become a universal system for classifying anatomical lesions. The aim of the scheme is to quantify the risk of intracranial hypertension (ICH), which derives from the presence or absence of mass lesions and the compression or absence of the basal cisterns, as well as to predict poor outcome in relation to previous findings. However, it is not devoid of certain limitations.

One is the overly sharp distinction between mass and diffuse lesions, when many patients have both types simultaneously; it does not differentiate between expansive lesions (subdural, epidural, intraparenchymal), though recognizing the different prognosis each implies. Another is the difficulty in choosing the reference CT: in 50% of cases new lesions can appear or pre-existing ones seen on the first scan may increase in size within hours or days following trauma.

The Rotterdam scale proposed by Mass in 2005 better standardises CT scan findings and could overcome some of the limitations inherent to the Marshall scale. However, the Rotterdam classification has not been fully validated. Currently, although it is not something completely innovative, the risk of death and poor outcome at 6 months is predicted with the use of prognostic models such as derivatives of the IMPACT CRASH registry. These models include simple factors present at hospital admission, including: age; motor response scored on the GCS; pupil reactivity; presence of hypotension or hypoxia; biological parameters such as blood glucose and hemoglobin; and injuries considered in the Marshall CT classification, in addition to the presence of epidural hematoma and subarachnoid hemorrhage.

34.4 Pathology of Brain Damage

TBI is characterized by lesion heterogeneity. However, what all lesions share is that they are produced by external forces: either by direct impact, sharp objects (knives or guns), heavy machinery, or rapid acceleration/deceleration. Recently, head-blast injury during armed conflict has gained clinical relevance. The nature, intensity, duration and area of impact of external forces all determine the extent and predominant type of damage. Although lesions evolve and overlap with time and are schematically arranged along a continuum, they may be classified into two basic types: primary and secondary damage.

34.4.1 Primary Brain Injury

Primary brain injury occurs immediately after the impact and may develop at the cellular level during the first hours after trauma, leading to functional or structural damage,

some of which is reversible or irreversible. Microscopically, primary injury is characterized by cell damage, tearing and retraction of axons, and vascular rupture and torsion. These changes lead to two types of macroscopic lesions: focal and diffuse. Focal lesions, produced by forces transmitted directly through the skull, can be single or multiple and usually occur in the frontal and temporal lobes or also on the lower surfaces of these lobes, where the nerve tissue lies in contact with bony prominences. They are found in 25-35% of severe TBI and in 5-10% of moderate TBI, and are more frequent in elderly patients. This type of injury encompasses skull fractures, lacerations, contusions, subarachnoid hemorrhage, and intracerebral and extracerebral hematoma (subdural and epidural). Focal lesions produce neurological deficits ensuing from tissue destruction and compression of neighbouring brain tissue and ischemia. Alterations in consciousness result when the lesion reaches a volume sufficient to produce a shift and herniation of the intracranial contents and subsequently affects the brainstem reticular formation. All these types of injuries can be easily demonstrated on a CT scan.

Diffuse axonal injury (DAI) refers to diffuse brain damage and includes hypoxic or ischemic brain damage. DAI is caused by rotation of the gray on the white matter, with the effect of forces acting on the axons in a linear or angular direction, producing a physical breakdown (primary axotomy), which occurs in <6% of the fibres affected, or a functional breakdown (deferred axotomy).Delayed axotomy is due to increased permeability to extracellular calcium in the nodes of Ranvier and the cytoskeleton itself. The accumulation of intracellular calcium initiates a process that leads to axon destruction after a few hours or days. Both primary axotomy and deferred histopathological changes are progressive and, sometimes contrary to what was previously thought, they are reversible. Microscopically, they manifest initially as abalone forms of axonal retraction, with the accumulation of microglial cells weeks later and, after a few months, the presence of long tracts with phenomena of Wallerian degeneration. Macroscopically, delayed axotomy is characterized by the presence of multiple small lesions in various different brain areas, including the centrum semiovale of the subcortical white matter of both cerebral hemispheres, the corpus callosum in the dorsolateral quadrant of the midbrain, the cerebellar peduncles, and even in the bulb. Patients with DAI fall into a deep coma from the time of injury because axonal involvement interrupts the signals ascending the reticular activating system, not usually present with increased ICP, and its prognosis is more unfavourable.

In the early phase of TBI, DAI is difficult to observe on a CT scan which may display an almost normal image. In the subacute phase, a magnetic resonance imaging (MRI) scan is very demonstrative in both fluid attenuated inversion recovery (FLAIR) and T2-weighted gradient-echo sequences. Since the FLAIR sequence may overestimate the true extent of damage, acute and diffusion sequences should always be added to reveal pre-existing pathological conditions.

Ischemic brain damage commonly accompanies or is superimposed on DAI; at times it may be extensive or limited to the perilesional area. This type of aggression may result from cerebral hypoxia, increased brain oxygen requirements, altered regulation of cerebral blood flow (vasoplegia), obstruction of microcirculation or excitotoxicity. It usually manifests as diffuse brain swelling; the CT scan will show obliteration of the basal cisterns and ventricles which causes increased ICP.

34.4.2 Secondary Brain Injury

Because there is no specific treatment for the primary lesion, early recognition and treatment of secondary injury is of paramount importance in TBI. This type of damage occurs

in response to the primary injury and is parallel in intensity to the severity of the primary lesion, the brain (Table 34.3) and systemic factors (Table 34.4) being involved in its genesis. It manifests with the presence of new lesions or an increase in previous injuries appearing within minutes, hours or days after TBI. Bleeding due to previous concussions or new contusions, cerebral infarction, brain swelling, cerebral edema, and hydrocephalus are all easily identifiable on a CT scan.

Among the secondary causes of intracranial injury, elevation of ICP is the most frequent and severe. It is seen in more than 50% of cases and has a negative effect on prognosis. A close relationship has demonstrated between elevated ICP and increased mortality and permanent sequelae. Similarly, the longer the duration of ICH, the worse the outcome. In the initial phase of TBI, although there may be other factors, the presence of intracranial hematoma or large contusions is the most common local cause of ICH. Regardless of the mechanisms leading to ICH, the latter exerts its deleterious effect through two mechanisms which may co-exist in the clinical setting: 1) cerebral pressure cones provoking herniation and brain death unless the situation is reversed; 2) development of ischemic cerebral hypoxia due to decreased global cerebral perfusion pressure (CPP).

- Arterial hypotension
- Hypoxemia
- Hypercapnia
- Anemia
- Hyperthermia
- Hyponatremia
- Hyperglucemia
- Hypoglucemia
- Acidosis
- Systemic inflammatory response syndrome

Table 34.3. **Secondary brain insults of extracranial origin.**

- Intracranial hypertension
- Mass lesions, ischemia/anoxia
- Cerebral edema
- Vasospasm
- Hydrocephalus
- Convulsions
- Carotid or vertebral arteries dissection

Table 34.4. **Secondary brain insults of intracranial origin.**

Cerebral edema is one of the most common mechanisms of secondary injury in TBI. Whether focal or diffuse, virtually all types of cerebral edema (vasogenic, cytotoxic, neurotoxic, interstitial, hydrostatic, osmotic) can be observed at some point in the evolution of TBI. However, in the initial phase (first 24 hours), it is neurotoxic and cytotoxic edema that accompany the most common primary lesion, followed by vasogenic edema after the blood-brain barrier has been damaged.

Hypertension and increased intracapillary hydrostatic pressure contribute to exacerbate this complication. In cerebral edema, intracranial volume and ICH are increased, cerebral compliance is decreased, and brain metabolism is altered. Altered permeability of the blood-brain barrier allows the passage of certain metabolites that damage cell membranes and create a vicious circle, given the high edematogenous capacity of these substances. Another way edema damages the brain is by cerebral hypoxia due to disperfusion in which edema fluid separates the capillaries carrying nutrients to the brain cells.

In most cases of TBI, and at any point in its evolution, another factor of secondary injury is cerebral hypoperfusion. Many circumstances may arise in the acute phase of TBI, the most common being a global or regional decline in CPP due to an increase in ICP or a decrease in mean arterial pressure (MAP). However, other mechanisms co-exist such as extrinsic stenosis of the cerebral arteries, especially of the posterior cerebral artery and anterior cerebral artery, generated by pressure cones that lead to brain herniation. Stenosis can provoke or exacerbate previous ischemia which appears on the CT scan as hypodense lesions of vascular distribution unrelated to cerebral contusions.

Another possible cause of ischemia, usually regional, is cerebral vasospasm. Cerebral vasospasm is seen on transcranial Doppler sonography in approximately 25% of patients with

traumatic subarachnoid hemorrhage, with a close relationship between vasospasm severity and the amount of blood visible on the CT scan. Besides causing direct damage due to ischemia, cerebral vasospasm can provoke reperfusion injury when the ischemic period has been reserved. Reperfusion injury induces ischemic foci outside the initial area. Some studies have demonstrated a higher incidence of stroke when cerebral vasospasm is associated with low CPP, and an improved prognosis of TBI when nimodipine is used to treat it. Also, reperfusion injury was observed, as our group has demonstrated, when extra-axial hematoma ischemia occurred in a brain that was decompressed very quickly.

During the acute phase of TBI, generalized or focal seizures may appear, with an estimated incidence of 6% in adults and 8% in children under 5 years of age. Penetrating injuries, cortical contusions or intracranial hematoma, and increased depth of coma are risk factors for early post-traumatic seizure. Early seizures exert their harmful effects via several mechanisms, primarily through increased cerebral blood flow (CBF) and cerebral oxygen consumption, which are associated with the release of excitatory amino acids. The increase in CBF, especially in a setting of decreased cerebral compliance, increases ICP as evidenced by sustained elevation or Lundberg A waves.

There is also the possibility of arterial dissection, mainly extracranial (carotid or vertebral) (up to 17% of cases) when TBI is associated with trauma to the neck area or skull base fractures in proximity to the carotid canal or the entry of the vertebral artery. Arterial dissection causes ischemia through the interruption or reduction of carotid or vertebral flow or by generating embolic phenomena, whose incidence has been estimated to be close to 60%. While not preventing its consequences, the CT scan shows signs consistent with ischemic stroke. Today, though disputed by the risks and lack of clear evidence, the careful use of heparin and mesh placement to restore flow and prevent emboli have been advocated.

Among the causes of secondary damage of systemic origin, arterial hypotension is the most common and arises not only in the pre-hospital phase but most often in the operating room during surgery for space-occupying lesions or in the ICU itself. Moreover, up to 8.5% cases of TBI do not show external causes that justify the onset of shock, being attributed to neurogenic origin in the context of severe diffuse lesions or to the massive use of diuretics. Although its frequency is high, more alarming is the impact it can have on outcome. CPP is decreased in hypotension, leading to cerebral ischemic hypoxia. It was observed that even brief episodes of hypotension raise the death rate of severe TBI from 27 to 50%. Because cerebral autoregulation is impaired and the coupling of cerebral blood flow and cerebral oxygen consumption is altered in the acute phase of TBI, any fall in MAP caused by a decline in CPP will result in global cerebral ischemia.

Finally, the effect of hypotension is exacerbated by co-existing hypoxemia, which is commonly encountered in clinical practice. Thus, while isolated hypoxemia increases the mortality rate by around 2%, mortality is more than 25 times higher when associated with hypotension. Extreme anemia (hemoglobin <7 g/dl), prolonged hyperthermia, and septic states, by decreasing the cerebral oxygen supply or increased metabolism, can aggravate situations of cerebral ischemia and hyponatremia, inducing cerebral edema and worsening the prognosis; however, as independent variables, the effect of these factors on the end result is not well established.

34.5 Pathophysiology

Regardless of the type of damage, primary or secondary, and the origin of the latter, intracranial or systemic, TBI develops over hours or even days if further secondary attacks

occur, triggering harmful biochemical processes responsible for increased ICP, disruption of the blood-brain barrier, genesis of cerebral edema, alteration of cerebral self-regulation, mitochondrial dysfunction, brain damage and late apoptosis. Current research into new drugs is aimed to stop or minimise this pathophysiologic cascade of events which, in simplified form, sequentially and synergistically involves the release of excitatory amino acid, cellular entry of calcium, production of free oxygen radicals, gene activation, activation of pro-inflammatory molecules, and so on.

Initially, the mechanical aggression of cell membranes and subsequent secondary attacks such as increased ICP or the presence of hypoxia/ischemia facilitate the excessive release of glutamate and other neurotransmitters (e.g., aspartate or glycine). These act on specific receptors and provoke intense cellular depolarization that results in: 1) the massive influx of sodium and water leading to cytotoxic edema and even cell death by explosion; and 2) the increase in sodium favours the influx of calcium into the cell. The accumulation of intracellular calcium exerts many negative actions and is the fundamental mechanism in the genesis of diffuse axonal injury. The cellular influx of calcium promotes the activation of inducible nitric oxide synthase (iNOS), and through it large amounts of NO. NO-induced vasodilatation, with abolished or altered cerebral self-regulation, produces vasoplegia and cerebral ischemia and elevates ICP.

During the ischemic period, the intracellular calcium overload induces the production of xanthine oxidase, which is inactive in the absence of oxygen. When reperfusion occurs, oxygen induces hypoxanthine, an intermediate DNA degradation product, to produce xanthine and uric acid, generating in the course of these reactions large amounts of oxygen-free radicals such as superoxide anion. This radical reacts with NO and generates peroxynitrite. These free radicals destroy the membranes by lipid peroxidation and cell nuclei, causing necrotic cell death. Also, free radicals injure the endothelial cells, producing a breakdown in the blood-brain barrier and vasogenic edema. Excess intracellular calcium also induces immediate and late axonal destruction by increasing the activity of specific proteases, i.e., the calpains that disorganize microtubules and neurofilaments. The calpains are now considered one of the factors responsible for traumatic brain atrophy through retrograde axonal degeneration.

The early activation of genes is another cause of delayed cell death by apoptosis. These genes induce the synthesis of molecules such as caspase 1 that suppress the inhibitory mechanisms of apoptosis. However, whether apoptosis in TBI is a harmful or a repair mechanism is still debated. Also, early gene expression (e.g., *c-fos*) following TBI may exert beneficial effects for the formation of nerve growth factor (NGF) and neuroprotective activity. Specifically, such gene expression would defend the brain against ischemia.

Today, the inflammatory component is recognized as a common pathophysiological element of TBI, essentially accompanying focal lesions such as contusions or subdural hematoma. Although its maximum expression occurs at 48 or 72 hours post-trauma, there is a release of pro-inflammatory cytokines, mainly IL 1, IL 6 and IL 18, from microglia, astrocytes, and polymorphonuclear cells. As with apoptosis, while excessive inflammation is detrimental because it stimulates the opening of the blood-brain barrier and the apoptotic pathway of complement activation, it is necessary for the removal of cellular debris and cell repair.

Expressed by the fall in ATP and oxygen consumption by about 50%, mitochondrial dysfunction has been implicated in apoptotic and necrotic cell death. It also appears to be involved in axonal disruption, which explains the modern concept of possible axonal regeneration and repair if mitochondrial function is restored within the first 72 hours. Several factors cause mitochondrial dysfunction: intracellular calcium overload that decreases the selective permeability of the membrane into the interior of ions that cause swelling; substances such as hydrogen cyanide, nitric oxide or carbon monoxide

interacting with the electron transport complex chain; hypoxia damage to mitochondrial structures; and certain genetic alterations which modify the phenotype of mitochondrial complexes.

34.6 Diagnosis of TBI

34.6.1 Systemic Injury

Various series have shown that between 25 and 80% of severe TBI cases involve multiple trauma or extensive trauma. Likewise, the co-existence of these associated injuries is considered a variable in forecasting models that predict the outcome of TBI. Therefore, the diagnosis and treatment of associated injuries, especially life-threatening injuries, are of paramount importance and should never be relegated, despite the severity of brain injury.

Advances in imaging techniques (latest generation multislice CT, MRI and ultrasonography) have facilitated the safe and prompt recognition of these lesions. Previously, we highlighted the association of cervical lesions and intracranial and extracranial vascular pathology; however, one must keep in mind injuries of the cervical spine and other regions of the spine, depending on the mechanism of injury, to recall that improper patient handling may cause or aggravate spinal cord injury.

There are two frequent and serious situations that can accompany TBI: 1) oxygenation or ventilation disorders ranging from minor alterations to gasometric parameters of acute life-threatening respiratory failure. The most common thoracic injuries are rib fractures, pulmonary contusions, and hematoma, hemo- and pneumothorax, and bronchoaspiration of blood or gastric content; and 2) hemodynamic alterations ranging from hidden hypoperfusion to refractory shock due to severe exsanguination. The causes include spinal shock, cardiac pump failure, or cardiac tamponade-bruising, lacerations and ruptures of the great arteries or solid organs, usually the liver and spleen, or pelvic fractures.

34.6.2 Neurological Exam

The neurological exam entails rapid but rigorous assessment of the level of consciousness, focal signs, brainstem reflex, pupillary examination and initial CT scan findings. The level of awareness reflects global brain dysfunction as a result of trauma. Despite the drawbacks outlined above, the GCS evaluation obtained after resuscitation remains the basic method to assess the level of consciousness. Along with its ability to classify TBI, the GCS is useful for clinical decision-making (monitoring, emergency surgery, etc.) and helps to predict the prognosis of TBI. The benchmark score is achieved on the side with better response, remembering that the most valuable of the scale's three components is motor score unaffected by difficulties in the verbal (intubation, tracheostomy) or ocular components (eyelid lesions).

The presence of focal signs, including in addition limb paresis or plegia, focal seizures and dysphasia, guides the classification of TBI severity and the likelihood of injury immediately amenable to surgical intervention on the side opposite the sign. Assessing the state of the pupils (pupil size and asymmetry) permits the assessment of the severity of traumatic injury and its topographic location and prognosis. In general, pupillary abnormalities reveal very severe TBI; and when there is bilateral fixed mydriasis, the injury is in the midbrain and the prognosis dims.

In patients with bilateral pupililary abnormality, the risk of mortality is >80%, which may be <15% if both pupils remain normal throughout the acute phase. The most frequent pupillary abnormalities are paralytic mydriasis of one or both pupils. Unilateral mydriasis occurs when the third cranial nerve is injured in its journey through the fissure of Bichat, the most common cause being herniation of the hook of the hippocampus, with transtentorial wedge pressure which compresses the ipsilateral oculomotor nerve and midbrain peduncle. Occasionally, orbital trauma associated with optic nerve damage causes anisocoria, which requires exploring the consensual reflex. By not reversing uncal herniation it would produce bilateral mydriasis due to injury against the free edge of the tentorium of the contralateral oculomotor nerve. Also, unilateral or bilateral mydriasis originates (dilated medium pupils), depending on the size of the lesion in dorsal midbrain lesions (quadrigeminal), where the nucleus of the oculomotor nerve has its origin, and in the ventral midbrain (cerebral peduncles). In this latter case, the pupils are at maximum dilation.

Miosis is observed less frequently in TBI, given as the cause of unilateral or bilateral lesions of the sympathetic fibres originating from the hypothalamus. Respiratory rhythm disorders are commonly seen in intense bilateral miosis with pontomesencephalic dorsal lesions (red nucleus). When miosis is unilateral, it usually indicates the development of transtentorial herniation and precedes paralyzed anisocoria. In case of bulbar symptoms, injury may occur in complete or incomplete Horner syndrome.

Hypodense space-occupying lesions	• Simple contusions • Hemispheric swelling • Hypodense vascular distribution
Hyperdense space-occupying lesions	• Epidural hematoma • Subdural hematoma • Intraparenchymal hematoma • Hemorrhagic contusions
Signs of diffuse axonal injury	• Corpus callosum injury • Mesencephalon-brainstem injury • Injury to basal ganglia • Subarachnoid hemorrhage • Intraventricular hemorrhage • Of the posterior cerebral artery • Other
Signs of increased cerebral volume	• Compression of base cisterns • Compression of fourth ventricle • Compression of third ventricle • Decrease in size of lateral ventricles
Vascular compression	• Of the anterior cerebral artery
Signs of intracranial hypertension	• Injury occupying large volume space • Signs of increased cerebral volume
Disturbances of clinically significant structures	• Subfacial hernia • Uncal hernia • Tonsilar herniation • Midline shift ≥5 mm • Bilateral injuries • Centroencephalic lesions • Diffuse axonal injuries

Table 34.5. **Guide to computed tomography interpretation. Modified from [Domínguez Roldán, 1997].**

Before the advent of CT, clinical examination of brainstem reflex (oculovestibular oculocephalic and reflexes) was an essential part of the neurological examination because of its prognostic implications, as it foreshadowed a negative outcome and a topographic location of the lesion (pontobulbal region). Today, it has lost value, as have other neurological signs because they are late. When altered or abolished, they reveal highly developed lesions that should have been previously diagnosed for more effective patient management.

Head CT scan is essential in the initial phase to determine the extent of structural damage and to detect surgical lesions. It also helps to classify the patient, predict final outcome, estimate the risk of ICH and response to therapy. For these purposes, and to establish a comparison between different series, the CT scan classification proposed by Marshall in 1991, despite the limitations mentioned above, is the most widely used scheme. The highest incidence of ICH and poor functional outcomes are observed in diffuse injury type IV and in non-evacuated space-occupying lesions >25 cc (type VI), followed by diffuse type III lesions and evacuated space-occupying lesions (type V). The incidence of ICH ranges from 10% in type I lesions to 40-60% in lesion types III, IV and VI.

Our group recommends adding the Marshall classification systematic reading of the CT (Table 34.5) to obtain valuable information for clinical decision-making and better classification of patients. Recent studies show a progression of structural damage within the first 9 hours, so it is advisable to repeat the initial CT after this period of time. Independently, CT should always be repeated whenever there are major injuries, neurological deterioration, or there is an unexplained increase in ICP.

In the initial or ICU phase, MRI does not provide useful information for immediate surgical decision-making. Furthermore, obtaining an MRI involves moving patients, interferes with resuscitation measures and is time-consuming. After this initial period, however, it can be very useful to show white matter lesions unexplained on the CT and may explain the clinical course of some patients. The most useful MRI techniques are T2-, FLAIR- and susceptibility-weighted imaging (SWI), and diffusion tensor imaging (DTI).

34.7 Treatment of TBI

34.7.1 Pre-hospital Management

At this stage, the main objective is to prevent and treat hypoxemia and hypotension because the brain is very vulnerable in these situations. Some studies have demonstrated a rate of hypoxemia (hemoglobin saturation <90%) between 45 and 55%, and hypotension (systolic blood pressure <90 mmHg) between 20 and 30%. Classical studies have shown that hypoxia is associated with poor outcome (OR 2.1) and hypotension (OR 2.7). In contrast, more recent studies have argued that normalisation of oxygenation (hemoglobin saturation >92%) and blood pressure improves the outcome.

- TBI with Glasgow Coma Score (GCS) ≤8
- Shock (systolic arterial pressure <90 mmHg)
- Airway obstruction
- Combative patient requiring sedation
- Prior to general anesthesia
- Chest trauma with hypoventilation
- Hypoxemia (PaO_2 <60 mmHg or pulse oximetry hemoglobin saturation <95%)
- Cardiac arrest
- Severe maxillofacial injury

Table 34.6. Indications for endotracheal intubation.

Current debate on tracheal intubation centres on the composition of the prehospital emergency team. In countries where emergency medical services involve paramedics, especially if not properly trained, intubation has been associated

with worse outcomes than in countries where emergency doctors perform intubation. Table 34.6 shows the criteria for tracheal intubation for airway protection and maintenance of hemoglobin saturation >95%.

Treatment of arterial hypotension entails surgically controlling the visible hemorrhage foci and restoring blood volume with colloid and crystalloid solution. Hypertonic sodium has not been shown to achieve greater benefits than isotonic saline, while the use of albumin to resuscitate patients may worsen the prognosis. TBI patients should be transferred to a medical centre with adequate clinical services and facilities (CT, MRI, ICP monitoring, etc.) and a neurosurgeon on duty. During transport, the patient should be placed in supine neutral position with a cervical collar and a nasogastric tube connected to a vacuum bag. Once the airway is secured and ventilation is effective, the use of analgesics (narcotics) and sedatives (benzodiazepines) can be very helpful.

34.7.2 The Emergency Room

At this stage, the aim is to stabilize hemodynamics and respiration and carry out diagnostic evaluation according to the recommendations of the American College of Surgeons Advanced Trauma Life Support (ATLS) protocol (Table 34.7). From a neurosurgical point of view, the priority is to detect and treat the most removable mass lesions. Therefore, TBI management relies on a multidisciplinary organization with pre-planned actions that can provide early treatment and quality. While there is consensus on the need to maintain hemoglobin saturation >92%, there are no studies that establish the optimum MAP in TBI. In >50% of patients with TBI, ICP levels are 20 mmHg above the target. When ICP is unknown, it is advisable to keep MAP >90 mmHg to preserve CPP at or above 60 mmHg.

Crystalloids and colloids allow rapid infusion of volume, taking into account that hypotonic fluid to plasma such as 5% dextrose and Ringer solution can induce osmotic swelling and increase ICP. As in pre-hospital resuscitation, the use of hypertonic solutions of 3% or 7.5% sodium alone or in combination with low-molecular-weight dextran does not improve neurological outcome. When, in spite of a rapid increase in volume, crystalloids and colloids do not achieve adequate MAP or CPP persists at <60 mmHg, the administration of vasopressors, usually norepinephrine or phenylephrine, should be considered.

Once hemodynamics and respiratory function are stabilized, a neurologic examination should be performed according to the guidelines given above. If during neurological clinical exploration there are warning signs of neurological impairment (GCS score ≤2, signs of cerebral herniation, unresponsive mydriasis such as unilateral or bilateral motor posturing, etc.), mannitol should be administered at a dose of 20% 1 g/kg, the patient hyperventilated to bring $PaCO_2$ to 30 mmHg, and CT and surgery performed, if needed.

Although >50% of patients with TBI present with associated traumatic lesions of varying severity, time should not be wasted on a thorough assessment of all possible traumatic injuries during this phase, but only to discard and to treat those that are life-threatening. As discussed above, modern scanners allow quick and safe imaging of all body areas where significant injuries are assumed, not to mention ruling out cervical spine injury. Up to 15% of TBI patients can have an injury at this level. Once a head CT scan is obtained, the neurosurgeon will decide the necessity of a surgical procedure. The surgical treatment of TBI is presented in another chapter of this book.

- Airway maintenance with C-spine control
- Breathing (oxygenation and adequate ventilation)
- Circulation and hemorrhage control
- Disability: neurologic status
- Exposure: completely undress the patient

Table 34.7. Interventions in the resuscitation phase.

34.7.3 The Intensive Care Unit

Cerebral Monitoring

During the ICU stay, the goal is to continue the prevention of secondary injury and provide the best physiological conditions for brain recovery. We do this by monitoring ICP and cerebral homeostasis and we prevent and treat brain swelling, cerebral intracranial hypertension (ICH), and hypoxia. Table 34.8 presents the key systemic and cerebral therapeutic objectives to obtain. In TBI, as in any other critical illness, surgical and medical complications may arise which will require care and general treatment that the ICU provides.

Although recent studies have questioned ICP monitoring, there is no doubt that a GCS score ≤8 portends a risk of IHC. Present in up to 77% of cases, this complication overshadows vital and functional prognosis. Moreover, it was found that in addition to increased ICP, cerebral hypoxia is the factor most often implicated in poor outcome. Cerebral hypoxia may co-exist with normal ICP and not all episodes of cerebral hypoxia are associated with increases in ICP. Therefore, in addition to ICP and CPP, other variables such as SjO_2 and cerebral oxygen partial perfusion pressure ($PtiO_2$) should be monitored and corrected.

According to the Braun Trauma Foundation's clinical guidelines, ICP monitoring is indicated in all patients with TBI who present a GCS score ≤8 and abnormal CT findings on admission, i.e., findings that do not qualify as diffuse brain injury type I according to the Marshall classification. The guidelines also state that ICP should be monitored in patients with TBI and a normal head CT scan who present at admission with two or more of the following characteristics: age >40 years; decerebrate posture; and unilateral, bilateral or systolic blood pressure <90 mmHg. The ICP will inform about the presence or absence of ICH (numerical value) and the exhaustion of the reserve of volumetric brain waves (abnormal recording) ICP is considered normal or "normalized" by active treatment when >20 mmHg with a closed skull or 15 mmHg with an open skull. In children, ICP is somewhat lower in both situations. The normal chart recording should be flat and present no spontaneous or induced oscillations. Pathological waves, primarily A and B, immediately signal a warning for the presence of neurological impairment in the presence or absence of high ICP, and indicate that the brain's compensation mechanisms have been overwhelmed by volume.

SjO_2 monitoring is the most common method to measure cerebral oxygenation, although $PtiO_2$ monitoring has been gaining acceptance, given its far greater stability and reliability and fewer technical complications. The only drawback of this method is the higher cost of catheters and the need for a specific monitor for recording. Although both methods explore cerebral oxygenation, the SjO_2 expresses purity in the balance between cerebral blood flow (CBF) and cerebral oxygen extraction or is redrafted if the CBF is sufficient, excessive, or insufficient to satisfy cerebral metabolic oxygen needs. Normal SjO_2 values range between 50 and 75%, considering hypoperfusion when SjO_2 is <50%, and contrary to absolute or relative hyperemia (luxury perfusion) when SjO_2 is >75%.

$PtiO_2$ monitoring, which has become the reference method to detect cerebral hypoxia, provides the value of the partial

SaO_2 >92%	Mean arterial pressure 90-120 mmHg
$PaCO_2$ 35-40 mmHg	Hemoglobin ≥9 g/dl
ICP <25 mmHg	CPP ≥60 mmHg
SjO_2 55-70%	$PTiO_2$ ≥20 mmHg
Mean velocity in MCA	60±10 cm/sec
Pulsatility index	<1.2

Table 34.8. Systemic and cerebral goals in TBI management.
MCA = Middle cerebral artery

	Hyperemia	Vasospasm
Increased velocity	Bilateral	Unilateral
MCA velocity >3 times ICA (LI)	No	Yes
Lack of dicrotic notch on the sonogram	Yes	No

Table 34.9. **Difference between hyperemia and vasospasm on TCD.**
ICA = Internal carotid artery
LI = Lindegaard Index
MCA = Middle cerebral artery

pressure of oxygen at the end of the capillary loop, reflecting mainly the balance between oxygen supply and consumption at the cellular level. The reference range of $PtiO_2$ is 15-40 mmHg (moderate cerebral hypoxia); 15 mmHg is defined as low hypoxia and values below 10 mmHg as critical hypoxia. Values >40-50 mmHg, by extrapolation from SjO_2, are considered luxury perfusion, although there is no absolute consensus on the latter.

Pattern	Value
Normal pattern	MCA mean velocity 60±10 cm/sec and PI <1.2
Hypoperfusion	MCA mean velocity <50 cm/sec
Hyperemia and vasospasm	MCA mean velocity >120 cm/sec
Circulatory arrest	Systolic spikes or sonogram absent

Table 34.10. **TCD hemodynamic patterns in TBI.**
MCA = middle cerebral artery.
PI = pulsatility index

Finally, transcranial Doppler ultrasound (TCD) monitoring provides valuable data to refine the treatment of severe TBI. TCD measures the flow rate in the large arteries at the base of the skull. Because the flow rate is directly proportional to CBF and inversely proportional to vessel radius, if the diameter is unchanged, any change in speed will translate into a change in CBF. Conversely, if the CBF seems stable, velocimetric changes will indicate modifications in the vessel radius as occurs, for example, in vasospasm. Cerebrovascular resistance is closely related to changes in ICP and CPP and is reflected by the pulsatility index (PI), an index automatically provided by the TCD device. In the acute phase of TBI, hemodynamic states are primarily normal, hypoperfusion, hyperemia, vasospasm and circulatory arrest. The TCD is normal when the values in the middle cerebral artery are about 60 cm/sec and the PI <1. Table 34.9 shows the data for the classification of hemodynamic states and Table 34.10 compares the differences between hyperemia and vasospasm.

Other methods such as continuous electroencephalogram (EEG) can be useful in identifying occult epileptogenic activity, present in 15% of cases, or cerebral microdialysis which indicates the presence of cerebral ischemia or hyperglucolysis. However, these methods are not available in most clinics. The interested reader is referred to other chapters of this book for a discussion of these topics.

General Measures

In patients with severe TBI, regardless of the ICP value, a set of general measures (Table 34.11) should be initiated immediately upon admission: to control or prevent elevation in ICP; prevent diffuse cerebral swelling; and to provide the metabolic substrates that will meet the consumptive demands of cerebral tissues. Essential steps are to ensure adequate oxygen delivery by means of adequate hemoglobin saturation and proper maintenance of blood volume by fluid replacement. As in the previous phases, the administration of isotonic crystalloid is recommended, essentially, 0.9% saline solution and

- Head 30° above the horizontal line
- Effective analgesia (opiates)
- Sedation (propofol/benzodiazepines)
- Normothermia (<37.5°C)
- Normovolemia (arterial lactate <2.2 mmol)
- Pulse oximetry (O_2 saturation >92%)
- Hemoglobin ≥9 g/dl
- Mean arterial pressure 90-110 mmHg
- Glucemia 140-180 mg/dl
- Plasma osmolarity >290 mOsm/l
- Seizure prophylaxis within 7 days of injury

Table 34.11. **General measures for treatment of TBI patients.**

colloids such as hydroxyethyl starch (HES) or gelatin. Unless there is hypoglycemia, one should avoid the use of glucose solutions as they can induce or aggravate hyperglycemia, which has been associated with worse outcomes in neurocritical patients. Furthermore, hypotonic solutions of 5% glucose may contribute to the formation of cerebral edema.

In cases where the administration of high replacement volumes is contraindicated (e.g., co-existing hyponatremia or ICH), an alternative is the use of hypertonic 7.5% sodium solutions at a dose of 4 ml/kg bolus weight. Also, to maintain a CPP of at least 60 mmHg, norepinephrine or phenylephrine in continuous infusion can be used when this objective is not achieved with volume replacement. Although the ideal hematocrit of these patients has not been established, the transfusion of packed red cells can be considered to maintain adequate oxygen delivery when hemoglobin levels are <9 g/dl.

In general, a combination of measures with sedation, and analgesia should be included. The most commonly used sedative agents are midazolam and propofol. The preference of one over another depends exclusively on the discretion of the attending physician. Propofol is inconvenient in that it tends to provoke arterial hypotension if the circulating blood volume is suboptimal and it requires adjusting the administration of lipids in the diet. The most common painkillers are opiates, especially morphine, and fentanyl, which in analgesic doses does not increase CBF or ICP.

Mechanical ventilation also forms part of the general measures, ensuring that $PaCO_2$ does not fall below 35 mmHg during the first 24 hours in order to prevent hypocapnia and cerebral ischemia. $PaCO_2$ <35 mmHg should be reserved exclusively for the active treatment of ICH, monitoring its effect on CBF through SjO_2 or $PtiO_2$.

While it is undisputed that silent or apparent seizures should be treated, anticonvulsant prophylaxis continues to be debated and views on its value are changing. For some time it was thought that it was effective in controlling early epilepsy (onset within the first week) and late epilepsy. There is currently no scientific evidence to support the use of anticonvulsants to prevent late post-traumatic epilepsy, and their use is indicated only during the first week. The most widely used agents are phenytoin, carbamazepine, and levetiracetam.

34.7.4 Treatment of Intracranial Hypertension

The specific treatment of IHC should be started when ICP exceeds 20 mmHg in an adult and 15 mmHg in both children and adults with an open skull for ≥30 minutes, and after having dismissed or surgically removed an expansive lesion. Figure 34.1 shows the treatment algorithm recommended by the Brain Trauma Foundation guidelines and adapted by our group. This guide is a step-by-step algorithm, structured in first and second level measures, reached by expert consensus with a generally low evidence level, but which are widely accepted and have demonstrated improved TBI results according to recent studies.

Although we argue that the best approach would be personalized treatment of a patient's cerebral hemodynamics, we refer to the Brain Trauma Foundation's clinical guide-

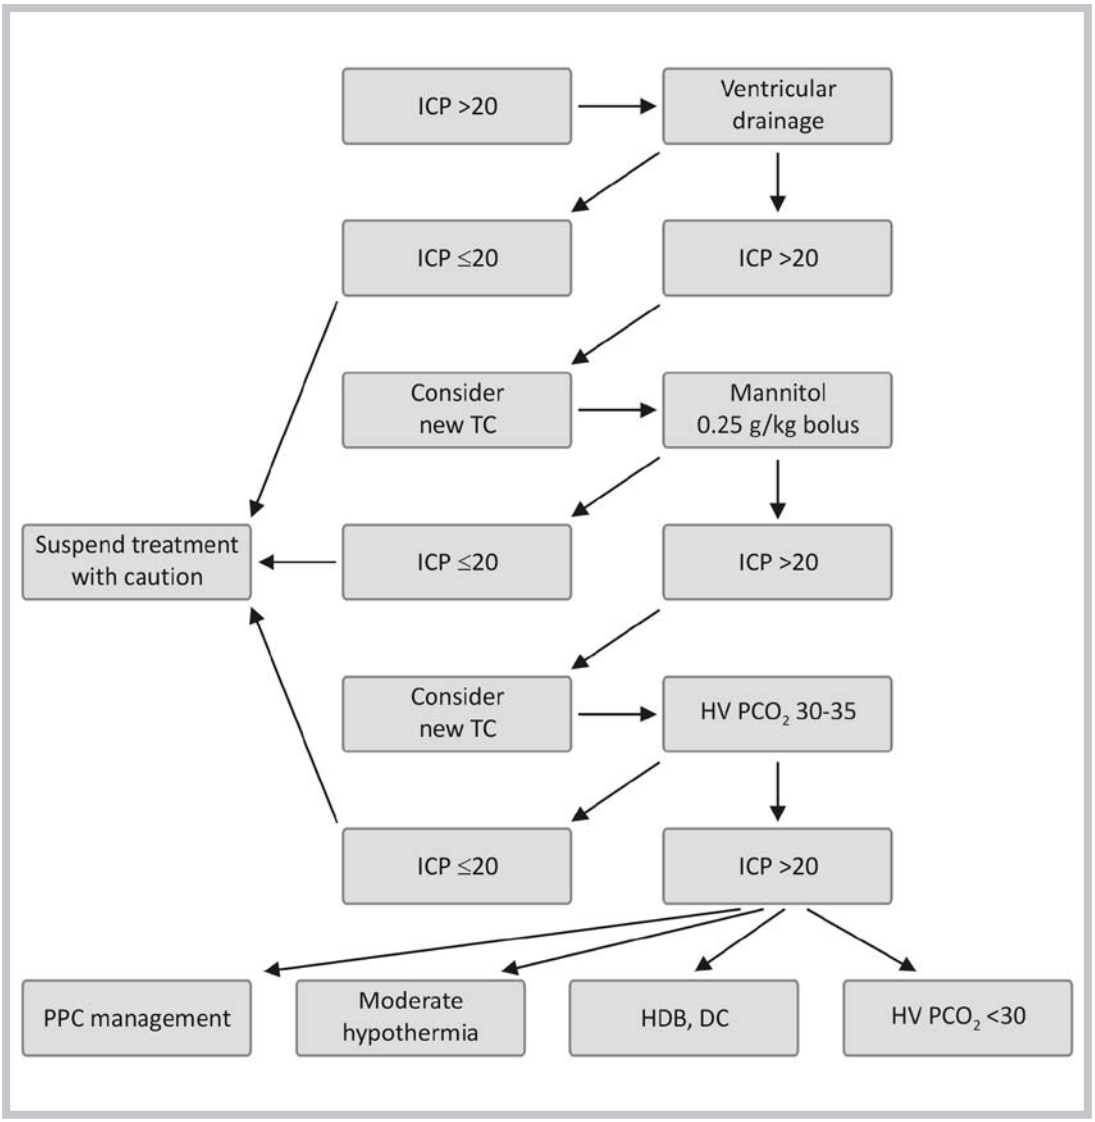

Figure 34.1. **Algorithm for the treatment of intracranial hypertension.**
HDB = Barbiturates in high doses
DC = Decompressive craniectomy
HV = Hyperventilation

lines. It should be noted that each successive therapeutic step is taken only if a previous step has failed (no control of ICP within 30 minutes of onset), without suspending the former agent but adding a new measure.

Accepted, although not unanimously, is the use of muscle relaxants as a first step to control ICP. The advantages to the use of muscle relaxants in continuous infusion are the control of ICP during tracheal suction manoeuvres, hygiene and patient repositioning, and easier adaptation to mechanical ventilation. The disadvantages are increased length of ICU stay, increased risk of ventilator-associated pneumonia, failure to maintain contact with the patient's neurological development and, sometimes, neuropathy and myopathy. Juul et al. in a study involving 326 patients failed to demonstrate longer time without ICH in patients who had received muscle relaxants. Therefore, muscle relaxants

(e.g., as pancuronium, vecuronium, rocuronium, cisatracurium, etc.) should be reserved for very specific occasions, advising the use of vecuronium by increased hemodynamic stability that its use entails.

First Tier Measures

When ICP is monitored with an intraventricular catheter, drainage of 2-3 ml of CSF through the ventriculostomy catheter reduces ICP, which on many occasions permits the control of ICP without the need to move on to other therapeutic steps. For this purpose, the drain should not be kept open continuously but for as long as required to normalise ICP. In other cases, especially in diffuse lesions with absent cisterns and/or compressed ventricles, this manoeuvre can be useless to normalise ICP. However, its major drawbacks are technical (i.e., inability to insert the catheter into the ventricle if there is displacement of the medial axis) and possible complications: infectious, since the operation and maintenance of the catheter over 4-5 days is associated with a high rate of infection and to a lesser extent (<1.5%) bleeding in the catheter line.

Osmotherapy represents the next therapeutic step. Mannitol is the most widely used agent, followed by hypertonic saline 3%, 7.5% and 24%. Few studies have compared these agents; however, according to some, hypertonic saline can provoke a more intense fall and lasting resolution of ICP, and would therefore be effective when ICH is refractory to other agents, while mannitol would more sharply increase CBF. However, the available evidence is still insufficient to recommend hypertonic saline over mannitol. The agents act through two different and complementary mechanisms. The first and immediate one is hemodynamic, which results in an increase in MAP, CPP and CBF. According to Rosner, it reduces ICP by activating the vasoconstrictor cascade. Another beneficial outcome in relation to its hemodynamic action is the improvement of cerebral microcirculation by reducing blood viscosity.

The second and most studied effect is the creation of an osmotic gradient that causes water to flow across the intact blood-brain barrier. Dehydration of the brain parenchyma facilitates the maximum reduction of ICP observed around 20 minutes post-infusion. When the blood-brain barrier is altered, worsening of edema has been reported with the use of mannitol, as well as an increase in bruises with the use of hypertonic saline. Favourable possible effects of mannitol are the decrease in CSF production and oxygen uptake of free radicals, while hypertonic saline has been reported to decrease endothelial edema and increase cerebral oxygen transport.

Mannitol 20% should be administered in bolus doses from 0.25 to 1 mg/kg as often as needed to be effective, but at least every 4-6 hours to maintain the osmolar gradient and avoid the rebound effect, not to mention that mannitol doses are higher (1 g/kg) when elevated ICP causes brain herniation. The dose of hypertonic saline is not well established, but it is recommended to be sufficient to maintain serum sodium >145 mEq/l. Our group employs bolus 4 ml/kg of 3% sodium, which is repeated as needed and osmolarity does not exceed 320 mOsm/l.

Osmotherapy, particularly when used for long periods, is associated with complications such as dehydration with subsequent hypovolemia, a complication that would buffer the hemodynamic and rheological effects and electrolyte abnormalities, especially hypernatremia, with the use of hypertonic saline, heart failure, bleeding diathesis, and phlebitis. Mannitol also has a toxic effect on the renal tubules, an effect that is greater in hypovolemia, use of nephrotoxic drugs, sepsis or previous kidney disease. Although the toxic action of mannitol is reversible, it is sometimes difficult to manage the patient.

When previous measures have failed, hyperventilation will be initiated, maintaining PCO_2 at 30-35 mmHg. Hypocapnia induces a decrease in CBF and thus cerebral blood

volume responsible for the decrease in ICP. PCO_2 levels below those recommended are dangerous because of the risk of producing ischemia due to both the vasoconstrictor effect of hypocapnia and the leftward shift that tissue alkalosis determines on the hemoglobin dissociation curve (Bohr effect). In our experience, one of the leading causes of cerebral hypoxia, $PtiO_2$ is evidenced by the decrease in $PaCO_2$, which currently prevents the routine use of hyperventilation. Moreover, a study on the effectiveness of prophylactic hyperventilation in TBI showed poorer outcomes in patients at 3 and 6 months after head injury. We must insist on the need to monitor SjO_2, or better $PtiO_2$, when hyperventilation is used for sustained treatment of ICH.

Second Tier Measures

The best overall management of TBI has led to a decrease in the number of patients with ICH refractory to conventional medical and surgical measures used to lower ICP. However, in approximately 12% of patients it´s necessary to proceed to second level measures, as refractory ICH is associated with a mortality of 84-100%. Since there is no scientifically established hierarchy in the use of these measures, we will describe them according to our own experience. Although its usefulness was questioned in a systematic review, high-dose barbiturates (HDB) are continuing to be administered now that numerous case studies have shown that these drugs can reduce mortality and decrease ICP in refractory ICH.

The main effects of HBD seem to lie in their property to couple CBF to metabolic demands, so that the drop in metabolic requirements in TBI would be accompanied by a parallel decrease in CBF and cerebral blood volume, thereby inducing a reduction in ICP and an improvement in CPP. Besides their effect on ICP, HDB have been attributed with neuroprotective properties which cause cerebral vasoconstriction which could decrease cerebral metabolism and inhibit lipid peroxidation mediated by oxygen-free radicals.

The most widely used HBD are pentobarbital and thiopental, which must be administered with a loading bolus and an hourly maintenance dosage. The usual loading dose for thiopental is 1.5 mg/kg over 30 minutes and 10 mg/kg over 30 minutes for pentobarbital. The maintenance dose is 1-6 mg/kg for thiopental and 5 mg/kg for pentobarbital. It was once advised to monitor plasma HDB levels to adjust the maintenance dose. However, monitoring HDB levels has not been helpful to avoid side effects nor to optimise their therapeutic effects. Currently, EEG monitoring is the preferred way to adjust the dose, mainly by bispectral index (BIS) monitoring; as they appear in bursts of EEG suppression, the greatest effect on metabolism and CBF is achieved.

Among the adverse effects of HDB the most pernicious is arterial hypotension, which occurs almost normally and should be prevented and treated vigorously, vasoconstriction (or cerebral vasoplegia), and decreased T lymphocyte activity. Arterial hypotension is more frequent in elderly patients with a history of cardiovascular diseases and in patients with hypovolemia, acidosis, hypoalbuminemia or infection. In patients treated with HDB it´s therefore necessary to carry out periodic analysis of plasma albumin, pH, blood gases and continuous MAP monitoring.

A further problem posed by HDB is the difficulty in the early diagnosis of infection because the patient may be hypothermic due to the action of HDB and peripheral leukocytosis may not be detectable. As a general guide, HDB can be more useful in patients with higher ICH when the CT scan shows signs of diffuse brain swelling, moderate hyperventilation reduces ICP, SjO_2 >70 mmHg or $PtiO_2$ >20 mmHg, and before a high-velocity TCD exam.

As second-tier therapy in refractory ICH, after the first 24 hours of TBI, and an absence of global ischemia or regional cerebral hypoxia as measured by oximetry ($PtiO_2$ or SjO_2), profound hyperventilation can be used ($PaCO_2$ 27±2 mmHg). As with HDB, hyperventilation is most useful when the CT shows signs of diffuse brain swelling, CPP >60 mmHg, SjO_2 >70 mmHg or $PtiO_2$ >20 mmHg, and TCD ultrasound shows high average velocity flow.

Although performed for over a century for treating ICP, decompressive craniectomy (DC) has attracted renewed and growing interest from groups that advocate it as a first- level procedure. However, controversy persists about its appropriateness. First, not all published series of adult patients have shown improved the results. The only prospective study conducted to date was positive but not statistically significant and involved in 13 pediatric TBI patients and 14 controls: It showed that ICH was reduced and that outcome was better in the patients who had received DC. The prospective, controlled Australian DECRAN study, which has recently been completed, has failed to demonstrate better outcome in the DC-treated group. We are awaiting the results of the European ICP Rescue study to know whether they contradict or otherwise confirm the DECRAN results.

Adding to the controversy over DC is the high rate of substantial complications: hematoma, intracranial cerebral hyperemia with or without associated edema, hydrocephalus, subdural hygroma, secondary heart attack, fungus cerebri and neurological deficits related to bone removal. Furthermore, mixed series can create confusion, since primary DC is not identical or prophylactic after surgery performed on an injury mass and cannot be compared with a secondary DC performed when other measures fail to control ICP.

Nonetheless, there is consensus that craniectomy in the treatment of refractory ICH should take place within the first 48 hours, with wide resection (15 cm x 15 cm), followed by duroplasty, bilateral in diffuse lesions and unilateral in mass lesions, and that the beneficial effect will depend on the amount of bone removed from the temporal base when the total size equals that of the mass lesion. Young patients without extremely elevated ICP, not at risk of dying or poor outcome, could benefit more from DC.

Increasing MAP, or the CPP-oriented strategy, is another second level option. It is based on the theory advanced by Rosner (Figure 34.2) that in TBI self-regulation is never lost but rather is shifted to the right, the critical point on the autoregulation curve, requiring, therefore, greater MAP to induce vessel narrowing. According to the author, the decrease in CPP initiates a cerebral vasodilator cascade that increases the cerebral blood volume, which, in turn, leads to an increase in ICP, thus closing a vicious circle.

In contrast, an increase in CPP through a decrease in ICP or an increase in MAP would trigger a beneficial vasoconstrictor cascade that reduces cerebral blood volume and controls ICP. To lower ICP, MAP should be gradually increased to a value that occurs in the fall of ICP. MAP values may sometimes be as high as 150-160 mmHg and sometimes do not lead to such a reduction in ICP, despite having exceeded these values. This expands the intravascular volume with saline. If MAP does not increase despite good vascular filling with fluids or its value is insufficient to trigger the vasoconstriction cascade, the infusion of vasoactive agents such as norepinephrine or phenylephrine may be an option for the stated objectives.

Renal failure is the most common complication when high-dose vasoactive drugs are administered to increase MAP. At this point, increasing MAP is usually reserved for patients with space-occupying lesions in which previous options have failed and there are no systemic contraindications to increasing MAP.

Another measure that appears and reappears as an option in second level treatment is controlled hypothermia. Its interest resides in the neuroprotective effect of controlled hypothermia. At the most studied temperatures (32-34°C) a reduction in systemic and cerebral demands of oxygen is reportedly coupled with a decrease in CBF and ICP, de-

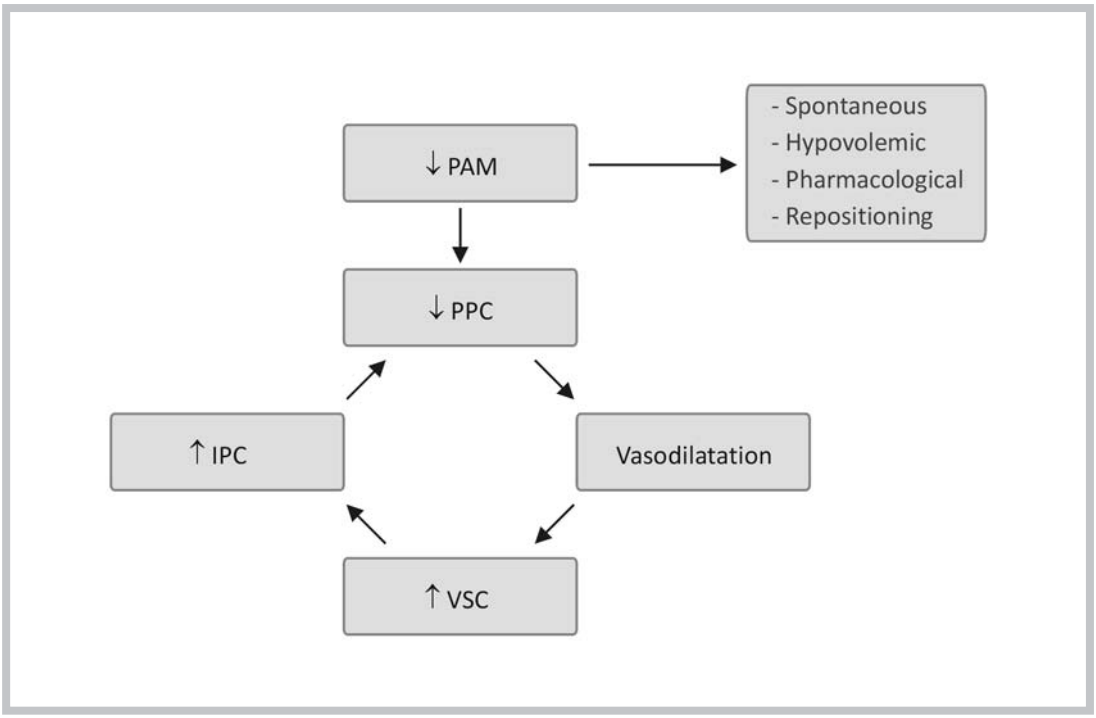

Figure 34.2. **Rosner vasodilator cascade.**

creasing the release of excitatory amino acids and protecting against free radicals. At lower temperatures (<32°C), however, hypothermia has been associated with immunosuppression, hypokalemia (with severe hyperkalemia during overheating that can result in cardiac arrest) and severe coagulation disorders. Studies involving small TBI populations, especially those by Marion in 1999, reported beneficial effects of hypothermia on outcome; however, a well-designed prospective and controlled study by Clifton in 2001 failed to demonstrate efficacy. Recently, the good results in neurological recovery obtained in patients resuscitated after sudden death from ventricular fibrillation has rekindled interest in hypothermia.

A recent meta-analysis of 13 studies involving more than 1300 patients with TBI, although mixing dishomogeneous data sets and procedures, reported a modest reduction in mortality and a slightly higher percentage of favourable outcomes. However, complications, especially pneumonia, may outweigh the neurological benefit. Therefore, pending the availability of new controlled studies, cautious use is recommended in centres with expertise in selected cases, with temperatures no lower than 33°C, with slow heating (>48 hours).

A different approach to the clinical guidelines issued by the Brain Trauma Foundation and the European Brain Injury Consortium is advocated by the school in Lund (Sweden). Its main objective is to control ICP, assuming that any increase results from vasogenic edema caused by an impaired blood-brain barrier and loss of cerebral autoregulation. The increase in MAP would be the force that in these pathophysiological conditions produces cerebral edema. To abort this cascade, MAP must be reduced, oncotic plasma increased and the venous vascular space collapsed with dihydroergotamine. Despite the good results reported by the Swedish authors, the shortness of the series and the lack of a control group currently make this therapeutic strategy unacceptable to the scientific community. Table 34.12 illustrates the Lund therapy protocol.

General measures	• Moderate head elevation (maximum 20°). Surgical evacuation of available hematomas and contusions. Insertion of ICP monitoring device • Avoid hyperthermia. At persistent high fever (>38.5°C) the temperature can be reduced with paracetamol or one bolus dose of methylprednisolone (10-15 mg/kg). Avoid active cooling • Mechanical ventilation to normal $PaCO_2$ (35-39 mmHg) and normal PO_2 (90-100 mmHg) • Effective sedation and stress reduction by using sedatives (midazolam, propofol, thiopental) combined with α_2-agonist. Thiopental should be used only at low doses (2-3 mg/kg bolus + 0.5-3 mg/kg/h IV) and for a maximum of 2 days • Normovolemia is mandatory. Use erythrocyte infusion to maintain normal hemoglobin (125-140 g/l) and albumin infusions to normal serum albumin concentration (35-43 g/l). Achieve normal plasma oncotic pressure by albumin infusion and diurectics (avoid mannitol). Minimize use of ADH analogue in polyuria • Use low-energy nutrition (15-20 kcal/kg/24 h) If possible, mainly enteral nutrition. Keep blood glucose normal (5-8 mmol/l) with insulin if necessary. Avoid hyponatremia • ICP can be controlled by normalizing plasma oncotic pressure and blood pressure, the latter by anti-hypertensive and catecholamine-reducing therapy with β_1-antagonist (e.g., metoprolol 0.04-0.08 mg/kg×6-8 IV, or corresponding doses continuously, or 50-100 mg × 2 PO) and α_2-agonist (e.g., clonidine 0.3-1.0 μg/kg×4-6 IV, or corresponding doses continuously or per os) and angiotensin II inhibitor (e.g., losartan 50 mg × 1-2 PO)

Treatment of raised intracranial pressure. Objectives: ICPC ≤20 mmHg + CPP=60 mmHg	• If ICP increases to a life-threatening level, despite the interventions described above, large unilateral or bilateral craniotomy may be life-saving by reducing ICP (decompressive craniectomy)
	• Dihydroergotamine at minimum necessary doses. Not indicated if: long bone fractures; subarachnoid hemorrhage, renal failure:
	  ▪ Day 1 maximum dose 0.6-0.8 mg/kg/h
	  ▪ Day 2 maximum dose 0.6 mg/kg/h
	  ▪ Day 3 maximum dose 0.4 mg/kg/h
	  ▪ Day 4 maximum dose 0.2 mg/kg/h
	  ▪ Day 5 maximum dose 0.1 mg/kg/h
	• CSF drainage should be avoided but drainage via ventricular catheter may be used to break an incipient Cushing reflex or a critically high ICP

Table 34.12. **Lund therapy protocol.**

When and How Should Treatment of ICH Be Discontinued?

Active treatment of ICH should be withdrawn in stages, beginning with the last measure initiated and leaving for last the general measures of treatment of TBI, i.e., analgesia and sedation. Treatment withdrawal should not begin until the following conditions are met: normalized ICP for at least 24 hours, CPP >60 mmHg; absence of abnormal ICP waves; midline centred on the CT scan, no vasospasm on TCD.

34.7.5 Evaluation of Results in TBI

The evaluation of treatment of TBI involves several objectives. First, to know our reality and compare it with accepted standards for our level of economic resources and technological complexity and training. This should lead, if not favourably compared, to establish an improvement plan, investigating our pockets of inefficiency in the integrated

treatment of TBI. Second, to design a neurocognitive rehabilitation plan and neurophysiotherapy program individualized to each patient. Finally, it is useful to evaluate the results of clinical trials of new drugs or procedures.

Conventionally, it's accepted that 6 months after the accident is an adequate time point to establish the result, given that in around 80-85% of patients marked changes will not occur after this time. In young people, however, particularly in those undergoing holistic rehabilitation, it is possible, and our experience corroborates this, can improve in cognitive areas beyond that period.

For these purposes, we have devised a simple global assessment scale, globally accepted as the GOS (Table 34.13), which is yielding ground in favour of a more elaborate version that will allow an intermediate number of categories such as the Extended Glasgow Outcome Scale (Table 34.14). However, more complex scales that measure quality of life and degree of recovery of higher brain functions are required, especially in intensive rehabilitation plans. Numbering among these latter scales are the Disability Rating Scale, currently widely used in clinical trials, the Barthel scale, and the QOLIBRI (quality of life in brain injury) scale. It is important, implying the possibility of some recovery, to neatly differentiate vegetative states from states of minimal response, since in the latter cases positive developments have been occasionally observed. Functional studies with MRI can help differentiate these situations.

Score	Response
1	Dead
2	Vegetative state (meaning the patient is unresponsive, but alive; a "vegetable" in lay language)
3	Severely disabled (conscious but the patient requires others for daily support due to disability)
4	Moderately disabled (the patient is independent but disabled)
5	Good recovery (the patient has resumed most normal activities but may have minor residual problems)

Table 34.13. Glasgow Outcome Scale Score.

Score	Response
1	Dead
2	Vegetative state
3	Lower severe disability
4	Upper severe disability
5	Lower moderate disability
6	Upper moderate disability
7	Lower good recovery
8	Upper good recovery

Table 34.14. Extended Glasgow Outcome Scale.

Any scale that we use must meet the following requirements:

- Easily completed by doctors or nurses with a minimum level of training.
- Validated in face-to-face use or by telephone.
- Good interobserver reproducibility.
- Integration of all domains related to functional recovery (activities of daily living, quality of life, neurocognitive function).

34.8 Conclusions

Despite marked progress in the diagnosis and pathophysiology of brain damage in recent years, proper treatment of TBI relies on:

- Knowledge of local TBI epidemiology to establish plans and rigorous prevention policies.
- Regional rapid-response systems with trained multidisciplinary teams able to handle all injuries associated with TBI.

- Regionalization of TBI care in hospitals with appropriate services and facilities (diagnosis, treatment and neuromonitoring) for the delivery of comprehensive treatment from the time of the accident until rehabilitation, including complications of critically ill patients.
- Adherence to clinical guidelines for TBI management.
- Rigorous assessment and plans to improve our results, after comparing them with the finest hospitals.

35 Surgical Management of Severe Traumatic Brain Injury

Randall Chesnut [1], Rodolfo Recalde [2]
[1] President of North America Brain Injury Consortium(NABIC). Director of Cranial and Spinal Trauma Center, Harboview Medical Center, University of Washington, USA
[2] Prof. Neurocirugia, Universidad de Buenos Aires, Servicio Neurocirugia, Hospital Alejandro Posadas, Buenos Aires, Argentina

35.1 Introduction

The incidence of morbidity and mortality after severe traumatic brain injury (STBI) is high, particularly among the young, many of which will suffer life-long disability. STBI demands urgent neurosurgical treatment since brain injury begins at the moment of the trauma and damage may worsen with time. STBI is a dynamic entity which can change within hours, which is why it requires continuous monitoring and multidisciplinary management. Early identification of patients who may need surgical treatment is critical because delays can result in poor outcome or even death. The objectives of this chapter are to describe the different types of lesions in STBI, differentiate which may need surgical or medical treatment, and provide some guidelines for STBI management.
Intracranial hematomas may be classified into intra-axial and extra-axial and all of them appear as hyperdense areas on the computed tomography (CT) scan in the acute phase. Because it is often a concomitant event, damage to adjacent parenchyma should also be ascertained. Treatment will usually be instituted in the acute phase, but we must differentiate which lesions to treat and when to treat them.
An extra-axial lesion refers to an intracranial hematoma located outside the brain in the epidural or subdural space. This is one of the most common neurosurgical emergencies related to head injury. Although similar in location, its prognosis is different.

35.2 Epidural Hematoma

Epidural hematoma is generally caused by a blunt injury but with enough energy to fracture the skull and disrupt the meninges. It is associated with a skull fracture in 30-90% of cases. Skull fracture or deformation following impact disrupts the meninges around the fracture; blood accumulates in the space created between the bone and the dura, usually due to laceration of the medial meningeal artery or the diploic veins or the dural sinuses. In young patients, the dura can be easily detached, especially in the temporal region known as Marchant's zone (the area on the sphenoid and occipital bones at the skull base from which the dura mater is readily detached). A temporal location is seen in up to 70-80% of cases and is often unilateral. In 50-68% of cases, epidural hematoma is associated with intradural lesions, subdural hematomas or cerebral contusions. The association with other injuries carries a poorer outcome.
Clinic presentation depends on the location and cause of bleeding (arterial or venous), tolerance of brainstem compression and elevation of ICP: 30-60% of patients may suffer loss of consciousness and 20% may be unconscious from the time of trauma. The classical "lucid interval" is seen in only one third of cases.

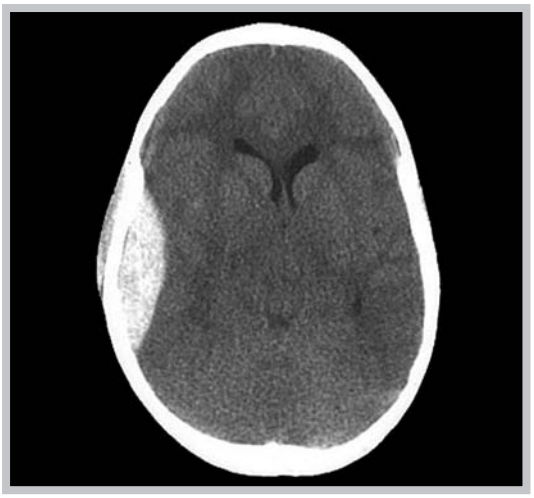

Figure 35.1. Temporal epidural hematoma displaying the typical biconvex lens appearance.

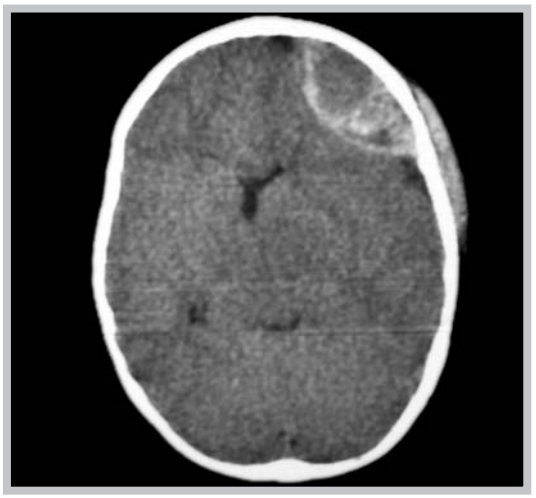

Figure 35.2. Frontal epidural hematoma in the hyperacute phase; note the hypodense areas inside the collection of blood typical of the hyperacute phase.

35.2.1 Diagnosis

CT scan without contrast and with bone window view is the study of choice for diagnosis. The hematoma appears as a hyperdense homogeneous lesion with the shape of a biconcave lens (Figure 35.1) in the temporal region and associated with a bone fracture. In a hyperacute state the appearance is heterogeneous with areas of hypodensity (Figure 35.2) suggestive of active bleeding. Hematoma enlargement is generally limited by the adherence of the dura to the bone sutures, which gives the lesion its typical appearance on the CT scan. It is important to examine the vertex because a hematoma may develop there in some cases.

35.2.2 Surgical Treatment

Most epidural hematomas must be treated surgically (Figure 35.3 A and B). Critical is the initial management in the emergency room and at the scene of the accident, as well as rapid specialist evaluation once the patient is stabilized. In patients presenting with progressive neurological deterioration it is very important to avoid secondary damage and to provide adequate brain resuscitation when needed. If the patient cannot be adequately stabilized and no other reason is found that justifies the neurological condition, or another studies are delayed as may happen in centres lacking available clinical services, urgent surgical evacuation as a salvage manoeuvre may be indicated [1].

We can use the side of pupil dilatation, the side opposite the motor deficit or even the side of the fracture on the x-ray film to determine hematoma location in 85% of cases. In stabilized patients, or those without progressive neurological deterioration, all necessary studies should be completed. Bone resection for hematomas in the temporal region should be performed up to the floor of the medial fossa if it is necessary to gain access to the proximal portion of the medial meningeal artery when bleeding cannot be controlled. Intracranial pressure monitoring is not necessary if there are no associated parenchymal lesions. There are reports of medical management for epidural hematoma. In most of these patients not treated surgically without clinical manifestations or any neurological deficit, the lesion volume is <40 ml. Such management entails prolonged hospitalization and serial CT scans to evaluate lesion resolution.

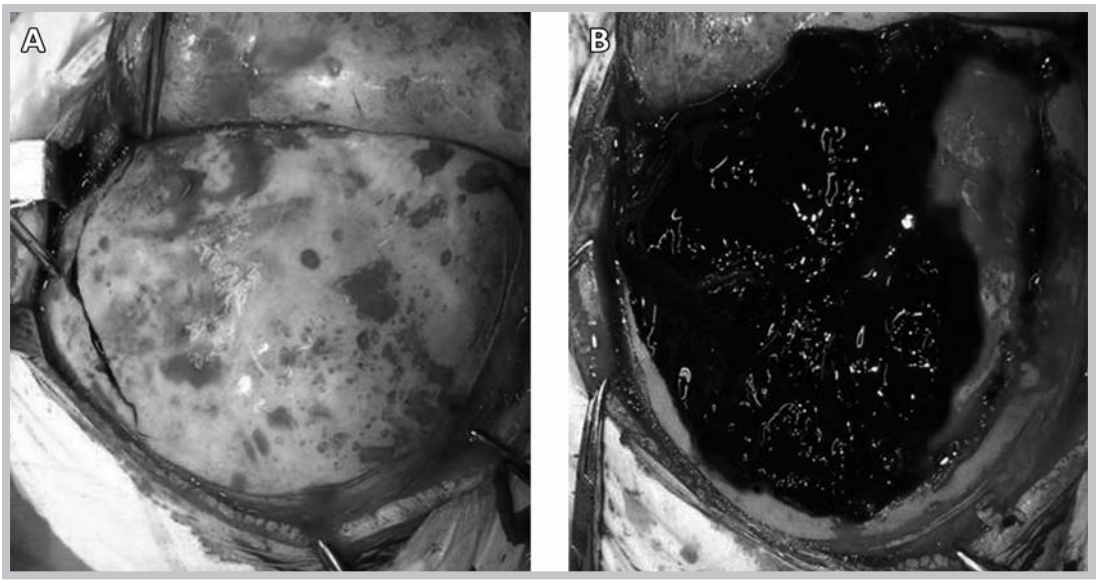

Figure 35.3. **Intraoperative image of an epidural hematoma. The fracture on the posterior temporal region can be seen, with protrusion of the hematoma through the fracture (A). A huge epidural hematoma in the same patient after craniotomy (B).**

Indications for surgery	• An epidural hematoma (EDH) >30 cm^3 should be surgically evacuated regardless of the patient's Glasgow Coma Scale (GCS) score • An EDH <30 cm^3 **and** with <15 mm thickness **and** with <5 mm midline shift (MLS) in patients with a GCS score >8 **without** focal deficit can be managed non-operatively with serial CT scanning and close neurological observation in a neurosurgical centre
Timing	• It is strongly recommended that patients with an acute EDH in coma (GCS score 9) with anisocoria undergo surgical evacuation as soon as possible
Type of surgery	• There are insufficient data to support one surgical treatment method. However, craniotomy provides a more complete evacuation of the hematoma

Table 35.1. **Guidelines for the surgical management of epidural hematoma.**

Prognosis is related to the level of consciousness, the presence of other neurological deficits and the severity of associated intracranial lesions. In patients admitted not in coma the outcome is favourable in 90-100% of cases and the mortality is 0-5%. In patients with a Glasgow Coma Scale (GCS) score <8 the outcome is favourable in 38-73% of cases and the mortality is 11-41%. The risk of mortality is three times higher if there are associated lesions (subdural hematoma or contusions).
Prompt diagnosis and surgical evacuation are key to achieving a good outcome if there are no associated lesions and neurological deterioration is related only to hematoma expansion. Guidelines for the management of these lesions are summarized in Table 35.1.

35.2.3 Non-surgical Management

There are reports of spontaneous resolution of epidural hematoma. This has been explained by reabsorption of the hematoma by the fibrovascular membrane over a period of 13 days. An epidural hematoma may increase in size during this time. Epidural hematomas that can be successfully managed with this criterion are those with a volume <44 cm^3. Special care must be taken if the lesion is located in the posterior fossa or the

middle fossa owing to the possibility of temporal lobe herniation due to brain swelling and brainstem injury. Any sign of neurological deterioration or signs and symptoms of increased intracranial pressure is an indication for surgical evacuation.

35.2.4 Prognosis

Global mortality is 0-10% but depends on the neurological state at the time of surgery. The mortality rate for comatose patients at surgery is 14-70%. Outcome is usually worse in patients older than 40 years or with lesions >150 cm^3 in volume

35.3 Subdural Hematomas

Subdural hematoma is an accumulation of blood between the dura and the brain. Road accidents are the most common cause. A subdural hematoma may be simple or complex. The simpler ones are not accompanied by parenchymal lesions and are usually caused by laceration of the bridging veins between the brain and the dural sinuses. Urgent evacuation is associated with good prognosis. Complex subdural hematoma is associated with parenchymal contusions and high intracranial pressure. Generally, it is located on the temporal, frontal or orbitofrontal lobe and the convexity in the interhemispheric space. The external margin is determined by the skull and the internal margin by the brain, which lends the margin its irregular shape. The volume may increase because of the lack of adherences on the subdural space.
But blood accumulation is not the only cause related to poor prognosis. Brain swelling and ischemia usually associated with subdural hematoma may be related to blood derivates and their neurotoxic action. This ischemic condition may not change with hematoma evacuation. The presence of this lesion justifies urgent surgical evacuation.

35.3.1 Clinical Manifestations

Signs and symptoms result from the mass effect of subdural hematoma, elevated intracranial pressure, location, size, association with another space-occupying lesions, and secondary insults. Early seizures are frequent (24%). Pupillary abnormalities may be seen, as well as motor deficits (<50% of patients); when present they may help localize the side of the lesion. But it should be kept in mind that in 25-30% of cases pupillary signs and in 38% of cases motor signs may give a false localization, which is why CT scan is of vital importance in the management of these patients.

Figure 35.4. **Fronto-temporo-parietal subdural hematoma, also known as hemispheric, with the shape of a biconcave lens and hyperacute content characteristic of a hyperacute lesion.**

35.3.2 Diagnosis

CT scan without contrast and with bone window view is the study of choice. The

CT scan will show a concave-convex lens next to the skull (Figure 35.4) generally over the parietal, temporal and frontal lobes and usually unilateral or occasionally bilateral (15% of cases). Subdural hematomas extend beyond the bone suture line, which helps to differentiate them from epidural hematoma. In 66-80% of cases subdural hematoma is associated with other intracerebral lesions (contusions, hematomas); it may be seen in a hyperacute state with characteristics resembling those of epidural hematoma and it may also be related to coagulation disorders. Interhemispheric subdural hematoma is uncommon.

35.3.3 Surgical Treatment

Factors to be weighed before operating on a subdural hematoma are the size, timing (time since the CT scan was performed and time elapsed since the trauma), presence of associated lesions and brain swelling [2].
Subdural hematoma carries a poorer prognosis than epidural hematoma. Prompt evacuation in the first 4 hours seems to be related to better outcome. The delay in surgical

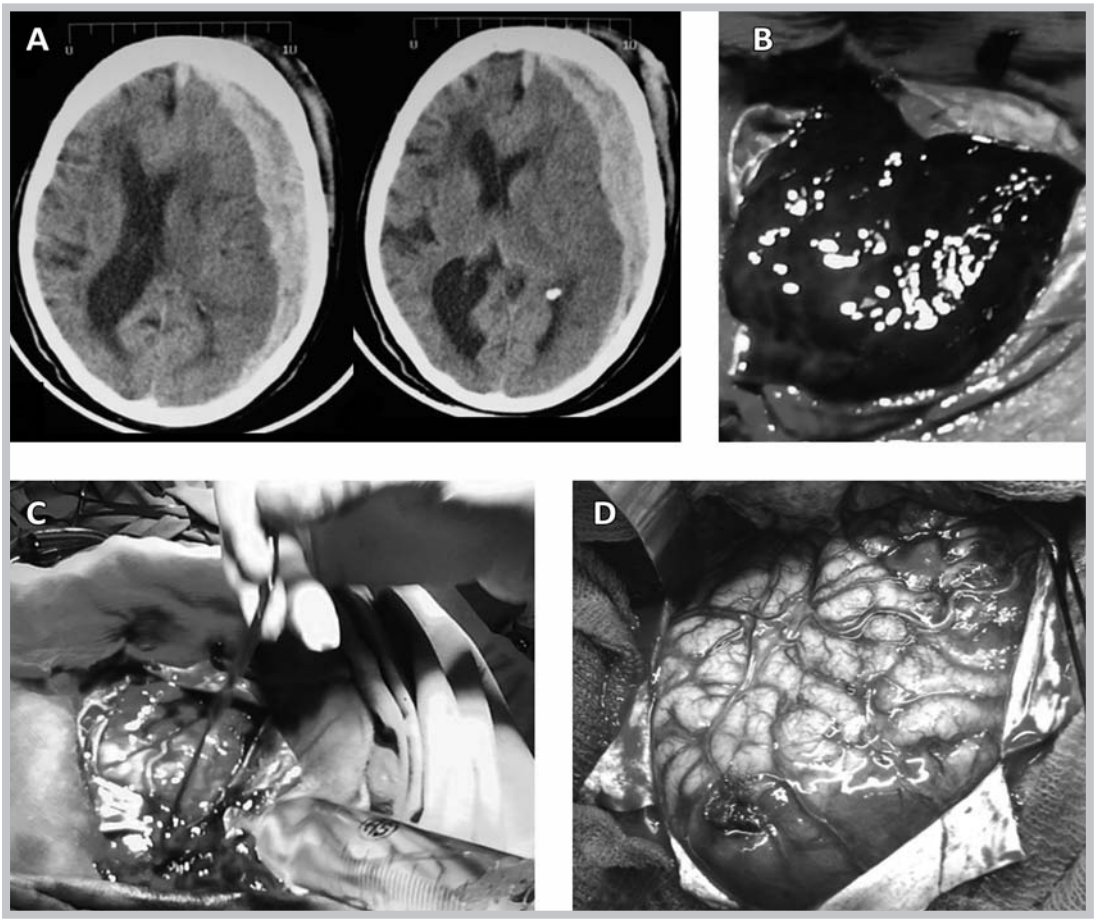

Figure 35.5. CT scan showing an acute hemispheric subdural hematoma with mass effect, midline shift and collapse of the subarachnoid space (A). Intraoperative image showing the large hematoma immediately after dural opening (B). Manoeuvres of washing and aspiration to achieve complete removal of the hematoma (C). Swelling, areas of contusion, and traumatic subarachnoid hemorrhage (TSH) of the brain after lesion evacuation (D).

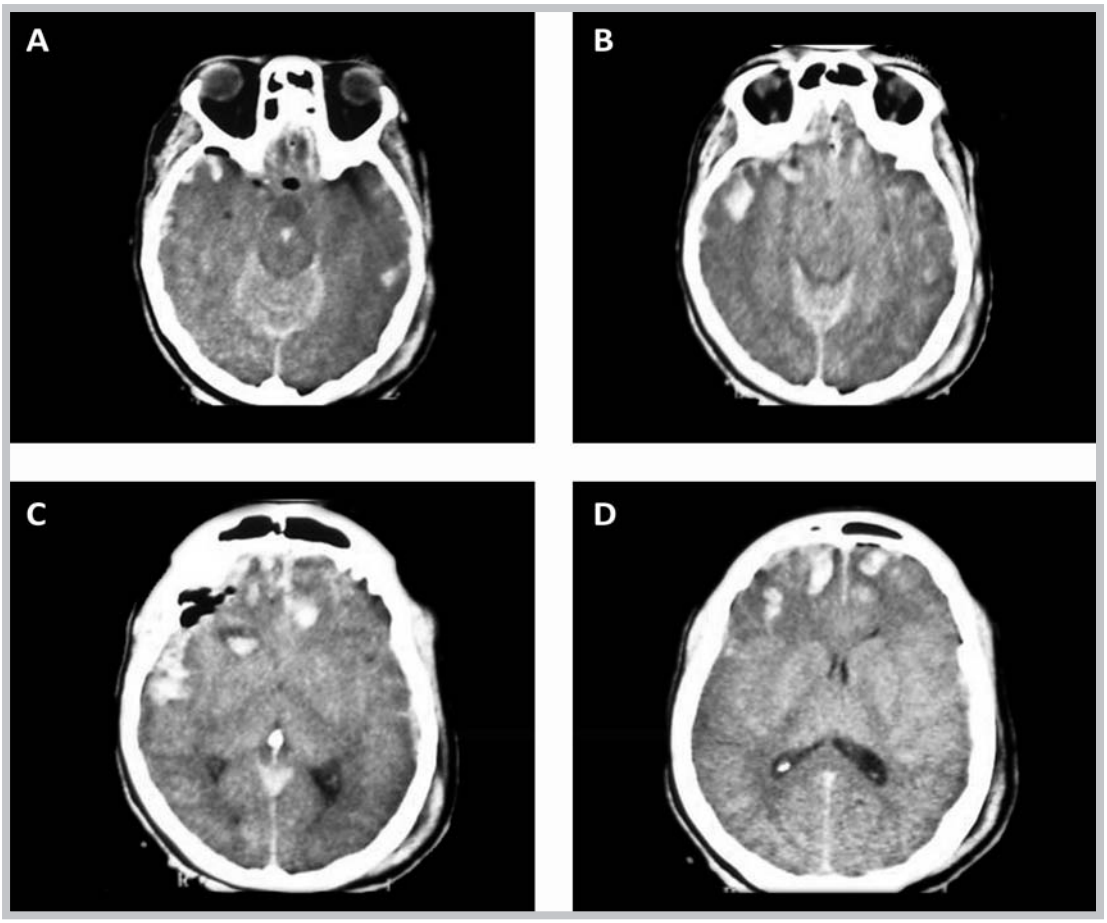

Figure 35.6. Multiple bifrontal contusions and left temporal with TSH.

evacuation once the decision is taken to operate does not offer any advantage, which is why the procedure should be done urgently (Figure 35.5).
Subdural hematoma <3 mm in diameter could be observed; but in patients with a GCS score <8 ICP monitoring is indicated with continuous follow-up by the neurosurgical team.

Indications for surgery	• An acute subdural hematoma (SDH) with a thickness >10 mm *or* a midline shift >5 mm on computed tomographic (CT) scan should be surgically evacuated, regardless of the patient's Glasgow Coma Scale (GCS) score • All patients with acute SDH in coma (GCS score <9) should undergo intracranial pressure (ICP) monitoring • A comatose patient (GCS score <9) with an SDH <10-mm thick and a midline shift <5 mm should undergo surgical evacuation of the lesion if the GCS score decreased between the time of injury and hospital admission by 2 or more points on the GCS and/or the patient presents with asymmetric or fixed and dilated pupils and/or the ICP exceeds 20 mmHg
Timing	• In patients with acute SDH and indications for surgery, surgical evacuation should be performed as soon as possible
Type of surgery	• If surgical evacuation of an acute SDH in a comatose patient (GCS = 9) is indicated, it should be performed using a craniotomy with or without bone flap removal and duraplasty

Table 35.2. Guidelines for the surgical management of subdural hematoma.

Unquestionable indications are those with clear neurological deterioration, presence of mass effect on the CT scan, intracerebral bleeding, compression of basal cisterns or midline shift >5 mm. There are patients in which the midline shift is considerably greater than expected as compared to the hematoma width. This should prompt us to consider the possibility of brain swelling or adjacent brain injury (infarction). Mortality increases the greater the difference between midline shift and hematoma width. Guidelines for the management of acute subdural hematoma are summarized in Table 35.2.

35.3.4 Postoperative Complications

The most common complications are hematoma recurrence, infection and intracerebral hematomas. The recurrence may be subdural or epidural or combined, the last of which is associated with coagulation disorders. Infections develop in <5% of cases. Increased ICP may be present in 50% of cases, which is why ICP monitoring is indicated.

35.3.5 Nonsurgical Management

Surgical evacuation is suggested for treating hematomas >4 mm in width. Smaller collections may resolve spontaneously. It is believe that the slow and progressive spread over the brain surface may help the hematoma to dissolve or to mix with the cerebrospinal fluid. In comatose patients with a midline shift <5 mm and a hematoma width <10 mm, conservative management with ICP monitoring could be appropriate. The factors to be considered when a nonsurgical decision is taken are: GCS score; hematoma width and volume; midline shift; basal cistern collapse; time elapsed since trauma and CT scan; IPC monitoring, pupillary and motor responses; use of opioids, sedatives and muscle relaxants; coagulation disorders and urgent availability of CT and neurosurgical team services.

35.3.6 Prognosis

Mortality related to subdural hematoma is between 42 and 90% according to different series. Younger patients (36-50 years) have better outcomes. The mortality rate in patients lucid at surgery is 6-10% but increases 4-6 fold in comatose patients. The mortality rate is twice as high when pupillary abnormalities are present as when not (75 vs. 35%). Timing is also an important factor for prognosis; Seelig reported 40% mortality for patients in coma operated within the first 4 hours versus 90% mortality for those operated 4 hours after trauma. There is no general consensus on whether hematoma size is a predictor of poor prognosis; however, its association with other intraparenchymal lesions seems to be related to the prognosis. Jamieson and Yelland compared the mortality rate in 3 patient subgroups: subdural hematoma without associated lesions (22%); subdural hematoma with increased ICP and temporal lobe contusions (>50%); and subdural hematoma with contusions (30%). Increased ICP during the pre- and postoperative period predicted poor prognosis.

35.4 Intra-axial Lesions

Intra-axial lesions refer to those located inside the brain. They are caused secondary to a direct blow to the skull area over the brain, thus injuring the small calibre vasculature, and are generally seen over the cortical and subcortical areas. They may evolve and grow in size over time.

35.5 Contusion and Cerebral Hemorrhage

Contusions are areas of brain damage with a variable degree of edema, ischemia, necrosis and bleeding. They may increase in volume with time, and coalesce to form an intracerebral hemorrhage. The edema that may be present from the beginning may also increase and generate mass effect. Intracerebral hemorrhage is a homogeneous collection of blood with well-differentiated margins and considerable diameter. Differentiating it from contusion is not usually easy.

Contusions are more frequent (89% of cases on autopsy) and are more often demonstrated on CT than intracerebral hemorrhage (20-40% vs. 15-20%, respectively). They are usually located on the frontal and temporal lobes. They tend more frequently to be multiple, whereas intracerebral hemorrhage is multiple in only 20% of cases.

Hypodense areas around contusions and intracerebral hemorrhage are related to low cerebral blood flow. Cytotoxic substances are released from these contused areas into the surrounding tissue and blood stream. The formation of free radicals, excitatory amino acids and the altered homeostasis of Ca and K in these areas further generate tissue injury. Some authors have argued that evacuation of these lesions may help to preserve more vulnerable cerebral areas.

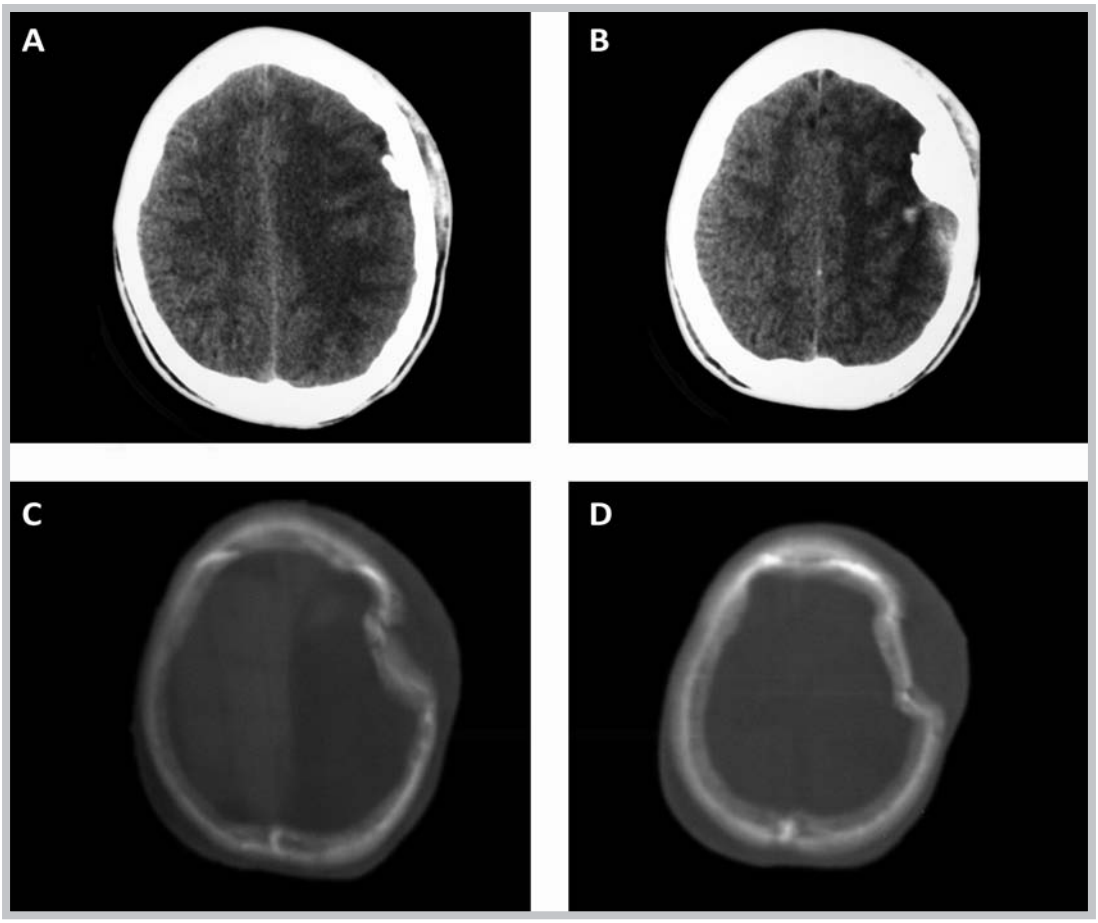

Figure 35.7. CT scan showing a left depressed skull fracture with an area of contusion and bone fragments over the brain (A). CT scan with bone window view showing the depressed skull fracture with a huge cephalo-hematoma (B).

35.5.1 Clinic Manifestations

Although contusions and intracerebral hemorrhage do not have a typical clinical presentation, more than 50% of patients present with a GCS score <8. Lesions located on eloquent areas will cause neurological deficits. Alteration of the level of consciousness may be due to big volumes and consequent ICP elevation or the association of diffuse bilateral lesions compromising the brainstem. The lesion may grow with time. Importantly, the definite volume will not necessarily show on the first CT scan, which is why CT scanning should be repeated every 8-12 hours, especially during first hours after trauma. Another dynamic component is edema which may evolve over the ensuing 7-10 days and cause delayed elevated ICP requiring prolonged ICP monitoring. A CT scan should be obtained 4-6 days after the trauma to determine evolution of the edema. Contusions and intracerebral hemorrhage on the temporal lobe may cause uncal herniation without increasing ICP. Surgical evacuation of lesions in this area with evidence of basal cistern collapse is advised to prevent this complication.

35.5.2 Diagnosis

The diagnosis is based on CT findings which show a pattern of multiple hyperdense spots <1 cm diameter surrounded by a circular hypodense area compatible with peripheral edema. Intracerebral hemorrhage is seen as hyperdense generally homogeneous lesions with a peripheral area of edema or ischemia that is better defined the day after the trauma (Figure 35.7).

35.5.3 Surgical Treatment

Contusions or intracerebral hemorrhage with mass effect and progressive neurological deterioration must be evacuated. Contusions over silent areas should be widely evacuated trying to resect all devitalized tissue, whereas the resection should be more modest in those located in eloquent areas. Small contusions not responsible for neurological

Indications for surgery	• Patients with parenchymal mass lesions and signs of progressive neurological deterioration referable to the lesion, medically refractory intracranial hypertension, or signs of mass effect on computed tomographic (CT) scan should be treated operatively • Patients with Glasgow Coma Scale (GCS) score of 6 to 8 with frontal or temporal contusions >20 cm^3 in volume with midline shift of at least 5 mm and/or cisternal compression on CT scan, and patients with any lesion >50 cm^3 in volume should be treated operatively • Patients with parenchymal mass lesions who do not show evidence for neurological compromise, have controlled intracranial pressure (ICP), and no significant signs of mass effect on CT scan may be managed non-operatively with intensive monitoring and serial imaging
Timing and type of surgery	• Craniotomy with evacuation of mass lesion is recommended for those patients with focal lesions and the surgical indications listed above, under Indications • Bifrontal decompressive craniectomy within 48 hours of injury is a treatment option for patients with diffuse, medically refractory posttraumatic cerebral edema and resultant intracranial hypertension • Decompressive procedures, including subtemporal decompression, temporal lobectomy, and hemispheric decompressive craniectomy, are treatment options for patients with refractory intracranial hypertension and diffuse parenchymal injury with clinical and radiographic evidence for impending transtentorial herniation

Table 35.3. **Guidelines for the surgical management of intraparenchymal lesions.**

deterioration, such as those located on the basal ganglia or white matter, should not be resected. Table 35.3 lists the recommendations for the management of these lesions [3].

35.6 Delayed Intracerebral Hematoma

These are hyperdense intracerebral lesions on the CT scan that were not present on first scan. The causes of these lesions are not clear; they usually occur in patients with coagulation disorders or those with hypoxia or hypotension. One theory relates their origin to the local loss of autoregulation. They may appear any time within the first 24 hours, 50% may appear after the 24 hours and very rarely after 7 days. They must be suspected whenever there is a sudden increase in ICP or neurological deterioration. In any of these circumstances a CT scan must be repeated even if the previous scan was normal.

35.7 Lesions of the Posterior Fossa

Lesions in of the posterior fosse account for 5% of post-traumatic lesions. Epidural hematoma is the most frequent and the etiology is similar to the lesions seen in the supratentorial compartment.

35.7.1 Clinical Manifestations and Diagnosis

One of the most important issues is that these lesions are located in a relatively small compartment near the brainstem and have different kinds of presentation. Diagnosis is based on CT findings and special care must be taken with regard to artifacts caused by the surrounding bone structures. We should look for asymmetries of structures and the fourth ventricle. For a better visualization, a special protocol for posterior fossa should be followed or a study with magnetic resonance imaging (MRI) obtained. The presence of hydrocephalus should prompt suspicion of a lesion of the posterior fossa.

35.7.2 Treatment

Intracerebral hemorrhage and/or contusions measuring 3 cm in diameter that show signs of progression should be evacuated, as should those in a deeper location. All ne-

Indications for surgery	• Patients with mass effect on computed tomographic (CT) scan *or* with neurological dysfunction *or* deterioration referable to the lesion should undergo operative intervention. Mass effect on CT scan is defined as distortion, dislocation, or obliteration of the fourth ventricle; compression or loss of visualization of the basal cisterns, or the presence of obstructive hydrocephalus • Patients with lesions and no significant mass effect on CT scan and without signs of neurological dysfunction may be managed by close observation and serial imaging
Timing	• In patients with indications for surgical intervention, evacuation should be performed as soon as possible because these patients can deteriorate rapidly, thus, worsening their prognosis
Timing and type of surgery	• Suboccipital craniectomy is the predominant method reported for evacuation of posterior fossa mass lesions, and is therefore recommended

Table 35.4. **Guidelines for the surgical management of posterior fossa mass lesions.**

crotic and contused tissue must be resected because it may generate edema or recurrence of blood accumulation and neurological deterioration. Hydrocephalus is resolved with a ventriculostomy and the CSF should be evacuated gradually in order to avoid ascending herniation of the posterior fossa contents. Since epidural hematoma in this area tends to expand and cross the midline and tentorium, all efforts must be made to identify and control the source of bleeding. Subdural hematoma should be evacuated, and contused tissue, if present, also resected to achieve adequate hemostasis. ICP monitoring has a limited value; pressure on the infratentorial space is poorly transmitted to the supratentorial space, and normal ICP does not ensure that the posterior fossa structures are out of danger [4]. Treatment guidelines are presented in Table 35.4.

35.8 Depressed Skull Fracture

Depressed skull fracture occurs when an object with a high level of kinetic energy hits against the skull and the energy is absorbed by the bone, causing deformation of the bone structure over the area of impact. Two groups of depressed skull fracture are distinguished: closed or simple when there is no continuity with superficial tissues (no skin laceration); and open or compound when there is laceration of the scalp adjacent to the fracture.

35.8.1 Diagnosis

X-ray in anteroposterior and lateral views may show the fracture; the Towne position may help to reveal fractures in the posterior fossa. CT scan with bone window view is the study of choice to detect even small depressed fractures and will help to evaluate the presence of associated lesions (Figure 35.7). Some linear anteroposterior fractures may be missed as they can be located in between CT slices in the axial plane. Coronal slices may help in such cases.

35.8.2 Treatment

Closed, linear cranial fractures are considered non-operative lesions unless associated with surgical intracranial masses. Compound depressed cranial fractures are depressed fractures with an overlying scalp laceration in continuity with the fracture site and galeal disruption, and have conventionally been treated with debridement and surgical elevation. Simple depressed cranial fractures that have no galeal disruption are traditionally managed with surgical elevation only if the extent of depression equals or exceeds the thickness of adjacent intact bone, or if there is an associated intracranial hematoma with mass effect that requires evacuation. The rationale for aggressive treatment of depressed skull fractures (DSF) stems from their association with infection and late epilepsy. Cosmetic deformity also plays a role in surgical decision making.

Compound depressed fractures are neurosurgical emergencies, and they should be solved in the first 24 hours, preferably the first 12 hours. The objectives of surgery are to remove foreign bodies and devitalized tissue, and to repair of tissue layers (dural, subcutaneous tissue, skin); bone fragments may be replaced if they are adequately disinfected and debrided. If surgery is done in the first 24 hours, without signs of infection and the dural can be closed in a watertight fashion, bone repositioning can be done safely and the risk of infection is the same as when we remove the bone fragments [5].

Indications for surgery	• Patients with open (compound) cranial fractures depressed greater than the thickness of the cranium should undergo operative intervention to prevent infection • Patients with open (compound) depressed cranial fractures may be treated non-operatively if there is no clinical or radiographic evidence of dural penetration, significant intracranial hematoma, depression >1 cm, frontal sinus involvement, gross cosmetic deformity, wound infection, pneumocephalus, or gross wound contamination • Non-operative management of closed (simple) depressed cranial fractures is a treatment option
Timing	• Early operation is recommended to reduce the incidence of infection
Timing and type of surgery	• Elevation and debridement are recommended as the surgical method of choice • Primary bone fragment replacement is a surgical option in the absence of wound infection at the time of surgery • All management strategies for open (compound) depressed fractures should include antibiotics

Table 35.5. **Guidelines for the surgical management of depressed cranial fracture.**

If the depressed fracture is located over the dural sinuses, bone removal is not recommended because of the risk of severe bleeding.
There is also some concern about delayed epilepsy related to DSF (incidence, 7.1-9.5%) and the duration of post-traumatic amnesia (<24 hours 5.4%, >24 hours 22%). Also, the presence of motor deficit, dural laceration and history of epilepsy may predispose to post-traumatic epilepsy. The incidence increases when these factors are combined. Table 35.5 summarizes the guidelines for the management of DSF.

35.9 Surgical Treatment of Increased ICP: Decompressive Craniectomy

In 1901 Kocher was the first surgeon to use decompressive craniectomy (DC) for the treatment of post-traumatic edema. In the ensuing controversy on the outcome after DC in these patients, the procedure was abandoned. We now know that elevated ICP in a setting of STBI is one of the most important independent predictors for mortality and morbidity. For patients who do not respond to first-line treatment for increased ICP, there are some second-line options proposed by the European Brain Injury Consortium (EBIC) [6] and the American Association of Neurological Surgeons (AANS) [7] that include barbiturate coma, controlled hyperventilation, hypothermia and DC. Although DC is currently a second-line treatment, some questions about the procedure remain unanswered: if DC changes the outcome of these patients, which group of patients are better candidates, which timing and the surgical technique are correct; issues that we will try to discuss below.

35.9.1 Indications

Presently, there is a lack of class I publications that support the routine use of DC for STBI. There is only one study in pediatric populations that favours the use of DC [8]. There is also a recent publication, the DECRA [9], that did not support the routine use of this procedure, but the study was later strongly criticized [10]. Rescue ICP (a randomized multicentre trial) is still ongoing and the results may perhaps answer questions about the usefulness of DC. Most publications are retrospective studies and only a few are pro-

spective non randomized in design. Most are class II; taken together the evidence shows that about 70% of patients who required DC will survive with a 51% of good outcome. These data are encouraging though they lack statistic evidence. Also, mortality is 30%, but prognosis is better if we compare with the data from the Traumatic Coma Data Bank (TCDB) in which patients had received only medical treatment.

The bulk of recent studies favour the use of DC [8,11-15]. There is no consensus about the timing of DC. One of the most important studies suggests that DC should be indicated in patients with brainstem signs secondary to increased ICP, CT findings compatible with diffuse encephalic lesion type III or increased ICP associated with neurological deterioration or the failure of medical treatment to keep ICP normal [12]. This large-scale study involved the largest population of patients to date but had some flaws related to the delay in the indications of DC and the inclusion of patients from the pre-CT scan era. A more recent publication suggests that DC is indicated when medical treatment fails to maintain normal ICP, with DC as an option of last resort. A very recent publication refers to DC as a preventive procedure even before adequate medical treatment is used; if the CT scan shows signs of poor prognosis or intraoperative findings (multiple con-

GCS score ≤8	
Marshall III-IV or non-evacuated lesion	
Adequate cerebral perfusion pressure (CPP)	• CPP ≥60 mmHg in adults • CPP ≥50 mmHg in infants
ICP >25 mmHg ≥5 minutes post-reanimation with medical treatment and within 48 hours of STBI	

Elevated ICP with no response to first level medical treatment	• Head and neck in neutral position
	• Head elevation 30°
	• Adequate sedation
	• Adequate analgesia
	• Muscular blockers if needed
	• Normothermia
	• Adequate oxygenation and ventilation
	  ▪ $SaPO_2$ ≥90%
	  ▪ PaO_2 ≥60 mmHg
	  ▪ $PaCO_2$ = 35-40 mmHg (normocapnia)
	• Na^+ ≥140mEq/l
	• Glucose = 80-150 mg%
	• Seizures or status epilepticus ruled out
	• Normal hemostasis
	• Hemoglobin ≥10g/l or hematocrit ≥30%

Increasing TIL (Therapeutic Index Level) in a few hours in order to obtain the same ICP	
Use of second and third level measures without achieving an ICP <20 mmHg	
Contraindication for the use of second and third level measures	• BAD IV: hemodynamic instability • Moderate/high hyperventilation: signs of ischemia as measured by PTO_2 or SjO_2/$DAVO_2$/EO_2 • Hypoperfusion pattern on Doppler ultrasonography
CT scan before DC	• To rule out the presence of new lesions not seen on previous images
Limited resources situation	• Unavailability of basic neurological monitoring

Table 35.6. **Indications for decompressive craniectomy.**

- Severe life-threatening extraneurological lesions
- Primary brainstem lesions
- Glasgow score 3/15 post-reanimation
- Age >60 years
- Bilateral unreactive mydriasis
- Massive cerebral infarction of dominant hemisphere
- Non-neurological causes of increased ICP (hyponatremia, hypovolemia, fever, hypercapnia, inadequate adaptation to ventilator, etc.)

Table 35.7. **Patients ineligible for decompressive craniectomy.**

tusions, generalized brain swelling), this suggests that the patient will have an increase in ICP [13,14,16,17]. It is well recognized that in young patients with slow progressive neurological deterioration early DC and adequate technique (extensive bone removal and dural plastic) may produce a good outcome.

The most commonly accepted criteria for the indication of DC are summarized in Table 35.6. They are based on initial CT scan and ICP management. The presence of borderline ICP increases with alpha or beta waves may help to decide whether to perform DC. Transcranial Doppler may also be useful in the decision-making process. Patients with worsening of the flow pattern and the presence of systolic peak have the worst outcome. This, together another factors, may help, especially if the indication for DC is unclear [9]. Also, it is very clear for some authors that patients with a GCS score <3, fixed dilated pupils, and signs of irreversible brainstem injury are not candidate for DC (Table 35.7).

35.9.2 Surgical Technique

There are two basic types of DC: hemicraniectomy and bicoronal. The election of the type of craniectomy will depend on the following criteria: CT findings; midline deviation; presence of multiple bilateral or unilateral contusions; and presence of symmetric collapse of basal cisterns (Table 35.8).

In hemicraniectomy (Figure 35.7) the incision is similar to that for trauma flaps, (big question mark) including the frontal, parietal and temporal bone, starting from the midline and finishing in front of the tragus. It is not necessary to expose the superior longitudinal sinus because of the risk of unnecessary bleeding and the space gain is not significant. Of great value is resection of all the temporal bone for adequate temporal lobe decompression as is the anterior two thirds of the parietal bone (Figure 35.8). As blood loss during craniectomy may be important, hemostasis is of great importance to avoid hypotension and secondary damage during the procedure. The dura is opened widely (Figure 35.8). If a contusion generates mass effect, it should be resected. A duroplasty is always recommended; autologous (galeal flap, temporal aponeurosis, facia lata aponeurosis) or heterologous (dural substitutes bovine, fibrillar, etc.) may be used in order to give adequate dural expansion. It is not necessary to close the dura in a watertight fashion. We pay particular attention to the galeal and skin closure to minimize the risk of CSF fistula.

In bicoronal craniectomy (Figure 35.9) as described by Polin et al. [18], the incision extends from ear to ear, trying to extend it as posterior as possible. We prefer to create two

Condition	Hemicraniectomy	Bicoronal
Midline shift	Yes	No
Unilateral multiple contusions	yes	No
Bilateral diffuse cerebral edema	No	Yes
Multiple bilateral contusions	No	yes

Table 35.8. **Guidelines to define type of decompressive craniectomy.**

The drawing shows the planned craniectomy for hemicraniectomy, bone of the fossa media to be removed (in grey) (A). Skin incision for DC (B). Intraoperative image showing swelling and multiple contusions over the brain (C). CT scan with 3D reconstruction of the area where the bone was removed (D).**

isolated bone flaps with an anterior-posterior bridge of bone over the midline 2-3 cm in width. As in hemicraniectomy, it is important to resect the temporal bone as basal as possible. Anteriorly, the frontal bone should be resected up to the supraorbital eminence while trying to avoid the frontal sinus because of the risk of CSF fistula through the sinus. The bone bridge over the superior sagittal sinus averts unnecessary blood loss and helps for a more easy craneoplasty surgery posteriorly. Some authors propose resection of this bone bridge and cutting of the falx at the base of insertion, but we believe this is unnecessary. With adequate bilateral exposure of the middle fossa, it is very important to avoid compression of the brainstem by the mesial aspect of the temporal lobe.

Intraoperative brain swelling it not commonly seen if the craniectomy is wide enough and timing is correct. The swelling may be also related to hyperperfusion phenomena, leading to intracerebral hematoma or cerebral infarction, especially if the surgery is delayed; therefore, we recommend performing the procedure as soon as possible.

The basic objective of DC is to resect an extensive portion of bone, especially in the temporal bone area, and to achieve a duroplasty without tension. The criteria for defining whether a bicoronal or hemicraniectomy should be performed (Table 35.8) depend on CT findings (midline shift, contusions, basal cisterns).

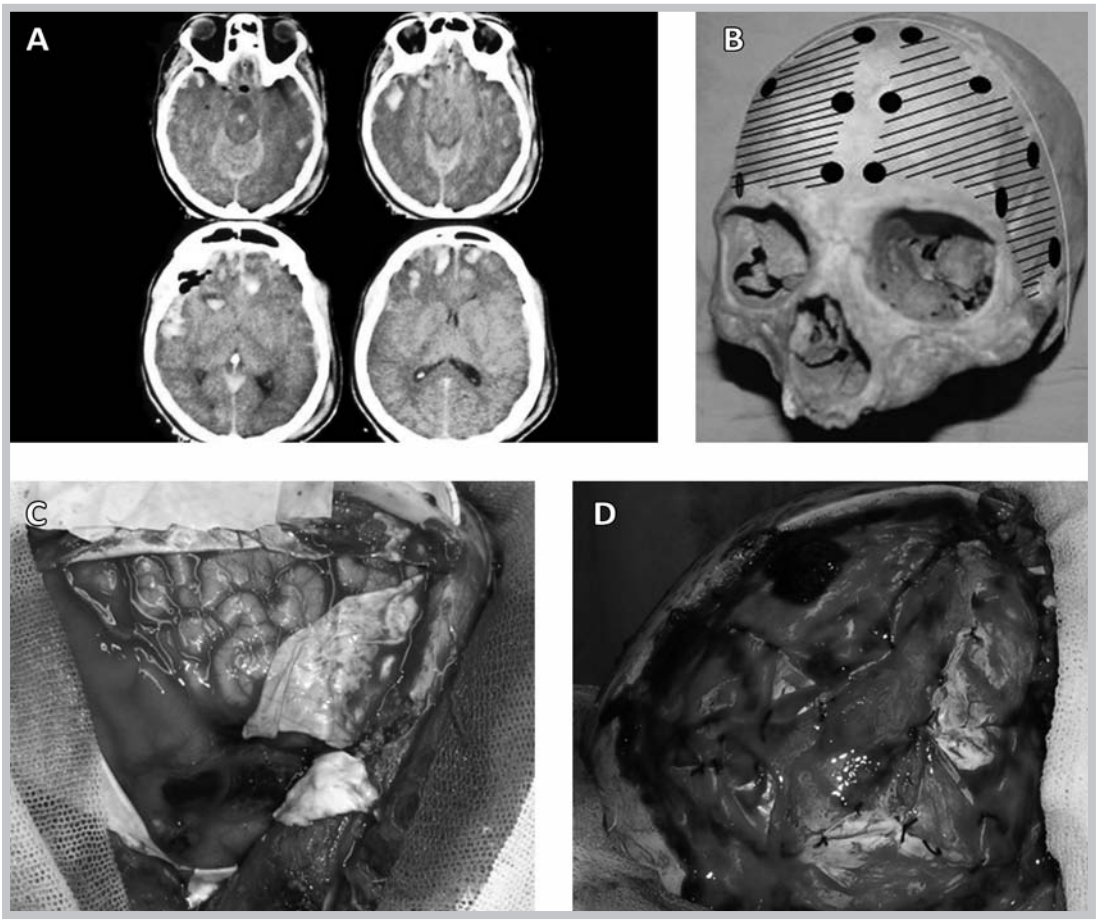

Figure 35.9. **CT scan of a patient with diffuse brain injury type III with multiple contusions; a bicoronal DC was performed (A). Surgical planning of the bicoronal DC; bone to be removed is marked with oblique lines (B). Intraoperative image showing the right hemisphere with frontal and temporal contusions, TSH and swelling (C). Photo showing a duroplasty with galea (D).**

The benefits of DC are improvement in cerebral perfusion as seen on SPECT (may be considered as hyperperfusion that could last up to 1 month with a peak during the first week), with right shift of the pressure-volume curve of ICP. Hyperperfusion phenomena could be deleterious if the DC is indicated too late. A reduction in ICP can be achieved (15-70%) with DC, but this is not always associated with a good outcome [12,17]. DC also improves cerebral oxygenation.

35.9.3 Complications

While DC can reduce ICP, certain physiological phenomena could give rise to possible complications, including altered CSF circulation, increased cerebral blood flow and cerebral metabolism (causing a hyperemic response), and loss of autoregulation mostly in the first 24 hours which generally resolves within 72 hours. Patients older than 60 years of age, with a history of anticoagulant therapy or a very low GCS score on admission are more prone to complications.

Immediate complications are an increase in the size of contusions or subdural hematomas, usually on the same side, and carry a poor prognosis if >20 cm^3 compared to the

initial lesions [19]. Another complication is cerebral herniation through the craniectomy (26% of cases), which may be caused by hyperemia during the first days and associated with the loss of autoregulation. If the craniectomy is small, we may see something known as cerebral fungus, which is extensive herniation of the brain with vascular cerebral alterations of the brain through the borders of the craniectomy which worsen the situation. Also, infections and CSF fistula may be seen in this period due to accidental opening of the frontal sinus, inadequate asepsis, or insufficient closure of the galeal and skin plane.

Other complications in the first 30 days include subdural hygromas caused by alterations in CSF dynamics that may lead to hydrocephalus (20-50% of cases), and may resolve spontaneously in several weeks or 2 months [20,21]. Paradoxal herniation is a sign of neurological deterioration with brainstem manifestations after a lumbar puncture in a decompressed patient and may occur days after the puncture; the mechanism is believed to be related to an increase in the negative pressure over the brain with the open skull. It is called paradoxical because the treatment is opposite to the management of a classic herniation; the patient should be positioned in the Trendelenburg position and hyperosmolar solution should be stopped. Closure of ventricular or spinal drainage or even cranioplasty are all alternatives for the management of this condition.

Hydrocephalus may appear after 1 month and is related to perturbations in CSF dynamics. Some authors advise resolving the cranial defect before beginning with surgical management of the hydrocephalus. Another complication seen in this period is the syndrome of the trephined characterised by headache, dizziness, irritability, memory disturbances and mood changes. Sometimes it can be associated with contralateral motor deficit. Theories to explain this condition include changes in atmospheric pressure [22], CSF dynamics [23,24], and disturbances in cerebral blood flow [25,26]; all of these symptoms resolve with cranioplasty. And if the bone flap was preserved on the subcutaneous plane of the abdomen with the idea of posterior reposition, 50% of partial reabsorption of the bone may occur if bone reposition is delayed.

DC may be considered a simple surgery if these details are kept in mind. Since the cases are usually emergency surgery, the surgeon should be fast while ensuring unnecessary blood loss and conditions of adequate asepsis.

35.9.4 Outcome

DC seems to offer a better outcome in patients with STBI with elevated ICP refractory to medical treatment [8,12,14,27]. There remain some questions about the procedure's real benefit in such patients, the timing, and if it is better than another second-line medical treatments. Comparative studies are needed to shed light on these issues.

36.1 Introduction

Traumatic brain injury (TBI) is a major problem worldwide. It accounts for at least half of all trauma-related fatalities and incurs significant health care costs for treatment, rehabilitation and convalescent care of surviving patients. In the United States alone, costs are estimated at 60 billion dollars annually in both direct medical and indirect costs such as loss of productivity [1]. Modern trauma response teams, neurosurgical centres, and intensive care treatments have reduced mortality rates in severe head injury patients to 20-30%, according to a recent series [2]. Pre-hospital care, rapid radiographic diagnosis, early surgical intervention, and ultra-modern monitoring modalities are largely responsible for these reductions. Contemporary clinical series identifying deleterious markers, such as hypoxia, hypotension and hyperpyrexia have also contributed greatly. Despite these efficacious clinical advances, there is much room for improvement in all areas of TBI [3,4].

36.2 Clinical and Cellular Pathophysiology of Severe Traumatic Brain Injury

The cellular pathways and patho-mechanisms involved in TBI are extensive and complex. The detailed biochemistry, genetic regulations, and molecular occurrences are reviewed elsewhere and are beyond the scope of this chapter. We will provide an overview of the basic cellular and clinical pathophysiology, with a focus on the most relevant aspects for neuro-monitoring.

36.2.1 Cellular Pathophysiology in Traumatic Brain Injury

The cellular processes that continue to cause neuronal damage after TBI are traditionally classified as secondary brain injury. Primary brain injury results from the immediate mechanical disruption of brain tissue caused by the direct trauma itself. These secondary cellular events are thought to occur hours to days after the initial trauma, and they may continue for weeks or months [6]. It is these secondary mechanisms that dictate management and intervention by the treating physician, and they are closely related to pa-

tient outcome. Disruptions in calcium homeostasis ensuing from TBI have been shown to cause numerous cellular events [7].

The influx of intracellular calcium may occur through a number of mechanisms: membrane-associated channels or receptors (including excitatory amino acid receptors); and membrane disruption or trauma-induced depolarization altering the Na^+-K^+ exchange system. In both experimental and clinical TBI, a release of or an increase in excitatory amino acid concentrations, particularly glutamate and aspartate, occurs minutes after the initial injury and often lasts several weeks [8,9]. These excitatory amino acids may bind specific receptors in the brain, notably N-methyl-D-aspartate (NMDA) and AMPA/kainate receptors, which gate monovalent and divalent cations such as sodium and calcium. Once inside the cell, calcium is involved in various different processes, including phospholipase activation which leads to membrane disruption, production of free radicals which leads to DNA damage, up- or downregulation of the genes that control cell survival or apoptosis, and mitochondrial disruption, ultimately resulting in cellular demise.

Calcium influx activates phospholipases, specifically phospholipase A2 and phospholipase C, resulting in cell membrane disruption and the generation of free fatty acids. These free fatty acids, along with intracellular free radical species (e.g., nitric oxide, superoxide, and hydrogen peroxide), represent reactive species that can damage DNA and cell membranes and may affect cerebral blood flow, blood-brain barrier permeability, and cerebral edema [10].

Intact mitochondrial function is central to cellular energy metabolism and homeostasis of glutamate and glycerol, which are released when free fatty acids are liberated from triglycerides as part of membrane breakdown. They can now be measured in the living human brain: glutamate values after severe head injury are up to 100 times higher than normal and glycerol levels are 30-40 times normal values. Elevated intracytoplasmic and, consequently, intramitochondrial calcium, interrupt oxidative phosphorylation and the electron transport chain. Cell death due to disruption of the oxidative process, mitochondrial swelling, and failure of Na^+-K^+ ATPase are directly related events.

Genetic alterations, including upregulation of the so-called immediate early genes c-fos and c-jun, have been shown to occur in both experimental and clinical models [11,12]. These factors alter the expression of both pro-apoptotic and anti-apoptotic genes, but their significance is not fully understood. Apoptosis, or programmed cell death, is also likely under genetic regulatory control. The balance between anti-apoptotic factors, such as Bcl-2 and Bcl-xl and pro-apoptotic factors such as Bax and Bak, ultimately determine the fate of the cell [13-16]. If this ratio is tipped towards apoptosis, the family of cystein proteases (caspases) are called into action. Caspases 8 and 9, the so-called initiator caspases, directly influence caspase 3, the final executioner. Activated caspase 3 seeks out and targets multiple intracellular components, including cytoskeletal proteins, nucleic acid repair proteins, and DNA-ases [16].

Numerous cytokines, growth factors and inflammatory mediators have been implicated in TBI [17]. Disruption of the blood-brain barrier permits neutrophils, macrophages, and other inflammatory cells access to the central nervous system (CNS). These cells, along with various mediators (e.g., IL-1, IL-6, ICAM-1, TNF-α, nerve growth factor, FGF, among others) all play a potential role in cell demise or restoration. When the blood-brain barrier is disrupted, adhesion molecules recruit incoming leukocytes, resulting in the local release of reactive oxygen species (ROS), causing cellular damage and death, as well as the release of further pro-inflammatory cytokines and mediators.

Many of these mediators can now be measured in the injured human brain by means of microdialysis and the newly available 100 kDa MW cut-off membranes. Antagonizing or altering these separate but interrelated processes has been the focus of innovative TBI treatment. Calcium antagonists, NMDA receptor blockers, free-radical scavengers, gene

regulators, anti-inflammatories, anti-apoptotics, and temperature regulation, to name a few, are possible points of therapeutic intervention.

36.3 Clinical Pathophysiology

Five clinical variables have consistently been shown to correlate with poor patient outcome following TBI: hypoxemia; hypotension; reduced cerebral perfusion pressure; elevated temperature, and raised intracranial pressure [18,19]. These clinical occurrences are often termed secondary insults, as they aggravate initial and secondary injuries. Only age and initial Glasgow Coma Scale (GCS) score are more potent predictors of outcome. These clinical and cellular events ultimately lead to cerebral ischemia and neuronal cell death. It is through the identification, recognition, prevention and treatment of these secondary insults that we can prevent secondary brain injury and ultimately improve patient outcomes [3].

Treatment paradigms such as optimizing cerebral oxygenation and perfusion, maintaining normal intracranial pressure, and aggressive medical and surgical interventions constitute the standard of care today. Continued medical support of all other body systems should always continue simultaneously.

In order to understand the pathophysiology of severe brain trauma, a brief review of normal cerebral physiology is necessary. The human brain uses glucose almost exclusively as its energy source to produce adenosine triphosphate (ATP). The pathway through which glucose is utilized depends on the availability of oxygen, oxidative phosphorylation in most instances, and anaerobic glycolysis when oxygen is unavailable. Oxidative phosphorylation is much more efficient, producing a total of 38 molecules of ATP per molecule of glucose, as opposed to a mere two molecules of ATP and two molecules of lactate with anaerobic glycolysis. Two parameters are used when discussing cerebral metabolism: the cerebral metabolic rate of oxygen consumption ($CMRO_2$) and cerebral metabolic rate of glucose consumption (CMRG). Globally, normal resting values are 3.3 mg/100 g/min and 5.5 mg/100 g/min, respectively, with grey matter values being typically higher than white matter values [20,21].

Despite its relatively small percentage of total body weight (3%), the human brain utilizes an astounding 20% of cardiac output to maintain its high metabolic demand. Although neurons constitute about 50% of the cellular make-up of the human brain, they account for 90% of energy expenditure [22]. Glial cells, on the other hand, consume only 10%. Most of this energy expenditure goes into neuronal communication and synaptic transmission: 25% for biosynthesis and cellular transport, and 25% for maintenance of membrane ionic gradients [22]. Because the human cerebrum lacks the capacity to store glycogen, the brain relies on a constant flow of blood to carry oxygen and glucose to its cells. Maintenance of a constant blood flow under varying physiological states is termed autoregulation. Multi-modality clinical monitoring now allows continuous measurement of brain tissue oxygen tension ($PtiO_2$: Licox system) and the lactate/pyruvate ratio, a direct indication of oxidative phosphorylation (low L/P ratio <20), and of anaerobic glycolysis (L/P ratio >20). Clinical treatments can be directed at optimizing these parameters (see below).

36.4 Autoregulation

Cerebral autoregulation is the ability of the cerebral vasculature to compensate by constriction and dilation so as to maintain cerebral blood flow (CBF) constant over a

wide range of mean arterial pressures. Several mechanisms and theories have been advanced, most notably pressure autoregulation and metabolic autoregulation models. Pressure autoregulation is described by Poiseuille's equation:

$$Flow(Q) = k(\Delta P \times r^4)/(8 \times l \times v)$$

wherein blood flow is proportional to the pressure difference and vessel size, and inversely proportional to vessel length and blood viscosity. Changes in perfusion pressure will therefore result in changes in blood flow unless vessel size is altered: when blood pressure and perfusion pressure, in turn, decrease, the cerebral vasculature must dilate to maintain a constant flow. Similarly, when blood pressure and/or perfusion pressure increase, the vessels must constrict to maintain blood flow constant (Figure 36.1).
This phenomenon is generally seen under normal physiologic conditions across a blood pressure range of 50-150 mmHg; however, longstanding hypertension causes a "right shift" of the autoregulatory curve. Failure of pressure autoregulation typically occurs outside this blood pressure range, and there is strong evidence that it may become dysfunctional after TBI [23,24].
Metabolic autoregulation is represented by the Fick equation:

$$CMRO_2 = CBF \times AVO_2D$$

Because the cerebral metabolic rate, cerebral blood flow, and arteriovenous oxygen difference are all interconnected, the brain is able to precisely match local cerebral blood flow to local metabolic needs. The exact cellular mechanisms behind pressure and metabolic autoregulation are not completely understood, but there is evidence that the vascular endothelium has an integral role. Studies have shown that an intact vascular endothelium is essential for maintaining cerebrovascular hemostasis, largely through local metabolites and vasoactive substances such as H^+, CO_2, adenosine, K^+, calcium, nitric oxide, endothelin and thromboxane [25]. All these substances have all been proposed as possible mediators of cerebrovascular reactivity.
Cerebral blood flow may be accurately measured in the intensive care unit (ICU) using xenon gas, the ^{133}Xe method, in xenon-enhanced computed tomography (CT). Howev-

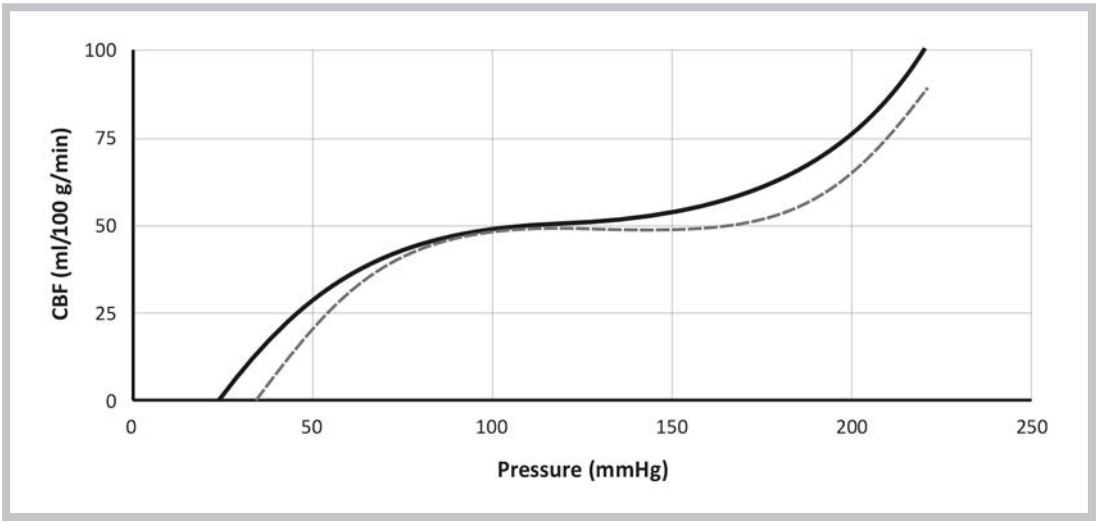

Figure 36.1. The cerebral blood flow (CBF)-pressure curve.

er, radiation exposure and costs limit the frequency of its use to 2-3 scans per patient. With the recent introduction of the Hemedex continuous CBF monitor based on a thermal diffusion method, both blood supply and metabolism can be measured in the ICU.

36.5 Secondary Brain Injury

Focal and global alterations in cerebral metabolism, cerebral blood flow, autoregulation, and intracranial pressure contribute to the development of secondary brain injury. The cerebral metabolic rate in head-injured patients is typically reduced, ATP generation is lower, and anaerobic glycolysis is critical under circumstances of severely reduced CBF or mitochondrial damage [26]. This results in increased lactate concentration and acidosis. Disturbances in autoregulation, or "dysautoregulation," a mismatch of cerebral blood flow and metabolism, and impaired CO_2 reactivity may occur together and have a harmful effect on the injured brain. These events, coupled with systemic perturbations, such as hypoxia and hypotension due to lung injury, airway obstruction or shock, can combine to wreak havoc on potentially salvageable neurons. Ischemic brain damage is very common after severe head injury, being demonstrated in up to 80% of autopsy subjects [27].

The brain's initial response to ischemia or declining blood flow is to extract escalating amounts of oxygen from the circulation. But when extraction reaches a maximum, further reductions in blood flow result in energy failure, mitochondrial and cell membrane disruption, cell swelling and cell death [28,29]. The ultimate determination of cell survivability versus cell death depends on a complex relationship between actual blood flow, duration and degree of ischemia, specific cell type, glucose concentration and temperature, among other factors. There seems to be a relatively constant value of blood flow associated with salvageable ischemic neurons and irreversible cell death: 18 cc/100 g/min and 8 cc/100 g/min, respectively [29].

Measuring cerebral perfusion pressure (CPP) is an indirect way to assess CBF in real time. Cerebral blood flow is related to intracranial pressure (ICP) and mean arterial pressure (MAP) by the equation:

$$CPP = MAP – ICP$$

Increased ICP is a common event contributing to secondary brain injury in severely injured patients, and it is often the main clinical concern that determines treatment.

36.6 Intracranial Pressure

The Monro-Kellie hypothesis states that the cranium is a rigid non-expandable box and that its contents consist of mainly three volumes: the brain (80%); cerebrospinal fluid (CSF) (10%); and blood (10%). In order for the pressure inside this rigid box to remain constant, the volumes of the contents must remain fairly stable. Any increase in volume of the original contents (hyperemia/edema) or owing to a mass-occupying lesion (hematoma) must be offset by a decrease in volume of one of the other components, otherwise the ICP will rise. The compensatory mechanism begins with the diversion of CSF and intracranial blood. Over 80% of severely head-injured patients have persistently elevated ICP [30]. In the healthy adult the ICP is 5-15 mmHg, and it is usually 0-10 mmHg

in children. Persistently elevated ICP has been associated with poor outcomes, and mortality is directly related to the degree and duration of elevated ICP [31,32].
As ICP rises and compensatory mechanisms reach their limit, CPP generally decreases, setting the stage for decreased blood flow, ischemia, and neuronal cell death. Much of the clinical care in the neuro-ICU is directed at preventing and managing increases in ICP by maintaining adequate perfusion pressures and aggressively avoiding ischemic situations brought about by hypoxia or hypotension. Other modalities include evacuation of intracranial mass lesions and limiting cerebral edema. Specifics on monitoring and treatment strategies for raised ICP will be discussed later in this chapter.

36.7 Intracranial Hypertension, Monitoring Modalities, and Treatment Strategies

36.7.1 Intracranial Hypertension

Elevated ICP is the leading cause of death in head-injury fatalities, and it is a major contributing factor to the secondary insult mechanism of brain injury. The capacity to accommodate up to 50 cc of new intracranial volume without a significant rise in ICP occurs by the displacement of venous blood into the general circulation and of CSF out of the cranial vault into the spinal subarachnoid space; however, these mechanisms are both age- and time-dependant. Since elderly people tend to have more cerebral atrophy, they may accommodate a larger amount of a slowly expanding volume. Younger individuals with an acute process, on the other hand, are much more likely to become rapidly symptomatic. All surgical lesions should be aggressively evacuated according to Brain Trauma Foundation surgical guidelines. Mass lesions will be discussed in the subsequent section.
Abnormal cerebral autoregulation, new hemorrhage, and cerebral edema are the major causes of delayed intracranial hypertension. Clinical trials have shown that head-injured patients with an ICP >20 mmHg, particularly when sustained or intractable to treatment, have a worse clinical outcome and are at high risk for the herniation syndrome [29-33]. There is also recent evidence that CPP <60-70 mmHg is associated with worsened parenchymal oxygenation, metabolism, and outcome [34]. Therefore, the goals of monitoring and treatment are to maintain adequate CPP, oxygenation, and metabolism, while limiting elevation in ICP, edema, and substrate perturbations.

Monitoring Techniques

Monitoring techniques in the head-injured patient can be loosely classified under three categories: pressure monitoring; blood-flow monitoring (Figure 36.2); and substrate monitoring (Figure 36.3). The choice between monitoring systems is becoming increasingly complex, and the capability to monitor multiple parameters such as oxygenation and substrate concentrations, as well as ICP is becoming increasingly common. As mentioned previ-

Figure 36.2. Cerebral blood flow monitoring device.

ously, brain ischemia, hypoxia, and cellular malfunction are common following TBI, and the reduction in blood flow and substrate delivery can occur within minutes, stressing the importance of early resuscitation and management of the intracranial environment.

Figure 36.3. Substrate monitoring.

Pressure Monitoring: Types and Indications

Lundberg introduced ventricular drainage as a management strategy for treating intracranial hypertension in the 1960s. However, the concept of ICP monitoring did not gain momentum until the mid-1980s with evidence-based literature describing the subarachnoid bolt. ICP monitoring technology has grown since its inception and current ICP monitoring options include subdural, epidural, parenchymal and intraventricular monitors. Today, most monitoring is limited to parenchymal and intraventricular monitoring because subdural and epidural monitors are inaccurate. Ventriculostomy is the gold standard for the evaluation of raised ICP. An intraventricular monitor allows for reliable diagnosis and the potential for therapeutic intervention through drainage of CSF for raised ICP. Intraventricular monitoring is a low-cost, highly accurate method; however, it carries a slightly higher post-insertion malfunction rate than parenchymal monitoring. Parenchymal monitors such as the fibre optic (Integra Neuroscience-Plainsboro, NJ) and transducer tipped devices, like the microstrain gauge (Codman-Raynham, MA.) are placed in the brain parenchyma but are generally more expensive and cannot be recalibrated once inserted [35-37].

The Brain Trauma Foundation Guidelines for the Management of Severe Head Injury recommend ICP monitoring in patients with a GCS score <9 and an abnormal CT scan (blood, edema, contusion) or a GCS score <9 with a normal CT scan, and two of the following three: 1) age >40; 2) systolic blood pressure (SBP) <90 mmHg; and 3) unilateral or bilateral motor posturing. With ICP and mean arterial blood pressure (MABP) measurements, cerebral perfusion pressure can then be determined to provide an indirect assessment of CBF. The CPP value necessary for preventing ischemia varies individually, depending largely on the integrity of autoregulation but generally lies between 50 and 70 mmHg [101,102].

36.7.2 Blood Flow Monitoring

Transcranial Doppler

Transcranial Doppler (TCD) is an inexpensive non-invasive tool that provides insight into cerebral hemodynamics, and it can alert the clinician to possible harmful events. TCD relies on an ultrasonic pulse signal that is transmitted through thin areas of the skull. Flow velocity through a vessel is determined, and flow volume may be calculated by multiplying the velocity by the cross-sectional area of the vessel. Since the amount of collateral flow and the actual vessel diameters are unknown, TCD cannot provide quantitative data on regional tissue perfusion. Changes in flow velocity can, however, provide relative data on changes in flow volume. Typically, flow velocities >200 cm/second indicate

severe vasospasm, vessel narrowing, and impending infarction. Hyperemia, a common occurrence in post-TBI, may also lead to elevated flow velocities. The so-called Lindegaard ratio or hemispheric index (middle cerebral artery [MCA]/extracranial internal carotid artery [ICA]) may help differentiate between the two situations, with normal values being <2 and critical values being >3 [38].

Xenon CT

Xenon CT is the most accurate non-invasive method for determining both regional and global cerebral blood flow. Xenon is a radiodense, inert and rapidly diffusible substance that allows precise quantitative measurement necessary for determining accurate blood flow values. Baseline plain CT scans are performed, followed by serial scans while the patient inhales 28-33% xenon. Complex mathematical models produce precise quantitative values, relying on Fick's principle which states the amount of a substance taken up by an organ equals the amount delivered minus the amount carried away by venous blood. Xenon CT is not devoid of technical pitfalls: patients must be free of cardiovascular disease, both functionally and structurally, in order to produce reliable results; and if portable CT is unavailable, moving the patient to the CT scanner multiple times may also become an issue. Two invasive methods for measuring continuous local CBF are now also available and have correlated well with xenon CT techniques: the thermal diffusion method (Hemedex) and the laser Doppler method. Both methods require open craniotomy or a twist-drill hole for placement, and both measure only small focal areas of brain tissue, which may or may not be representative of the global blood flow picture. Both are under evaluation in many centres.

Near-infrared Spectroscopy

Near-infrared spectroscopy (NIRS) technology has been developed as an emerging method for monitoring cerebral oxygenation, blood flow, and blood volume in both adults and children [39,43]. The technique involves the transmission of light from an emitting source through the brain to a sensor. Some studies suggest it can monitor cerebral oxygenation, blood flow, and blood volume in both adults and children [39-43]. NIRS has received technical criticism because, while transmission of the light source works well in neonates due to their semitransparent skull and scalp, monitoring in adults can be problematic due to dilution of the brain NIR signal by extracerebral tissues such as the skull bone marrow and scalp [44,45]. The emitter and detector are separated by specified distances on the scalp with the premise that a fixed amount of transmitted, reflected, and scattered light follows an elliptical path whose depth of penetration is proportional to the distance of separation between the emitter and the detector (Figure 36.2) [45]. Cerebral oximeter (Somanetics Inc, Troy, MI, Invos Cerebral Oximeter) is one such product used to estimate blood oxygen saturation in the brain. Optical transceiver pairs are placed on the scalp, and the attenuation of light signals at two wavelengths is used to estimate regional blood oxygen saturation. Its use in both operative procedures and ICU settings have been reported. Brawanski et al. demonstrated a correlation between intraparenchymal oxygen probes and NIRS probes in 9 patients following TBI, and Kirkpatrick et al. found that NIRS probes recorded changes in cerebral oxygenation that recovered once blood flow was restored during vessel cross-clamping in carotid endarterectomy [46]. The use of NIRS in conjunction with a bolus injection of indocyanine green (ICG) has been used to measure CBF. NIRS measurements may help to identify critical clinical parameters and guide treatment directions. As it is not sufficient as a stand-alone monitoring technique, these values should be considered in context with other monitoring methods.

Laser Doppler Flowmetry

Laser Doppler flowmetry (LDF) relies on an implanted subcortical fibre optic laser probe (diameter, 0.5-1 mm) that measures the shift of reflected laser light produced by the progression of red blood cells recorded in blood perfusion units (BPU.) Laser light from one fibre is scattered within the tissue and some is scattered back to the detector probe, which is another optical fibre that collects the backscattered light from the tissue and returns it to the monitor. The light returned to the monitor undergoes signal processing, wherein the emitted and returned signals are compared to extract the Doppler shift related to moving red blood cells. A BPU is a relative units scale determined using a carefully controlled motility standard comprising a suspension of latex spheres undergoing Brownian motion. The greatest benefit of LDF is that the data are presented in real time and variations in blood flow are detectable immediately. A major drawback is that the data are a qualitative and not a quantitative analysis. When used in conjunction with xenon CT, an absolute value can be determined, with xenon acting as a calibrator for the LDF [37,47].

Thermal Dilution Flow

Thermal dilution flow (TDF) methods (Hemedex, Codman, Cambridge, MA) are based upon the conductance of small amounts of heating between two small gold electrodes, one equipped with a sensitive thermocouple sensor. CBF is proportional to heat conductance, and the values are thus absolute. The probes are usually configured for placement in the deep white matter rather than the grey matter, with correspondingly much less CBF change (e.g., normal CBF in white matter is 22 ml/100 gm/min versus 80 ml/100 gm/min in the grey cortex). The sensors are usually placed via a “bolt” immobilizing system, but they can be placed at craniotomy (e.g., for aneurysm clipping). Clinical acceptance of either of these monitoring techniques has been slow thus far perhaps due to the reporting of relative values and the questionable reliability and validity of the commercial systems [27]. The development of non-invasive methods to assess both regional and global blood flow and oxygenation together are also being developed and may one day replace LDF and TDF.

36.7.3 Oxygen and Temperature

$SjvO_2$

Jugular venous oxygen saturation ($SjvO_2$) monitoring involves cannulation of the internal jugular vein and advancement of the catheter into the jugular bulb (about 13 cm) cephalically to the level of C1, confirmed with lateral and/or anteroposterior plain x-ray. Jugular venous oxygen saturation sampling was first utilized in the 1930s as a promising method to detect post-traumatic changes in global cerebral oxygenation, but its subsequent use has proved to be more difficult than originally envisioned [48]. The concept of $SjVO_2$ monitoring is based upon the fact that most (about 80%) of the cerebral venous blood drains into the internal jugular veins, so that jugular venous blood indicates brain events. The normal range of $SjvO_2$ is 50-75%, but typically lies between 50-60% in most patients. When CBF decreases, oxygen extraction increases to compensate it, and the cerebral metabolic rate does not change initially. If this relationship continues and decreases in CBF surpass this compensatory mechanism and the supply is unable to meet demand, the metabolic rate decreases and anaerobic metabolism takes over. $SjVO_2$ decreases <50% are associated with altered brain metabolism, and values <20% are associated with irreversible ischemic injury and poor outcome [49]. In head-injured pa-

tients, however, $SjvO_2$ measurements are widely variable, ranging from 34 to 96% in some series [50]. Measurements of $SjVO_2$ are obtained by draining blood from the internal jugular venous catheter. Widespread use of this monitoring method has been limited however, due to catheter migration, technical difficulties of insertion, poor positioning, calibration errors (e.g., light absorbance), and the difficulty in differentiating regional versus global brain oxygenation, leading to a reported 50% error rate [48,51-53]. Questions concerning the reliability, validity and new $PtiO_2$ technology (see below) have limited the use of $SjVO_2$ monitoring to a few centres.

$PtiO_2$/PbO_2

The Licox monitor is a direct means to measure brain oxygen and temperature. The probe measures 0.8 mm and is placed into brain tissue to determine local or regional oxygenation and neighbouring brain temperature depending upon the insertion site. The Licox (GMS-Integra, Kiel-Mielkendorf, Germany) system [54] is a small and easily inserted miniaturized Clark electrode with a polyethylene sheath (sampling area approximately 14 mm^2), and it has proved to be an accurate measurement of partial pressure of oxygen (Figure 36.4). Diffusion of oxygen from red blood cells to the extracellular space provides the substrate measurement, and the Licox system integrates both venous and arterial oxygen tension in the measured area [55]. Conformation of sensitivity can be accomplished by altering inspired FiO_2 to 100% following intracerebral placement, often referred to as an "oxygen challenge" [56]. When inserted near an area of injury or penumbra, the probe can detect localized hypoxia or evaluate global brain oxygenation. Normal brain tissue oxygenation (partial pressure of brain tissue oxygen [$PbtO_2$]) is 20-35 mmHg. Current Brain Trauma Foundation guidelines indicate a $PtiO_2$ of 15 mmHg. Values <10-14 mmHg should be considered a sign of tissue hypoxia [35,52] and values <5-10 mmHg indicate impending neuronal death and infarction.

In early trials, Robertson and Valadka et al. demonstrated that when pO_2 was maintained at normal values, it was a predictor of better outcomes in TBI patients. Bard et al. later showed some correlation with duration of low $PtiO_2$ and poor outcome. Van den Brink et al. looked at 101 patients with non-penetrating head injury and a GCS score ≤8 and found that the magnitude and length of time of low $PtiO_2$, as measured with the Licox system, was an independent predictor of unfavourable outcome and death. The authors noted that the device demonstrated little zero drift and that the values were reliable over the time course of monitoring [57].

Placement location remains a complicated issue to resolve. Studies have shown that direct placement of the catheter in contused brain provides inaccurate responses following increased FiO_2, suggesting that CBF may be inadequate to provide oxygen delivery in these contused areas [58]. Accordingly, some groups recommend placement in non-contused white matter of the frontal lobe in diffuse injury or on the affected side in a unilateral injury [54,58]. Although these measurements may help to identify critical clinical parameters and guide treatment directions, most authors agree that PO_2 monitoring is not sufficient as a stand-alone monitoring technique [55]. These values should be taken in context with other monitoring methods and

Figure 36.4. Licox system.

should help guide rather than dictate clinical action. The risk of infection or catheter-related hemorrhage is minimal. A randomized clinical trial of $PtiO_2$ versus non-$PtiO_2$ monitoring-guided therapy is currently underway in the United States (the "BOOST" study). The Licox probe also has an incorporated thermocouple allowing for brain temperature monitoring.

Hyperthermia in human and animal studies has proved to be another secondary insult resulting in poor outcomes [59]. Cerebral temperature typically differs from core temperature. Schwab et al. cite 1.5°C ± 0.3. A growing body of evidence in both animals and humans suggests that induction of mild hypothermia (32-35°C) early after injury may arrest or slow secondary brain damage mechanisms.

Microdialysis

The cerebral microenvironment changes rapidly after TBI. Excitatory amino acid release, calcium influx, pump and membrane failure, and lactate accumulation are just a few of the derangements. Many of these changes can be detected with the use of microdialysis in humans. Correlations between adverse clinical events (e.g., elevated ICP, hypotension or hypoxia) and increased dialysate concentration (lactate, potassium, excitatory amino acids [EAA]) or decreased levels (glucose) after head injury have also been reported [60-64]. Belli et al. noted that elevated lactate/pyruvate (LP) ratios and glycerol levels preceded malignant increases in ICP, suggesting that biochemical failure could be detected early [65] (Figure 36.6).

Such cerebral substrates can be collected utilizing a fine coaxial probe (diameter, 0.62 mm) with a dialysis membrane (typically 20 kDa MW cut-off) placed directly into the brain. The probe is slowly perfused with a sterile mock extracellular fluid (ECF) solution, allowing continuous sampling of the parenchymal extracellular environment across the dialysis membrane [66]. High-performance liquid chromatography (HPLC) techniques in small aliquots of dialysate fluid (60 µl) allow for the identification and measurement of various molecules, including glucose, lactate, potassium, pyruvate, nitric oxide, and glutamate [60,61,67].

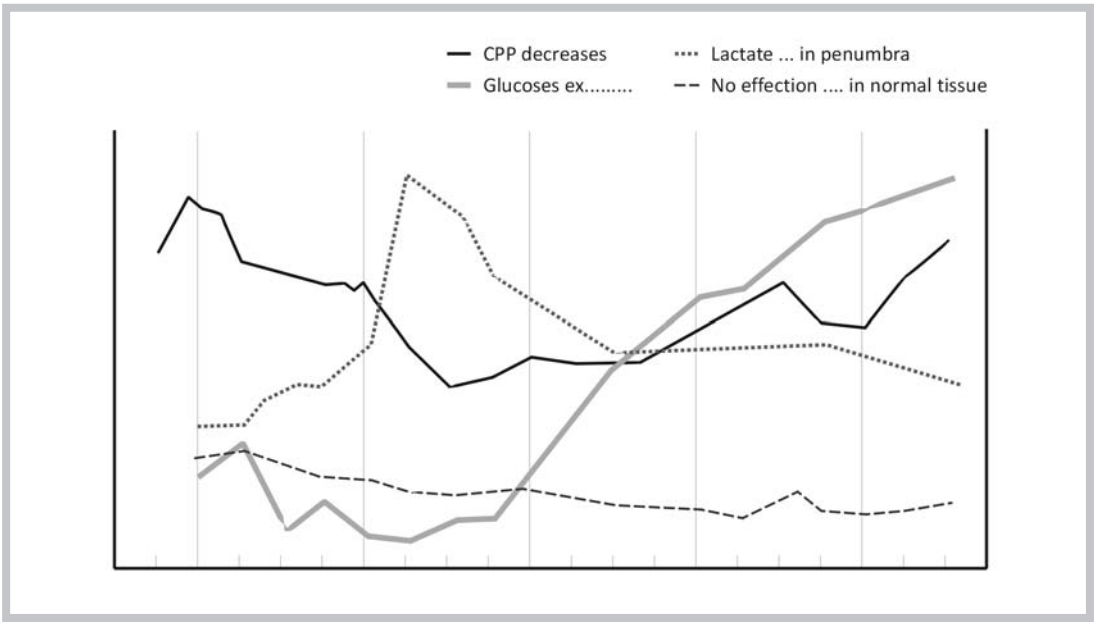

Figure 36.5. Effcects of lactate/pyruvate and glycerol levels on ICP.

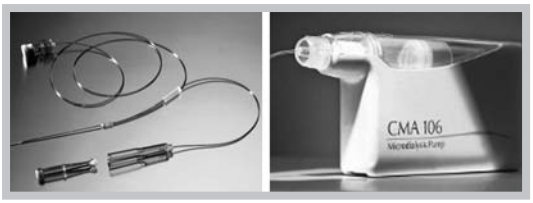

Figure 36.6. Microdyalisis system.

This tool was first utilized clinically in the 1980s by Meyerson et al. prior to lesioning for Parkinson's disease [68] (Figure 36.6). As with most monitoring systems, microdialysis may be combined with other modalities such as ICP and PO_2 probes [69]. Microdialysis has many limitations, however, one being that measurements are representative of relative concentrations of the extracellular molecules and so do not represent absolute concentrations, creating a problem when attempting to compare data between different machines and centres [70]. Other disadvantages are the lack of specificity of some results, sampling limitations of the microenvironment surrounding the catheter induced by cell edema, and changes in the ECF space [35,58,71,72], poor temporal resolution, and lengthy (1 hour) substrate analysis time. The use of microdialysis probes with a much higher molecular-weight cut-off (e.g., 100 kDa) allows protein fragments and small peptides such as cytokines (e.g., IL-1, IL-6, trophic factors, and amyloid precursor protein fragments) to be measured serially in the human brain following TBI and subarachnoid hemorrhage (SAH) [73]. Ongoing clinical investigations may address these drawbacks and eventually propel microdialysis into mainstream neurological ICU use.

36.7.4 Monitoring of Seizures and Spreading Depression: EEG/ECoG/CFM

Monitoring for epileptiform activity in the acute and subacute period post-TBI is an important adjunct to ICP, brain oximetry and CBF, as the incidence of subclincal/non-motor or partial seizures can be as high as 17-20% and chemical paralysis may mask overt motor seizures [35,74,75]. Electroencephalographic (EEG) data have also be used as an independent prognostic indicator and to institute therapeutic interventions before irreversible damage ensues [76,77]. The presence of epileptiform activity has also been linked to episodic increases in ICP and lactate/pyruvate ratios as measured by microdialysis [78]. Monitoring should continue until the ICP has normalized or cerebrovascular autoregulation has been re-established [78]. Additional benefits of obtaining EEG data post-TBI include testing the efficacy of new drugs without lengthy waiting to determine outcome measures. Vespa et al. studied 94 moderate to severe TBI patients and reported a 22% non-convulsive seizure rate. Classen et al. validated this study in 2004 and reported a 18% seizure rate in the same population.

Newer continuous EEG machines are smaller and portable, contain data reduction software, and real-time remote analysis, eliminating the need for a full-time technical assistant at the bedside [66]. The simplest form of EEG monitoring includes a non-invasive strip of 2-4 electrodes (e.g., Bispectral Index [BIS]) that analyzes the depth of sedation, reports on whether seizure activity is present, and can correlate with the GCS score [79]. A downside of this technique is that it cannot regionalize information. Larger units including 8-14 channel 10-12 electrode montages that are more regionally specific and can collect specific information such as alpha, delta, beta, and theta proportions of the raw EEG [76-78]. Several international studies are currently evaluating monitoring of cortical activity following decompressive craniectomy [80,81]. During the procedure, an electrocorticogram (ECoG) 6-electrode recording strip is placed on an area of the cortex near the parenchymal site of injury. Incorporated software provides data analysis and storage. The strip allows for bedside removal once the monitoring period is complete.

Cortical spreading depression (CSD), as previously described by Leao, refers to a wave of depressed cortical activity or amplitude that spreads slowly across the cerebral grey matter and can be diagnosed by the ECoG [82]. The depression is accompanied by a transient loss of ion homeostasis, changes in glucose and lactate, and an increase in CBF and oxygen followed by oligaemia. ECoG changes are similar to those recorded during peri-infarct depolarization (PID) which occur in the periphery of infarct regions [80,83-85]. PID and CSD differ from one another, however, in that PID contributes to irreversible ischemic damage, while it is unclear whether CSD can harbour long-term effects. It may precede certain events (e.g., seizures) and in some cases may even have a protective effect on the injured brain [81,86,87]. Differentiation between these two phenomena is critical.

CSD is not caused by one single mechanism. Animal studies suggest the influence of many different causative agents such as potassium and glutamate that flush out of the cells and into the ECF [88]. Although experimental work on this concept in animals spans 60 years, it has only recently been demonstrated that CSD post-TBI in humans is common, and it may even be more likely to occur in younger patients [80,89,90].

Fabricius et al. examined the incidence of co-occurrence of spreading depression and seizures following acute brain injury [81]: 54 patients were included in the study and each had a 6-electrode cranial strip placed below their craniotomy site; 19 of 54 patients exhibited cortical spreading depression, and in 8 of these 19 patients co-occurrence of seizures and CSD was documented. Three of these 19 patients had CSD that preceded a seizure, signifying the potential of CSD to trigger full seizures; however, this was not seen consistently. Only one of the seizures was observed clinically. More research into these two potentially co-occurring phenomena is necessary. Because CSD and PID events in animals can be attenuated with N-methyl-D-aspartic (NMDA) acid receptor blockade, monitoring these changes in humans may provide an important selection tool for those patients who could benefit from these therapies in the future [90].

36.7.5 Neuromonitoring-based Treatment Strategies

As mentioned earlier, the goals of monitoring and treatment are to maintain adequate cerebral perfusion, oxygenation, and metabolism, while limiting ICP elevation, desaturation, edema, and substrate perturbations. Specific values that may serve as a guide include maintenance of CPP between 60 and 70 mmHg, ICP <20 mmHg, $SjvO_2$ >50 mmHg, and local tissue oxygenation >15-20 mmHg. Traditionally, treatment of elevated ICP has proceeded in a step-wise fashion, beginning with a low-risk and high-benefit profile before progressing to high-risk therapy such as barbiturate coma. Elevation of the head of the bed to 30-45 degrees, maintenance of normotension, normothermia, and normocarbia, prevention of hypoxia, and sedation and analgesia remain the initial steps in the management of most head-injured patients. These are first-tier treatments in severe TBI. Progression to higher tier therapies should be initiated when there is a rise in ICP, and substrate deficiencies in multi-modality monitoring require some unique and specific interventions, as discussed below.

Osmotic Diuretics

Mannitol, currently the osmotic diuretic of choice, is initially given as a bolus of 0.25-1 gm/kg. It reduces ICP within 15 minutes, and its effects typically persist for 3-4 hours. The therapeutic effects of mannitol include initial improvement in red blood cell rheology, blood flow and oxygen delivery to the brain, as well as delayed osmotic water withdrawal from the brain into the circulating blood volume [91]. There is also weak evi-

dence that concomitant use of loop diuretics, such as furosemide, results in a greater and more sustained decrease in ICP when compared to mannitol use alone [92]. Clinical effects seem to peak when serum osmolarity is kept between 300 and 320 mOsm, and elevations beyond 320 mOsm can result in renal failure. Some authors advocate the use of hypertonic saline, but evidence does not support a superior effect in TBI.

CSF Drainage

The first step in managing a new rise in ICP is to rule out an evolving or delayed mass lesion by CT scan. Once this has occurred, and assuming a ventriculostomy is in place, drainage of 3-5 ml of CSF should be the initial therapeutic modality. In patients with intracranial hypertension, drainage of even a small amount of CSF may be very effective. An additional theoretical advantage of CSF drainage involves removal of potentially neurotoxic compounds from the CSF, such as glutamate, aspartate, and calcium. These compounds have been shown to be present after TBI, and facilitation of their removal may have a theoretical advantage.

Sedation and Neuromuscular Paralysis

An additional therapeutic option involves heavy sedation and/or neuromuscular paralysis. Agitation, anxiety, posturing, and resistance to mechanical ventilation can all contribute to elevations in ICP. Sedatives, such as midazolam or lorazapam, propofol coupled with narcotics such as morphine or fentanyl, and neuromuscular blocking agents such as vecuronium or rocuronium, are all commonly used agents. Specifics on dosing and benefit/side effect profiles are beyond the scope of this chapter. Routine neuromuscular paralysis of head-injured patients has been shown to increase pulmonary complications and prolong ICU stay however, and should therefore be reserved for those patients with persistent elevation in ICP [93].

Hyperventilation

Lundberg was the first to introduce hyperventilation as a form of treatment for intracranial hypertension in the 1950s, associating a significant decrease in ICP in patients with tumour or TBI when arterial PCO_2 was reduced from 40 to 25 mmHg [94]. Subsequent animal models confirmed that hyperventilation leads to cerebral vasoconstriction, decreased CBF and blood volume, and a reduction in ICP. Research has shown that CBF in the pericontusional area is indeed close to the ischemic/infarction threshold (<18 ml/gm/min) and that further reductions in blood flow may tip this balance towards brain ischemia. Routine hyperventilation to an arterial PCO_2 of 20-25 mmHg was shown to worsen outcome in a randomized controlled trial [95]. It is now recommended that PCO_2 be kept at or near 35 mmHg whenever possible. Aggressive hyperventilation should only be employed to treat acute changes and only for short periods of time; and $SjvO_2$ or $PTiO_2$ measurements should augment these treatments to ensure adequate oxygenation.

Decompressive Craniectomy

Although surgical indications will be addressed in subsequent chapters, decompressive craniectomy for treating refractory intracranial hypertension will be discussed briefly here. Decompressive surgical procedures remain controversial, but there is some evidence that they may reduce mortality rates. For example, Gower et al. reported a reduction in mortality from 80 to 40% in patients undergoing subtemporal decompression in the face of refractory intracranial hypertension. The “Guidelines for the Surgical Management of Traumatic Brain Injury” recommend the following: “Decompressive proce-

dures, including subtemporal decompression, temporal lobectomy, and hemispheric decompressive craniectomy, are treatment options for patients with refractory intracranial hypertension and diffuse parenchymal injury with clinical and radiographic evidence of impending herniation".

Two ongoing clinical trials, the Rescue-ICP (British Medical Research Council) and the DECRA (Australian Medical Research Council), should clarify the role of this treatment in the next few years.

Barbiturate Coma

Barbiturate use is considered the last line of treatment options for patients with refractory intracranial hypertension. Its use may be beneficial due to the action of different mechanisms, including free radical scavenging, lowering of cerebral metabolic rate, cerebral vasoconstriction in uninjured areas shunting blood to injured areas, calcium homeostasis, and lysosomal stabilization. Although routine use of barbiturates in unselected patients has not been shown to reduce morbidity or mortality after severe head injury, Eisenberg et al., in a randomized multicentre trial, showed a two-fold greater chance of controlling ICP in patients with refractory intracranial hypertension when barbiturate coma was induced [96].

Since barbiturates can cause profound hypotension, and neurologic exams cannot be performed during its use, patients with cardiovascular instability are not usually candidates. Pentobarbital is the most common agent, and systemic monitoring with Swan-Ganz catheters is recommended. Barbiturates can be useful in a select group of patients however, and those with sustained refractory intracranial hypertension likely have no other option.

Hypothermia

Studied and used intermittently for decades, hypothermia is attracting renewed interest. Therapeutic moderate hypothermia (32-35°C) has been shown to lower ICP and has been linked to improved outcome after TBI [97,98]. Hypothermia reduces CBF, metabolism, and inflammation, much akin to barbiturate use. At our institution, we treat most severe head injuries with 48-72 hours of moderate hypothermia, instituted as soon as possible after the injury.

36.8 Conclusions

Traumatic brain injury is common worldwide; treatment outcomes continue to improve through continued research and clinical advances. The trauma victim should be rapidly identified, stabilized and transferred to a trauma care facility where care should be smoothly transferred to an awaiting multidisciplinary team ready to combat all possible injuries. Rapid cardiovascular stabilization, radiographic diagnosis, and intervention should be the goal in every case. Treatment in the ICU should continue with the same vigilance and attention, as many outcomes continue to be determined by ICU management. Multi-modality neuro-monitoring continues to expand through information and randomized controlled trials, and new product developments and improvements. Most modalities on their own do not paint a clear portrait, but when combined the synergy of multi-modality monitoring has the potential for the sum to be greater than the parts. All of these products show great potential for application in appropriate contexts and interventions. Their wider acceptance may ultimately lead to better patient outcomes.

37 Prognosis in Traumatic Brain Injury

Pablo Andrés Perel [1]

[1] Senior Clinical Lecturer. Centre for Global Non Communicable Diseases. London School of Hygiene & Tropical Medicine

37.1 Introduction

37.1.1 Definition

Traumatic brain injury (TBI) is caused by a blow or jolt to the head or a penetrating head injury that disrupts normal brain function. TBI is also referred to as traumatic head injury which can involve any traumatic injury to the head, face or skull and may or may not be associated with a TBI.

37.1.2 Pathophysiology

Primary injury occurs immediately after the impact; this is followed by a secondary injury which, some authors believe, is responsible for part of the neurological damage observed in TBI. Edema formation, both vasogenic and cytotoxic, in a rigid structure such as the skull is followed by increased intracranial pressure (ICP) once the compensatory mechanisms are surpassed. The increased ICP reduces cerebral perfusion and the consequent ischemia generates further neurological damage.

37.1.3 Severity

TBI is a heterogeneous condition encompassing a wide range of manifestations from minor symptoms to profound coma. The Glasgow Coma Scale (GCS), the standard method for evaluating level of consciousness, comprises three different domains (motor, verbal and ocular). Adding the different components on the GCS, the total scores can range between 3 and 15 points (Table 37.1), wherein a GCS score ≤8 indicates severe TBI, a GCS score between 9 and 12 moderate TBI, and a GCS score ≥13 mild TBI.

	Score
Eye opening	
Spontaneous	4
To sound	3
To pain	2
None	1
Total eye score	1 to 4
Motor response	
Obeys commands	6
Localising	5
Normal flexion	4
Abnormal flexion	3
Extending	2
None	1
Total motor score	1 to 6
Verbal response	
Orientated	5
Confused speech	4
Words	3
Sounds	2
None	1
Total verbal score	1 to 5
Total GCS score	**3 to 15**

Table 37.1. Glasgow Coma Scale.

37.1.4 Mechanism

TBI can be classified as closed or penetrating. While closed TBI often results from road traffic accidents, penetrating TBI is more commonly the result of gunshot wounds. Some studies have shown that penetrating TBI is associated with a worse outcome. For example, Peek-Asa et al. studied 795 patients with moderate or severe TBI. After adjusting for GCS, age, gender, and presence of multiple trauma, the patients with penetrating injuries had an odds ratio of 6.6 (95% CI 3.9-11.1) for mortality compared to those with closed injuries.

37.1.5 Structural Damage

Structural damage can be assessed by neuroimaging (computed tomography – CT). It can be divided into diffuse axonal injury, focal contusions and intracranial bleeding. The latter can also be classified according to its location within the cranium. Epidural hematoma refers to collection of blood between the skull and the outer layer of the meninges (the dura mater) and is usually caused by a tear in the middle meningeal artery. Subdural hematoma refers to collection of blood between the dura mater and pia layers and has a typical crescent-shaped appearance on imaging scans. Subarachnoid hemorrhage is the accumulation of blood in the subarachnoid space and intraparenchymal hemorrhage occurs within the brain parenchyma.

37.1.6 Outcomes

In-hospital mortality and disability at 6 months are the most frequently used outcome measures in TBI research. According to the International Classification of Functioning, Disability and Health (ICF), disability can be defined under a biopsychosocial model that includes biological, individual and social perspectives on health. Disability includes: a) impairments (problems in body functions); b) activity limitations; and c) participation restrictions. Different scales have been developed for assessing disability after TBI. The most widely used in TBI research is the Glasgow Outcome Scale (GOS) devised more than 30 years ago. This scale reflects disability in terms of activity limitations and participation restriction rather than impairment. It encompasses five categories: death; vegetative state; severe disability; moderate disability; and good recovery. In randomised clinical trials (RCTs), it is generally dichotomized into favourable (moderate disability, good recovery) and unfavourable outcome (severe disability, vegetative state, death). The GOS assesses how well patients function in their daily social interactions and is generally completed 6 months after hospital discharge.
