The underlying reason for high blood pressure in the setting of acute stroke is not known. In part, could be just the reflection of inadequately treated or undetected chronic hypertension [24]. However, the tendency to spontaneous reduction in the subacute phase of the stroke supports the role of other transient and stroke-specific related mechanisms [25]. Stroke involves transient or permanent damage to the areas affected in the brain regulation of cardiovascular functioning, including BP. The parasympathetic and sympathetic nervous systems are lateralized to the left and right cerebral hemispheres, respectively [26]. Prefrontal and insular cortices provide inhibitory and excitatory input, respectively, through pathways that connect to the nuclei in the brainstem, particularly in nucleus tractus solitarius and ventrolateral medulla [27,28]. Further modulation is provided by cingulated cortex, amygdala, and hypothalamus. Because of the widespread distribution of these areas, most stroke lesions involve these areas to a varied extent.
Increased sympathoadrenal tone [29] with subsequent release of renin and vasoconstriction of arterioles results from: 1) direct injury to inhibitory or modulatory brain regions, or 2) indirect effects of reduced parasympathetic activity [30], which leads to impaired cardiac baroreceptor sensitivity in patients with stroke [31]. Although direct injury is the most likely explanation, an indirect effect of muscle paralysis or the release of neurotransmitters such as nitric oxide during ischemia may be contributing factors to altered activity of these nuclei [32,33]. Other stress responses to hospitalization, headache, urinary retention, or concomitant infection [34] may lead to abnormal autonomic activity and raised levels of circulating catecholamines [35] and inflammatory cytokines [36], and subsequently may contribute to the hypertensive response. Presumably, these abnormal autonomic responses normalize over a few hours secondary to spontaneous or therapeutic recanalization and resolution of the ischemia and perhaps because of other neural compensatory mechanisms [37]. The aforementioned mechanisms suggest that the primary cause of the acute hypertension response is damage or compression of specific regions of the brain that mediate autonomic control.

68.5 Management of Acute Hypertensive Response in Stroke Patients

Acute hypertensive response can be observed in all type of acute stroke subtypes. However, differences in underlying mechanism mandate different management strategies. Intravascular volume depletion has been identified in patient with acute stroke which may result in a natural hypertensive or hypotensive response as well as on an exaggerated hypotensive response to antihypertensive medication [38-40]. An acute hypertensive response after stroke usually follows one of the four most common courses: 1) spontaneous decline without antihypertensive medication; 2) no clear decline, or even an elevation; 3) modest decline with antihypertensive medication (approximately 10 to 15% reduction for the baseline value); or 4) an intense decline with antihypertensive medication (more than 20% from the baseline value).

68.6 Acute Hypertensive Response in Patients With Intracerebral Hemorrhage

Non traumatic ICH results from rupture of blood vessel in the brain. It is a major public health problem with an annual incidence of 10 to 30 per 100.000 inhabitants [41,42]. Long term uncontrolled arterial hypertension constitute the common cause of non traumatic ICH in adults [4]. Most bleeding in hypertension- related ICH occurs at the or near the bifurcation of the small penetrating arteries that originate from the basilar, middle cerebral, anterior and posterior cerebral arteries [43]. The most common sites of ICH are basal ganglia, thalamus, pons, cerebellum, and deep cerebral white matter. Intracerebral hematoma induces injury of the neurons and glial cells by mechanic disruption, causing oligemia, neurotransmitter release and final mitochondrial dysfunction with membrane depolarization [44-46]. Ultimately, depending on the degree of mitochondrial dysfunction the perihematoma region can suffer from temporary metabolic suppression (hibernation) [47] to cellular edema and necrosis.

Three phases have been described for cerebral blood flow and metabolic changes in the peri-hematoma region based on recent laboratory and clinical studies [48]. A hibernation phase is seen during the first 48 hours. This phase is described by a reduction in rCBF and metabolism, in both ipsilateral and contralateral hemispheres. This has also been proven by using PET scan, demonstrating decrease rCBF and oxygen extraction flow (OEF) [49]. A reperfusion phase is seen between 48 hours and 14 days. This consists of a heterogeneous pattern, including areas of normal, hypo- and hyper-cerebral perfusion. The normalization phase is observed after 14 days and consists of normal blood flow except in non-viable tissue. Based on this assumption, blood pressure reduction in the period of hibernation should be relatively safe. Hemostasis is initiated by local activation of hemostatic pathways and mechanical tamponade. There is evidence that products of the coagulation, particularly thrombin and hemoglobin breakdown products that can trigger activation of the microglia with a secondary cascade of injury inducing edema around the hematoma [50-53]. One third of subjects presenting with ICHs continue to demonstrate hematoma expansion (with subsequent deterioration and death) in the first few hours after onset [54]. An initial systolic BP more than 200 mmHg is associated with hematoma expansion [55] and increased mortality [56] among patients with ICH. Persistently higher systolic BP is also associated with perihematoma brain edema formation [57]. Reducing BP may reduce the rate of hematoma expansion, although conclu-

sive evidences are not available. Recent studies suggest that reduction of BP may be tolerated because of reduced metabolism (hibernation) [58] and preserved autoregulation in the perihematoma region [59].

A multicenter prospective observational study reported the use of intravenous labetalol, hydralazine, and/or nitroprusside for maintaining blood pressure more than 160/90 mmHg within 24 hours of symptom onset among patients with ICH [60]. Low rates of neurological deterioration and hematoma expansion were observed in treated patients. Patients treated within 6 hours of symptom onset were more likely to be functionally independent at 1 month than patients who were treated between 6 and 24 hours. Another study evaluated the tolerability and safety of intravenous nicardipine infusion within 24 hours of symptom onset to reduce and maintain MAP equal or less than 130 mmHg, consistent with previous American Heart Association/American Stroke Association Stroke Council guidelines (ASA) [61]. The primary outcome of tolerability was achieved in 86% of the patients. Low rates of neurological deterioration and hematoma expansion were observed among treated patients. Indirect comparisons suggest that intermittent intravenous bolus regimens of antihypertensive agents have greater variability in BP control than continuous infusion regimens.

The current ASA Stroke Council guidelines recommend [62] that «until ongoing clinical trials of blood pressure intervention for intracerebral hemorrhage are completed, physicians must manage blood pressure on the basis of the present incomplete evidence» by maintaining systolic blood pressure less than 180 mmHg in the acute period with short half-life intravenous antihypertensive drugs. The European Stroke Initiative guidelines [63] recommend lowering the blood pressure in patients with intracerebral hemorrhage to maintain a systolic blood pressure below 180 mmHg. Both guidelines consider more aggressive systolic blood-pressure lowering in the absence of clinical signs of high intracranial pressure or chronic hypertension. Recent data suggest a greater therapeutic benefit with more aggressive lowering of blood pressure [64]. In one observational study, hematomas enlarged in 9% of patients with systolic blood pressure maintained below 150 mmHg and in 30% of those with systolic blood pressure maintained at less than 160 mmHg or a higher threshold. The Antihypertensive Treatment of Acute Cerebral Hemorrhage (ATACH) trial [65] and the Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage (INTERACT) trial [66]reported that aggressive reduction of blood pressure to less than 140 mmHg probably decreases the rate of substantial hematoma enlargement without increasing adverse events. In subgroup analyses from INTERACT, patients recruited within 3 hours and those with an initial systolic blood pressure of 181 mmHg or more seemed to have the greatest benefit with aggressive lowering of blood pressure. No difference in rates of death and disability at 3 months were seen between patients treated with aggressive and conservative lowering of blood pressure in ATACH or INTERACT studies, although the analyses were limited by small sample sizes. Because the effect on clinical outcome has not been fully assessed, the more conservative targets set in the ASA Stroke Council and the EUSI guidelines should be followed. Great caution is advised about lowering blood pressure too aggressively without concomitant management of cerebral perfusion pressure.

68.7 Acute Hypertensive Response in Patients With Ischemic Stroke

Ischemic stroke results from occlusion of an artery with subsequent reduction in rCBF, demarcated into regions of severe reduction (core) and moderate reduction (penum-

bra) [67]. The penumbra remains viable for hours because some degree of blood flow is sustained through collateral supply; however, it is theoretically vulnerable to further ischemic injury with systemic BP reduction because of impaired regional autoregulation, particularly during rapid BP reduction [68]. Conversely, in an experimental model of focal cerebral ischemia and reperfusion, BP reduction reduced infarct size and deficits [69]. Therefore, a period of vulnerability to progression of ischemic deficits may exist after which there may be benefit from BP reduction. A higher rate of death or dependency was observed in patients with initially high or low systolic BP (U-shaped relationship) among 17,398 ischemic stroke patients randomized in the International Stroke Trial [70]. The relationship appeared to be mediated in part by increased rates of early recurrence and death that resulted from presumed cerebral edema in patients with high BP and increased coronary heart disease events in those with low BP. Recent data suggest that wide fluctuations (not initial values) of BP in the first few hours in patients with acute ischemic stroke may be associated with an increased risk of death at 90 days [25,71].

The management of high BP in acute ischemic stroke is highly controversial because of a lack of reliable evidence from randomized, controlled trials. There are three major studies looking into the management of the high blood pressure after acute ischemic stroke. The Low Dose Beta Blockade in Acute Ischemic stroke (BEST) study [72], revealed a greater mortality among patients in whom a beta blocker therapy was started in the first 48 hours after symptoms onset. The Intravenous Nimodipine West European Stroke Trial (INWEST) found a significant correlation between diastolic blood pressure reductions with nimodipine and worsening of the neurological status (within 24 hours of symptoms onset) [73]. Patient with a diastolic blood pressure reduction of more than 20% or diastolic blood pressure of less than 60% have a higher risk of dependency and death at 21 days. A meta-analysis evaluating the use of oral versus intravenous calcium channel blocker initiated six hours to five days after symptom onset in acute ischemic stroke patients found that intravenous administration, higher doses, and administration within 12 hours of symptom onset were associated with an increased risk of poor outcomes [74].

The Acute Candesartan Cilexetil Evaluation in Stroke Survivors (ACCESS) trial [75] treated patient with acute ischemic stroke and systolic blood pressure higher than 200 mmHg and diastolic blood pressure higher than 100 mmHg within 6 to 24 hours or systolic blood pressure higher than 180 mmHg and diastolic blood pressure higher than 105 mmHg within 24 to 36 hours with the angiotensin receptor antagonist candesartan or placebo. The primary outcome was disability at three months measured by the Barthel index. Patients that were found to have hypertension (daytime systolic blood pressure >135/85 mmHg) at seven days after the qualifying event were started on cardesartan (placebo treated patients), the doses of candesartan was increased or a second antihypertensive medication was added. The twelve months cumulative mortality (2.9% versus 7.2%) and the incidence of new vascular events (9.8% versus 18.7%) were less in the candesartan treated group. Unfortunately, there was no difference in the primary outcome.

The post hoc analysis of hypertensive patients in the National Institute of Neurological Disorders and Stroke (NINDS) recombinant tissue plasminogen (rtPA) trial [76] who received antihypertensive therapy (intravenous labetalol and/or nitroprusside in selected patients) but no rtPA therapy within 24 hours of randomization showed no difference in rates of deterioration or death at 24 hours or in rates of favorable outcome at 3 months compared with hypertensive patients who received neither antihypertensive medication nor rtPA.

The results from various studies suggest somewhat contradictory consequences of antihypertensive treatment in acute ischemic stroke: INWEST showed a detrimental effect;

ACCESS, a favorable effect; and post hoc analysis of NINDS rtPA study showed no effect. The current recommendations regarding BP management in acute ischemic stroke are based on 2 observations [77]. BP reduction is associated with an increased risk of neurological deterioration and worse outcome in patients with ischemic stroke in some studies, although a causal relationship has not been demonstrated conclusively [78,79]. The benefit of acute BP lowering (unlike chronic treatment) in patients with ischemic stroke remains unclear. There may be a reduction of cardiovascular events with early institution of angiotensin receptor antagonists; however, the benefit is not conclusively related to BP reduction [75]. Therefore, in the absence of definitive benefit, both the ASA and the European Stroke Initiative are consistent in not recommending routine lowering of BP unless it is repeatedly exceeds 200 to 220 mmHg systolic or 120 mmHg diastolic in the acute period [77,80].

68.8 Acute Hypertensive Response in Patients With Ischemic Stroke Receiving Thrombolytics

The acute hypertensive response among patients with acute ischemic stroke receiving thrombolysis is frequently transient [81] and tends to resolve with vessel recanalization [82]. Uncontrolled hypertension in patients with acute ischemic strokes before receiving intravenous rtPA has been associated with increased risk of ICH [83]. In a large audit of practices and outcomes in 29 hospitals in the Cleveland (Ohio) metropolitan area, BP parameters recommended by the NINDS rtPA trial were not followed in 52% of the 70 patients treated with intravenous thrombolysis. The result was a 16% rate of symptomatic ICHs [84]. A quality improvement program in 9 of these hospitals decreased the rate of noncompliance to BP recommendations to 6% in 47 patients subsequently treated with rtPA [85]. The rate of symptomatic ICH dropped to 6%, which indirectly supports the beneficial value of BP control in reducing rtPA-related ICHs. Both the ASA and European Stroke Initiative guidelines recommend the reduction of BP according to the eligibility thresholds for inclusion in the NINDS rtPA efficacy trial before thrombolytics are administered. In the NINDS rtPA efficacy trial, patients were not eligible if they required aggressive antihypertensive therapy, defined as use of intravenous nitroprusside or repeated intravenous infusions of other medications. A post hoc analysis reported the frequency, course, and treatment of hypertension (more than 185/110 mmHg before randomization or 180/105 mmHg within the first 24 hours after randomization). Antihypertensive treatment before and after treatment with rtPA was used in 9% and 24%, respectively, of the patients treated with rtPA [76]. Prethrombolysis use of antihypertensive treatment did not adversely affect the rate of favorable outcomes at 3 months. Post-thrombolysis hypertension and use of antihypertensive treatment correlated with a lower rate of favorable outcome at 3 months. It remains unclear whether this adverse effect was related to more severe ischemic injury, persistent vascular occlusion, or pronounced reduction in BP. Patients treated with thrombolytics and antihypertensive therapy were more likely to have an abrupt decline in BP than those who were not treated. The higher susceptibility to hypotension associated with antihypertensive treatment after thrombolytic use (not seen in the placebo group) may be related to recanalization or reperfusion; however, the rate of ICH among patients with acute hypertension with appropriate control was similar to that observed in nonhypertensive patients. Early blood pressure reduction with rapid acting antihypertensive agents appears to be appropriate for a safe and beneficial thrombolysis in acute ischemic patients.

68.9 Chronic Arterial Hypertension and Stroke

Chronic hypertension is the most important risk factor for stroke [1]. Chronic hypertension predisposes to stroke by: 1) accelerating atherosclerosis of the aortic arch and large cervico-cranial arteries, 2) causing structural alteration in the small-diameter penetrating cerebral arterioles, and 3) promoting cardiac disease that may be complicated with stroke. Moreover, uncontrolled hypertension is an independent risk factor associated with intracerebral hemorrhage associated with use of oral anticoagulant for prevention of stroke in patients with atrial fibrillation [86,87]. In atrial fibrillation patients, routine blood pressure lowering is likely to provide protection against major vascular events additional to that conferred by anticoagulation [88]. Epidemiologic observations have been showed that treating hypertension dramatically decreases the incidence of intracerebral hemorrhage and can substantially reduce the incidence of the ischemic stroke [89]. In the randomized Perindopril Protection Against Recurrent Stroke Study, in 6,105 participants with prior stroke or TIA, intracerebral hemorrhage was reduced by 76% (95% CI 55-87) by lowering blood pressure 12/5 mmHg using perindopril and indapamide [90]. In 611 participants with hemorrhagic stroke as their qualifying event, a blood pressure reduction of 11/4 mmHg reduced subsequent strokes (most hemorrhagic) by 49%. The large effect of blood pressure lowering on hemorrhagic stroke was also seen in a primary prevention trial using different antihypertensive agents (Systolic Hypertension in the Elderly Program) [91].

Long term arterial hypertension produces a constellation of cerebral parenchymal lesions due to chronic arteriolar disease also known as small vessel cerebral disease or microangiopathy. Chronic hypertension induces structural changes in cerebral arterioles between 50 and 400 μm [92]. The so called “end arteries”, including the long penetrating arteries (lenticulostriatral arteries) and penetrating arteries arising from a large medium size arteries, have no collateral vessel anastomosis. These arteries that supply the basal ganglia, thalamus, hemispheric deep white matter and pons are more directly exposed to the high pressure than the arterioles of similar caliber in the cerebral cortex, which are protected by a gradual stepdown in the caliber. Approximately half of the total vascular resistance in the brain can be traced to the small intraparenchymal arteries [93]. In chronic arterial hypertension, the resistance in these vessels increases in order to protect arterioles and capillaries and keep the cerebral blood flow within normal limits [94]. The cerebral microcirculation is directly or indirectly involved in chronic arterial hypertension. The endothelial cells became functional and structurally abnormal permeating circulating macromolecules by enhanced transcytosis, opening of endothelial junctional sites, and loss of the net negative charge of the endothelium allowing the tunica media to interact with vasoconstrictors released from the platelets such as thromboxane and serotonin. The endothelial dysfunction is expressed as an imbalance in the production of EDRF (endothelium-derived relaxing factors) and EDCF (endothelium-derived constricting factors) in arteries and arterioles of the brain favoring vasoconstriction. These functional changes translate in structural abnormalities in the small brain blood vessels also known as cerebral hypertensive microangiopathy or small vessel disease.

The most common pathological findings of the hypertensive microangiopathy are: microatheroma, lipohyalinosis, fibrinoid necrosis, and microaneurysm. These vascular lesions are the subtract for the most common parenchymal brain lesions found in patient with long standing arterial hypertension: lacunar infarcts [95], subcortical leukoencephalopathy [96], leukoaraiosis [97], and small deep intraparenchymal hemorrhage. The cumulative long term consequences of these lesions in the brain are mainly related to

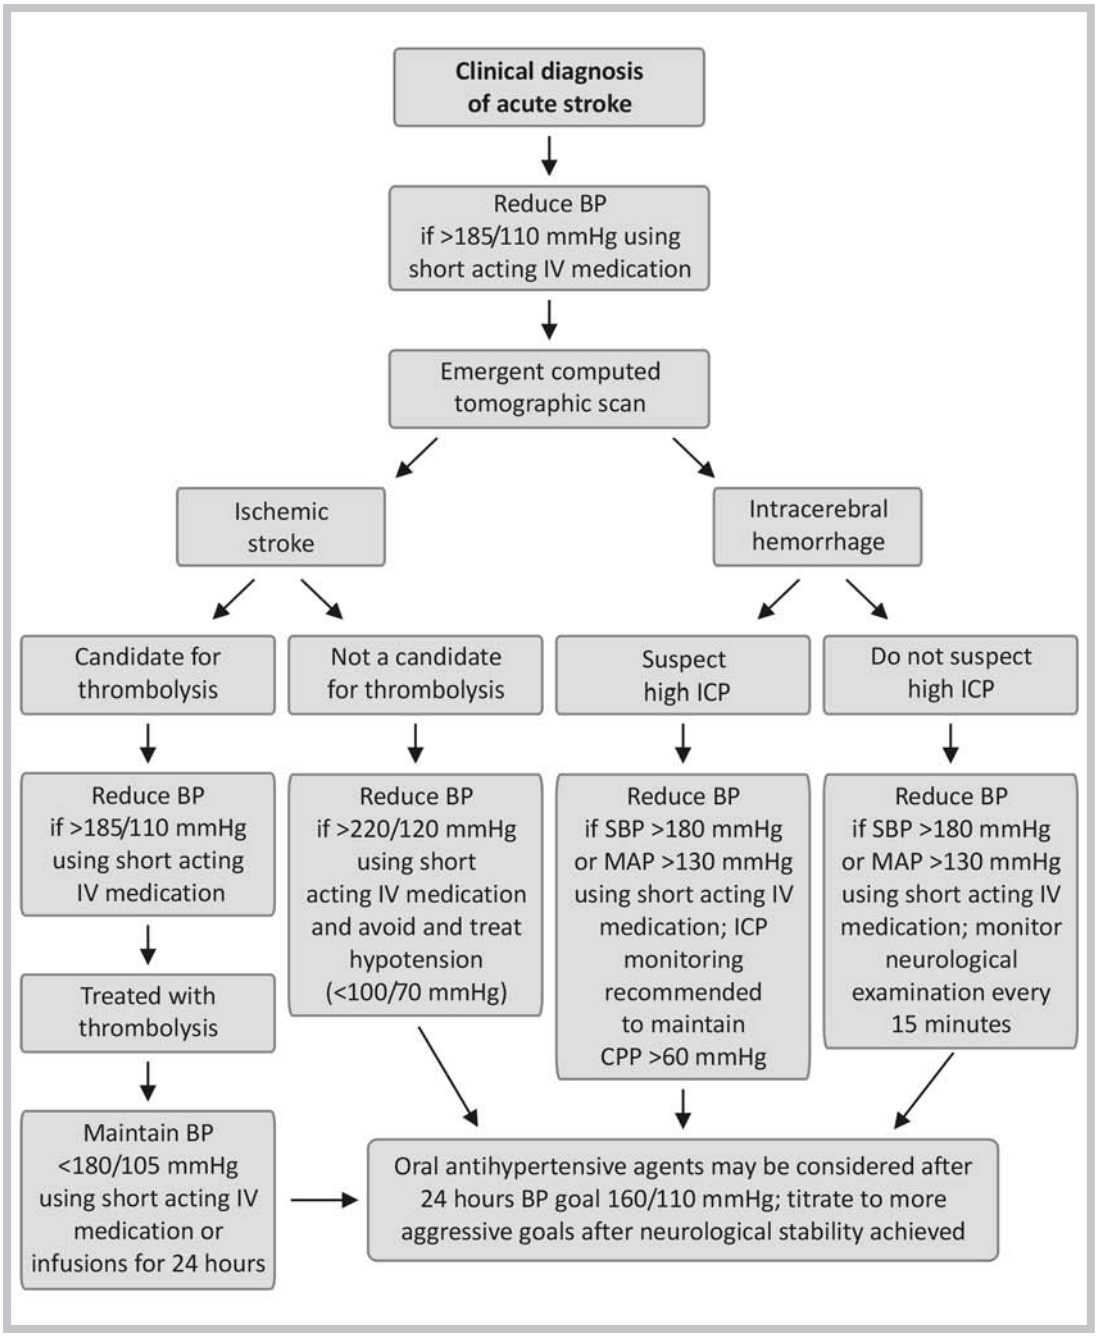

Figure 68.1. **Algorithm for treatment of acute hypertensive response among patients with stroke and stroke subtypes. Based on the NINDS rtPA prethrombolytic protocol for patients with acute ischemic stroke, for short-term BP management by Emergency Medical Services without delaying early diagnosis and differentiation. The Emergency Medical Services BP management practices vary considerably in the absence of distinction between ischemic stroke and ICH. Based on recommendations of the ASA, Stroke Council, and/or European Stroke Initiative. The recommended BP treatment threshold is similar to the existing ASA and European Stroke Initiative recommendations for patients with ICH. Based on recommendations of JNC 7 and the ACCESS protocol.**

CPP = cerebral perfusion pressure

a stepwise cognitive decline defined as subcortical vascular dementia. Adequate treatment of the arterial hypertension can diminish these devastating cerebral complications. In a patient with chronic hypertension who suffers from an acute ischemic stroke, it is recommended the cautious use of antihypertensive medication in order to prevent hypotension with consequently worsening of the ischemic penumbra. The decision to continue or discontinue antihypertensive agents must be made on a case-by-case basis with the intent to avoid hypotension, excessive hypertension, and myocardial ischemia. Reduction of the dose of the current agent or a change to a short-acting intravenous antihypertensive agent may be considered. Another issue is the timing of initiation or aggressive titration of oral antihypertensive treatment in patients with stroke who have chronic hypertension or undetected hypertension. In the California Acute Stroke Prototype Registry, great variability in practices between hospitals and considerable room for improvement was noted among two thirds of patients with acute ischemic cerebrovascular events discharged from the hospital that were given 1 or more antihypertensive medications [98]. The heterogeneity in practice despite the definitive benefit demonstrated in clinical trials is concerning [99-101].

Theoretically, oral hypertensive agents can be initiated at 24 to 48 hours after symptom onset, because most of the acute processes, such as ischemic penumbra and hematoma expansion, are uncommon after the first 24 hours. In the ACCESS trial treatment was started with daily candesartan or placebo on day 1. On day 2, the dosage was increased 2- or 4-fold if BP was higher than 160/100 mmHg. If patients in the candesartan group showed a hypertensive profile on day 7 (mean daytime BP equal or higher than 135/85 mmHg), candesartan was increased or an additional antihypertensive drug was added [75]. The results support early initiation of antihypertensive treatment with gradual titration to more aggressive BP treatment targets. The JNC 7 report recommends that BP is maintained at intermediate levels (around 160/100 mmHg) until neurological stability is achieved. Special circumstances such as elevated ICP, progressive cerebral edema, ongoing cerebral ischemia due to occlusive vessel disease or symptomatic cerebral vasospasm, and postoperative cerebral changes require individualized management.

After the first week, or when neurological stability is achieved, a more aggressive treatment can be initiated for secondary prevention of recurrent stroke [7]. The ASA recommends that antihypertensive therapy be considered for all patients with ischemic stroke or transient ischemic attack, because benefit is seen in persons with and without a history of hypertension. Special consideration may be necessary for patients with bilateral severe carotid stenosis, who may bear a high risk of stroke with aggressive BP lowering until carotid revascularization is performed [102,103]. Figure 68.1 shows the algorithm for treatment of acute hypertensive response among patients with stroke and stroke subtypes.

69 The Anticoagulated Patient in the Acute Phase of Intracerebral Hemorrhage

J. Claude Hemphill III [1]

[1] Associate Professor of Clinical Neurology and Neurological Surgery, University of California, San Francisco, Director, Neurocritical Care, San Francisco General Hospital, San Francisco, CA, USA

69.1 Introduction

Intracranial hemorrhage is the most serious and feared complication of warfarin anticoagulation. As evidence for the benefit of warfarin for stroke prevention in atrial fibrillation has mounted in the past two decades, the use of long-term warfarin anticoagulation has increased dramatically. Concurrently, the incidence of anticoagulant-associated intracerebral hemorrhage (ICH) has increased. It has been estimated that anticoagulants may be associated with as many as 17% of ICH cases, up from 5% twenty years ago [1]. Furthermore, oral anticoagulant use with vitamin K antagonists such as warfarin increases the risk of hematoma expansion in the setting of acute intracranial hemorrhage and through this mechanism increases the risk of death or serious disability [2]. While non-coagulopathic ICH has a high 30-day mortality rate of around 40% in most clinical series, the mortality in coagulopathic patients is nearly doubled. Additionally, while it is now recognized that hematomas frequently expand in non-coagulopathic ICH in the first few hours after onset, coagulopathic patients continue to bleed more often and for a longer duration [2]. Thus, reversal of coagulopathy is of the highest priority in the acute ICH patient presenting while being treated with warfarin or other anticoagulants.

While the focus of this chapter is on reversal of coagulopathy in patients who develop acute non-traumatic ICH while on oral anticoagulants, the principles of risk of hematoma expansion and need for urgent coagulopathy reversal apply to those patients with other conditions (such as acute head trauma) or those who are coagulopathic for other reasons (such as unfractionated heparin, low-molecular weight heparin, thrombolytic therapy for myocardial infarction or stroke, or underlying liver failure). Several basic principles apply to the acute management of patients who present with intracranial hemorrhage and coagulopathy. These relate to the timing, efficacy, and utility of clinical and neuroimaging assessments and help determine the best current approach for these patients.

The first principle is the absolute necessity for reversal of the coagulopathy as soon as possible. Because bleeding is ongoing in many cases of ICH, and likely most cases of anticoagulant-associated ICH, then every minute means that there is increased risk of continuing bleeding, and therefore worsened patient outcome. It must be emphasized that treating the coagulopathy does nothing to treat the initial underlying cause of intracranial hemorrhage. Thus, cessation of intracranial bleeding can be viewed as hyperacute preventive therapy in order to preserve the current status of a patient and allow treatment of the underlying condition (such as hypertensive ICH or head trauma). Second is the understanding that small hemorrhage size or good clinical status does not mean that

coagulopathy reversal is less urgent or necessary. In fact, patients with smaller hemorrhages and with a favorable neurological examination have the most to lose from hematoma expansion. Unfortunately, paradoxically many times these patients receive less urgent care than lose who are already moribund because of the mistaken reliance on their current clinical status. Finally, many patients with oral anticoagulant-associated hemorrhage present with a therapeutic INR (usually between 2.0 and 3.0), not necessarily a supratherapeutic INR. While very high INR levels further increase the risk of continued bleeding, all INR elevations in this setting should be corrected to normal. These and other basic principles of acute care for anticoagulant-associated ICH help to clarify optimal characteristics for warfarin-reversal algorithms (Table 69.1).

- Normalize INR (and other coagulation parameters) as soon as possible
- All patients should have immediate coagulopathy reversal, even if hemorrhage is small and clinical condition is good
- Level of INR elevation does not influence timing of reversal. All levels of INR elevation (modest <2.0, therapeutic 2.0-3.0, supratherapeutic >3.0) require urgent correction
- Initial correction must include longer acting agents (e.g. vitamin K) to avoid rebound INR elevation later

Table 69.1. **Principles of coagulopathy reversal in anticoagulant-associated ICH.**

69.2 Options for Warfarin Reversal

Warfarin is a vitamin K antagonist and therefore acts to inhibit γ-carboxylation of coagulation factors II, VII, IX and X as well as the inhibitors protein C and S [3]. Warfarin reversal can be achieved through three different pathways:

- Direct competition by administering vitamin K.
- Replacement of native coagulation factors using (fresh frozen) plasma or a prothrombin complex concentrate (PCC).
- Bypassing the central part of the coagulation cascade through the use of recombinant factor VIIa (rFVIIa) [3].

The different pharmacological and blood product options which are available target these different mechanisms and each has specific characteristics related to ease of administration, timing and duration of effect, and cost which may potentially influence the choice of their use. Agents used are summarized in Table 69.2.

Agent	Pro	Con	Usefulness for urgent reversal
Vitamin K	Inexpensive; directly reverses warfarin effect	Slow onset of action	Poor
Fresh frozen plasma	Contains all coagulation factors	Large volumes usually needed; requires cross-matching and thawing	Fair
Prothrombin complex concentrate	Rapid onset; small volume	Expensive; variable factor concentrations in different preparations	Good
Recombinant Factor VIIa	Rapid onset; small volume; thrombin burst	Very expensive; acts directly on only a single factor; INR correction may be “lab artifact”	Good

Table 69.2. **Options for urgent warfarin reversal.**

69.2.1 Vitamin K

Administration of vitamin K is a central part of any warfarin reversal strategy. However, its slow onset of action makes it a poor choice as a single agent. It usually takes at least 2 to 6 hours, and frequently 12 to 24 hours, for vitamin K to effectively reverse the effect of warfarin [3,4]. Vitamin K is inexpensive with a 10 mg dose costing $6.82 at San Francisco General Hospital in 2012. While the most efficacious route of administration is still debated, the effect of vitamin K is more rapid when given intravenously. Anaphylaxis from intravenous administration has been a previous concern but is likely extremely rare (3 per 10,000 doses in one study) [4]. Because of the short half-life and duration of action of the other warfarin-reversal options, vitamin K should be administered in all patients in order to avoid a rebound in coagulopathy after initial correction. Subcutaneous administration does not carry the same rare anaphylaxis risk as the intravenous route, but the onset of action is not as rapid or reliable.

69.2.2 Fresh Frozen Plasma

Fresh frozen plasma (FFP) is a blood product which contains all the coagulation factors in an unconcentrated form. Because of this, the volume of FFP required to reverse a high INR to below 1.5 is often 800-3500 ml. Given that each unit may be about 200 ml in volume, the often-used clinical practice of giving two units of FFP and rechecking the INR is insufficient for urgent warfarin reversal. Furthermore, the actual levels of vitamin K dependent clotting factors in each unit of FFP are not standardized and may vary widely. FFP requires compatibility testing and thawing prior to administration, thus there is an inherent delay in initiating FFP transfusion. Cost is moderate with a unit of FFP at $75 in 2012 at San Francisco General Hospital. However, for a patient requiring 2000 ml, this would translate roughly to $750. As a blood product, there is risk of blood-borne infection and transfusion-associated lung injury. Additionally, the rapid transfusion rate and large volume of FFP often required for urgent warfarin reversal could lead to intravascular volume overload. Therefore, even though FFP is often considered the standard current treatment, it remains a poor overall choice for acute warfarin reversal because of inherent time delays in administration and large volumes usually required.

69.2.3 Prothrombin Complex Concentrates

Prothrombin complex concentrate (PCC) is a generic term for many different products which are derived from plasma and contain factors II, VII, IX, and X in varying concentrations. Originally designed as factor IX concentrates, there are at least ten different PCC products which are available in different parts of the world and which contain varying levels of factors II, X, and especially VII [5]. For example, a PCC product available in the United States, Bebulin®, contains low levels of factor VII, while Beriplex®, a PCC product available in other parts of the world, contains all four factors as well as protein C and S [3,5]. PCCs are available as a concentrate which can be reconstituted to a total volume of about 50-150 ml in about 15 minutes and delivered in 10-30 minutes depending on volume and rate of infusion. For each IU (international unit) of PCC per kg body weight, the plasma concentration of factor IX increases by 1% [3]. Optimal PCC dosing (INR-based versus standardized fixed dose) remains somewhat controversial, although individualized dosing may ensure INR correction more rapidly. For example, in order to correct an INR of 4.5 (~10% of factor IX concentration) to an INR of 1.4 (~40% factor IX), would require a dose of at least 30 IU/kg. The corresponding dose of FFP would be 30 ml/kg

(2100 ml for a 70 kg patient). PCCs work very rapidly and can correct the INR within minutes. Thus, they are very good agents for acute warfarin reversal because of the small volume, range of coagulation factors provided, and rapid onset of action. PCCs are significantly more expensive than vitamin K and FFP, with a 3500 IU dose (50 IU/kg for a 70 kg person) costing $3150 in 2012 at San Francisco General Hospital. Concern for thrombotic complications exists with acute PCC administration but this has not been systematically studied. Because of the potentially short duration of action of PCC, vitamin K should always be concurrently administered to avoid rebound coagulopathy. When using PCC preparations with low amounts of factor VII, co-administration of one to two units of FFP may also be considered.

69.2.4 Recombinant Factor VIIa

Recombinant factor VIIa (rFVIIa) is an approved medication for the treatment of hemophilia, has been tested in clinical trials for non-coagulopathic ICH, and used off-label for warfarin-related ICH as well as traumatic hemorrhage. rFVIIa leads to a burst of thrombin activity and interacts with tissue factor. Because even low doses of rFVIIa correct the INR, the INR cannot be used as a reliable indicator of cessation of bleeding in patients who have received rFVIIa. It is not known whether other emerging coagulation tests such as thromboelastography might be better measures. Because of this, optimal dosing is not known. rFVIIa is administered as a single one-time bolus over 2-5 minutes and 80-90 μg/kg is a commonly used dose. Onset of action is very rapid and this makes it a potentially very good agent for acute warfarin reversal. In clinical trials involving non-coagulpathic ICH patients, rVIIa was associated with a small increase in arterial thrombotic events [6]. Of all the current warfarin-reversal options, rFVIIa is the most expensive, with a 5600 μg dose (80 μg/kg for a 70 kg person) costing $8375 at San Francisco General Hospital in 2012. Vitamin K should always be administered concurrently to avoid rebound coagulopathy.

Convert INR to % of estimated circulating functional prothrombin complex (PC)	• >5=5% • 4.0-4.9=10% • 2.6-3.2=15% • 2.2-2.5=20% • 1.9-2.1=25% • 1.7-1.8=30% • 1.4-1.6=40% • 1.0=100%
Calculated dose	• Target in %PC – current estimated %PC x kg=IU of PCC or ml of FFP needed
Example	• Present INR 4.5 • Target INR 1.4 • Body weight 70 kg • (40-10) x 70=2100 IU of PCC or 2800 ml of FFP needed

Table 69.3. **INR-based dosing for PCC and FFP for warfarin reversal [15]. From University of California, San Francisco Neurovascular Service.**

69.3 Current Studies: Benefits, Evidence, and Challenges

As of this writing, there are no prospective, randomized, controlled clinical trials comparing the various warfarin-reversal strategies. Specifically, there are no controlled trials assessing whether PCC or rFVIIa are clearly superior to a strategy of FFP and vitamin K, or comparing PCC and rFVIIa against each other regarding clinical outcome. However, there have been several small retrospective and prospective studies evaluating the effectiveness of INR reversal between the various agents.

In a retrospective study of 69 patients with anticoagulation-associated intracerebral hemorrhage treated with FFP alone or in conjunction with vitamin K, 17% of patients

did not have correction of the INR to <1.4 even at 24 hours after emergency department arrival. Earlier time to initiation of FFP transfusion was significantly associated with INR reversal [7]. This study and others suggest that a significant proportion of patients treated with FFP alone (with or without vitamin K) will not be adequately reversed and that adequate reversal using FFP takes many hours.

Another retrospective study compared 55 patients who were treated with either PCC (with or without FFP and vitamin K), FFP (alone or with vitamin K), and vitamin K monotherapy. Patients treated with PCC were less likely to have hematoma expansion. However, when including only patients who had reversal of the INR to <1.4 within 2 hours, there was no difference in hematoma expansion [8]. This suggests that it is the speed of reversal rather than the agent itself that is most important. However, achieving full reversal within 2 hours with FFP is difficult for the reasons noted previously. Outcome was generally poor, with 77% of patients having a modified Rankin Scale score of 4 to 6. In a different retrospective review performed in Sweden, there was no difference in mortality irregardless of treatment with FFP, PCC, or vitamin K [9].

Several small case series have found that rFVIIa effectively and rapidly reduces the INR in patients with anticoagulant-associated ICH and may limit hematoma expansion [10]. While INR correction has generally been interpreted in these reports as demonstrating effective warfarin reversal, given the fact that even low doses of rFVIIa correct the INR, the true efficacy of this treatment approach remains unclear.

Thus, there is limited evidence to support a specific treatment regimen for warfarin-related ICH. Randomized trials using patient mortality and neurological function as outcome have been proposed. However, these are challenging to design due to the large sample size required, frequent poor outcome of anticoagulant-associated ICH patients, and variability in available products in different areas of the world. Thus, current approaches derive more from consensus-based guidelines driven from concern for rapid and safe coagulopathy correction.

69.4 Other Anticoagulants

Spontaneous (or traumatic) intracranial hemorrhage in patients receiving unfractionated heparin (UFH) or low molecular weight heparin (LMWH) is less common than with warfarin and usually occurs in-hospital or in the context of treatment of another condition such as myocardial infarction or stroke. Protamine directly reverses the effect of UFH with 1 mg of protamine reversing approximately 100 units of UFH. Thus, the dose in a bleeding patient who had just received a 10,000 unit bolus of UFH would be 100 mg. There is no definitely effective reversal agent for LMWH. Protamine may be partially effective and there are case reports of the use of rFVIIa. At present, there have been no randomized studies of intervention for thrombolysis-associated intracranial hemorrhage and optimal treatment remains unknown for this relatively uncommon complication. Current recommended therapy includes the administration of platelets (6-8 U) and cryoprecipitate containing Factor VIII [11].

69.5 Treatment Algorithms and Guidelines

Despite the lack of evidence from randomized clinical trials for an optimal treatment regimen for anticoagulant-associated ICH, there are numerous consensus-based inter-

national guidelines which address this issue and provide a general framework. In general, these guidelines come from larger recommendations on overall use of antithrombotic agents [12-14], but at least one guideline is specific to ICH [11]. Overall, these guidelines emphasize the high morbidity associated with warfarin-related intracranial hemorrhage and the urgency of rapid reversal. Several of these guidelines make the distinction between patients with an elevated INR who are not bleeding, have no significant bleeding, or who have life-threatening bleeding. Given the high risk of ongoing hemorrhage and the high rate of death and disability from anticoagulant-associated intracranial hemorrhage, we believe that it is most appropriate to consider any intracranial bleeding in a patient with an elevated INR due to warfarin use as life-threatening regardless of hematoma size or the patient's clinical condition at first evaluation.

The 2007 American Heart Association ICH management guidelines state that PCC, factor IX complex concentrate, and rFVIIa all lower the INR very rapidly, but have a risk of thromboembolism. FFP is considered another choice but is associated with greater volumes and longer infusion times. This evidence is considered as class IIb (usefulness/efficacy is less well established by evidence or opinion) [11]. It should be noted that these guidelines also recommend that intravenous vitamin K should be given in patients with warfarin-related ICH and consider this as class I evidence (conditions for which there is evidence for and/or general agreement that the treatment is useful and effective).

The American College of Chest Physicians 8th edition of Evidence-based Clinical Practice Guidelines state that warfarin should be stopped and that PCC, rFVIIa, or FFP should be given, supplemented by vitamin K (10 mg by slow intravenous infusion) [12]. Guidelines from the UK recommend discontinuation of warfarin, vitamin K (5 mg intravenous or oral), and administration of PCC (50 U/kg fixed dose) or FFP (15 ml/kg fixed volume) [14]. Finally, guidelines from the Australasian Society of Thrombosis and Hemostasis are somewhat more complex and provide several different tiered options based on availability of different compounds. In these guidelines, all patients should have warfarin discontinued and receive vitamin K 5-10 mg intravenously. They then recommend giving Prothrombinex-HT (a PCC compound) in a dose of 25-50 IU/kg and FFP 150-300 ml total. If either FFP or Promthrombinex-HT are not available then just the available agent (PCC or FFP) should be given with vitamin K.

Thus, all current guidelines emphasize the importance of rapid reversal of coagulopathy and all recommend the use of vitamin K (usually intravenously). However, none provide a specific target INR indicating adequate reversal. Additionally, all make mention of the use of PCC (or rFVIIa) given the rapid onset of action of these agents and the shortcomings of FFP alone. However, the lack of clear evidence limits the ability to make stringent recommendations regarding agent and dose. Figure 69.1 provides and example of enlargement of hematoma due to warfarin anticoagulation, while Figure 69.2 shows the proposed algorithm for hyperacute warfarin reversal.

69.6 Conclusions

Anticoagulant-associated intracranial hemorrhage is increasing in incidence. Because it is associated with high risk of ongoing bleeding, death, or disability, urgent reversal of coagulopathy is of the highest priority. Several agents are available, all with various positive and negative attributes. All protocols for warfarin-related intracranial hemorrhage emphasize immediate cessation of the anticoagulant medication and immediate administration of vitamin K (usually intravenously). The use of PCC or rFVIIa may reverse coagulopathy more rapidly than FFP alone, but randomized trials testing this have yet to be performed. Furthermore, cost and availability of these agents may limit their widespread use.

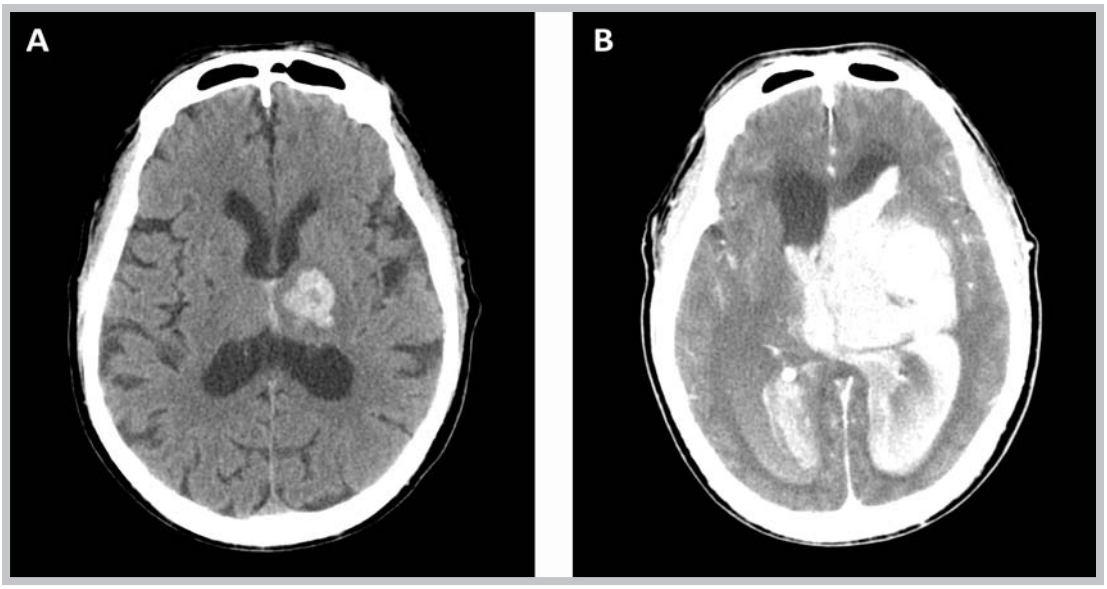

Figure 69.1. **Enlargement of hematoma due to warfarin anticoagulation. 64 year old woman with hypertension and atrial fibrillation, receiving long-term warfarin oral anticoagulation for cardioembolic stroke prevention. Initial INR 4.5. Panel A demonstrates the non-contrast head CT scan at initial presentation, which likely represents a hypertensive ICH occurring while the patient was being treated with warfarin. At this time she was alert, with normal language, and a mild right hemiparesis. Fresh frozen plasma was ordered, cross-matched, thawed and intravenous administration begun. 10 hours later the patient deteriorated due to massive hematoma expansion (Panel B) and later died.**

70 What is the Optimal Level of Hemoglobin in Neurocritical Care Patients?

Silvana Naredi [1]

[1] Dept of Surgical and Perioperative Sciences, Anesthesiology and Intensive Care, Umea University, Umea, Sweden

70.1 Introduction

In red blood cells, hemoglobin is a carrier for oxygen and delivers oxygen to the tissues. Red blood cell transfusion is a potentially life-saving therapy in order to replace losses in hemoglobin to maintain oxygen delivery to vital organs. The main objective of red blood cell transfusion is to increase tissue oxygenation and thereby reduce oxygen debt. After red blood cell transfusion, an increase in hemoglobin concentration is readily measured, but the effect of red blood cell transfusion on utilization of oxygen in peripheral tissue is rarely measured. Clinical studies attempting to determine the effects of red blood cell transfusion on oxygen kinetics have not provided definitive answers.

Transfused red blood cells may increase tissue oxygenation not only as an oxygen carrier but also as an oxygen sensor with the capacity to regulate microvascular blood flow by release of vasodilators, such as nitric oxide (NO).

Transfusion of red blood cells, may, however be associated with negative effects. The delivery of oxygen to the tissue can be lower than expected, and the transfused red

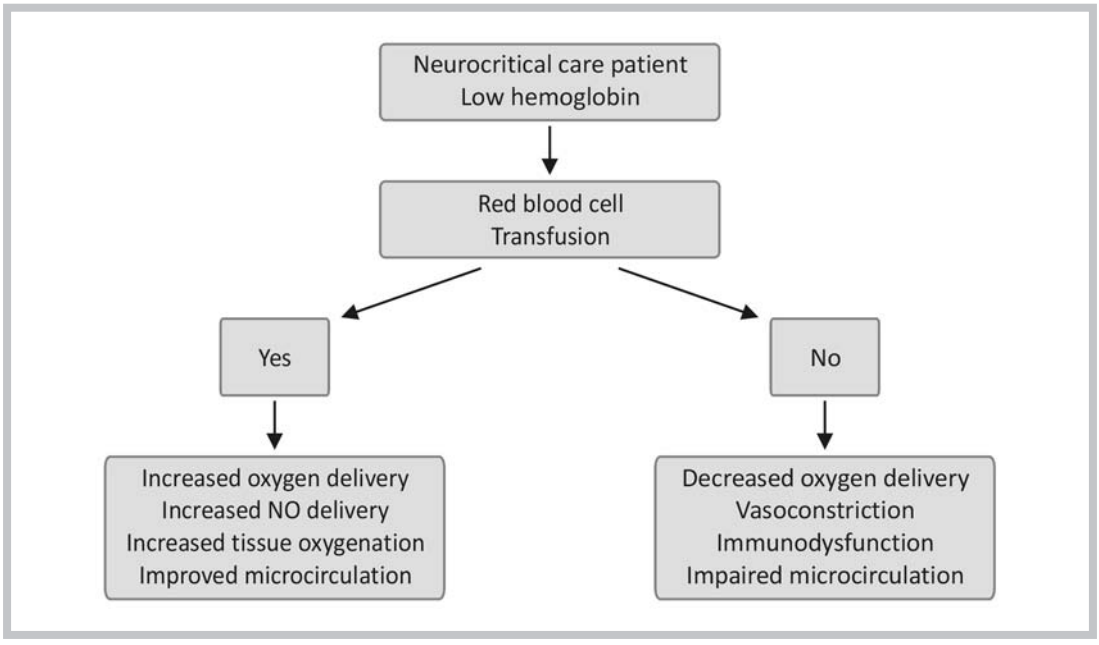

Figure 70.1. Pro-con red blood cell transfusion.

blood cells units can enhance an inflammatory response with possible impairment of microcirculation.
Clinical studies have demonstrated an association between red blood cell transfusion and increased mortality and morbidity in general critical care patients. These results cannot be directly transferred to the neurocritical care patient. For the neurocritical care patient, we still lack convincing studies of effects on outcome of red blood cell transfusion.
This chapter will discuss:

- The normal physiology concerning red blood cells and hemoglobin.
- The beneficial and harmful effects of red blood cell transfusion.
- The target levels of hemoglobin in patients with neurological/neurosurgical acute injury such as traumatic brain injury, subarachnoid hemorrhage and ischemic stroke.

70.2 Red Blood Cells and Hemoglobin

Red blood cells are biconcave discs with a diameter of about 7.5 µm. The capillary diameter is 3-8 µm, which implies that the red blood cells must possess the ability of deformation to pass the capillary network and deliver oxygen to the tissues. The red blood cells carry hemoglobin, and hemoglobin has four important functions: 1) to facilitate O_2 transport; 2) to facilitate CO_2 transport; 3) to act as a buffer; 4) to transport NO.

70.2.1 Oxygen (O_2) Transport

The total sum of the oxygen delivered to the whole body or to specific organs, is the product of blood flow and arterial oxygen content. The arterial oxygen content is mainly dependent on the hemoglobin level. More than 99% of the oxygen is transported by hemoglobin. Oxygen delivery must be sufficient for the metabolic demand of the tissues. Oxygen is not stored in tissues and must be delivered continuously in adequate amounts for avoidance of anaerobic metabolism and production of lactate. The cerebral metabolic rate in the human brain is on average 3.5 ml/100 g brain/minute. This represents approximately 20% of the total body resting oxygen consumption. Aerobic metabolism is the primary energy source for the brain and the brain is dependent on a continuous delivery of substrate, including glucose and oxygen. The brain is thus extremely sensitive to decreased delivery of oxygen.
The affinity for oxygen to hemoglobin is an important factor for oxygen delivery to the tissues. Increased affinity means that less oxygen is liberated in the tissues.
Important factors affecting the affinity for oxygen in hemoglobin are: pH, temperature, and concentration of 2,3-diphosphoglycerate (2,3-DPG).
2,3-diphosphoglycerate is plentiful in red blood cells and it enhances the ability of red blood cells to release oxygen in tissues. For example, high altitude triggers a rise in 2,3-diphosphoglycerate concentration in red blood cells, which subsequently increases the release and availability of oxygen in tissues.

Factor	Effect
Decrease in pH	Decrease in oxygen affinity
Increase in temperature	Decrease in oxygen affinity
Decrease in 2,3-diphosphoglycerate	Increase in oxygen affinity

Table 70.1. Factors affecting the affinity for oxygen in hemoglobin.

The uptake of oxygen in the tissue is less in the alcalotic than in the acidotic patient.
A fall in 2,3-diphosphoglycerate is associated with an increased hemoglobin affinity for oxygen, resulting in less oxygen liberated to the tissues. In stored red blood cells 2,3-diphosphoglycerate is decreased within 48 hours of storage.
The delivery of oxygen to a tissue increases with raised hematocrit up to a certain level. Above that level there is a net reduction in oxygen delivery most likely due to the simultaneous increase in blood viscosity. While a normal hematocrit of 35-45% is optimal in healthy individuals, it may vary in critically ill patients due to different pathophysiological conditions depending on type of illness and quality of the blood transfused (see below).
In summary, the brain is dependent on a continuous delivery of oxygen in order to survive. Hemoglobin carries more than 99% of the oxygen. The optimal hematocrit may vary in patients with different pathophysiological conditions.

70.2.2 Carbon Dioxide (CO_2) Transport

CO_2 is the major end product of oxidative metabolism. Since CO_2 is able to convert into carbonic acid when hydrated, and accumulation of carbonic acid, H_2CO_3, can produce problems in the tissue, an effective elimination of CO_2 from the tissue is essential. The focal point of CO_2 transport is the hydration reaction; $CO_2 + H_2O = H_2CO_3$. The rate of this reaction is fastest in the red blood cell by the help of carbonic anhydrase. In the red blood cell, H_2CO_3, dissolves into hydrogen ion, H^+ and bicarbonate, HCO_3^-. The H^+ generated in the red blood cell is buffered by hemoglobin and HCO_3^-, is pumped back into plasma in exchange for chloride. In summary, hemoglobin plays a major role in the elimination of carbon dioxide (CO_2) from the tissue.

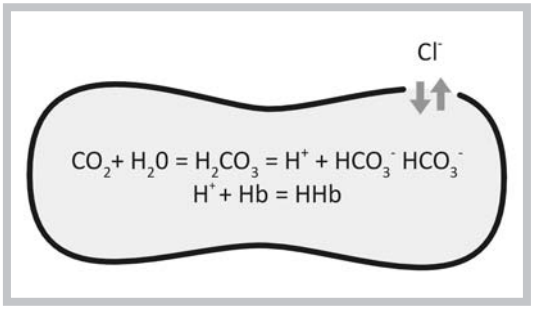

Figure 70.2. **Transport and reactions of CO_2 in the red blood cell. In the red blood cell, the reaction, $CO_2 + H_20 = H_2CO_3$, is facilitated by carbonic anhydrase. Carbonic anhydrase is only present in the red blood cell. Carbonic acid, H_2CO_3, dissociates into hydrogen, H^+, and bicarbonate, HCO_3^-. The hydrogen ion is buffered by hemoglobin, Hb, and forms HHb. A large fraction of the bicarbonate produced is pumped back into plasma in exchange for chloride, Cl^-.**

70.2.3 Hemoglobin as a Buffer

Hemoglobin has an important role in $CO_{2\ transport}$. By transporting CO_2, hemoglobin acts as an important buffer for the hydrogen ions produced by the hydration of CO_2 (see above, CO_2 transport). Hemoglobin in blood has six times the buffering capacity of the plasma proteins.

70.2.4 Transport of Nitric Oxide by Hemoglobin

Nitric oxide is a potent vasodilator that is produced in endothelial cells and acts more or less exclusively at its site of synthesis. New evidence suggests that red blood cells distribute nitric oxide (NO), thereby matching blood flow to tissue oxygen demand. This mechanism could provide an explanation for physiological matching of blood flow to tissue oxygen levels, by mediating dilatation of blood vessels under low oxygen conditions, and constriction of blood vessels when oxygen levels are high.

In summary, nitric oxide can be transported by hemoglobin. Hemoglobin can thus be an important factor for physiological matching of blood flow to metabolic demands.

70.2.5 Red Blood Cells and Blood Volume

The red blood cells comprise about 40% of normal blood volume. The red blood cells are, therefore, of importance to maintain normovolemia. In a pathophysiological situation with increased transcapillary leakage it will, therefore, be more difficult to maintain normovolemia at a low than at a normal hematocrit. In summary, the red blood cells contribute to maintenance of normovolemia.

70.3 Transfused Red Blood Cells

A main goal of red blood cell transfusion is to increase the hemoglobin concentration, and thereby improve O_2 delivery to tissues.
The efficacy of stored red blood cells to maintain the biological activity of red blood cells has been questioned. Transfusion of large amounts of stored red blood cells can possibly lead to adverse clinical consequences. Transfused red blood cells may be ineffective transporters of oxygen, especially in compromised critically ill patients who have microcirculatory abnormalities from a number of pathologic processes and the content of leukocytes (see below) and other inflammatory components can trigger inflammation in a compromised host.

70.3.1 Red Blood Cells and Storage

During storage, red blood cells undergo changes in morphology, associated with biochemical and biomechanical changes, collectively referred to as storage lesions. There is strong laboratory evidence suggesting that prolonged red blood cell storage may be deleterious and clinical studies have reported an association between prolonged storage and adverse clinical outcome. Storage lesions ultimately include loss of deformability. Loss of deformability in combination with increased interactions with vascular endothelium compromise microvascular flow. The unloading of oxygen to the tissues will be impaired by the well-documented depletion of 2,3-DPG in red blood cells that occur after storage for more than 48 hours.

70.3.2 Transfused Red Blood Cells and Immunodysfunction

Perhaps the most negative characteristic of transfused red blood cells units is the content of white blood cells. The immunomodulating effects of red blood cell transfusion

Characteristic	Effect
Compromised deformability	Microvascular obstruction
Depletion of 2,3-diphosphoglycerate	Increased affinity for O_2, reduced ability to unload O_2
Pro-inflammatory effects	Immunodysfunction
Depletion of NO	Vasoconstriction

Table 70.2. **Possible negative characteristics of stored transfused red blood cells.**

have mainly been attributed to leukocytes and inflammatory mediators in the supernatant liquid, denoted as transfusion related immunomodulation (TRIM). TRIM is supposed to be mediated by white blood cells in the transfused red blood cell unit. The donated white blood cells may either down-regulate the immune function of the recipient or trigger TRIM effects by soluble mediators released in the red blood cell unit during storage. Randomized controlled trials comparing the risk of postoperative infection or short-term (three months) mortality between non-leukocyte depleted versus leukocyte depleted red blood cell transfusions have reported conflicting results.
A clinical situation where randomized controlled trials clearly have revealed that the use of leukocyte depleted red blood cell transfusion reduces short-term mortality is in cardiac surgery patients. Many blood transfusion services have added universal leukocyte depletion to the routine processing of all blood components and the majority of red blood cell transfusions in Western Europe and North America are today depleted of white blood cells. Noteworthy, the published studies on harmful effects of red blood cell transfusion in critical ill patients have used mainly non-leukocyte depleted blood.
In summary, storage of red blood cells can alter the biological effects negatively. Content of leukocytes in transfused red blood cells units can induce immunodysfunction.

70.4 Red Blood Cell Transfusion in Neurocritical Care Patients

There are studies in critically ill patients indicating that a liberal transfusion policy is ineffective and even potentially harmful. Interestingly, a well-known and world wide accepted treatment approach in severe sepsis and septic shock, i.e. the early goal directed therapy, contains a recommendation of red blood cells transfusion to achieve a hematocrit of at least 30%, if the central venous saturation is under 70%. In the treatment group 68% of the patients received red blood cell transfusion compared to 45% in the control group. The inhospital mortality in the treatment group was 31% versus 47% in the control group. This indicates that critically ill patients with severe sepsis had a lower mortality if transfused to a hematocrit of at least 30% in the presence of hypoxemia.
The applicability of a restricted transfusion policy to neurocritical care patients has been questioned, given that impaired oxygen delivery is an important cause of secondary brain injury. The brain is more than any other organ depending on a continuous supply of oxygen and only moderate reductions in oxygen delivery to an injured brain could lead to cerebral hypoxia.
Most of the studies concerning the level of hemoglobin and outcome after neurocritical care are prospective or retrospective cohort studies and therefore despite multivariate analysis, the relationship between red blood cell transfusion and increased adverse events may still be a result of confounding factors. There are studies that have reported an association between red blood cell transfusion and increased mortality, but it has to be taken into consideration that the amount of blood transfused may reflect injury severity rather than the blood transfusion per se.
No evidence based optimal hemoglobin level exists for patients receiving neurocritical care. Randomized controlled studies regarding the optimal hemoglobin concentration in neurocritical care patients are lacking.

70.4.1 Traumatic Brain Injury

Patients with traumatic brain injury have been thought to be particularly susceptible to injury from anemia, due to the well-documented association of increased mortality and

worsening functional outcome in the presence of hypotension and hypoxia. Few studies have investigated the effects of anemia in patients with traumatic brain injury. Retrospective studies have revealed that any period of anemia in traumatic brain injury is associated with a significant increase in morbidity and mortality, but also that red blood cell transfusion in traumatic brain injury patients, whether or not anemia is present, is an independent risk factor for complications and mortality. The Transfusions Requirements in Critical Care, TRICC, trial was a randomized controlled clinic trial investigating liberal (hemoglobin level 10.0 g/dl to 12.0 g/dl) versus restrictive (hemoglobin level 7.0 g/dl to 9.0 g/dl) transfusion policy in critically ill patients. The results from the trial were published in *New England Journal of Medicine* in 1999. Primary outcome in the TRICC trial was mortality at 30 days. Although overall results from the original TRICC trial suggested that a restrictive red blood cell transfusion strategy was safe, it was suggested that subgroups of patients may exist, who are especially vulnerable to effects of anemia. A subgroup analysis from the TRICC trial in patients with traumatic brain injury was published in 2006, and even though no significant difference in mortality between a restrictive and a more liberal transfusion strategy could be detected, the mortality rate at 30 days was 13% in the liberal transfusion group and 17% in the restrictive transfusion group. Thus, the liberal transfusions strategy seemed to be at least as safe as the more restrictive transfusion policy. The subanalysis of the TRICC trial concerning patients with traumatic brain injury could not recommend a specific transfusion trigger level in those patients, but the authors concluded that the brain could be an organ that is especially vulnerable to adverse effects of anemia.

It may also be of importance that during the TRICC trial, red blood cells units were not universally leukocyte depleted. Perhaps physiological indications of the need for red blood cell transfusion other than the hemoglobin level could be triggers for transfusion of red blood cells in the future. Recent studies have documented that red blood cell transfusion increases brain oxygenation, measured by brain tissue partial pressure of oxygen ($PtiO_2$) catheters, in most patients with traumatic brain injury and subarachnoid hemorrhage. A limitation of these studies is that $PtiO_2$ might not be an accurate tool to demonstrate the effect of transfusion on oxygen uptake by the tissues.

Normalization of the hemoglobin level would theoretically improve the oxygen transport capacity to injured areas of the traumatized brain, in spite of limitations in this capacity in stored red blood cells. Arguments can be given that patients with a traumatic brain injury would benefit from keeping a normal hemoglobin level in order to optimize oxygen delivery to the traumatized brain. This approach has been adopted in the Lund-concept for treatment of severe traumatic brain injury, the outcome data presented with this approach is good, even though of course this can not be attributed only to the hemoglobin level.

More prospective investigations are required to determine the effects of anemia and the potential benefits and optimal indications for red blood cell transfusion in patients with traumatic brain injury. The hemoglobin threshold may not be identified as the treatment goal, rather more sophisticated methods of neuromonitoring may be necessary to guide the need for red blood cell transfusion.

In summary, no evidence based hemoglobin level can be recommended for patients with traumatic brain injury, but the existing data taken together support a hemoglobin level near normal, that is, a target hemoglobin value around 110 g/l.

70.4.2 Subarachnoid Hemorrhage

Patients with subarachnoid hemorrhage, especially those with a manifest cerebral vasospasm, are vulnerable to hypoxic episodes. Limited oxygen delivery due to anemia,

could have deleterious effects. The optimal transfusion threshold for patients suffering from non-traumatic subarachnoid hemorrhage is debatable. Current practice most often uses a liberal approach. Anemia after subarachnoid hemorrhage has been identified as an independent predictor of infarction, death and dependency. Retrospective studies have reported that subarachnoid hemorrhage patients with higher initial and mean hemoglobin value had improved outcome. Anemia seems to be a predictor of adverse outcome in subarachnoid hemorrhage patients, even when baseline differences in clinical and radiographic severity are taken into account. However, data suggesting an association between red blood cell transfusion and adverse outcome after subarachnoid hemorrhage have also been reported. The triple-H (hypervolemia, hypertension, hemodilution) therapy, used for treatment of cerebral vasospasm, could be one reason for anemia in patients with subarachnoid hemorrhage.
It remains unclear whether anemia after subarachnoid hemorrhage reflects general illness severity or whether the treatment for anemia, red blood cell transfusion, directly contributes to poor outcome. Randomized trials that compare liberal and restrictive transfusion strategies in patients with subarachnoid hemorrhage are needed.
In summary, no evidence based hemoglobin level can be recommended for patients with non-traumatic subarachnoid hemorrhage, but the existing data supports a near normal hemoglobin level. In patients with non-traumatic subarachnoid hemorrhage, the target hemoglobin value could be 100-110 g/l.

70.4.3 Ischemic Stroke

Patients with ischemic stroke have an injured brain that theoretically would benefit from a constant and normal delivery of oxygen. The effect of red blood cell transfusion on outcome in patients with ischemic stroke has been scarcely investigated. Elevated hematocrit has been associated with greater infarct size, early mortality and major disability in patients with ischemic stroke. Elevated hematocrit could be caused by decreased fluid intake and hypovolemia. Hemodilution on the other side has not been proven to improve survival or functional outcome after ischemic stroke. A too low hematocrit may decrease oxygen transport to the injured brain and a too high hematocrit may increase blood viscosity and thus impair microcirculation.
In summary, no evidence based hemoglobin level can be recommended for patients with ischemic stroke. Theoretically normovolemia and a near normal hemoglobin level would be of value for avoiding secondary insults in the injured brain.

70.5 Conclusion

Red blood cell transfusion is a potentially life-saving therapy in order to maintain oxygen delivery to an injured brain. Transfused red blood cells may not only increase oxygen delivery but also possibly influence tissue oxygenation by the capacity to regulate microvascular blood flow. The efficacy of stored red blood cells to maintain their biological activity has been questioned, due to storage damages.
Patients with **traumatic brain injury** may, based on the data presented, benefit from hemoglobin levels near normal. In patients with traumatic brain injury, the target hemoglobin value could be around 110 g/l.
Anemia has been identified as an independent risk factor for unfavourable outcome after **subarachnoid hemorrhage**. The existing data support a near normal hemoglobin lev-

el. In patients with non-traumatic subarachnoid hemorrhage, the target hemoglobin value could be 100-110 g/l.
The optimal hemoglobin level in patients with **ischemic stroke** is barely investigated. Theoretically would normovolemia and a near normal hemoglobin level be of value for avoiding secondary insults in the injured brain.

71 Optimizing Cerebral Perfusion Pressure in Acute Brain Injury

Pedro Kurtz [1], **Neeraj Badjatia** [2]

[1] Neurological Intensive Care Unit, Department of Neurology, Columbia University Medical Center, New York, USA

71.1 Introduction

The management of cerebral perfusion pressure (CPP) is an integral part of hemodynamic resuscitation of brain injured patients. CPP, the difference between mean arterial pressure (MAP) and intracranial pressure (ICP), plays a major role in defining blood flow to the injured brain. The clinician's main task at the bedside is to ensure adequate delivery of oxygen and nutrients to match neuronal metabolic demands and avoid secondary brain injury. Since delivery is dependent on cerebral blood flow (CBF), finding the optimal CPP is crucial to limit secondary injury and improve outcomes.
The objective of this chapter is to discuss how to define and achieve optimal CPP goals based on individual patient profiles and different clinical situations.

71.2 Multimodal Monitoring

A comprehensive approach to goal-directed interventions requires that organ function is assessed to indicate the need and evaluate the response to specific treatments. The ideal monitoring tools in the ICU should be continuous, noninvasive and accurate measurements of the end-organ function of interest. In order to monitor cerebral function parameters there are no good substitutes to intracranial probes that measure intracranial pressure, brain tissue oxygen tension and aerobic metabolic activity. Our approach to multimodal monitoring focuses on systemic and cerebral parameters and the interrelation between them, as shown in Table 71.1.
Hemodynamic monitoring is a cornerstone of the management of critically ill neurological patients. We use either Vigileo™ or PICCO™ devices to monitor mean arterial pressure and pulse-contour analysis of the arterial waveform to generate continuous cardiac output [1-5]. Both technologies also offer continuous measurement of stroke volume variation (SVV) which is used as an estimate of fluid responsiveness in mechanically ventilated patients. The PICCO™ further calculates extravascular lung water (EVLW) and global end-diastolic volumes based on a transpulmonary thermodilution curve [5]. Through a central venous line, preferably on the subclavian site, central venous pressure (CVP) and oxygen saturation are continuously monitored. Arterial lactate and arterial-venous delta CO_2 (a-v ΔCO_2) allow estimation of tissue hypoperfusion and inadequate systemic CO_2 washout, an indication of inappropriate cardiac output [6-10].
Multimodal monitoring parameters of brain function are shown in Table 71.1. It is composed of intracranial measurements of ICP, partial pressure of brain tissue oxygen ($PbtO_2$), microdialysis, brain tissue perfusion (Hemedex™) and cortical depth continuous electroencephalography (cEEG) [11,12]. In addition to the intracranial monitoring, surface cEEG and jugular bulb oxymetry complete the armamentarium of tool avail-

Modality	Purpose and general goals	Description and comments
Systemic		
Continuous cardiac index (CI)	Above 2.5 l/min/m^2	BSA indexed cardiac output based on pulse contour analysis of arterial waveform
Mean arterial pressure (MAP)	Above 70 mmHg	Invasive MAP through radial or femoral artery
Stroke volume variation (SVV)	Below 10%	Ventilation induced variability of stroke volume
Global end diastolic volume index (GEDI)	Above 600 ml/m^2	Estimated maximal volume of 4 heart chambers based on transpulmonary thermodilution curve
Central venous oxygen saturation (scO_2)	Above 70%	Blood oximetry measured by central venous catheter located at right atrium or superior vena cava
Central venous pressure (CVP)	Above 5 mmHg	Intravascular pressure measured by central venous catheter located at right atrium or superior vena cava
Extravascular lung water index (ELWI)	Below 10 ml/kg	Estimate of the intra-thoracic volume of water outside the blood vessels base on transpulmonary thermodilution
Cerebral		
Continuous eletroencephalography (cEEG)	Seizure and ischemia detection	Surface continuous EEG with quantitative parameters
Intracranial pressure (ICP)	Below 20 mmHg	Intracranial parenchymal or ventricular pressure
Cerebral perfusion pressure (CPP)	Above 60 mmHg	MAP-ICP
Brain tissue oxygen tension ($PbtO_2$)	Above 15 mmHg	Partial pressure of oxygen measured at brain tissue level
Cerebral microdialysis	Lactate/pyruvate ratio <40 and glucose >0.7 mmol/l	Lactate, pyruvate and glucose measured at brain tissue level
Brain tissue perfusion (rCBF)	Above 20 ml/100 g/min	Regional brain tissue perfusion based on thermodilution method
Depth continuous EEG	Seizure and ischemia detection	Subcortical continuous EEG
Jugular venous bulb oximetry (sjO_2)	Above 65%	Blood oximetry measured at jugular venous bulb

Table 71.1. Multimodal monitoring. Systemic and cerebral parameters.

able. The intracranial modalities are usually used as a bundle, inserted into a multi-lumen bolt and/or tunneled in, as necessary. $PbtO_2$ is a measure of tissue oxygen tension and is believed to reflect the balance between delivery, consumption and tissue diffusion of oxygen [13-16]. Microdialysis allows measurement of glucose, lactate and pyruvate in a small volume of tissue around the catheter. High lactate/pyruvate (L/P) ratios indicate anaerobic metabolism and if associated with low brain glucose, suggest tissue metabolic crisis [17,18]. Tissue perfusion around the area of the probe is estimated through a thermodilution method between two thermistors along the probe (Hemedex™) [12,19].

71.3 Goal Directed Systemic Resuscitation

Systemic hemodynamic resuscitation should always precede brain targeted interventions. Comatose patients with severe brain injury are likely to be mechanically ventilated and should be monitored with an invasive arterial line, a central venous catheter and an intracranial pressure probe. Semi-invasive continuous monitoring of cardiac output and stroke volume variation are possible through pulse contour analysis of the arterial waveform. GEDVi is used as a volumetric static measure of preload and extra-vascular lung water measurements as an indicator of pulmonary edema. Central venous pressure and central venous oxygen saturation ($scvO_2$) complement this comprehensive list of hemodynamic monitoring parameters.

Markers of end organ hypoperfusion, such as high lactate and low central venous oxygen saturation, indicate inadequate oxygen delivery and should prompt interventions in order to achieve optimal mean arterial pressure and cardiac output [9,10,20]. Assessment of fluid responsiveness should follow based on GEDV and stroke volume variation (SVV). SVV greater than 10% and GEDVi less the 600 ml/m^2 generally indicate that the patient will respond to a fluid challenge with either 500 ml of crystalloid or 250 ml of colloid [21]. An increase in cardiac output confirms the response to the fluid challenge.

After optimal preload is achieved, MAP should be maintained above 70 mmHg with norepinephrine and cardiac index kept above 2.5 l/min/m^2 with dobutamine or milrinone, if necessary. After hemodynamic stabilization, end organ perfusion parameters should be reassessed. Urine output >0.5 ml/kg/h, clearance of arterial lactate, $scvO_2$ >70% and delta a-v ΔCO_2 <6 are good indicators of effective systemic resuscitation.

71.4 Multimodal Monitoring and Goal Directed Cerebral Resuscitation

The goal of advanced neuromonitoring in patients with severe brain injury is to allow early detection of complications and ensure adequate delivery of oxygen and nutrients to the brain in order to avoid permanent damage. After the primary event, a number of processes can lead to secondary brain injury. Nonconvulsive seizures after traumatic brain injury, vasospasm after subarachnoid hemorrhage, expansion of the hematoma after intracerebral hemorrhage and increased ICP after cardiac arrest are examples of detectable complications that progress in the ICU and can be captured by comprehensive monitoring of brain function [22-31]. Early detection and prompt intervention can potentially prevent irreversible damage.

Continuous multimodality neuromonitoring includes ICP, $PbtO_2$, microdialysis, continuous EEG (surface and depth) and tissue perfusion. These probes are introduced at the bedside through a multi lumen bolt and/or tunneled in subcutaneously. All the data is stored and continuously displayed at the bedside along with systemic monitoring parameters.

An integrative approach to brain oxygenation, metabolism, electrical activity and perfusion allows the clinician to understand the pathophysiology of events and to individualize clinical therapy. Small elevations in ICP below traditional thresholds may compromise perfusion and lead to brain tissue hypoxia and metabolic crisis. Early treatment to optimize perfusion may reverse these alterations and avoid a vasodilatory cascade that leads to refractory intracranial hypertension [32]. Similarly, a reduction in regional blood flow to ischemic levels may cause reduced alpha/delta ratios, elevated lactate/pyruvate

ratios and low $PbtO_2$ [14,18,33]. Early CPP optimization and balloon angioplasty may also reverse ischemia and avoid permanent deficits.

CPP is the primary determinant of cerebral blood flow and oxygen delivery to the brain [34-36]. It is thus a powerful and practical tool at the bedside to achieve adequate balance between oxygen and nutrient delivery and the brain's metabolic demand. Instead of relying on arbitrary thresholds to target CPP, functional assessment of the brain permits goal directed management of cerebral hemodynamics and individualized targets of optimal CPP.

The main goals when optimizing CPP are to maintain $PbtO_2$ >15 mmHg, sjO_2 >65%, L/P ratio <40 and regional perfusion >20 ml/100 g/min [18,37]. The first step is usually to optimize cardiac preload with fluids in patients who are fluid responsive. Once adequate preload and an SVV<10% are achieved, MAP and cardiac output can be improved with vasopressors and inotropes, respectively. We initially keep cardiac index above 2.5 and CPP above 60 mmHg.

CPP and cardiac output, though critically important, are only 2 pieces of the homeostatic puzzle where factors such as blood rheology, serum osmotic pressure, glucose and arterial pO_2 influence ongoing neuronal injury. Taking into account the complexity and interactions between these variables, efforts are undertaken to adjust sedation, serum osmolarity, blood glucose control and exclude surgical complications through neuroimaging while hemodynamic is optimized.

When brain physiological targets are not yet achieved, further efforts to increment CPP and cardiac output are undertaken. Supranormal levels are defined as optimal if they correlate with improvements in the cerebral oxygenation and metabolic profile.

71.5 Specific Situations

71.5.1 Subarachnoid Hemorrhage (SAH)

Patients with aneurysmal SAH are at increased risk for rebleeding, hydrocephalus and vasospasm. The highest rates of rebleeding occur in the first 3 days after SAH and surgical clipping or endovascular coiling of the ruptured aneurysm should be pursued as soon as possible after admission. While the aneurysm is unsecure, systemic hypertension should be avoided but hemodynamic stability is crucial to avoid cerebral hypoperfusion, acute ictal infarcts and cerebral circulatory arrest [38].

Liberal fluid resuscitation with crystalloids is commonly necessary in poor grade SAH patients before securing the aneurysm. Although frequently hypertensive, patients are admitted with relative intravascular volume depletion – due to natriuresis and systemic inflammatory response – and 2 l of normal saline are acutely administered to maintain organ perfusion. If a MAP goal of 70 mmHg is not achieved, norepinephrine is initiated. If, instead, the MAP is higher than 130 mmHg or systolic blood pressure is above 180 mmHg, continuous infusion of nicardipine is started to avoid unsafe blood pressure levels.

Comatose patients with suspected hydrocephalus should emergently have an extraventricular drain (EVD) placed and ICP monitored [38]. Once the aneurysm is treated and multimodality monitoring data is available, optimal CPP should be pursued as described previously.

Vasospasm is a major concern after SAH, especially between days 4 and 14 after the initial hemorrhage. Up to 50% of patients will develop symptomatic vasospasm after SAH. Especially those who present with diffuse and thick cisternal blood are at increased risk

for delayed infarcts due to vasospasm. There is increasing evidence that multimodality monitoring allows detection of cerebral ischemia due to vasospasm before clinical signs develop [14,15,18,27,33]. Integrating electrical activity monitoring through quantitative EEG, oxygenation with $PbtO_2$ and oxidative metabolism measured by microdialysis may create a window of opportunity for intervention before clinical signs appear and permanent deficits take place. Recent evidence suggests this window may vary from hours to a few days [17,39].

Dynamic changes in alpha/delta ratio, a relative reduction in $PbtO_2$ or elevation in lactate/pyruvate ratio should alert the bedside nurse or clinician of potential ongoing ischemia. Repeated clinical and transcranial Doppler examinations usually follow. If vasospasm is suspected, especially in a comatose or sedated patient, a perfusion CT scan is indicated to evaluate the extent of the perfusion deficit. At the same time a trial of increased CPP and cardiac output is undertaken with reversal of the altered parameter as the goal. A positive response to improved cerebral blood flow is seen within minutes for the continuously measured $PbtO_2$ and qEEG parameters and is reflected in the next 1 to 2 hours of microdialysis measured lactate and pyruvate. If a positive response is achieved, these supranormal levels of cardiac output and CPP are defined as optimal. Caution is advised in patients with stunned myocardium for excessive MAP and CPP may result in increased left ventricular afterload and lead to reduced cardiac output and pulmonary congestion [40]. Angiography and definite treatment with intra-arterial vasodilators and balloon angioplasty are often necessary for refractory symptomatic vasospasm [41].

71.5.2 Traumatic Brain Injury (TBI)

A recent update of the Brain Trauma Foundation Guidelines for the management of patients with severe TBI addresses the evidence available on CPP management, including the role of brain tissue oxygenation and metabolism [37]. It suggests there is a clinical threshold of CPP, between 50 and 60 mmHg, below which cerebral blood flow is compromised and poor outcome is more likely. Studies have shown that CPP values below 60 mmHg are associated with low $PbtO_2$ and jugular venous oxygen saturation and that these findings are related to poor outcome. Microdialysis studies have also suggested that ischemia, as measured by altered L/P ratios, is more frequent when CPP trends below 50 mmHg.

The guidelines' update also emphasizes recent evidence from a randomized clinical trial comparing treatment based on CPP and ICP goals. CPP was kept above 70 mmHg in one group while the other group was treated to maintain ICP below 20-25 mmHg and avoid CPP <50 mmHg. There was no difference in outcome between the 2 groups and the CPP-based management group had a five-fold increased incidence of acute respiratory distress syndrome (ARDS) [42].

Similar results were found in a retrospective analysis of a RCT where CPP-targeted therapy was associated with ARDS and this complication was strongly related to vasopressor administration [43].

The body of evidence available suggests that finding an optimal CPP is crucial to the management of patients with TBI [37]. The optimal level should be individualized after assessing cerebral autoregulation, oxygenation, metabolic and electrical profiles and their responses to changes in CPP. We assess autoregulation in the acute phase after severe TBI through the moving correlations between MAP and ICP (pressure reactivity index) [44,45] and CPP and $PbtO_2$ (oxygen reactivity index) [46]. Impaired autoregulation indicates that cerebral blood flow is dependent on CPP and that unnecessary high CPP

levels may lead to increased cerebral blood volume and intracranial pressure. Initially we avoid CPP levels below 60 mmHg. Intracranial pressure levels above 25 mmHg are treated with sedatives/analgesics and osmolar therapy followed by hypothermia and barbiturates in refractory cases [37]. Concomitantly, optimal CPP is pursued.

Cardiac preload assessment always precedes efforts to increase systemic vascular resistance with vasopressors and myocardial contractility with inotropes. The goal is to avoid CVP <5 mmHg, keep GEDVi >600 ml/m^{2}and maintain stroke volume or pulse pressure variation below 10%. Extreme caution to avoid unnecessary fluid overloading is warranted during the course of fluid resuscitation. We prefer using fluid boluses of crystalloid as needed instead of continuous infusion of large volumes of fluid. After every fluid challenge cardiac output improvement is reassessed. Ineffective fluid challenges will fail to increase cardiac output and thus cerebral blood flow, and contribute to pulmonary edema. Although we do not consider high extravascular lung water measurements as a contraindication to fluid administration, special caution is warranted in patients with values above 10 to 15 ml/kg [5,47].

Vasopressors and inotropes should be initiated for patients who fail to maintain minimum values of CPP (>60 mmHg) and cardiac output (>2.5 l/min/m^2) after fluid resuscitation. The next step is to titrate CPP and CI to meet individual needs based on physiological information from multimodality monitoring. In patients that present with reduced $PbtO_2$ and elevated L/P – less than 15 mmHg and above 40, respectively – despite hemodynamic stability, a trial of increased CPP and/or cardiac output is attempted [48,49]. Dynamic improvement of oxygenation and metabolism suggest that the supranormal values achieved are necessary to maintain brain homeostasis and avoid secondary injury.

71.5.3 Intracerebral Hemorrhage (ICH)

The presence and severity of acute hypertension may affect outcome after intracerebral hemorrhage (ICH). There is reasonable evidence that elevated admission BP is associated with increased risk of deterioration, death or dependency after ICH [22,29]. Though, the target BP to pursue and the drug of choice to achieve it are still a matter of debate. Recent guidelines suggest maintaining SBP below 160 mmHg and MAP below 110 mmHg in patients at risk for deterioration and high ICP during the acute phase after ICH [50]. We usually start a continuous infusion of nicardipine in all ICH patients with SBP greater than 160 mmHg or MAP greater than 110 mmHg.

Comatose patients with intracranial mass effect associated with the hematoma or perihematomal edema regularly undergo multimodal monitoring. The main objective is to achieve adequate BP control without compromising cerebral perfusion and metabolism. Some authors suggest there is a penumbra region around the area of the hematoma with impaired autoregulation and at risk for ischemia [51]. The monitoring probes are usually directed to the ipsilateral hemisphere in the perilesional region. This approach to probe placement may potentially detect regional hypopefusion and diagnose expansion of perihematomal edema.

Initial CPP is targeted between 60 mmHg and 80 mmHg and finer adjustments are made based on $PbtO_2$ and microdialysis values. If CPP levels of 60 to 70 mmHg are tolerated without evidence of brain tissue hypoxia or metabolic distress MAP is titrated to achieve this goal with either vasopressors such as norepinephrine or vasodilators such as nicardipine. Although the relationship between hematoma growth and hypertension is still controversial, CPP levels above 80 mmHg are usually avoided in the first 72 hours post ICH and, when deemed necessary, titrated with extreme caution.

71.5.4 Post Cardiopulmonary Resuscitation

There is little evidence on CPP management in patients that survived a cardiac arrest, especially after hypothermia was instituted as an evidenced-based treatment by the International Liaison Committee on Resuscitation (ILCOR) [52-54]. Furthermore there is negligible data and experience with intracranial multimodal monitoring of these patients [31].

Cardiac arrest causes a global ischemic injury to the brain followed, after return to spontaneous circulation (ROSC), by a potentially harmful reperfusion injury. Patients that survived cardiac arrest used to have devastating outcomes, especially those with delayed time to ROSC and non ventricular fibrillation rhythms [53,55]. Since hypothermia was incorporated to the armamentarium of treatment for these patients, improved outcomes have been consistently shown in clinical trials and real world case series, even for severely ill patients with cardiogenic shock and time to ROSC of up to 30 minutes [53].

Although hypothermia can potentially ameliorate the effects of a global hypoperfusion injury to the brain, we believe it should be part of a comprehensive approach to avoid secondary injury that includes systemic and cerebral hemodynamic management guided by multimodal monitoring. Continuous EEG and jugular bulb oxymetry monitoring have been shown to be associated with outcome after cardiopulmonary resuscitation [56-58]. Studies conducted before the hypothermia era suggest that the presence of non-convulsive status epilepticus (NCSE) and elevated jugular bulb saturation indicate poor prognosis. More extensive monitoring of cerebral function including intracranial pressure, tissue oxygenation, metabolism and perfusion may help titrate systemic drivers of cerebral blood flow such as CPP and cardiac output. All patients treated with hypothermia after cardiac arrest in our ICU undergo invasive arterial pressure, semi-invasive cardiac output and continuous EEG monitoring. Initial hemodynamic goals include euvolemia – optimized preload – with MAP above 80 mmHg and CI above 2.5. If post resuscitation myocardial stunning is present, patients may require vasopressor and inotropic support to achieve these goals and care should be taken not to overload the patient and cause impaired lung gas exchange. Once multimodal monitoring data is available hemodynamic variables are titrated to keep CPP >60 mmHg, ICP <20 mmHg, CBF >20 ml/100 g/min, $PbtO_2$ >15 mmHg and L/P ratios <40. These levels are derived from other scenarios of severe brain injury and need to be tested in prospective trials of patients after cardiopulmonary resuscitation.

With increasing numbers of patients undergoing hypothermia treatment in the post resuscitation phase and more comprehensive monitoring of cerebral function, the pathophysiology of the ischemia-reperfusion injury caused by cardiac arrest will be better understood. This can potentially lead to specific approaches that avoid secondary injury during the hypothermia, rewarming and post rewarming phases. We believe that better understanding and targeted treatment can further improve outcomes of cardiac arrest survivors.

71.6 Conclusions

CPP management after severe brain injury is part of a comprehensive approach that includes goal-directed systemic and cerebral hemodynamic management. The first step should always be to achieve optimal preload and adequate volemic status through targeted fluid resuscitation. Vasopressor and inotropic support may be necessary at this early resuscitation phase to guarantee systemic end-organ perfusion.

Optimal CPP is then pursued. In general, the goal of achieving optimal CPP is to guarantee adequate delivery to meet the brain's metabolic demands. CPP and cardiac output are major determinants of CBF. Thus, oxygen and nutrient delivery to the tissue are directly related to CPP and cardiac output. The purpose of multimodal monitoring is to allow goal-directed management of cardiac output and CPP guided by measures of brain tissue perfusion, oxygenation and metabolic function. This approach allows not only early detection of harmful complications but also guides treatment towards a healthier profile of brain function, potentially preventing secondary brain injury and improving patients' outcomes.

72 Pathophysiology and Management of Cerebral Vasospasm after Aneurysmal Subarachnoid Hemorrhage

Fred Rincon [1], Stephan A. Mayer [2]

[1] Department of Medicine, Division of Neurology, Critical Care and Cardiovascular Diseases, Cooper University Hospital, Camden, USA
[2] Department of Neurology and Neurosurgery, Division of Neurocritical Care, Columbia University Medical Center, New York, USA

72.1 Introduction

Subarachnoid hemorrhage (SAH) from spontaneous rupture of cerebral aneurysms of the base of the brain is the cause of 5-10% strokes annually in the United States [1]. Epidemiological studies suggest that the incidence rates vary substantially according to the geographic region with the highest rates seen in Japan and Finland [2,3]. The mortality after SAH has historically been high, ranging from 30-70% and about 10-20% of these patients experience severe long-term neurological disability. Approximately 12% of these patients will die before arriving to the hospital, 25% of patients will die within 24 hour before any medical or surgical intervention; and historically 40-60% will die within 30 days of admission [4]. The outcome after SAH depends on several factors, including age, the severity of the ictus, medical management strategies, and the incidence of medical complications [5].

One of the most important complications seen after SAH is cerebral vasospasm (CV), which occurs in up to 70% of the survivors. The incidence of CV correlates with a 1.5-3 fold increase in the baseline mortality [4]. The diagnosis of CV may be suspected on the basis of daily thorough neurological examinations, variations of transcranial Doppler (TCD) waveforms and results, and with cerebral angiography, which serves as the gold standard for its diagnosis. Most often, CV begins on the third day after SAH (index day 3), and reaches its acme on the 6th to 8th day after the ictus. The symptomatology is related to the vascular region of cerebral ischemia, and if CV is severe enough and remains untreated, cerebral infarction may occur. Aside from its effect on mortality, one of most important aspects of CV is its refractoriness to established medical interventions, thus emphasizing the need for additional research into the physiopathology of SAH-induced cerebrovascular dysfunction. Although it is well recognized that the volume of blood on computed tomography (CT) is the most reliable prognostic factor for developing vasospasm [6], the precise pathophysiology of CV remains poorly understood.

72.2 Pathophsyiology of Cerebral Vasospasm

Since the demonstration of arterial narrowing during CV by Ecker in 1951 and Weir in 1978 [7,8], it has been shown that SAH is associated with arterial narrowing, which in

turn may be related to cerebral ischemia, infarction, and increased morbidity and mortality. Important well studied variables associated with the development of CV include: hemoglobin products, entotelin-1 (ET-1), and decrease of nitric oxide.

72.2.1 Hemoglobin

When ferrous hemoglobin is released from the blood in the subarachnoid space, it leads to delayed arterial spasm by physiopathologic mechanisms that are poorly understood. According to Pluta et al. [9], explanations for this phenomenon include: neuronal apoptosis, scavenging or decreased production and levels of nitric oxide (NO), high ET-1 levels, direct oxidative stress on smooth muscle cells, free radical production and lipid peroxidation of cell membranes, modification of potassium and calcium channels, and differential gene upregulation. Oxidative stress in the subarachnoid space has also been reported to activate protein kinases. In this particular scenario, C and Rho kinase activation lead to smooth muscle cell constriction. Rho kinase in particular, initiates vascular contraction through protein kinase C-δ activity, which also induces proliferation and growth of vascular smooth muscle cells, a possible mechanism for the phenotypic change and remodeling of vascular smooth muscle seen in vasospasm [9]

72.2.2 Endothelin 1

After experimental isolation of a potent vasoconstricting peptide known as ET-1 from pig endothelial cells, elevated levels of this protein were also seen in the cerebrospinal fluid of patients and animals with CV. It appears that oxy-hemoglobin causes an increase in ET-1 synthesis from endothelial cells. Similarly, astrocytes may synthesize ET-1 in response to ischemia and leucocytes that have infiltrated the subarachnoid space after SAH may produce ET-1 as well. Furthermore, cerebral arteries may become sensitized to ET-11, leading to increased cerebrovascular tone even in the absence of an increase in ET-1 levels [9].

72.2.3 Nitric Oxide

Inhibition of smooth muscle relaxation can also cause or contribute to arterial narrowing because of the basic myogenic tone of the cerebral vasculture. Nitric oxide (NO) is a potent vasodilator produced by the endothelium, and plays an important role in the maintenance of cerebrvascular tone. According to Pluta et al, several mechanisms have implicated NO in the physiopathology of vasospasm after SAH: 1) the disappearance of neuronal NO synthase immunoreactivity from arteries in spasm, 2) endothelial NO synthase dysfunction in cerebral vessels after SAH, and 3) the affinity for NO of the heme moiety in hemoglobin [9]. New strategies for NO-based therapy against vasospasm include: gene therapy, pre-clinical and early clinical trials of NO donors administered intra-arterially, intrathecally, locally or intravenously [9].

72.3 Medical Treatment of Cerebral Vasospasm

Medical treatment in the Neurological Intensive Care Unit (NICU) is instituted in all SAH patients with adequate hemodynamic support, nutritional support, prevention of fever, hyperglycemia, and of medical complications.

72.3.1 Fluid Management and Normovolemia

Maintenance of normovolemia is key in the management of SAH patients (Diringer et al. 2011; Solomon et al. 1988), though the prophylactic use of the so called "triple – H therapy" (hypervolemic, hypertensive, hemodylution) is not indicated as initial management, it is occasionally instituted for those patients with confirmed vasospasm (Lennihan et al. 2000). The rationale of "Tiple-H" in the management of cerebral vasospasm is that the maintenance of high circulating blood volume may be associated with enhancement of CBF in the setting of vasospasm. This observation has recently been challenged by studies that have demonstrated that CBF is mainly dependent on the induced hypertension component rather than the volume component (Muench et al. 2007). Current guidelines for the management of SAH do not endorse the use of "Triple-H" therapy in the setting of cerebral vasospasm but on maintancence of euvolemia (Diringer et al. 2011).

72.3.2 Calcium Antagonists

Of the numerous types of calcium channel blockers, nimodipine is the most widely administered based on its relative selectivity for dilation of the cerebral arteries as compared to the systemic vasculature. While nimodipine does not appear to decrease angiographic vasospasm, multiple trials have shown it to improve outcomes by decreasing the incidence of cerebral ischemia [11,12]. A dose of 60 mg PO q4h in normotensive patients or 30 mg PO q4h in hypotensive patients can be administer up to index day 21.
Nicardipine is another dihydropyridine calcium antagonist that displays regional selectivity on vascular smooth muscle. Unlike nimodipine, nicardipine may be administered intravenously. Initial dose-escalation studies demonstrated that intravenous nicardipine results in angiographic and symptomatic improvement in patients with vasospasm, with higher doses being limited by medical complications such as hypotension, pulmonary edema, and renal failure [13]. Subsequent prospective, randomized controlled studies have demonstrated that while nicardipine significantly lowers the incidence of documented vasospasm, it confers no benefit in neurologic outcome [14-16].
Recent trials have tested the efficacy of local prolonged-release nicardipine-loaded polymers implanted at the time of aneurysm clipping into the basal cisterns close to the proximal cerebral arteries, with the medication being released over 14 days. The second work confirmed reductions in vasospasm (ARR 66%) and delayed ischemic lesions (ARR 33%) with significantly better outcomes [17,18]. This type of therapy is a promising alternative for the management of vasospasm but needs further study in randomized controlled setting.

72.4 Endovascular Treatment

Angioplasty and intra-arterial vasodilators, either alone or in combination, are the mainstay of therapy of vasospasm after SAH.

72.4.1 Balloon Angioplasty

Angioplasty commonly results in excellent, and nearly always permanent, angiographic reversal of vasospasm. By stretching the artery, balloon dilatation leads to an immediate and profound impairment in smooth muscle function, with in vitro and in vivo studies demonstrating both a functional and morphologic change in these fibers. Observations

indicate that earlier treatment with balloon angioplasty for patients with medically intractable vasospasm may result in better clinical outcomes. Rosenwasser et al. sought to define a time frame in which balloon angioplasty would be maximally effective and determined that early treatment within 2 hours was associated with better angiographic outcomes and clinical improvement [19].

72.4.2 Intra-arterial Vasodilators

The ability to reach distal vessels beyond the limits of balloon angioplasty makes intra-arterial administration of vasodilator an attractive approach to endovascular treatment of vasospasm. Papaverine, a non-specific smooth muscle relaxant, has been used in refractory vasospasm but recent reports concerning its plausible association with worsening focal cerebral edema and seizures have limited its use with newer agents such as verapamil and nicardipine being preferred in most centers despite the lack of head to head trials.

72.5 Novel and Experimental Treatment

72.5.1 Drainage of Clots and CSF Manipulation

Initial experience in Japan has demonstrated that CSF clearance by lumbar drainage provided protective effects against vasospasm (ARR 34%) [20]. Similarly, fenestration of lamina terminailis has shown to reduce the incidence of vasospasm in preliminary studies [21].

72.5.2 Statins

In a retrospective series, patients who received statin therapy for at least 1 month before SAH demonstrated an 11-fold decrease in the risk of developing symptomatic vasospasm after SAH and a recent prospective, double-blind, randomized placebo-controlled clinical trials of statins given for 14 days after SAH, the incidence of symptomatic cerebral vasospasm was significantly reduced in treated patients [22-24].

72.5.3 Clazosentan

There have been many clinical trials, but until the arrival of clazosentan, a selective endothelin 1A receptor antagonist, it has not been possible to reproducibly break the chain of vasospasm. Clazosentan did, however, effectively prevent and reverse arterial narrowing in one work, providing what was thought may at last be an effective treatment. However, the subsequent multicenter CONSCIOUS trial, despite significant reductions in angiographic vasospasm, failed to show any effect on long-term outcome [25].

72.5.4 Fasudil

Intra-arterial fasudil hydrochloride (a Rho-kinase inhibitor) is part of the multimodal therapy strategy after SAH in some centers in Japan, along with the use of cisternal urokinase injection, drainage of subarachnoid blood, and strict maintenance of conventional medical therapy. The results of this multimodality treatment strategy with fasudil when compared with patients without multimodal therapy was a decrease in incidence of vasospasm from 57% to 37% with subsequent reduced morbidity and mortality.

72.6 Conclusions

Cerebral vasospasm is as an important cause of poor outcome after an otherwise successful treatment of aneurysmatic subarachnoid hemorrhage (SAH). Current manage-

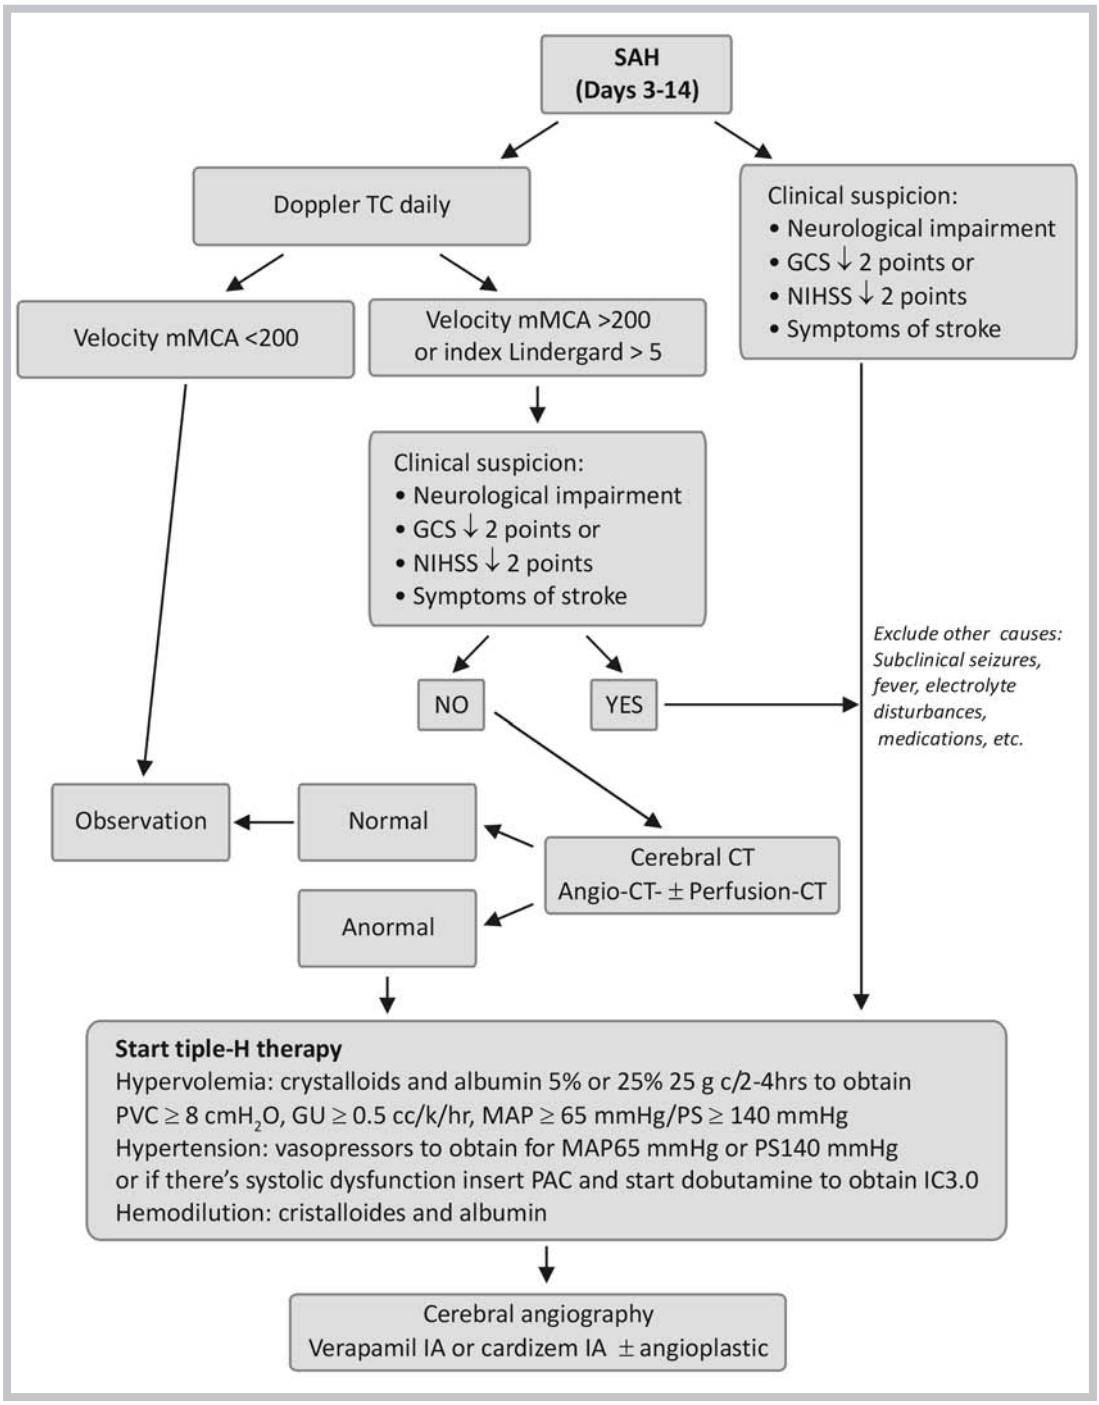

Figure 72.1 **Management of cerebral vasospasm after aneurysmal subarachnoid hemorrhage. Columbia University Protocol.**

ment of this condition includes maximal medical therapy with a regimen of euvolemia and induced hypertension, oral calcium channel antagonists, and with endovascular approaches. Novel and exciting alternatives are being studied and the development of promising alternatives will likely follow [26].

Figure 72.1 summarizes the management of cerebral vasospasm after aneurysmal subarachnoid hemorrhage according to Columbia University Protocol.

73 Intensive Care Management of Poor-grade SAH Patients. An Overview

Gerrit Alexander Schubert [1], **Claudius Thomé** [1]

[1] Department of Neurosurgery, Medical University Innsbruck, Austria

73.1 Introduction

Subarachnoid hemorrhage (SAH) still poses a significant challenge to neurocritical care, as its cumulative morbidity and mortality remains persistently high, despite continuous research efforts. Diagnostics, monitoring and treatment are certainly a multidisciplinary effort, involving neurosurgeons, neurologists, neurointerventionalists and intensive care physicians alike.

Patients suffering a spontaneous, non-traumatic subarachnoid hemorrhage (incidence 10-15/100.000 per year) usually complain of a split-second onset of most severe headache. It is often accompanied by neck stiffness, and patients may demonstrate (transient) focal neurological deficits or even sudden loss of consciousness. Despite the characteristic symptomatology many patients are presented to a dedicated neurovascular center only in a delayed fashion. Cumulative mortality may amount up to 50%, with 10-15% of all patients with SAH not reaching a treatment facility in time.

The severity of SAH is commonly graded according to the initial neurological presentation: the Hunt and Hess grading (HH) [2] or the World Federation of Neurological Surgeons score (WNFS) [1]. Overall morbidity and mortality are clearly associated with the initial neurological deficit and increase dramatically with HH or WFNS grade (i.e. survival in HH IV-V as low as 20%). Patients with poor-grade SAH (HH IV-V) account for about 20-30% of all patients admitted with SAH, and they require the most intensive, highly specialized neurocritical observation and treatment. At the same time they may represent the group of patients who benefit the most, since 40% will achieve a favorable outcome with sophisticated treatment while 90% will die or become severely disabled if not treated adequately.

73.2 Diagnostics

Initial work-up includes cranial computed tomography (CT) to show characteristic hyperdense distribution of the extravasated blood within the subarachnoid space; sensitivity for SAH is 98% within the first 12 h, decreasing thereafter. If the initial CT is negative, but SAH is suspected, a lumbar puncture has to be performed to rule out recent hemorrhage. As acute SAH is caused by an intracranial aneurysm in 85% of cases, CT is then followed either by CT-angiography (CTA) or conventional digital subtraction angiography (DSA) and three-dimensional reconstruction, the choice of diagnostics means depending on the institution´s infrastructure. CTA being an inexpensive and less invasive diagnostic tool, it can be performed immediately after the initial CT scan. It is now gen-

erally considered to yield sufficient information about the source of bleeding to develop a treatment plan, in particular if DSA is not readily available. However, in up to 20% of cases, aneurysms smaller than 4 mm or particularly close to the skull base may be missed due to limitations in collimation or imaging artifacts. Depending upon the preference of the treating physician, an additional conventional angiography should be obtained, if the quality of CTA is limited or CTA is negative despite typical localization of subarachnoid blood.

73.3 Early Management

Upon completion of the initial work-up poor-grade SAH patients should be admitted to an ICU facility as soon as possible. Patients usually present hypertensive, and an arterial line for blood-pressure management is mandatory. Early re-rupture of an unsecured aneurysm is estimated to occur in 4% of cases within the first 12 hours, but this risk may increase to 20% in poor-grade SAH, and it increases overall mortality to over 70%. We generally advocate a target systolic blood pressure of 120-140 mmHg before the aneurysm is secured, also carefully avoiding critical hypoperfusion and infarction. Alpha- and beta-receptor antagonists such as labetalol are preferred over cerebral venodilators such as nipride and nitroglycerine. Other general monitoring parameters include continuous ECG and oxygen saturation, to detect detrimental arrhythmias or hypoxemia; ECG abnormalities are estimated to occur in 50 to over 90% of patients, though the significance in the acute phase is not clear. Intubation and central line access is required in all comatous or unstable patients. If the patient cannot be sufficiently assessed clinically (neuro checks to be performed hourly) or impending hydrocephalus is suspected (generally in about 20% of patients, but more frequent in poor-grade cases), an intracranial pressure monitoring should be put into place, preferably an external ventricular drain with the option of ICP treatment by drainage. Single-shot antibiotic prophylaxis before insertion is recommended while continuous use of antibiotics is not. While ventriculitis due to the indwelling catheter is a potential complication, the risk of infection may be reduced by tunneling the drain, but not by frequent exchange of the catheter. If an EVD or intraparenchymal pressure measuring device is in place, cerebral perfusion pressure (CPP) can be calculated and corrected to be above 60 mmHg. Patients should observe strict bed rest with the head and upper torso elevated around 30°; they should receive adequate analgesia and provocative actions such as Valsalva maneuvers (e.g. during defecation or vomiting) should be minimized through use of laxatives and antiemetics respectively. Any coagulation pathology should be corrected rapidly, antifibrinolytic agents should be avoided and coagulation factors, thrombocytes or vitamin K are substituted as needed.

73.4 Treatment of the Aneurysm

While there is general consensus that a ruptured aneurysm should be secured within the first 48-72hrs and as completely as possible in order to minimize the risk of recurrent hemorrhage, there is also persistent debate as to how these aneurysms should be treated. The ISAT study compared clipping of an aneurysm with coiling and found a 7% reduction in morbidity associated with interventional treatment [3]. However, only 4.4% of patients investigated presented with poor-grade SAH, and conclusions from this study have to be drawn cautiously when discussing treatment option for patients HH° IV-

V. Also, analysis of this data does not take into account neither the anatomical location, configuration or orientation of the aneurysm, nor the particular expertise and infrastructure available in the respective department. Therefore, no general recommendation can be derived from this study for patients with poor-grade SAH. The interdisciplinary decision has to be made on an individual basis of numerous considerations in each case, and complimentary use of both techniques may represent an additional option. While smaller aneurysms presenting with a high dome-to-neck ratio (usually greater than 1.5:1), particularly in the posterior circulation, may be amenable to interventional treatment, blister-like aneurysm with particularly fragile wall-composition, broad-based or partially thrombosed aneurysms or those involving several efferent vessels (such as many MCA aneurysms) may be better suited for open surgery and reconstruction, possibly with additional options such as revascularization through bypass-application; space-occupying lesions such as intracerebral hemorrhages or subdural hematomas may also advocate for an open approach with the chance of evacuation. Another advantage is the option of opening up Liliquist membrane or the lamina terminalis to potentially reduce the risk of hydrocephalus. It remains a matter of debate, whether the so-called "definite" treatment (clipping) may indeed be superior to a technique that shows compaction and re-perfusion in follow-up angiography in 50-70% of coiled aneurysms, particularly in larger aneurysms (greater than 8-10 mm). The clinical implications of these differences, for example in younger patients, are still unclear, as longer follow-ups of aneurysms with reperfusion characteristics are still lacking. In poor-grade patients often demonstrating brain swelling and intracranial hypertension, an interventional approach may be preferable, particularly if the patients is clinically unstable or in severely reduced physical condition (with a rate of favorable recovery of about 35%); securing the aneurysm can facilitate more aggressive medical treatment afterwards, despite a higher rate of neck remnants or reperfusion in this particular subgroup. An open operation, in many instances, poses a greater immediate, perioperative risk of complications in a critically ill patient. However, one has to also appreciate the duration of the treatment, and difficulties in coiling due to the location or a particularly complex anatomy of the aneurysm might also favor a direct and open approach. Recently, the surgical approach has been greatly facilitated by the introduction of intraoperative indocyanine-green videography, where complete occlusion of the aneurysm and perfusion of important perforators can be assessed immediately [4].

Morbidity and mortality remain high for both coiling and clipping in patients with poor-grade SAH, but some studies have shown considerably better outcome in patients HH IV (44%) vs. HH V (13%). Age is another strong predictor of poor outcome. If elderly and/or multimorbid patients present with a prolonged comatous state (HH V, GCS 3-4), severe SAH on imaging scan and/or an absence of improvement after successful ICP management, the initial decision can be deferred to first determine the chance for meaningful recovery. Despite the data supporting the early exclusion of an aneurysm from the circulation, in these rare cases, observation and conservative treatment might constitute a sensible alternative to aggressive early treatment, including surgery.

73.5 Late Management

Once the aneurysm is secured, restrictions in blood pressure can be lowered. Spontaneous blood pressure may be allowed, although a minimum CPP of 60 mmHg should always be maintained. As soon as intracranial pressure and hemodynamics as well as ventilation parameters are stable, sedation should be weaned to determine neurological

function. Depending on the initial severity of the hemorrhage (and possibly on the severity and duration of intracranial hypertension), recovery of function might be protracted. This holds true for those patients with higher HH grade in particular. The following parameters of metabolism and electrolyte balance have been shown to significantly improve outcome and recovery and should be adhered to strictly:

- Hemoglobin >10 g/dl.
- Normoglycemia.
- normocarbia; pO_2 >100 mmHg.
- Normotermia.
- Intravenous fluid management: 0.9% normal saline 140-150 ml/h with 20 mEq KCl/l; central venous pressure greater than 4 mmHg.
- Enteric nutrition with continuous infusion from day 2 onwards.

Additional neuroprotective measures such as hypothermia (33-34°C) may improve outcome, but they are employed only in some centers; hypothermia in particular requires an extensive infrastructure as well as a great expertise, as complications such as coagulopathy, arrhythmia and overwhelming infections are frequent. The use of prophylactic anticonvulsants is controversial, but is advocated by some centers but not all (peri/postoperative risk about 4%; load with IV phenytoin, if needed); use of steroids is not recommended. To avoid gastric stress ulcers, treatment with proton pump inhibitors is advocated. Cerebral salt wasting and SIADH are frequent complications after SAH, causing profound hyponatremia and worsening in outcome, therefore warranting tailored fluid treatment and/or the use of hydrocortisone. Other common complications after SAH include (neurogenic) pulmonary edema (23%) and arrhythmias (25-100%), as well as imbalances in hemostasis and electrolytes (28%), sepsis, meningitis and multi-organ failure; and again, patients in poor-grade SAH are at higher risk for developing these complications. Physical therapy is recommended early on to avoid development of contractures and thrombosis, the risk of the latter also being reduced by routine use of (sequential) compression devices or stockings.

73.6 Management of Elevated ICP

Elevated ICP on the basis of hydrocephalus is a frequent complication after SAH (incidence 20-25%, posterior > anterior circulation) and is more common in poor-grade SAH patients and in patients with intracerebral or intraventricular extension of the hemorrhage. While sometimes mechanical blockage of intraventricular foramina due to intraventricular blood clots prevents drainage into the spinal canal, most often a compromised re-absorption of CSF is assumed, a term phrased malresorptive hydrocephalus. This is believed to result from occlusion of the villi within the plexus/ependyma and is treated with placement of an intraventricular catheter. ICP in an awake patient should not exceed 25 mmHg (20 mmHg in sedated patients), however, transitory increases (possibly due to external manipulation, pulmonary complications or coughing) can be tolerated if recovery is prompt and does not exceed more than 10-15 minutes. In rare cases, patients may be awake and asymptomatic with an elevated intracranial pressure of more than 30 mmHg, and while this probably does not pose a significant risk for the patient, the relevance of these findings is still not completely clear. Technical problems have to be ruled out, but asymptomatic increase in ICP may also be the first symptom of hyperemia. In fact, elevated ICP might be caused by a variety of other reasons, the most serious being global parenchymal swelling, intraventricular/intraparenchymal hemorrhage or space-occupying ischemia. If ICP is not amena-

ble to immediate relieve via CSF drainage, the following actions should be considered in consecutive order:

- Exclude new pathology (urgent CT scan, check serum electrolytes).
- Deep sedation (with continuous EEG monitoring): morphine/benzodiazepines (may consider barbiturate coma).
- Moderate hyperventilation (pCO_2 of 32 mmHg, only in absence of severe vasospasm or eminent infarction).
- Mannitol IV 125 ml/q4h until effect is only short lasting.
- Consider placing a lumbar drain (only with well defined basal cisterns) and use as needed (check pupils for signs of herniation).

Hypertonic saline solution, repeat as necessary until critical sodium level.
Consider decompressive craniectomy in selected patients.
If the ICP is controlled for more than 48hrs without or decreasing amount of CSF drainage, test occlusion under neurological monitoring is advocated to determine the necessity of further CSF drainage. Slow weaning by way of increasing outflow resistance (elevating the draining valve successively higher) has been not proven to be more beneficial than abrupt closure of the drain. About 50% of poor-grade patients will require permanent drainage, i.e. a ventriculo-peritoneal/-atrial shunt.

73.7 Management of Delayed Vasospasm

Delayed vasospasm occurs angiographically in up to two-thirds of patients, while symptomatic ischemia is present in about 30% of patients. Outcome is affected adversely, and vasospasm is the most significant cause for morbidity and mortality of those patients reaching medical care in time. Monitoring poor-grade SAH patients is essential to detect neurological deterioration, since the incidence of vasospasm is highest in this group: HH I 22%, HH V 74%. Our department has developed a standardized approach for SAH patients to detect and treat vasospasm (Figure 73.1). First choice of monitoring always includes neurological assessment if the patient is rousable without focal neurological deficit. If a patient recovers after the initial insult and is awake for several days after the treatment of the aneurysm, neurological assessment in combination with transcranial doppler sonography (TCD) may be sufficient monitoring to exclude clinically relevant vasospasm. However, as most patients with poor-grade SAH do not recover sufficiently to be monitored clinically, discussion of most further treatment issues has to be focussed on intubated patients with impaired consciousness. Despite its limited sensitivity, TCD is an established bedside tool, where flow of the intracranial vessels can be assessed non-invasively. Usually, the flow velocity within the proximal MCA is measured for the ease of accessibility from the second day after hemorrhage. Not only absolute flow values are important in the management decision (norm ~55cm/s); while an increase of more than 50cm/s from one day to the other or an absolute flow exceeding 160cm/s may already raise suspicion as to the development of vasospasm, the Lindegaard index (ratio of flow velocity within the MCA/extracranial ICA) is more sensitive and specific. An index of greater than 3 is highly suspicious of ensuing vasospasm (which should prompt further diagnostics including conventional angiography), while increased flow velocities and an index of less than 3 may indicate hyperemia. If the latter scenario coincides with refractory elevation of ICP, a quantitative measurement of CBF, such as XeCT may help to frame a therapeutic decision, such as moderate hyperventilation to minimize the effects of hyperemia and/or lower ICP.

Conventional angiography, however, is still considered the gold standard in the diagnosis of vasospasm. It should be performed routinely on day 7-9 after SAH where the risk of vasospasm is highest. Imaging may also serve as a control for clip- and coil-positioning and determine the necessity of further follow-ups (conventional angiography versus CTA or MRA). If angiography demonstrates significant vasospasm, adequacy of cerebral perfusion is the main goal of future treatment. In selected cases, spontaneous upregulation of mean arterial blood pressure and tachycardia is observed, and this might suffice to prevent critical hypoperfusion. A new deficit in an awake patient (new focal deficit, confusion/lethargy, neglect) should always prompt rigorous assessment of hemodynamics and the need of further imaging. CT scanning can exclude hydrocephalus and subacute infarction. However, if CT scanning is normal, but hypoperfusion due to impending vasospasm is suspected, mean arterial blood pressure should be increased to levels above 90 mmHg empirically until diagnostics such as angiography can be performed.

If a patient cannot be assessed clinically, as is the case in most poor-grade SAH patients, the need for further means of monitoring arises. ICP measurement is mandatory in all unconscious patients, and elevation should be treated accordingly (see above). For the treatment of vasospasm, our department has implemented a modified approach to the widely-used concept of triple-H therapy (hypertension, hypervolemia, hemodilution), a therapy concept both moderately plausible but unproven at the same time. Since complications such as pulmonary edema, myocardial infarction and electrolyte imbalance are frequent (20-30%), the widely propagated hypervolemia has been omitted since its efficacy is not proven and reduction in regional cerebral blood flow has been observed [5]. Moderate hemodilution with a hematocrit around 30-35% is usually achieved automatically when keeping patients normovolemic after surgery. While sedation sometimes is required, depending on the severity of vasospasm a mean arterial blood pressure of at least 100 mmHg (or sometimes >120 mmHg) is mandated, usually requiring the use of vasopressors. The efficacy of hypertension has to be assessed either by way of intermittent global CBF measurements (such as XeCT, to some semiquantitative extent also perfusion CT or MRI), more practical, however, are continuous measurements. Various, validated intraparenchymal probes exist to indirectly measure CBF (thermal diffusion flowmetry=TDF probe; brain tissue oxygen tension=$p_{ti}O_2$ probe) or the change in local metabolism (microdialysis). As the area of parenchyma analyzed with these probes is spatially very restricted, the application of this technique to detect distant vasospasm may be limited as well, but their usefulness to estimate efficacy of treatment has been repeatedly demonstrated. Placement of the probe is essential and should be aimed at potential areas of misery perfusion. In most cases, placement may be guided by angiography, which identifies hypoperfused territories at greatest risk for infarction. It seems plausible to guide treatment according to the results obtained within these critical regions, since they are most vulnerable and are likely to turn ischemic. Even though pathophysiology may vary significantly throughout the brain, it is suspected that “healthy” territories are less susceptible to modulation and are more robust to changes in perfusion. Different ranges of critical values have been identified for most methods. The critical threshold for $p_{ti}O_2$ (usually advocated over holohemispheric measures such as jugular venous oxygen saturation=$S_{jv}O_2$) and the thermal probe is generally considered to be around 10-15 mmHg and 15 ml/100 g x min respectively, with values below indicating impending hypoxia or ischemia. For microdialysis, a variety of metabolic markers can be analyzed. Lactate, the calculated ratio of lactate and pyruvate as well as glutamate mirror the extent of change towards anaerobic metabolism, with an increase implying ischemia. However, it has to be stated critically, that these metabolic markers usually are only obtained after a relevant change in metabolism has already occurred and therapeutic relevance remains limited.

ICH = intracerebral hemorrhage
IVH = intraventricular hemorrhage
MAP = mean arterial pressure

There is continuous effort to prevent the development of vasospasm, and an abundance of studies is available regarding its etiology and possible treatment options. Inflammation as well as scavenging of nitric oxide by oxyhemoglobine and liberation of ET-1 are only some of the major pathways currently open for discussion as to the development of vasospasm. At present, therapy mostly consists of minimizing the effects of vasoconstriction. One of the most widely used and most extensively studied prophylactic treatment involves calcium antagonists such as nimodipine, the only FDA approved medication. Interestingly, however, only oral nimodipine was found to effectively reduce neurological deficits and improve overall outcome (doses usually starting at 60 mg/q4h, than tapering after 8-14 days) [6] with no apparent effect on angiographic vasospasm; neuroprotective effects or improvement of collateral circulation are assumed. Contrarily, intravenous calcium antagonists are prone to cause hypotension due to their vasodilatatory function. The use of IV nimodipine in poor-grade patients who cannot take oral medications (crunched tablets have shown to have significantly lower efficacy) and have a high risk of impaired autoregulation, has to be viewed critically. Application of magnesium sulphate might be useful, as hypomagnesemia occurs in up to 50% of cases and is also associated with the occurrence of delayed ischemic deficits and poor outcome, convincing evidence, however, is lacking as well.

CPP-monitoring is essential to avoid the risk of critical hypoperfusion. Angiography followed by either mechanical dilatation (transluminal balloon angioplasty=TBA) or application of intraarterial vasoactive substances such as papaverine (usually 200-300 mg applied over 30 mins) or calcium antagonists are other treatment options at institutions where an experienced neurointerventionalist is available. Their effectiveness, however, is usually limited to cases with localized, preferably single-vessel narrowing, and a preceding CT scan without signs of infarction. In those selected cases, repetitive treatment may be necessary, and generalized or diffuse multi-vessel vasospasm is mostly less susceptible to this kind of intervention. TBA in poor-grade patients is associated with worsening in outcome. An ongoing multicenter investigation is looking into the benefits of emergency angiography followed by vasodilatatory measures versus conventional, conservative treatment in those patients who develop new focal deficits without signs of infarction on recent CT scan.

One recent study has analyzed the effect of clazosentan, an ET-A receptor antagonist that experimentally has been shown to ameliorate the deleterious effects of ET-1 in particular [7]. While angiographic vasospasm and incidence of ischemia was influenced favorably, overall clinical outcome did not change significantly. Other multicenter trials are concerned with the role of NO-donors, statins and magnesium sulfate in ameliorating cerebral vasospasm. The application of slow release pellets of nicardipine, deposited intraoperatively in close proximity of larger vessels has gained substantial interest as of late, as the occurrence of vasospasm and subsequent infarction is significantly lower in those patients [8]. It will be the aim of future investigations, if treatment with nicardipine pellets remains equally effective when applied intraventricularly only, a treatment option tailored specifically for patients treated interventionally, as is suggested in many poor-grade SAH patients.

73.8 Conclusion

The treatment of subarachnoid hemorrhage is particularly challenging in poor-grade SAH patients, as morbidity and mortality increase exponentially. After successful treatment of the offending aneurysm, close neurological and multimodal monitoring are es-

sential to anticipate potentially treatable complications such as refractory ICP elevation and delayed vasospasm in order to improve overall outcome.

74 Paroxysmal Sympathetic Hyperactivity in the Neurocritical Care Unit: Definition, Clinical Picture, Etiology, Diagnosis and Management

Ian J Baguley [1]

[1] Clinical Senior Lecturer, University of Sydney and Honorary Associate Professor, Macquarie University, Australia

74.1 Introduction

Elevated physiological parameters are extremely common following severe acute neurological insult. For example, such features occur in between 62% [1] and 92% [2] of patients admitted to the intensive care unit (ICU) following traumatic brain injury (TBI). However, a smaller number of such patients develop excessive sympathetic responses that have the potential to produce additional morbidity. This latter group represents an ill defined and under-recognized disorder that is known by various names but termed paroxysmal sympathetic hyperactivity (PSH) in this article. Using PSH to describe this condition was suggested by Rabinstein in 2007 [3] and represents a more accurate clinical description of the syndrome than other frequently used terms such as dysautonomia, sympathetic storm and paroxysmal autonomic instability with dystonia (PAID) [4]. In particular, PSH is a more specific term than dysautonomia and identifies the dominant role of the paroxysmal sympathetic overactivity, while not limiting motor activity to dystonia as suggested by the term PAID. There are currently at least 5 sets of overlapping diagnostic criteria used to describe the syndrome, the first proposed in 1999 [5].

In the first weeks post injury, individuals with PSH show frequent, prolonged and intense episodes of sympathetic and motor overactivity, often occurring on a background of elevated heart rate (HR) and temperature. The paroxysmal sympathetic changes are variable in severity but include documented heart rates up to 190 beats per minute, respiratory rates of 60 breaths per minute, core temperatures up to 42°C, blood pressures of 170/120 mmHg and sweating severe enough to affect the patient's fluid balance [5]. This sympathetic hyperactivity is accompanied by assorted forms of motor overactivity such as decerebrate or decorticate posturing, dystonias, rigidity and spasticity. The pattern of posturing is most often asymmetrical and may not fit into classical decorticate or decerebrate postures [6].

The impact that PSH has on heart rate can be seen in Figure 74.1. This 24 hour Holter monitor data comes from an individual 28 days post TBI. Mean daily HR was 129 beats per minute (bpm), ranging from a minimum of around 70 to a maximum of 182. As can be seen, the subject had multiple paroxysmal episodes over the 24 hours, each lasting

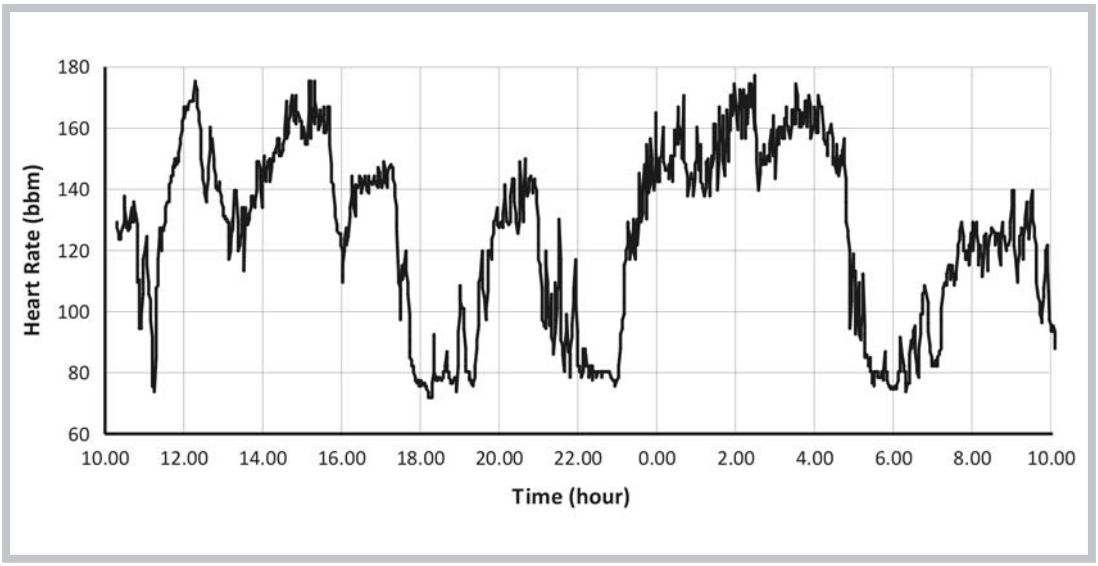

Figure 74.1. **Minutely Heart Rate in an untreated dysautonomic subject (heart rates are minutely values derived from a 24 hour Holter monitor recording).**

between 2 and 6 hours. While the subject had several episodes with heart rates below 80 bpm (amounting to 11% of the day), heart rates above 140 bpm totaled 39% of the day.

With increasing time post injury, paroxysms decrease in duration, frequency and magnitude. The reduction in severity of paroxysms usually coincides with an observable improvement in neurological status [5,7], although whether this is causative or an epiphenomena has not been identified. As subjects improve, paroxysms become rarer and resting blood pressure, respiratory rate, heart rate and temperature trend towards normal values.

While TBI accounts for an estimated 80% of published cases of PSH, many other neurological disorders have been reported to cause PSH. These include (in order of decreasing frequency) severe hypoxic brain injury, stroke (hemorrhagic stroke in particular), acute hydrocephalus and tumors. There are also isolated case reports of uncommon etiologies, such as PSH following infection [8] and hypoglycemic coma [9]. However, despite the wide range of etiologies associated with the disorder, the limited available data suggests that the syndrome itself is equivalent irrespective of the causative condition.

74.2 Pathophysiology

The earliest theories for PSH suggested that seizure activity was the likely etiology [10]. For this reason the syndrome was termed diencephalic epilepsy. However, multiple attempts to either identify or treat epilepsy in these patients have produced negative results (for example [7,11-14] The limited autopsy and pathophysiological data suggest the syndrome results from a relative disconnection of pathways at or around the level of the midbrain (reviewed in [15]).

Most disconnection theories suggest that paroxysms are driven by upper brainstem and diencephalon lesions, with clinical features arising from either excitatory or inhibitory centers in these areas. However, more recent evidence suggests that spinal cord pro-

cesses are instrumental in initiating the condition. Two studies have assessed the effect of standardized nociceptive stimuli in driving paroxysms. In the first study, endotracheal tube suctioning of severe TBI survivors on day 7 post injury found that PSH subjects had heart rate increases of twice the magnitude (16% vs. 8% averaged over 100 beats) and of longer duration when compared to non-PSH subjects [16]. In a separate study, subjects with PSH a mean of 5 years post injury (the majority of whom were no longer exhibiting paroxysms) showed disproportionately excessive sympathetic responses to the nociceptive stimulus of botulinum toxin A injections [17]. These studies provide empirical support to anecdotal reports dating back to 1954 [18] that multiple physical stimuli can provoke sympathetic paroxysms.

When considered as a whole, the literature suggests that PSH results from a combination of both cerebral and spinal cord changes. A theoretical model, the Excitatory/Inhibitory Ratio (EIR) model, has been proposed to promote testing of the interaction of spinal and cerebral influences on PSH [19]. This model highlights the previously noted physiological similarities of PSH and autonomic dysreflexia [20,21] (that is, sympathetic over-responsivity to stimuli resulting from the loss of supraspinal inputs) and combines them under a common pathophysiological process. This integrative model suggests that the causative brainstem centers are predominantly inhibitory in nature, and that damage to these structures predisposes the spinal cord to overreact to afferent stimuli in a manner akin to that which produces allodynia (where non-painful stimuli become perceived as nociceptive) [22].

74.3 The Clinical Relevance of PSH

In injury severity matched cohorts, prolonged PSH is associated with worse outcome following severe TBI [5,8]. Such individuals have been found to have prolonged swallowing abnormalities, longer duration of coma and post traumatic amnesia [5]. In addition, subjects with PSH often display features consistent with “locked-in” syndromes [2,23], a situation that can result in under-managed pain or a misdiagnosis of persistent vegetative state. Affected individuals show reduced capacity for voluntary movement, particularly during paroxysms, and may be exacerbated by under-managed spasticity and dystonia [5]. In addition, posturing subjects show increased metabolic rates [24,25] resulting in a highly catabolic state [26] and an estimated 25% loss of body weight in the first weeks post injury [2]. Affected individuals have also been found to be significantly more likely to develop heterotopic ossification [27]. These factors combine to place the individual at risk of developing critical illness or compression neuropathies, longer hospital admissions [2,5] and greater overall health care costs [2]. It has been argued that early identification of PSH may minimize unnecessary diagnostic testing [28], promote timely and appropriate intervention [29]. and minimize secondary morbidity [5,30].

As recovery continues, posturing patterns may change, revealing an underlying spastic tetraplegia or other focal neurological deficit. Most subjects are left with some permanent degree of dystonia and spasticity [2]. Sweating patterns change from whole body to upper trunk, head and neck, before ceasing entirely [31]. Three studies have reported changes in sweating in a longitudinal fashion. In two of these, paroxysmal diaphoresis resolved a mean of 2.5 months post injury in 35 subjects [5] and 5.9 months post-injury in 87 subjects [8]. In another study, 22 of 31 subject’s features had settled by 6 months post injury [32]. While the overt features of sympathetic hyperactivity settle over time, the tendency to display paroxysmal tachycardias remains evident for at least 14 months post injury [30].

74.4 Management

Despite the impressive nature of the symptomatology and the largely circumstantial evidence promoting the importance of early intervention, there is surprisingly little literature available to guide management [4,21]. As the diagnosis of PSH is currently one of exclusion, other primary disease processes such as acute hydrocephalus and sepsis need to be considered and treated. Various autonomic emergency syndromes with similar symptom complexes (for example, malignant hyperthermia and neuroleptic malignant syndrome) should be ruled out. A careful examination for evidence of triggering [16] and treatment of potential noxious stimuli (such as undiagnosed fractures, heterotopic ossification, pressure areas, painful spasticity or dystonias, infection, etc.) may decrease the frequency or severity of paroxysms [21,33]. In this context, one author has suggested pre-treatment of patients prior to nociceptive procedures being undertaken to reduce "triggering" of paroxysms [33].

In spite of these possible interventions, conservative measures alone are rarely sufficient to control the paroxysmal sympathetic overactivity in severe cases. Although a large number of medications have been used to treat the condition, information regarding their efficacy is largely restricted to anecdotal reports and has been reviewed elsewhere [3,4,21,34]. Accepting the limitations of current literature, a range of medications from many classes of neurologically active agents may be beneficial. In particular, these medications include alpha and beta antagonists, dopamine agonists, GABA A and B agonists, opioids and gabapentin.

The most effective intervention appears to be intrathecal baclofen (ITB), with anecdotal reports of a large reduction or cessation in paroxysmal sympathetic overactivity [29,35-38] However, deciding when to consider implementing ITB therapy can be difficult. Many subjects will exhibit paroxysmal overactivity lasting for only a few months [5,27], the procedure is invasive and has a relatively high complication rates (20-50% [39]). On the other hand, ITB is also effective for managing spasticity [40] and this may have long-term advantages in such patients. Intravenous morphine and midazolam are also effective, but their sedative effects limit their usefulness during rehabilitation [21].

Gabapentin has been reported to reduce the number and severity of sympathetic paroxysms [9,29] and allowed an overall reduction in other medications, including ITB, without a recurrence of symptoms [29]. However, the drug should be trialed at a low starting dose (e.g., 100 mg) to minimize the risk of marked bradypnea or sedation, presumed to result from a sudden loss of sympathetic drive [14].

Drugs with sympathetic activity have also been commonly used. Of the beta-blockers, propanolol has the largest literature base, with mixed reports between those where it has been useful and where it has been unable to control paroxysms [4]. Recent research suggests that beta-blockers improve survival post TBI [41] and propanolol has long been known to decrease catecholamine levels following TBI [42,43]. Labetalol has little literature available, evenly split between beneficial and unhelpful. Clonidine also reduces catecholamine levels [44], but has been reported to be useful in less than half of the cases in the literature [4]. It has been suggested that clonidine may control sympathetic crises but requires high doses (for example, 800 µg 2nd hourly) [45].

Several other pharmacological agents show a mixed picture in terms of efficacy. Dopamine agonists, predominantly bromocriptine, have a patchy literature of cases with at least partial efficacy versus where no effect was observed [4]. Benzodiazepines also present a mixed picture, with anecdotal reports favoring diazepam and midazolam [7]. Drugs that have been reported to be ineffective include methadone [7,11], metoprolol [13,29,33], oral baclofen [7,35], and phenytoin [11,28,46]. Oral dantrolene has been reported to be unhelpful in all but one patient [7,11,47].

It is readily apparent that there is insufficient available literature to provide a definitive protocol to guide management. However, in terms of minimizing the possibility of adverse drug reactions, it would appear appropriate to utilize morphine/midazolam, gabapentin and/or propanolol in the first instance. There are occasional reports of excellent efficacy with bromocriptine, suggesting it may have a secondary role. ITB is most useful in cases that are resistant to oral medication, are of greater severity or longer duration.

74.5 Current Controversies

Despite increasing research into PSH over the last decade, the current estimated incidence of the condition varies across a considerable range (between 8 and 33%) [4]. Also complicating the literature are the large number of synonyms used for the condition (around 33 in total), most of which have only been used once or twice in the literature. The more commonly used names include dysautonomia, autonomic dysfunction syndrome, paroxysmal sympathetic storms, paroxysmal autonomic instability with dystonia and so on [4]. Another difficulty with research into the condition is the 5 current sets of overlapping diagnostic criteria [5,27,34]. In addition, it has recently been suggested that the concept of "triggering" of paroxysms following minor stimuli has been proposed as a clinical sign that may help to differentiate individuals with and without the syndrome [16]. While moves to critically appraise these criteria have begun [48], there is insufficient research available to be able to establish consensus criteria at this time.

Linked in with the issue of the lack of diagnostic criteria, there has also been a lack of quantitative mechanisms to investigate the pharmacological management of dysautonomia. Dysautonomic subjects tend to show marked day to day variability in their presentation (as illustrated in Figure 74.1) and an appropriate research tool would need to accurately measure the frequency, severity and duration of paroxysms over time. Recently, a number of tools have been proposed to overcome this limitation including event related heart rate changes and heart rate variability paradigms, either over 5 minute intervals [16] or 24 hour time scales [9]. Research techniques such as these are required to raise awareness of the syndrome and to properly evaluate treatment efficacy.

74.6 Key Concepts

Research suggests that PSH is a distinct but under-recognized clinical syndrome that can result from numerous forms of acquired brain injury. While short duration sympathetic hyperactivity does not appear to be associated with worse outcome, clinical research suggests that prolonged dysautonomia places a considerable burden on both patient and health care services. There is potential for reducing this burden through timely recognition and intervention, however, the field is hampered by a lack of clinical awareness, a poor understanding of pathophysiology and anecdotal management protocols. Investigatory techniques are becoming available that will allow the development of evidence based treatment paradigms for the first time. However, due to the relatively low incidence of the condition, multicentre research using standardized nomenclature and diagnostic criteria will be required to achieve this aim. It is hoped that more effective treatment protocols will, in turn, result in improved outcomes for individuals affected by this condition.

75.1 Introduction

At first glance, the term "neuromuscular weakness" may lead a reader's mind to consider the neuromuscular junction as the region of most interest; however, this couldn't be further from the truth. Neuromuscular weakness can result from insults to the spinal cord, motor neuron, root and nerve, neuromuscular junction or muscle. In general, and due to the diverse clinical settings in which neuromuscular weakness can present, some key points are universal to all. First, use a systematic approach to localizing the weakness to the brain, spinal cord, peripheral nerves, neuromuscular junction or muscle. Next, in importance is to review all data included in the medical chart. In addition, obtain a history from family members to establish the patient's baseline neurologic and mental function prior to admission. Common risk factors for acquired neuromuscular weakness to keep in mind include autoimmune disorders, steroid use, sepsis, the systemic inflammatory response syndrome (SIRS), multi-organ failure, and extended duration of intubation. Physical examination should be conducted with an emphasis on the distribution of weakness, reflexes and sensory exam. When it is time to complement the examination with objective testing, electrodiagnostic studies such as nerve conduction studies, electromyography, repetitive nerve stimulation (train of four), somatosensory evoked potentials (SSEP) and electroencephalogram are crucial. These studies help to place the lesion in the central versus the peripheral nervous system, establish if the patient is globally weak but cooperative versus encephalopathic and neuropathic versus myopathic. This chapter discusses diseases based upon their anatomical location and begins by describing the clinical presentation and exam. Next, diagnostic and management strategies key to patients are described.

75.2 Spinal Cord

75.2.1 Normal Spinal Vasculature

Spinal cord injury due to ischemia is not a common presentation (1-2%) with respect to vascular neurology; however, this group of diseases and their respective clinical syndromes require clinicians to act immediately. We begin by briefly describing the normal vascular supply to the entire adult spinal cord in a general manner to help provide a framework to understand spinal cord injury. Next, we will discuss the salient clinical features, exam findings, diagnostic and management principles of a few important causes of vascular myelopathy.

Three major arteries, two posterior spinal arteries and one anterior spinal artery, dominate the spinal cord vasculature. The two posterior spinal arteries begin as branches off of each vertebral artery, respectively. The anterior spinal artery is formed by one branch off each vertebral artery, which then joins to form the anterior spinal artery. Contributing to the anterior spinal artery blood volume in the cervical and high thoracic region is a group of radicular arteries originating from the vertebral artery, the deep cervical artery, and the ascending cervical artery. The mid-thoracic region (T3 to T7) is often considered a "watershed region" due to its lack of a substantive, major feeding artery to the anterior spinal artery blood volume. The next major contribution to the anterior spinal artery comes in the low thoracic high lumbar region called the arteria radicularis anterior magna (artery of Adamkiewicz). The artery of Adamkiewicz is a major feeding artery that contributes to the anterior spinal artery by supporting arterial blood supply to the spinal cord from T8 to the conus medullaris. The posterior and anterior spinal arteries communicate with each other through multiple small vessels at each spinal level.
The spinal cord venous system is similar to its arterial counterpart because of its anterior and posterior arrangement. Here, the venous system incorporates one large posterior spinal vein and one anterior spinal vein. When visualized, both the anterior and the posterior spinal vein run along the midline of the cord. Unlike the arterial system, the posterior one half of the spinal cord will drain into the posterior spinal venous system and the anterior one half will drain into the anterior venous system. The deep veins of the spinal cord parenchyma drain the right and left half of the cord, respectively, and anastomose with their respective central spinal vein. Each spinal cord segment is connected by a valveless external and internal venous plexus. These plexuses ultimately drain into multiple radicular veins located throughout the length of spinal cord.

75.2.2 Anterior Spinal Artery Syndrome

In general, the anterior spinal artery supplies the anterior two-thirds of the spinal cord. Within the anterior two thirds of the spinal cord itself are major tracts that carry ascending and descending information. The clinically relevant tracts are the corticospinal and the spinothalamic tracts which are responsible for motor and sensory (pain and temperature) modalities, respectively. Ischemia to the anterior spinal artery can occur due to:

- Occlusion secondary to external compression (bone fragment, herniated disk).
- Aortic dissection.
- Vasculitis.
- Atherosclerosis of the aorta.
- Postinvasive vascular or thoracoabdominal surgery.
- Fibrocartilaginous embolism.
- Systemic hypotension due to shock or cardiac arrest.
- Angiography.
- Vertebral artery dissection (often traumatic).
- Arterial embolic phenomena.
- Cocaine abuse.
- Hypercoagulable state.

At onset, symptoms tend to evolve over minutes. Initially, pain or paraethesias can be reported in a radicular/girdle-like distribution or ascending from the lower extremities. As soon as the pain is noticed, the patient may begin to sense motor dysfunction below the highest vascular level of ischemia. The most common motor presentation is paraplegia due to spinal shock; however, ischemia to the corticospinal tract above C7 can produce quadriplegia in selected patients. Development of peak motor symptoms can take

up to 12 hours; and, in addition to motor deficits, the key feature on clinical examination is a new separation of sensory modalities. A sensory level (loss of function) to pain and temperature can be demonstrated below the level of the lesion, while the patient's dorsal column function (preserved deep pressure sensation, joint position sense, two-point discrimination and vibration) remains intact. Furthermore, ischemia will also affect the autonomic pathways, resulting in the loss of bowel, bladder and sexual function. Vascular supply to the spinal cord has been oversimplified for the sake of our discussion, but the examiner must remember that a measurable degree of variability between persons exists and that some patients may present with a patchy distribution of symptoms. Initial examination of patients with anterior spinal artery ischemia should demonstrate areflexia, sensory level to pain/temperature and flaccid weakness below that level in the early stages. Over time, due to the destruction of the corticospinal tracts, the patient's initial flaccid paralysis will transition into upper motor neuron signs and spasticity in the neurological exam. Unless contraindicated, contrast-enhanced magnetic resonance imaging (MRI) is the initial imaging modality of choice for acute spinal cord injury due to ischemia; however, imaging within the first 24 hours after symptom onset may or may not demonstrate an abnormality. This said, MRI soon after the initial clinical examination is very helpful to rule out extrinsic causes of myelopathy and hemorrhage. After 24 hours, MRI in more than 50% of patients will demonstrate appreciable abnormalities on primary T_1 and T_2-weighted sequences. First, attention to the T_2 sequence may demonstrate a hyperintense, pencil-shaped lesion in the anterior aspect of the cord that studies suggest is seen in patients with anterior spinal artery syndrome. Fat saturation suppression sequence can help delineate if there is vertebral bony infarction as well, which is also associated with anterior spinal artery infarct. In addition, most authors agree that swelling of the spinal cord will be seen by the fifth day as a T_2-weighted hyperintensity and increase in spinal cord caliber. Diffusion weighted imaging (DWI) of the spinal cord is a potential tool, but current variability of image quality due to surrounding artifacts increases the false positive rate, making DWI not very reliable at this time. Angiography does play a role if T_2-weighted images reveal a "flow void" or dilated vessels on the surface of the spinal cord. Radiographic evidence of abnormal vessels, either extramedullary or intramedullary, may suggest that a spinal vascular malformation is present. Finally, the natural evolution of anterior spinal artery ischemia is visible with serial MRIs. T_1 contrast enhancement will demarcate the infarct, some hemorrhagic transformation (hyperintensity on T_1-weighted images) may be seen, and eventually cord atrophy will be the end result. Cerebrospinal fluid (CSF) evaluation does not help to rule out disease; and, unless spinal vascular malformation has been ruled out, lumbar puncture is a relative contraindication because it can create a pressure gradient that could lead to further spinal cord infarction. There are no clear management strategies for spinal cord ischemia. Acute placement of a lumbar drain has been performed with the goal of improving perfusion pressures. Further management principles should mirror those derived from cerebral stroke guidelines, which include permissive hypertension, fever control and avoidance of both hyperglycaemia and hyponatremia. Prognosis varies from case to case, but it should include aggressive physical rehabilitation. The only long-term complication that has been established as secondary to spinal cord ischemia is neuropathic pain which takes months to present and may or may not develop in all patients.

75.2.3 Spinal Vascular Malformations

Spinal cord vascular malformations are a group of rare and complicated vascular malformations that account for 15% of space-occupying lesions in the spinal canal. There are

several classifications based on various anatomical and radiographic features. For this chapter, we will discuss spinal arteriovenous malformations (S-AVMs) and dural arteriovenous fistulas (D-AVFs) separately.

Dural arteriovenous fistulas (D-AVFs) are the most common type (70%) of spinal vascular malformations. They are commonly found in the mid-thoracolumbar region and most often in men. Initial presentation is often after the fourth decade of life, and since they present later in life, they are thought to be acquired lesions. D-AVFs can be classified as being located intradural (most common) or epidural, and can be further distinguished based on one or multiple arterial feeders. Intradural D-AVFs are highly unlikely to rupture or enlarge enough to cause mass effect; instead, the most consistent course of the pathology is venous hypertension due to the transmission of arterial pressures without an intervening capillary bed. In addition to venous hypertension, the decreased arteriovenous perfusion gradient causes suboptimal drainage of the surrounding normal spinal veins, which results in spinal cord edema. Over time, this process leads to enlarged, engorged and tortuous veins. Both spinal cord edema and abnormal veins are often seen in tandem on MRI T_2-weighted sequences as central cord hyperintensity and "flow voids" on the surface of the spinal cord. These multiple pathologic processes work simultaneously and eventually result in progressive spinal cord ischemia and myelopathy.

Spinal arteriovenous malformations (S-AVMs) comprise a group of lesions of both acquired and hereditary origin. Multiple classifications are based on angiography, biological and genetic influences. S-AVMs are true AVMs of the spinal cord because they derive from both spinal arteries and spinal veins. If classification is based on the nidus located either intramedullary or extramedullary (perimedullary), 80% of spinal AVMs are located intramedullary and 20% extramedullary. For the purposes of this chapter, we have organized S-AVMs based on their anatomic location and features as described in Table 75.1.

Glomerular type S-AVMs are sometimes referred to as "nidus type" AVM because the nidus is quite compact and resembles those found in cerebral AVMs. The glomerular type nidus is located intramedullary, involves multiple anastomoses between the anterior and posterior spinal arterial system and is often found in the cervical or thoracic region. The term "juvenile type" is appropriate if the nidus diffusely infiltrates the spinal cord. The perimedullary type of S-AVM can be further distinguished based on the angiographically quantified volume of blood that is shunted with the amount of venous dilation present. In addition, another feature of perimedullary lesions is that they are often found near the conus medullaris. Other features of spinal AVMs that distinguish them from D-AVFs include aneurysm formation (20-40% of intramedullary S-AVMs), hemorrhage, development of a space-occupying lesion, and vascular steal phenomenon.

The initial presentation of spinal arteriovenous malformation varies widely and is based on the specific location and complexity of the malformation. Venous hypertension evolves in a chronic process; but due to the unpredictable nature of the pathology, D-AVF can present in many ways. These presentations are acute motor symptoms that can occur at any time, with slow insidious presentation over months due to a progressive myelopathy or with a relapsing remitting course. In addition, patients may also develop pain, bladder dysfunction, spasticity and sexual dysfunction. Unlike D-AVFs, S-AVMs most commonly present with hemorrhage by the third decade of life. The initial clinical presentation may be acute back pain with mixed motor and

Intramedullary	• Glomerular type – compact nidus • Juvenile type – diffuse nidus
Extramedullary (perimedullary) type	• Low shunting • Intermediate shunting • High shunting

Table 75.1. **S-AVMs classification based on their anatomic location and features.**

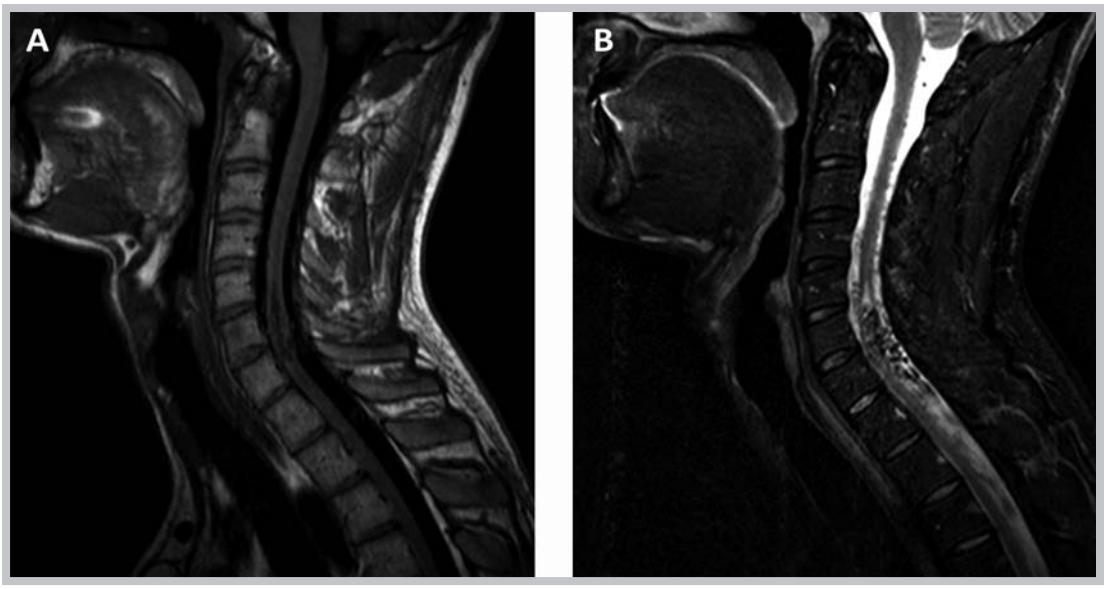

Figure 75.1. **(A). Sagittal T_1 sequence showing increased spinal cord diameter at C6-C7 and hypointense images within the cord suggesting the presence of vascular structures. (B). sensory deficits. Since hemorrhage is not a uniform process; deficits on presentation are based on the level, location and extent of insult to the spinal cord.

Neurologic examination may demonstrate both upper and lower motor neuron signs. The initial exam should involve inspection of the skin, paraspinal muscles and bone. This can provide clues to the diagnosis in the genetic and hereditary forms of S-AVMs. For both D-AVFs and S-AVMs, the initial workup of choice is MRI with contrast material. This imaging modality has supplanted plain films, computed tomography (CT) and myelography, except when MRI is contraindicated. Even when using a combination of images generated from T_1, T_2 and T_1 postcontrast weighted images, MRI may not be able to visualize what type of spinal vascular malformation is present but should be able to visualize cord edema and "flow voids". In addition, where available, MR angiography (MRA) with contrast of the spinal arterial system has been shown to help identify the arterial feeder(s). Examples are shown in Figures 75.1, 75.2, 75.3 and 75.4. Ultimately, the goal standard for the management of any spinal vascular malformation via endovascular, surgical or a combination thereof remains catheter angiography. Initial management will be determined by the presentation, evidence gathered by imaging and in consultation with neurosurgery and interventional neuroradiology. Supportive care is the mainstay of treatment until a definitive treatment plan has been decided on.

75.2.4 Acute Transverse Myelitis

Figure 75.4. Digital angiography in a patient with an arteriovenous malformation (arrows) within the spinal canal at the levels of the chest and abdomen.

Acute transverse myelitis (ATM) is a syndrome of multiple neurologic deficits due to a focal inflammatory attack of the spinal cord. Although the name may imply the pathologic process was not present until symptoms arose, ATM is often the clinical presentation of a pathologic process that was previously unrecognized, subacute, acute or chronic or secondary to another disease. Although ATM can have vascular and structural aetiologies, our focus will be on pathologic processes where inflammatory activity leads to focal demyelination or destruction of the spinal cord. Publications often state that ATM has a bimodal distribution during the first and third decades of life. In reality, this is not absolute. As we improve in diagnosing patients with multiple sclerosis, Devic's disease (neuromyelitis optica) and autoimmune-associated transverse myelitis, we encounter patients who can develop spinal cord lesions at any point during their disease. As an acute attack evolves and maximal deficits

are reached, up to 50% of patients will develop motor paralysis and 80-95% will experience sensory disturbances below the level of the lesion. The diagnosis of ATM is often secondary to another disease or medical history:

- Multiple sclerosis.
- Devic's disease (neuromyelitis optica).
- Recent infection.
- History of radiation exposure.
- Post-vaccination.
- Autoimmune-associated systemic illness.
- Neoplastic (paraneoplastic disorder or neoplasm causing compressive myelopathy).
- Idiopathic.

Since the clinical presentation will depend on multiple factors, no pathognomic sign or syndrome exists. A patient may present with his or her own distinct constellation of symptoms. When gathering the initial history of symptom presentation, "the tempo" will help differentiate inflammatory from vascular aetiology. Maximal clinical deficits should rapidly occur with vascular lesions, whereas inflammatory lesions can take up to 7 days to peak. Acute transverse myelitis occurs mostly in the thoracic region but cervical and lumbar segments are also vulnerable. Inflammatory lesions are not confined by anatomical or vascular boundaries; therefore, patients can present with a mixture of deficits in motor, sensory and autonomic function due to the compact anatomical arrangement of the spinal cord. Inflammatory ATM is often the end result of another disease process or seen for the first time in a "previously healthy" patient; hence, the past medical history, review of systems, and family history should be explored in detail. The review of system should be directed towards episodes of transient weakness, sensory disturbance, episodes of visual changes, recent febrile illness or contact with an ill person, Uhthoff's sign (worsening of neurologic symptoms during exercise or excess body heat), dry mouth or dry eyes. The family history is important to look for associated demyelinating or autoimmune diseases that run in the family. Another important feature on exam is Lhermitte's sign (electrical sensation running down the spine with flexion of the neck). On clinical exam, most patients will have a sensory level and sensory disturbance below the level of the lesion. In addition to motor weakness and sensory disturbance, autonomic symptoms such as bowel or bladder incontinence, urinary urgency, inability to completely void the bladder and sexual dysfunction can be present.

Once a complete neurologic exam has been performed and a patient demonstrates myelopathic features, an MRI with contrast should be one of the first actions taken. If MRI is contraindicated, then a CT-myelogram of the spinal cord can help to rule out compressive lesions. The first question to answer with neuroimaging is to rule out a compressive structural or vascular lesion that correlates with clinical symptoms on exam. If MRI demonstrates a compressive or vascular lesion, a neurosurgical consultation should be obtained immediately. In ATM, sagittal T_2-weighted sequences demonstrate focal area(s) of hyperintensity often associated with an increase in the calibre of the spinal cord due to inflammation and edema. If focal, isointense areas of atrophy are noted; this may suggest previous episodes of transverse myelitis. To fully evaluate a focal hyperintensity, both the axial and sagittal T_2 image sequences should be scrutinized simultaneously. Inflammatory lesions usually affect both the gray and white matter of the cord, involving up to half the diameter of the cord, and are often eccentric. Hyperintense lesions specific to multiple sclerosis should only span roughly two vertebral bodies. Lesions spanning more than three vertebral bodies imply either systemic disease associated ATM or Devic's disease. In addition to neuroimaging of the spine, MRI with contrast of the brain is also useful to understand if the current acute illness is part of a larger process. Inflammatory lesions are a dynamic process; therefore, if the first MRI obtained is "non-diag-

nostic", a repeat MRI 7 days later should be performed (Figure 75.5). Finally, if both brain and spine MRI only demonstrate spinal cord lesions, visual evoked potential (VEP) is still valuable to detect occult central nervous system (CNS) demyelination.

Diagnosis and management of patients with ATM begin with basic serology, specialized serology and CSF analysis as listed below. Basic serology is meant to establish a baseline prior to immune-directed therapy and to rule out infection. In fact, in patients with a known history of demyelinating disease, an infection could have been the trigger for the ATM attack. Specialized serology is important for two groups of patients: first, for patients with known systemic autoimmune disease and, second, for patients with no significant past medical history. For example, in patients with known systemic lupus erythematosus (SLE) it is important to establish if their disease is active or dormant in relation to the attack. The second and most important group of patients are those considered "previously healthy" yet harbouring an occult disease. Swift pursuit of the underlying aetiology has both immediate and long-term implications when treating ATM. For example, in a small group of patients with Sjögren's syndrome-associated ATM, their SS-A and SS-B serum titers can be negative on initial presentation. These patients require salivary gland lip biopsy to establish the diagnosis; however, if the biopsy is taken after multiple days of corticosteroid therapy, the biopsy results may return non-diagnostic. Furthermore, if the ATM occurred in a setting of occult autoimmune disease, then long-term treatment should incorporate management of the new diagnosis. Basic CSF studies in patients with ATM should demonstrate high protein levels and very mild pleocytosis due to breakdown of the blood-brain barrier. The remaining panel of viral PCRs (polymerase chain reaction) should be considered as well. Tests that should be performed are summarized in Table 75.2.

Figure 75.5. **MRI, sagittal T_2 sequence. Patient with ATM: extensive hyperintense area (predominantly central) involving the medulla oblongata, the whole cervical spinal cord, and the first segment of the thoracic cord.**

All of these studies are aimed to help the clinician tailor a treatment regimen that will ultimately involve immunosuppression. Historically, when treating ATM, corticosteroid therapy has been the mainstay and should begin immediately once concurrent infection has been ruled out. The CBC, urinalysis, blood cultures and CXR help to rule out infection prior to corticosteroid treatment and establish a baseline prior to therapy. In addition, a baseline CBC helps to place eventual elevation of the white blood cell (WBC) count into context due to demargination and not infection. At our institution, we treat patients for 5 days with 1 g IV solumedrol per day for an initial attack of ATM. In addition to corticosteroid therapy, advances in immune-directed therapy have added an entirely new dimension to what is available for patients affected by ATM. Intravenous immunoglobulin (IVIg) and plasma exchange have been tested in randomized trials and proved to complement corticosteroid therapy, while chemotherapies and monoclonal antibodies are now being incorporated

Basic serology	• Complete blood count with differential (CBC)
	• Comprehensive metabolic panel (CMP):
	  · Includes basic metabolic profile and liver function tests
	  · Magnesium
	  · Phosphate
	• Coagulation profile
	• Urinalysis and culture
	• Blood culture, two sets
	• Chest x-ray (CXR)

Specialized serology	• Oligoclonal bands (both CSF and serum samples required)
	• Neuromyelitis optica (NMO) antibody
	• Systemic autoimmune panel:
	  · Antinuclear antibodies (ANA)
	  · Sjögren's syndrome (SS-A, SS-B
	  · Anti-double stranded DNA antibody
	  · Rheumatoid factor
	  · Anti-cardiolipin antibody
	  · Lupus anticoagulant
	  · Complement levels
	  · Angiotensin converting enzyme (ACE)
	• Human immunodeficiency virus (HIV) and human T-lymphotropic virus (HTLV)
	• Mycoplasma titer
	• Lyme titer
	• Hepatitis panel
	• B12
	• Rapid plasma reagin (RPR)
	• Thyroid stimulating hormone (TSH)

CSF analysis	• Cell count with differential
	• Bacterial, viral and fungal culture
	• Acid-fast bacilli smear
	• Polymerase chain reaction (PCR):
	  · Herpes simplex virus I and II (VI to be considered in immunocompromised patients)
	  · Varicella-zoster virus (VZV)
	  · Cytomegalovirus (CMV)
	  · Epstein-Barr virus (EBV)
	  · Enterovirus
	  · West Nile virus
	• CSF ACE (if history of systemic sarcoidosis is present)
	• Paraneoplastic panel (patient with history of neoplasm)

Table 75.2. Serological tests.

into regimens for patients with refractory or recurrent attacks. With respect to ATM, plasma exchange versus IVIg has been a topic of debate and research; nonetheless, plasma exchange is superior to IVIg in this case for the following reasons. Plasma exchange in a setting of Guillain-Barré syndrome and myasthenia gravis has been shown to deliver immune induction slightly faster than IVIg, with a peak efficacy of IVIg 2-3 weeks after administration. Furthermore, in the author's opinion, ATM is often antibody mediated as evidenced by the long list of diseases associated with it. Moreover, our ability to identify antibodies is still limited and is demonstrated by the fact that up to one third of ATM is ultimately diagnosed as "idiopathic". Furthermore, plasma exchange offers a very effective means of initially treating patients with ATM without committing patients to long-term immunosuppression. Due to the risks associated with plasma exchange, most patients should be started on IV corticosteroid therapy, with the decision to add plasma exchange based upon the underlying aetiology, extent of neurologic deficits, and clinical judgment.

Management Principles for Plasma Exchange and IVIg

Here we will discuss some of the finer points of using plasma exchange and IVIg in clinical practice. The dosages and duration of treatment apply to ATM and the remaining diseases discussed in this chapter unless specifically stated otherwise.

Therapeutic plasma exchange was first used to treat myasthenia gravis; since then its application has been extended to treat many disease processes where antibody or suspected antibody-mediated disease occurs.

The actual procedure should be performed in consultation with the institution's blood bank. Current use of plasma exchange is based on North American and French trials, and although no "optimal" standard of care has been established, general practice still follows these studies. The goal of plasma exchange is to remove the offending IgG and IgM from the bloodstream. Studies have demonstrated that in total, 45% of IgG and 75% of IgM are located in the intravascular space. Plasma exchange every other day will rebalance the antibodies in the intravascular space, which then allows for their removal. Therefore, plasma exchange should involve 250 ml per kilogram of body weight (per exchange) every other day for a total of five exchanges. As a result, based on the kinetics (half-life) of autoantibody resynthesis (5-6 weeks for IgG and 5-6 days for IgM), therapeutic plasma exchange should offer a 1-month window to begin immune modulation if warranted. Plasma exchange itself is a very dynamic process. The fluid removed can be replaced with either albumin solutions or fresh frozen plasma (FFP). The preferred solution is 5% albumin (in saline), which significantly reduces the rate of adverse events but does not confer a therapeutic advantage; and FFP should be avoided unless required to treat a concurrent disease. Due to the need for large bore central venous access, plasma exchange requires special attention to the patient's baseline coagulation profile and platelet function.

The current and recent medications list should be screened for use of anticoagulants and antiplatelet agents such as Coumadin or Plavix, which may delay initiating plasma exchange. Due to the inherent movement of large volumes of blood during plasma exchange, anticoagulation is needed to prevent clotting. Citrate is the agent of choice and works by binding free ionized calcium from within the blood, preventing it from participating in coagulation. As a consequence, some patients may develop hypocalcaemia.

Patients should be informed that they might experience perioral and peripheral paraesthesias, which are transient and related to the plasma exchange. In addition, electrocardiographic changes including prolongation of the QT interval may also occur as a result of hypocalcaemia. A further consequence of citrate use in plasma exchange is the transient diuresis of electrolytes secondary to the renal excretion of this large cation. Another management point to consider when using plasma exchange is the fluid shifts that occur. As a result of the volume of whole blood removed from the body for exchange, hypotension can be the immediate consequence; and, once the blood is returned with 5% albumin, patients with cardiac or renal insufficiency may develop volume overload due to the oncotic pressure inherent to albumin.

Finally, due to the non-specific nature of exchanging serum plasma with 5% albumin in saline, fibrinogen and clotting factors themselves are lost in the process. This is another reason why plasma exchange occurs every 48 hours to allow for the resynthesis of fibrinogen and clotting factors. When treating a patient with plasma exchange, daily CBC, basic metabolic panel (BMP), coagulation profile and electrolyte levels (ionized calcium, magnesium and phosphate) should be performed and replacement given when needed. Once therapy is complete, removal of the central venous access should be delayed for 48 hrs until the international normalized ratio (INR) falls below 1.4.

IVIg is a pooled product derived from many patients' plasma; its mechanism of action is not fully understood. In the author's experience, the following ideas are useful to remember when treating patients with IVIg. When treating diseases discussed in this chapter, unless stated otherwise, utilize a total IVIg dose of 2 g/kg ideal body weight. This dose of 2 g/kg is given in divided doses of 0.4 g/kg per day over 5 days in order to minimize side effects in patients who have never received this medication. If future rounds of IVIg are required, in select patients the total dose of 2 g/kg can be divided over 3 days. When calculating the dosing for your patient, you may land on a dosage that is in between two vial sizes. We recommend to simply round up to the next highest dose. For example, if your calculation equals 32 g/day, round up to the nearest vial, such as a 35 g vial. Second, the clinician should be aware of common side effects (flulike symptoms, headache, hypotension, aseptic meningitis) and potential adverse events (myocardial infarction, stroke, renal failure, venous thrombosis, anaphylaxis) secondary to IVIg administration and discuss these with your patient prior to starting therapy. This will increase both adherence to the protracted time needed to infuse each dose and patient tolerance of side effects.

Subsequently, when ordering baseline serology, also include a serum IgA level to screen for patients with IgA deficiency who may be at risk for anaphylaxis. Many IVIg formulations are available. At our institution we attempt to minimize the risks by using only IgA depleted, sucrose-free IVIg. In addition, running the infusion overnight (6-8 h infusion time) minimizes patient discomfort and being bound to an IV pole. Between each infused dose of IVIg, we suggest continued IV hydration; daily basic serology (BMP, CBC, magnesium, phosphate) should be drawn with attention to changes in renal function, down trending WBC count and platelet levels or changes in electrolyte levels. Finally, 5 days of IVIg infusion and maintenance fluids may cause volume overload in some patients; therefore, concurrent use of diuretics may be warranted in those with cardiac and renal insufficiency.

75.3 Anterior Horn Cell to Neuromuscular Junction

We continue our discussion of neuromuscular weakness, transitioning from the spinal cord to anterior horn cell, peripheral nerve, neuromuscular junction. The topics discussed in this section do not represent all entities that can cause neuromuscular weakness along the peripheral nervous system (PNS); instead we have selected a few topics which are important to understand. It is essential to recognize that neuromuscular weakness in the PNS can present in multiple settings. The emergency room, after treatment of another disease, prolonged hospitalization or intensive care unit (ICU) stay, discovered postoperatively are all clinical settings in which neuromuscular weakness can clinically appear for the first time. Some examples of neuromuscular weakness due to disease of the PNS include:

- One third of patients treated for status asthmaticus.
- Prevalence of up to 46% of patients with a median duration of 7 days in the ICU who were admitted for sepsis, multiorgan failure or prolonged mechanical ventilation.
- Within the group of patients diagnosed with acquired neuromuscular weakness, the specific incidence was 34% for critical illness myopathy (CIM), 35% for critical illness sensorimotor polyneuropathy (CIP), and 30% for combined CIM/CIP in the same patient.
- The risk of acquired neuromuscular weakness is increased with elevated plasma glucose levels.

75.3.1 West Nile Virus

We begin our look at neuromuscular weakness by discussing a viral illness that can affect the anterior horn cell. West Nile Virus (WNV) was first isolated from a woman in Uganda in 1937 and the first case documented in the United States wasn't until 1999 in New York. Since then, the Centers for Disease Control (CDC) reported over 11,000 cases of this illness and over 1000 deaths as of 2007. WNV is an arthropod-borne and maintained Flavivirus which utilizes mosquitoes as vectors and birds to amplify. Based on data from 2002-2007, the peak incidence of human infection is the summer months of July through September. In addition, cases of West Nile transmission have been reported via organ transplant, blood transfusion, breast milk and transplacentally from mother to foetus. The mechanism of viral entry into the CNS is unknown, but histopathology studies demonstrate the virus has a predilection for neurons.

In the clinical arena, WNV infection leading to neurologic disease is actually quite rare. Data combined from both North America and Europe estimate that up to 70-80% of infections are asymptomatic, 20-30%, develop West Nile Fever (WNF), and only 1% demonstrate neurologic disease or West Nile neuroinvasive disease (WNND). WNF emerges after a 2-14 day incubation period with clinical signs and symptoms similar to the common flu such as headache, myalgias, weakness, fever, nausea and vomiting, diarrhoea and abdominal pain. Patients with WNF can experience lingering symptoms that last weeks to months, but usually recover without sequelae. The 1% who develop WNND can present in three different ways, or in combinations thereof. WNND can present as West Nile encephalitis (WNE), meningitis or flaccid paralysis. About 25-35% of patients will present with pure signs and symptoms of meningitis (fever, nuchal rigidity, photophobia and phonophobia) without encephalitis, whereas 60-75% patients with WNND will present with WNE. This group is characterized as having encephalitis with focal neurologic deficits such as tremor, myoclonus or Parkinsonian features (rigidity and bradykinesia). Furthermore, WNE carries a higher mortality rate of up to 20%, especially with increased age, when compared to WNF and the meningitic form. When the virus attacks motor neurons, the clinical presentation of WNV is an acute, asymmetric flaccid paralysis that begins in one or more limbs. Initially, patients may complain of pain in the limb(s) that subsequently become paralyzed. The weakness can ascend in 50% of cases to include bilateral facial muscles, but the infection should spare sensory modalities. In cases where flaccid paralysis resulted in respiratory neuromuscular weakness, the mortality increases to 50%.

Patients presenting with high fever and meningitis, encephalitis or paralysis should trigger a high index of suspicion for WNV if their history includes spent many hours outdoors during the summer months. CSF evaluation demonstrates pleocytosis, with <500 cells and often lymphocytic in predominance. Furthermore, CSF protein can be elevated and glucose should be normal. Diagnosis is confirmed by IgM antibody to WNV in the CSF if collected within 8 days of illness onset or from serum if collected within 8-14 days of illness onset. While PCR can diagnose diseases such as herpes encephalitis with great accuracy, WNV PCR is positive in only 50% of patients. What can also make arriving at a final diagnosis more difficult is that the serum test of WNV also cross-reacts with other known flavivirus infections such as Japanese encephalitis, St. Louis encephalitis, yellow fever and Dengue. As a result of WNND mimicking other diseases on initial presentation, neuroimaging and electrodiagnostic studies serve to rule out other diseases rather than rule in WNV. If WNND is suspected in the spinal cord, MRI may demonstrate T_2-weighted hyperintensity in the anterior (ventral horns) spinal cord. Ultimately, the diagnosis of WNV infection is made on the basis of strong clinical suspicion and diagnostic laboratory testing.

There is no specific treatment for any form of WNV infection and care is only supportive. Recovery from flaccid paralysis does occur, but can take many months and requires aggressive physical rehabilitation.

75.3.2 Guillain-Barré Syndrome

Guillain-Barré Syndrome (GBS) affects one to four persons per 100,000 annually worldwide and two per 100,000 annually in the United States. Most patients who experience GBS ultimately recover; however, up to 20% have permanent disability. Respiratory failure is an initial presentation in 10% of patients with 30% of remaining patients eventually requiring mechanical ventilation. If intubated, the most common causes of morbidity in a GBS patient include systemic infection, venous thromboembolism and cardiac arrhythmia secondary to dysautonomia. Two-thirds of patients, 2 to 4 weeks prior to the onset of neurologic symptoms, will have suffered from an acute illness. Upper respiratory infection, *Campylobacter jejuni* infection, and CMV are the most common preceding illnesses associated with GBS. In addition, other diseases associated with developing GBS include hepatitis, HIV, herpes virus, influenza, mononucleosis, systemic lupus and lymphoma. Also, when GBS is suspected, inquiring as to any recent vaccinations is also important because epidemiological links have been reported.

Within the first 2 weeks of symptom onset, GBS has certain typical clinical features. Symptoms begin as a progressive ascending weakness from the legs, depressed or absent reflexes and distal extremity paraesthesias. On initial presentation, patients may recall experiencing difficulty with tasks dependant on proximal muscles such as rising from a chair or climbing steps and may complain of low back pain. Acutely, the incidence of weakness is 60%, paraesthesias is 80%, both at the same time is 30%, areflexia is 70% and hyporeflexia is 30%. With time, GBS symptoms tend to evolve with increasing both the areas and magnitude involved, so a typical GBS patient will eventually have weakness in all limbs, areflexia and paraesthesias. As previously stated, weakness in a typical

GBS variants	• Miller-Fisher Syndrome: · Ophthalmoplegia, areflexia, ataxia • Axonal loss variants • AMAN (acute motor axonal neuropathy) • AMSAN (acute motor sensory axonal neuropathy) • Pharyngeal-cervical-brachial
AIDP (acute inflammatory demyelinating polyradiculopathy)	
Tick paralysis	

Poisoning	• Marine toxin ingestion: severe paraesthesia with limited weakness:
	  · Ciguatoxin (salt water fish that consume certain types of algae)
	  · Tetrodotoxin (pufferfish consumption)
	  · Saxitoxin (shellfish consumption)
	• Heavy metals:
	  · Arsenic: distal extremity paraesthesia followed by glove and stocking, large and small fibre sensory loss
	  · Gold: complication of rheumatoid arthritis treatment, polyneuropathy with or without stomatitis and dermatitis
	  · Thallium: found in rodenticides and insecticides
	• Result of homicidal or suicidal action

Table 75.3. **Differential diagnosis of a patient who presents with GBS, a GBS variant or a clinically similar picture.**

GBS patient is an ascending process beginning in the lower extremities followed by the arms; however, a minority of patients (5-15%) will clinically present with cranial nerve deficits first, then a descending pattern of weakness. Facial and neck weakness will occur in half of patients with ptosis in 5-10%, ophthalmoplegia in 15%, and oropharyngeal weakness in 40%. Diaphragmatic dysfunction is seen in up to 50% of patients, with a combination of both weak shoulder shrug and neck flexion as surrogate markers heralding diaphragmatic weakness and respiratory failure. Sensory symptoms can precede weakness by 1 to 2 weeks, with an early nondescript complaint of generalized malaise and pain (>50%) in the spine. The typical paraesthesia described by patients begins in the fingers as "pins and needles" and is seen first before sensory changes are reported in the distal extremities. As the sensory symptoms evolve, they transition from paraesthesias to a lack of sensation and numbness. Unlike weakness, sensory disturbances in the face and trunk are rare. Autonomic dysfunction, including tachy-brady arrhythmias, orthostatic hypotension, ileus, bladder dysfunction, and abnormal sweating, is seen in up to 50% of patients. Most symptoms will plateau within 2 weeks; rarely, some will take 4 weeks.

The differential diagnosis of a patient who presents with GBS, a GBS variant or a clinically similar picture is very broad and beyond the scope of this chapter, but is listed in Table 75.3.

The diagnosis of GBS is based on typical clinical presentation, lumbar puncture and neurophysiology studies (nerve conduction studies). Lumbar puncture should demonstrate elevated protein and very mild pleocytosis. Elevated CSF protein (50-200 mg/dl), which should peak between the second and third week, results from breakdown of the blood-brain barrier; moreover, a patient suspected to have GBS without elevated CSF protein for 2 weeks should be considered rare. CFS pleocytosis should be <10 cells/mm^3 within the first 2 weeks of illness. Caution should be used when making decisions in immunocompromised patients because the sensitivity and specificity of CSF studies in patients with suspected GBS are limited. Specialty serology and CSF PCR to be considered include serum anti-ganglioside antibody panel, *Mycoplasma pneumoniae* serum titre, CMVs and EBV PCR. Patients with a good clinical history and exam, even after repeatedly normal CSF examinations, still should be diagnosed with GBS until proven otherwise. Finally, nerve conduction studies should be performed to confirm the clinical diagnosis. The results will vary based on at what time point in the illness the patient was examined and which nerves were examined. A patient clinically diagnosed with GBS should demonstrate progressive loss of compound muscle action potentials (CMAPs), slowed nerve conduction velocities and loss of F wave and/or H reflex. Initial examination may be normal and repeat studies may be warranted.

The most common cause of respiratory failure in GBS patients is diaphragmatic weakness. Anticipation of respiratory complications begins on admission with bedside spirometry. Twice daily evaluation will establish a baseline and monitor the need for ventilatory support. Predictors of the need for early intubation and mechanical ventilation include:

- Patients with increased respiratory rate and shortness of breath during speaking.
- Time between onset of disease and hospital admission <7 days.
- Inability to lift the head and severe bulbar dysfunction.
- Repeated cough, difficulty with secretions and aspiration after swallowing.
- Vital capacity (VC) <60% of predicted or <15 ml/kg to 20 ml/kg.

Anticipation of early respiratory failure and the need for elective intubation during the daytime is crucial to avoid "crashing" in the middle of the night. Light sedation will be required to maintain ease of ventilation in a patient with neuromuscular weakness and preserved mental status. Most patients with GBS who evolve to require intubation may

require mechanical ventilation for 2 to 3 weeks; therefore, early tracheotomy should be considered, especially in patients with predominantly bulbar symptoms.

When GBS is suspected, the following recommendations should be considered. The mainstay of medical treatment for a patient with GBS is either IVIg treatment or plasma exchange. Both have been studied in trials which evaluated them individually and in combination. Plasma exchange and IVIg have been shown to carry equal efficacy, but plasma exchange requires central venous access and therefore confers a greater risk for side effects. Combining the two is not recommended. Steroid therapy is not recommended because it has not been shown to be superior to either IVIg or plasma exchange and carries long-term sequelae in patients potentially bed-bound for an extended period. IVIg should be considered for patients with a symptom onset <2 weeks but who remain ambulatory. The recommended regimen is 2 g/kg (ideal body weight) divided into 5 doses given once daily as 0.4 g/kg (ideal body weight). Plasma exchange is recommended in patients who are non-ambulatory within the first 4 weeks of symptom onset and those who require urgent mechanical ventilation

In the authors' experience, the following pearls are useful tips to remember when treating patients with IVIg. First, when calculating the dosing, you may land on a dosage that is in between two vial sizes. We recommend simply rounding up to the next highest dose (calculated 32 g per day rounded to a 35 g vial). Second, familiarize yourself with the common side effects (flulike symptoms, headache, hypotension, aseptic meningitis) and potential adverse events (myocardial infarction, stroke, renal failure, anaphylaxis) secondary to IVIg administration and discuss these with your patient because this will increase both adherence to the protracted time needed to infuse each dose and patient tolerance of side effects. Subsequently, when ordering baseline serology, also include a serum IgA level to screen for patients with IgA deficiency who may be at risk for anaphylaxis. Many IVIg formulations are available. At our institution we attempt to minimize the risks by using only IgA depleted, sucrose-free IVIg. In addition, running the infusion overnight (6-8 h infusion time) minimizes patient discomfort and being bound to an IV pole. During treatment, we suggest continued IV hydration. Daily basic metabolic panel (BMP) and complete blood count (CBC) should be performed with attention to renal function, WBC count and platelet levels. Finally, 5 days of IVIg infusion and maintenance fluids may create volume overload for some patients and therefore concurrent use of diuretics may be warranted in those specific circumstances.

75.3.3 Myasthenia Gravis

Myasthenia Gravis (MG) is an autoimmune neuromuscular disease of the neuromuscular junction (NMJ) that leads to painless, fatigable muscle weakness. The autoimmune antibody produced most commonly is targeted at the postsynaptic skeletal muscle nicotinic acetylcholine receptor (AChR). The antibodies themselves are not directly pathologic, instead they trigger the processes: complement-mediated lysis of the postsynaptic muscle membrane, immune-mediated destruction of AChR, and blocking of the AChR. Approximately 80-85% of patients with MG are seropositive for postsynaptic AChR antibodies and 10-15% of seronegative myasthenia gravis patients are positive for antibodies to muscle-specific receptor tyrosine kinase (MuSK) antibodies. These antibodies act to ultimately decrease the total number of functional postsynaptic receptors. Population studies demonstrate a prevalence of 20 per 100,000, with a bimodal distribution of both early and late onset. Early-onset women outnumber men during the second and third decades of life, while late-onset men outnumber women during the sixth and seventh decades. Thymic hyperplasia is found in up to 50% of patients with MG and 10-15%

of patients may also have a thymic tumour. Thymectomy is recommended for patients with generalized weakness prior to the age of 50 years. Approximately 15 to 25% of patients with generalized weakness due to a myasthenic exacerbation will evolve into myasthenic crisis requiring ventilatory support, with a mortality rate of 4 to 13%. Respiratory weakness is the initial presenting symptom in 1% of patients.

The initial clinical presentation can occur in a variety of clinical settings, from the outpatient clinic to the ICU. The key feature to MG is fatigable weakness which may be reported as worse at the end of the day, with proximal muscles more affected than distal muscle groups. In addition, fatigue should improve with rest, which differentiates MG from generalized exhaustion. The most common presenting symptom in MG is ptosis and diplopia; within 2 years of diagnosis, 85% of these patients will go on to experience an episode of generalized weakness. Ptosis can vary between each eye, daily, and even throughout the day. Seeking a previous picture or accounts from family members of changes noticeable to others is important in establishing a baseline. Pupillary response is not affected in MG and ptosis can be worsened in the contralateral lid by manually retracting the more affected lid. Diplopia is due to cranial nerve III, IV or VI weakness in either eye or simultaneously with no discernible pattern. Patients can also present with a "pseudo-intranuclear ophthalmoplegia" (INO) due to ocular muscle weakness. When attempting to elicit ptosis, the examiner should fatigue the patient with sustained upgaze for 60-180 seconds, while having the patient sustain gaze in any field for 30 seconds should test cranial nerve weakness. Bulbar weakness can be noted with drooping at the corner of the mouth when smiling, recent history of dysphagia and dysarthria. Dysphagia is often due to soft palate and tongue weakness that may lead to difficulties with swallowing a food bolus. Furthermore, difficulty chewing food due to muscle fatigue is not uncommon and weakness with jaw opening but not with closure is common in MG patients. Patients may also note a change in their voice to a more hypophonic/nasal quality due to a combination of facial and tongue weakness. If the neck muscles are involved, flexors are usually weaker than extensors. Testing muscle weakness in limb muscles is often facilitated by having the patient repeat functional actions 10 to 20 times in between examinations to check for diminishing strength. Having the patient raise their leg and hold it at 30-40 degrees for 1-2 minutes, or rising from a chair or squatting 10-20 times are simple tests for revealing fatigable weakness. Finally, one of the most feared complication is respiratory weakness, which may be underappreciated in a patient with a chief complaint of generalized weakness. Often, these patients are tachypneic and have shallow breathing. Any combination of weakness with inspiration/expiration and a weak cough in the setting of tachypnea are signs of impending respiratory failure. Even in a patient with a known history of MG, differential diagnosis for localized or generalized weakness should also include these entities:

- GBS (Guillain-Barré Syndrome).
- GBS Mimics:
  - Miller-Fisher Syndrome.
  - Acute motor axonal neuropathy (AMAN).
  - Acute motor sensory axonal neuropathy (AMSAN).
  - Pharyngeal-cervical-brachial acute demyelinating polyneuropathy (AIDP).
  - Heavy metal neurotoxicity with arsenic, gold or thallium.
  - Organophosphate exposure.
  - Drugs: amiodarone, cytarabine, suramin.
  - Acute intermittent porphyria.
- West Nile Virus.
- Lambert-Eaton Syndrome.
- Botulism.

- Motor neuron disease.
- Recent cosmetic Botox application.
- Cholinesterase overdose.

In a patient with a previous diagnosis of MG, exacerbations can be due to many reasons. Recent illness (urinary tract infection, respiratory infection) or a decrease in baseline steroid or immunosuppression can trigger an exacerbation. Many medications are also known to trigger exacerbations such as calcium channel blockers (diltiazem, verapamil), aminoglycosides (gentamicin, clindamycin) and beta blockers. During pregnancy, the immediate post-partum period and during labour, medications such tocolytic agents (terbutaline), as well as magnesium sulphate, can worsen myasthenic symptoms.

The diagnosis of myasthenia gravis is based on history and physical findings, then confirmed by serum studies, neurophysiologic testing and/or pharmacologic testing. Classic pharmacologic testing has been based on edrophonium (tensilon) testing. This test is the classic method for evaluating a patient with observable or subjective weakness; however, it is no longer performed routinely in the United States due to risks to the patient and lack of the medication itself. If the test is being considered, it should be deferred in patients with respiratory insufficiency because it can increase pulmonary secretions. Most pharmacologic confirmation comes from a diagnostic and therapeutic trial of cholinesterase inhibitor and the most commonly prescribed drug is oral pyridostigmine bromide (Mestinon). Patients can sense an onset of the medication effect within 30-45 minutes, which allow for this diagnostic and therapeutic trial to easily occur in an emergency room setting. One indirect method that acts as a local cholinesterase inhibitor is the “ice pack” test. By placing a small bag of ice on the lid of a patient with ptosis, the breakdown of acetylcholine should be slowed temporarily and the ptosis should improve. Nerve conduction studies and electromyography (NCS/EMG) testing performed by a trained neurophysiologist is a very important tool in the diagnosis of MG. Such testing should be performed in all patients suspected with MG to narrow the differential diagnosis. Patients with MG should have normal nerve conduction studies and EMG should rule out myopathy plus demonstrate no spontaneous discharges. The next step in neurophysiologic testing is repetitive stimulation. Repetitive stimulation (2-5 Hz) should cause a decreasing response and lead to failure at the neuromuscular junction. Yet, repetitive nerve stimulation sensitivity is not equal for all forms of MG (50-100% for generalized MG vs. 10-20% for ocular MG). When in doubt, a single fibre EMG (SFEMG) is recommended, which is a specialized type of EMG performed by a neuromuscular specialist. Due to the complex nature of antibody testing, most often the previously mentioned methods for diagnosing the various forms of MG can be performed in a variety of clinical settings when a diagnosis is needed immediately. When sending serology to confirm the diagnosis of MG, the most common study is for anti-acetylcholine receptor antibodies. As previously mentioned, this can be found in a majority of patients with generalized MG (80-85%); however, its absence can be seen in patients with ocular MG (up to 50%) and therefore does not exclude the diagnosis of MG. When a patient is classified as “seronegative” MG, then further antibody tests can be ordered. Anti-muscle specific tyrosine kinase (anti-MuSK) antibodies are found in up to 40% of patients deemed “seronegative” with generalized MG. Finally, acetylcholine receptor-blocking antibodies and receptor-modulating antibodies can also be found in a small percentage of patients.

Management of MG in the outpatient setting is beyond the scope of this chapter. Here, we will discuss management of MG exacerbations in the emergency room, inpatient and ICU settings. Enough emphasis cannot be placed on the importance of both a thorough history and physical exam when an examiner first encounters a patient with neuromuscular weakness. Especially in patients with MG, understanding their previous med-

ication regimen, any recent changes to it, and working with their neurologist is key to a successful inpatient encounter. Management begins with deciding the level of acuity, which is aided by evaluating the patient's respiratory status; hand-held spirometry is key to making this decision. Often, temporary increases in a patient's Mestinon or prednisone dose and concurrent treatment of the underlying trigger can allow a patient to follow-up with their neurologist for minor exacerbations. Once a patient is felt to require inpatient admission, a few simultaneous events should occur. The goal of basic serology (BMP, CBC, CPK, calcium, magnesium, phosphate, coagulation profile, blood culture and urinalysis) is to discover the triggers for exacerbation, such as infection, and to establish a baseline prior to immune directed therapy. Next, a CXR is important to diagnose and treat aspiration pneumonia or atelectasis. Once the patient is stable, an infused CT scan of the chest is important to evaluate for thymoma. During initial clinical assessment, if the patient demonstrates "paradoxical breathing" (movement of chest outward and abdomen inward), shortness of breath (inability to count beyond 20 in one breath) and/or tachypnoea, the physician in charge should anticipate the probable evolution of a myasthenic exacerbation of a myasthenic crisis. Myasthenic crisis can be defined as a patient who develops respiratory insufficiency that may necessitate mechanical ventilation. To help quantify a patient's respiratory status, immediate bedside spirometry should be performed. Initial data from bedside spirometry should include maximum inspiratory pressure (MIP), maximum expiratory pressure (MEP), vital capacity (VC), and forced vital capacity (FVC). The following parameters are influential when interpreting the data:

- Normal vital capacity (VC) is approximately 50 ml/kg:
  - Cough is impaired with VC <30 ml/kg.
  - Increased likelihood of mechanical ventilation need with VC 15-20 ml/kg.
- Hypercapnia is common with MIP lower than -20 cmH_2O.
- Effective clearance of pharyngeal secretions is decreased when MEP <40 cmH_2O.
- Bedside spirometry may be difficult to perform in a patient with facial weakness.

In addition to bedside spirometry, further data to be collected are arterial blood gases, continuous pulse oximetry, cardiac telemetry and serial mental status assessment. Arterial blood gas (ABG) provides a baseline for future ventilatory management, current ventilation efficiency (hypercapnia) and screening for atalectasis-induced hypoxia due to ventilation-perfusion (V/Q) mismatch. If ABG is not obtainable, then a venous blood gas (VBG) can indirectly demonstrate arterial CO_2 (arterial CO_2 >50 and/or PaO_2 <70 mmHg are indexes which may warrant mechanical ventilation). Continuous pulse oximetry (SpO_2) is a useful tool; however, one should recall that a SpO_2 >90% is equivalent to an arterial pressure of O_2 > 60 mmHg; therefore, hypoxia can occur even if the machine isn't beeping. Cardiac telemetry is also important because arrhythmias are a common cause of death in myasthenic crisis. Serial mental status examination is a useful means to monitor the patient for respiratory compromise and decreasing airway protection.

Evaluation for early elective mechanical ventilation will avoid emergency intubations and decrease the risk of aspiration pneumonia. When in doubt, elective intubation is probably the safer choice. The two modalities for mechanical ventilation are non-invasive, positive pressure ventilation using continuous positive airway pressure/bi-level positive airway pressure (CPAP/BiPAP) and oral intubation. The first choice, non-invasive positive pressure ventilation, may be a viable option in patients without hypercapnia and it may afford enough time for medical therapy to take effect. Signs that positive pressure ventilation is no longer efficient include a worsening ABG, increasing patient anxiety due to "air hunger" or decreasing mental status. Especially with a change in mental status, the patient will no longer be able to protect their airway by removing the facemask. Invasive mechanical ventilation is the next step in providing ventilator support. Synchronized intermittent mandatory ventilation with tidal volumes around 7-10

ml/kg, pressure support of 5-15 cmH_20, positive end-expiratory pressure (PEEP) of 3-15 cm are parameters that may be needed to maintain PaO_2 >90, and PCO_2 <40 is a good starting point when ventilating patients with neuromuscular weakness. One final note regarding mechanical ventilation is to not overlook the importance of discussing with the patient and family members the future possibility of ventilatory support prior to its need. Especially in the elderly or those with advance directives, knowing that intubation during a myasthenic crisis often acts as a temporary bridge, helps patients and their families make fully informed decisions. This also allows the clinician to make an educated decision if respiratory failure occurs in the middle of the night and the patient no longer retains a decision making capacity.

Treatment strategies for both myasthenic exacerbation and myasthenic crisis involve a combination of pyridostigmine bromide (PO or IV), prednisone (PO and/or IV), intravenous immunoglobulin (IVIg) or plasma exchange. Please refer to the previous section (Guillain-Barré syndrome) regarding "pearls" when using IVIg or plasma exchange. The first decision to make is to use either IVIg or plasma exchange; this decision is a balance between the risks and benefits of each therapy applied to the patient at hand. In fact, both IVIg and plasma exchange can be considered inducers of immunosuppression, with corticosteroids as the vehicle to maintain this goal. Current thinking is that mild to moderate myasthenic exacerbations can be successfully treated with IVIg (0.4 g/kg for 5 days). Initial concomitant introduction of high-dose steroid therapy is not recommended due to the possibility of exacerbating myasthenic symptoms; however, if the patient begins to improve by day 3, one can consider its addition. Oral prednisone (40-60 mg) can be initiated based on the patient's treatment plan after induction of immunosuppression. Patients who evolve into a myasthenic crisis or present with one require plasma exchange therapy, which provides slightly more robust results in a shorter time period. In addition, it has been suggested the risk of IV steroids worsening symptoms is decreased with concomitant plasma exchange therapy due to their mechanism of action with plasma exchange. With any suspicion of pneumonia or other source of infection, treatment of that infection is equally important.

75.3.4 Critical Illness Sensorimotor Polyneuropathy and Myopathy (CIP/CIM)

This condition has been present for many years but only recently has it been further characterized as common complication of sepsis and multiorgan failure. The incidence of critical illness polyneuropathy (CIP) and critical illness myopathy (CIM) approaches 70% in patients with sepsis, up to 100% in patients who also develop multiorgan failure, and is seen in 50-80% of patients who are in an ICU setting for more than 7 days. CIP/CIM is often first discovered as difficulty weaning a patient from mechanical ventilation or when recovering from prolonged encephalopathy. The incidence of CIM peaks during the sixth decade of life, while the pathogenesis of CIP/CIM is currently based on its association with risk factors identified, including hyperglycaemia, corticosteroid therapy, severity of illness, duration of ICU stay, vasopressor support, and many others. CIM is commonly seen in patients exposed to corticosteroids (methylprednisolone, hydrocortisone, prednisone, betamethasone, dexamethasone) and neuromuscular blockade agents such as pancuronium, vecuronium, atracurium) and prolonged exposure to propofol.

Clinical presentation of CIP varies slightly with CIM. Initially, it is helpful to establish the patient's baseline functional status by chart review and/or speaking with family members. CIP should be suspected in an ICU patient who demonstrates diffuse, distal muscle

weakness; on bedside examination, their weakness may be severe enough to resemble a patient with quadriplegia. CIP affects the sensory nerves greater than the motor nerves; therefore, patients on reflex exam will be hyporeflexive or areflexic. Yet, up to one third of patients may have retained reflexes and cranial nerves are often spared. Often patients who initially begin with CIP can develop CIM secondary to denervation, which is why these two disease processes can be difficult to clinically distinguish by examination alone. In a patient with previous spontaneous movements and intact sensation, failure to withdraw to painful stimuli applied to a distal extremity should suggest sensory loss. CIM should be suspected in a patient with equal distribution of weakness in both proximal and distal muscle groups. Often, reflexes are normal or slightly decreased and the sensory exam should remain intact. Whenever evaluating a critically ill patient, it is important to assure that the patient is awake, alert, and understands your commands. A complete neurologic examination, serology, electroencephalogram (EEG) and imaging should be performed to ensure no confounders are present. If on clinical exam focal deficits are elicited, then the diagnosis of CIP/CIM should fall lower on the differential.

Diagnosis of CIP/CIM is based on the diagnostic information obtained by electrodiagnostic studies, specifically, nerve conduction studies (NCS) and electromyography (EMG). It should be kept in mind that in patients with CIP or CIM, NCS/EMG results may be less robust due to surrounding electrical interference in the ICU setting. With pure CIP, nerve conduction studies should demonstrate normal nerve conduction velocities and distal latencies, with reduced to absent compound muscle and sensory nerve action potentials (CMAP and SNAP). The reason for a reduced or absent CMAP may be due to muscle inexcitability rather than axonal loss. EMG in CIP may show abnormal spontaneous activity in both proximal and distal muscle groups and reduced motor unit potentials due to denervation. NCS in CIM should demonstrate preserved conduction velocities and distal latency and low amplitude CMAPs. If weakness is mild, CMAP may be normal. In CIM, once myopathic changes have occurred, motor unit potentials are small and polyphasic, with early recruitment and fibrillation potentials. Direct muscle stimulation may be a helpful technique in distinguishing CIP from CIM because with CIM, the muscle is electrically unexcitable. Diagnosis can also be further aided in CIM by ruling out mimics including hypokalaemia, hypophosphataemia and hypermagnesaemia. With respect to creatine kinase (CK) in CIM, it may be elevated up 100 times above normal but 15% of patients can have a normal CK level as well. Finally, when CIP or CIM is suspected, nerve and muscle biopsy is the gold standard for diagnosis. Selecting where to biopsy should be based on an area that has not undergone extensive disease because results may be non-diagnostic. In CIP, nerve biopsy may demonstrate axonal degeneration of motor and sensory nerves without evidence of inflammation or primary demyelination. CIM muscle biopsy features range from atrophy of type I or type II fibres, with necrosis as a variable but often minimal finding. In CIM, electron microscope ultrastructure evaluation demonstrates a selective loss of myosin thick filaments, which is the key finding.

Unfortunately, no specific treatment regiment has been defined for CIP or CIM. Early and definitive treatment of the underlying aetiology for sepsis and SIRS in concert with intensive serum glucose control is the best prevention. In addition, aggressive physical rehabilitation provides the best chance to regain function.

75.3.5 Poisoning of the Neuromuscular Junction

The neuromuscular junction is a dynamic arena where multiple processes occur at all times to ensure proper muscle contraction. In the previous sections we examined acquired injury to the peripheral nervous system (PNS); in this section we will examine poi-

soning specific to the neuromuscular junction. Poisoning of the neuromuscular junction can be broadly categorized into pharmacologic, biologic and environmental.

Pharmacologic: Persistent Neuromuscular Blockade

Residual neuromuscular blockade has recently increased in incidence as the utilization of neuromuscular blockade has moved beyond intubation and the operating room. Agents for neuromuscular blockade are grouped into two categories: depolarizing (succinylcholine) and non-depolarizing. Depolarizing agents act by binding to the postsynaptic nicotinic acetylcholine receptor, leading to persistent depolarization. The mechanism of action for this group limits its current use beyond rapid sequence intubation. Non-depolarizing agents bind with postsynaptic nicotinic acetylcholine receptors and prevent acetylcholine from reaching its target, thereby preventing depolarization. This mechanism of action leads to fewer side effects; and, therefore, especially in the ICU setting, non-depolarizing agents are utilized. Commonly used non-depolarizing agents used and clinical settings where they are applied are summarized in Table 75.4.

Since these medications are used frequently without side effects, concurrent factors have been identified which can increase the risk for neuromuscular weakness due to residual neuromuscular blockade. Advanced age, renal insufficiency (pancuronium, vecuronium and rocuronium), hypermagnesaemia, metabolic acidosis and edematous states which require higher doses for clinical effect are all clinical situations which can prolong neuromuscular blockade. Also, some medications including beta-blockers, calcium channel blockers, aminoglycosides, clindamycin and cyclosporine have been implicated. Furthermore, some data suggest that concurrent corticosteroid and pancuronium or vecuronium use can have myotoxic side effects. If residual neuromuscular blockade is suspected, clinical features on examination are: persistent, flaccid, areflexic quadriplegia, ptosis and ophthalmoplegia (rarely seen in CIP and CIM), and no spontaneous respiration.

Diagnosis of residual neuromuscular blockade is often made at the bedside using a technique called train of four (TOF). TOF uses common, easily accessible nerve and muscle units to test for contraction when supramaximal stimulation is applied. When using TOF, always clean the patient's skin with alcohol, place the electrodes <6 cm apart with the negative electrode distally, and skin temperature should be >32^0 C. The most common nerve and muscle unit used is the ulnar and adductor pollicis. If this is not accessible, then the tibialis posterior and the flexor hallucis brevis muscle are also acceptable. Elec-

Common agents	• Benzylisoquinolinium compounds:
	  ▪ Cisatracurium
	  ▪ Atracurium
	• Aminosteroid compounds:
	  ▪ Pancuronium
	  ▪ Vecuronium
	  ▪ Rocuronium

Common clinical settings	• Facilitating mechanical ventilation
	• Shivering protocols in cooled patients
	• Treating malignant elevated intracranial pressure
	• Reduce muscle contraction and oxygen consumption associated with:
	  ▪ Tetanus
	  ▪ Drug overdose
	  ▪ Status epilepticus
	• Eliminate movements that interfere with beside diagnostic or therapeutic procedures

Table 75.4. **Commonly used non-depolarizing agents used and clinical settings where they are applied.**

trical stimulation occurs with four shocks at 2 Hz and allowing at least 10 seconds between rounds. If no neuromuscular blockade is present, all four shocks should result in muscular contraction of the same amplitude (height). Loss of the contraction from the fourth shock equates to a 70% neuromuscular blockade, with subsequent shocks three and two lost equalling up to 100% neuromuscular blockade. Another measure of body neuromuscular blockade is the TOF ratio, which is obtained by dividing the amplitude of the fourth shock by the first shock, but this requires EMG assistance. EMG assistance does help to distinguish neuromuscular blockade from CIP by demonstrating and absent CMAP but SNAP should be normal.

Treatment is based on reversal of the non-depolarizing agent and time. Paralysis can be transiently reversed with neostigmine or edprophonium but they should not be used routinely and only as needed. Reported side effects of neostigmine include arrhythmias, bronchospasm and the potential for acetylcholinesterase inhibitor to cause neuromuscular junction desensitization itself. Ultimately, weakness should resolve within a few days after discontinuation of a neuromuscular blockade agent.

Biologic: Organophosphate Poisoning

This entity is important to recognize because of the widespread use of organophosphate (OP) compounds, including insecticides, livestock and agriculture. They are also used in chemical warfare and suicide. Ultimately, these compounds act as irreversible cholinesterase inhibitors, specifically for both plasma and acetylcholinesterase inhibitors. OP enters the human body via ingestion, inhalation, injection and absorption across the skin.

Clinical examination of a patient with OP poisoning demonstrates the classic symptoms of excessive cholinergic stimulation seen in many areas of the body. Classic examples relate to muscurinic overstimulation that results in bradycardia, bronchospasm, diarrhoea, lacrimation, salivation, miosis, vomiting and urination. Nicotinic overstimulation of the CNS leads to agitation, confusion, coma and respiratory failure. Finally, overstimulation of the neuromuscular junction leads to fasciculation, muscle weakness and paralysis. Current diagnosis relies on recognition of the clinical signs, suspicion based on recent history, and confirmation using serum assays of plasma acetylcholinesterase activity.

Treatment always begins with basic life support ABCs (Airway, Breathing and Circulation). Crisis situations involve airway management with attention to the removal of excess secretions and atropine sulphate to treat CNS overstimulation. Additional help with managing secretion production can be aided by using Robinul (glycopyrrolate). If seizures occur, the drug of choice is a benzodiazepine. It should also be remembered that for rapid sequence intubation of this patient population, succinylcholine should be avoided because it is dependent on the acetylcholinesterase enzyme for degradation. Next, decontamination of the patient by washing with soap and water should hydrolyze the OP compound and prevent its further absorption. Also, healthcare providers should protect themselves and other patients from exposure by using gloves and a protective gown. Overall, atropine is the drug of choice due to its ability to enter the CNS; however, some controversy exists over the selective addition of pralidoxime (2-PAM), which acts as an antidote by binding to the OP molecule.

Environmental: Botulinum Poisoning

Botulinum toxin poisoning can be seen in both adults and infants, from unintended exposure and as a consequence of its expanded medical application. Currently, the U.S. Food and Drug Administration approves botulinum toxin for the treatment of strabismus, cervical torticollis and blepharospasm; however, there are many more off-label and cosmetic uses today as well. Botulinum toxin is produced by *Clostridium botulinum*,

a spore-forming anaerobic, Gram-positive bacillus. Historically, because botulinum toxin is ubiquitous in soil and water, toxicity commonly appeared secondary to ingestion. Clinical botulinum toxicity has been documented to occur in persons exposed to preformed toxin (adult and infantile ingestion, inhalation, injection) and colonization by *Clostridium botulinum* with subsequent toxin production (wound and gastrointestinal tract). Although seven types of botulinum toxin are known, types A, B, E and F are most frequently the cause of botulism in humans. Botulism is considered a public health issue; therefore, confirmed cases should be reported to state health officials so that a possible outbreak can be caught early. As previously mentioned, the clinical circumstances where botulism occurs are through ingestion, infection, inhalation and injection. The least prevalent is via inhalation, but the implications of aerosolization of botulinum toxin are far-reaching and its use may be seen as a biological weapon. Injection of preformed botulinum toxin is seen with injection drugs (black tar heroin and cocaine) and medical application. Drastically smaller doses of the toxin are used in medical and cosmetic applications; as a result, the only adverse events are seen when therapeutic doses extend beyond their target muscles. Infection of a wound with *Clostridium botulinum* is seen with IV drug use when dirty needles are shared; therefore, an injection drug user with respiratory weakness should not be missed. The last clinical scenario to consider is ingestion of the bacteria or preformed toxin. This has become exceedingly rare as preventative measures with food preparation have advanced.

Overall, botulism presents with multiple cranial nerve palsies, followed by symmetric, descending flaccid paralysis. Prominent ptosis, dilated pupils, blurred vision, diplopia, dysarthria, dysphonia and general facial weakness are the clinical manifestations of multiple cranial nerve palsies from botulism. As the paralysis descends, constipation will eventually occur in all patients. Diagnosis of botulism is very difficult due to both the general lack of cases seen in practice and the broad differential diagnosis of painless, descending weakness (stroke syndromes, Guillain-Barré Syndrome and its variants, myasthenia gravis, Lambert-Eaton Syndrome, tick paralysis). Initial history, recent travel, food ingested in the last week, and any history of IV drug use should place botulinum on the differential. Common serology, radiology and CSF studies will be normal in a patient infected with botulinum toxin. The key to diagnosis is isolation of the toxin from the wound or food samples, secretions, stool, serum or gastric secretions.

Treatment is based on a two-armed approach. First, patients suspected of botulism should be immediately admitted to the ICU and monitored frequently for signs of respiratory insufficiency. Since botulinum toxin causes paralysis of skeletal muscle, patients with air hunger and hypoventilation may not present with agitation. Furthermore, if paralysis compromises respiratory function, recovery can take weeks to months. This is why intensive care is so important to help bridge patients to recovery. Second, the only specific targeted treatment for botulism is botulinum antitoxin. Antitoxin can prevent further weakness and paralysis by binding to free toxin; however, if given once the toxin has bound to nerve endings, its utility is greatly diminished. Again, working with your state and local agencies is key to treatment by isolating those infected and preventing further spread of the disease.

75.4 Myopathy

Among the many aetiologies for acute neuromuscular weakness, encountered in both the inpatient and ICU setting, one source of weakness that can go unrecognized is systemic muscle decompensation. Myopathies are commonly chronic disease processes

Inflammatory myositis	• Polymyositis dermatomyositis
Viral myopathy	• Influenza A and B (most common reported) • Enteroviruses (coxsackie B and ECHO virus) • HIV • HTLV-1
Endocrine myopathies	
Hypokalaemic periodic paralysis	

Table 75.5. **Myopathies that should be recognized and treated when a patient is suspected of having systemic muscle weakness.**

due to a variety of conditions such as autoimmune connective tissue diseases, secondary to infection (bacterial, viral, fungal and parasite) or sequelae of treatment regimens. Critical illness myopathy is the most prevalent myopathy that will be seen in the intensive care setting; however, in Table 75.5 there is a selection of myopathies that should be recognized and treated when a patient is suspected of having systemic muscle weakness.

For patients with suspected inflammatory myositis, a disciplined approach to the history and exam is very important because patients with polymyositis often lack the cutaneous features of patients with dermatomyositis. One clue to inflammatory myopathies is an association with autoimmune connective tissue diseases. Dermatomyositis on clinical examination should reveal nearly pathognomonic cutaneous signs of both a heliotrope rash and Gottron's papules. The heliotrope rash is a dusky erythematous rash with a symmetrical periorbital distribution. Gottron's papules are slightly violaceous papules localized to the dorsal and extensor surface of multiple bony joints. The most common joints involved are the metacarpal and interphalangeal joints, while less common areas are the wrists, elbows and knees. Since inflammatory myopathies are mostly chronic, initial complaints are myalgia, fatigue and proximal, symmetric muscle weakness. Patients will report difficulty with repetitive movements such as climbing stairs or raising their arms. Rarely, patients will experience an acutely malignant acceleration of weakness involving the pharyngeal muscles, increasing the risk for aspiration; and, ultimately, if the diaphragm is involved, respiratory compromise will occur.

The most commonly seen viral myopathy is due to influenza A or B inflection. In addition to typical upper respiratory complaints, myalgias are often only initially present. With time, a focal, intense myositis affecting the calf muscles appears, which is a hallmark of influenza infection. Also, another less common consequence of influenza (HIV and enterovirus as well) infection is rhabdomyolysis. Whereas influenza causes a focal myositis, HIV infection can cause a wide variety of muscle diseases including myopathy, polymyositis and rhabdomyolysis. HIV myopathy can occur during both the acute infection as well as late disease; it should be considered a diagnosis of exclusion after medication-induced (HAART) or opportunistic infections, and wasting have been ruled out.

Endocrine myopathies can be caused by pituitary, thyroid, parathyroid or adrenal dysfunction. In reality, these endocrine organs are interconnected physiologically and therefore a lack of function in one area may lead to a loss of function downstream. For example, loss of proper hypothalamic function often leads to secondary pituitary and adrenal dysfunction. If endocrine dysfunction is suspected, the clinical examination should reflect the underlying endocrine loss or gain of normal activity.

Periodic paralysis is an episodic weakness due to channelopathies at the muscle membrane. These abnormal ion channels lead to hypoexcitability or hyperexcitability. Hyperexcitable muscle clinically presents as either myotonia (delayed relaxation after voluntary muscle contraction) or paramyotonia (myotonia that worsens with exercise), whereas hypoexcitation of the muscle membrane leads to periodic paralysis. The most common channels found to cause myopathies include sodium, calcium and potassium. Here, our focus will be on the sodium channelopathy on that leads to hypokalaemic pe-

riodic paralysis. These episodes of periodic paralysis can be precipitated by large carbohydrate meals, electrolyte disturbances and thyrotoxic states.
Diagnosis of myopathic disease should include serologic markers of muscle disease. These markers include creatinine kinase (CK), aldolase, aspartate aminotransferase (AST), alanine aminotransferase (ALT) and lactate dehydrogenase (LDH). These initial studies help with diagnosis and also serve as a baseline to follow once treatment is started. Electrodiagnostic studies in acute weakness, both electromyography and nerve conduction studies, are crucial to categorizing neuropathic versus myopathic weakness as well.

75.5 Conclusion

Pathognomonic signs are very rare and the underlying aetiology almost never reveals itself when a patient presents for the first time with neuromuscular weakness. Every encounter should begin with a history of present illness that inquires about recent illness, transient neurologic symptoms, and focuses the symptoms tempo, localization and progression. Neuromuscular disease can be localized to the central nervous system or the peripheral nervous system; therefore, a complete neurologic examination is crucial to guide what the next step should be. Patients who present with acute onset of bilateral lower extremity weakness and myelopathic features should receive an MRI with contrast as soon as possible. On the other hand, patients presenting with a progressive weakness should be monitored for respiratory compromise because their symptoms may yet plateau. Electrodiagnostic studies, serology and CSF studies will always help narrow the differential diagnosis, but ultimately each clinician should use their clinical exam to define the diagnosis and therapy to use. Corticosteroid therapy has been used in many clinical settings, but recent advancements in immune therapy provide us with a more effective means to treat patients with a wide variety of neuromuscular disease. Weakness leading to respiratory compromise is one of the most important complications to avoid, which is why early aggressive intervention can often prevent this from occurring. Finally, prognosis is often determined by the patient's condition prior to insult, location and severity of the injury, and the potential for rehabilitation.

76 Acute Paraplegias and Quadriplegias of Non-traumatic Cause

Rubén Manzi [1], Daniel A. Godoy [2], Pablo Correa [1]

[1] Neurosurgical Department, Sanatorio Pasteur, Catamarca, Argentina
[2] Neurointensive Care Unit, Sanatorio Pasteur. Intensive Care Unit, Hospital Interzonal de Agudos ''San Juan Bautista'', Catamarca, Argentina

76.1 Introduction

The part of this chapter gives a brief overview of the problem, listing the steps to be followed so as to obtain a first diagnosis and save time using systematic reasoning and approach.
The second section provides the reader with basic information about the distinct etiologies.
How to approach a recent motor deficit without indicators of brain compromise.
Here, we present a step-by-step approach to initial diagnostic and treatment:

- The first question to be answered when facing a recent non-brain motor deficit (quadriplegia/paresis or paraplegia/paresis) is: Is the motor deficit medullar or non-medullar? According to semiology, there are flaccid paraplegias of medullary origin, flaccid paraplegias of non-medullary origin, and spastic paraplegias. We will use here the term “paraplegia” which embraces possible cases of quadriplegia.
- The second issue to be resolved is whether we are dealing with a hyperacute, acute or subacute case. This will give us a guideline to the etiological definition.
- The third issue is an approximate definition of the topography. This is a key element for the correct choice of complementary studies.
- Once steps 1-3 have been accomplished, we should define what type of studies should be carried out.

76.2 Overview

76.2.1 First Step: Is the Deficit Medullary or Non-medullary in Origin?

The data from the patient’s clinical history that become relevant are:

- Discomforts that preceded the deficit. The presence of fever, paraesthesias, radicular pain prior to the deficit can be indicators of the Guillain-Barré syndrome. Intense pain in a well-defined segment of the vertebral column can be an indicator of a medullary compression syndrome.
- Pre-existing pathological data, such as metabolic disease or exposure to toxic agents can be signals of a peripheral injury (diabetic polyneuritis, toxic causes such as alcoholism, plumbic neuritis, etc.). The presence of a severe oncologic or rheumatologic disease can be an indicator of extrinsic medullary compression.

- Test findings provide clues to identify the problem as a medullar injury or a non-medullar injury (roots, plexuses, nerves, neuromuscular junction).

Flaccid paraplegia of medullary origin results from injuries to the motor neurons of the anterior horns of the spinal cord as well as their intramedullar axis-cylinder prolongations. In such cases there are signs of paralysis, flaccidity or accented hypotonia, sphincter dysfunction, deep areflexia, Babinski's sign, and others which can be present from the very beginning or emerge suddenly, reflexes of medullary automatism, anaesthesia with a well-defined topography and rapid trophic phenomena, as well as vasomotor paralysis. Initially, there can be bladder retention (balloon) and intestinal paralysis (abdominal strain) prior to incontinence.

Spastic paraplegias ensue from bilateral injuries of the pyramidal tract; they are characterized by paralysis with spasticity and evident hypertonicity. Spasticity usually predominates over paralysis. Initially, they can go through a more or less brief phase of flaccid paralysis or gradual simultaneous paralysis and spasticity. The lower limbs are usually extended with tight thighs and knees as well as cauda equina. There will be spastic muscles. The pyramidal syndrome is evident: osteotendinous hyperreflexia, clonus and Babinski's sign. According to the level of damage, the cutaneous abdominal reflexes can be missing or can also be missing earlier in multiple sclerosis. The reflexes of medullary automatism are usually exaggerated, sphincter function is also compromised and walking becomes difficult or impossible. Less frequently, spastic paraplegias are of the flexion type instead of the extension type. In general, they are the result of medullary compression processes, though some other causes such as multiple sclerosis, syringomyelia or other inflammatory processes (syphilis, tuberculosis, etc.).

Flaccid paraplegias of non-medullary origin can have radicular and neuritic causes. If the pain is radicular (polyradiculoneuritis, Guillain-Barré syndrome), a hypotonic quadriplegia with distal hyporeflexia or areflexia will be present. In this case, neither the Babinski sign nor sphincter function is affected and sensitive function is also preserved. Quadriplegias caused by severe polyneuritis are predominantly distal in the motor deficit and

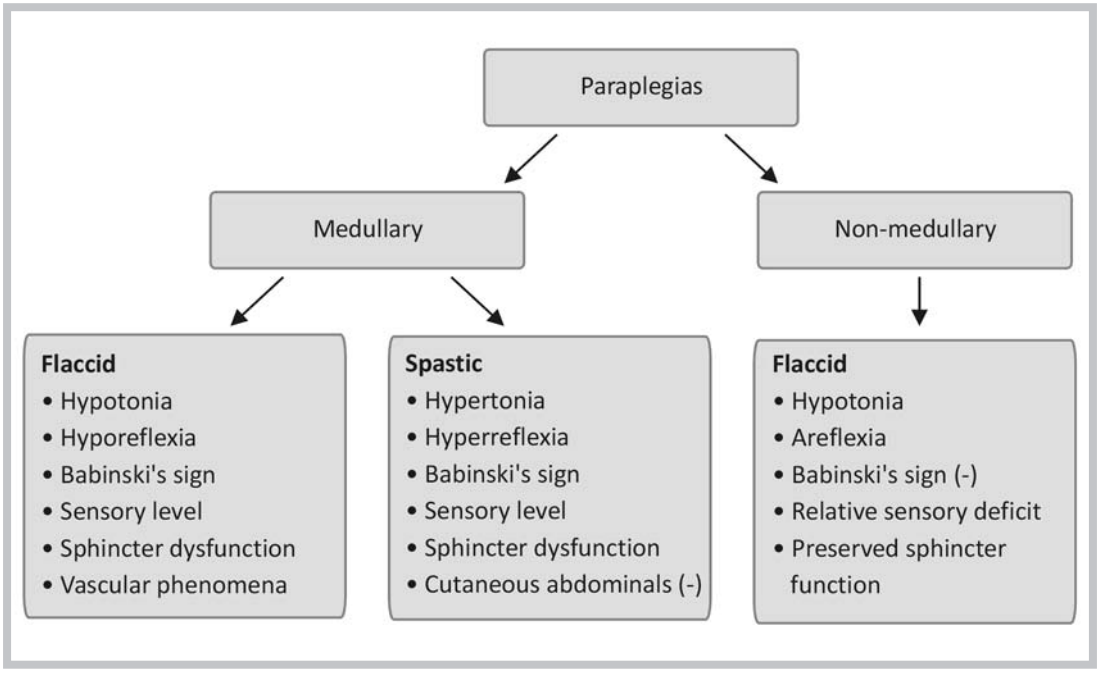

Figure 76.1. Flow chart for the management of paraplegias.

the sensory deficit is usually in the area of the hands and feet, in many cases with a clear tendency towards hyperaesthesia. Figure 76.1 shows the flow chart for the management of paraplegias.

76.2.2 Second Step: Are We Dealing With a Hyperacute, Acute or Subacute Injury?

Hyperacute injuries manifest suddenly and evolve within a couple of minutes or hours. They generally present as a syndrome of complete or almost complete medullary section, i.e., they start as a spinal cord shock with the interruption of motor, sensory and vegetative functions below the level of the injury. This kind of evolution could indicate the possibility of an epidural hematoma or a hematomyelia. Medullary infarction also leads to a sudden deficit, however, as the anterior spinal artery is compromised, it affects the anterior two thirds of the medulla; as a consequence, deep sensibility of the posterior third remains unaffected.

Kind of injury	Examples
Hyperacute (within minutes or a few hours)	• Epidural hematoma • Hematomyelia • Medullar infarct
Acute or subacute (within several hours or days)	• Extrinsic compression (spinal metastasis, epidural abscesses, intradural extramedullary tumours, etc.) • Intrinsic compression (intramedullary tumours) • Inflammatory-degenerative lesions (multiple sclerosis, Devic's disease, etc.)

Table 76.1. Hyperacute, acute or subacute injuries.

Acute and subacute damage develops over several hours or days. It could result from myelopathies, with the presence of more or less complete medullary syndromes or radicular injuries (classical Guillain-Barré syndrome or its variants) or other acute neuropathies (toxic, acute porphyria, multiorgan failure, etc.). Numbering among acute or subacute medullary injuries are extrinsic compressive injuries (secondary tumour metastases to the spine, epidural or subdural abscesses, etc.); extramedullary or intradural tumours (meningioma, schwannoma) and intramedullary tumours (ependymoma, glioma, etc.) (Table 76.1). Inflammatory-degenerative diseases such as transverse myelitis or Devic's disease must also be considered.

76.2.3 Third Step: What Topography Does the Injury Have?

Assuming that the patient's medical history and the neurological test have already told us whether the lesion is medullary or non-medullary, we will now consider some simple elements that can help us to identify the topography.

Segmental sensory responses:

- C3 innervates the front aspect of the neck.
- D4 borders on D5 at the level of the nipples or the equivalent area in males.
- D6 and D7 border on the xiphoid appendix.
- D10 and D11 are located at the level of the navel.
- D12 and L1 are located in the inguinal region.

Resolution of some osteotendinous reflexes (deep reflexes):

- The bicipital reflex has its centre in cervical segments IV, V and VI.
- The patellar reflex corresponds to lumbar segments II, III and IV.
- The Achilles reflex corresponds to lumbar segment V and to sacrum segments I and II.

76.2.4 Fourth Step: What Studies Should Be Carried Out?

If a primary medullary injury is suspected (intramedullary tumour, syringomyelia, demyelination disease, etc.) or secondary medullary injury (compression caused by tumour, epidural hematoma, pyogenic collections, etc.), magnetic resonance imaging (MRI) will be the most preferable study. If there is a suspicion of multiple injuries, MRI is mandatory. It should be borne in mind that computed tomography (CT) with contrast fluid administration can provide rapid screening, with good definition when there is suspicion of multiple tumour metastases to the bone. There is no doubt that due to the notable

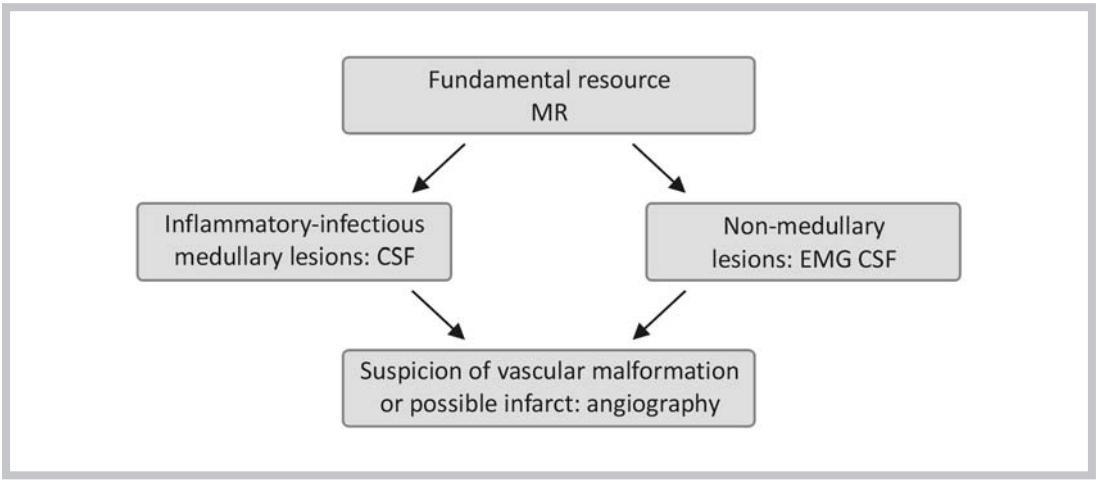

Figure 76.2. Tests that should be performed.

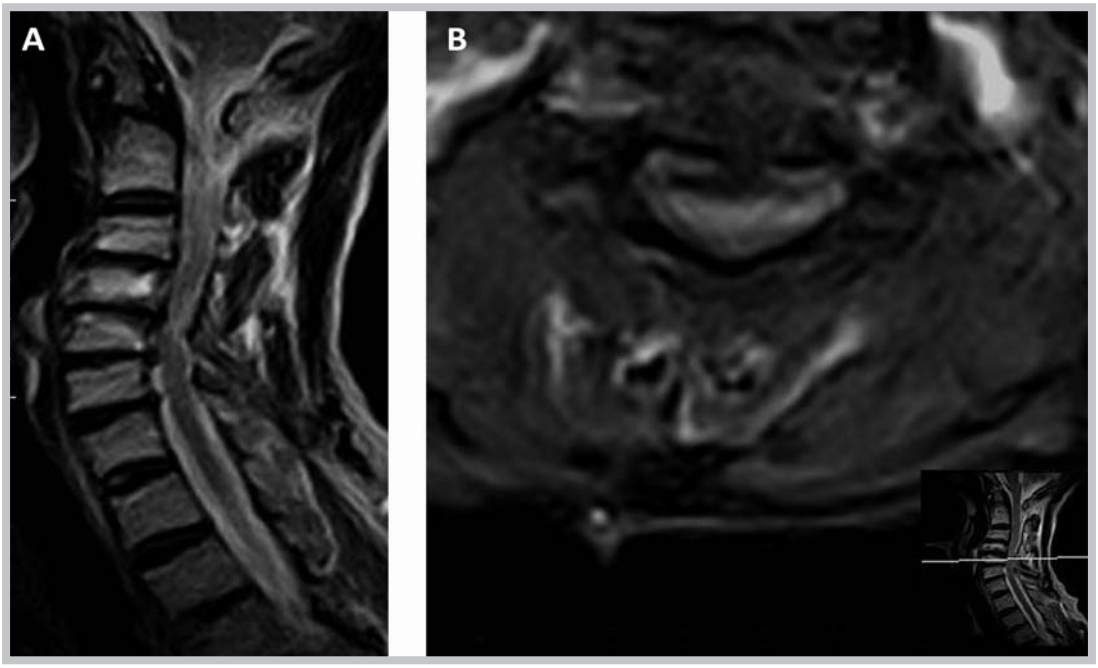

Figure 76.3. A 68-year-old woman with progressive quadriparesis and pyramidal signs. The MR images show the spondyloarthrotic changes and a narrow canal and the secondary myelopathy, with signal changes in medullary area [Images courtesy of the Neuroradiology Department, Sanatorio Pasteur, Catamarca].

development of neuroimaging techniques, the diagnosis is based fundamentally on MR in most cases.
If there is suspicion of a flaccid paraplegia of non-medullary origin, electromyography (EMG) and laboratory tests must be used. The typical cerebrospinal fluid (CSF) albuminocytologic dissociation (hyperalbumin with normal cellulose) is found in the Guillain-Barré syndrome. This finding can be present after the first week and only rarely will the CSF remain normal until the tenth week. Figure 76.2 summarizes essential tests, while Figure 76.3 shows some explicative images.

76.3 Etiology

Here we present a brief overview of the clinical picture, together with recommended management of the most frequent paraplegias of non-traumatic cause.

76.3.1 Extrinsic Medullary Compression

The most frequent medullary compression is caused by oncological disease. It can be a pre-existing cancer or one whose onset becomes evident from the metastasis that causes the compression.
It must be taken into account that cancer is not the only cause of medullary compression. There are other less frequent causes such as epidural abscesses, epidural hematoma, lipomatosis, etc.

76.3.2 Epidural Metastasis

Due to its frequency and impact, epidural metastasis stands out among other etiologies. It is estimated that at some point between 5% and 10% of all cancers develop metastases in the spine. The most frequent ones are lung cancer, breast cancer, melanoma, lymphoma, prostate and colon cancer. In almost one third of cases, multiple spinal metastases are found and in 70% of cases they are located in the dorsal spine. Lymphomas can be located in the epidural space without bone involvement.
Mechanical compression is not the only factor responsible for signs and symptoms. There is also secondary damage caused by venous obstruction or arterial ischemia. The spinal cord edema can generally be improved with the use of corticoids at a first stage.
Pain is usually the earliest symptom. It can be local, increasing while in bed, or it can also be radicular. When percussion of the spinous process causes precisely located pain, this can lead us to suspect mechanical spinal cord compression.
The onset of paraparesis at a later stage worsens the prognosis. In general it will be a case of acute or subacute paraparesis that will develop pyramidal signs. Motor difficulty can result from impairment of the spinocerebellar tracts, and the symptoms will be clumsiness and ataxia.
Sphincter function is usually affected at a later stage and can be interpreted as sign of poor functional prognosis.
Hypoesthesia and anaesthesia affecting well-defined segments of the body are detected in almost half of patients at diagnosis. Sensory examination must not be omitted, although it is usually an element that has been found to be subjective. It should be taken into consideration that it is a very helpful sign in topographical orientation, without forgetting that the level can be found several levels below that of the injury.

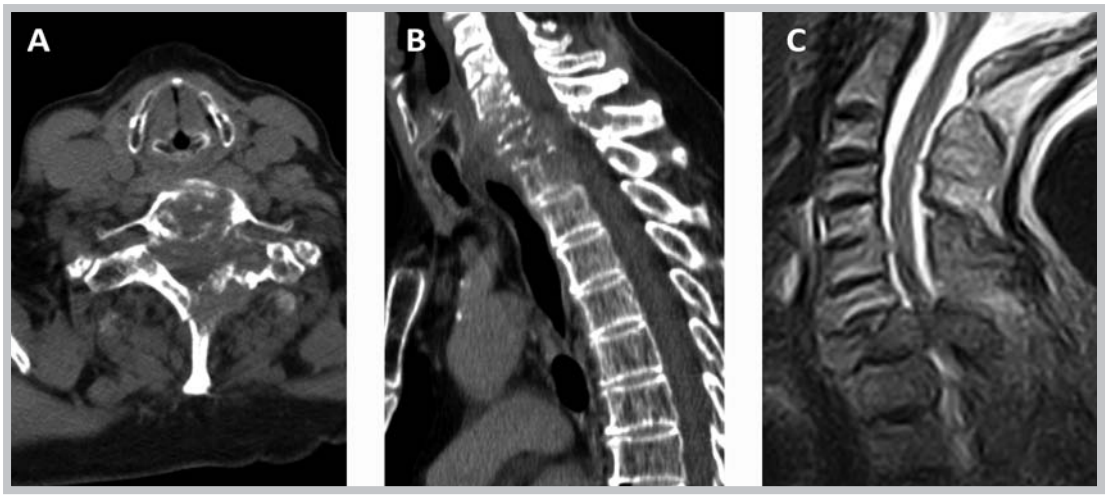

Figure 76.4. An 86-year-old woman with paraplegia caused by metastasis to D1 from lung cancer. Radiotherapy was prescribed. (A) CT scan; (B, C) MRI images. Note the better bone definition with CT and the better definition of medullary changes with MRI [Images courtesy of the Neuroradiology Department, Sanatorio Pasteur, Catamarca].

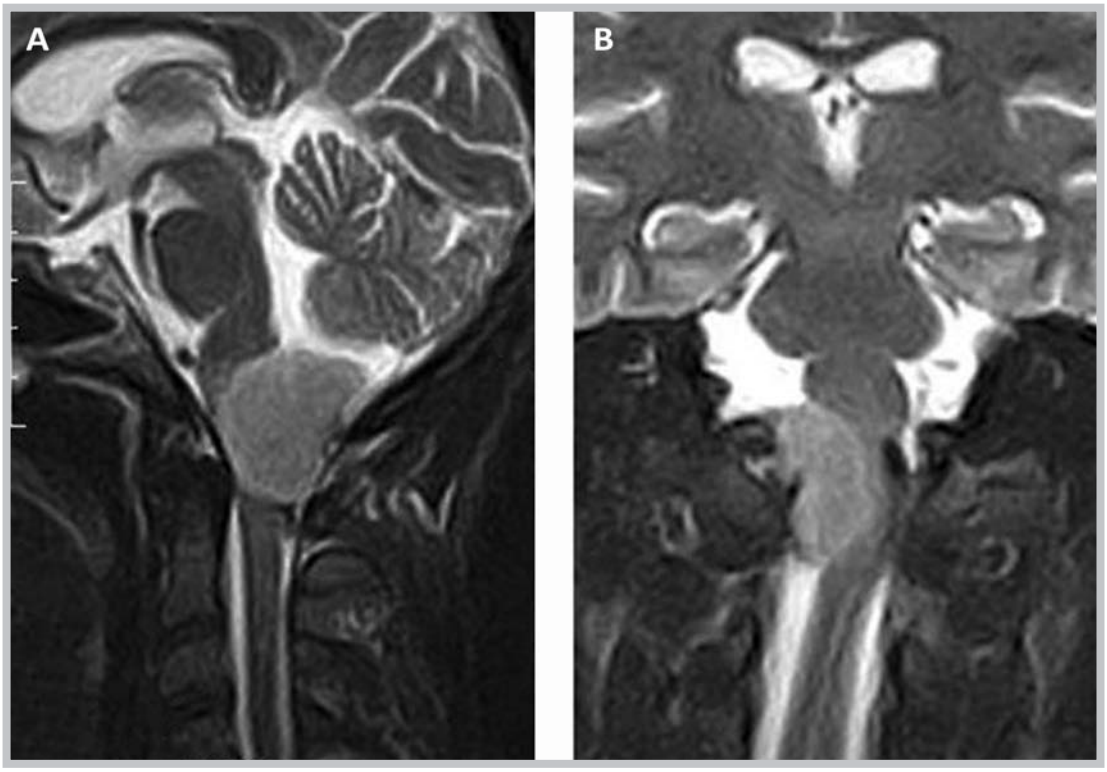

Figure 76.5. A 52-year-old woman with minor quadriparesis and some pyramidal signs. MR images showing a meningioma of the magnum foramen. Extramedullary intradural compression [Images courtesy of the Neuroradiology Department, Sanatorio Pasteur, Catamarca].

Certainly functional MRI will provide the most reliable information (see Figures 76.4 and 76.5 for examples). Differential diagnosis will include other causes of extradural compression (bar discs, spondylolisthesis, epidural hematoma, etc.), extramedullary or in-

tradural neoplastic processes (meningioma, schwannoma), intramedullar processes (ependymoma, astrocytoma, transverse myelitis, etc.).

76.3.3 Metastasis Treatment

The functional impact at diagnosis is essential for establishing the prognosis. In general terms it can be said that if the patient has had paraplegia for longer than 24 hours, the prognosis is poor. Histology and tumour staging will complete the prognosis. There is some evidence of types II and III but a few of type I to define the therapeutic behaviour. It is generally recommended that patients experiencing pain without a neurological deficit should be examined as soon as possible. If neurological signs are found, we are dealing with an emergency and such patients must be hospitalized. High-dose endovenous corticoids must be administered, for example in an initial bolus of 96 mg dexamethasone plus another 96 mg/day.
Generally speaking, radiotherapy is the first option in spinal metastasis. It seems that similar results are obtained with decompression laminectomy, though with higher associated morbidity. In such cases, the tumour site must be considered, as well as the existence or not of a defined histology since this is the opportunity for the etiological definition. Figure 76.6 shows an example of clinical findings in these kind of patients.

76.3.4 Spontaneous Epidural Hematoma

This is a rare and hyperacute cause of paraplegia. The diagnosis can be established on the basis of MR findings. The image will show a bright signal in T_1, and occasionally an

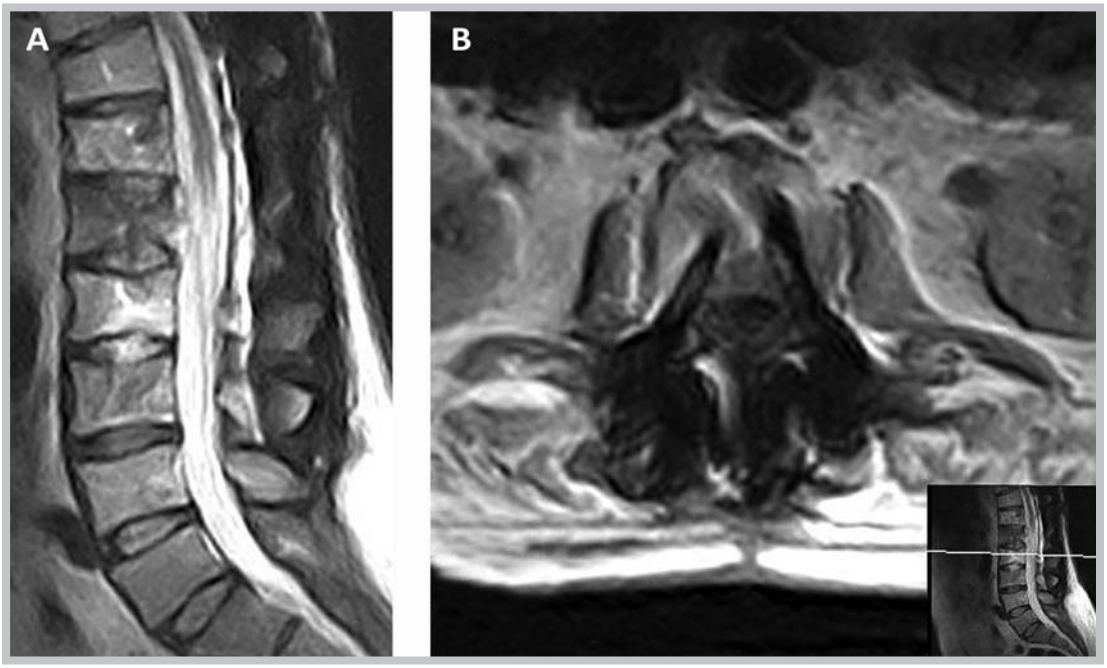

Figure 76.6. **A 60-year-old man with lumbar metastasis from prostate cancer. When he consulted, paraplegia had already begun. He was prescribed surgical decompression and stabilization with a titanium prosthesis. The motor deficit was reduced and the patient could walk again. He was later irradiated [Images courtesy of the Neuroradiology Department, Sanatorio Pasteur, Catamarca].**

empty signal in arteriovenous malformation (AVM). Anticoagulant treatment and possible hemorrhagic diatheses must be investigated. If we are uncertain about the cause, an arteriographic study should be obtained. If the patient's general condition does not improve at diagnosis, urgent surgical decompression is indicated. It is worth remembering that a major epidural circulation is the cause of the more frequent presence of hematomas in this space rather than medullary subdural hematomas.

76.3.5 Epidural Abscess

The hematogenic route can be the result of cutaneous, pulmonary or pelvic infection. It could be an infection caused by continuity from one vertebra to another or the result of an invasive procedure (lumbar or anaesthesia puncture). The most frequent pathogen is *Staphylococcus aureus*.
The symptoms are a combination of pain, deficit signs and fever. The condition can worsen rapidly and can be injurious, which is why it is advisable to adopt an aggressive approach and operate the patient immediately.

76.4 Intramedullary Injuries

76.4.1 Hematomyelia

Hematomyelia is less frequent than epidural hematoma and its causes can be the same. Intramedullary AVMs are found more often in the cervical area. Intratumoural bleeding must always be considered.

76.4.2 Medullary Infarction

Injuries in the aorta (dissecting aneurysm, traumatic or surgical injuries) can affect the anterior spinal artery. A hemodynamic shock or an embolic accident can also be the cause of an ischemic event. It usually appears as a medullary section, without pain (except for the pain that an aorta dissecting aneurysm may cause) and with the preservation of deep sensibility. MR may show spinal cord enlargement in T_2 with a bright signal in the anterior medullary area. These findings are not consistent; however, this study will serve to exclude other causes of spinal cord injury. In general, this is a case of hyperacute paraplegia. It must be taken into account that transient ischemic medullary attacks can be present as a result of vascular malformations, embolus, temporary increases in venous pressure, etc. In such cases, differential diagnosis will include other causes of transient medullary dysfunction such as narrow canal, demyelination disease, tumours, etc.

76.4.3 Acute Transverse Myelitis

Practice shows that acute transverse myelitis is most often idiopathic, and only in one third of cases can an etiological definition be reached. Those caused by infections can be viral (adenovirus, HIV, herpes virus, etc.) or non-viral (luetic vasculitis, tuberculosis, mycoplasma, etc.). Their etiology can be related to post-immunization reactions or collagen diseases or paraneoplastic (bronchogenic carcinoma) processes.

A particular group (<10%) evolves in time towards multiple sclerosis; its frequency is higher among children and young adults and most often arises in the dorsal area. MR can be normal in at least 50% of cases in the acute stage. When it is positive, local edema is perceived with a poorly defined bright signal in T_2 and possible highlighting with contrast. Since the onset of multiple sclerosis remains possible, the brain must be examined for other injuries. The CSF can show cellularity and high protein levels. A hyperacute presentation usually carries a poor prognosis. Complete recovery is achieved in one third of cases, partial in another third, and loss of walking ability and sphincter control in the remaining third. Young age, incomplete set of symptoms, maintenance of deep sensibility and a MR with few findings are indicators of a better prognosis.

76.4.4 Devic's Disease (Optic Neuromyelitis)

Devic's disease differs from multiple sclerosis and can be monophasic or recurrent. Medullary damage is usually acute while optic damage can be acute or subacute and symptoms can appear simultaneously or sequentially. In the recurrent types, medullary onset is usually separated in time from optic symptoms (>3 months). Most relapses occur within a period of 6 months, affecting mainly older adults with an associated autoimmune disease. MR usually shows lesions of more than three spinal cord segments. Hyperintense signals in T_2 in the optic nerves, chiasm and spinal cord must be searched for (Figure 76.7). Over the following weeks, treatment with steroid pulses and oral steroids is used.

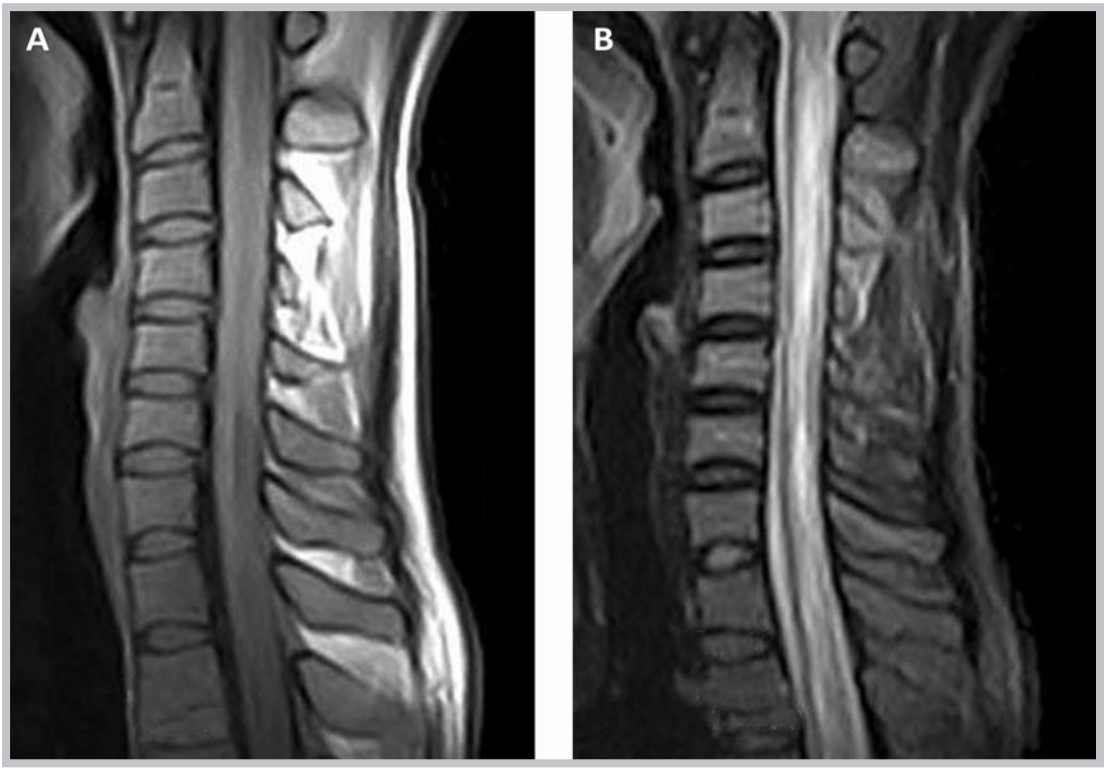

Figure 76.7. **T_1 and T_2-weighted images of the cervical spinal cord in Devic's disease (young woman). Small hypointense signal is seen in T_1. T_2 shows hyperintense signal covering several medullar segments [Images courtesy of the Neuroradiology Department, Sanatorio Pasteur, Catamarca].**

76.4.5 Intramedullary Tumours

The most frequent intramedullary tumours are astrocytoma (30%) and ependymoma. Glioblastoma, dermoid tumours and oligodendroglioma are much less frequent.
Onset is normally marked by pain followed by motor disorders that usually appear after sensory symptoms. These can be a spinal cord hemisection syndrome (Brown-Séquard) or a syringomyelia syndrome (segment paraesthesia or a level deficit in the upper limbs and dissociated anaesthesia).
MR is the imaging study of choice, though it can lead to wrong conclusions when it shows edema or cystic injuries that can be misinterpreted as necrosis.
The evolution of the patient's general condition is gradual, subacute, though it can have an acute or hyperacute onset in children.
Ependymomas in general have a better surgical prognosis than astrocytomas, with total resection achieved in more cases. Astrocytomas in general cannot be excised completely because of a lack of well-defined planes. In more serious astrocytomas, surgery and radiotherapy are combined.

77 Status Epilepticus

Isis Duran [1], Thomas P. Bleck [2]

[1] Neurocritical Care Fellow. Department of Neurology and Clinical Neurological Sciences, Northwestern University Feinberg School of Medicine, Chicago, IL, USA
[2] Professor of Neurological Sciences, Neurosurgery, Medicine, and Anesthesiology. Associate Chief Medical Officer (Critical Care) and Assistant Dean, Rush Medical College, Chicago, IL, USA

Two to three million people in the United States suffer from epilepsy. Approximately 15 percent of these patients will experience status epilepticus (SE) in their lifetime, leading to an estimated 100,000 to 200,000 cases per year [1]. The definition of SE is based on the clinical manifestation as well as the duration of seizure or seizures [2]. Nonconvulsive status, a common presentation of SE, is a frequently missed or delayed diagnosis in critically ill patients [3,4].
The mechanism by which SE develops is thought to be via an imbalance between inhibitory and excitatory factors in the central nervous system, and can arise from several different etiologies [5]. The consequences of SE have been studied in animals [5]. The longer the seizure, the higher the morbidity and mortality in patients [5]. Recognizing and treating SE in the acute and intensive care setting is essential for all health care providers, including internists, emergency care physicians, intensivists, nurses and paramedics.

77.1 Definition

Longer seizures are more difficult to break and cause significant brain damage. The Working Group on SE of the Epilepsy foundation of America defines SE as continuous seizure activity greater than 30 minutes, or two or more sequential seizures without full recovery of consciousness [6]. Animal studies from the 1970s have shown that seizures lasting longer than 30 minutes cause considerable brain damage, affecting even subcortical structures [7]. However, because seizures lasting longer than 5 minutes are unlikely to remit spontaneously, and due to the brain damage observed with long seizure activity, a revised definition of SE has been proposed: a continuous, generalized convulsive seizure lasting greater than five minutes, or two or more seizures without recovery of consciousness [8].
The definition of nonconvulsive SE (NCSE), variously termed intensive care unit (ICU) status, subtle status, and epileptic encephalopathy, generates more controversy. NCSE is characterized by many clinical states, depending on the regions of the brain involved. Signs and symptoms of NCSE can range from diminished responsiveness, aphasia, occasional automatisms, and is therefore under-diagnosed [9,10]. Recent data suggests that in an ICU population, 5% to 10% of comatose patients examined by EEG (electroencephalogram) were in NCSE [11,12]. This proportion rises sharply, to more than one third of patients, in the neurologic ICU [13]. Studies in adults, as well as in the pediatric population, show that a significant proportion of patients in convulsive status or after an isolated seizure go on to nonconvulsive status [12,14]. Without EEG monitoring following the convulsive state, NCSE would be missed.

77.2 Pathophysiology

More than a prolonged seizure, SE represents a state in which the normal balance between inhibitory and excitatory factors in the brain breaks down. GABA-mediated inhibition of an ictal focus will normally prevent secondary generalization of a seizure [15]. Recurrent or prolonged seizures enable a neurochemical feedback loop that lacks a normal inhibitory network, perpetuating more ictal activity [15].
The initial systemic effects of convulsive SE reflect the body attempt to maintain homeostasis, involving elevations of blood pressure, blood glucose, and heart rate [16]. This is accompanied by a transient increase in lactate and decrease in pH. After about 30 minutes, efforts to maintain homeostasis exhaust, and significant compromise to systemic stability follows, resulting in electrolyte imbalances, hyperthermia, and respiratory failure [16]. Initially cerebral blood flow is maintained to meet the elevated demands, but neuronal damage ensues when blood supply no longer matches the increased oxygen and glucose consumption [17]. The mismatch between blood supply and demand is not the only mechanism by which tissue damage occurs, as studies that have controlled for these factors still show damage in animal models [7]. Complex neurotoxic cascades against which therapy might be aimed (such as GABA agonists or NMDA receptor antagonists) are thought to be an important cause of neuronal damage [16]. The systemic and cerebral effects of NCSE are thought to be much less severe or lasting, confer a better prognosis than convulsive status. As such, aggressive treatment is controversial [18,19].

77.3 Classification and Clinical Manifestations of SE

In the ICU, generalized convulsive SE (GCSE) and NCSE are the two most common types. GCSE is generally diagnosed on a clinical basis, as convulsions are obvious. NCSE has two main subtypes described below, generalized and focal, which have in common only a persistent dysfunction of the neurologic examination, and usually require EEG for diagnosis.
GCSE is usually overt and relatively easy to diagnose clinically, although subtle motor manifestations may not be as apparent and also require EEG for diagnosis [20, 21]. Generalized bisynchronous convulsions, either clonic, tonic, or both, with loss of consciousness, are the typical clinical manifestation. In the ICU, GCSE is an important cause of death, with mortality approaching 20-25% [21].
NCSE describes a variety of continuous nonmotor seizures that can present clinically in many ways, including confusion, psychiatric symptoms, aphasia, and coma [10]. Generalized SE without convulsions (absence) and focal SE with alteration of consciousness (complex partial) are two seizure types classified by their EEG pattern since the clinical manifestations may be similar. A prospective study of 236 comatose patients at the Medical College of Virginia Hospitals found that EEG demonstrated 8% of patients to be in NCSE. In the ICU, NCSE occurs in up to 10% of patients with altered mental status [15].
Focal SE (epilepsia partialis continua, or simple partial SE) without impairment of consciousness, is much rarer in the ICU, and can be exceedingly difficult to control [21]. This type of seizure may present as continuous, repeated focal motor (twitching of one limb), focal sensory, or focal cognitive impairment (aphasia). By definition, this seizure type is not generalized, therefore it is not considered GCSE. Due to its common motor involvement, simple partial seizures do not fit neatly under the category of NCSE. A separate scheme, based on area of cortical involvement, is proposed in some literature [21].

77.4 Etiologies

It is important to identify the causes or predisposing factors leading to SE to optimize management. Nearly all acute or chronic brain lesions, in addition to numerous metabolic or toxic derangements, can cause SE [22,23]. These include anticonvulsant noncompliance or discontinuation, withdrawal or overdose of medications, alcohol withdrawal, acute structural injury (stroke, trauma, encephalitis), hypo- or hyper-glycemia, uremia, hepatic encephalopathy, and electrolyte abnormalities. In a population-based prospective epidemiologic study in Richmond, Virginia, the most common cause of SE in an urban setting was anticonvulsant withdrawal (26% of cases); the second most common cause was related to alcohol (24% of cases). Drug toxicity and CNS infection were among the most common causes as well, at about the same rate, 10% and 8% of cases [1,2]. In the pediatric population from Richmond, antiepileptic medication withdrawal was an important cause, but infection, either of the CNS or causing febrile seizures, was by far the most common cause of SE, occurring in 35.7% of cases [24,25]. Some studies report up to 51% of SE cases in children to be secondary to infection [26]. Other authors have reported a higher frequency of stroke, anoxia and hypoxia in the community compared to that seen in an urban hospital setting [1,2].

77.5 Management and Treatment of SE

Because the systemic effects of SE compromise cardiovascular and respiratory function, airway, breathing and circulation must be assessed and secured promptly. In the field, a blood glucose level can easily be obtained. Once IV access has been obtained, a dextrose bolus (along with thiamine) can be administered if hypoglycemia is diagnosed. Basic laboratory studies should be obtained, including basic metabolic panel, anticonvulsant levels, complete blood count, urinalysis, and urine toxicology screen [2]. If the preliminary studies discussed or the history are not forthcoming as to the etiology of the seizure, further workup should include neuroimaging, and lumbar puncture. A CT scan without intravenous contrast is usually available in emergency departments, and should identify conditions that need to be immediately addressed, such as an intracranial hemorrhage, hydrocephalus, or mass effect from a space occupying lesion (including abscess, tumor, or subacute infarction). A lumbar puncture should be considered in a febrile patient, especially where another source of fever cannot be found. An MRI of the brain will be more sensitive for acute ischemia, and may provide more clues as to the nature of space occupying lesions, but is rarely the first investigation to perform in the SE patient. Animal models demonstrate that despite adequate oxygenation, control of blood pressure, and temperature, significant brain damage occurs after 30 minutes of seizure activity [7,17]. Treatment should therefore be aimed at controlling SE as soon as possible. Benzodiazepines remain the first line of therapy in SE because of their potential to rapidly control seizures [27]. The three most commonly used benzodiazepines are diazepam, lorapezam and midazolam.

Diazepam is more lipid solubile than lorazepam; this allows it to rapidly cross the blood-brain barrier and therefore can control seizures in as little as 10-20 seconds. Also because of its high lipid solubility, its effects in the CSF wear quickly when it redistributes in adipose tissue, and there is a high chance of recurrent seizure if no other medication is added [28].

Lorazepam has a slightly slower slower onset of action due to its lower lipid solubility. However, a head to head comparison of lorazepam (up to 2 doses of 4 mg) to diazepam

(10 mg) intravenously, showed no significant difference in the times for onset of action. It also found that there was no significant difference between the two medications in the rate of seizure control [29]. The clinical advantage of lorazepam is its longer duration of action [30]. The Veterans Affairs SE Cooperative Group conducted a study of 570 patients with either overt GCSE or subtle SE to four different treatment groups: lorazepam, phenytoin, diazepam plus phenytoin, or phenobarbital. In the group with overt GCSE (384 patients), lorazepam was found to be most effective in controlling seizures within 20 minutes, and preventing recurrence within 60 minutes. This advantage was attributed to lorazepam ease of use and, at least when compared to phenytoin, faster infusion rate [31].

Midazolam is thought to be as effective in controlling seizures as lorazepam and diazepam. Additionally, it may be advantageous to use in a seizing patient where intravenous access may be too difficult to obtain, as it is available in an intramuscular formulation due to its high water solubility [30]. Diazepam in a rectal gel formulation is another option when IV access is an issue [32], and is a favored method of seizure termination in children, although buccal midazolam may be more effective [33]. Midazolam is also considered very effective treatment in refractory SE.

Based on the VA Cooperative Study cited above, lorazepam is the drug of first choice, and should be given as a 0.1 mg/kg infusion over about four minutes. Another agent should be used if his dose is reached without seizure termination [2].

Fosphenytoin is highly water soluble, in contrast to phenytoin, which requires sodium hydroxide at a pH of about 12 and propylene glycol for solubility. Fosphenytoin, therefore, can be delivered several times faster than phenytoin, at 150 phenytoin-equivalents mg/min vs. 50 mg/min of phenytoin, without the risks of irritation at the infusion site of phenytoin, or the severe tissue damage which often follows extravasation [2]. However, fosphenytoin is no less likely to produce hypotension or cardiac arrhythmias than phenytoin. Fosphenytoin was found to be effective in controlling 93.8% of seizures in a small group of 81 patients. Additionally, it is better tolerated, and plasma concentrations can actually be achieved more rapidly with fosphenytoin than phenytoin infusion [34]. The traditional dose of phenytoin is 15-20 mg/kg load in acute SE; fosphenytoin is administered at the same dose, as it is manufactured in phenytoin equivalents. Fosphenytoin, the prodrug of phenytoin, is bioequivalent to phenytoin when given intravenously [35]. Fosphenytoin may be given intramuscularly, but this is of little relevance in the treatment of SE as the patient will not achieve a useful serum concentration of phenytoin for several hours. Phenytoin should not be given intramuscularly because it forms sterile abscesses from which the drug is released over days. In the VA Cooperative Trial, phenytoin alone was the least useful of the four anticonvulsant regimens tested for the termination of SE [31].

Barbiturates and benzodiazepines act on the same $GABA_A$ receptor subtype, but have different mechanisms of action by acting on a different part of this chloride channel; barbiturates appear to stabilize the open configuration, leading to hyperpolarization and amplification of GABA inhibition [36]. The benzodiazepines, in contrast, increase the affinity of the receptor for GABA without affecting the open time of the channel. Phenobarbital and pentobarbital are the two most commonly used barbiturates in the treatment of SE.

Phenobarbital was found to be slightly less effective than lorazepam, and slightly more effective than diazepam plus phenytoin in the VA cooperative study [31]. Each of these three arms was statistically superior to phenytoin alone. While it is still the agent of choice in neonates [37], it is generally not used as a first-line agent in adults because of its slow administration and side effect profile, although a small randomized control study did not demonstrate significant difference of intubation, hypotension or cardiac arrhythmia [38].

The VA cooperative study demonstrated that if SE does not respond to one agent, adding a second rarely results in termination of SE [31]. Non-sedating agents such as levetiracetam and valproate are important in these situations, as the only alternative is induction of coma with anesthetic antiepileptics and burst suppression. Although these agents require further study to define their role in status epilepticus, they show promise.

Levetiracetam. The efficacy of levetiracetam in the setting of SE has not been studied in direct head to head trials. Although it is not approved by the United States Food and Drug Administration, it shows promise in a few recent case series of SE and refractory SE as adjunctive therapy to benzodiazepines, or other first line pharmacologic agents [48-50]. These studies do not classify patients according to etiology of SE, which is an important factor in the prognosis of SE.

The Spanish Group for the study of IV levetiracetam in SE conducted a multi-center retrospective observational study of patients in SE who were treated with a benzodiazepine plus a second standard agent, with IV levetiracetam administered as a third agent in refractory cases, or earlier in treatment in patients with contraindications to first line treatments (such as phenytoin). Forty patients were analyzed. Leveteracitem was found to be effective in terminating SE in more than half the patients, and higher efficacy was seen with earlier use of the drug. Unlike in prior studies, the Spanish group classified patients in terms of etiology, and found lower efficacy in patients with tumors, and those with acute CNS injury (such as stroke and trauma). In comparison, those with chronic injury, toxic metabolic injury, medication non-compliance, treatment was more effective. Levetiracetam is well tolerated, with few side effects (predominantly neuropsychiatric symptoms such as pyschosis, agitation, or sedation), and few drug interactions. Leveteracitam can be considered as adjunctive therapy in the current management of SE.

Valproate. There is limited available data for the efficacy of valproate in the treatment of SE. Some limitations to the use of valproate in SE is that the FDA approved of infusion rate may not be high enough to effectively terminate seizures, since rapid infusion may cause hemodynamic compromise. Maximum rates of 6 mg/kg/min after a loading dose of 20 mg/kg has been found to be safe [53].

Rapid infusion may also cause hyperammonemic encephalopathy, characterized by decreased level of consciousness, nausea and vomiting, cognitive impairment, or focal neurologic deficits. Carnitine supplementation during Valproate therapy is recommended for the prevention of valproate induced hyperammonemic encephalopathy in high risk patients [52]. Since risks factors for carnitine depletion include the presence of concomitant neurologic or metabolic disorders, and receipt of multiple antiepileptic drugs, most patients in status epilepticus can be considered high risk.

Experience with valproate is limited [51-54]. In one retrospective study, valproate was found to control seizures at a higher rate than Levetiracetam [51]. In a small case series, it was found to be as effective in terminating seizures as phenytoin [54]. Valproate can be considered as adjunctive therapy following administration of benzodiazepines if seizures continue.

Topiramate. A recent retrospective case study of a few patients in refractory SE found topiramate to be effective in terminating seizures, in a variety of seizure types and after failing first and second line agents [56]. The efficacy of topiramate may be attributed to the drug's broad mechanism of action and potentiating effects at various sites. Case reports suggest that topiramate may be used safely and considered as a second line agent in cases of refractory SE [57-58]. Given limited experience with this agent, it is not broadly recommended in the literature, and prospective studies must be conducted to determine its efficacy in SE.

77.6 Treatment of Refractory SE

Although the majority of patients in SE will respond to initial treatment, the addition of a second conventional agent is unlikely to be effective [31,39]. For this reason, authors argue that refractory SE should be defined as failure to one first-line agent [40] and a more definitive strategy is recommended [2]. By the time a patient is considered to be in refractory SE, endotracheal intubation prior to initiation of definitive therapy is necessary if this has not already been accomplished. Blood pressure support will likely be necessary with intravenous fluids and vasopressors. Additionally, EEG monitoring should be available emergently, as it will be necessary to recognize seizure termination in a sedated patient with compromised neurologic exam, and is the only guide of therapy.

Therapy for refractory SE should proceed on three fronts: termination of SE, prevention of its recurrence, and treatment of its complications.

Pentobarbital is initially loaded at a dose of 5-12 mg/kg, followed by continuous infusion, titrated to achieve seizure termination. Burst suppression is defined as episodes of flat or near-flat electroencephalographic activity, 5-10 seconds long, with shorter intrusions of epileptic activity (Figure 77.1).

Burst suppression pattern is used as a clinical tool to avoid over-medicating when the neurologic exam is obliterated by anesthetic medications. This EEG pattern has often been suggested as a goal for therapy in refractory SE, but achieving burst-suppression is neither necessary nor sufficient for the control of SE. Therefore, the goal should be seizure suppression; this is usually maintained for 12 to 24 hours, and then decreased by some arbitrary degree, such as 50%, for several hours while observing for seizure recurrence. Simultaneously, an anticonvulsant or an appropriate combination is added, with the goal of maintaining a seizure free state once barbiturate is cleared. Continuous EEG

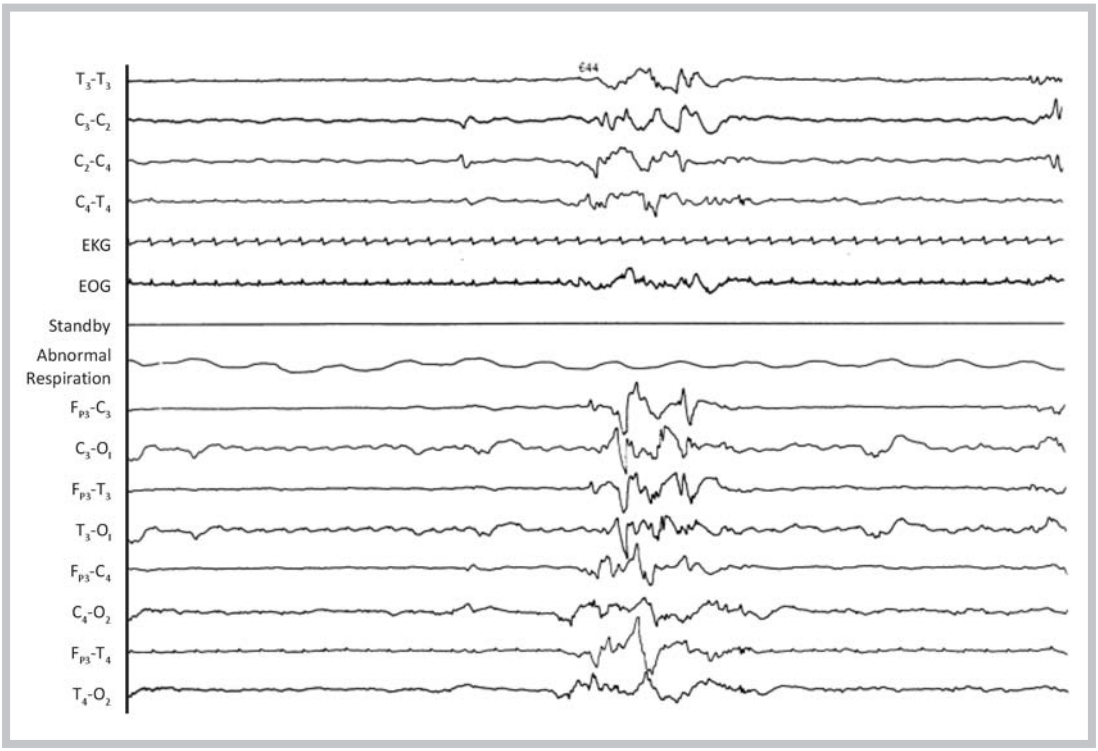

Figure 77.1. EEG burst suppression pattern (HF 70 Hz, LF 1 Hz SEN 5 μV/mm) [54].

monitoring is required during this weaning process, as recurrence of seizure activity prompts a return to the previous dose with adjustments in doses or types of the other anticonvulsants [21].

Midazolam infusion in the setting of refractory SE offers a favorable pharmacokinetic profile [40]. One small study showed rapid control of seizure that had failed multiple medications, including diazepam, lorazepam, phenytoin, with or without phenobarbital, with minimal hypotension [41]. In critically ill patients, midazolam can accumulate, es-

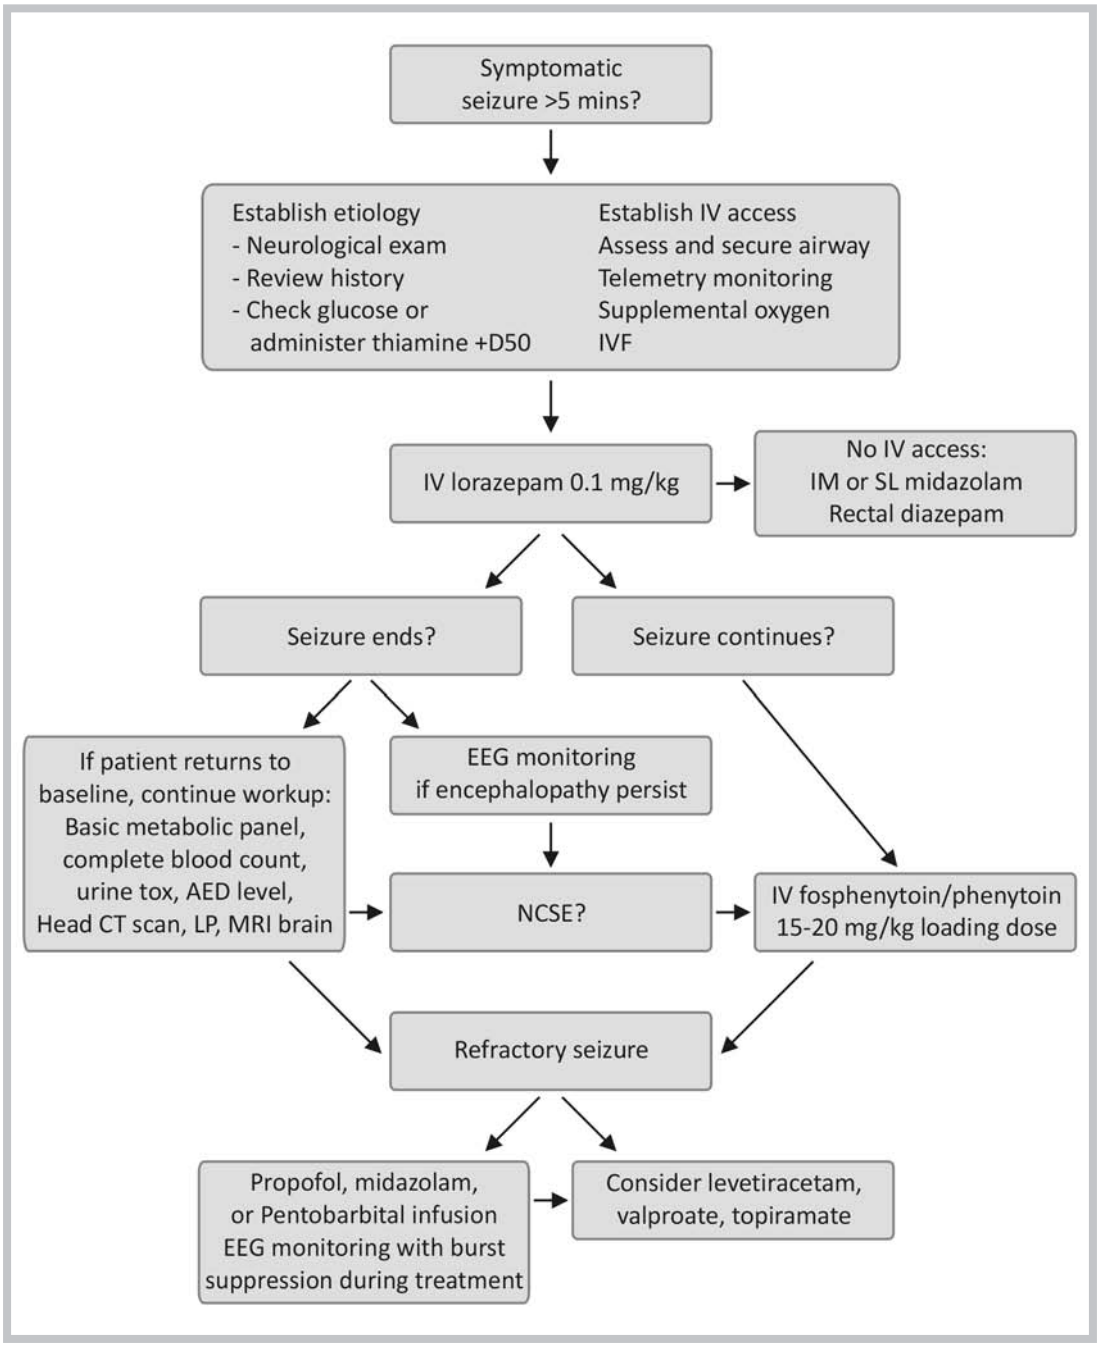

Figure 77.2. **Management of status epilepticus.**

pecially as increasingly higher doses of midazolam are usually required to maintain burst suppression. Some studies have shown that there may be lower mortality in a select group of patients treated with a midazolam infusion compared to those treated with a propofol infusion [42].

Propofol has a very short half life in comparison to the alternatives discussed for refractory SE treatment. Additionally it is highly lipid soluble and therefore fast acting in CNS. Several studies and reviews have demonstrated its effectiveness in treating refractory GCSE and NCSE [43-46]. Some recent studies have suggested an increased mortality associated with propofol infusion [41], but others have not supported this trend when compared to pentobarbital or midalozam at anesthetic doses for the treatment of SE [46]. Care must be taken to not discontinue propofol abruptly, as this may be associated with recurrent seizures. Hypotension is more common with propofol than with midazolam. Triglyceride levels must be monitored during prolonged infusion as development of hypertriglyceridemia may prompt discontinuation of propofol infusion. The clinician should observe carefully for development of the the propofol infusion syndrome, which may manifest as either a metabolic acidosis or rhabdomyolysis. If either of these occur, propofol should be discontinued and another agent substituted.

77.7 Conclusions

In the ICU, mortality associated with SE is high, and irreversible brain damage ensues quickly. The detection and diagnosis of SE, along with identification of its etiology, is crucial for clinicians at all stages of this condition, as the goal must be termination of seizure as soon as possible. A systematic yet aggressive approach to the treatment of SE is recommended. The clinician must be prepared to escalate rapidly to more potent anesthetic medications while providing basic life support measures, until either clinical or electrographic end of seizure is apparent.

78 Metabolic Encephalopathies

Bryan Young [1], **Christopher Brooks** [1]

[1] The University of Western Ontario, London, Ontario, Canada

78.1 Definition and General Clinical Manifestations

Metabolic encephalopathies are characterized by a general impairment of cerebral activity in the absence of overt structural abnormalities or visible inflammatory reaction. There is a spectrum of degrees of impairment of consciousness ranging from delirium to coma. Milder degrees of encephalopathy often show marked fluctuation in degrees of alertness and awareness within a day, in contrast to the dysfunction found in neurodegenerative disease and structural brain lesions. Also, in contrast to dementing illnesses, patients with metabolic encephalopathies are as likely to be disoriented in place as well as in time, while demented patients typically develop disorientation in time before they lose spatial orientation. Brainstem reflexes are typically spared, with the exception of Wernicke's encephalopathy, in which ophthalmoplegia is a common and helpful diagnostic feature. Motor signs that suggest a metabolic encephalopathy include tremor, asterixis and multifocal myoclonus. Metabolic tremor is typically of the postural-action type rather than alternating/rest or intention tremor. Asterixis is a loss of postural tone, often revealed by having the patient hold the arms outstretched with the wrists dorsiflexed and the fingers extended. The lapse of tone causes a "flapping tremor" that may be synchronous or asynchronous; this has its origin in the brainstem reticular formation (It should be noted that unilateral asterixis is sometimes/rarely found with parietal lobe lesions or with structural midbrain damage.) Multifocal myoclonus, a sign specific for metabolic/toxic encephalopathies, is the asynchronous jerking of various muscles in various limbs in a seemingly random fashion. Again, the origin of multifocal myoclonus is in the nucleus reticularis gigantocellularis in the medulla.

78.2 Differential Diagnosis of Metabolic Encephalopathy

The history can provide useful clues as the cause of the encephalopathy, e.g., a past history of illnesses and associated medications, e.g., diabetes mellitus, cancer, alcoholism, thyroid disease, pulmonary disease, or tuberculosis. Recent illnesses, especially associated with fever or infection or sudden collapse due to seizures, can help point to a metabolic encephalopathy, although a central nervous system infection sometimes must be considered. Conversely, a history of brain tumor or systemic cancer, previous stroke or trauma suggest a structural brain lesion. Interviewing relatives or cohabitants, reviewing medical records, looking for health information on the patient, e.g., information bracelets, and drug lists can be helpful.

Next one should examine the patient to help determine the site of the brain dysfunction. Intact brainstem reflexes points to a cause above the brainstem. In that event, lateralizing signs, e.g., hemiplegia or focal seizures suggest a supratentorial structural lesion, although some metabolic disorders, e.g., acute hepatic encephalopathy or hypoglycemia, can occasionally produce "focal signs". Delirium, acute confusional state, is in itself usually due to a metabolic or drug-related encephalopathy, although CNS in-

flammation may also produce this picture. Subhyaloid hemorrhages in the fundi almost always relate to a ruptured intracranial aneurysm; Roth spots (white-centered retinal hemorrhages) suggest endocarditis or leukemia. Meningismus, suggestive of meningeal irritation from blood or infection, disappears in deep coma.

The general examination should be performed systematically. Vital signs can be helpful, e.g., fever (usually an inflammatory process that is systemic or in the central nervous system) or severe hypertension (raising the possibility of a hypertensive encephalopathy or pointing to underlying renal disease or drugs). Marked hypothermia in itself can produce coma, but can also be found in some septic patients and in myxedema coma, some with Wernicke's encephalopathy and intoxications. Severe hypotension may relate to septic shock or adrenal failure/crisis. Examining the respiratory pattern, coupled with blood gas determination, can help narrow the diagnostic possibilities. For example, hy-

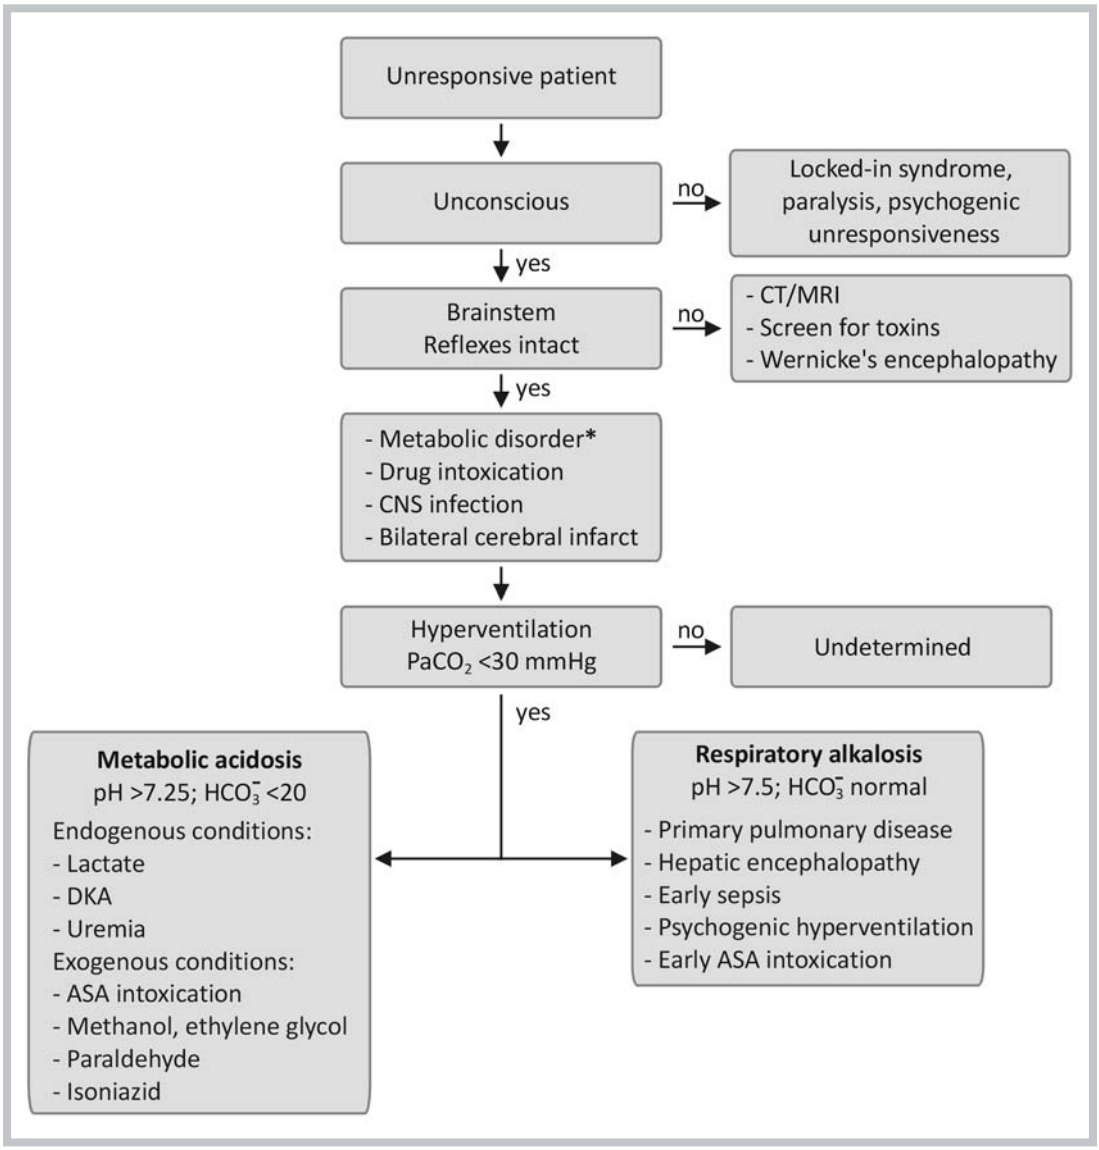

Figure 78.1. **Algorithm for the unresponsive patient.**
* Tests for metabolic disorder: EEG, laboratory, cultures

Encephalopathy	Distinguishing clinical features	Laboratory features
Hepatic encephalopathy	Hyperventilation, jaundice, ascites	Abnormal liver function tests, increased INR (with acute liver failure), respiratory alkalosis, triphasic waves on EEG
Hypoglycemia	Seizures, myoclonus, sweating, agitation progressing to stupor or coma	Serum glucose <2.5 mmol/l, MRI may show DWI changes in cerebral cortex, hypocampus, but sparing of thalamus and cerebellum
Hyperglycemia	Often seizures and fluctuating signs in nonketotic hyperglycemia, hyperventilation in DKA	Serum glucose usually >20 mmol/l for coma
Hyponatremia	Vomiting, seizures, focal signs (occasionally)	Cerebral edema, serum sodium often <120 mmol/l for severe encephalopathy; CPM if overly rapid correction
Hypernatremia	Preceding dehydration (e.g., gastroenteritis), seizures	Serum Na usually >160 mmol/l for severe encephalopathy; brain shrinkage; subdural hematomas
Hypermagnesemia	Profound weakness, parasympathetic paralysis	Serum Mg usually >2.5 mmol/l for severe encephalopathy
Hypomagnesemia	Preceding muscle cramps, hyper-reflexia, seizures	Serum Mg usually <0.5 mmol/l for coma
Hypophosphatemia	Seizures, myoclonus, profound weakness, coma often after refeeding nutritionally deprived individuals	Encephalopathy usually with serum PO_4 <0.5 mmol/l
Hypercarbia	May have papilledema with raised ICP, tremor, asterixis and myoclonus	$PaCO_2$ usually >60 mmHg; pH <7.2 with acute respiratory failure with coma.
Hypercalcemia	Preceding renal stones, bone pains	Serum Ca usually >3 mmol/l; findings associated with underlying cause, e.g., malignancies, hyperparathyroidism
Hypocalcemia	Hyperexcitability, tremor, chorea, seizures	Symptomatic when serum Ca <0.5mmol/l
Hyperthyroidism	Tachycardia, sweating; warm skin; tremor; goiter; ophthalmoparesis (e.g., inferior rectus deposits lead to impaired upgaze)	Elevated free T4 and T3, reduced TSH in serum
Hypothyroidism	Hypothermia and bradycardia, thick tongue; pale, puffy skin, slow relaxation of DTRs	With primary thyroid failure: elevated TSH, low T4 and T3, elevated $PaCO_2$, EEG is suppressed in voltage and slow in frequency
Adrenal insufficiency	Hypotension, hyperpigmentation of gingivae and palmar creases	Hyperkalemia, hypoglycemia, low serum cortisol
Septic encephalopathy	Paratonic rigidity, features of systemic inflammatory response syndrome, e.g. fever or hypothermia, tachycardia.	Increased WBC, evidence of infection or systemic inflammation; slowing or triphasic waves on EEG
Uremic encephalopathy	With acute uremia, hyperexcitability, multifocal myoclonus, seizures	Elevated serum urea and creatinine

Table 78.1. **Principal metabolic encephalopathies.**

perventilation due to a metabolic acidosis limits the possibilities to renal failure, diabetic ketoacidosis, lactic acidosis, exogenous agents (e.g., methanol, ethylene glycol, and salicylates). Hyperventilation with respiratory alkalosis can occur with early sepsis or the initial phase of salicylate intoxication, acute pulmonary disease or hepatic failure. The general examination may also reveal the stigmata of chronic liver disease; needle tracks suggest drug intoxication or infection. Cherry-red lips imply carbon monoxide intoxication; fever and a cardiac murmur suggest bacterial endocarditis. A tongue bitten on its lateral aspect suggests a convulsive seizure. Purpuric lesions may be found in meningococcemia or thrombotic thrombocytopenic purpura.

Psychogenic unresponsiveness or pseudoseizures may also mimic acute encephalopathies. One looks for inconsistencies and normal findings on exam to help. A history of psychiatric illness also raises, but does not in itself establish, the possibility of non-organic brain disease.

Laboratory tests are helpful, but should be guided by the history and examination findings. As mentioned, blood gas determination is invaluable in cases of hyperventilation. For apparent diffuse encephalopathies the following are indicated: hemoglobin, white blood count and platelet count in the peripheral blood, serum electrolytes, calcium, magnesium, glucose, urea, creatinine and a screen for drugs (often guided by toxidromes). When indicated, liver function tests, blood cultures, thyroid and adrenal function, carboxyhemoglobin, and special hematological tests (screening for disseminated intravascular coagulation or TTP) should be conducted. Electroencephalography can be of great help in diagnosing nonconvulsive status epilepticus, which could mimic metabolic coma, as well as in helping to confirm the latter (e.g., trochaic waves are most commonly seen in hepatic of renal failure or with sepsis-associated encephalopathy). Periodic epileptiform discharges from the temporal lobes in the context of an acute febrile encephalopathy favors herpes simplex encephalitis. Lumbar puncture is indicated for meningitis and encephalitis and to confirm subarachnoid hemorrhage if the diagnosis is in doubt after neuroimaging. Neuroimaging with CT or MRI is helpful in ruling in or out structural brain lesions. TA classification of metabolic encephalopathies is provided in Table 78.1, which lists principal metabolic encephalopathies, along with some distinguishing clinical and laboratory features.

78.3 Hepatic Encephalopathy

Hepatic encephalopathy can be divided into acute and chronic, two quite different disorders in terms of their underlying liver disease, clinical presentations and treatment. They will be discussed separately.

78.3.1 Acute Hepatic Encephalopathy

Acute liver failure is due to impaired hepatocellular function and develops within 6 months from onset; a subset, acute fulminant liver failure, develops over 8 weeks.

Acute liver failure is commonly due to acetaminophen poisoning, viral and auto-immune hepatitis, ecstasy and other toxins, liver infarction, Wilson's disease, Bud-Chiari syndrome, acute fatty liver of pregnancy, lymphomatous infiltration, heat stroke and malignant hyperthermia are other causes.

Ammonia is still thought to play a key role in the pathogenesis of both acute and chronic hepatic encephalopathy, even though serum ammonia concentrations show at best only a crude correlation with the severity of brain dysfunction [1]. Glial swelling, related to in-

creased glutamine production and mitochondrial toxicity, account for most of the cerebral edema. As a corollary, one should not be overly pessimistic when diffusion-weighted MRI scans show marked signal change in the cerebral cortex (Figure 78.2).
Acute hepatic failure most often presents in a dramatic fashion with rapid development of delirium or organic psychosis (Grade 1 hepatic encephalopathy is associated with an agitated delirium; Grade 2 is associated with blunting of consciousness) that can quickly progress to stupor (Grade 3 encephalopathy) and coma (Grade 4). Seizures can accompany severe or rapidly progressive disease. These features may occur so abruptly that they may precede the usual signs associated with liver failure, e.g., jaundice.
Cerebral edema is common with acute hepatic failure (most commonly the acute fulminant type). This can be life-threatening and needs to be detected and managed aggressively. We have found serial CT head scans to be an effective means of monitoring cerebral edema, especially if "baseline" CT head scans are done when the patient presents (before established encephalopathy) [2]. This is probably more practical and safer than intracranial pressure (ICP) monitoring, which shows rises only when compensatory mechanisms are exhausted. The main advantage of ICP monitoring is that allows for adjustment of blood pressure to allow a mean cerebral perfusion pressure of at least 60 mmHg. Intermittent hypertonic saline (rather than mannitol) with hypothermia are sometimes helpful, but hepatic transplantation should be considered in severe, rapidly progressive cases.

78.3.2 Chronic Hepatic Encephalopathy

Chronic hepatic failure, which takes over 8 months to become manifest, almost always relates to shunting of blood from the portal to the systemic circulation, bypassing the detoxifying effect of the liver on blood from the gut. Urea cycle abnormalities constitute a rare cause of chronic ammonia intoxication.
Chronic hepatic encephalopathy most often relates to varices (allowing portal-systemic shunting) associated with alcoholic and viral hepatitis, Wilson's disease and transjugular intraheptic shunts (TIPS). Rarely urea cycle abnormalities produce hyperammonemia, which can produce a syndrome indistinguishable from encephalopathy due to liver dysfunction.
Cerebral edema is not as common with chronic hepatic encephalopathy as with the acute form, as the brain can compensate in the former. Severe exacerbations may be accompanied by seizures, coma and brain swelling, however.
Management consists of reducing ammonia production in the gut by limiting protein in the diet and the use of lactulose, detecting and treating precipitants (including gastrointestinal bleeding, intercurrent infections and electrolyte disturbances), using nonabsorbable antibiotics to kill bacteria in the gut and, in severe cases, hepatic transplantation. Sedative drugs should be avoided. Seizures are managed symptomatically; we have used various agents, but those without clearance by the liver, e.g., levetiracetam or gabapentin, have some advantages.

78.4 Uremic Encephalopathy

Central nervous system complications of uremia can be divided into direct effects of acute and chronic renal failure as well as side effects/complications of therapy (Table 78.2).

Treatment	Neurological complications
Dialysis	• Dialysis dysequilibrium (related to osmotic shifts and cerebral edema) • Wernicke's encephalopathy (related to loss of thiamine during dialysis) • Dialysis dementia (related to aluminum poisoning from dialysate or phosphate binders – now rare) • Posterior reversible leucoencephalopathy syndrome (PRES), related to accelerated hypertension
Renal transplantation	• PRES related to calcineurin inhibitors (cyclosporine, tacrolimus) • Opportunistic infections (e.g., *Crypococcosus* or aspergillosis) due to immunosuppression • CNS lymphoma/post-transplant lymphoproliferative disorder (after immunosuppression) • Ischemic stroke: often related to comorbidities, e.g., hypertension, dyslipidemia

Table 78.2. Complications of therapy of renal failure.

Both acute and chronic uremic encephalopathy relate to accumulation of uremic toxins and the loss of homeostasis normally provided by the kidneys. There is probably no single "uremic toxin", but many compounds that play a synergistic role: guanidino compounds, parathormone, urea, middle molecules, phenols, amines, myoinositol, aluminum and other chemicals [3]. Poor clearance of drugs can contribute to encephalopathy and we have seen encephalopathy due to the use of standard antiepileptic drugs that rely on renal clearance, e.g. gabapentin and levetiracetam. One should not ignore encephalopathies due to the disorders that caused renal failure, e.g., systemic lupus erythematosis and other autoimmune disorders, diabetes mellitus and severe hypertension.

78.4.1 Acute Uremic Encephalopathy

As with acute liver failure, the neurological presentation is dramatic. Impairment of alertness and awareness can vary from a mild confusional state, through delirium to stupor and coma. Acute uremia is often accompanied by signs of increased excitability, including myoclonus (usually multifocal), seizures and tremor. Asterixis can be prominent. Hyperventilation may reflect agitation or a metabolic acidosis.
Investigations reveal the biochemistry of acute renal failure, with elevated serum urea (usually >27 mmol/l) and creatinine (usually >300 µmols/l), electrolyte disturbances and a metabolic acidosis.

78.4.2 Chronic Uremic Encephalopathy

Chronic uremic encephalopathy is much more insidious than the acute form. Patients often fluctuate in impairment of mental status; they show sleep disturbances. In severe cases the same motor findings as in acute uremia may be present. With dialysis therapy, these more dramatic manifestations are uncommon. It should be noted that the PRES (Table 78.1), which typically presents with cortical blindness, seizures and varied degrees of impaired consciousness, is more a feature of chronic than acute uremic encephalopathy; it can also be seen as a complication of calcineurin inhibitors.
Management of uremic encephalopathy is largely symptomatic. Seizures may require maintenance antiepileptic medications, e.g., phenytoin or valproate. Myoclonus in uremia often responds to clonazepam. Hypertension should be treated appropriately, both in the acute and chronic situations. The neurological complications are minimized by ad-

equate dialysis therapy and eliminated by renal transplantation (although the latter may have complications of its own. See Table 78.2).

78.5 Sepsis-associated Encephalopathy (SAE)

Sepsis, the systemic response to micro-organisms or their toxins, is produced by inflammatory mediators or cytokines in the presence of infection. Brain dysfunction or encephalopathy is a common accompaniment to sepsis. Septic encephalopathy, or better, sepsis-associated encephalopathy (SAE) is a common problem with potentially serious consequences. In our studies of hospital patients with bacteremia, 87% had abnormal electroencephalograms (EEG) and 70% were diagnosed with neurologic symptoms ranging from lethargy to coma. Forty-six percent of these patients with brain dysfunction were in the intensive care unit, with the rest on the wards. Survivors of severe sepsis were sometimes left with debilitating cognitive and behavioral problems that persisted for years or were irreversible [4].

The diagnosis of SAE is one of exclusion. One should exclude direct central nervous system infection, e.g., meningitis, drug-induced encephalopathy and other conditions, e.g., bilateral subdural hematomas, that are capable of causing fluctuating mental status and symmetrical motor signs without lateralizing features.

As with uremia, there is unlikely to be a solitary mechanism for SAE. Cytokines undoubtedly play a role. Indeed, interleukins 1 and 6 and tumor necrosis factor alpha may act on the brain to alter hypothalamic nuclear function [5] and tryptophan metabolism [6]. Some of our SE patients with post-mortem examinations had multiple microscopic infarctions [7]. Indeed, reduced cerebral blood flow and increased cerebrovascular resistance are found in human cases of SE. Microthromboses and microinfarctions may also occur, as well as damage from oxidative stress. At least some of these phenomena likely relate to the production of cytokines [e.g., tumor necrosis factor-α (TNF-α), interferon-γ (IFNγ) and interleukins] and their effects on the production of nitric oxide (NO) by endothelial nitric oxide synthase (eNOS) [8]. Inhibition of eNOS leads to impairment of the microcirculation of the brain and other organs by causing vasoconstriction. In addition, sepsis is a procoagulant state that rests with endothelial dysfunction: endothelial cells convert protein C to activated protein C that has anti-inflammatory and profibrinolytic properties. The brain may be similar to other organs in this respect. Apoptotic mechanisms may also be operative [4]. Some effects may be purely metabolic, e.g., altered amino acid mix (higher aromatic vs. branched chain amino acids), which could alter the neurotransmitter balance; the metabolic effects of other organs can affect the brain [4].

Clinically the neurological manifestations begin with altered mental status, often a fluctuating confusional state or delirium, which may be accompanied by hyperventilation. The level of consciousness deepens with worsening of the systemic illness; indeed brain function acts as an index of the severity of the systemic inflammatory response syndrome and failure of other organs. The principal motor finding is paratonic rigidity or *gegenhalten*, a velocity-dependent increase in the resistance to passive movement of the limbs or neck. If the movements are rapid the increase in tone is felt by the examiner; if the movements are made very slowly, there is no increase in tone. Tremor, multifocal myoclonus and seizures are not common in SAE [4].

The EEG reflects in an objective manner the severity of the encephalopathy and systemic illness [9]. Mild cases show mild slowing. As the encephalopathy worsens delta (waves of 4 Hz or less) appear, followed by triphasic waves and then a burst-suppression pattern

as the encephalopathy worsens. The EEG changes are usually reversible and some patients even with burst-suppression can survive without serious brain dysfunction.
Management of SAE is chiefly treatment of the underlying systemic infection [4]. Prompt antimicrobial therapy, drainage of abscesses, activated protein C, which antagonizes the procoagulant effects of sepsis, can help the systemic illness and may also benefit the brain [4]. Other complications, e.g., seizures, must be managed symptomatically, e.g., with phenytoin.

78.6 Key Concepts

- Metabolic encephalopathies are common and varied. A common feature is that, at least in mild-moderate cases, they are not associated with structural changes in the brain.
- Changes in mental status vary from delirium to deep coma. In the early phase of most metabolic encephalopathies, there is often marked fluctuation in mental status.
- Cranial nerve functions are spared (except for ophthamoplegia in Wernicke's encephalopathy).
- Motor findings typical of metabolic encephalopathies include postural-action tremor, asterixis and multifocal myoclonus. Seizures, usually generalized in type, may occur in some encephalopathies.
- Specific laboratory tests are ordered to confirm the specific diagnosis, depending on the history and physical examination. The EEG can be helpful in grading the encephalopathy and in establishing that the condition is a metabolic encephalopathy and in differentiating it from structural lesions, encephalitis and seizures.

79 Hypoxic Ischemic Encephalopathy Post Cardiorespiratory Arrest

Luis Castillo Fuenzalida [1], Cristián Pérez Ríos [1]

[1] Department of Intensive Care Medicine. Critical Patient Center
Clinical Hospital Universidad Católica of Chile

79.1 Introduction

Sudden cardiac death is an unexpected event, without traumatic cause, which affects approximately 300,000 people in the United States of America and more than 600,000 people in Europe each year. It is characterized by the cessation of effective cardiac functioning, with or without symptoms, for a period of less than 1 hour. The cessation of cerebral blood flow derived from it causes neurological injury with varying evolution and prognosis.

Cardiopulmonary resuscitation (CPR) is a manoeuvre that attempts to restart spontaneous circulation and maintain perfusion of different organs. Between 1% and 2% of patients with sudden death receive CPR, where chest compression is the main measure for attempting to restore flow. Under the best circumstances chest compressions generate from 25% to 30% of normal cardiac output, bringing about systolic pressure that reaches between 60 and 80 mmHg, while diastolic pressure rarely exceeds 20 mmHg. This creates a severe compromise in cerebral perfusion, which is barely able to retain between 10% and 15% of the normal flow. As a result, recovery without residual neurological damage is rare, and many of the survivors evolve with neurological damage of varying degrees of severity or progress to a persistent vegetative state. Moreover, there are no effective indicators of the neurological functioning status after the event, a situation that creates uncertainty in the medical team, family grief and a high economic cost.

79.2 Development

The brain is highly dependent on oxidative metabolism, and in spite of accounting for only 2% of body weight, it is responsible for 20% of total oxygen consumption and 60% of glucose consumption. It does not have an energy reserve, and in low input conditions, its ability to compensate by increasing oxygen extraction is much lower than in other tissues. This makes it highly susceptible to states of hypoxia and ischemia, where rapid changes in mitochondrial function occur, affecting cell survival. The cells in the cerebral cortex are especially affected, since they consume 75% of the cerebral metabolic requirements [1]. Under conditions of adequate oxygen supply, ATP used as an energy source is produced by glycolysis and oxidative phosphorylation. In the cytosol, glucose is converted to two pyruvate molecules that are oxidized and produce acetyl coenzyme A, which enters the mitochondria to form part of tricarboxylic acid, and by means of oxidative phosphorylation, generates 36 ATP molecules for each glucose molecule.

Under anaerobic conditions, decoupling occurs between oxygen transport and consumption. Pyruvate, instead of oxidizing to produce acetyl coenzyme A, is acted upon by lactate dehydrogenase (LDH), becoming a lactate with potentially harmful effects at the neuronal level.
The energy produced in these processes generates an electrochemical gradient that preserves the transport of hydrogen ions by means of the inner mitochondrial membrane.
More than 95% of the carbohydrates that enter the brain are used by the mitochondria, while more than 95% of ATP is generated by mitochondrial oxidative phosphorylation. Hence, ensuring blood flow and constant oxygen supply is necessary to maintain neuronal functioning.

79.3 Damage Mechanisms

After circulation stops, three stages have been described in cerebral blood flow (CBF); the first, immediately after the event, is characterized by moderate non-uniform hyperaemia where there is a release of neuronal nitric oxide, endothelial damage by reperfusion and exposure of membrane phospholipids, which, together with free radical generation, increase endothelial and diffuse cellular damage.
A second delayed hypoperfusion stage, where there is vasospasm, cytotoxic edema and no reperfusion phenomenon, which causes a decrease of up to 50% in cerebral blood flow, occurs between 2 and 12 hours after circulatory arrest.
Finally, there is the third, less defined stage, where the CBF can return to normal or be reduced to a minimum.
As there is a decrease in CBF, interference is generated in the mitochondrial oxidation processes, as is the production of free radicals and the accumulation of amino acids, with harmful potential at the neuronal level. All of this is a continuous process where injuries have been found to occur twice and several agents have been identified.
At first, when the decrease in CBF generates a loss of consciousness in a matter of seconds, global hypoxia causes an increase in compensatory CBF, with a sharp reduction in ATP production. This starts to be processed by glycolysis, depleting reserves of glycogen and high-energy phosphates (energy failure) within minutes, producing membrane alterations (depolarization failure), and generating lactic acid and the release of glutamate with cytotoxic effects (anaerobiosis-acidosis).
Under these conditions, during the first minutes after oxidative phosphorylation is stopped, the brain has two rescue paths to maintain intracellular ATP production. The first is a reaction catalyzed by creatine kinase, which produces a reversible transference of phosphate from phosphocreatine (PCr), converting ADP to ATP, and the second a reaction catalyzed by adenylate kinase, in which two ADP molecules are transformed into one ATP molecule and one AMP molecule.
Next, the glycolytic production of ATP starts to be regulated mainly by the inhibition or activation of phosphofructokinase (PFK), which catalyzes the conversion of fructose 6-phosphate to fructose 1,6-diophosphate. PFK is inhibited at a low pH, but in hypoxia/ischemia situations, it stops responding to this stimulant, significantly increasing its activity.
Most of the ATP formed is used to maintain ionic transmembrane gradients. It is worth noting that intracellular potassium levels are approximately 30 times higher than extracellular levels, sodium and chloride levels around 7 times less, and calcium levels around 10,000 times less. Because of this, the decrease in energy production significantly compromises homeostasis.

As indicated above, the energy obtained by glycolysis generates lactate and hydrogen ions; this causes the intra- and extracellular pH to immediately begin to descend. The speed of this decline is directly proportional to pre-ischemic glucose levels. The interval between the onset of ischemia and complete cellular depolarization is called anoxic depolarization (AD) and can be prolonged or decreased depending on the amount of energy substrate produced, so that in pre-ischemic hyperglycaemic states the AD time will be longer and the pH will have a greater decline than in normoglycaemia.

In turn, acidosis inhibits ion flow through the plasma membrane, reducing the energy requirements for maintaining ionic gradients. Therefore, pre-ischemic hypercapnic states also prolong AD time.

Calcium, in a wide variety of cells, acts as a messenger ion, transmitting messages received at the cell surface to the intracellular machinery. This requires only a low ionic flow through the cell membrane, at very low and closely controlled concentrations. When the concentrations increase, they are detrimental to normal cell functioning, and prolonged increase can result in cell death.

At rest, calcium concentration in the medium surrounding the cells is usually from 1 to 2 mM, whereas the intracellular concentration is nearly 0.1 µM (100 nM). During the AD period, the cells obtain more than 90% of the calcium from the extracellular fluids, and when they are activated, the level of pre-ischemic calcium is reduced to approximately 0.1 mN, while in the cytosol it increases up to 500 to 1000 nM.

Calcium cell traffic is mainly by channels with NMDA receptors, using a sodium-calcium exchanger, where for every three sodium molecules mobilized inside, one calcium molecule is transported to the outside. The energy source is the sodium electrochemical gradient. So, in AD states, the sodium gradient collapses and the electrochemical gradient of calcium ions reverts the pump, causing a massive calcium transit into the cell, which leads to its accumulation in the mitochondrial matrix of values up to nearly 0.5 µM, while in the endoplasmic reticulum, the concentration can reach up to 100 µM [2].

Just as the pre-ischemic glycaemic levels influence the AD time, they also influence calcium flow during ischemia. In this sense, high glucose levels reduce cellular calcium flow. Because acidosis significantly reduces uptake, the majority of the calcium in these conditions enters the cell thanks to the reverse sodium/calcium exchange, significantly increasing the amount of the latter in the glial cells, which adversely affects their survival.

In this first stage, we could say that, after periods of transient ischemia, mitochondrial metabolism after 1 or 2 minutes is capable of complete and immediate recovery, but if ischemia is prolonged, there are significant alterations in the concentrations of the metabolites involved in the energy generation processes. After 15 minutes of ischemia, glucose and glycogen levels are depleted, lactate increases significantly and high-energy phosphate levels decline markedly. The metabolites involved in the citric acid cycle also undergo significant changes; succinate increases by approximately 270 times, malate, citrate and fumarate decrease, and levels of substances such as GABA, alanine and ammonia increase.

Without a rapid supply of blood and oxygen, these processes inevitably cause cell death in a matter of minutes. However, after successful resuscitation, there are more detrimental effects on the mitochondrial level, due to the reperfusion of ischemic cells, with two major agents: calcium and oxygen.

At approximately 5 minutes of reperfusion, the high-energy phosphate levels recover; much of the ammonia is detoxified by amidation of glutamate in the astrocytes in an ATP-dependent process and through the action of glutamine synthetase, with the consequent formation of glutamine.

It has been shown that immediately after reperfusion, lactate levels remain high, on some occasions three times higher than normal, which suggests that in this period there is an alteration in the use of pyruvate by the mitochondria, probably due to a temporary inhibition of pyruvate dehydrogenase. It is further believed that in this period the substrate for high-energy phosphate formation is the succinate of the mitochondrial respiratory complex type II, in a reaction that generates electron loss, which, in turn, leads to the release of free oxygen radicals. These act at the level of membrane lipids, causing peroxidation with primary necrosis, or trigger apoptosis.

Together with the release of free radicals, the presence of other mediators during the reperfusion stage (6 to 24 hours after) creates chemical cascades that result in excitotoxicity in vulnerable neurons.

As stated above, calcium concentrations are higher at the blood level than the intracellular level, allowing a transmembrane gradient to be maintained, which uses the ATP as an energy source. During reperfusion, re-oxygenation causes constant overloads of intramitochondrial calcium, causing iron release and increasing free radical production. In addition to all of this, there is an increase in platelet aggregation, vasoconstriction and pre-capillary edema [3].

Intracellular calcium influx caused by mitochondrial bioenergetic dysfunction repletes the endoplasmic reticulum and mitochondria, and causes damage in two ways. The first is by acting as a protease and phospholipase enzyme co-factor, causing delayed death of neurons, oligodendrocytes and astrocytes. Second, it acts together with oxygen in the generation of free radicals. It is worth considering that free radicals in physiological conditions are present in the mitochondrial transport chain, where they maintain stability thanks to chemical and physical coupling, and where their harmful effect is inhibited by defence mechanisms. Numbering among these mechanisms are the maintenance of low partial pressure of oxygen at the cellular level, an adequate enzymatic breakdown by enzymes and removers such as superoxide dismutase and catalase, and the presence of antioxidants such as alpha tocopherol (vitamin E) and ascorbic acid (vitamin C).

Superoxide dismutase inactivates the superoxide ions, while catalase counteracts the effects of hydrogen peroxide. This is important in therapy, as we will see later.

Under anaerobic conditions, ATP is degraded in supranormal quantities via ADP-AMP, producing inosine and hypoxanthine, and finally urate acid through xanthine dehydrogenase. In the next process the increasing calcium in the cytosol activates proteases, converting xanthine dehydrogenase to xanthine oxidase, and stimulating the production of superoxide anion.

Once formed, these radicals combine with iron salts in the Haber-Weiss reaction to form perhydroxyl radicals, a chemical process that occurs only in the presence of free iron, such as in hemorrhage or in cells with a high iron reserve such as myoglobin. Free iron is not normally found in peripheral circulation, but under certain conditions, such as severe hypoxia, it is released from ferritin, just as superoxide anions are also capable of dissociating the ferritin iron complex. Under hemorrhage conditions, levels are optimal for these deleterious reactions. Polyunsaturated fatty acids in the middle layer of the membranes are the target of perhydroxyl radicals.

Under hypoxic ischemic conditions, proteases and phospholipases activated by calcium attack the membrane and convert it to a new source of oxygen radical production, perpetuating the damage.

The superoxide anion, in turn, steals a proton from the polyunsaturated fatty acid, creating a lipid with an unpaired electron. This new lipid radical reacts with oxygen during reperfusion and forms a new peroxyl lipid radical, which, in turn, removes a proton from another polyunsaturated acid, creating a new radical and giving rise to a chain reaction.

In the formation of free radicals, arachidonic acid also plays a key role. It is degraded by three enzymatic pathways: that of cyclooxygenase, which forms prostaglandins and thromboxanes that have effects on microcirculation, the lipoxygenases that release leukotrienes and cause edema and necrosis in microcirculation, and cytochrome P450 that acts directly upon the formation of free radicals. These three pathways interact at different levels of the cascade, inhibiting or stimulating the other components.
There are other mechanisms in the formation of free radicals, mediated by membrane-binding enzymes on the surface of neutrophils and phagocytes, and are activated by bacterial or cytokine endotoxins in the so-called respiratory burst.
A second mechanism associated with calcium involves mitochondrial activation of permeability, by means of opening non-selective pores in the inner membrane, causing a decoupling of oxidative phosphorylation and the physical rupture of the mitochondrial outer membrane [4].

79.4 Nitric Oxide

Nitric oxide, a simple molecule synthesized from L-arginine by the nitric oxide synthase in endothelial cells, is a reactive free radical that inhibits mitochondrial respiration, and which has been linked as a messenger mediator in the central nervous system (CNS). There is evidence that it contributes to excitotoxicity.
There are several isoforms, and among these, some are neuronal, activated by high concentrations of cytosolic calcium. Once formed, it spreads to neighbouring cells and reacts with guanylate cyclase, inducing the formation of cyclic guanosine monophosphate from guanosine triphosphate. This compound relaxes muscle cells, including blood vessels. Nitric oxide in the presence of superoxide anions gives rise to the formation of highly reactive nitrite peroxide, which is damaging to cells.
The resulting fall in cyclic GMP leads to vasoconstriction. Moreover, nitric oxide can be altered to a chemical state with opposite effects, for example, a protective effect in the presence of electron donors such as cysteine or ascorbate, forming a nitrosonium ion. This is because of the union to a regulatory site in the most prominent part of the excitatory amino acid receptor, resulting in decreased activity in this receptor.
The deleterious effects of the free radicals occur during reperfusion, after ischemia, and the ability to neutralize this effect is called antioxidant capacity.
Based on these findings, research on these compounds has attempted to attenuate hypoxic ischemic damage, such as N acetyl cysteine, dimethyl sulfoxide, allopurinol, 21-aminosteroid, and calcium channel blockers; we will go into detail on these later. However, none of these compounds have been successful in a clinical setting, perhaps due to the treatment starting after the damage has been done.

79.5 Role of Excitatory Amino Acids

Excitotoxicity is a process by which the excessive release of synaptic glutamate activates postsynaptic receptors and leads to large neuronal loads of calcium and sodium, which ultimately cause cell death. In this process, there are other alterations in mitochondrial function, such as the loss of membrane potential, release of the cytochrome c in the cytosol, and increase in the production of oxygen free radicals, events that seem to occur in varying degrees and constantly producing neuronal injury. It has been suggested that

the release of cytochrome c induced by calcium may be the cause of increased production of free radicals in excitotoxicity.
Deterioration in the electron transport chain caused by loss of cytochrome c causes metabolic failure and loss in ionic homeostasis, leading to neuronal death, probably due to oxidative stress. While the accumulation of mitochondrial calcium with the generation of free radicals can contribute to a prolonged alteration in calcium regulation, it is not sufficient to trigger acute neuronal degeneration. For this reason, it is suggested that glutamate action on receptors in the synaptic gap is necessary to produce damage.
Normally, glutamate is released in the synaptic gap, where it makes contact with its receptors. At the distal end of the synapse, glutamate breaks down to glutamine, and then goes one of two ways: uptake and entry into the pre-synaptic gap, or reuptake by a glutamate transporter and release in a nearby astrocyte for later transformation in an energy-dependent process.
In energy deficit situations like ischemia, glutamate is accumulated in the extracellular space due in part to the decline in the transmembrane sodium and potassium gradients, which is coupled with an alteration of the glutamate transporter in the astrocyte, or otherwise because its function can even be reversed, producing more extracellular glutamate.
Moreover, cell damage causes glutamate to leave the injured cells and enter the extracellular space, and due to the high content in each cell, this can cause considerable damage in neighbouring cells.
With the abnormal accumulation of excitatory amino acids, such as glutamate and aspartate, neuronal over-stimulation is produced, which ultimately leads to cellular dysfunction and neuron death. The inhibitory effect is from the gamma-amino butyric acid that modulates the action of the excitatory amino acids.
In the synaptic gap, there have been identified at least three types of glutamate receptors, with different anatomical locations and functions. They are classified according to their typical agonists, such as N methyl aspartate (NMDA), quisqualate (QA), kainate (KA), and 2 amino 4 phosphonobutyrate (AP4). These receptors modulate the activity of sodium, calcium, chloride, magnesium and other ions, along with water flow into the cell. In summary, the action of these receptors is central to the concept of excitotoxicity. Glutamate accumulation in extracellular space causes neuronal over-stimulation with excess anionic and cationic fluxes, in addition to intracellular edema and osmotic lysis, causing instant cell death.
This effect, plus the damage from increased cytoplasmic calcium, causes neuronal damage. There have been attempts to reverse this damage by intervening independently or jointly in both pathways.

79.6 Pathology

For these reasons, cell damage in hypoxic ischemic encephalopathy (HIE) is heterogeneous and multifactorial. Its intensity depends on several factors, such as variability in neuronal susceptibility, the white matter being more vulnerable than the gray matter, age and prior vascular conditions of the patient, degree of hypoxia and hypoperfusion, glycaemic level prior to the event, blood pH and duration of the injury. During periods of ischemia <5 minutes, only the susceptible neurons in the hippocampus (zones CA1 and CA 4-6) and Purkinje cells in the cerebellum die [5,6].
At least two factors are involved in this process 1) amino acid receptor distribution and the zonal differences in their concentrations, which causes damage in zones with

higher receptor density, and 2) the damage from reperfusion through the action of free radicals, above all in zones with a high iron concentration, such as the thalamus, globus pallidus, substantia nigra, and several cortical layers. If the injury is prolonged, necrosis can occur in the middle layer of the cerebral cortex (layers 3, 5 and 6), amygdaloid nucleus and basal ganglia [1,4]. The presence of diffuse cerebral edema is frequent.

Histopathologically, microvacuolization and neuronal cytoplasmic eosinophilia have been described after 1 hour. If the patients survive long enough, gliosis is produced in the dead neurons. Autopsies of patients who, after surviving cardiac arrest, remained in a persistent vegetative state, revealed extensive cortical laminar necrosis and multiple microinfarctions.

79.7 Evaluation and Prognosis

Evaluation of patients with HIE is based on a detailed clinical examination, considering the variables that may affect the neurological examination such as drugs, metabolic encephalopathy and seizures.

However, data published suggest that a clinical examination alone predicts the prognosis in only 58% of cases, improving up to 82% when combined with evoked potentials and electroencephalography (EEG), which alone could predict the prognosis at 59% and 41%, respectively.

79.8 Clinical Evaluation

Several clinical signs have been described which point to ominous prognoses; however, their sensitivity and specificity are motives for controversy. It is known that among patients who wake up, 90% do so within the first 3 days, and waking up after this time is associated with a persistent vegetative state. The possibility of waking up decreases 50% the first day, 20% the third day, and 10% the seventh day.

It has been agreed that clinical, laboratory and imaging data must be used to improve prognostic accuracy.

In the clinical examination, brain stem reflexes must be examined: corneal, oculocephalic, oculovestibular and pupillary. This last reflex has been used to predict prognosis, since immediately after recovery from sudden cardiac arrest, the absence of the pupillary reflex is not a sign of a poor prognosis; rather, its presence constitutes a factor of a good prognosis. If the absence of pupillary reflex persists for 12 hours after sudden cardiac arrest, it becomes a sign of a poor prognosis. The persistence of fixed pupils on the third day is a sign of a poor prognosis.

Motor responses. These are differentiated as localization, withdrawal, decerebration or decortication rigidity, or the absence of response, and the less sustained the response in a given time, the worse the prognosis. The withdrawal reflex is an indicator of a good prognosis; however, its absence is not necessarily synonymous with a poor prognosis.

Involuntary movements. The presence of brain stem automatisms (blinking, swallowing, cough, etc.), myoclonus and nystagmus suggests indemnity of the brain stem. It must be considered that blinking, myoclonus and nystagmus can also be observed in patients in non-convulsive epileptic states. An involuntary conjugate eye movement has been described, characteristic of HIE, called ocular dipping, and it consists of extreme vertical

deviation of the downward gaze that is maintained for several seconds to then quickly return to neutral.

Myoclonus. Initially, this was reported as a sign of dying because all those who experienced it later died; however, this finding was later contradicted by several reports of cases that showed great variation in the values of sensitivity and specificity for this sign in relation to neurological prognosis (sensibility, 25-92%, and specificity, 16-85%). Moreover, there were also reported cases of survival after the appearance of myoclonus, and convulsive activity of some sort is reported in 30% of patients (17% myoclonus, 33% partial seizures and 50% generalized). Overall survival for the group that experienced convulsions was 32%, and 43% for the group that did not experience convulsive activity according to this study. Later studies reported no relationship between the presence of convulsive activity and the neurological prognosis either, except in cases with convulsive states, in which it was determined that there is a higher risk of persistent coma and brain death. The presence of myoclonic status and conjugate vertical upward gaze deviation on the first day are signs of a poor prognosis.

The absence of pupillary reflexes, together with the absence of motor response to pain and potential altered evoked potentials, on the third day after the event, is associated with a poor neurological prognosis with a specificity of 100% [7].

79.9 Glasgow Coma Score Assessment

The Glasgow neurological scale (GCS) has been used as a neurological predictor in different pathologies. With respect to HIE, several systematic reviews show that a GCS score <5 in the first hours is not useful as a predictor of poor prognosis, but a score ≥10 is a predictor of a good prognosis. Basetti et al. used the GCS together with somatosensory evoked potentials, and found that a GCS ≤8 in addition to alteration of evoked potentials had a specificity for brain death of 97%. In a review done in 2004, it was found that the absence of motor response a poor prognosis likelihood ratio of 9.2. In these circumstances the isolated use of the Glasgow scale as a prognostic predictor is not considered viable.

79.10 Evoked Potentials

voked potentials have been studied as prognostic predictors for coma for more than 20 years. Their advantage is that they can be carried out at the bedside, are non-invasive and easily reproduced, and are not affected by sedation or metabolic encephalopathy.

Evoked potentials can provide information about the location and severity of dysfunction in sensory pathways of the CNS. Alteration of evoked potentials has been associated with a poor prognosis; however, their normality does not predict recovery. There is consensus that late latency responses (N70), which represent the activity of cortico-cortical interactions, have a greater prognostic value than measurement of short latency responses (N13, N19). Most projects use somatic-sensory evoked potentials (SSEP) of the median nerve, which come from the somatosensory cortex. If the cortical bilateral somatosensory response is absent within the first 8 hours after the event, the mortality rate is 98%. Auditory evoked potentials have a poor correlation with prognosis (Figure 79.1 and 79.2).

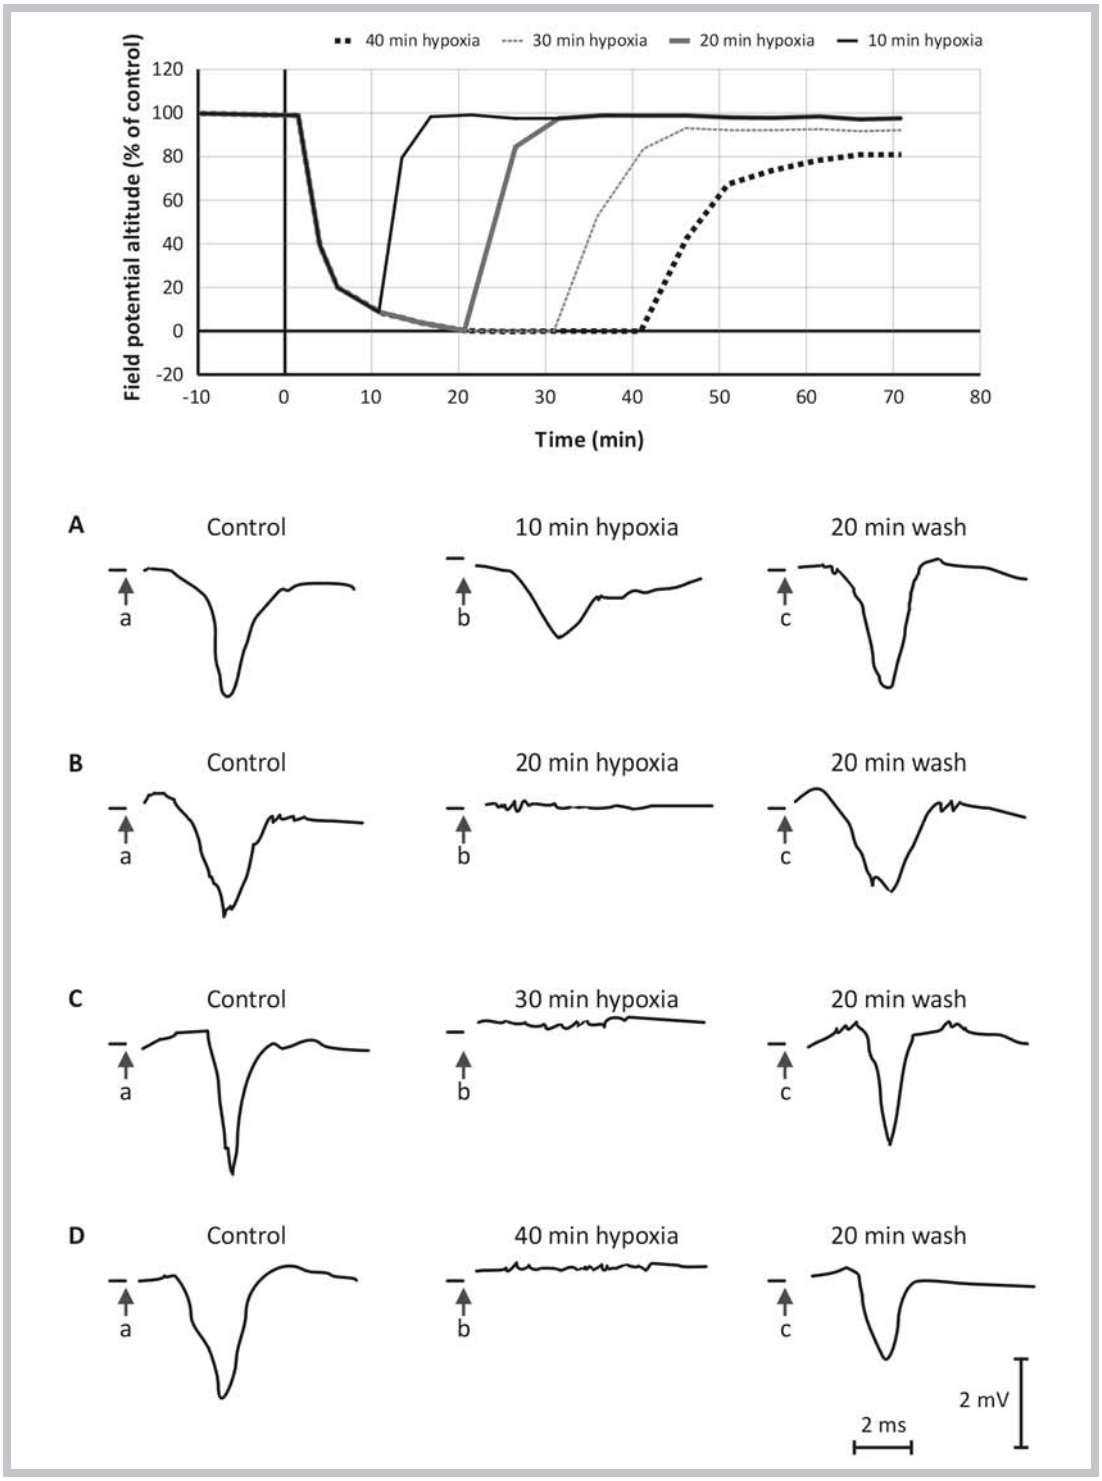

Figure 79.1. **The effects of oxygen deprivation on corticostriatal field potential in Wistar rats. The upper part shows the effects of different periods of hypoxia on the field potential amplitude. In all of the experiments, hypoxia was initiated at time 0 and lasted 10, 20, 30 or 40 minutes. At the bottom, A, B, C and D represent the field experiments showing the potential amplitude before (a), in (b) and after (c), in different periods of hypoxia. Calibrations in D also apply to A, B and C.**

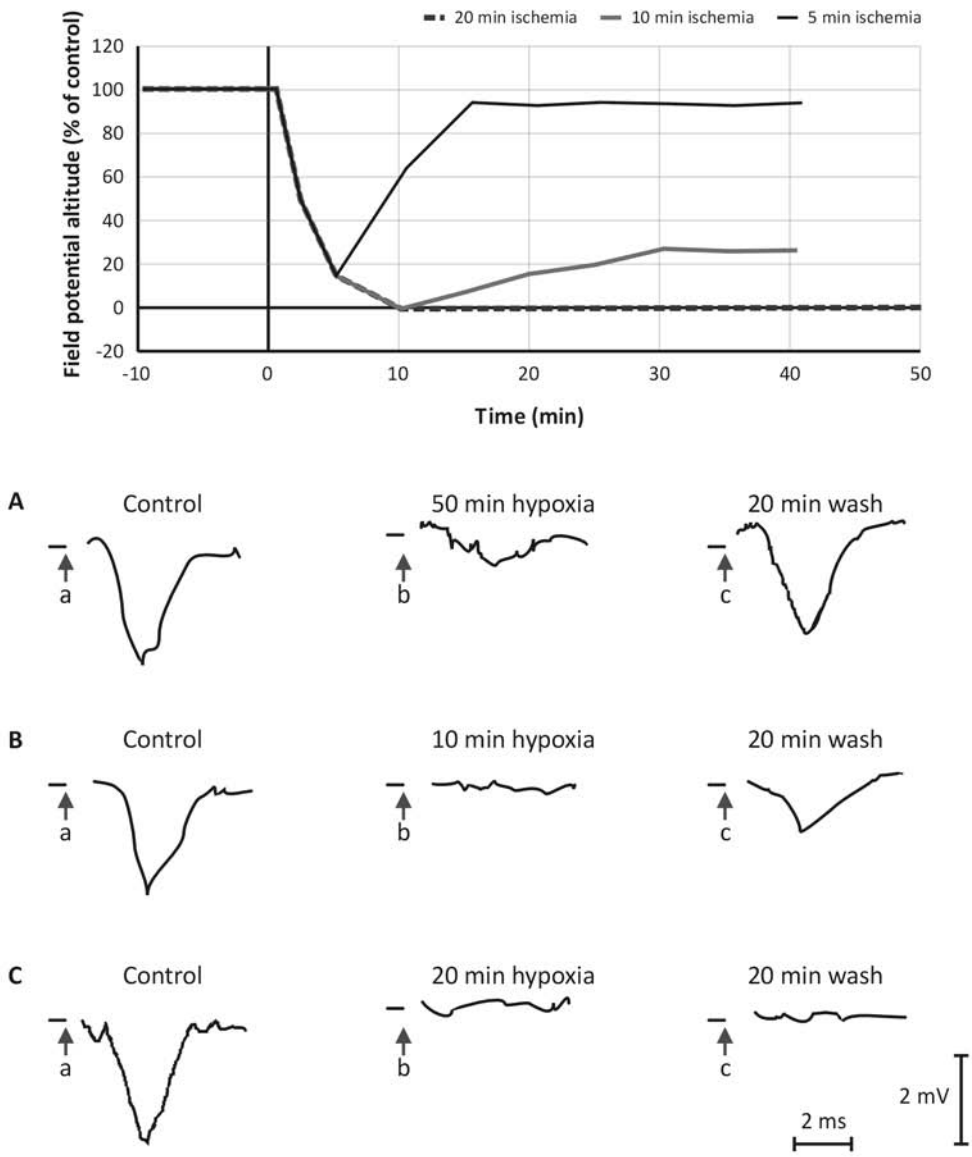

Figure 79.2. **The effects of ischemia on corticostriatal field potentials of the brains of Wistar rats. The upper part shows the effects of different ischemia periods on the field potential amplitude. In all of the experiments, ischemia started at time 0 and lasted 5, 10 or 20 minutes. At the bottom, A, B and C represent experiments showing the potential amplitude before (a), in (b) and after (c), from different ischemia periods. Calibrations in C also apply to A and B [15].**

79.11 The Electroencephalogram

This simple method is available in most centres and has high sensitivity. It has even been used as a form of continuous monitoring in patients with HIE. It must be taken into ac-

count that its interpretation can be affected by pharmacological action, particularly benzodiazepines and barbiturates.
There is some consensus that some patterns show poor prognosis: suppression paroxysm, presence of periodic discharges and electrical silence. In 1990, an electroencephalographic (EEG) grading scale was created which was applied 24 hours after successful cardiopulmonary resuscitation, yielding prognostic values with 98.4% veracity; since then, several studies have attempted to verify these findings. The scale assigns 5 grades, where grades 1 and 2 are predictors of full recovery, and grades 4 and 5 denote a poor neurological prognosis (Table 79.1).

Grade I	Dominant alpha rhythm with some theta-delta activity, reactive
Grade II	Theta-delta activity with some normal alpha activity, reactive
Grade III	Predominantly theta-delta activity without normal alpha activity
Grade IV	Low voltage delta activity, not reactive Alpha coma (generalized non-reactive alpha activity) Paroxysm-suppression pattern
Grade V	Isoelectric

Table 79.1. **EEG grades in patients with HIE.**

79.12 Neurobiochemical Markers

The difficulty in establishing a clinical prognosis has led to research into finding biochemical markers that have a close correlation with neurological prognosis.

79.12.1 Creatine Kinase Isoenzyme BB in Cerebrospinal Fluid

The brain is rich in creatine kinases and its BB enzyme, and it does not have types MM and MB. For this reason, CKBB activity is not affected by extracerebral factors. At experimental levels a good correlation has been shown between the elevation of this enzyme and the degree of neurological damage. The peak elevation occurs within the first 48 to 72 hours after cardiac arrest, has a sensitivity of 82% and a specificity of 85%, and a positive predictive value for persistent vegetative state of 0.96 when levels reach or exceed 50 UI/l, reaching a specificity of 100% with cut-off values of 205 IU/l.

79.12.2 Serum Neuron-specific Enolase

Levels reflect structural brain damage; values of 33 ng/ml predict persistent coma or brain death with a specificity of 100% and a sensitivity of 80%. However, one limitation is that there is no temporal correlation known to confirm a prediction.

79.12.3 Serum Astroglial S100 Protein

Just like neuronal enolase, S100 protein reflects structural brain damage. Values ≥0.2 ng/ml from the second day on have a positive predictive value of 100% for mortality, while values <0.2 ng/ml within the first 14 days show a survival prognosis of 89%. When the evaluation is conducted immediately after the event, S100 protein values are significantly higher in patients with persistent brain damage than in those who recover without neurological sequelae.

A systematic review of the usefulness of biochemical markers as predictors was published in 2001, which concluded that although the CKBB results were interesting, there were methodological flaws and an inadequate number of patients; therefore, they are insufficient as isolated prognosis guides.

79.13 Images

During the first 24 hours, the brain computed tomography (CT) scan lacks sensitivity, so a slight or moderate alteration can pass unnoticed, while if there is evidence of injury, the damage is significant. The most common early finding is the disappearance of grooves caused by cerebral edema. After 48 hours, hypodense lesions in the cerebral cortex, cerebellum and basal ganglia appear evident on the image. Bordering infarcts and brain atrophy are evident in the following days.

Magnetic resonance imaging (MRI) is more sensitive for detecting infarctions and cerebral edema, above all with the diffusion technique, which can appreciate gray matter alterations during the acute period, alterations in the white matter during the subacute period, and return to normal during the chronic phase. From the second week on, in T_1, T_2 and fluid-attenuated inversion recovery (FLAIR) sequences there appear hyperintense cortical lesions, which represent cortical laminar necrosis.

As for other techniques, such as MR spectroscopy and single-photon emission computed tomography (SPECT), some interesting data have been presented, but their diagnostic and prognostic values are still under study.

79.14 Therapeutics

Successful resuscitation of a patient from a sudden death event is only the beginning of a therapeutic process which under the best circumstances will return the patient to daily activity with total self-sufficiency. However, the figures derived from several studies are not as encouraging in these results; they indicate that barely 20% of patients return to absolute self-sufficiency without residual or minimal deficit.

Some 80% of survivors end up with a result that can vary from partial to total dependence, with the consequent family and social costs.

Managing a patient after a sudden death episode is therefore extremely complex, and all information that can be obtained is critical, both for immediate management as well as subsequent therapeutic decisions. In this sense, it is very important to know the levels of self-sufficiency prior to the event, the associated co-morbidity that can have a triggering or aggravating effect, and the perspective from the social and family environment.

A few years ago, treatment of patients suffering from cardiorespiratory arrest was based on cardiovascular resuscitation and general medical treatment. The absence of specific therapies marked an uncertain, and usually poor neurological prognosis, the majority evolving to total dependency, persistent vegetative state or death [8].

In recent years, different measures have been questioned in the treatment of HIE, most of which supported by pathophysiological reasoning, as several studies have failed to demonstrate significant differences in their use in clinical practice. However, the use of induced hypothermia has shown promising results.

Currently, we have measures directed at counteracting different points in the chain of injury. Among general neurological protection measures are ensuring CBF by maintaining normal or moderately high blood pressure, providing adequate oxygen supply to reach a PO_2 of 100 mmHg, and trying mild hyperventilation, 30 to 35 mmHg.
In an injured brain, it is necessary to prevent further damage that could worsen its condition; as we have seen, hypoxia and ischemia bring about greater fragility and predisposition to injury from other causes. Under these conditions, considering that 30% of patients have seizures, the prophylactic use of anticonvulsants is recommended. Achieving metabolic stability, with internal environmental balance and no imbalances in either glucose or intra- and extracellular components, is one of the primary objectives. Within these, there is a special attention to calcium, since as we have seen it plays a significant role in many neuronal injury processes.

79.14.1 Calcium Antagonists

Numerous studies have failed to demonstrate the usefulness of calcium in ischemic encephalopathy, despite having a pathophysiological basis that supposes a beneficial effect. More than 30 studies that included oral and intravenous calcium antagonists were analyzed, many of which were excluded due to methodological flaws, and none showed a clear benefit. It is worth noting that a statistically significant difference was found in one study, where a subgroup that received nimodipine within the first 12 hours of the event was analyzed. This suggests that failure to prove utility is probably due to administration subsequent to establishment of the injury [9].

79.14.2 Hypothermia

Around 40% of patients survive cardiorespiratory arrest in the extra-hospital environment, but it is estimated that near 20% of these will have limiting neurological damage. Hypothermia has been used as a therapeutic method with good results; however, the exact mechanism by which it acts on HIE is not known. Many mechanisms have been proposed, including reduction of released mediators during hypoxia, delayed production of enzyme products and free radicals, protection of lipid membranes, decreased metabolism and cerebral oxygen demand, reduced intracellular acidosis, reduced intracranial pressure, and protection of ongoing ischemia. Early work on the use of hypothermia began in 1950 when it was used in cardiac surgery. In the 1990s its use was intensified in experimental animal models, and most recently it has been used in human studies in an attempt to find its application in different, mostly neurological, pathologies.
Canine models showed a lower incidence of neurological deterioration after the application of hypothermia, and interestingly, an increase in tolerance to global ischemia, which increases as temperature decreases. For example, if the temperature is reduced from 37°C to 25°C, the time without damage lasts 5 times longer [10].
In humans, two prospective, multicenter, randomized controlled studies have been performed to date; the first was done by a European group and included 273 patients who suffered extra-hospital cardiac arrest, 136 of which were treated with hypothermia between 32° and 34°C for 24 hours, while in 137 normothermia was maintained. After 6 months, the neurological outcome in 55% of patients in the hypothermia group was good, with independence and re-insertion to work, at least part time, as compared with 39% of patients in the control group. (RR 1.4, 1.08-1.81); the number needed to treat (NNT) was 6 (95% CI 4-25]. The mortality at 6 months was 41% in the treated group and

55% in the control group (RR 0.74, 0.58-0.95); the NNT was 7 (95% CI, 4-33). There was no difference in medical complications between the groups [11].

The second study was done in Australia and included 77 patients resuscitated from an extra-hospital cardiac arrest; 43 were treated with hypothermia at 33°C for 12 hours and in 34 normothermia was maintained. At discharge, 49% of the patients treated with hypothermia had a good neurological state, being discharged to their homes or a rehabilitation centre, while in the normothermia group, only 26% achieved this goal (p=0.046). There was no statistical difference in terms of mortality (51% in hypothermia and 68% in normothermia). There were also no significant medical complications reported in the group treated with hypothermia [12].

It must be noted that in both studies, there is a duality in the result of hypothermia application, since almost all treated patients either die (41% and 51%, respectively) or end up without severe neurological damage (55% and 49%, respectively).

In a meta-analysis by Holzer et al., it was found that hypothermia at 33°C applied to resuscitated patients with extra-hospital cardiac arrest statistically increased the possibility of patients with a favourable neurological recovery at discharge (OR 1.68, 1.29-2.07), with an NNT between 4 and 13 [13].

Since 2003, with these data, the International Liaison Committee on Resuscitation (ILCOR) has incorporated moderate hypothermia at 32-34°C for 12 to 24 hours as a recommendation for patients who have been resuscitated from extra-hospital cardiac arrest [14].

Figure 79.3 shows a patient with HIE secondary to a sudden cardiac death episode under moderate intravascular hypothermia, while Figure 79.4 summarizes the flowchart for resuscitated sudden death event.

Figure 79.3. **Patient with HIE secondary to a sudden cardiac death episode under moderate intravascular hypothermia. The monitor to the right displays a temperature of 33.1°C.**

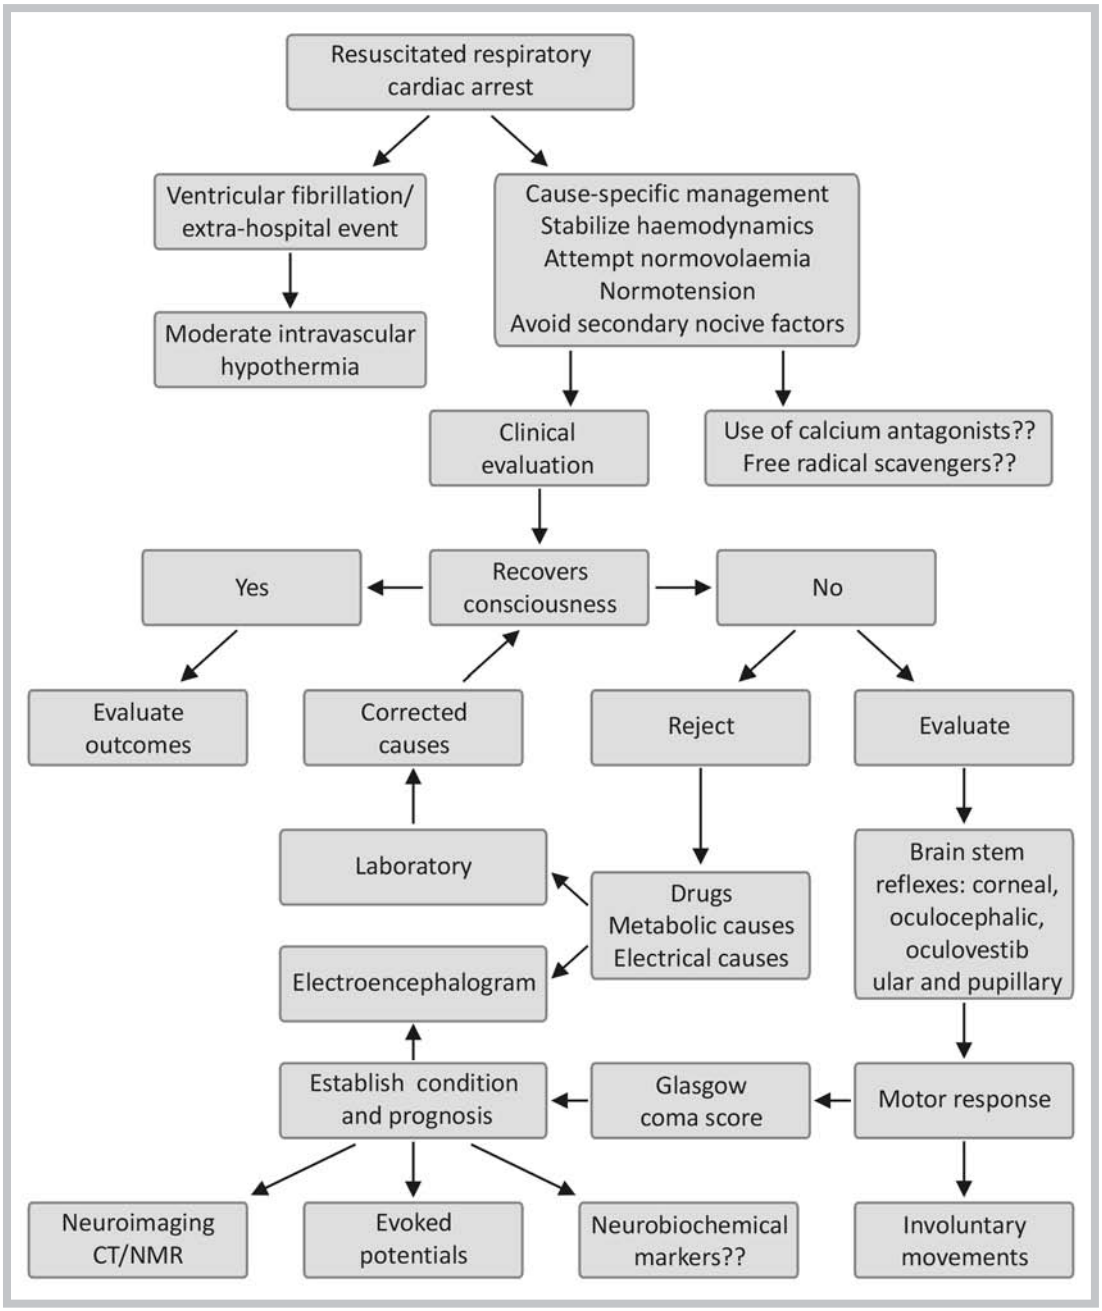

Figure 79.4. **Flowchart for resuscitated sudden death event, with an emphasis on addressing hypoxic ischemic encephalopathy.**

80 Perioperative Management of Patients With Brain Tumours

Pablo Curino [1]

[1] Department of Neurology, Oncology and Anatomopathology, Hospital Municipal de Agudos, Bahia Blanca, Argentina

80.1 Introduction

In recent years advances in cancer treatment have been generally encouraging except in the treatment of gliomas: its natural history remains unchanged and its prognosis is grave. Unlike other tumours, malignant gliomas have not benefitted from adjuvant therapies or new imaging or neurosurgical techniques.
The therapeutic approach to tumours arising in the central nervous system (CNS) differs consistently in both practice and theory from that to other kinds of tumours. For example, the concepts of benign and malignant, which are absolute for tumours with other localizations, are only relative when applied to the CNS: a brain tumour composed of benign cells but located in a vital area can be considered life-threatening although the tumour and its cells would not be classified as malignant.
The prognosis of such tumours depends on: tumour histopathology and anatomic localization, and patient age and neurological state.

80.2 Epidemiology

Primary brain tumours consistently contribute to morbidity and mortality in all age groups. In paediatric patients, brain tumours are the second most common type of cancer after leukaemia. In adults, primary brain tumours are the 13th most frequent of all cancers. Depending on the age of the population studied, the incidence of these cancers has been estimated to be between 4.8 and 10.6 years of age per 100,000 inhabitants/year. In the United States, the incidence can vary for different geographical regions. The sex distribution also differs, with benign tumours more prevalent in females, while malignant tumours and the overall number are more prevalent in males. Statistical data show a mortality rate of 6.5 per 100,000 inhabitants/year for males and 4.5 for females. The incidence of brain tumours increases dramatically with patient age, peaking between age 75 and 85 years in both females and males; the most frequent brain tumours in the elderly are multiform glioblastoma and astrocytoma. Although only 1.5% of all cancers are observed in children, the incidence of CNS tumours in children is high, accounting for the second leading cause of cancer in this population. Medulloblastoma is the most frequent in children and, together with cerebral astrocytoma, is considered a typical paediatric tumour.

80.3 Classification

Brain tumours are found in around 1-2% of autopsies. The histological classification of CNS tumours has evolved since the first scheme devised by Bayley and Cushing in 1926.

Tumours of glial tissue	Tumours of the meninges	Germ Cell Tumours	Tumours of the sellar region	Others
• Astrocytic tumours: astrocytoma, glioblastoma multiforme • Oligodendroglial tumours: oligodendroglioma • Ependymal tumours: ependymoma • Choroid plexus tumours: papilloma, carcinoma • Embryonal tumours: medulloblastoma • Pineal parenchymal tumours	• Meningioma • Hemangiopericytoma • Melanocytic tumour • Hemangioblastoma	• Germinoma • Embryonal carcinoma • Teratoma • Endodermal sinus tumour	• Pituitary adenoma • Pituitary carcinoma • Craniopharyngioma	• Metastatic tumours • Nerve sheath tumours • Schwannoma • Neurofibroma • Primary CNS lymphoma

Table 80.1. **Histological classification of central nervous system tumours.**

Slow-growing tumours (low grade)	• Grade I tumours: benign, slow growing and circumscribed • Grade II tumours: grow slowly, but with imprecise boundaries, or extension
Rapidly progressive tumours (high grade)	• Grade III tumours: anaplastic tumours, their evolution is faster • Grade IV tumours: malignant tumours show histologic evidence of very rapid growth in all regions examined

Table 80.2. **Tumors classificaion according to their rate of malignancy.**

In 1979 the World Health Organization (WHO) established a useful classification which has been revised many times over the years (Table 80.1) [1]. As shown in Table 80.2, tumours can be classified according to their rate of malignancy (in particular, astrocytoma).

80.3.1 Description by Tumour Type

Astrocytoma

Astrocytoma accounts for 25-30% of all gliomas. They arise in the brain hemispheres in adults and in the cerebellum in children. They are characterized by slow growth and infiltration.

Oligodendroglioma

Oligodendroglioma accounts for 6% of gliomas and is the most common between the fourth and fifth decades of life. It is most frequently found in the temporal and frontal lobes.

Malignant Gliomas

Malignant gliomas are the most frequent and varied primary brain tumours. They are responsible for 2% of all tumour-related deaths. The most common histopathological types are glioblastoma multiforme, anaplastic astrocytoma, and anaplastic oligodendro-

glioma. They are characterized by a high rate of local recurrence after surgical treatment, with local progression and ultimately death. They are mainly disseminated in the white matter or cerebrospinal fluid (CSF). Unlike other advanced malignant tumours, they don't cause distance metastases.

Glioblastoma Multiforme

Glioblastoma multiforme is the most severe and aggressive type of astrocytoma (grade IV WHO). The average 2-year survival is 10%.

Meningiomas

Meningiomas account for 15-20% of primary intracranial tumours. They are more frequent in persons between 20 and 60 years of age. They originate from the arachnoidal cells in the meninges. Usually benign in nature, they are typically well encapsulated and can be found anywhere in the brain (supra- and intratentorial).

Secondary Tumours (Metastases)

Cancer cells can break away from the primary tumour site and travel through blood, cerebrospinal fluid and lymphatic vessels. The brain is a preferred site for melanoma and small-cell lung cancer metastases. In males, metastases usually originate from the lung, colon and kidney. In females, they most often spread from breast cancer, lung, colon and melanoma. Spinal metastases occur in 5% of cancer patients, frequently in those with breast or prostate cancer or multiple myeloma.

80.4 Clinical Features

Many different signs and symptoms can be present. The tumour can be asymptomatic, totally aspecific or inclusive, depending on its characteristics and type.
For example, glioblastoma multiforme, characterized by rapid growth, differs from meningioma, which can evolve for years. Also localization, speed of growth, presence of edema and size can all influence clinical features. This aspect should be taken into consideration in diagnosis because it can influence the prognosis.
Another fundamental aspect is that tumours can produce symptoms similar to those of other CNS diseases, but unlike CNS diseases, tumours typically have a slow and progressive onset (for example, motor deficit due to cerebrovascular injury has a rapid onset, while the onset is slow and worsens over time if the cause is neoplastic).
The most frequent onset signs are progressive neurological deficit (68%) and, less frequently, motor debilitation (45%) [2].
Endocranial tumour presentation can distinguished on the basis of three clinical symptoms:

- Altered higher mental functions.
- Intracranial hypertension syndrome.
- Syndromes specific to certain kind of tumours.

80.4.1 Altered Higher Mental Functions

Cognitive Impairment

The most common signs are emotional liability, altered behaviour, asthenia, depression (it is always important to rule out organic causes in depressive patients). Patients lose in-

terest in their routine activities and display lack of initiative, apathy and indifference to everyday social activities. They frequently forget things and find it difficult to remember recent facts; sometimes signs of dementia are present.

Cephalea

Headache is a temporal sign in almost the one third of patients and is an onset symptom in 55% of cases. Varied in nature, headache lacks any typical feature; it may occur more often at night or it may be more intense in the morning (the more frequent presentation). Usually, it worsens with cough; in 40% of cases it is associated with nausea and vomiting, which can sometimes alleviate the pain.
It is difficult to distinguish tumour-associated headache from other kinds of headache (e.g., tension, migraine, etc.). In 77% of cases, tumour-associated headaches are resemble tension headaches and in 9% present migraine features [3]. But in only 8% of cases do patients present with such features.

Seizures

Seizures occur in 20-50% of patients and can constitute the onset symptom in 25% of cases. They can be generalized or partial and can occur before or after (weeks, months) the onset of other symptoms. «A first seizure during adult life is always suggestive of a tumour».

80.4.2 Intracranial Hypertensive Syndrome

The syndrome is characterized by the classical triad of headache, vomiting and papilledema, although the last sign is noted more often in frontal tumours. With the advent of more sophisticated imaging methods, it may become a diagnostic feature before disease onset.

80.4.3 Specific Symptoms of Specific Tumours

In some patients with intracranial tumours signs and symptoms allow clinical localization of the lesion; for such tumours the onset signs are specific. For example, acusticus neurinoma, hypophysis adenoma, craneopharyngioma, brainstem glioma, cavernous sinus meningioma, and olfactory groove meningioma among others. In this group of tumours, signs and symptoms of brain alteration or intracranial hypertension syndrome do not occur or have a late onset.

80.5 Diagnosis

Careful history taking and neurological examination are the first steps to reach a diagnosis. Some specific symptoms, together with disease progression, are important in differential diagnosis. For example, typical headache (predominantly during the night, no improvement with pharmacologic treatment, accompanied by vomiting) or the first seizure episode.
Computed axial tomography (CT) and magnetic resonance imaging (MRI) are the gold standard diagnostic techniques. Some other techniques, described later in this chapter, may also be of help.

80.5.1 Computed Tomography

Different images are obtained depending on the tumour, and can vary from hypodense images that enhance heterogeneously and serpiginously following contrast infusion (e.g., in high-grade astrocytoma) or well-circumscribed images with intense homogeneous enhancement as seen in meningiomas. CT images can help the clinician by visualizing calcium (which is more visible on CT than on MRI scans) or small bleedings.
Performing CT is important because it can aid in the etiologic diagnosis and highlight features such as metastases that are not otherwise visible with other techniques. For example, metastases commonly release the contrast agent in a ring-shaped hypodense area (edema), causing displacement of adjacent structures.

80.5.2 Magnetic Resonance Imaging

MRI is the gold standard for diagnosis and planning surgical treatment. It is much more precise than CT in differentiating between different kinds of tumours and grade of malignancy, and it is able to show small tumours localized to such areas as the posterior fossa which are not visible by CT. With MRI we can see image features suggestive of some kinds of tumours.
Glioblastoma multiforme crosses the corpus callosum to the opposite side, yielding a butterfly wing-like appearance on MRI.
Meningioma appears as a homogeneous, clearly circumscribed area, with broad implantation on the underlying dura mater.
MRI allows us to know whether a tumour is limited or metastasis should be suspected; furthermore, it allows the identification of typical tumours, such as acoustic neurinoma or the adenoma of the hypophysis.
It also plays an important role in the postsurgical follow-up and in the control of recurrent diseases.

80.5.3 Spectroscopy

Spectroscopy is used to study brain metabolites, allowing the differential diagnosis with other diseases (e.g., ischemia, infectious lesions).

80.5.4 Cerebral SPECT

Single-photon emission computed tomography (SPECT) helps in identifying recurrent tumoural lesions and differential diagnosis with radionecrosis.

80.5.5 Magnetic Resonance Angiography

Angiography studies the vascular supply to the tumour, identifying the lesions at high risk of bleeding and the anatomic relationships between the tumour and the vessels around it.

80.5.6 Functional Magnetic Resonance Imaging

Functional magnetic resonance imaging (fMRI) delimits the relationships between the tumour and the brain's vital areas, such as the motor area, speech or vision area. Its ba-

sic principle is identification of the cerebral areas with maximum oxygen consumption. To study the motor area of the upper limbs, fMRI is performed while the patient does repeated movements of the fingers of the hand that we wish to study.

80.6 Treatment

Treatment of brain tumours will take into consideration different the patient's age, general health condition, neurological status, and tumour characteristics (localization, type, size).

80.6.1 Control and Observation

In small benign tumours or those localized to the deep areas of the brain, periodical controls with MRI are carried out every 6 months or once a year. This management is usually reserved to small meningiomas or low-grade astrocytomas, given that in these last cases follow-up control should take into consideration the possibility that the tumour can change its biologic behaviour.

80.6.2 Biopsy

Although information on tumour type can be gleaned from imaging studies in some cases, today it would be unthinkable to initiate treatment without the certainty of diagnosis**.** Stereotactic biopsy plays an important role in establishing the histological diagnosis of tumour in non-surgical cases in which accurate diagnosis may minimize the risk of complications (0.5% chance of bleeding). This procedure is useful in order to maintain the patient's quality of life because it can be done on an outpatient basis, under anaesthesia, with a small incision, and can be performed in 24 hours.
It is indicated in deep tumours, tumours located in eloquent areas, surgically inaccessible tumours, and large tumours invading the other hemisphere through the corpus callosum, multiple images as in MRI.

80.6.3 Surgery

Surgical removal is the most important method in the treatment of all primary brain tumours. It has three essential and immediate aims:

- Establish the histological diagnosis.
- Alleviate intracranial pressure and mass effect, thus improving neurological function.
- Allow oncologic cytoreduction to improve survival, and improve the safety and efficacy of co-adjuvant treatments such as radiotherapy.

With technical and theoretical advancements in neurosurgery, ever safer and more effective treatments have been developed. Tumours that were once considered inaccessible, such as those localized to deep regions, can now be safely managed with the help of surgical microscopy, microsurgery and microinstruments. Very few intracerebral tumours cannot be reached via direct surgical access with current technologies, ultrasound aspiration, intraoperative echography, intraoperative resonance, stereotaxic surgery and neuronavigation. Together, these innovations expanded surgical strategies for patients with brain tumours.

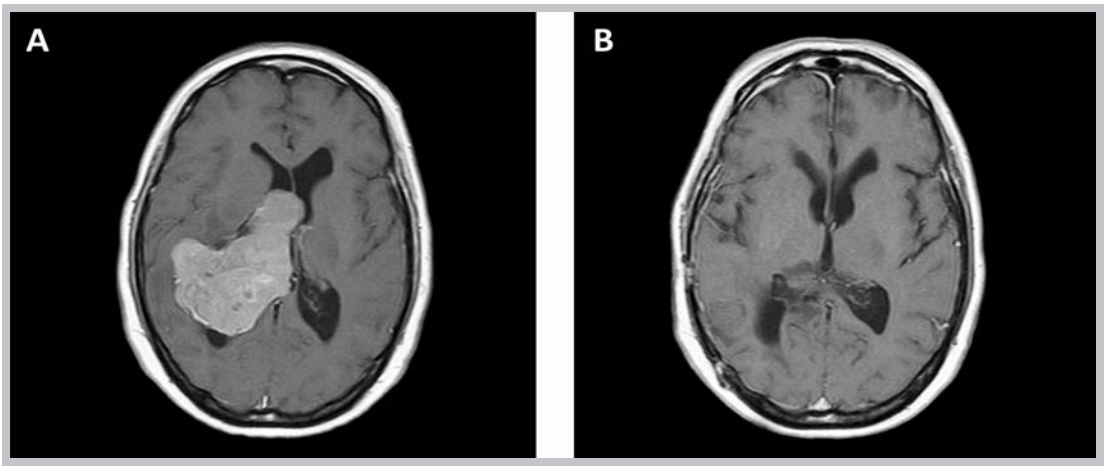

Figure 80.1. **Before surgery (A) and after surgery (B).**

In the majority of extra-axial benign lesions (meningiomas and acoustic neurinomas), the aim of surgery is complete removal. In such cases, it is important to eliminate as much of the tumour as possible, while minimizing the risk of possible trauma to adjacent neurological structures. These goals can be obtained with the use of intrasurgical electrostimulation techniques that can alert the surgeon to the presence of vulnerable neurological structures.

The same concept of complete removal is applied to benign tumours, usually meningiomas or even large tumours in deep brain areas, which can be managed with these new techniques without the risk of neurologic impairment (Figure 80.1).

In intra-axial infiltrating tumours, mostly originating from the glia, surgery allows histological diagnosis and provides a means of temporal control; surgery can reduce mass effect and intracranial hypertension. Because of their locally aggressive nature, malignant brain tumours are not currently curable and their control requires multimodal strategies. Despite discussion on the role of aggressive surgery in the treatment of these lesions, most neuro-oncologists agree that "cytoreduction" and elimination of the tumoural mass are the goals of surgical resection, when they are obtained without causing neurological impairment [4,5].

Morbidity and mortality after brain surgery has decreased consistently in the last decades. The 30-year mortality rate after brain tumour removal is generally <3%. The number of surgical complications depends on the nature of the tumour and its location. Severe complications (perioperative hemorrhage, infection and permanent neurological lesions) occur in <10% of patients [6].

80.6.4 Radiotherapy

The efficacy of radiotherapy has been demonstrated in the treatment most malignant brain tumours. Once the anatomopatologic diagnosis has been established and surgical resection completed, radiotherapy is usually indicated. Although different histological tumour types have different sensitivity to radiation, the improvement in 1-5-year survival obtained with this technique makes its use incontestable in most CNS tumours. The main limiting factor of its long-term effects is the level of the dose or radiation exposure, which can be higher than the CNS can tolerate. Even with exposure to radiation doses within the established limits (40-60 Gy), the brain is vulnerable to many toxic ef-

fects. Acute reactions immediately after radiation ensure from acute brain tumefaction and manifest as an increase in neurological deficit. Fortunately, such reactions respond well to steroids and are generally reversible. Within 1-3 months after irradiation, a similar but late syndrome, also reversible with steroids, may appear. A less common brain reaction is radiation necrosis, which can appear months or years after radiotherapy. It is a progressive brain reaction that is probably caused by direct toxicity in the brain and its microvascularization. Patients will present with insidious and progressive deterioration, focal neurologic signs and dementia. Radiation necrosis can be difficult to distinguish from tumour recurrence, because they share similar clinical and image features. In such cases, they can be differentiated by stereotactic biopsy or brain SPECT. Therapy can include steroids or decompressive treatment. Many patients have already arrived at a terminal stage, so that the most adequate treatment is conservative and palliative in most cases.

When survival is prolonged, different additional complications of long-term radiation appear that are increasingly worrying: hypopituitarism, occlusive arterial disease and radiation-induced oncogenesis. Tumours associated with radiation (meningiomas, sarcomas and gliomas) are a rare and late complication that can appear decades after irradiation to the brain. More worrying are the risk of radiation in small children, leading to learning difficulties, hypophyseal insufficiency, myelopathies and spinal cord deformities, accompanied by the adverse events due to medications. Since myelinisation of the CNS is completed between 2-3 years of age, radiotherapy before this age is particularly hazardous and should be avoided.

80.6.5 Chemotherapy

Following brief episodes of optimism, chemotherapy has brought about no important improvement in the treatment of malignant brain tumours. Practically all the available anti-cancer agents for the treatment of hematologic or systemic malignant neoplasms have also been studied in brain tumours. Apart from recent discoveries in paediatric tumours such as germinoma and medulloblastoma, chemotherapy has shown no efficacy in improvement. In oncologic terms, brain tumours, with their highly defined localization, relatively small tumoural mass and non-metastatic nature, could well be responsive to chemotherapy. Nonetheless, these factors are contrasted by the peculiar complexity of the CNS, where the blood-brain barrier limits the access of most anti-cancer agents. Even if the blood-brain barrier's integrity can be altered by different brain tumours, penetration by most chemotherapeutic agents is still limited. Nonetheless, a few liposoluble, low-molecular-weight and apolar agents exist that can pass across an intact blood-brain barrier. Among these, nitrosoureas, hydroxyurease and diazoquinon (AZQ).

The access of other less permeable agents (methotrexate, vincristine, cisplatin) can be improved by the rupture of the osmotic blood-brain barrier or with intrathecal or intracerebral administration. Among these agents, nitrosoureas and hydroxyurea are the most extensively studied. A recent analysis of prospective studies performed during the last 10 years demonstrated that chemotherapy administered after surgery and radiation therapy for malignant gliomas obtained a small improvement in survival. The 24-month median survival rate was 23.4% in the patients treated with chemotherapy and 15.9% in those treated with radiotherapy and surgery. This improvement, small but statistically significant, can be masked by other variables, such as age and functional status at tumour onset.

80.7 Complications and Postsurgical Management

As mentioned, variability in brain tumour is common, so that it is difficult to establish general rules for their management, depending as it does on tumour type, localization, and procedure among others. So we have patients who only undergo stereotactic biopsy and those who require therapy in order to go on breathing sensors for measuring intracranial pressure (ICP.)

Analogously, the same control should be maintained in a patient operated for a tumour of the posterior fossa, where edema can rapidly decompensate the patient, to a patient treated for a small convex meningioma with a Glasgow Coma Scale (GCS) score of 15.

Some general criteria and complications that can present in all operated tumours exist, as well as criteria that can be applied to all neurocritically ill patients.

On the basis of our experience, we recommend that the patient should stay for a minimum of 72 h in the intensive care unit (ICU); everybody knows the need for beds in our health system, but it is not uncommon that a patient who has performed well the first 24 hours will be transferred to a general ward, and then worsen again, and re-enter the ICU. In general, the cause is tumoural edema, which, as we will see, differs from traumatic edema which is sometimes present.

For example, we can operate metastasis in the posterior fossa, obtain a very immediate good postsurgical outcome, only to see edema develop days later when the patient is in the operating room. This edema can compress the brainstem and decompensate it rapidly, with the risk of late arrival because of not being in a place where it can be continuously monitored.

If the patient had a good neurological status before surgery and if the surgical procedure was not very invasive, administering therapy is recommended. On the contrary, if the operation lasted for many hours or in the case of large tumours, even if benign (basal meningiomas or others similar), it is sometimes recommended that the patient remain on assisted mechanical ventilation (AMV) and then be weaned gradually.

In such cases, or whenever the patient must remain on AMV, or when GCS cannot be assessed, a sensor to measure ICP should be placed. This highlights the need for close respiratory and hemodynamic monitoring in the first hours postoperatively, as well as monitoring the level of consciousness, electrolytes, coagulation and arterial blood gases, 24 hour-antibiotic prophylaxis, and control of arousal and pain.

Although neurological and extraneurological complications may arise, this chapter will cover only the first and most important, ones.

80.7.1 Convulsive Seizures

Almost 60% of patients with brain tumours can experience convulsive seizures or their first seizure episode after diagnosis or neurosurgery. Seizure is considered a consequence of craniotomy and occurs during the first week after surgery. The incidence of sudden seizures is between 4 and 19% in recent studies; the incidence of late attacks is 17-70%.

Seizures are complications exclusive of supratentorial lesions, particularly in the temporal, frontal, parasellar and parietal regions; even if some cases they have been reported after posterior fossa surgery, seizures most commonly occur in cortical tumours.

This complication can also be caused by indirect causes such as electrolyte abnormalities, hypoxia, or hypoglycaemia. The most common seizures in these cases are generalized, focal or simple and rare.

The consequences of seizure are severe neural lesions, increased intracranial pressure, and secondary increase in cerebral perfusion pressure; the systemic effect is hypoxia, metabolic acidosis and hyperthermia.
Prophylactic treatment is controversial. It is always necessary to take into consideration that medications can have adverse events and can interfere with steroids and chemotherapy [7].
A recent meta-analysis concluded that there is evidence both in favour and against prophylactic therapy; therefore, the decision to start anticonvulsive treatment for prophylaxis should be taken on the basis of individual risk factors, cortical localization and discussion with the patient.
The drug of first choice in adults is diphenylhydantoin, starting at a dose according to the patient's body weight. The aim is to maintain blood levels to presurgical standard values, followed by postsurgical maintenance doses.
Also controversial is how long the patient should receive anticonvulsants after surgery. This choice depends on many factors: presence of seizures before surgery, type of pathology, type of resection (total, partial), surgery area, encephalographic and tomographic findings. On this one can decide when to start treatment, which in some cases can continue for years and in others for months.

80.7.2 Postsurgical Intracranial Hemorrhage

Postsurgical hemorrhage is quite a frequent complication and a potentially very severe one after this kind of surgery. In order to avoid it, careful surgical technique and careful pre-surgical and post-surgical control of coagulation and platelet function should be performed.
Postsurgical intracranial hemorrhage is estimated to occur in 2-10% of cases, extradural hemorrhage in 0.9-7.1%, and intracerebral in 3.9%.
The main causes of postsurgical intracerebral hemorrhage are: inadequate haemostasis, high arterial pressure both peri- and/or postsurgery, sudden ventricle decompression, difficulties in tumour dissection, direct arterial lesion, alteration in blood circulation, thrombocytopenia. A higher incidence of hemorrhage is observed in primary gliomas.
There are two peaks of presentation: the first and most important one occurs within the first 6 hours after surgery and the second starting after the first 24 hours; the second one is closely related to the occurrence of perilesional edema. Morbidity and mortality are high (almost 30%), with major complications in 60% of cases.
The prognosis is worse in the following cases: hematoma >3 cm, suprasellar hemorrhage, and cerebral hemorrhage associated with intraventricular extension. Almost 40% of these patients die during the following 48 hours.
Early diagnosis is essential to avoid complications. The key to early diagnosis is immediate postsurgical neurological control in the ICU with neuromonitoring when needed, and intracranial pressure monitoring.
Progressive deterioration in the level of consciousness and neurologic focality (pupils, motor, seizures, etc.) or a sudden increase in intracranial pressure should prompt immediate treatment.
Maintaining normal arterial pressure is important because it is one of the main risk factors for hemorrhage (tumours have neoformation of vessels with weaker walls). Besides the misconception of not lowering blood pressure to prevent secondary injury, it is essential not to apply criteria of other diseases to tumours since they can show a very specific behaviour. This concept is even more important in cerebral ischemia where the risk of hemorrhage is high.

80.7.3 Cerebral Edema

Cerebral edema can be defined as the increase of water in cerebral tissue sufficient to produce clinical symptoms. The brain has three anatomic compartments that can accumulate excessive amounts of liquids:

- The vascular compartment composed of arteries, capillaries and veins.
- The cellular compartment composed of cells and their subcellular extensions.
- The extracellular compartment composed of interstitial spaces and the cerebrospinal fluid spaces.

Expansion of the volume of any one of these compartments can cause cerebral edema. Usually, two main types of cerebral edema are distinguished:

- Vasogenic edema ensuing from an increase in blood-brain barrier permeability.
- Cytotoxic edema characterized by abnormal water uptake by the cellular elements of the brain.

Vasogenic edema is seen in the vicinity of tumour masses because tumour cells release transudative microvascular factors such as proteases which weaken the microvascular blood-brain barrier and allow the passage of blood proteins. The small protein fragments generated by this protease activity will exert effects via vasogenic spread into the white matter of the brain.

The composition of the fluid of edema is similar to plasma (143 mEq/l Na^+, osmotic pressure 14 mmHg). This reflects the direct contribution of plasma extravasation. The high K^+ content of edema fluid (4.75 mEq/l), compared to the plasma concentration (3.94 mEq/l) or in the CSF (3.4 mEq/l), causes the extravasation of ions from the damaged tissue [8].

The main cause of vasogenic edema is the average arterial pressure that causes the filtration of plasma into the extracellular compartment and controls its subsequent formation. The relationship is direct and immediate. We can state than an increase in blood pressure is followed by a proportional increase in edema volume and speed of its formation. A decrease in blood pressure causes a decrease in both parameters (increase and formation of edema). From this we can appreciate the importance of maintaining normal blood pressure values.

The dimensions of edema depend on the degree of the alteration of the blood-brain barrier, the kind of lesion, and the length of time the blood-brain barrier remains open.

From a clinical point of view, the most important consequence of edema dissemination is related to local mass effect. With the expansion of edematous tissues, there is an increase in intracranial pressure and a deviation of cerebral compartments that can cause brainstem compression and produce rostro-caudal deterioration, characterized by bradycardia, hypertension and cardiorespiratory collapse. Edema- induced cerebral herniation is one of the most fearful postsurgical consequences of brain tumour.

Edema can occur in every kind of tumour, but it is more frequent in primary gliomas and metastatic tumours. It shouldn't be forgotten that, more than the type of the tumour, surgery characteristics and tumour localization are predisposing factors.

As mentioned, edema is often responsible for the patient's deterioration in the 48 hours following surgery.

Cerebral edema responds to glucocorticoids (another important difference from other pathologies is that traumatic or ischemic edema cannot be treated with corticoids), in particular dexamethasone 4 mg every 6 hours.

If the patient does not respond to corticoids, edema should be treated in the same way as in other neurocritically ill patients, sometimes with cranial decompression.

80.7.4 Hyponatremia

Hyponatremia is defined as a sodium concentration <130 mEq/l. In this hydroelectrolytic disorder, early diagnosis and treatment are essential to prevent severe neurological manifestations, including the patient's death. Hyponatremia is a common problem in the critically ill neurosurgical patient.
An alteration associated with this complication is cerebral salt wasting.
Hyponatremia is more frequent in tumours of cranial base and especially in the hypothalamic area and in hypophyseal adenomas.
While in the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), treatment is with fluid restriction, in the cerebral salt wasting syndrome it is necessary to add sodium and volume.
Its evolution should be closely controlled with a complete endocrinologic assessment to determine hypophyseal imbalance, especially hypothyroidism and suprarenal failure.

80.7.5 The Syndrome of Inappropriate Antidiuretic Hormone Secretion (SIADH)

SIADH is characterized by excessive levels of ADH as a result of increased secretion of ADH from the neurohypophyseal cells or by ectopic production. It is associated with malignant tumours, pulmonary diseases, substance abuse or different kinds of CNS illnesses that include traumatic brain injury, intracerebral hemorrhage, and infectious diseases.
The primary pathogenic mechanism underlying SIADH is excessive antidiuretic hormone (ADH) release causing renal water reabsorption and resulting in expansion of the CSF volume; it is also associated with continuous secretion of sodium by the kidney. The standard diagnostic criteria are:

- Low levels of plasma sodium (<135 mEq/l).
- Low serum osmolarity (<280 mOsmol/l).
- High levels of urinary sodium (>18 mEq/l).
- Urinary osmolarity higher than serum osmolarity.
- Normal renal, thyroid and adrenal function.
- Absence of peripheral edema or dehydration.

The diagnosis should not be performed when severe pain, nausea, stress or hypotension are present, because they can stimulate the secretion ADH.

Treatment

Fluid restriction is the treatment of choice in patients with SIADH, usually with 500-1000 ml/24 h of an iso-osmolar solution, until sodium levels normalize. If hyponatremia is severe (<110-115 mEq/l) 3% or 5% hypertonic saline solution and furosemide should be administered. It is recommended to restore the normal sodium level approximately to 2 mEq/h in order to avoid pontine myelinolysis.

80.7.6 Cerebral Salt Wasting

Hyponatremia in patients with CNS disease can also be caused by cerebral salt wasting (CSW), especially hyponatremia that develops 2 weeks after a cerebral lesion. CSW refers to the loss of renal sodium during intracranial disease leading to hyponatremia and decreased extracellular fluid volume. It is frequently present in patients with subarach-

noid hemorrhage. Evidence from published trials shows that it is more common than SIADH in neurosurgical patients. Important for the diagnosis is to consider volaemia, a negative salt balance before or during hyponatremia, and enhanced response to replacement of volume and salt than to fluid restriction. These are the characteristics of CSW that differentiate it from SIADH. Failure to distinguish properly between the two disorders will result in treatment indicated for one disorder being inappropriately administered for the other, with potentially serious adverse outcomes.
The normal sodium concentration in urine is >50 mEq. The mechanism by which cerebral disease leads to renal salt wasting is poorly understood; neural or hormonal mechanisms can be involved. One of the possible processes is the central elaboration of a circulating natriuretic factor.

Treatment

Unlike SIADH patients, patients with CSW benefit from volume expansion with fluid therapy, even if some controversy exists about adequate treatment.
While the administration of solutions containing sodium can be effective, hypertonic solutions have recently been shown to be potentially effective (with close analytical and intracranial pressure monitoring) Sodium administration corrects both the depletion of volume and the hyponatremia. Some authors say that increasing the volume of sodium during CSW can only lead to increased renal sodium secretion, and instead recommend as more appropriate preventing the depletion of the volume reduction of renal sodium secretion; fluorocortisone acetate, a mineralocorticoid enhances sodium resorption by acting directly on renal tubules.
CSW can be associated with headache, anorexia, nausea/vomiting, and weakness. Unless treated, it can lead to comitial seizure, cerebral edema, apnoea, coma and death.
The differential diagnosis is very important because fluid restriction can improve the outcome in patients with SIADH but worsen it in patients with CSW.
Vasopressin, an arginine receptor antagonist, is one of the agents for the treatment of hyponatremia. Its therapeutic effects have been studied since 1992 and its use in neurological patients is in the experimental phase. It acts on arginine vasopressin (AVP) receptors: V1a receptors are present in many tissues, including blood vessels and hepatocytes, V1b receptors are found on the hypophysis and V2 on the renal medulla. They may reduce permeability and may have a corrective effect on hypo-osmolar hyponatremia, as in the case of SIADH [9].

80.7.7 Hydrocephalus

Hydrocephalus can present as a complication of the tumour; however, initial symptoms can be a consequence of hydrocephalus and not of the tumour. It may also be a squela of surgical tumour removal.
In some cases, surgical removal of the mass will relieve the pressure on the CSF spaces within the brain and reverse the hydrocephalus. In others it is necessary to divert the CSF flow either with a shunt procedure or endoscopic third ventriculostomy. It is important to remember that brain tumours usually don’t have metastases outside the CNS, so the possibility of a peritoneal tumour is extremely rare.
If there is a high risk of postoperative hydrocephalus, ventricular drainage is recommended even if there is no increase of the ventricle. A small edema in the posterior fossa can rapidly cause compression on the fourth ventricle and stop the drainage of CSF.
External ventricular drainage should usually be performed. A drain is left, most often in the occipital horn, and after a few days, if ventriculomegaly is not present, the system is closed, and it is removed if no clinical or topographic alterations are present.

As in any other diseases, if a drain must remain for more than 7 days, it should be changed to prevent infection [10].

80.7.8 Intracerebral Hypertension

In patients undergoing surgery for a brain tumour in whom postoperative GCS assessment is not likely to be possible, an intracranial pressure censor should be placed. It can be removed only when the patient can be clinically evaluated.
Monitoring should continue even if the blood pressure is normal for many days, until the situation is resolved.
A common error is to remove the sensor when blood pressure values normalize for 24 or 48 h; this can lead to possible both neurological (edema or infection) and extraneurological complications.
When intracerebral hypertension is develops, and systemic causes have been excluded, CT should be performed to investigate for bleeding, edema or hydrocephalia (the first two are the most common causes).

80.8 Conclusion

We are only at the beginning of the treatment of brain tumours. Even with the significant improvements in recent years we have been unable to significantly improve the life expectancy of patients with a brain glioblastoma.
Without doubt, the advancements in all fields are very important.
Nowadays, histological diagnosis of a brain tumour should be completed with immunohistochemical analysis and, possibly, with the evaluation of chromosomic alterations and other genetic analyses that allow the identification of different subtypes of glia tumours and the prediction of clinical results and response to treatment. The loss of PTEN and amplification of the epidemic growing factor receptor (EGF) define glioblastoma, while alteration of p53 and of the alpha-receptor of platelet-derived growth factor (PDGF) and p16 are associated with secondary glioblastomas deriving from low-grade astrocytomas. In oligodendrogliomas, on the contrary, the allelic loss of chromosomes 1p and 19q is, at the moment, considered predictive of prolonged response to chemotherapy and overall survival. Diagnostic techniques are sometimes precise and show the exact shape of the tumours, allowing higher precision in the surgical approach, spectroscopy, angioresonance, functional resonance, with sometimes better and more useful information.
Thanks to advanced techniques such as microsurgery, perisurgical morbidity and mortality rates are currently, even if not totally, absent.
The hope is that in the future, with advances in intrasurgical imaging (echography or intrasurgical magnetic resonance), surgical navigation systems assisted with orders and functional maps will allow the neurosurgeon to recognize the extension of infiltrative tissue and can resect more extensively with lower risk.
Hyperfractionated regimens in accelerated radiotherapy schemes and radiosurgery (especially indicated for metastatic tumours, VIII for neurinoma or meningioma <3 cm) have been used.
TMZ, an imidazolid derivative that alkylates DNA, is a promising new drug discovered in recent years, with an optimum safety profile, even in elderly patients. The response rates are 5.4-23.8% in patients with glioblastoma [10], with a 6-month progression-free survival of 26% and 31.8%, respectively [11].

Most of these advancements (stereotactic surgery or low-invasive, radiosurgery) have been developed to improve the quality of life of these patients, avoiding major procedures, adverse events or prolonged hospitalization, while rapidly obtaining the same results. This should always be taken into consideration in this pathology.

81.1 Introduction

Surgery of the central nervous system (CNS) is complex and the potential for complications is high. Postoperative intensive therapy in the intensive care unit (ICU) relies on rigorous neurological examination, monitoring of heart rate, arterial pressure, and respiratory rate, and control of glycaemia, sodium, and other variables.

Monitoring allows the earlier identification of neurological deficits, metabolic complications, and respiratory and cardiovascular events. One of the differences between the ICU and the other hospital units is the level of detail in which patients are routinely monitored.

Careful monitoring permits rapid diagnosis of complications and earlier detention of changes in the patient's condition, which assures a better prognosis. A multidisciplinary team of doctors, nurses, physiotherapists, speech therapists, nutritionists and psychologists plays an essential rule in postoperative recovery. This trained team allows recovery with a minimum of sequelae.

81.2 The Neurosurgical Patient in the Intensive Care Unit

81.2.1 Monitoring and Diagnosis of Clinical Complications

The aim of monitoring during the postoperative period is to favour fast recovery and a hospital discharge without complications. In the ICU we mainly monitor the respiratory and cardiovascular system, body temperature, glucose metabolism and water-electrolyte balance.

Respiratory System

Patients submitted to intracranial surgery usually arrive at the ICU still in anaesthetic coma, intubated, and remain under invasive mechanical ventilation until full recovery of consciousness, which will depend on metabolization of the anaesthetics administered for surgery and the presence or not of cerebral injuries after the operation.

The respiratory system must be continuously monitored, specifically the respiratory rate, pulse oximetry and capnography.

The respiratory rate is an important predictor of evolution of the illness. One study observed that the ICU team presented an error of 20% in more than one third of times from direct counting the respiratory rate when compared to counting for objective tracing. In the ICU impedance monitors are frequently used to measure the respiratory rate. Many of these devices use ECG derivations which measure the impedance generated by changes in the distance between derivations due to abdominal-chest movement during breathing.

The pulse oximeter is a non-invasive device that estimates the saturation of hemoglobin for oxygen (SaO_2). SaO_2 and PaO_2 are related through the hemoglobin dissociation curve. The value shown for the oximeter is called peripheral oxygen saturation (SpO_2).

The pulse oximeter (SpO_2) estimates a SaO_2 that is usually within 2% of the difference of the real value as determined by one co-oximeter. Studies show that to maintain a PaO_2 of 60 mmHg, the SpO_2 must be around 92%. A randomized study involving 20,000 patients assigned the subjects to use or not of continuous oximetry during the operative and perioperative period. The authors concluded that oximetry allows the detection of many events of hypoxia and their prompt correction. In seriously ill neurological patients, hypoxia is one of the main mechanisms of secondary brain injury.

The data collected by the Traumatic Coma Data Bank (TCDB) demonstrate that hypoxemia occurs in 22.4% of patients with serious traumatic brain injury (TBI) and that this leads to a significant increase in morbidity and mortality. Jones et al. found that the duration of hypoxemia (SaO_2 <90% for an average duration of 11 to 20 min) is an independent predictor of mortality. These data corroborate the importance of continuous pulse oximetry during the postoperative period after neurosurgery.

Continuous monitoring by capnography measures and generates the curve of exhaled PCO_2. The plateau of the curve is determined by mean alveolar PCO_2, which is in equilibrium with pulmonary $PaCO_2$. PCO_2 measured in the final portion of the plateau is closely correlated to $PaCO_2$. Cerebral blood flow is sensitive to $PaCO_2$. There is an inverse linear relationship between cerebral blood flow and $PaCO_2$. A fall in $PaCO_2$ from 40 to 20 mmHg leads to vasoconstriction and reduces cerebral bold flow by 40%, whereas an increase in $PaCO_2$ to 80 mmHg produces vasodilatation and almost doubles the cerebral blood flow. Hyperventilation causes cerebral vasoconstriction and reduces cerebral blood flow, which could raise the risk of cerebral ischemia. A randomized study found a worse prognosis in patients with serious TBI who had been prophylactically hyperventilated. In conditions of low cerebral complacence, modest rises in $PaCO_2$ increase the cerebral blood volume and can result in accentuated rises in intracranial pressure.

These data indicate that with adequate $PaCO_2$ monitoring iatrogenic cerebral ischemia and worsening of intracranial hypertension can be prevented. Capnography is essential in the neurosurgical patient and PCO_2 must be kept to around 35 mmHg.

Arterial gas analysis and chest X-ray are essential for adjusting the ventilation before and after extubation and diagnosis of any pulmonary complications induced by mechanical ventilation (atelectasis, pneumothorax, pneumomediastinum).

Pulmonary Complications

The development of pulmonary complications significantly contributes to mortality in seriously ill neurosurgical patients and worsening of the neurological evolution. The main pulmonary complications after neurosurgery are pneumonia and atelectasis (17-25% of cases).

Pneumonia. The incidence of pneumonia after craniotomy is 21% (Figure 81.1). The factors contributing to an increased risk of infection are: reduced level of consciousness, use of corticoids, advanced age (>70 years), cardiac insufficiency, cancer surgery (specifically glioma and meningioma), smoking, diabetes mellitus, pulmonary and liver

diseases. The microorganisms most often responsible for pneumonia are Gram-negative bacilli in 50% and Gram-positive bacteria in a small percentage. The mortality rate is high (33-70%).

Atelectasis. Central respiratory depression, injury of the cervical and thoracic spinal cord, hypoventilation because of pain, altered consciousness, bronchial blockage due to mucus plugs, and traumatic pulmonary compression due to pneumothorax, haemothorax and pleural effusion contribute to the formation of atelectasis. It is the main cause of immediate postoperative low fever (24 to 48 hours after surgery). Large areas of atelectasis are responsible for a scenario of serious hypoxemia. Treatment includes manoeuvres of alveolar recruitment (positive end-expiratory pressure [PEEP], increase of the inspiratory time) and physiotherapy. Inadequate resolution and respiratory insufficiency are indications for fibrobronchoscopy.

Figure 81.1. Condensation in left lung base with pleural spill after cerebral tumor resection (Author's personal archive).

Respiratory insufficiency. Respiratory insufficiency is a life-threatening complication after neurosurgery. The neurological causes are the pathologies that determine altered level of consciousness or reduced ventilation. The level of consciousness is related to the loss of the ability to keep the airway open and compromises normal breathing. Reduced ventilation can result from a partial or complete loss of the diaphragm's innervation (injuries of the upper cervical spinal cord) which reduces lung capacity. The pulmonary causes are atelectasis, pneumonia, gastric aspiration, pulmonary thromboembolism, bronchospasm, neurogenic pulmonary edema, and the adult respiratory dysfunction syndrome (ARDS).

In the immediate postoperative period, hypoventilation can occur due to the accumulation of anaesthetics in body fat, leading to renewed sedation. This occurs with halothane and opioids.

Cardiovascular System

Monitoring of mean arterial blood pressure is essential, since hypotension is the leading cause of secondary neuronal injury, and hypertension can lead to bleeding and increase cerebral edema and intracranial hypertension. Automatic non-invasive monitoring of arterial pressure is recommended in patients with hemodynamic stability. This technique has significant limitations in patients who present sudden fluctuations in arterial pressure. It is not indicated for patients in which accurate measuring of arterial pressure is important. The invasive arterial pressure monitoring detects sudden pressure changes and extreme blood pressure levels and facilitates the repeated collection of tests and arterial blood gas analysis. The average arterial pressure must be the value used for decisions in seriously ill patients. In the direct measure of arterial pressure an invasive line is necessary; however, the risk of complications is low. Placement of an invasive arterial pressure (usually in a radial artery) is recommended in the first 24 hours after neurosurgery.

In the immediate postoperative period the average arterial pressure must be kept between values considered normal (80-100 mmHg), while taking into consideration the age group, the nature and extent of the injury, and the previous blood pressure levels of the patient. Invasive monitoring of arterial pressure will continue after 24 hours postoperative in cases which hemodynamic instability is not reached.

The American Heart Association considers continued monitoring with ECG an intervention class I for all patients in intensive care. The incidence of arrhythmias after major surgery is high.

The urinary debit is usually voluminous with the use of mannitol, and blood volume replacement with crystalloids must be intensified to prevent depletion of the extracellular space.

Cardiovascular Complications

Arterial hypertension. Arterial hypertension is frequent in the immediate postoperative period and has been reported in 70-90% of patients. It is due to sympathomimetic stimulation caused by the increase of circulating catecholamines and oxygen consumption. Administration of sodium nitroprusside can be a powerful and safe way to treat serious hypertension. This drug is a cerebral vasodilator but causes a minimum rise of intracranial pressure. Esmolol, a fast-acting beta-blocker, can be used in a similar way, without the risk of increasing intracranial pressure. In patients with chronic hypertension, it seems appropriate to start previous oral anti-hypertensive medication at about half to the two thirds of the previous dose as soon as possible. Frequent rest and sedation reduce the hypertensive condition of a more delayed postoperative patient.

Cardiac complications. Cardiac arrhythmias appear in up to 28% of cases and most often they are supraventricular. Cardiac complications in any patient submitted to surgery may be anticipated thorough preoperative evaluation. The incidence in patients without previous cardiac disease is very low (<0.2%) and the detection of risk factors is of extreme importance. Studies identify risk factors of heart complications in patients not submitted to heart surgery. Evidence of heart attack of the myocardium in last the 6 months, diagnosis of unstable angina, presence of congestive cardiac insufficiency, chest X-ray with signs of pulmonary congestion, valve disease (mainly aortic stenosis), age >70 years, emergency surgery, arrhythmias, and generally unfavourable conditions are the main data to be collected and identified in neurosurgery patients in the preoperative period.

In patients who experience a heart attack of the myocardium in the last 3 to 6 months, the rate of having one again is 30%, whereas in those who suffered a heart attack more than 6 months earlier this rate falls to 5%. Reinfarction occurs in the first 72 hours after surgery, but it can appear until the sixth day after surgery. More than half of these heart attacks are quiet, in which case ECG and serial enzyme dosage are indicated until the sixth postoperative day in patients at high risk. ECG abnormalities are found in 40-60% of patients with subarachnoid hemorrhage due to aneurysm rupture. The most frequent are S-T segment alterations or arrhythmias. A heart attack secondary to subarachnoid hemorrhage has been reported, but it is extremely rare. These ECG alterations can come from injury to the hypothalamus and high levels of catecholamine.

Patients must have their medications optimized during the preoperative period, once 60% decompensated in the first postoperative hours. Left acute cardiac insufficiency can occur after subarachnoid hemorrhage due to aneurysm rupture, mainly in patients with the worst clinical severity.

In patients with heart valve disease, prophylaxis for bacterial endocarditis may be recommended. In those with valve prostheses and under anticoagulation, the therapy should be suspended during the preoperative period. The risk associated with discontinuation of anticoagulant therapy depends on the type of valve, the localization

and factors of associated risks. In patients with only one aortic valve prosthesis and without associated risk factors, the anticoagulant is suspended 3 days before surgery. When the thromboembolism risk is high, intravenous heparin is initiated before surgery with INR <2 and suspended 8 hours before surgery. The TTPA has to be normal 6 hours after heparin suspension. Patients at higher risk of thromboembolism are those with mitral valve prosthesis, atrial fibrillation, previous thromboembolism, ventricular dysfunction, mechanical tricuspid valve or with more than one mechanical valve. A period of 5 to 7 days after-craniotomy is probably a safe break to restart anticoagulation.

Body Temperature

During the immediate postoperative period, hypothermia must be avoided since it causes tremors which increase oxygen consumption, cardiac debit and/or blood pressure. All these alterations favour brain hyperaemia which can contribute to delirium in older patients, difficult to control arterial hypertension and intracranial hypertension. The best way to limit the development of tremors in the postoperative period is to maintain normothermia.

Fever. Fever is very frequent in serious neurosurgery patients due the high risk of nosocomial infections. The role of hypothermia in neuroprotection remains uncertain, but there is consensus that hyperthermia negatively impacts on neurological recovery. Currently it is known that a gradient exists between central body temperature (oesophageal, rectal) and brain temperature. The brain temperature is underestimated, which increases the risk of secondary neuronal injury. An aggressive antithermic treatment for fever and general cooling measures are indicated.

Glucose Metabolism

Metabolic monitoring mainly involves blood glucose control. Glucose measurement every 4 hours is recommended to prevent a neurological catastrophe during the postoperative period. Prospective and randomized studies in critically ill patients have demonstrated that the evolution is better in the surgical group that receives insulin therapy and remains euglycaemic (80-110 mg/dl) than in those with glucose levels between 180 and 200 mg/dl. Hyperglycaemia (>200 mg/dl) worsens the neurological evolution. Hypoglycaemia can lead to irreversible neuronal injury and must be prevented to the maximum. In the postoperative period the objective is to keep the patient euglycaemic (≤140 mg/dl) without a significant increase in the risk of hypoglycaemia episodes.

Electrolyte Control

Much attention must be directed to prevent electrolyte disturbances in the postoperative period. Disturbances occur through alterations between extracellular volume and sodium concentration.

Hyponatremia. Hyponatremia is frequent in seriously ill neurological patients. The measure of serum sodium does not allow to distinguish between hyponatremia associated with hypervolaemia or hypovolaemia. Hyponatremia associated with hypo-osmolality contributes to the increase in intracellular volume which causes or aggravates cerebral edema and intracranial hypertension and with hyperosmolality can lead to cerebral infarction. The main causes of hyponatremia/hypovolaemia in the postoperative period are: diuretic, mannitol, vomiting, diarrhoea and mineralocorticoid deficiency. In these situations, arterial pressure, urinary debit and urinary osmolality can be low, but urea and creatinine will be raised. Replacement with isotonic solutions (physiological saline 0.9%) allows the correction of these electrolyte imbalances. Anoth-

er important cause of hyponatremia is the cerebral salt loss syndrome, which causes the release of natriuretic factors leading to increased diuresis, natriuresis and hypovolemia with normal or raised urinary osmolality. Hyponatremia is corrected by the replacement of solutions with higher sodium concentration (physiological saline 3%). In the presence of hyponatremia in the postoperative period, the syndrome of inappropriate antidiuretic hormone secretion (SIADH) is always part of the differential diagnosis, since it demands management in the opposing direction from other aetiologies. This syndrome is caused by the inappropriate secretion of the antidiuretic hormone and is associated with water retention and hypervolemia with high urinary osmolality. The treatment of the SIADH consists of water restriction of 500 ml/day if sodium is <120 mEq/l and 1000 ml/day if sodium is 120-130 mEq/l. If sodium is <115 mEq/l, convulsions or a coma state caused by hyponatremia or in the presence of pathologies in which water restriction is contraindicated (period of vasospasm), a 3% saline solution can be administered.

81.2.2 Prophylaxis of Clinical Complications in the Postoperative Period

Beyond routine monitoring, care postoperative includes the prophylaxis of infection, deep venous thrombosis and upper digestive hemorrhage.

Prophylaxis of Infections

The utility of antibiotic prophylaxis has been widely discussed over the last decades. Controlled studies have finally demonstrated the effectiveness of appropriate antibiotic therapy. Prophylactic antibiotic therapy reduces the incidence of surgical site infections and meningitis during the postoperative period. Anti-staphylococcal agents are studied and recommended. In craniotomies (clean surgeries) the use of cefazolin is recommended in one dose 30 minutes before scalp incision or in special cases of 24-hour antibiotic treatment (ventriculoperitoneal shunt placement).

Prophylaxis of Deep Venous Thrombosis and Pulmonary Thromboembolism

Deep venous thrombosis (DVT) of the lower extremities occurs in 29-43% of neurosurgical patients and the incidence of pulmonary thromboembolism (PTE) is 15%. The risk factors are immobilization for prolonged periods, paralysis of the lower extremities, prolonged surgery (+4 hours), advanced age, neoplasia, direct injury lower limb veins, previous PTE, cerebrovascular disease, use of oral contraceptives, obesity, cardiac congestive insufficiency, hypercoagulability, and pregnancy. Due to the high morbidity and mortality of DVT/PTE, prophylaxis is essential. Some studies confirm the utility of pneumatic compression of the lower limbs before surgery until the patient can walk again. Early mobilization can prevent the formation of venous thrombi. Beyond mechanical support, the use of low-dose heparin or low-molecular-weight heparin is recommended. Low-molecular-weight heparin (enoxaparin 40 mg 1x/d SC, nadroparin 7500 U 1x/d SC) or non-fractionated heparin (heparin 5000 U SC 8/8 hours) initiated 24 hours after the procedure are more efficient in PTE prevention than compression therapy. There is a non-statistically and significant risk of bleeding with this therapy. The American College of Chest Physician places neurosurgery patients in the category of high risk for PTE in the perioperative period. The association of mechanical and pharmacological prophylactic treatments in these patients is indicated.

Prophylaxis of Upper Gastrointestinal Hemorrhage

Neurological patients are at an increased risk of gastrointestinal bleeding or gastric perforation. In an endoscopic evaluation of neurointensive patients, erosions of the gastrointestinal mucosa were seen mainly in patients with secondary intracranial hypertension to brain tumours, TBI or intracranial surgery. In a cohort study of neurosurgical patients in the ICU (excluding TBI) it was observed that 6.8% had gastrointestinal complications in the postoperative period. The majority presented bleeding but a small number evolved with bleeding and perforation. The main risk factors were: SIADH, coma before surgery, postoperative complications, age >60 years, and CNS infections. Corticoids, extensively used in the neurosurgery population, contribute to the formation of gastrointestinal ulcerations. The risk of developing ulcers is twice higher and intestinal perforation can occur in corticosteroid users. In these patients medical prophylaxis of stress ulcers is indicated. Sulcrafate provides efficient prophylaxis without excessively increasing gastric pH (less risk of ventilator-associated pneumonia). However, the difficulty to manage sulcrafate and the reduction in the absorption of anticonvulsants and other drugs delivered by nasogastric catheter make H2 blockers and proton-pump inhibitors the best alternatives for a short postoperative period. Probably, there is no need for pharmacological prophylaxis in patients on an oral diet. In pharmacological prophylaxis ranitine must be used in patients <65 years of age at a dose of 50 mg IV from 8/8 hours or 150 mg OD from 12/12 hours and in those >65 years a dose of 50 mg IV for 12/12h. Omeprazole at a dose of 20-40 mg/d IV or OD.

81.2.3 Monitoring and Diagnosis of Neurological Complications

The neuro-check is a quick neurological evaluation but it does not substitute complete neurological examination. It includes serial recording of the Glasgow Coma Scale (GCS), pupillary size, symmetry and photoreactivity, type of breathing and presence of focal neurological deficits. Any variation in this neurological evaluation must be interpreted as a signal of worsening of the patient and be followed by complete neurological examination and diagnostic and therapeutic measures. The frequency of neuro-check (Table 81.1) changes according to the pathology and clinical evolution of the patient. In the postoperative period, monitoring of the GCS and pupils every 15 minutes until extubation identifies neurological complications in a prompt and effective way. Over the next 6 hours after extubation, a complete neuro-check can be performed every 30 minutes and then every hour up to 24 to 48 hours after surgery. The indications for motoring of intracranial pressure after craniotomy are very varied and controversial.

Intracranial Hypertension

Elevated intracranial hypertension (ICH) causes injury to the brain by compression, herniation and ischemia. It is generally accepted that monitoring and aggressive treatment of ICH can reduce secondary ischemia and improve the neurological evolution. Intracranial hypertension is common after neurosurgery. A retrospective study monitored

Postoperative patient	Glasgow Coma Scale	Pupils	Breathing	Focal deficit
Intubated	Every 15 minutes	Every 15 minutes	-	-
Extubated (first 6 hours)	Every 30 minutes	Every 30 minutes	Every 30 minutes	Every 30 minutes
Extubated (after 6 hours)	Every hour	Every hour	Every hour	Every hour

Table 81.1. **Frequency of neuro-check in the postoperative period.**

514 patients after elective intracranial surgery and verified the presence of ICH in 18.4% of supratentorial surgeries and 12.7% of infratentorial interventions. Of these patients with ICH, clinical deterioration occurred in only 52.8%. The neurological examination does not always allow early diagnosis of hypertension. Hypertension is characterized by chronic headache, nausea, vomiting, reduced level of consciousness and neurological compromise. Some measures to control and prevent hypertension include: headboard elevated to 30 degrees; prevention and treatment of arterial hypertension; treatment for pain, nausea and vomiting; prevention and treatment of tremors; and maintenance of adjusted ventilation and oxygenation. The most common causes of hypertension in the postoperative period are: edema; hemorrhages; cerebral hydrocephalus; pneumoencephalus; and cerebral infarction.

Cerebral Edema

Apart from localization and type of neoplasia, the main focus in the immediate postoperative period is cerebral edema. The development of edema in the immediate postoperative period is associated with manipulation of deep structures and the removal of cerebral tumours. In response to direct trauma from surgical intervention and tissue retraction, there occur relative tissue ischemia, reduction in venous return and reduction in cerebral complacency. Cerebral edema can develop with increased intracranial pressure. The use of the electrocautery increases the local injury and is directly associated with cerebral tissue trauma.

Edema appears 4 to 5 hours after surgery and peaks within 48-72 hours (Figure 81.2). Clinical manifestations correspond to the cerebral area injured. Motor or sensory alterations of the mental state, deficits and paralyses of cranial nerves are common. Transtentorial herniation can occur, worsening the prognosis. Brain CT confirms the diagnosis and excludes such other complications as hydrocephalus and hemorrhage. The tomographic findings are: deletion of ridges; reduction of the size of the ipsilateral ventricle; midline deviation; hypodensity and deletion of the interface between the white and gray matter. After diagnosis with CT, treatment must be initiated. The main objective is to maintain cerebral perfusion pressure (CPP) >60 mmHg and ICP <20 mmHg. The headboard of the bed must remain high (30 degrees) to aid cerebral venous return. Adequate cerebral perfusion pressure is kept by the infusion volume and use of vasoactive drugs. $PaCO_2$ must be kept around 35 mmHg. Hyperventilation ($PaCO_2$ 25-30 mmHg) is indicated when clinical signals of herniation are present. In patients with ICH on mechanical ventilation, sedation is mandatory (benzodiazepines, opioids, propofol). Corticoid administration (dexamethasone in 4 doses every 6 hours up to a dose of 10-40 mg) is recommended for patients submitted to brain tumour resection. The clinical response of cerebral edema to dexamethasone for primary malignant cerebral tumours is less dramatic than for metastasis, and meningomas less than gliomas. In patients with external ventricular derivation

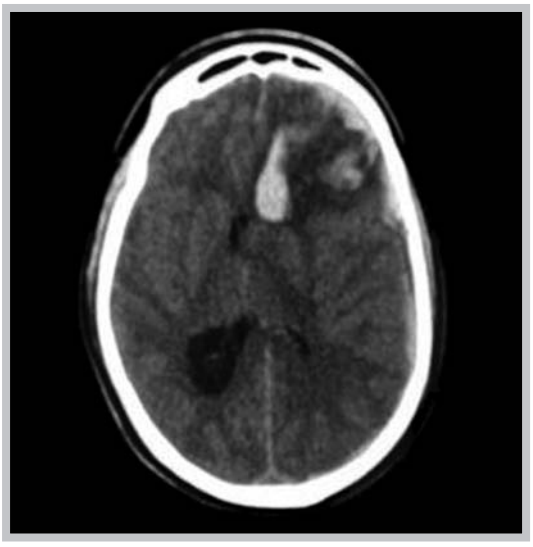

Figure 81.2. **Cerebral edema in the left frontal region with minor bleeding. Immediate postoperative period after tumor resection (Author's personal archive).**

(EVD), cerebrospinal fluid drainage can assist in the control of ICP. The administration of mannitol at a dose of 0,25 to 1 g/kg must be quickly initiated and monitored with serum osmolarity (serum osmolarity kept <320 mOsm). The alternative to this osmotic therapy is hypertonic saline solution in bolus (physiological saline 3 20%), being mainly indicated in patients refractory to mannitol or in the presence of renal function loss. Decompressive craniectomy is indicated in patients with a persistent rise in ICP, despite optimized medical treatment. In the presence of unilateral cerebral edema following cerebral tumour resection, the removal of a great bone flap with dural plastic has had success in reducing ICP.

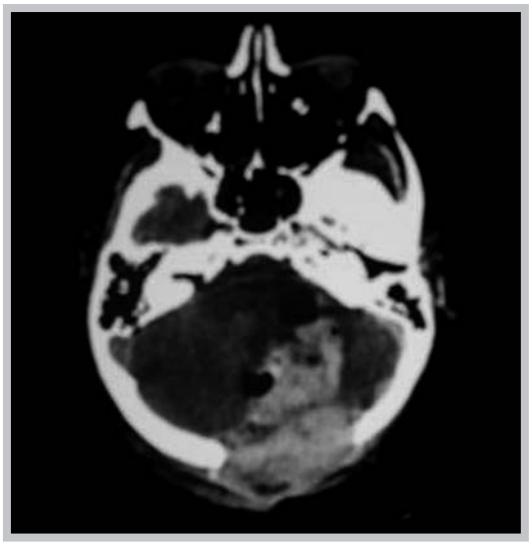

Figure 81.3. **68-year-old woman submitted to posterior tumor resection of the fossa. Deterioration of consciousness (GCS from 15 to 4) during the immediate postoperative period. Emergency CT showing major hemorrhage in the operative stream bed (Author's personal archive).**

Hemorrages

The occurrence of hemorrhage in the immediate postoperative period and the development of epidural, subdural or intraparenchymal haematoma is always a feared complication, because it is a significant and potentially avoidable situation. Accurate estimation of the incidence of haematomas became possible with the advent of tomography in clinical practice. Currently, the incidence of extradural haematoma after neurosurgery varies between 0.9 and 7.1%, whereas the incidence of intracerebral haematoma is of 3.9%. Surgery for ventriculoperitoneal derivation is associated with a very small percentage of bleeding in the surgical site.

The diverse causes associated with this fearful complication are related to the surgical technique and clinical morbidities. Inadequate perioperative haemostasis, inadequate tissue suture, important tissue retraction, abrupt ventricular decompression, direct injury of the cerebral vessels, arterial hypertension and thrombocytopenia. Cerebral tumour resection (resection of malignant tumours) and craniotomy for haematoma draining are associated with a higher incidence of hemorrhage.

Clinical manifestations include chronic headache, new neurological deficit, convulsive seizures, reduced level of consciousness, signs of transtentorial herniation with hypertension, bradycardia and respiratory insufficiency. In patients with bleeding in the posterior fossa, the manifestations are related to the degree of compression of the brainstem and are predominantly related to cardiovascular and respiratory decompensation. The diagnosis is based on head CT (Figure 81.3) and the treatment is emergency surgery for draining the haematoma and relief of intracranial hypertension.

Hydrocephalus

Surgery of the posterior fossa and intraventricular space are often associated with hydrocephalus in the postoperative period. Hydrocephalus can occur in patients with subarachnoid hemorrhage and intracerebral hemorrhage with or without intraventricular extension.

The initial manifestation can be chronic headache or paralysis of cranial nerves, especially cranial nerves III, IV and VI, but also it can present with rapid neurological deterioration.

Ventriculostomy, lumbar puncture and third ventriculostomy endoscopy are all viable methods for handling an acute hydrocephalus.

Ventriculostomy is the most commonly used technique: it can be a heroic measure; it can help to stabilize the patient and gains time for a definitive treatment or time for the base condition to resolve itself and CSF flow to return to normal.

Pneumoencephalus

Pneumoencephalus consists of intracranial air in the following compartments: epidural, subdural, subarachnoid and intraventricular. It is one of the causes of deterioration of consciousness after surgery of the posterior fossa and supratentorial procedures. The risk is higher when the patient is operated in a seated position. Air in the epidural space occurs after surgery involving the skull base where an extensive bifrontal craniotomy is made. Measures in the intraoperative period to prevention the development of pneumoencephalus include closing of the dura mater, reconstruction of the skull base, re-expansion of the intracranial contents and placing a drain in the epidural space. The clinical signals of hypertensive pneumoencephalus generally occur within 2 to 4 days after the operation. Accumulated air causes mass effect and has important clinical repercussion (Figure 81.4).

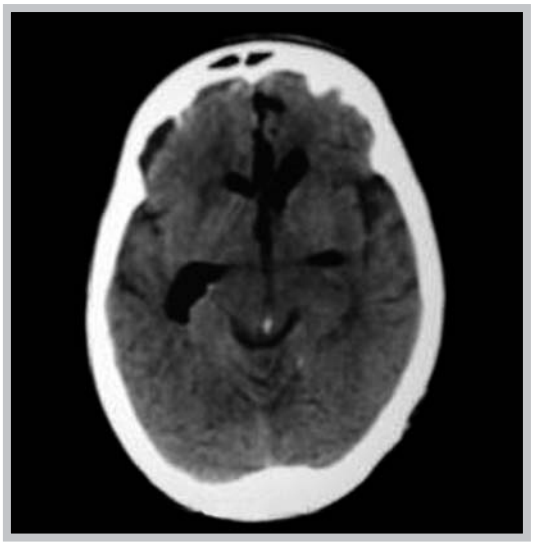

Figure 81.4. **Patient submitted to cerebral tumor resection, with intense chronic headache in the immediate postoperative period but without focal deficit. Emergency CT showing major pneumoencephalus (Author's personal archive).**

The more common clinical manifestations are chronic headache (38%), nausea, vomiting and deterioration of the level of consciousness, with mental confusion or lethargy. It can evolve to coma without focal neurological signals. Hyponatremia is common and convulsive seizures can worsen the situation. Air is evident on the head CT up to 7 days after surgery. Simple pneumoencephalus does not require treatment. In the attempt to promote the reabsorption of pneumoencephalus, some authors suggest keeping the patient with the headboard flat for 48 to 72 hours and with 100% of oxygen. It is thought that ventilation with 100% allows a nitrogen exchange for oxygen of the intracranial air, which is quickly absorbed by the bloodstream. Hypertensive pneumoencephalus must be evacuated (aspiration or catheter placement) with urgency like intracranial haematoma. Surgery can be necessary to repair a skull base fracture or CSF fistula.

Cerebral Vasospasm

The main focus in the immediate postoperative period after clipping of cerebral aneurysm for subarachnoid hemorrhage is the prevention of vasospasm. Up to 70% of hemorrhage cases present vasospasm diagnosed through some complementary examination such as transcranial Doppler (Figure 81.5) or cerebral arteriography (Figure 81.6).

However, clinical vasospasm (cerebral ischemic deficit or cerebral infarction) occurs in up to 35% of patients with hemorrhage and is the leading cause of morbidity and mortality in survivors. The main risk factors of vasospasm are: higher clinical severity, greater blood volume on the CT scan, hypotension, hypovolaemia, hyponatremia, hyperthermia and hyperglycaemia. The use of nimodipine to prevent vasospasm has been vastly

studied. A meta-analysis of 8 studies, evaluating 1574 patients with subarachnoid hemorrhage (Hunt-Hess I to III) evidenced that the use of the nimodipine improves the immediate prognosis, and in 3 months in 27% of cases, reduces the neurological ischemic deficit in 33%, reduces incidence of cerebral infarction on CT in 21%, and reduces the incidence of vasospasm on arteriography in 20%. The recommendation is administration of oral nimodipine at a dose of 60 mg every 4 hours (IV with greater hypotension) for 21 days. From a hemodynamic point of view, it is clear that hypotension and hypovolaemia worsen the prognosis and must be prevented in all patients after subarachnoid hemorrhage. However, there are no data supporting the prophylactic use of HHH therapy (hypertension, hypervolaemia, haemodilution) in patients with subarachnoid hemorrhage without clinical evidence of vasospasm.

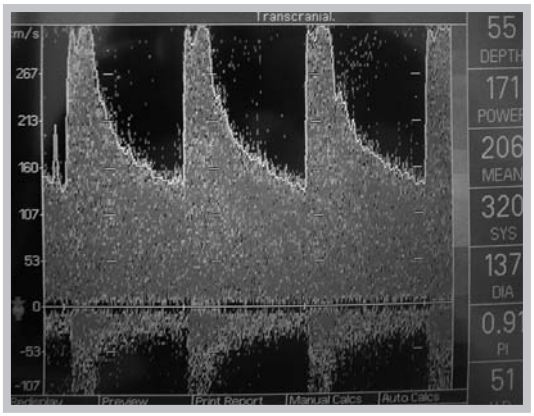

Figure 81.5. **Transcranial Doppler showing severe vasospasm (average speed >200 cm/s) in the right middle cerebral artery.**

Figure 81.6. **HSA Hunt-Hess III. Arteriography showing vasospasm of the basal artery. (Author's personal archive).**

Convulsions

The incidence of early convulsions (first 7days after surgery) varies between 4 and 19% of cases. When late convulsions are considered, the incidence increases up to 70%. They can be focal or generalized. The situations considered at risk for seizure occurrence include:

- Surgery involving the supratentorial compartment: frontal region, parasellar, temporal and parietal. Convulsions after posterior fossa surgery are rare and result from retraction of the supratentorial structures.
- Specific pathologies: cerebral abscesses, cerebral tumours, cerebral arteriovenous malformations, cerebral aneurysm, ventriculoperitoneal shunt, cerebral convulsions before surgery, haematomas, electrolyte alterations, hypoxia, hypoglycaemia.

Patients who do not present a crisis before surgery and submitted to surgery in the supratentorial compartment for some of the pathologies mentioned above must receive an anticonvulsant. Phenytoin is the most widely used anticonvulsant. The loading dose is between 15 and 18 mg/kg before surgery and 5 mg/kg after surgery. In primary cerebral tumours, 75% of convulsions occur with the 3 first months after surgery. Many authors recommend prophylaxis with phenytoin for 3 months. Meningomas are associated with higher rates of convulsions in the postoperative period than other tumours; it has been

suggested that they must be prophylactically treated for 12 months. Some prospective studies concluded that there is no advantage in anticonvulsant prophylaxis in patients with metastatic tumours except in melanoma. Patients who will be submitted to surgery for aneurysm must receive an anticonvulsant only during the perioperative period. Serious TBI must be treated for 1 week. Prophylaxis is effective in the early phase but not in the delayed phase after traumatic convulsive illness.

Convulsions in the immediate postoperative period should arouse the suspicion of haematoma, edema, infarction or metabolic disorders (hypokalemia, hyponatremia, hypoglycemia). Laboratory examinations and skull CT should be obtained to establish a diagnosis of the complications and to plan new surgical intervention, if necessary.

The consequences of convulsive seizures are directly related to the cerebral tissue and systemic effects. The direct effects on the brain include neuronal injury with increased intracranial pressure secondary to the increase in cerebral blood flow. The systemic effects include hypoxia, metabolic acidosis and hyperthermia. This leads to secondary neuronal injury to edematous tissue, creating a vicious cycle that increases the final injury and the recurrence of new convulsive seizures.

81.3 Central Nervous System Infections

Postoperative craniotomy infections are uncommon (incidence around 7%). They include wound infections, osteomyelitis, bacterial meningitis, subdural and epidural empyema and cerebral abscess. Prophylactic antibiotics are effective to decrease infections incidence in clean craniotomy postoperative. Risk factors to infection include diabetes mellitus, immunossupression drugs, craniotomy time, skin disease, drains, an extended surgical time (more than 4 hours) and hemostatic clips. Bacterial meningitis could occur in any intradural surgical interventions and it could be devastating. Bacterial meningitis incidence is around 0.5-0.7% after clean craniotomy. It could be more frequent after external ventricular drainage and in the presence of liquoric fistula. Bacterial meningitis could be as acute and sub-acute presentation, with low-grade fever in the begining. It is suspected in the presence of fever of unknow reason, loss of consciousness and seizure convulsive. Ventriculitis could occur. The diagnostic is confirmed by cerebrospinal fluid (CSF) exam that shows increase white cell count with neutrophil-predominant, low glucose concentration, high protein level and high level of lactate. Prophylatic antibiotic could difficult the diagnostic. When this happens, CSF findings may resemble those of viral meningitis. Microbiological culture of the sample could identify the organism in 70-85% of cases but results can take up to 48 hours to become available. The agents more common are aureus staphylococci, epidermidis staphylococci and gram-negative bacilli. Third-generation cephalosporin and vancomicyn are usually associated to treatment before culture result. Shunt ventricular must be removed.

81.4 Conclusions

This chapter outlines an approach to the postoperative management of the neurosurgical patient. Postoperative care after neurosurgery is a routine situation in the ICU and demands the attendance of specialized team. Here we emphasize the importance of ICU monitoring of neurological complications to minimize morbidity and mortality. Rigorous monitoring of the respiratory system, cardiovascular system, the nervous system, and glu-

cose and sodium metabolism is essential. We discuss the risk factors related to clinical and neurological complications such as cerebral edema, surgical site hemorrhage, convulsions, and pneumoencephalus. Neurological and non-neurological complications are frequent and must be diagnosed promptly to minimize sequelae and allow adequate recovery.

82 Neurologic Emergencies During Pregnancy

Javier I. Diaz-Mendoza[1], Panayiotis N. Varelas[2]

[1] Senior Staff Pulmonary and Critical Care Medicine, Henry Ford Hospital, Detroit, USA
[2] Associate Professor of Neurology, Wayne State University, Director NICU, Senior Staff Neurology and Neurosurgery, Detroit, USA

82.1 Introduction

Complications associated with pregnancy are common, and sometimes require close monitoring in intensive care units (ICUs). Neurologic manifestations during pregnancy can be related to primary involvement of the nervous system, like cerebrovascular disease, or as part of systemic diseases, like preeclampsia. Because of the complexity and importance of functional outcome of the mother and foetus, these complications should be managed in specialized ICUs, where the neurologist and the obstetrician work very closely. An attempt to materialize this idea has been made, and neuroscience intensive care units (NSICU) have been created to meet this goal. Although there are still no data to support this new approach, the idea is becoming more attractive around the world. Here, we present the most common clinical situations for which admission to a NSICU may be a reasonable alternative to a general ICU.

82.2 Pre-eclampsia and Eclampsia

Preeclampsia (PE) and eclampsia (EC) are major causes of maternal and fetal morbidity and mortality, involving 15-20% of pregnancies in the developed countries and even higher rates in the less developed parts of the world. Maternal complications include renal failure, the HELLP syndrome (haemolysis, elevated liver enzymes and thrombocytopenia), liver failure, cerebral edema with seizures and death.

Preeclampsia is defined as the association of newly diagnosed hypertension after 20 weeks of pregnancy and either proteinuria or generalized edema or both. PE can be classified as mild or severe (Table 82.1). Eclampsia refers to the occurrence of seizures during or after pregnancy which are usually preceded by signs of PE. However, up to 38% of EC cases will develop with no prodromic PE [1].

- Systolic blood pressure ≥160 mmHg or diastolic blood pressure ≥110 mmHg on 2 occasions 6 or more hours apart in a pregnant woman who is on bed rest
- Proteinuria, with excretion of ≥5 g of protein in a 24-hour urine specimen or 3+ or greater in two random samples collected 4 or more hours apart
- Oliguria, with excretion <500 ml of urine in 24 hours
- Pulmonary edema or cyanosis
- Impaired liver function
- Visual or cerebral disturbances
- Pain in the epigastric area or right upper quadrant
- Decreased platelet count
- Intrauterine growth restriction

Table 82.1. Criteria for severe preeclampsia (one or more of the listed.) Adapted from [ACOG Committee on Practice Bulletins--Obstetrics. ACOG Practice Bulletin. Diagnosis and management of preeclampsia and eclampsia. *Obstet Gynecol* 2002; 99: 159-67].

82.2.1 Epidemiology

The incidence of PE is around 5-10% of pregnancies [2], and 1:2000 deliveries for EC, with higher numbers in developing countries. Maternal mortality is 1.8% if EC is present, and this is second only to embolic events [3]. Additionally, 20-50% of obstetric admissions to the NSICU are related to PE [4]. Risk factors for developing PE include: poor nutrition, nulliparity, multiple gestations, maternal age (<18 or >35 years), diabetes, pre-existing hypertension, previous EC, hydatidiform mole, hydrops fetalis, and family history [5].

82.2.2 Pathophysiology

PE is characterized by systemic vascular endothelial dysfunction. It is associated with endothelial damage as well as impaired vascular homeostasis. The decreased amounts of vasodilators like prostaglandin I2 and nitric oxide, as well as the increased amounts of vasoconstrictors (thromboxane A2 and endothelin) found in PE will result in diffuse maternal vasospasm and microangiopathy with increased capillary permeability and tissue edema. That explains why the use of antiplatelet agents (specifically low dose aspirin) during pregnancy has been shown to reduce the relative risk of PE and serious adverse outcome [6,7]. Autoantibodies against angiotensin II type I receptors have been found in patients with PE, a finding that could explain in part the pathogenesis of PE [8]**.** Abnormal placentation and placental hypoxia also play a major role in PE. Recent studies showing overexpression of proteins like soluble fms-like tyrosine kinase 1 (sFlt-1) and soluble endoglin (sEng) contributing to endothelial dysfunction and precede clinical symptoms of PE [9] are becoming the base for the developing of new therapeutic options.

Cerebral pathology shows disruption of the tight junctions and extravasation of fluid into the perivascular spaces, with white matter edema and cortical micro- and macrohemorrhages. Also areas of infarction are seen in the parieto-occipital watershed zones as a consequence of the associated vasospasm [5]. The classic posterior reversible encephalopathy syndrome of PE and EC may be explained by the increased permeability of the posterior cerebrum's blood-brain barrier seen in pregnant rats [1]0.

Eclamptic encephalopathy is believed to be associated with an impairment of cerebral autoregulation since this develops at considerably lower pressures than those reported for hypertensive encephalopathy. This suggests that the autoregulatory curve is shifted to the lower range of pressures (to the left) during pregnancy or that autoregulatory capacity is severely affected [11].

82.2.3 Clinical Presentation

The classic triad of hypertension, proteinuria and edema is not necessarily present in all patients with PE. Atypical presentations of PE include patients with gestational hypertension without proteinuria, capillary leak syndrome (facial edema, ascites and pulmonary edema) with proteinuria but without hypertension and gestational proteinuria alone. Furthermore, PE and EC can present before 20 weeks of gestation, as well as in the late post-partum (>48 hours but <4 weeks after delivery) [12], which makes diagnosis and management even more difficult.

Seizures are the hallmark of EC, and are usually generalized tonic-clonic, but occasionally may have a focal onset (frequently over the face) [13]. Seizures in the late post-partum are only present in 3% of patients with EC [14]. Absence of prodromic PE is variable and seizures can be the first manifestation in up to 60% of patients with EC [15]. Head-

ache, photophobia, visual hallucinations or confusion are also associated with EC. Transitory blindness secondary to cortical ischemia can be seen in 2.3% of patients with EC [16]. Retinal artery vasospasm or retinal detachment is less common. The presence of coma carries a poor prognosis.

82.2.4 Radiographic Features

Most patients with EC will have a normal computerized tomography (CT) of the head [1]7; however, some may present with focal subarachnoid or intraparenchymal hemorrhage, occipital symmetric hypodensities (in patients presenting with cortical blindness) and cerebral edema (focal or generalized) [18].

Low-signal intensities in T_1 and high-signal intensities in T_2-weighted images (with a high diffusion coefficient, i.e., without diffusion restriction) can be seen on magnetic resonance imaging (MRI) of the brain [19]. In early EC, hyperperfusion-induced vasogenic edema without cerebrovascular spastic change can be suggested by MRI perfusion-weighted images obtained by multi-slice FAIR (flow-sensitive alternating inversion recovery) method [20]. These reversible lesions are also seen in hypertensive encephalopathy and posterior leukoencephalopathy syndromes [17].

82.2.5 Management

Management of PE revolves around close monitoring and judicious timing of delivery. It will depend on the evaluation of possible maternal and fetal complications. In general, patients with severe PE or EC should be admitted early to the NSICU, since the course of the disease is unpredictable and can progress rapidly. It is wiser to deliver than to delay once the foetus is between 32 and 34 weeks and can be safely delivered. There is little or no place for conservative management if the patient has developed EC, pulmonary edema, cerebrovascular accident, renal failure or liver injury [21]. The management of these patients in the NSICU is mainly related to management of blood pressure, intravascular volume, intracranial dynamics, and prevention and treatment of seizures.

Blood Pressure Control

The blood pressure (BP) goal should be to keep the systolic <160 mmHg and the diastolic <105-110 mmHg. Invasive BP monitoring is indicated once the patient is in the NSICU. The choice of antihypertensive medication should depend on the physician's experience and familiarity with a particular medication. Drugs that are safe in pregnancy and have been used for the acute management of BP include labetalol, hydralazine and some calcium channel blockers (sustained-release nifedipine and nicardipine).

Intravenous (IV) labetalol is effective in decreasing BP, with a rapid-onset effect and less reflex tachycardia than other drugs. It can be given as a 10-20 mg IV dose, and can be repeated every 10 to 15 minutes, up to a maximum total cumulative dose of 300 mg. Labetalol can also be used as a constant infusion (1-2 mg/min).

Hydralazine has been used extensively in the management of PE, however an old study showed a higher incidence of hypotension with its use [22]. Despite this study, many experts consider the drug as an acceptable antihypertensive. It should be given as 5-10 mg IV doses that can be repeated every 20 to 30 minutes. If a total dose of 30 mg does not achieve optimal BP control, a different agent should be considered.

Nicardipine has been less used for the management of PE. IV administration should be given as continuous infusion starting at 5 mg/h and increased by 2.5 mg/h every 15 minutes to a maximum of 15 mg/h.

Diazoxide has been used alone or in association with hydralazine when adequate BP control was not achieved by a single agent. Miniboluses of diazoxide (15 mg every 3 minutes to a maximum of 300 mg) have shown to be safe and effective in a randomized control trial [23]. The use of immediate-release nifedipine is not encouraged due to its association with excessive reduction in BP with serious cardiovascular outcomes [24].

Nitroprusside is contraindicated in the later stages of pregnancy due to possible fetal cyanide poisoning if used for more than 4 hours; however, it can be considered as a last resort agent to treat severe refractory hypertension.

Angiotensin converting enzyme (ACE) inhibitors and angiotensin II receptor blockers (ARBs) are contraindicated at all stages of pregnancy because of their teratogenic effect. They also can play an unknown significant role in the pathogenesis of PE [25,26].

Intravascular Volume

Since patients with severe PE are at high risk of developing pulmonary and cerebral edema, overall in the postpartum [27], volume status should be carefully assessed. Total fluid intake should not exceed 80 ml/h [26]. Invasive haemodynamic monitoring can be useful in complicated patients, like those who are unresponsive to antihypertensive therapy, or have developed pulmonary edema refractory to diuresis and acute renal failure [28].

It is important to consider the physiologic changes that pregnancy brings. Maternal blood volume and cardiac output increase progressively through pregnancy, reaching 30-50% above baseline levels by about 28 weeks. Also, systemic vascular resistance and pulmonary vascular resistance are decreased by 20-30% in the near-term patient. During labour, cardiac output increases by a further 10-15%, augmented during contractions by the return of 300-500 ml of blood to the central circulation. Immediately after delivery, there is an increase in preload, producing an increased cardiac output that remains for 48 hours after delivery [29].

Intracranial Dynamics

The management of cerebral edema and elevated intracranial pressure in PE and EC is no different from non-pregnant patients. The role of oxygenation, hyperventilation, correction of hyponatremia, and the use of mannitol or loop diuretics are general measures that can be taken but have not been tested in controlled studies. It is important to mention that mannitol crosses the placenta and causes fetal dehydration, cyanosis and bradycardia (in animal studies); it remains as a FDA category C medication. However, mannitol can be used in life-threatening situations during pregnancy [30] at a dose of 0.25 to 0.5 g/kg of pregnancy maternal weight every 4 to 6 hours intravenously.

The use of pyridoxal phosphate, which promotes GABAergic synaptic activity and normalizes the electroencephalographic (EEG) findings seen in EC [31], has not been studied and remains controversial.

Seizure Management

Magnesium sulphate is the drug of choice to prevent and treat convulsions in women with PE and EC. Magnesium increases the production of prostacyclin, which causes vasodilation, leading to a higher cerebral blood flow and to a short-lived antihypertensive effect. It also blocks the Ca^{++} influx through the NMDA glutamate receptors (pre- and post-synaptically), reducing neuronal excitability [7,32]. It has been shown to decrease the progression from severe PE to EC [33,34], as well as to decrease the risk of abruptio placentae and maternal mortality [33]. A randomized, controlled study also showed the superiority of magnesium sulphate over phenytoin in the prevention of EC in hypertensive pregnant women [35].

Furthermore, patients with EC treated with magnesium sulphate had a 52% lower risk of recurrent seizures compared to diazepam and a 67% lower risk compared to phenytoin in the Eclampsia Trial Collaborative Group [36]. Maternal and infant mortality did not differ. Magnesium sulphate is also more effective than nimodipine for prophylaxis against seizures in women with severe preeclampsia [37].

Although there is no consensus on the optimal magnesium regimen, it is frequently started with a bolus of 4 to 6 g IV over 5 minutes, followed by 1 to 2 g/h IV as a continuous infusion for at least 48 hours post-partum in the case of EC. It can be stopped after 24 hours post-partum if it is used as prophylaxis of seizures in severe PE [38]. The dose should be adjusted in women with renal insufficiency (usually half the dose if serum creatinine is >1.3 mg/dl) [5]. Patients should be monitored in the NSICU for signs of potential magnesium toxicity, which include loss of patellar reflexes, increasing drowsiness, dysarthria, muscle weakness and respiratory depression. If this occurs, serum magnesium levels should be measured (therapeutic levels 4-8 mEq/l), and if they are elevated, magnesium infusion should be discontinued. Calcium gluconate (1 g IV in 10% solution) should be given as antidote in case of impending respiratory arrest. If seizures recur, a loading dose of phenytoin can be tried (18 mg/kg IV at a maximum rate of 50 mg/min).

Termination of Pregnancy

Termination of pregnancy should be decided by obstetricians based on maternal and fetal monitoring. The patient should be hemodynamically stable and seizure free. As mentioned before, there is no benefit to the mother continuing pregnancy once severe PE is diagnosed. If the delivery is done before 32 weeks, steroids are given to promote fetal lung maturity and caesarean section is advised. After 34 weeks, vaginal delivery is preferred [38].

82.3 Hellp Syndrome

The HELLP syndrome is characterized by haemolysis with microangiopathy, elevated liver enzymes and low platelet count. It complicates 2-12% of patients with severe preeclampsia (0.2-0.6% of all pregnancies)2. It is associated with high maternal morbidity but not mortality. Perinatal mortality, on the other hand, ranges between 7 and 20% [39]. The rate of recurrent preeclampsia in patients who had HELLP syndrome is around 20%, whereas the rate of recurrence of HELLP ranges between 2 and 19% [40].

82.3.1 Pathophysiology and Clinical Features

The HELLP syndrome belongs to a group of thrombotic microangiopathy disorders, together with the haemolytic uremic syndrome. The alteration in the maternal-fetal immune balance induces platelet aggregation, endothelial dysfunction and arterial hypertension. Furthermore, excessive activation or defective regulation of the complement system plays a major role in HELLP, leading to enhancing of procoagulant activity and thrombosis [41].

There are no diagnostic clinical features to distinguish HELLP from preeclampsia [40]; most patients present with upper abdominal pain, headache, nausea and vomiting, edema and weight gain, hypertension and proteinuria [2]. Symptoms typically develop during the third trimester, however, second trimester and postpartum presentations are also possible (up to 25%). Shortness of breath and chest pain with no other symptoms have also been described [42]. Some patients can be asymptomatic.

The diagnosis requires the presence of the three laboratory criteria: microangiopathic haemolytic anaemia (schistocytes in blood smear), elevated aminotransferases (AST or ALT >70 U/l), and thrombocytopenia (<100,000 cells/µl). Lactate dehydrogenase (LDH) levels in serum are also elevated.
Computed tomography (CT) of the liver may show subcapsular haematoma, intraparenchymal hemorrhage or infarction or hepatic rupture [43].
Other complications associated with the HELLP syndrome include acute renal failure, disseminated intravascular coagulation, abruptio placentae, the adult respiratory distress syndrome (ARDS), intracranial hemorrhage (intracerebral, intraventricular and retinal [44-46]) and retinal detachment. Ischemic cerebellar strokes have also been reported [47,48]. Cerebral angiography or transcranial Doppler sonography may reveal diffuse vasospasm [43]. Vasogenic cerebral edema has been also reported [49].
It is important to differentiate between the HELLP syndrome and acute fatty liver of pregnancy (AFLP) because they may have the same clinical presentation. AFLP will present more frequently with prolongation of prothrombin time (PT) and activated thromboplastin time (aPTT), hypoglycaemia, and elevated creatinine levels. Patients with thrombotic thrombocytopenic purpura (TTP) will more often have fever than those with the HELLP syndrome [50]. Acute myelogenous leukaemia mimicking the HELLP syndrome has also been described [51].

82.3.2 Management

Management of the HELLP syndrome includes stabilization of the mother (hypertension, seizure prophylaxis), fetal monitoring, and early delivery. Delivery is the only definitive therapy.
Antihypertensive drugs used in HELLP are the same as those used in PE. Prophylactic magnesium sulphate should also be given to prevent seizures. Platelet transfusion is indicated if there is significant maternal bleeding or if the platelet count is <20,000 cells/µl. Plasma exchange with fresh frozen plasma (FFP) could be considered if thrombocytopenia, haemolysis and organ dysfunction persist >72 hours postpartum [52].
The use of dexamethasone in patients with the HELLP syndrome is controversial. Previous studies have shown that dexamethasone is associated with faster platelet count recovery and shorter hospitalization [53]. However, a recent randomized trial showed no benefit of dexamethasone compared to placebo in the resolution of laboratory or clinical parameters, frequency of maternal complications, need for rescue therapy, or length of hospitalization54. Corticosteroids are recommended in patients with less than 34 weeks of pregnancy since they improve perinatal outcome by accelerating fetal lung maturity.
Hepatic hemorrhage without rupture (subcapsular haematoma) is managed conservatively with close monitoring, correction of coagulopathy by transfusion of blood products and consideration of percutaneous embolization of the hepatic arteries. Surgical intervention is indicated if the patient is haemodynamically unstable. Liver rupture is a life-threatening complication that requires aggressive supportive care and immediate laparotomy. Use of recombinant factor VIIa [55] and liver transplantation [56] have also been reported in patients with intractable hemorrhage.

82.4 Myasthenia Gravis

Myasthenia gravis (MG) is a chronic autoimmune disorder of neuromuscular transmission characterized by varying degrees of weakness and easy fatigability of the skeletal

muscles. Some 85% of patients with MG will have antibodies against the acetylcholine receptor (AchR) in the postsynaptic membrane of skeletal muscles, leading to a reduction in the available receptors and decreased neuromuscular transmission. Precipitants of MG crises include stress, systemic illness, infections, thyroid disorders, use of corticosteroids, surgery with general anaesthesia and pregnancy [57]. During pregnancy, the course of the disease is unpredictable; worsening of symptoms occurs more likely during the first half of pregnancy and postpartum [58].

82.4.1 Clinical Course

The course of MG during pregnancy is unpredictable. Many studies have shown worsening of symptoms in 40% of pregnant women with MG on average [59,60]. However, other studies showed an incidence of only 10-19% of worsening of symptoms, with the majority of patients remaining stable or improving (59% and 22%, respectively) [61,62]. On the other hand, almost all studies agree that most diagnoses of MG and deterioration episodes occur during the postpartum period. In a large Norwegian study, half of the diagnoses of pregnancy-associated MG were made in the postpartum [62]. A Taiwanese study of 12 pregnant women with MG showed that 11 women had clinical deterioration in the postpartum [60]. The highest risk for maternal mortality and clinical deterioration is within the first year after diagnosis, which is why delaying pregnancy for at least 1 to 2 years after diagnosis [63] is recommended. The course in one pregnancy does not predict the course in subsequent pregnancies [61].
Transient neonatal MG, due to the crossing of maternal antibodies through the placenta into the fetal blood, has been reported to be between 10 and 20% [64]. The duration of illness and therapy of women with MG does not correlate with the manifestations of neonatal MG [65]. Preterm rupture of amniotic membranes was also reportedly higher in the MG group [66].

82.4.2 Management

MG crises are usually due to severe dysphagia and aspiration. In the NSICU they could arise after the use of neuromuscular junction blocking medications. The initial manifestations of respiratory failure are mild and can be missed. It is recommended to follow arterial gases and pulmonary function tests. PaO_2 <60 and $PaCO_2$ >45, vital capacity <15 ml/kg and a negative inspiratory force (NIF) of less than -25 cmH_2O are indications for elective intubation and mechanical assistance. Due to decreased pulmonary compliance, plateau airway pressures up to 35 cmH_2O can be tolerated without alveolar overdistension [67]. Most patients with MG will be extubated within 2 weeks [68], however tracheostomy should be considered if this time is longer.
Fetal monitoring such as non-stress tests and fetal breathing can be unreliable in patients with MG since fetal movements can be affected. The use of magnesium in women with preeclampsia and MG is contraindicated due to increased neuromuscular blockade [69]. Patients might experience fatigue during the expulsive phase of labour due to weakness of the striated muscle of the pelvic floor, which could lead to the use of outlet forceps or vacuum extraction. The incidence of postpartum hemorrhage can be higher also. It is recommended to perform close monitoring of respiratory function during labour since fatigue and hypoventilation have been described in patients with MG. Parenteral administration of medications like neostigmine are preferred over oral medications due to errant intestinal absorption. Caesarean sections are performed more frequently in women with MG [66].

The treatment of MG during pregnancy is no different from non-pregnant population, but some considerations should be taken. Acethylcholinesterase inhibitors (neostigmine and pyridostigmine) remain the keystone of treatment. Breastfeeding should be avoided since these medications are excreted with the milk. Corticosteroids should be continued (if they were started before pregnancy) [70], but stress doses are recommended during labour. Other medications, like azathioprine, cyclosporin A and methotrexate should be avoided due to maternal and fetal risks [59,61,62]. Thymectomy during pregnancy has beneficial results [61], even in the incidence of neonatal MG62. Plasmapheresis and intravenous immunoglobulin (IVIG) are effective for MG crisis [71-73] and can be used during pregnancy.

82.5 Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is an acute inflammatory, demyelinating polyradiculoneuropathy characterized by progressive motor weakness, areflexia, and ascending paralysis. Symptoms are preceded by back pain or leg paraesthesias in 50% of patients. Cerebrospinal fluid shows elevated protein levels without cells. Finding prolonged distal latencies and F-waves as well as anti-ganglioside antibodies will strength the diagnosis [74,75].

82.5.1 Epidemiology

The incidence of GBS in the general population is approximately 0.75-2 in 100,000 per year [76]. During pregnancy, the relative risk is low (0.86) but increases during 30 and 90 days postpartum (2.21 and 1.47, respectively), suggestive of a putative hormonal role [77]. This might be explained by the increase of anti-inflammatory Th2 cytokines during pregnancy and the elevation of pro-inflammatory Th1 cytokines in the postpartum [78]. Maternal mortality is not affected by GBS, however, if the onset is during the third trimester, there is a higher risk for respiratory failure which can increase maternal mortality. Recent studies have shown that although ventilatory support was required in 33% of cases, mortality was zero [76]. Fetal survival is close to 96%. There has been only one report of congenital GBS from a mother with GBS [79].

82.5.2 Management

The management of GBS in pregnancy should be done in the NSICU and does not differ from its management in the general population. Supportive care should be offered to patients until muscle strength is regained. The use of plasmapheresis and intravenous immunoglobulins (IVIG) has been studied extensively in general population with GBS but not in pregnant women [80,81]. However, case reports with successful outcomes have been mentioned. Either IVIG alone [82-85] or plasmapheresis alone [86,87] or a combination of plasmapheresis and IVIG (in that order) [79,88,89] was successful in pregnant women.

One of the keys in the management of GBS is close monitoring of respiratory function. Assessment of forced vital capacity (FVC), the ability to cough and to protect the airway should always be considered in these patients. Respiratory failure is usually more insidious than in MG. If FVC is <1.5 l, patients should be admitted to the NSICU, and mechanical ventilation should be started if it is <15 ml/kg.

Autonomic dysfunction is seen in patients with GBS. Dysrhythmias and dramatic blood pressure fluctuations are the cause of admission to the NSICU. Fetal monitoring should

be carried out as indicated, although normal fetal activity is seen even during periods of maximal maternal paralysis.
GBS does not have an impact on uterine contraction and assisted vaginal delivery by vacuum extraction is preferred.
It is important to mention that the risk of venous thromboembolic disease (VTE) is higher in patients with GBS as well as in pregnant women. Thus, pregnant women with GBS should be treated prophylactically with unfractionated heparin or low-molecular-weight heparin. The use of inferior vena cava filters during pregnancy has not been reported, however, temporary filters with later removal have been used in small series of patients [82-85]. The management of VTE with anticoagulation during pregnancy follows the recent guidelines from the American College of Chest Physicians and is discussed in the Stroke section of this chapter.

82.6 Cerebrovascular Disease

The incidence of pregnancy-related stroke is higher than non-pregnancy-related stroke, with an incidence of 34.2 per 100,000 deliveries in one of the largest population-base studies performed in the United States to date [90]. In this study, the risk of stroke in-

Ischemic	• Watershed: severe hypotension, Sheehan's syndrome • Eclampsia: choriocarcinoma • Angiopathies: ▪ Infectious: syphilis, borreliosis, tuberculosis, malaria, Chlamydia pneumoniae, herpes zoster, mycoses ▪ Inflammatory: collagen disorders, granulomatous angiitis of the nervous system, sarcoidosis, Takayasu's disease ▪ Non-inflammatory: dissection, postpartum cerebral angiopathy, Moya-Moya, fibromuscular dysplasia, atherosclerosis, subarachnoid hemorrhage, vascular malformation ▪ Haematologic diseases: protein C, S, antithrombin III deficiency, factor V Leiden, homocystinuria, paraneoplastic coagulopathy, disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, sickle cell disease, antiphospholipid antibodies, Sneddon's syndrome ▪ Cardiac or pulmonary disorders: infective or marantic endocarditis, atrial myxoma, fibroelastoma, rheumatic heart disease, mitral valve prolapse, prosthetic valve, patent foramen ovale, amniotic fluid/ fat/air embolism, atrial septal aneurysm, atrial fibrillation, acute myocardial infarct, dilated cardiomyopathy, peripartum cardiomyopathy, hereditary hemorrhagic telangiectasia ▪ Metabolic or channel dysfunction: CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy), migraine ▪ Air, fat, amniotic fluid embolism
Intracerebral hemorrhage	Eclampsia, hypertension, cerebral venous and sinus thrombosis (see below), angiopathies (see above), choriocarcinoma, arteriovenous malformation (AVM), aneurysm, bacterial endocarditis, pituitary apoplexy, anticoagulation, cocaine abuse
Subarachnoid hemorrhage	Aneurysm, AVM, eclampsia, angiopathies (see above), choriocarcinoma, cerebral venous and sinus thrombosis (see below), bacterial endocarditis, pituitary apoplexy, anticoagulation, cocaine abuse
Cerebral venous and sinus thrombosis	Hematologic diseases (see above), volume depletion, brain, sinus or mastoid infection, eclampsia, caesarean section

Table 82.2. Causes of stroke during pregnancy.

creased with age (>35 years) and was associated with African–American race, migraine, thrombophilia or thrombocytopenia, smoking, lupus, cardiac disease, sickle cell disease, hypertension (chronic or gestational), postpartum hemorrhage, preeclampsia, transfusion and postpartum infection. Most strokes occurred at the time of delivery or postpartum (41% and 48%, respectively).

Cerebrovascular disease in pregnancy can be caused by three mechanisms: arterial infarction, hemorrhage or venous thrombosis. In one study, out of 16 patients with cerebrovascular disease, 9 had ischemia, 5 had hemorrhage, and 2 had venous thrombosis [91]. Kittner et al. showed that the relative risk of developing a cerebral infarction during pregnancy was 0.7 but increased to 8.7 in the postpartum period. Also, the relative risk of developing intracerebral hemorrhage was 2.5 during pregnancy and increased to 8.7 in the postpartum period [92].

There are different causes for developing stroke during pregnancy (Table 82.2). The hypercoagulable state caused by pregnancy, as well as anatomical changes and the presence of vasculopathy such as postpartum angiopathy, are risk factors that contribute to the development of cerebrovascular disease [93].

The diagnostic workup for stroke in pregnant women is similar that in non-pregnant women, with certain considerations for the radiologic procedures. The use of abdominal shields during CT and digital angiography (especially during the first trimester) will limit radiation exposure of the foetus to an acceptable 2 mRads [94]. Since there are limited studies referring to the exposure of the foetus to iodinated or gadolinium-based contrast (both cross the placenta), it is recommended to use low-osmolality CT contrast agents [95].

82.6.1 Ischemic Stroke

Preeclampsia and eclampsia are considered to be the most common cause of ischemic pregnancy-related strokes, accounting for 25-45% of cases [96]. Furthermore, the risk of ischemic stroke persists beyond pregnancy and puerperium. Women with a history of preeclampsia are 60% more likely to have a non-pregnancy-related ischemic stroke [97]. The risk of stroke is also increased in the adult offspring born from preeclamptic mothers [98].

Elevated blood pressure may play a role in the increased risk of stroke seen in women with preeclampsia. Martin et al. found that 96% of preeclamptic-related strokes had systolic pressures >160 mmHg right before the stroke. In contrast, sustained diastolic pressures >105 mmHg before stroke was not associated with the development of preeclamptic-related strokes [99].

Choriocarcinoma, a trophoblastic tumour associated with molar pregnancy, is another cause of pregnancy-related stroke. Approximately 20% of cases will metastasize to the brain, causing invasion of the cerebral vessels that will lead to local thrombosis and distal embolization or pseudoaneurysm formation and cerebral bleeding. Measurement of beta-human chorionic gonadotrophin in serum should be part of the stroke workup diagnosis in pregnant women, since its levels are markedly increased [100].

Postpartum cerebral angiopathy is characterized by reversible multifocal vasoconstriction of the cerebral arteries101. It presents with sudden headache, photosensitivity, vomiting, altered mental status, seizures and transient or permanent focal neurological symptoms. Transient ischemia, cerebral infarction and intracranial hemorrhage have been reported [102]. Multifocal segmental narrowing of the cerebral arteries, with reversibility and complete resolution after 4-6 weeks is the most common finding on neuroimaging studies [103,93]. Management with the use of systemic steroids [102], as well

as vasodilators, hypervolaemic therapy and cerebral angioplasty [104] has been reported in uncontrolled studies. Although most patients will improve with general measures, few will develop intracranial hemorrhage or progress to maternal death [105].

Paradoxical embolism, based on the presence of patent foramen ovale (PFO) which permits right-to-left shunting of venous emboli into the arterial circulation, has been reported as a cause of ischemic stroke during pregnancy [106]. Antiphospholipid antibody syndrome is a cause of spontaneous abortions, however, transient ischemic attacks and true cerebral infarcts have been reported during pregnancy and puerperium, leading to adverse pregnancy outcomes [107].

Peripartum cardiomyopathy, a type of dilated cardiomyopathy that presents during the last month of pregnancy or within 5 months after delivery, is a well-established risk factor for cardioembolic stroke [108]; and prophylactic anticoagulation is recommended.

Cervical artery dissection, associated with hormonal changes during pregnancy and straining of the arterial wall during delivery [109,110], has been reported in 6-7% of cases of pregnancy-related strokes.

The management of ischemic strokes during pregnancy is rarely done in the NSICU, except in large strokes, with potentially elevated intracranial pressure or need for respiratory and haemodynamic support.

Thrombolysis for the management of acute stroke during pregnancy is controversial. There are no large or controlled studies investigating its efficacy and safety during pregnancy. Reports of individual cases and small series have shown successful outcomes. Teratogenicity has not been reported with its use, but the risk for maternal hemorrhage is high. In a review of off-label thrombolysis for acute ischemic stroke, symptomatic intracranial hemorrhage was described in one of 11 pregnant women [111]. Another review of 172 pregnant women described maternal hemorrhage in 8% of patients after the use of thrombolytics [112]. The risk and benefits to mother and foetus must be carefully considered before using thrombolytics.

The use of aspirin during the first trimester of pregnancy is controversial [113]. Low-dose aspirin (<150 mg/day) appears to be safe during the second and third trimester of pregnancy. This was shown in a large randomized trial involving more than 9000 patients with preeclampsia [114], as well as women with recurrent fetal loss and antiphospholipid antibodies [115]. Low-dose aspirin may also be used for secondary prevention of stroke during pregnancy for high-risk women [116]. The potential risk of aspirin in pregnancy includes maternal and fetal hemorrhage and premature closure of the fetal ductus arteriosus. The use of other antiplatelet therapies like clopidogrel and dipyridamole has not been evaluated sufficiently during pregnancy.

Maternal deaths associated with ischemic events are uncommon, and when they do occur they usually result from secondary hemorrhage [117]. The risk of recurrence in subsequent pregnancies is 2.3% within 5 years, and even higher in patients with stroke of definite cause [118].

82.6.2 Hemorrhagic Stroke

The risk of intracranial hemorrhage (ICH) during pregnancy is higher than in non-pregnant women. Its incidence in the United States, taken from the Nationwide Inpatient Sample (from 1993 to 2002), was 6.1 pregnancy-related ICH per 100,000 deliveries and 7.1 pregnancy-related ICH per 100,000 at-risk person-years (compared to 5.0 in non-pregnant women) [119]. The increased risk of ICH associated with pregnancy was largely attributable to ICH occurring in the postpartum period. These numbers differ from those found in Chinese women, who had a higher incidence of hemorrhagic (65% of pregnan-

cy-related stroke) compared to ischemic stroke [120], with 58% occurring in the prepartum period [121]. Significant risk factors for ICH in pregnant women are advanced maternal age, African-American race, pre-existing hypertension, preeclampsia/eclampsia, coagulopathy, and tobacco abuse [119]. The in-hospital mortality rate for pregnancy-related ICH is around 20% [119], with an average maternal case-fatality of 30% [120]. The risk of ICH in a subsequent pregnancy is unknown [94].

The incidence of subarachnoid hemorrhage (SAH) during pregnancy is 20 per 100,000 deliveries [92], with the most common causes being ruptured cerebral aneurysm and arteriovenous malformations (AVM). Aneurysms are more likely to rupture in the later stages of pregnancy, and up to 6 weeks postpartum [109,122]. Advancing gestational age, haemodynamic and endocrine changes during pregnancy increase the risk of bleeding [122], which makes it difficult to extrapolate results from the non-pregnant population that shows a low risk of bleeding from small or anterior circulation unruptured cerebral aneurysms [123,124]. AVM accounts for almost 50% of all ICHs in pregnant women [125], with 94% occurring during pregnancy and only 6% during labor [122]. Rebleeding during pregnancy occurs in almost 30% of cases [125]. Non-aneurysmal SAH has been reported in the context of pregnancy-induced hypertension and eclampsia also [126].

Women with asymptomatic AVM or aneurysm may undergo correction by embolization, endovascular coiling or surgical clipping. Clipping of the aneurysm can be achieved during any stage of pregnancy and is associated with lower maternal and fetal mortality [94,122]. Endovascular coiling has been reported to be successful [127-129], however, exposure to radiation and contrast material during the first trimester still carries a risk to the foetus and is to be discussed with the patient [123,128].

The management of cerebral vasospasm from ruptured aneurysm does not differ from that in non-pregnant women. Induced hypervolaemia can be achieved with crystalloids or colloids, although there are no data supporting “triple H therapy” in pregnant women. Vasopressors should be used cautiously since they could decrease uteroplacental blood flow. Nimodipine is considered a category C drug by the FDA but it has been used during pregnancy before. Balloon angioplasty has been reported to be successful in eclampsia-related vasospasm [104] but it has not been used in SAH. Delivery is preferred after the aneurysm is secured, but that will depend on the pregnancy stage and viability of the foetus. Before 34 weeks, mother and foetus will need close monitoring until delivery. Vaginal delivery is preferred if pregnancy is at term, but caesarean should be considered on the basis of obstetrical principles with evaluation of risks [130,113].

Treatment of AVMs is the same as in non-pregnant women. However, in patients with high operative risk or inoperable lesions, conservative management should be pursued during pregnancy. Stereotactic radiosurgery and embolization are good options after delivery. Caesarean section is preferred in such cases. Surgery may improve outcome in low-risk surgical candidates and also in comatose patients with large haematomas [125]. Use of external ventricular drainage and intraventricular thrombolysis with r-tPA has been reported in intraventricular hemorrhage caused by Moyamoya disease in pregnant women with relative good outcomes [131-133].

82.6.3 Cerebral Venous Thrombosis

Pregnancy is a predisposing factor for developing cerebral venous thrombosis (CVT). Ischemic strokes caused by CVT have been reported to be 38% in Canada [134] and 39% in Taiwan [135]. The incidence in India is estimated to be between 200 and 500 cases per 100,000 deliveries [136], which is 30 to 50 times higher than in the United States (8.9 cases per 100,000 deliveries) [137]. Most cases occur in the puerperium (73%)

[135,138]. The death rate from all-cause CVT is 2-10%, although mortality is significantly lower for pregnancy-associated CVT [139].
Traumatic damage to the endothelial lining of cerebral sinuses and veins during labour, hypercoagulable states, and stasis of intracerebral blood flow may be the reason for the occurrence of most pregnancy-related CVT [140]. The risk of CVT increases with hypertension, advancing maternal age, caesarean delivery, associated infections and excessive vomiting during pregnancy [141]. Hypercoagulable state (like protein S and C deficiencies, lupus and antiphospholipid syndrome) has been found in 64% of pregnancy-associated CVT [135]. It is important to mention that protein S and anti-thrombin III levels are normally decreased during pregnancy [142], and that their levels should be repeated again after delivery before being attributed as a cause of CVT. Homocysteinaemia has also been associated with CVT during pregnancy [143].
Headache is the most frequent symptom of CVT and occurs in 75-95% of cases. Isolated intracranial hypertension with headache, vomiting and blurred vision (caused by papilledema) accounts for 20-40% of cases of CVT [138]. Post-delivery headache should not be easily attributed to spinal anaesthesia during labour [144], and prompt diagnosis of CVT should be made by magnetic resonance imaging/venography (MRI/MRV), helical CT venography or angiography [145].
Anticoagulation, fluid administration, antibiotics for infection, and measures to reduce elevated intracranial pressure are used in the management of CVT. Anticoagulation is usually given for 6 months in patients with idiopathic venous thrombosis and indefinitely in those with persistent or familial thrombophilic conditions. The use of unfractionated heparin and low-molecular-weight heparin is safe during pregnancy and supported by guidelines [116]. Close monitoring of activated partial thromboplastin time and factor Xa should be maintained, respectively, with the use of these two types of heparin. Because warfarin has teratogenic effects, its use is contraindicated at least during the first 12 weeks of pregnancy. The safety and benefit of anticoagulation, given the high risk of hemorrhagic conversion, has not been evaluated in pregnant women. Studies in the non-pregnant population have shown that anticoagulation is effective, even in patients with hemorrhagic venous infarction [146,147]. An uncontrolled study, showed a mortality benefit of using heparin in pregnancy-related CVT (24% vs. 45% of those who did not receive heparin), with only one fatal hemorrhage in the heparin group [148]. Also, combined intrathrombus r-tPA and IV heparin has been reported in one 9-week pregnant and two postpartum women with good outcomes [149,150]. Prophylactic anticoagulation during subsequent pregnancies is not indicated [145,151].

82.7 Pituitary Apoplexy

Hemorrhage within the pituitary gland is referred to as apoplexy, and ischemic infarction with necrosis of the gland was first described in 1937 by H.L. Sheehan in postpartum women. The exact pathophysiology of Sheehan's syndrome is unknown, but it is thought to be secondary to drastically reduced blood flow to an organ that enlarges in a closed space during pregnancy. It occurs in approximately 1-2% of women with significant post-partum hemorrhage (defined as >1-2 litres of blood and hypovolaemic shock). Asymptomatic pituitary apoplexy (PA) has been found in 10-30% of patients harbouring pituitary tumors [152,153], including patients with prolactin or growth hormone-secreting adenomas and lymphocytic adenohypophysitis [154-158].
There is a vast spectrum of presenting symptoms, ranging from headache and mild visual changes to adrenal crisis, coma, and death. Symptoms result from swelling and ex-

pansion of the hemorrhage, causing compression on nearby structures. Acute onset headache is the most frequent symptom [159]. Visual field deficits, especially bitemporal heteronymous hemianopia are found in 62% of cases of PA. Hypothalamic compression may lead to autonomic dysfunction, deficient thermoregulation and hormonal deficiencies. Involvement of the cavernous sinus and cranial nerves (III, IV, VI and V1 or V2) by lateral extension may lead to different degrees of ophthalmoparesis and pain. Hemorrhagic extension into the subarachnoid space can cause SAH or "chemical" meningitis [153,155]. Sheehan's syndrome presents with panhypopituitarism (hypotension, hypoglycaemia, lactation failure). Altered mental status and coma are seen in 19% of patients. Because this condition can be fatal, rapid diagnosis is important. MRI has shown to be 100% sensitive in the diagnosis of pituitary hemorrhage and adenomas and is considered the test of choice for final diagnosis.

The management of PA should be emergently started. Treatment of common electrolyte abnormalities and corticosteroid replacement (hydrocortisone at stress dosage) should be provided. L-thyroxine should also be given. Diabetes insipidus from compression on the pituitary stalk, hypothalamus or posterior pituitary gland may lead to profound water deficit, so that vasopressin or desmopressin (DDAVP) should be given [159,160]. Neurosurgical consultation for decompression is indicated if involvement of the visual pathway or progression of neurologic signs is present [161]. Bromocriptine is given in neurologically stable patients.

82.8 Status Epilepticus

Most seizures during pregnancy occur in women who already have epilepsy. During pregnancy most women will continue their previous level of seizure control, although 15-30% may experience an increase in seizures [162]. Status epilepticus (SE) occurs in only 1-2% of pregnancies. Pregnancy is not a risk factor for SE in pregnant women without a history of epilepsy [163]. A large prospective registry of antiepileptic drugs and pregnancy showed that 1.8% of pregnant women on antiepileptic drugs had SE, with a similar distribution across all three trimesters [164].

The differential diagnosis for new-onset seizures during pregnancy should be the same as in the non-pregnant population, after eclampsia is excluded, overall during the third trimester. Structural and metabolic changes related to pregnancy may precipitate new-onset seizures. Structural changes include intracranial hemorrhage of multiple types, cerebral sinus thrombosis, brain tumours and ischemic stroke; metabolic causes include hyperemesis gravidarum, hypoglycaemia, acute hepatitis (fatty liver of pregnancy or viral hepatitis), acute intermittent porphyria and infections [162,165]. Herpes encephalitis, the MELAS syndrome (mitochondrial encephalopathy, lactic acidosis, and stroke-like episodes), and cavernous angioma have also been describe as causes of SE in pregnancy [166-168].

Pregnancy-induced changes in antiepileptic drug pharmacokinetics are a major factor affecting changes in seizure control in pregnant women with epilepsy, although compliance is also a significant factor. Increased plasma clearance of antiepileptic drugs with advancing gestation, has to be balanced against an increased ratio of unbound free-to-total drug level [169,170]. Therefore, free levels, and not total drug levels, should be checked every month during pregnancy in order to make appropriate changes in the dosage [171].

The effect of SE on the foetus is controversial. It has been related to increased spontaneous abortion and fetal death [172]; however, recent data have reported that only 1/36

pregnancies with SE was complicated with stillbirth, and none was associated with maternal mortality [164].
The treatment of SE should not differ from that in non-pregnant women, with the goal being always to stop electrical and clinical seizure activity early, giving support to the mother and fetus [173]. Intravenous vitamin B6 should be considered, since its levels may be decreased during pregnancy in pyridoxine-dependent epileptics [174,175]. Administration of intravenous antiepileptics should not be delayed because of concerns about teratogenic effects. Medications like phenytoin and valproic acid, with a high protein-bound rate, should be initially administered in lower dose to avoid toxic-free drug levels [176], however, full dosage can eventually be given if seizures continue [177,178]. There are no data about the use of midazolam for SE in pregnancy.
Delivery should be started if there is an obstetrical indication. Neonates should be supported in the neonatal ICU if benzodiazepines or barbiturates were given.

82.9 Management of Intracranial Hypertension During Pregnancy

The management of intracranial hypertension in pregnant women does not differ much from that in non-pregnant patients, apart from special consideration to the potential side effects of the drugs given to decrease intracranial pressure to the mother/foetus unit. Close communication between the obstetrician, the patient's family and the neurointensivist is the key to the best possible outcome.
Unfortunately, none of the various different measures taken to reduce intracranial pressure have been tested in pregnant women; however, there have been some reports of their use in pregnancy, with controversial results [179,180].
General measures like sedation, analgesia, head-of-bed elevation (to 30°), management of hyperthermia and even intubation with assisted ventilation should be considered the ABCs in the management of a pregnant patient in which intracranial hypertension is suspected.
Propofol is the drug of election in pregnant women who require intravenous sedation since it is considered a category B drug. Owing to its very fast onset of action (30 seconds) and short duration (3-10 minutes), it is used broadly in patients who need frequent neurologic exams. Careful monitoring of metabolic acidosis, hyperkalaemia, elevated CPK, triglyceride levels and possible infection is needed with prolonged use.
Etomidate by intravenous infusion has been recommended for sedation by the American Stroke Association guidelines for the management of intracerebral hemorrhage in non-pregnant adults [181]. This can be extrapolated to pregnant women since it is considered a category C drug. However, it is important to consider the potential adrenal insufficiency side effect it causes, which can lead to severe hypotension. Furthermore, previous studies showed increased mortality with etomidate infusion in trauma patients [182].
Benzodiazepines, including midazolam, are considered category D drugs during pregnancy, however, their use has been reported [179]. Although fetal outcomes are poor with its use, it may be used in special circumstances when no other sedatives can be administered.
In terms of analgesia, intravenous morphine and alfentanil are recommended for intracerebral hemorrhage [181]. Both drugs are category C/D in pregnancy and their benefits should be evaluated before being used in pregnant women. Remifentanil, a category C drug, has a very fast onset of action (1-3 minutes) with a short half-life (3-10 minutes).

Moreover, it tends to decrease the needed dose of propofol when used together for sedo-analgesia [183].

Other measures to decrease intracranial pressure are more invasive and include hyperventilation, osmotic therapy, barbiturate coma and hypothermia. Most might be associated with poor fetal outcomes but should be considered in life-threatening situations after discussion with the obstetrician and patient's family.

Hyperventilation is one of the most effective methods available for the rapid reduction of intracranial pressure, however, it has a transient effect (<6 h) and is associated with decreased cerebral blood flow, for which its use has declined considerably over the years. Also, the alkalaemia caused by hyperventilation can lead to a shift in the oxygen-hemoglobin dissociation curve to the left, which impairs the release of oxygen from maternal to fetal blood, causing hypoxemic damage in the fetus [184].

Mannitol is used in intracranial hypertension as an osmotic agent. It reduces cerebral water content, cerebrovascular volume and decreases intracranial pressure. Mannitol is considered a category C drug during pregnancy, crosses the placenta, and can cause fetal dehydration. Animal studies have shown an increase in fetal blood-brain barrier permeability caused by mannitol-induced hyperosmolality [185]. However, mannitol can be used in life-threatening situations during pregnancy at a dose of 0.25-0.5 g/kg of pregnancy maternal weight every 4 to 6 hours intravenously.

Barbiturates in high doses are effective in lowering refractory intracranial hypertension by depressing cerebral metabolic activity, which reduces cerebral blood flow and leads to a fall in intracranial pressure. Barbiturates are considered category D drugs and are contraindicated during pregnancy, however, they still can be used in life-threatening conditions. Infant monitoring in the ICU is recommended after birth if barbiturates were used.

Cerebral temperature is a major factor in ischemic brain damage. Hypothermia ameliorates brain damage by redistributing oxygen and lowering glucose consumption sufficient to permit tolerance to prolonged periods of oxygen deprivation. Furthermore, cooling to 32-34oC can lower refractory intracranial hypertension, but it is also associated with a high rate of complications including pulmonary, infectious, coagulation, and electrolyte problems [186]. Fetal bradycardia is associated with maternal hypothermia, which is usually reversible once normothermia is achieved. Animal studies have shown normal fetal survival after mothers were exposed to temperatures of 20-24°C for 20 minutes [187]. Long-term fetal complications of hypothermia have not been studied yet.

83 Headache in the Emergency Department: Diagnosis and Management

Jaime Gállego [1], Jon Toledo [2], Pablo Irimia [2]

[1] Neurology Service, Hospital de Navarra, Pamplona, Spain
[2] Clínica Universidad de Navarra, Pamplona, Spain

83.1 Introduction

Headache is a frequent source of care in the emergency department (ED), where it represents the fifth most frequent cause of consultation, accounting for 1-4% of all visits [1,2], and it is one of the most common reasons for calling the attending neurologist [3]. Nonetheless, most individuals who suffer severe headaches do not use emergency services for evaluation [4]. Most patients have primary headaches (migraine and tension headache), but headache may be a symptom of a variety of life-threatening conditions such as subarachnoid hemorrhage (SAH), intracranial hemorrhage, tumour, encephalitis, meningitis, vasculitis, venous sinus thrombosis and toxic-metabolic syndrome.
Clinical history and thorough clinical examination are useful in most cases to distinguish primary from secondary headache. It is extremely important to know and identify the warning signs that help us to exclude secondary causes. In a patient presenting with headache at the ED, the clinician must quickly determine the correct headache diagnosis and exclude secondary causes, assess the need and type of complementary examinations, including the implementation of the appropriate therapeutic options.

83.2 Primary or Secondary Headache

The most common headaches are called primary, in which there is no structural or metabolic cause explaining the symptoms, i.e., different variants of migraine and tension headache, accounting for over 90% of headache consultations.
We should not forget that, although primary headaches are not symptomatic of severe intracranial injury, pain treatment should not be delayed. The remaining percentage is secondary headaches, where the pain is a clinical manifestation of an underlying structural pathology [5]. In secondary headache, the diagnosis does not depend on headache characteristics, but rather is determined on the basis of the presence of a specific condition, as defined by the International Headache Society, in close temporal relationship with the headache.
Primary headache accounts for 64-98% of non-traumatic causes of ED presentation for headache [5-7]. The fundamental goal of the clinician encountering a patient with headache in the ED is to precisely identify secondary headache that could compromise the patient's life [8] (Table 83.1), especially the so-called dangerous headaches [9].

Primary headache	• Migraine • Trigeminal autonomic cephalalgias • Stabbing headache • Thunderclap headache • Hypnic headache • Headache associated with sexual acitivity or exercise • Cough headache	
Secondary headache	Traumatic	• Subdural/epidural haematoma
	Cerebrovascular disease	• Aneurysmal subarachnoid hemorrhage • Unruptured aneurysms • Stroke • Primary intracerebral or intraventricular hemorrhage • Arterial dissection • Cerebral venous thrombosis • Vasculitis (including temporal arteritis or giant cell arteritis) • Pituitary apoplexy
	Central nervous system (CNS) infections	• Meningoencephalitis (bacterial, viral, mycosis) • Brain abscess
	Non-vascular disease	• Intermittent hydrocephalus (colloid cyst) • Idiopathic intracranial hypertension • Intracranial hypotension (idiopathic or post-puncture) • Intracranial tumours • Chiari malformation • Optic neuritis
	Toxic or metabolic disorders	• Pheochromocytoma • Thyroid disease • Drug-induced • Substance withdrawal • Hypercapnia
	Hypertensive encephalopathy	
	Rhinosino-ocular diseases (sinusitis, acute glaucoma)	
	Secondary to systemic processes	

Table 83.1. **Most common causes of headache treated in emergency services. Modified from [10].**

83.3 Headache History

Clinical history taking is more important in headache than in any other neurological disorder. It is important to establish the location of headache, its intensity, form of onset and precipitating factors. The approach is different when it comes to patients with acute headache of recent onset or when a patient has recurrent episodes of long-term headache [8,10]. With regard to the time of evolution, the headache may be of recent onset or chronic or recurrent. In recent-onset headache, the question of the first episodes of primary headache should be considered, which may hereafter be recurrent, but we must also consider the possibility that it is a secondary headache. Defining the quality of pain is not often possible in the ED setting. Migraine is often hemicranial but it may also

be bilateral. Migraine attacks last longer than 4 hours without treatment. Cluster headache is unilateral and periorbital, accompanied by excruciating pain that typically appears in the classic form at regular intervals, usually 24-48 hours for certain periods (2-3 months) and then remitting during the rest of the year. Its average duration in 15-60 minutes (range 10-180 min) in 65% of patients. Tension-type headache is usually diffuse or arises in different locations.

The onset form and triggers are essential clues to diagnosis, especially when there is abrupt onset of pain [11]. In headache of a sudden onset, the presence of subarachnoid hemorrhage (SAH) must be excluded; it is therefore essential to perform appropriate examinations even if the headache is of short duration, had ceased before reaching the ED, and the neurological examination values are normal. Several prospective studies have shown that among patients with headache of sudden onset (reaching maximum intensity within 1 minute) the cause is an SAH in 11-25% of cases [3-10].

It is important to establish if the headache is triggered by intense physical activity or effort; also this fact leads to a possible diagnosis of SAH. An interesting aspect is so-called thunderclap headache. This kind of headache has a sudden onset, with maximum intensity, is often described by patients as the worst in their life, and precedes, in almost

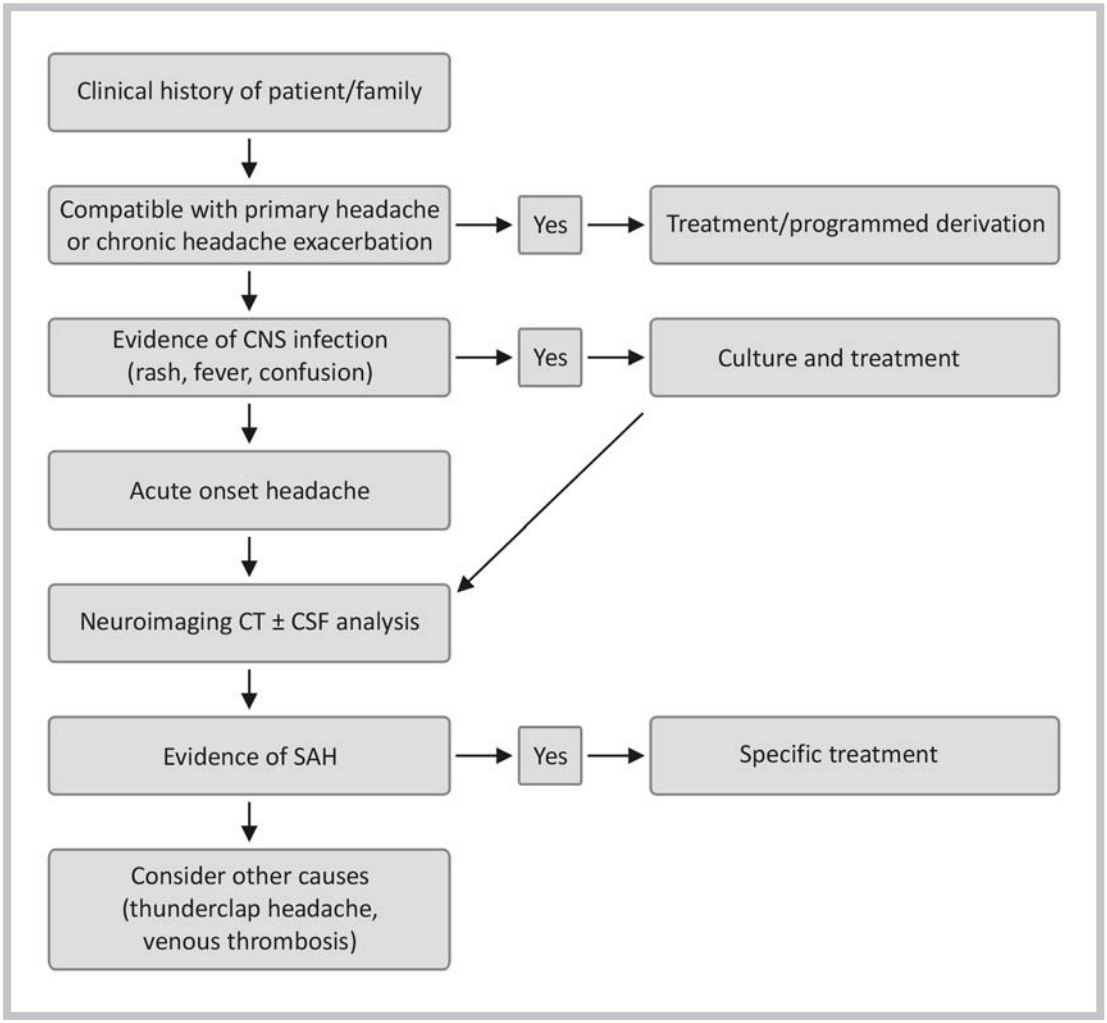

Figure 83.1. **Initial evaluation of headache in the Emergency Department. Modified from [10].**

Figure 83.2. 67-year-old patient with headache as manifestation of temporal arteritis.

half of cases, within a variable time, a SAH [5,9-12].

Although complete agreement is lacking, it is thought that in some cases it may be due to a minor bleeding (warning leak) – the so called "sentinel headache" – or be produced by aneurysmal expansion without rupture. It can be confused with influenza, migraine, sinusitis, etc. [13]. Therefore, urgent examination of normal brain imaging and normal cerebrospinal fluid (CSF) are required to exclude it.

Other cerebrovascular disorders, such as cerebral hemorrhage, cerebral venous thrombosis, malformations and unruptured aneurysms, arterial dissections, angiitis of the central nervous system (CNS), benign angiopathy, reversible hypertensive encephalopathy, certain medications and vasoconstrictors, and pituitary apoplexy can all cause thunderclap headache. Hypertension and hypotension of the CSF, meningitis, encephalitis, and sinusitis can also cause it. Therefore, the diagnosis of primary thunderclap headache is a diagnosis of exclusion. In primary thunderclap headache the headache may recur during the first week. There is no specific treatment; treatment is symptomatic and triptans and ergot should be avoided.

Headache due to increased intracranial pressure (e.g., tumours) runs a course that may be intermittent at first and then permanent. It improves with rest and worsens with Valsalva manoeuvres and effort. Its association with other neurological symptoms (diplopia, paresis, etc.) orients toward a symptomatic nature of headache (Figure 83.1).

One thing to keep in mind is the patient's age. Headache that starts after 50 years of age should lead us consider the possibility of temporal arteritis or other secondary aetiologies (Figure 83.2).

The onset of migraine attacks over age 50 years is very rare because over 90% of patients with migraine suffer their first seizure before the age of 40 years (Table 83.2).

Age at onset	New-onset pain or chronic headache
Type at onset	Acute, subacute or chronic
Duration	Temporal pattern and frequency of attacks
Migraine pain location	Holocranial, facial, occipital
Accompanying symptoms	Nausea, vomiting, phonophobia, photophobia, aggravation with physical activity, autonomic symptoms
Other symptoms preceding or accompanying pain	Photopsia, blurred vision, loss of vision
Pain features	Throbbing, squeezing, burning, stabbing, electric shock
History of headache	Personal/family, similar/different
Precipitating and aggravating factors	Alcohol, food, sleep, menstruation
Treatment	Drugs and dosages previously consumed and therapeutic response

Table 83.2. Headache history.

83.4 Physical Examination

It is necessary to perform complete neurological examination to look for any type of neurological deficit. Vital functions are also important: temperature, blood pressure, pulse, palpation of head and cranial (temporal and neck) arteries, especially in people over 50 years of age, and examination of the neck and shoulders.

Fundus examination is mandatory to rule out the presence of papilledema, a finding characteristic of increased intracranial pressure caused by tumour or venous thrombosis, signs of subhyaloid bleeding (typically associated with SAH) (Figure 83.3).

It is also important the evaluation of meningeal signs and auscultation of possible cervical-cranial murmurs. The presence of fever or rash should lead the physician to con-

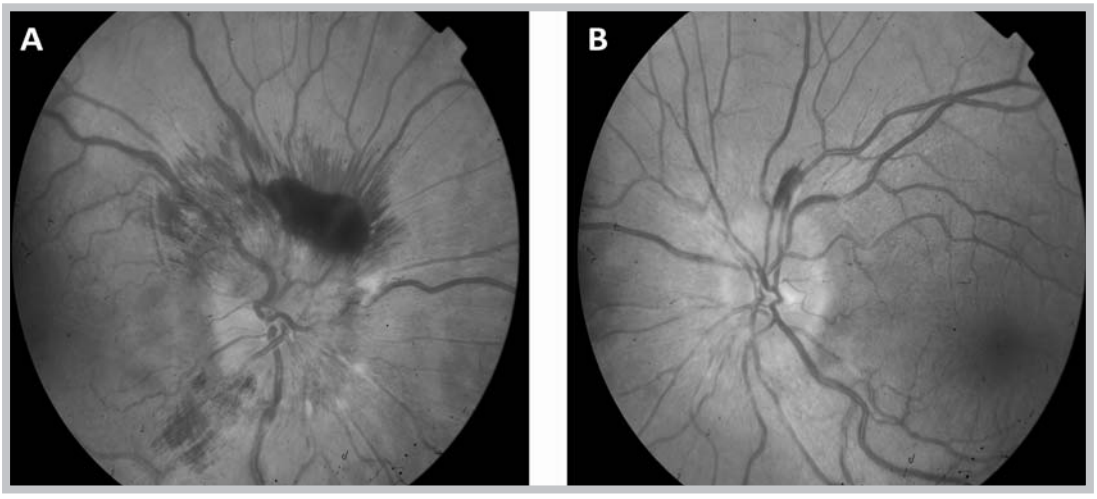

Figure 83.3. **Fundoscopy with bilateral papilledema. Optic disc swelling in a patient with a brain tumor; hemorrhage is also observed.**

- Severe headache, sudden onset
- Recent worsening of chronic headache
- Headache frequency and/or increasing intensity
- Unilateral location, always on the same side (except for cluster headache, paroxysmal hemicrania, occipital neuralgia, trigeminal neuralgia, migraine and other primary headaches consistently unilateral)
- Accompanying manifestations:
  - Conduct disorders or behavioural changes
  - Seizures
  - Focal neurological
  - Papilledema
  - Fever
- Nausea and vomiting not explained by primary headache (migraine) or systemic disease
- Presence of meningeal signs
- Headache precipitated by physical exertion, coughing or postural change
- Primarily nocturnal headache
- Atypical headache
- New headache in patients with cancer or AIDS
- Headache in immunosuppressed patients
- Headache in pregnancy or postpartum
- Progressive headache refractory to treatment

Table 83.3. **Alarm signs in headache.**

sider a diagnosis of meningitis. Blood pressure >120 mmHg diastolic and/or 200 mmHg systolic may cause headache. A unilateral Horner syndrome without symptoms of cerebral ischemia raises the differential diagnosis of arterial dissection and cluster headache. In cervical arterial dissections, it is relatively common that clinical manifestations are restricted to the presentation of neck, face or head pain with no symptoms associated with cerebral ischemia [14].

History taking and physical examination will help to identify the so-called "flags" criteria (Table 83.3) that suggest a secondary etiology [10-15]. The most important warning signs are pain that starts suddenly after physical exertion or Valsalva manoeuvres and has an explosive onset. Other warning signs are the appearance of headache in patients over 50 years of age, abnormal neurological examination, headache with autonomic symptoms or previous visits to the ED for any other symptoms accompanying the headache.

83.5 Risk Stratification. Complementary Studies

An algorithm is structured by assumptions and clinical scenarios that can be a useful tool for ordering and conducting additional tests in the ED.

83.5.1 Analytical Studies

In patients over 50 years of age it is necessary to order a C-reactive protein and erythrocyte sedimentation rate (ESR) test to rule out temporal arteritis. In those under 50 years, analytical examinations are not usually ordered unless there is suspicion of an infectious process or a history of repeated vomiting and dehydration or suspected electrolyte disturbances (at least electrolyte and renal function tests should be ordered).

83.5.2 Neuroimaging

As shown in the algorithm, the decision to obtain an imaging study is based on the clinical history. There are several clear indications, especially when clinical data or findings on examination suggest a secondary headache when pain characteristics do not conform to a primary headache, and especially in the presence of alarm criteria [15-19].

Indications for head CT in the ED	• Acute-onset severe headache • Subacute with progressive worsening • Associated neurological deficit • Papilledema or nuchal rigidity • Nausea and vomiting, fever unexplained by systemic illness • Not classifiable by history • Headache in patients who doubt the diagnosis, in those with marked anxiety or fear of a possible serious intracranial process
Indications for MRI in headache	• Hydrocephalus on cranial CT to reveal obstruction • Suspected space-occupying lesions in the posterior fossa, sella or cavernous sinus • Cough headache, in order to exclude Chiari type I disease • In intracranial hypertension with normal CT, in order to exclude cerebral venous thrombosis • Suspected CSF hypotension headache

Table 83.4. Indications for CT and MRI in headache.

For the assessment of brain parenchyma, the imaging study of choice is an urgent computed tomography (CT), initially without contrast material. On the contrary, if we suspect a Chiari malformation or cavernous sinus pathology, magnetic resonance imaging (MRI) is preferred. It must be remembered that CT has a lower sensitivity in visualizing lesions of the posterior fossa, sella, cavernous sinus, malformations of the occipito-vertebral hinge (Chiari malformation) or in some specific entities that produce headache secondary to CSF hypotension or cerebral vein thrombosis. The sensitivity and specificity of CT for diagnosing SAH (Figure 83.3) are higher than 98% [20].

83.5.3 Study of Cerebrospinal Fluid

Cerebrospinal fluid analysis should be performed if there is clinical suspicion of CNS infection or SAH with inconclusive CT findings. CSF examination is essential in cases of clinical suspicion of SAH with normal CT. Only exceptionally, when puncture is performed in the early phase of bleeding, the CSF may be normal [21]. It is not uncommon that there is suspicion of a SAH after traumatic lumbar puncture with contaminated blood. In such cases, the doubt can be resolved by performing a lumbar puncture in another interspinal space. It may also be useful to perform a differential count on the number of red blood cells per ml among samples from three different tubes, but xanthochromia has much more value and utility for distinguish between traumatic lumbar puncture or SAH [10]. Xanthochromia should be quantified by spectrophotometry, which can persist in more than 70% of cases after 3 weeks. Xanthochromic liquid can also be seen in the presence of protein levels, hyperbilirubinaemia or hypercarotinaemia. Lysis of erythrocytes with the release of oxyhemoglobin, bilirubin and methemoglobin pigments takes place within a few hours of bleeding. Oxyhemoglobin can be detected within 2 hours and hemoglobin in around 10 hours [13,23-25].
In case of suspected meningitis, encephalitis or SAH with normal CT, lumbar puncture is indicated. In general, brain CT should be done before performing a lumbar puncture because of the risk of herniation (and death) associated with the presence of intracranial space-occupying lesions. Liquoral study is not indicated in patients with a brain abscess.

83.6 Secondary Headaches

The constellation of fever, malaise, headache and purulent rhinorrhoea are characteristic of acute sinusitis. Characteristically, pain intensity increases when bending forward and its location varies depending on the sinus involved, being frontal when the frontal sinus is involved, antral with frontal irradiation in case of the maxillary sinus, retro-orbital and midline in case of haemoptysis, and posterior or anterior in case of sphenoid [26].
A new onset of **arterial hypertension** can be a cause of headache; and in pregnant women, blood pressure measurement should be performed at the onset of headache.
The presence of an elevated ESR (>50) in patients over 50 years of age should arouse suspicion of **temporal arteritis**, which is usually present with hemicranial headache with frontotemporal predominance, jaw claudication, constitutional symptoms (asthenia, anorexia, sweating) and visual disturbances that can lead to permanent blindness if corticosteroid therapy is not initiated early. On examination, hardening of the artery, absence of a palpable pulse and pain on palpation can be present. Treatment with prednisone 1 mg/kg/day should be started, with a subsequent tapering down.
Closed-angle glaucoma causes intense pain in the eye and orbit, and vegetative symptoms are often associated with a significant unilateral loss of visual acuity. Physical ex-

amination shows red eyes, median pupil unresponsiveness and increased intraocular pressure. If the headache is associated with neck pain, arterial dissection should be included in the differential diagnosis.

There are also headaches **induced by certain medications** such as nifedipine, nitroglycerin, dipyridamole or sildenafil. Sometimes the headache may be an accompanying symptom or the only symptom of myocardial ischemia. Typically, the headache is triggered by exercise and disappears at rest or after administration of sublingual nitroglycerin [27].

83.7 Headache in Cerebrovascular Disease

Headache occurs at the onset of some nosologic entities of cerebral vascular disease. The one most frequently is associated with headache is SAH (98%), and it may have a prognostic value when there is an arterial aneurysm. It is also frequent in intracerebral hemorrhage and much less often seen in atherothrombotic brain infarction and cardiac embolism.

If the pain is cervical or facial, the underlying process is likely to be dissection pressure. In certain circumstances it is possible that the clinical manifestations are limited to neck, face or head pain, oculosympathetic paralysis associated with ipsilateral Horner syndrome without symptoms of cerebral ischemia, raising the differential diagnosis with cluster headache or a variant migraine.

83.8 Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) is due to primary blood extravasation primarily and directly into the subarachnoid space. This distinguishes it from secondary SAH, where the bleeding comes from another location, such as the brain parenchyma or ventricular system. Here we refer to primary SAH. The most common cause (85%) is rupture of an aneurysm, followed by non-aneurysmal perimesencephalic SAH with excellent prognosis (10% of cases), and finally a strange miscellany of other aetiologies (vascular diseases, tumours, etc.) [29].

Although the classic presentation of sudden, intense headache, meningism and focal neurological signs is quite recurrent, it is not unique, and some patients may have other symptoms [30].

Therefore, the degree of suspicion should be high in the presence of an atypical headache (“the worst I have had”, according to patients, very intense or different than usual), especially if associated with any of the following signs and symptoms: loss of consciousness, diplopia, seizures or focal neurological signs.

The existence of a retinal or subhyaloid hemorrhage in this context confirms the diagnostic probability. The most common test is brain CT scan, indicated in an emergency, with a sensitivity of 98% when performed within 12 hours after onset, 93% within 24 hours, and 50% within the week of the episode [30]. There is blood, with a hyperdense area in the subarachnoid space at the convexity or in the basal cisterns. This will allow to identify certain complications (cerebral edema, hydrocephalus, cerebral infarction). If the CT scan is negative, equivocal or the image quality is inadequate, the diagnosis must be confirmed by lumbar puncture. The presence of hemorrhagic CSF is a diagnostic indicator. In case of doubt, the CSF should be centrifuged and examined for signs of subacute hemorrhage, such as xanthochromia and oxyhemoglobin or bilirubin.

Cerebral angiography is still considered the gold standard for diagnosis of cerebral aneurysmal disease. However, this method is invasive and not without neurological and/or non-neurological complications that can be permanent.

Currently, CT angiography or MR angiography are routinely used to search for aneurysms in individuals with a high probability of having them: family members of patients with aneurysms, patients with fibrous dysplasia and polycystic kidney disease. The images are usually of good quality and show the aneurysm size, its neck, and its relationship with the originating and surrounding vessels (Figure 83.4).

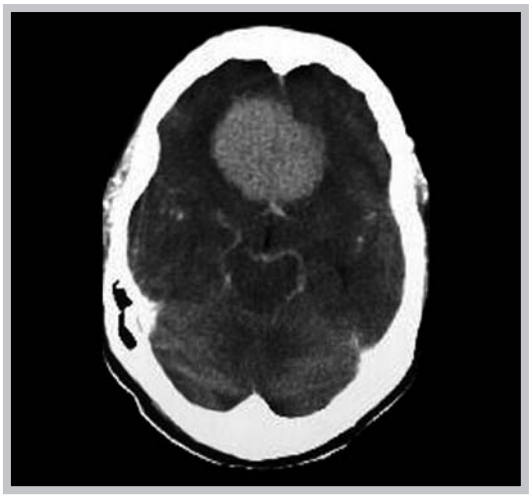

Figure 83.4. **Brain CT with contrast. Frontal meningioma.**

Pituitary apoplexy is a rare entity, clinically characterized by a sudden onset headache followed by vomiting, vision changes, ophthalmoplegia, and decreased level of consciousness [31]. It may be indistinguishable from SAH [32]. The clinical syndrome usually evolves from a few hours to 2 or 3 days. However, stroke may be an incidental finding on tumour resection, subclinical pituitary apoplexy, without prior symptoms.

The incidence varies in different series of surgically treated pituitary adenomas (range, 0.6-9.1%). We believe that MRI, and diffusion and perfusion sequences in particular, add important information for the comprehensive assessment of patients with pituitary apoplexy. MRI not only allows to fully evaluate tumour characteristics and size, but also helps to assess areas of cerebral ischemia and vascular compromission. The most recent application of neuroimaging techniques may be helpful in the correct evaluation of the extent of injury and the decision for early or delayed surgery in these patients.

83.9 Cerebral Venous Thrombosis

Headache is the most common symptom (80-90%) and often present in cerebral venous thrombosis [33]. In this condition, early diagnosis is crucial, given the high probability of recovery when anticoagulant treatment is promptly initiated. It has no specific features, and it's often diffuse with a wide variation in severity.

Around 25% of patients with intracranial hypertension have venous thrombosis. The presentation is usually subacute (days), but it can be acute or chronic. It is a persistent pain that worsens with recumbency and is exacerbated by Valsalva manoeuvres. It's often associated with other signs of intracranial hypertension, focal deficits or focal seizure syndrome.

Migrainous infarction. This entity is defined as one or more symptoms of migraine aura not fully reversible within 7 days, associated with the presence of infarction on neuroimaging studies. It's not always easy to determine if it originates from a migraine attack, especially in patients who have associated vascular risk factors. Its diagnosis is necessary to exclude other causes of stroke by appropriate examinations. Although its mechanism is not fully understood, the epidemiological association between the two entities is unquestionable [34].

83.10 Idiopathic Intracranial Hypertension

Idiopathic intracranial hypertension (IIH) is characterized by increased intracranial pressure without evidence of intracranial pathology. This is a relatively common disease with an incidence of approximately 1-5/100,000 patients/year. It is much more common in obese women of reproductive age, with a male: female ratio of 15:1. Intracranial pressure is high (>200 mmH_2O), as measured by monitoring the epidural or intraventricular pressure or by lumbar puncture. In general, the diagnostic criteria for IIH are based on the symptoms and signs of intracranial hypertension (ICH) and in the absence of laboratory-test abnormalities, including CSF analysis and neuroimaging – preferably magnetic resonance (MR) angiography. Headache is a common symptom of IIH, so that headache associated with IIH is included in the classification of the International Headache Society. However, the characteristics of headache in IIH can be heterogeneous and often present a clinical profile similar to that of some temporary primary headaches. In conclusion, headache associated with IIH presents nonspecific characteristics which can sometimes mimic either primary headache or tension-type headache.
Detailed history taking is essential to search for additional symptoms such as visual disturbances, diplopia, or tinnitus. Fundus examination is mandatory.
The headache must meet one of the following characteristics: daily presentation, a diffuse and/or constant ache (not pulsed) or aggravated by coughing or exertion. It has been observed that about 70% of headache patients have visual disturbances with different characteristics such as blurred vision, decreased visual acuity or visual appearance of scotomas. Less common is the onset of diplopia or cranial nerve VI alterations, which occur in nearly one in three patients with headache. These visual symptoms serve as diagnostic support for suspected ICH [35].

83.11 CSF Hypotension Headache

Intracranial hypotension syndrome is usually secondary to lumbar puncture or trauma. It is characterized by the postural headache associated with low CSF pressure. In healthy humans, the mean CSF pressure is 150 mmH_2O (range 65-200 mmH_2O) in the decubitolateral position. The symptoms of intracranial hypotension occur at pressures <65 mmH_2O.
The brain is held in the cranial cavity and floats on the CSF; the brain's weight in air is 1500 g but only 50 g in the CSF. Therefore, if the volume of CSF is decreased, the

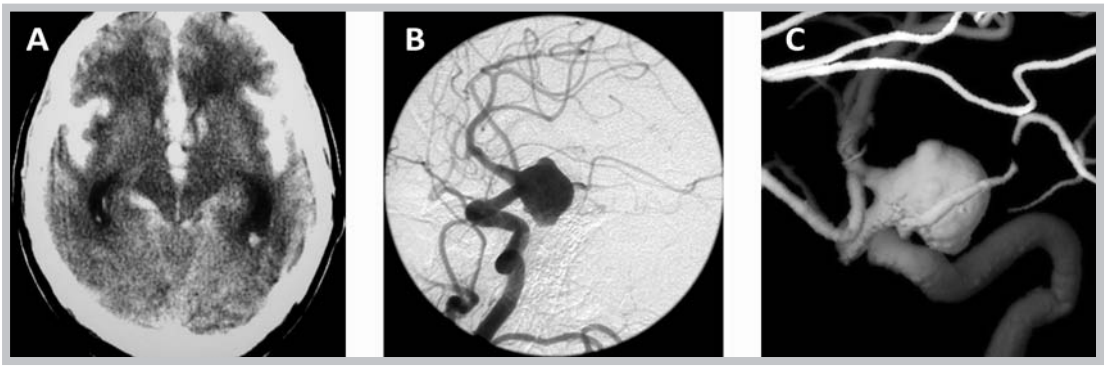

Figure 83.5. **Brain CT without contrast. Angiography and CT neuroimaging study in a patient with massive subaracnoidal hemorrhage and saccular aneurysm.**

brain descends retrocaudal, carrying with it pain-sensitive structures, particularly cranial nerves V, IX and X, and the first three cervical roots. This downward shift is most evident in the standing position, owing to the effect of gravity, and thus worsens the headache. In intracranial hypotension, headache is a constant symptom rather than hypertension. According to the criteria of the International Headache Society, intracranial hypotension can be classified into:

- Spontaneous without evidence of CSF leakage or systemic disease.
- Symptomatic after lumbar puncture (diagnostic myelogram, anaesthesia), trauma (cranial or spinal), postoperative (craniotomy, spinal surgery, post-pneumonectomy), malfunctioning CSF shunt, liquorrhoea, pituitary tumour, systemic disease (dehydration, diabetic coma, hyperpnoea, meningoencephalitis, uraemia, systemic infection).

If there is no clinical history of lumbar puncture, the hypotension should be confirmed by lumbar puncture and CSF pressure measurement. MRI with gadolinium shows diffuse dural uptake (Figure 83.5). MRI is a sensitive technique to locate CSF leakage, but its value has to be established when taking the patient's clinical data into consideration [36].

83.12 Primary Headache Treatment in the Emergency Department

83.12.1 Migraine

Migraine accounts for 37-48% of presentations at the ED for headache. It is characterized by a progressive-onset headache that lasts between 4 and 72 hours, often accompanied by nausea, vomiting, phonophobia and photophobia, and typically worsens with physical activity (Table 83.5).

In general, patients have previously experienced similar attacks and the reason for seeking attention in the ED is that the pain has not responded to usual treatment. According to the International Headache Classification, acute attacks of migraine (72 hours of evolution) of known status is distinguished from the so-called "migraine status", when migraine pain lasts more than 72 hours and is very disabling [5].

Any analgesic or nonsteroidal anti-inflammatory drug (NSAID) may resolve a moderate-intensity crisis, but the most commonly used are oral naproxen or ibuprofen, intramuscular diclofenac 75 mg and intravenous ketoralac (30-60 mg) [37,38].

Criteria	Description
A	At least 5 attacks fulfilling criteria B, C and D
B	Headache attacks lasting 4-72 hours (when not treated or treatment not successful)
C	Headache has at least 2 of the following characteristics: • Unilateral location • Pulsating quality • Moderate intensity or severe pain • Aggravated by routine physical activity (e.g., walking or climbing stairs) or conditions to avoid such activity
D	Pain associated with at least one of the following symptoms: • Nausea, vomiting or both • Photophobia and phonophobia
E	Pain not attributable to another disease

Table 83.5. **Diagnostic criteria for migraine without aura.**

Patients with nausea and vomiting may be given metoclopramide associated with NSAIDs for pain [39,40]. Clinical trials have shown that metoclopramide has, in itself, an analgesic effect on migraine [41].

In an acute migraine of severe intensity that motivates an ED visit, first of all it should be determined whether the patient can tolerate oral medication. If oral medications cannot be given, subcutaneous triptans (sumatriptan) or inhaled (sumatriptan, zolmitriptan) are indicated.

It should be remembered that triptans should not be administered if ergot or other triptans have been recent taken, which are contraindicated in patients with ischemic heart disease, intermittent claudication and uncontrolled hypertension. Sometimes, adequate hydration improves the symptoms.

If the patient is markedly anxious or has sleep disorders, benzodiazepines such as diazepam at low doses (5-10 mg) should be considered, which are often given in combination with NSAIDs intramuscularly (diclofenac and diazepam 5 mg). Chlorpromazine also has an analgesic effect and has been used in patients with migraine of long duration or status migrainosus. It can be administered IV or IM (0.1 mg/kg to 37.5 mg).

Side effects may include drowsiness and hypotension, so that when administered intravenously, it is recommended to administer 500 ml pre-saline solution and inject the medication slowly over at least 15 minutes [42].

In case of status migrainosus or long-lasting migraine, steroids such as dexamethasone or methylprednisolone could be used. Although no clinical trials have confirmed its effectiveness, most experts believe that dexamethasone is the treatment of choice in status migrainosus. The dose is not well established; a 4-20 mg bolus has been admin-

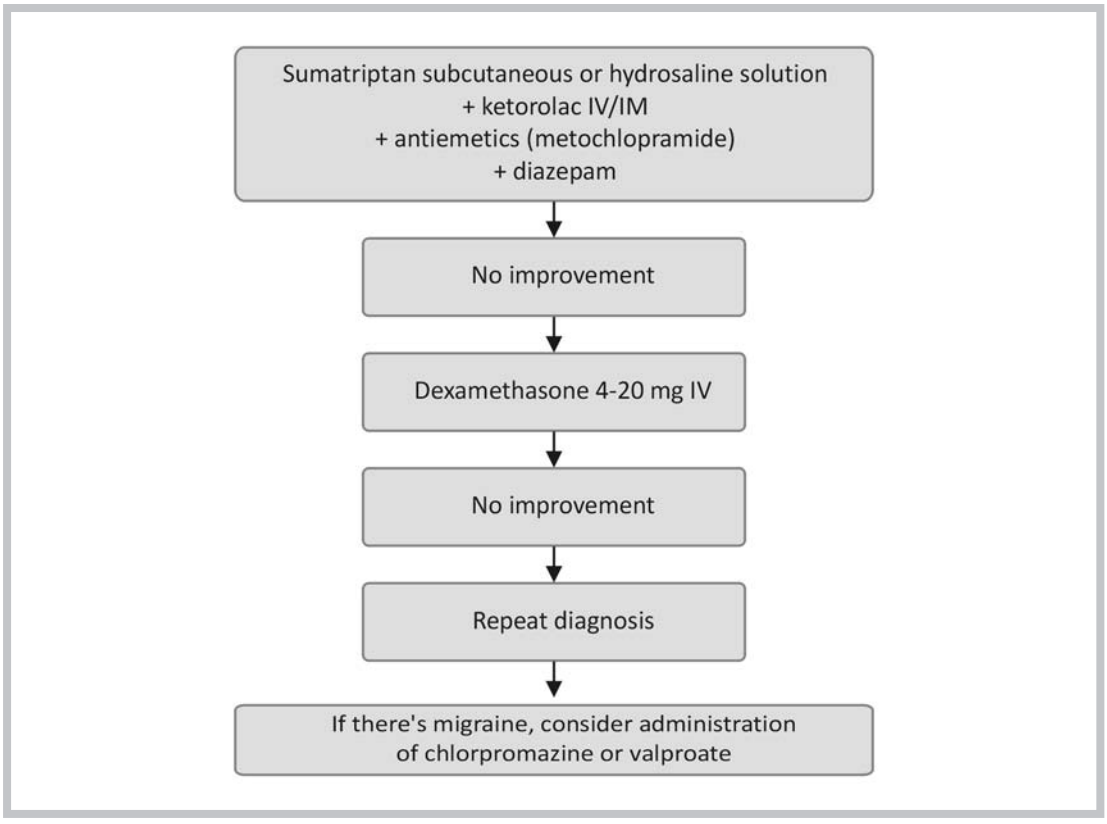

Figure 83.6. **Algorithm for the treatment of migraine and long-lasting migraine. Adapted from [8].**

istered, typically half a dose of 12-16 mg. Methylprednisolone may be administered during pregnancy.
Another possibility in emergency treatment is valproic acid. The doses are slightly lower than those used for treating convulsions and are administered by rapid infusion [43-45]. Therefore, in long-lasting migraine or in status migrainosus, subcutaneous sumatriptan or NSAIDs combined with metoclopramide are recommended. If the headache does not improve, the next step is to administer steroids. If the pain persists, the diagnosis should be reconsidered and, if the diagnosis of migraine is confirmed, chlorpromazine or valproate should be administered [46,47].

83.12.2 Cluster Headache and Other Trigeminal Autonomic Cephalagias

Trigeminal autonomic headache is the most frequent cluster headache. Patients present with a crisis of short duration (generally between 30 minutes and 3 hours), which is accompanied by different symptoms, from autonomic ipsilateral symptoms, to pain (lacrimation, rhinorrhoea, conjunctival injection and/or miosis), and a major state of anxiety. Unlike migraine, cluster headache attacks are accompanying by restless or agitation. Acute treatment is with subcutaneous sumatriptan (6 mg), whose effectiveness has been sufficiently demonstrated, or inhaled triptans, with modest effect, or oxygen [48,49].
Oxygen is effective in about 80% of patients. More than 9 litres per minute of inhaled oxygen should be administered to be effective. Generally, we recommend using 10 l/min high-flow oxygen. Since oxygen masks are normally perforated on both sides, the holes should be covered to increase treatment effectiveness; otherwise a mask a with reservoir should be used. Although the time required for oxygen to be effective is variable, it is generally recommended to apply it for 10-15 minutes.
The long-term approach to these patients should be made by neurologist [50].
SUNCT (short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing) is a rare form of paroxysmal headache [50]. Most often it is idiopathic, although there are descriptions of cases secondary to lesions affecting the trigeminal nerve. The differential diagnosis of trigeminal neuralgia (TN) and SUNCT is not always straightforward and, indeed, some authors have expressed doubt that it is really two different entities. It is included within the trigeminal-autonomic headaches in Group 3 of the International Classification of Headache [5]; it is significantly more frequent in males, and the average age at onset is 50 years.
Presentation is defined by at least 20 attacks of unilateral, stabbing or pulsating type pain in the orbital, supraorbital or temporal region, and a duration of 5-240 seconds.
Pain occurs together conjunctival injection and tearing, and the attacks appear with a frequency between 3 and 200 a day. In 47% of cases of SUNCT, a nuisance baseline is described. The pain attacks may be triggered by tactile stimulation in a, trigeminal or extratrigeminal trigger zone [51,52] or by head movements. The pathophysiology involves a central origin, with generally bilateral hypothalamic activation, which disinhibits the trigeminal-autonomic reflex [50,53]. The pain is mediated by the first branch of the trigeminal, while autonomic symptoms derive from activation of the parasympathetic branch of the seventh pair, specifically, the greater superficial petrosal nerve. SUNCT has been reported secondary to posterior fossa pathologies such as strokes, tumours, vascular malformations, morphological alterations or arterial plaques of demyelination. The symptomatic control of SUNCT is usually not simple; while it may respond to antiepileptic drugs such as topiramate or gabapentin, the most effective responses are obtained with lamotrigine.

Nerve infiltration and the use of oxygen or indomethacin are ineffective. The differential diagnosis between SUNCT and NT of the first branch of the trigeminal nerve is quite often difficult. It is accepted that in NT painful episodes are shorter, about 6 seconds on average, respond to analgesic block, and have a refractory period. Autonomic symptoms are not prominent and generally appear during particularly intense and prolonged attacks, and a certain time after the onset of pain.
Good response to the administration of lidocaine has been described [54]. Vascular microdecompression has shown dramatic results in selected patients [55,56].

Aspects That Shouldn’t Be Forgotten

84 Neurocritical Care for After Endovascular Procedures: Perioperative Management

Paul M. Vespa [1]

[1] Associate Professor of Neurosurgery and Neurology, Director of Neurocritical Care, David Geffen School of Medicine at UCLA Healthcare, Los Angeles, CA, USA

84.1 Introduction

Subarachnoid hemorrhage (SAH) is a life threatening critical neurologic illness, most often caused by a ruptured aneurysm that requires rapid diagnosis and critical care [1,2]. This is often preceded by a warning leak [3], such as headache [4]. SAH afflicts about 30,000 patients in the US each year, with higher percentages amongst Asian and Latin American Populations [5]. There is a "golden day" after SAH, namely the initial 24 hours, that are absolutely critical in which occlusion of the aneurysm and correction of physiological derangement must be timely done [6]. However, on a more global perspective, the critical care of SAH is sequential process with different treatment strategies based on the time after SAH. This starts with hemodynamic and airway stabilization, and progresses in a stepwise fashion to the diagnosis of aneurysmal bleed by computerized to-

	Treatments used	Goals
Initial stabilization		
Airway	Oxygen, ventilator	PaO_2=100; CO_2=40
Blood pressure	Nicardipine, labetalol	SBP <140 mmHg
Fluid	Normal saline	Euvolemia
Cardiac function	Fluids, beta blockade	No ischemia, normal cardiac output
Renal function	Fluids, $NaHCO_3$, N-acetyl cysteine	Avoid acute kidney injury
Glucose control	Insulin drip	Normal glycemia, 80-110 mg/dl
Intracranial pressure	Ventriculostomy	ICP <20 mmHg, avoid hydrocephalus
ICU post-coiling		
Blood pressure	Norepinephrine	SBP=120-220 mmHg
Fluid balance	Normal saline	Euvolemia to hypervolemia
Cardiac function	Fluids, beta blockade	No ischemia, normal cardiac output
Renal function	Fluids, $NaHCO_3$, N-acetyl cysteine	Avoid acute kidney injury
Sodium balance	Hypertonic saline, fludrocortisone	Na=138-145 mEq/dl
Glucose control	Insulin drip	Normal glycemia, 80-110 mg/dl
Intracranial pressure	Ventriculostomy	ICP <10 mmHg, clear excess blood from the CSF space
Temperature control	Surface or intravascular devices	T=36-37°C

Table 84.1. Goal directed neurocritical care for SAH.

mography and angiography, occlusion of the aneurysm, treatment of hydrocephalus, treatment of pulmonary and cardiac complications, diagnosis and treatment of vasospasm and treatment of early hydrocephalus. This stepwise treatment paradigm requires a multidisciplinary critical care approach [7,8]. Early endovascular treatment or surgical clipping of aneurysms is critical [9-13], but frequently a large number of critical care problems complicate the post-coiling care of the patient. In this chapter we will focus on the critical care of the post-coiling SAH patient. The goals of treatment are often time-based, and these goals change based on whether the aneurysm is coiled or not. Table 84.1 outlines the overview of the goal-directed neurocritical care for SAH. We will discuss this temporal strategy in sequence.

84.2 Preoperative Stabilization and Critical Care

It is standard practice to admit all SAH patients to an intensive care unit. Prompt attention to the airway and to hemodynamic instability is critical. Ideally, the patient should be admitted to a neurointensive care unit, with nursing staff specially trained to recognize evolving changes in the neurologic examination. Hourly neurologic checks, including measurement of the Glasgow Coma Scale and close attention to changing motor and pupil signs, are the primary clinical monitors to be followed. In addition, routine vital signs and measurement of mean arterial pressure and ICP are initial goals. To be more specific, there are three crisis domains that require goal directed critical care necessary for these patients: 1) cardiac crisis, 2) hyperglycemic crisis, and 3) intracranial pressure crisis. Cardiac crisis typically takes the form of stunned myocardium. This has many names including contraction band myonecrosis, and tako tsubo syndrome. In this cardiac crisis, there is an acute global hypokinesis with congestive heart failure and pulmonary edema. The electrocardiogram typically has widespread symmetric inverted T waves (Figure 84.1), and the troponin values are in the range of 1.0-10 ng/dl. The crisis is not due to coronary artery disease, although some believe that coronary artery vasospasm occurs in conjunction with this syndrome. Reduction in blood pressure, sedation, and fluid balance are typically needed to improve this syndrome. However, hypotension may occur in severe cases, due to cardiac shock, and patients may require inotropic support and mechanical ventilation for stabilization. The syndrome is rapidly reversible and typically lasts for 48-72 hours. In preparation for endovascular treatment, central venous access, arterial blood gas analysis, and hemodynamic support are necessary. The use of continuous infusion of low dose propofol in combination with a narcotic is typically sufficient to induce the level of anesthesia necessary for the endovascular procedure. The use of beta blockade, in the form of metoprolol or a similar agent, may lessen the duration of the cardiac crisis, but not all patients can tolerate this due to hypotension.

Figure 84.1. Example of electrocardiogram.

Hyperglycemic crisis is common acutely after SAH, and are due primarily to catecholamine induced stress. The glucose values typically are in the 200-300 mg/dl range. The severity of hyperglycemia correlates well with the clinical severity of the SAH, with Hunt Hess grades 4-5 hav-

ing the highest blood glucose levels. The degree of hyperglycemia however is an independent predictor of poor outcome, even when severity of SAH is factored in [8]. Hence, immediate evaluation and regularly scheduled glucose checks are needed. In the acute phase of SAH, with the potential for impending brain ischemia, glucose control is advisable, although the exact thresholds are presently unknown. Moderate glucose control with goals of 100-140 mg/dl seem to be a reasonable goal, in the absence of data suggesting otherwise.

Intracranial pressure (ICP) crisis related to acute hydrocephalus is a serious concern after SAH. Patients may develop hydrocephalus resulting in elevation of ICP to values ranging from 30-60 mmHg. Diagnosis is frequently made by computerized tomographic imaging. An example of this is shown in Figure 84.2. Placement of an external ventriculostomy catheter is frequently needed, and should be done before exposing the patient to the supine position for angiography and embolization.

Close attention to fluid balance, with a goal of early euvolemia, is necessary. This can be facilitated by placement of a radial arterial line and a central venous catheter into the subclavian or the internal jugular vein. Measurement of blood pressure and right atrial (RA) pressure allow for prompt control of hypertension and for management of fluid status. These patients often require control of systemic hypertension and volume resuscitation. Before the aneurysm is secured, the mean arterial blood pressure is ideally

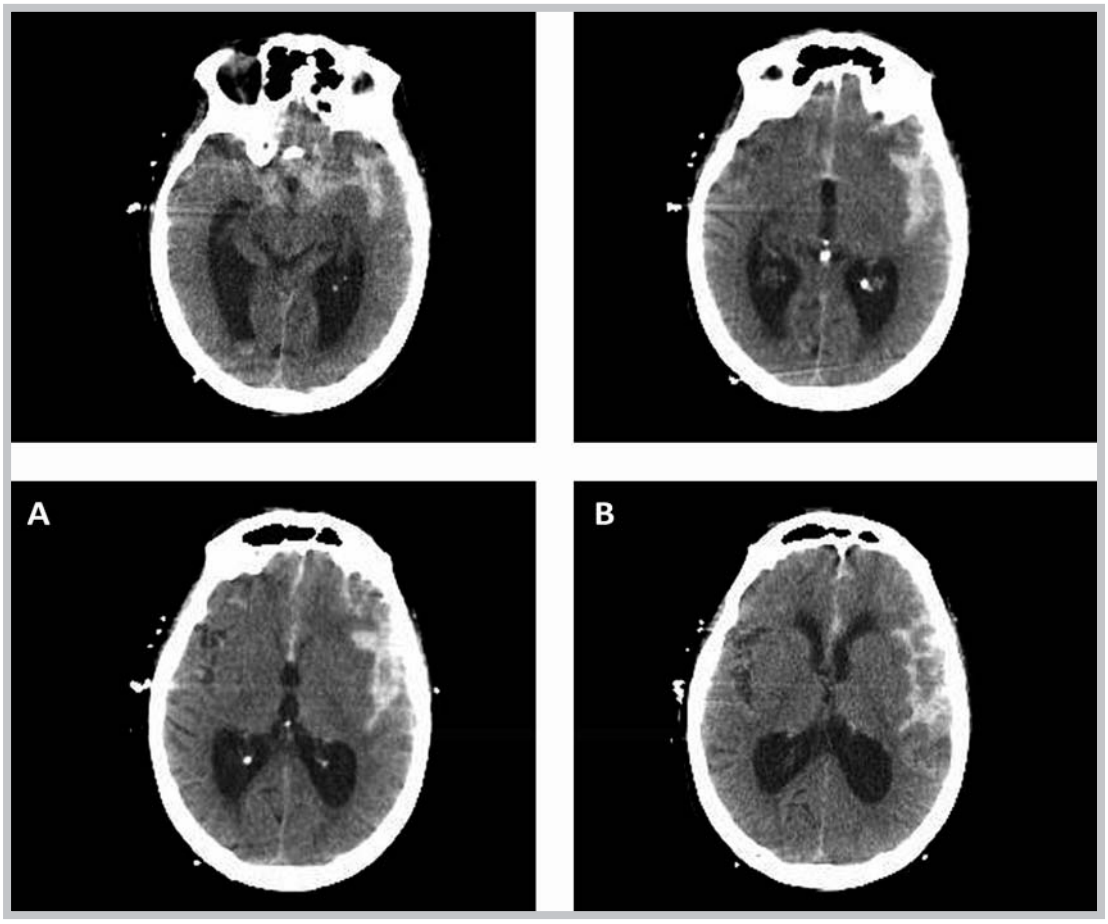

Figure 84.2. **Example of computerized tomographic imaging. Progressive wavelet level: 3-4 (A). Progressive wavelet level: full (B).**

kept at the lower range of blood pressure autoregulation (e.g., 80 to 90 mmHg), and the RA pressure at 5 to 10 mmHg. Agents that are commonly used include intermittent bolus doses of labetalol (10 to 20 mg every 1 hour) or other agents such as nicardipine or hydralazine. Antiadrenergic compounds are usually the most successful in treating the catecholamine-induced increase in blood pressure. If this does not work, then continuous infusions of esmolol or nitroprusside may be needed to control blood pressure. One must consider that reduction in blood pressure may also reduce cerebral perfusion pressure and thereby induce brain ischemia. Thus, if uncertain about ICP, clinicians should maintain the MAP above 90 mmHg to avoid ischemia. Preventing acute kidney injury is also an important consideration, given that patients are exposed to radiologic contrast agents. While there is no consensus about how best to prevent acute kidney injury, several options have been demonstrated to be of benefit [14]. Pre-angiography hydration and the minimum dose of intravenous contrast are the two most critical elements to prevent acute kidney injury during angiography. The use of N-acetylcysteine, sodium bicarbonate infusions, and acetozolamide have been advocated by many to be useful. In a randomized controlled trial, Merten et al. demonstrated that the use of sodium bicarbonate in the maintenance hydration fluid resulted in less contrast-related acute kidney injury.

84.3 Critical Care During the Endovascular Procedure

Until recently, the critical care of patients during the endovascular therapy has not received much attention. Important considerations during the procedure include adequate airway protection and oxygenation, sedation, blood pressure management, and management of ICP. Airway protection may be attained through the use of elective endotracheal intubation. If the patient is somewhat somnolent or has a preoperative Hunt and Hess grade of 3 or worse, then endotracheal intubation is indicated. Oxygenation and airway protection are further facilitated by adequate sedation. Sedation that can be easily adjusted and is rapidly metabolized is most useful and permits the interventional team to examine the patient intermittently if needed. Agents that fullfill these requirements include short-acting benzodiazepines, such as midazolam and propofol. Additionally short-acting inhalational agents may be used. A caveat that should be kept carefully in mind is that all of these agents may reduce blood pressure and consequently reduce cerebral perfusion pressure if autoregulation is impaired, which is often the case. Thus, close monitoring of blood pressure and supplemental use of vasoactive agents may be necessary to avoid adverse reductions of blood pressure.

Similar concerns of hemodynamic support and adverse cardiac responses to sedatives and anesthetics should be kept in mind during the intervention. Cardiac arrhythmias are well known to occur early after SAH, and they require prompt attention. Below, we consider several possible cardiopulmonary complications that may first arise during interventional treatment. A minimum of cardiac and central venous pressure monitoring has been our standard for making prompt diagnoses of such difficulties. Airway and respiratory support, with maintenance of the airway and normal carbon dioxide through endotracheal intubation and mechanical ventilation is critical.

Measurement of ICP and cerebral perfusion pressure is an important aspect of critical care during the endovascular treatment. A ventriculostomy permits drainage of CSF and subarachnoid blood, and it is the preferred method for acute management of changes in ICP, without the use of hyperventilation or diuretics (i.e., mannitol) [15]. These latter two methods of reducing ICP have adverse side effects, such as brain ischemia from hy-

perventilation or hypovolemia from mannitol-induced diuresis. These are best avoided in the acute phases of SAH. ICP should be maintained in a normal range of 15 to 20 mmHg. This range should permit adequate perfusion pressures while the risk of aneurysm rerupture is avoided. The latter may occur owing to unintentional overdrain-age of CSF or sudden changes in ICP. Thus, with use of the ventriculostomy, the drainage point should be set to a water level between 15 and 20 cm so that sudden declines in ICP are avoided. In addition to monitoring the acute angiogram and embolization treatment, the clinicians should monitor ICP during papaverine infusion and angioplasty for vasospasm, because they both have been associated with increased cerebral blood volume and increases in ICP. Finally, monitoring ICP can provide guidance as to the adequacy of sedation and blood pressure in the setting of a comatose patient who is unable to be adequately examined.

84.4 Post-procedural Neurocritical Care

84.4.1 Treating Medical Complications

Recently, Solenski and colleagues [16] have shown that medical complications after SAH are responsible for additional morbidity and mortality (approaching 40%), nearly equal to the primary neurologic morbidity. The attributable death rate caused by medical complications is approximately 23%. Thus, early assessment of arterial blood gases, chest radiograms and airway stability, and continuous pulse oximetry are required for the appropriate treatment of these patients. Indeed anticipation of full ventilator support during the period of aggressive intravascular volume therapy should be anticipated and the family and medical consultants informed and educated about this issue.

Acute pulmonary edema and hypoxemia are nearly universal in SAH [17]. This is because of neurogenic pulmonary edema and is not to be related to hypertensive, hypervolemic, and hemodilutional (HHH) therapy or fluid overload. Initial widened alveolar-arterial PO_2 gradients, pulmonary edema, and respiratory distress occur acutely in more than 80% of patients and lead to prolonged hospital stays and increased costs. In addition to the acute cardiac insufficiency, there seems to be a neurogenic origin for this hypoxemia that is out of proportion to cardiac failure or fluid overload. The need for aggressive maintenance of intravascular volume in euvolemic or hypervolemic states elicits the subtle pulmonary dysfunction and triggers fulminant pulmonary edema. Treatment of acute pulmonary edema may include the use of dobutamine [18], gentle diuresis, and augmented positive end-expiratory pressure (PEEP).

Early cardiac dysfunction, including diffuse contraction band necrosis and segmental wall motion abnormalities, occurs in a sizable minority of SAH patients. [19] The dysfunction is caused in large part by neurogenic sympathetic overactivity as well as by the surge in systemic catecholamines. Several reports of cardiac arrhythmias in the acute stages of SAH exist. The occurrence of arrhythmias and wall motion abnormalities predisposes the patient to decreased cardiac output and thus reduced cerebral perfusion. This cardiac dysfunction is often reversible but can give rise to early pulmonary and cardiovascular insufficiency. If doubt arises as to the function of the cardiovascular system or the pulmonary function, prompt evaluation with a right heart catheterization or echocardiogram should be entertained.

In addition, evaluation for concurrent myocardial ischemia or pneumonia should be performed. Management of these complications encompasses many common means (i.e., antibiotics) with the caveat that volume depletion and diuresis should be minimized in

patients who have primary ischemic injury or in whom vasospasm or reduced cerebral perfusion pressure exist. In the latter situation, a relative compromise in tolerating excessive pulmonary edema may be necessary to ensure adequate perfusion of the brain. Contrary to typical intensive or cardiac care protocols, hydration rather than diuresis is the goal.

Hyponatremia is a frequent complication after SAH. This is likely due to cerebral salt wasting. Replenishment with hypertonic saline and supplemental mineralocorticoid administration, typically with fludrocortisone, is necessary, in order to maintain sodium in the normal range, 138-145 mEq/dl.

Avoid of fever is a very important feature as well. Fever can exacerbate neurologic damage, and has been linked as an independent factor affecting poor neurologic outcome [20,21]. The use of surface cooling devices or intravascular cooling devices has become commonplace. The goal temperature is typically 36-37°C, with strict avoidance of any fever. The use of antishivering protocols is critical to implementing this control and avoiding unnecessary metabolic challenges to the patient [22]. Medications such as buspirone, and meperidine are important adjunctive agents that limit the extent of shivering and thereby facilitate the positive effects of cooling.

84.4.2 Treating Neurologic Complications

Often, obstructive hydrocephalus occurs within the first few hours after SAH. It can be life threatening because of brain-stem compression and occlusion of large as well as smaller penetrating blood vessels. Deterioration of the level of consciousness early after the primary event is the most common presentation. The use of a ventriculostomy for ICP measurement and drainage of CSF should be performed on an individual basis for acute hydrocephalus, based on the severity of clinical neurologic dysfunction and the CT scan appearance of trapped temporal horns or obliterated basilar cisterns. Several reports suggest a beneficial effect of ventriculostomy to relieve hydrocephalus and to improve patient outcome [15,23,24]. The use of ventricular drainage is a usefull early test of possible neurologic viability and chose operative candidates in whom neurologic improvement occurred after CSF drainage. Thus, the ventriculostomy may serve as both a therapeutic device as well as an indicator of which severe-grade patients should be aggressively treated.

Many have found that early drainage or lavage of the CSF space decreases the incidence of vasospasm after SAH [25] and that the infusion of thrombolytic agents may aid in this process with the timing of such intervention usually after the aneurysm has been secured. However, sudden drainage of CSF may precipitate rerupture of the aneurysm, mainly because of the transmural pressure across the aneurysm wall exceeding the intraventricular pressure. Thus, caution must be exercised during placement of a ventricular drain and during draining of fluid. One must limit the amount of CSF drained and the equilibrium CSF pressure at which the fluid drains. A practical approach is to drain CSF if the ICP exceeds 20 mmHg until the aneurysm is occluded. The drain is set at a 15 to 20 cm height such that the intraventricular pressure does not drop below this value during the draining process. Thus, one may avoid excessive ICP or dangerous hydrocephalus while avoiding unintentional aneurysm rerupture.

Rehemorrhage after the primary event is the most worrisome initial neurologic complication. Kassell and co-workers [9,11] have shown that early operative management decreases the risk of rehemorrhage and improves outcome. In most centers, early clipping of the aneurysm or endovascular treatment occurs within 24 to 48 hours after rupture. Subsequent intensive care unit care then makes use of neurologic monitoring, especially

the neurologic examination, ICP monitoring, transcranial Doppler ultrasound, and continuous EEG [6,26]. These techniques are used in a complementary fashion to detect and treat vasospasm and other neurologic complications such as seizures. Refinements in the application of these techniques and the use of hypervolemic-hypertensive-hemodilutional therapy offer the hope of decreasing the morbidity from vasospasm and improving the outcome [6].

In summary, the prompt recognition of SAH and the acute management of neurologic and medical problems is necessary to prevent additional morbidity and to maximize the neurologic recovery of patients suffering from SAH.

84.4.3 The Use of Neurologic Monitoring

One of the hallmarks for neurocritical care is the use of specific neurologic biomarker monitoring instruments to detect delayed cerebral ischemia, seizures, and other forms of neurologic deterioration [6,26]. Continuous EEG monitoring has the potential to detect vasospasm-related cerebral ischemia [1,6]. Several quantitative parameters, namely the percent alpha variability (PAV) and the alpha/delta ratio are sensitive indicators of cerebral ischemia. A typical example of the serial changes in cEEG PAV are seen in Figure 84.3. PAV detects vasospasm before more conventional measures, such as the transcranial Doppler ultrasound, CT angiography, or the clinical exam. In our hands, we use PAV as an early indicator of cerebral ischemia, and will induce hypertension while awaiting confirmatory testing, even if the neurologic exam is unchanged.

Cerebral microdialysis is another important neurologic monitor for the detection of vasospasm-related cerebral ischemia. The principal findings on microdialysis with ischemia are: 1) a reduction in brain glucose and 2) an increase in the lactate/pyruvate ratio. Several groups have demonstrated utility in using cerebral microdialysis for this type of monitoring.

Similarly brain tissue oxygen monitoring ($PbtO_2$) is a regional tissue monitor that indicates the balance of oxygen delivery and oxygen consumption in the brain. This monitor is capable of detecting reductions in the combination of cerebral blood flow and oxygen content [27].

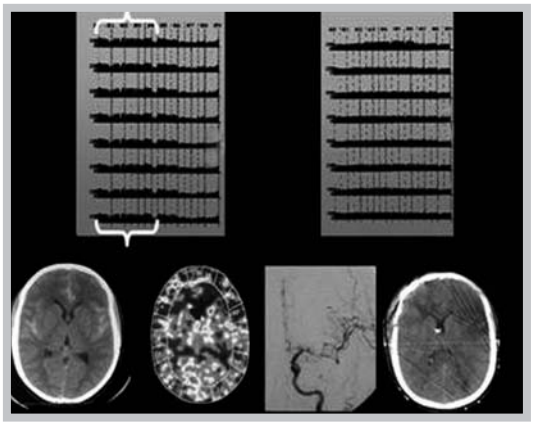

Figure 84.3. **A typical example of the serial changes in continuos EEG PAV.**

84.5 Conclusions

The acute management of aneurysmal SAH requires a comprehensive approach entailing acute critical care and stabilization, occlusion of the aneurysm, and intensive care management of acute neurologic complications. The development of endovascular treatment of aneurysms has added an important, less-invasive treatment to the regimen available in treating aneurysms. An integrated approach of providing critical care before, during, and after the occlusion of the aneurysm is an important concept that should be the goal. Debate and controversy remain regarding which aneurysms are best

suited to endovascular treatment or to surgical treatment; an evolving experience and clinical trials will provide further guidance. Nonetheless, some aneurysms may require both surgery and endovascular treatment [19]. Finally, close neurologic observation and directed specialized monitoring techniques are required for providing directed critical care in the acute period after SAH.

85 Neurological Complications of Heart Surgery

Roberto Fernández Torrón [1], Pablo Irimia Sieira [1], Eduardo Martínez-Vila [1]

[1] Department of Neurology. University Clinic of Navarra. Faculty of Medicine. University of Navarra, Pamplona, Spain

85.1 Introduction

Heart surgery is one of the most frequent procedures in developed countries. However, although the number of patients subjected to valve surgery has remained virtually unchanged over the last few years, coronary vascularization procedures are still rising. Recent progress in surgical techniques, anesthetic procedures and intra- and post-operative monitoring techniques have made it possible to operate older patients with greater comorbidity whilst reducing the morbidity/mortality related to the surgery itself. However, peri-operative complications that affect the central nervous system (CNS) can still be considered common, with relatively high morbidity and mortality rates, significant personal, family and social impact, and a high consumption of health resources. The most frequent complications arising from heart surgery are mainly focused on ischemic stroke, confusion syndromes and neuropsychological abnormalities.
In spite of the fact that neurological complications affecting the CNS are the most common and important, it is not uncommon that peripheral nervous system (PNS) involvement, mainly plexopathies and neuropathies, occurs after heart surgery (Table 85.1).

Location	Neurological complications
Central Nervous System	• Ischemic stroke • Hemorrhagic stroke • Epileptic seizures • Coma • Encephalopathy • Confusion syndrome • Neuropsychological dysfunction
Peripheral Nervous System	• Brachial plexopathy • Cubital neuropathy • Phrenic neuropathy • Intercostal neuropathy • Femoral neuropathy • Anterior ischemic optic neuropathy

Table 85.1. Most frequent neurological complications in heart surgery.

85.2 Complications of the Central Nervous System

85.2.1 Epidemiology

Those studies that assessed the incidence of CNS complications during the peri-operative period of heart surgery have found widely varying results. This is most probably due, amongst other factors, to differences in the surgical technique used, prior patient comorbidity, anesthesia time, length of follow-up, variations in terms used to define complications, neuroimaging techniques used and the retrospective or prospective nature of the study. Indeed, the peri-operative existence of a neurological dysfunction has

been defined in various ways, using terms such as "encephalopathy", "delirium", "confusion", "agitation", "stroke", "alteration of memory", with no uniform criteria having been used or, at times, established to define them. In this context, in an attempt to unify the criteria used to evaluate the neurological complications following coronary revascularization, the so-called Multicentre Group for the study of Perioperatorive Ischemia proposed classifying them as follows:

- Type I: Focal lesions, including stroke, confusion syndrome, transient ischemic attack, stupor, and coma.
- Type II: Cognitive dysfunction, memory deficit, and convulsive seizures.

It is estimated that the incidence of ischemic stroke following coronary revascularization surgery is between 1.5% and 5.2% and increases for valve replacement surgery and other invasive open surgery procedures. Approximately 60% of strokes occur during the first two days of the post-operative process, and virtually of them during the first nine days. During the first few weeks following surgery, the rates of encephalopathy and neuropsychological dysfunction vary between 3% and 79%.

85.2.2 Risk Factors

Table 85.2 highlights the main risk factors for the development of neurological complications during the peri-operative period of heart surgery.

Atherosclerosis of the ascending aorta. This is possibly the most important risk factor for developing type I and II neurological complications following heart surgery. The incidence of cerebrovascular disease in patients with aortic atherosclerosis is 8.7%, compared to 1.8% in other patients. A correlation has been observed between the severity of aortic atherosclerosis and the risk for developing cerebrovascular disease; this is 3% in patients with moderate involvement and 4.8% in those with severe atherosclerosis (>5 mm).

History of cerebrovascular lesion. This is an independent risk factor that increases the possibility of suffering a new cerebrovascular event by 8.5% and which worsens prior symptoms by up to 35%. The need to maintain anticoagulant treatment after some heart surgery procedures and heparinisation during extracorporeal circulation may favor the hemorrhagic transformation of previous cerebral infarctions.

Carotid stenosis. The existence of a stenosis greater than 80% is associated with an 11-18.8% higher risk of suffering from ischemic stroke, encephalopathy or a neuropsychological abnormality following myocardial revascularization. This increase may be due to a reduced perfusion distal to the stenosis or thromboembolic complications.

Elderly age. An age of 70-75 years or older is also an independent risk factor for the development of some kind of cerebrovascular complication following heart surgery, as it is associated with a higher probability of presenting atherosclerotic lesions in the aorta, carotid and intracranial arteries.

High blood pressure is an independent risk factor for the development of both type I and type II neurological complications.

- Elderly age
- Diabetes mellitus
- High blood pressure
- Atherosclerosis of the proximal aorta
- Carotid and/or intracranial artery atherosclerosis
- History of cerebrovascular disease
- Heart failure
- Severe or moderate left ventricular dysfunction
- Post-operative atrial fibrillation
- History of unstable angina or recent myocardial infarction
- Peripheral arteriopathy
- Kidney failure
- Prior lung disease

Table 85.2. **Risk factors for the development of neurological complications of the central nervous system in heart surgery.**

Diabetes mellitus and intra-operative hyperglucemia are also risk factors, especially in women.
Heart function. The existence of low cardiac output (pre- or post-operative), the presence of atrial or ventricular thrombi, the development of post-operative arrhythmias and a history of coronary disease or unstable angina increase the risk of type I and II neurological complications.
Type of surgery. Closed surgery techniques, such as coronary bypass, entail less risk than open heart surgery procedures (valve replacements). The use of intermittent aortic clamp and intra-aortic contrapulsation ballon are independent risk factors for type I neurological complications.

85.2.3 Etiopathogeny

The fundamental etiopathogenic mechanisms of neurological complications in the patient subjected to heart surgery involve cerebral embolism and hypoperfusion.

Cerebral Embolism

Cerebral embolism is the main mechanism involved in producing neurological complications that occur during the peri-operative period of heart surgery, especially in interventions with extracorporeal circulation.
Depending on the origin and nature of the emboli, the cerebral complications produced may, in general terms, be due to thromboembolic or atheroembolic phenomena, or gas embolism. Emboli may derive from atherosclerotic, generally ulcerated, lesions of the aortic arch or supra-aortic trunks, mural thrombi, from the cardiopulmonary bypass circuit, pre-existing cardiac lesions (hypofunctional ventricle, atrial dilatation), calcified valves or be generated by post-operative arrhythmias (atrial fibrillation). The neurosonological studies performed to date have revealed that aortic handling maneuvers, especially clamping and declamping (the origin of more than 60% of emboli detected), are the main causes of rupture of the atheroma and subsequent formation of emboli. Ischemic lesions may also occur days after surgery as the activation of coagulation factors in operated patients promotes a state of hypercoagulability and the formation of thrombi on stenotic arteries, with the subsequent development of thromboembolic phenomena. Conversely, gas emboli enter the arterial circulation after being generated in arterial cannulation sites, open heart chambers or arterial anastomoses and they are the most frequent emboly type detected during extracorporeal circulation.
Macro- and microemboli can be differentiated on the basis of their size (diameter greater or lesser than 200 microns). Macroemboli are usually produced in relation to rupture of the atherosclerotic plaque and mainly cause focal neurological deficits of greater or lesser severity upon occlusion of median and large calibre arteries. Microemboli (comprised of fibrinoplatelet aggregates, atheromatous detritus, lipids, air, etc.) usually affect “borderline” vascular areas between the medial and posterior cerebral artery or the medial cerebral artery and the anterior cerebral artery. Sometimes, microemboli may produce lesions that are similar to those of hypoperfusion and evolve with clinical symptoms of neuropsychological dysfunction, confusion syndromes or give rise to lacunar syndromes.

Hypoperfusion

The second mechanism implicated in the origin of peri-operative neurological complications is hypoperfusion. Cerebral hypofusion may be due to the existence of low blood flow, arterial hypotension, hypovolemia or incorrect positioning of the aortic cannu-

la. It is favored by the coexistence of prior intra- or extracranial arteriopathy or by a low availability of collaterals from the Willis polygon. Cerebral circulation has self-regulation mechanisms where cerebral blood flow (CBF) is kept virtually constant under a mean blood pressure margin between 30 and 100 mmHg. In addition to the pressure (arterial or from the extracorporeal circulation pump) and flow characteristics (normally lower than physiological flow during extracorporeal circulation), CBF depends on other factors such as the acid-base equilibrium, hypoxemia, arterial pCO_2 or the anesthetic technique used. These self-regulation mechanisms mean that elderly patients with high blood pressure, diabetes or a history of cerebrovascular disease keep the self-regulation curve shifted to the right. A mean blood pressure that would be suitable in other circumstances may result in a state of hypoperfusion as a result of insufficient CBF, thus meaning that these patients would require higher perfusion pressures than the normal population. In addition to contributing by themselves to hypoperfusion, a low mean blood pressure and reduced blood flow result in a lower ability to dissolve and fragment circulating microemboli, thereby increasing the risk of infarction in borderline areas, as well as neuropsychological complications. Hypoperfusion secondary to insufficient perfusion pressure, either intra-operative or during the immediate post-operative period, may be the cause of multiple bihemispheric ischemic lesions with subcortical predominance.

Clotting Disorders

The need to maintain a state of anticoagulation during the procedure in some procedures of heart surgery may result in cerebral hemorrhagic complications. This is particularly significant in elderly patients, where the presence of silent vascular lesions and the coexistence of atherosclerotic arteriopathies, such as amyloidosis, is more frequent.

Systemic Inflammatory Response

It should also be taken into account that the significant inflammatory response that generally arises during cardiopulmonary bypass could, at times, lead to conditions ranging from lung dysfunction to temporary multiple organ failure. Although no direct causal relationship between a systemic inflammatory response and neurological damage has been demonstrated, it is possible that this contributes to its development and progress, especially neuropsychological abnormalities.

85.3 Most Common Central Nervous System Complications

The clinical CNS manifestations that may present in a patient who has undergone heart surgery cover a range of possible signs and symptoms, which will depend on the location, number and kind of lesions produced. Among the main neurological complications, the following entities and syndromes should be considered (Table 85.1).

85.3.1 Ischemic Stroke

Early strokes, which are present during the first few hours of surgery, are the most frequent complication and have been attributed to intra-operative emboli or as a consequence of hypoperfusion states. When stroke symptoms occur later, the most frequent cause is cardiac arrhythmia (especially atrial fibrillation) or detachment of aortic atheroma. Initially, patients who have suffered stroke take longer to recover from the anesthesia.

Patients with hemispheric infarctions will present contralateral weakness or hemianesthesia, hemianopsia, aphasia or hemispatial neglect. Cerebellar infarctions may evolve with vertigo, nausea, vomiting, dysarthria, vertical nystagmus and ataxia. Infarction in the brainstem will give rise to cranial nerve paralysis and motor or sensory deficits that vary according to the location and size of the lesion. Infarctions in the protuberance may lead to "locked-in syndrome", which should be differentiated from coma. These patients present quadriplegia, bilateral facial paralysis, anarthria and paralysis of the horizontal gaze, but comprehension and vertical eye movements are preserved.

Hypoperfusion-related cerebral infarctions typically affect borderline areas, limiting regions whose irrigation depends on two or three vascular areas. The most commonly affected areas are those located between the medial and anterior cerebral arteries and the medial and posterior cerebral arteries. Infarctions in the borderline area between the anterior cerebral artery and the medial cerebral artery produce contralateral hemiparesia, which mainly affects the arm, and transcortical motor aphasia if the dominant hemisphere is affected. Bilateral infarctions in this same area may very characteristically produce bilateral involvement of the proximal musculature of the upper limbs ("man-in-the-barrel syndrome"). Infarctions in the borderline area between the medial and posterior cerebral arteries may cause sensory, visual-field or language deficits. Bilateral infarctions, which are produced by either hypoperfusion or embolism, may produce a reduction in the level of consciousness or similar brainstem lesions.

85.3.2 Hemorrhagic Stroke

The presence of cerebral or subarachnoid hemorrhage has occasionally been reported following congenital cardiopathy procedures and in heart transplant recipients. The pathophysiological mechanism proposed for these cases is the rupture of small arteries as a result of increased CBF or because of clotting disorders, especially in patients with vascular risk factors, cerebral arteriopathy or silent vascular lesions. Patients with endocarditis also present an increased risk of intracranial hemorrhage during heparinisation, which is performed during the cardiopulmonary bypass. This risk may be minimised using an extracorporeal circulation circuit that allows to reduce systemic heparinisation.

85.3.3 Epileptic Seizures

Epileptic seizures have been documented in 0.6-3.5% of operated heart surgery patients. They are generally a manifestation of cortical infarctions and may evolve into epileptic status in cases of serious metabolic abnormalities (hyponatremia, hypoglucemia), hypoxia and associated pharmacological toxicity (lidocaine, procainamide).

85.3.4 Coma

The coma state occurs as a complication of focal lesions (ischemic or hemorrhagic) in the brainstem, hemispheric lesions with compression of the brainstem because of edema, global cerebral hypoperfusion, convulsive state and serious metabolic abnormalities. Patients in coma as a result of diffuse anoxic brain damage usually will be affected by myoclonus and convulsions (Lance-Adams myoclonic encephalopathy) with uncertain prognosis. Clinical evolution to a persistent vegetative state may be observed in patients with long-term global cerebral ischemia.

85.3.5 Confusion Syndrome

This should be suspected in patients with slow recovery from anesthesia or who, once awake, present a state where agitation, disorientation and visual hallucinations alternate with a reduced level of consciousness, generally stupor. Confusion syndrome in heart surgery patients occurs between 3% and 32% of patients, especially those with previous psychiatric disease, alcohol consumers or with prior cerebrovascular disease. The clinical symptoms of encephalopathy may arise following metabolic abnormalities (liver, kidney or thyroid failure) as a manifestation of right parietal infarctions or because of diffuse cerebral dysfunction of ischemic origin. This situation can improve spontaneously or evolve toward different degrees of neuropsychological dysfunction or death.

85.3.6 Neuropsychological Dysfunction

This mainly consists of attention deficit, difficulty concentrating, memory alterations, changes in character, altered executive functions, etc. It appears in 50-70% of patients during the first week of the post-operative period and remains in 30-50% at 6 weeks and 20-40% at 6 months and 1 year post-surgery. Despite appearing to be a transitory and reversible abnormality, long-term follow-up studies suggest that up to 42% of patients present neuropsychological dysfunction at 5 years.

Short-term cognitive abnormalities (from the first week up until 1 year post-op) mainly imply changes to memory and visuospatial skills. They are usually transitory and reversible deficits. Their etiology is multifactorial and is related to hypoperfusion and the release of microemboli during extracorporeal circulation, although it is possible that, especially during the first few days, there is an underlying effect of the drugs used during anesthesia, sedation and analgesia.

Long-term cognitive abnormalities have been observed in longitudinal studies at one and five years post-intervention. The main impairment occurs to psychomotor reactivity, whereas verbal learning and memory remain unchanged. It cannot be ruled out that the subcortical damage which appears in the long-term may be due to the presence of vascular risk and comorbidity rather than the effect of surgery.

85.4 Diagnosis of Central Nervous System Complications

The diagnosis of neurological complications in a patient who has undergone heart surgery should include a case history and neurological examination, as well as cerebral neuroimaging techniques, epiaortic ultrasound, neurosonological studies and the determination of biochemical markers.

85.4.1 Case History and Neurological Examination

All patients who will undergo heart surgery should have a detailed history aimed at the investigation of vascular risk factors and history of neurological and, especially, cerebrovascular disease. Patients should be examined before and after the intervention in order to identify new signs not present in prior examinations. Early neurological examination following surgery should be exhaustive and especially thorough in those patients with risk factors as they are the ones with the highest probability of presenting neurological complications. It is recommended to perform a neuropsychological assessment during

the post-operative period, especially after day 3-5 to avoid an effect of the anesthesia and sedatives. The Mini-Mental State Examination has been proposed as a screening element, and batteries of neuropsychological test should be reserved for those patients with specific dysfunctions (visuospatial abnormality, change in character, etc.).

85.4.2 Neuroimaging Techniques

Neuroimaging techniques should be performed on those patients with symptoms of neurological dysfunction following surgery. Computed tomography (CT) has been the standard imaging technique for the initial and urgent assessment of the patient following heart surgery for many years due to its ability to detect hemorrhage in the hyperacute period, ischemia-related parenchymatous abnormalities, and its more widespread availability in a hospital setting.

However, given the known limitations of CT, brain magnetic resonance (MR) enables very small lesions to be identified, can perfectly determine the regions of posterior circulation and has a high sensitivity for the detection of ischemic lesions and edema, even in their early stages. Multimodal MR, which includes the use of diffusion-perfusion sequences and gradient echo, has a high capacity and reliability for studying the location, number and size of ischemic lesions, the detection of hemorrhages and their parenchymatous complications, such as cerebral edema. By identifying potentially recoverable ischemic tissue (mismatch), MR also facilitates the selection of patients who are candidates for therapeutic interventions, such as mechanical extraction of the thrombus. The diffusion sequences (Figure 85.1) also detect silent infarctions and enable the prognostic utility in patients with post-surgical infarctions and neuropsychological dysfunction to be assessed. Although MR is a technique of choice due to its high diagnostic efficacy, it is contraindicated in the presence of pacemakers and Swan-Ganz catheters. Valve displacement or heating of the ferromagnetic material or the valvuloplasty ring are potential risks that should be studied on a case-by-case basis [www.mrisafety.com]. Performing a brain MR during the patient's pre-operative assessment, especially in those patients with multiple vascular risk factors, also helps to establish a risk profile as silent ischemic lesions can be detected.

85.4.3 Epiaortic Ultrasound and Neurosonological Study

Epiaortic ultrasound is a highly sensitive technique that can be used to determine the severity of atherosclerosis of the ascending aorta, which is one of the main risk factors for the development of neurological complications. It has been demonstrated to be superior to manual palpation and transesophageal ultrasound and is used for intra-operative diagnosis of aortic atherosclerosis.

A carotid color Duplex scan is a necessary tool for both the screening of at-risk patients and diagnosing a post-operative arterial occlusion. Carotid stenosis is a risk

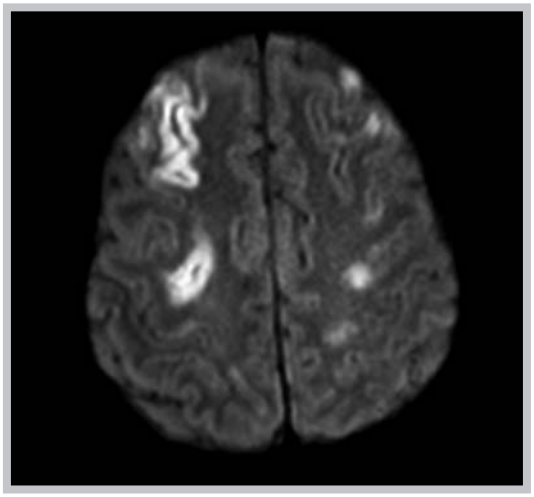

Figure 85.1. **Cerebral magnetic resonance, diffusion sequences, axial plane. Ischemic lesions in borderline areas in both brain hemispheres following heart surgery.**

factor for the development of neurological abnormalities as it is both a source of emboli and because it contributes to cerebral hypoperfusion in low flow situations. Guidelines of the American Heart Association propose performing a carotid eco-Doppler for patients with stenosis of the anterior descending artery, peripheral vascular disease, smokers, a history of transient ischemic attack (TIA) or previous stroke, carotid murmur or aged older than 65 years.

Transcranial Duplex monitoring during cardiopulmonary bypass has shown the existence of microemboli (documented in the form of HITS – High-Intensity Transient Signals) and could be useful for monitoring cerebral perfusion during surgery.

85.4.4 Biochemical Markers of CNS Complications

The quantification of various substances released following a hypoxic-ischemic cerebral lesion could be a marker for brain damage. Although the concentration of several substances in both serum and the cerebrospinal fluid has been studied (brain-specific CPK, adenylate cyclase, neurospecific enolase, myelin basic protein, S-100 β, etc.), their clinical utility has not been demonstrated. An association has recently been found between pre-operative serum concentrations of anti-NMDA anti-receptor antibodies and the subsequent development of neurological abnormalities, although this requires further confirmation.

85.5 Treatment of CNS Complicacions

The therapeutic direction for heart surgery complications in the CNS can be focused on three aspects: preventive treatment, neuroprotective treatment during surgery and treatment of neurological complications.

85.5.1 Preventive Treatment

A pre-operative assessment reduces the risk of neurological damage by enabling pre-existing modifiable risk factors to be identified and treated. An optimum control of blood pressure, glycemia and heart and kidney function prior to surgery reduces the risk of suffering a subsequent neurological complication. Because of their etiopathogenic importance, carotid stenosis and aortic atheromatosis require special consideration.

Carotid stenosis. Carotid endarterectomy performed prior to, or together with, myocardial revascularization is usually recommended in patients with symptomatic carotid stenosis or in asymptomatic patients with carotid stenosis (unilateral or bilateral) greater than or equal to 80%. This intervention reduces mortality and the risk of developing ischemic stroke after heart surgery.

Aortic atheromatosis. When the aorta presents a thickness above 3 mm, it is essential to choose the area to perform the clamping, aortic cannulation and proximal anastomosis of the aortocoronary grafts carefully, or even consider revascularisation surgery without extracorporeal circulation. No benefit of pre- or intra-operative endarterectomy has been demonstrated.

85.5.2 Neuroprotective Treatment

Protection of the CNS during heart surgery includes pharmacological and non-pharmacological measures.

Non-pharmacological measures

In procedures with extracorporeal circulation, temperature, acid-base balance and blood pressure are related to the risk of development of CNS abnormalities:

- **Temperature** of the cardiopulmonary bypass. Systemic hypothermia reduces cerebral metabolism (7% for each Celsius degree) and has a protective effect against transitory ischemic attacks. Moderate hypothermia is normally used in both closed-chamber procedures that require extracorporeal circulation (32°C) and open procedures (28°C). The beneficial effects of hypothermia disappear when reheating of the system begins. Hyperthermia, with temperatures over 41°C, increases cerebral metabolism, denatures proteins, and facilitates gas embolism, therefore this process should always be performed very gradually.
- **Acid-base equilibrium**. Hypothermia alters the acid-base balance and as a consequence affects CBF. The main techniques to regulate the acid-base balance during hypothermia are alpha-stat and pH-stat. In alpha-stat, measurement of the pH and CO_2 is performed directly in blood at 37°C, whereas in pH-stat this is performed using values adjusted for the patient's current temperature. The use of pH-stat requires the addition of CO_2 to the circulation during the hypothermic phase of cardiopulmonary bypass, thereby increasing the risk of embolization. Acid-base regulation by means of the alpha-stat technique is recommended as it preserves cerebral self-regulation and reduces the risk of embolization and subsequent neuropsychological abnormalities.
- **Blood pressure**. The majority of patients tolerate mean blood pressures to between 50 and 70 mmHg during extracorporeal circulation well. However, elderly and hypertensive patients will require higher values as their cerebral self-regulation curve is shifted to the right. Hypotension should be avoided during the procedure as this causes cerebral hypoperfusion, less clearance of circulating microemboli and a higher risk of cerebral ischemic lesions and the development of neuropsychological abnormalities.
- **Surgical position**. Placing the patient in the Trendelemburg position seems to reduce the risk of gas embolization, especially during open chamber procedures.
- **Intraoperative monitoring**. Transesophageal echocardiography enables the detection of permeable oval foramen, thrombi in the left atrium in patients with atrial fibrillation, air retention in open chamber procedures, mural thrombi in the left ventricle, thrombosis in the valve prosthesis, valvular vegetations, dissection of the proximal aorta and atherosclerosis of the aorta to be detected, thus allowing the risk of neurological complications to be reduced. Epiaortic ultrasound can also help to locate the most ideal place to perform aortic clamping, thereby reducing possible disruption of the atheroma.
- **Kind of surgery**. Coronary revascularization surgery, which is performed without extracorporeal circulation, is less invasive and reduces the complications of cardiopulmonary bypass. This technique requires a careful positioning and very close cardiac monitoring. The heart rate needs to be controlled pharmacologically (under 75 beats/minute) to reduce the movement of the heart in the surgical field and reduce myocardial consumption during the procedure. A reduction in ischemic stroke has been observed in high-risk patients treated with this kind of surgery, although its influence on the risk of neuropsychological complications is debatable.

Pharmacological Measures

Strategies for pharmacological protection attempt to interfere with the metabolic cascade that occurs during and after cerebral ischemia in order to prevent or delay cell death. NMDA receptor antagonists, calcium and sodium channel blockers, antioxidants,

complement inhibitors, magnesium sulfate, leukocyte adhesion inhibitors, barbiturates, amongst other agents, have been studied. Although several drugs have shown neuroprotective effects in experimental models of both focal and global ischemia, none has demonstrated clinical efficacy in humans. Patients treated with aprotinin, a non-specific serine-protease inhibitor, to reduce bleeding during heart surgery seem to present a lower incidence of infarction in the post-operative period. The possible neuroprotective effect of citicoline is currently being assessed in a double-blind placebo-controlled clinical trial in patients with cerebral infarction. Citicoline could be of great use in patients undergoing heart surgery given its excellent safety profile.

85.5.3 Treatment of Complications

Ischemic Stroke

Patients who present a cerebral infarction during the peri-operative period are not candidates for endovenous thrombolytic treatment as their use is specifically contraindicated up to 14 days later due to their high risk of hemorrhage. Despite this limitation, intra-arterial treatment and mechanical thrombolysis are two possible therapies that could be applied in selected patients. Intra-arterial thrombolytic treatment during the first 4.5 hours of symptom onset has been administered to patients with ischemic stroke 2-9 days post-surgery, with high recanalization rates and no significant side effects being documented. Mechanical extraction of the embolus (MERCI system) has been successfully applied to selected patients with a therapeutic window of up to eight hours.

As in all cases of cerebral ischemia, oxygenation, blood pressure, glycemia and body temperature should be monitored and corrected, just as for any other patient who has undergone an ischemic stroke, but taking the underlying heart disease and the surgery performed into account. Hypoxia in patients with saturations below 92% should be treated. Low blood pressure should be avoided and treated posturally, with fluid therapy and, if necessary, low doses of phenylephrine. High blood pressure during the acute phase of stroke is usually reactive and tends to reduce spontaneously over the next few days, therefore blood pressure values need not be “normalized”. In principle, the general treatment criteria established for acute phase ischemic stroke, which are covered in another chapter of this book, should be followed. Isotonic fluids can be administered to prevent dehydration, although a volume overload that may worsen the cerebral edema and heart failure should be avoided. Hyperglycemia is an independent predictor of worse neurological evolution, therefore it should be controlled early and glucose-containing solutions should be avoided. Hyperthermia is also an independent predictor of worse neurological evolution, therefore it should be treated vigorously using physical measures and antipyretics (paracetamol).

Anticoagulation therapy with unfractionated or low molecular weight heparin has not been shown to be beneficial for the acute treatment of atherothrombotic or hypoperfusion-related stroke and increases the risk of systemic complications such as hemopericardium. Anticoagulation therapy should be considered in the case of stroke with a demonstrated and persistent cardioembolic source by weighing up the risk/benefit ratio. The use of platelet anti-aggregants (acetylsalicyclic acid) following coronary revascularisation surgery has been shown to be safe and effective as it improves the prognosis of the infarction.

Hemorrhagic Stroke

Attempts should be made to normalize the abnormal coagulation status and the general treatment protocol for acute phase stroke should be followed.

Confusion Syndrome and Post-anoxic Encephalopathy

Confusion syndrome and post-anoxic encephalopathy should be treated vigorously and the underlying causes that may trigger them, especially reversible metabolic abnormalities, corrected. Post-anoxic myoclonic encephalopathy may be treated with piracetam at high doses (up to 24 g/day); valproic acid can be associated according to the response. Atypical neuroleptics should preferably be used for patients with acute confusion syndrome; benzodiazepines should be avoided if possible.

Epileptic Seizures

The cause should be treated whenever possible, and symptomatic treatment with antiepileptic drugs (carbamazepine, oxcarbazepine, gabapentin, levetiracetam, etc.) should be administered. Endovenous levetiracetam or valproic acid according to protocol, instead of phenytoin, is recommended in the case of status epilepticus.

Neuropsychological Dysfunction

Cognitive rehabilitation is recommended and, depending on the intensity and kind of deficits detected, specific treatment by specialized personnel should be considered.

85.6 Complications of the Peripheral Nervous System

Post-operative complications that affect the CNS are highly relevant from the clinical point of view because of their prognosis and risk of disabling sequelae. In contrast with the severity of these complications, little attention has been paid to neurological abnormalities that affect the peripheral nervous system, thus meaning that they are frequently underdiagnosed. However, it is estimated that 2-15% of patients who have undergone heart surgery present post-operative brachial plexopathies and 1-30% neuropathies affecting the phrenic or intercostal nerves.

85.6.1 Brachial Plexopathy

This may occur as a consequence of traction of the brachial plexus, its compression between the clavicle and the first rib with sternal retraction, and during dissection of the internal mammary artery. It manifests clinically as pain, motor weakness, paresthesias and decreased osteotendinous reflexes in the upper limb. Paresthesias are more frequent in the fourth and little fingers and may also present upon compression of the cubital nerve in the elbow. Weakness in the extensor muscle of the second finger of the hand and the small abductor muscle of the thumb differentiates plexopathy from cubital neuropathy.

85.6.2 Phrenic Nerve Neuropathy

The incidence of phrenic nerve neuropathy has been estimated at between 1% and 30% of patients, although its frequency has decreased significantly in the last few years. Lesion of the phrenic nerve occurs upon application of ice to cool the heart, a procedure that is used increasingly infrequently. Patients who present bilateral dysfunction of the phrenic nerve require prolonged mechanical ventilation. Most make a full recovery during the first year.

85.6.3 Intercostal Neuropathy

Dissection of the internal thoracic artery may be associated with a lesion of the anterior intercostal nerves. Intercostal neuropathy evolves clinically with paresthesia and "burning pain" in the sternal region and the left anterolateral region of the thorax. Symptoms are usually partially or fully reversible, although patients may require up to two years to recover.

85.6.4 Femoral Neuropathy

The production of a femoral neuropathy following insertion of an intra-aortic balloon as a result of local trauma, vascular occlusion or formation of pseudoaneurysms has been reported.

85.6.5 Optic Neuropathy

Visual impairment due to ischemic optic neuropathy is rare and occurs as a result of embolism in approximately 0.1% of heart surgery patients.

85.7 Diagnosis and Treatment of Complications of the PNS

Diagnosis is based on clinical data, and symptoms usually remit once the acute phase is ended and the general condition improved. Most lesions occur because of reversible disruption of the myelin sheath (neurapraxia) and usually have a good prognosis, therefore early rehabilitation is recommended. If symptoms do not improve within three weeks of evolution, electroneurography and an electromyogram should be performed to assess damage to axons and to locate the site of the lesion. Administration of vitamin B12 may be useful in both cases. In case of dysesthesias or painful hyperalgesia, treatment with carbamazepine, oxcarbazepine or gabapentin, amongst other drugs, is indicated.

86 Neurogenic Cardiopulmonary Injury

Alejandro A. Rabinstein [1]

[1] Professor of Neurology. Medical Director, Neurological Intensive Care Unit, Saint Marys Hospital, Mayo Clinic. Rochester, MN, USA

86.1 Introduction

The occurrence of neurogenic pulmonary edema (NPE) in patients with acute and severe cerebral injuries has been noted since the beginning of the 20th century.
The first cases were reported in epileptic patients with uncontrollable seizures and, during the First World War, in soldiers with severe cerebral trauma, NPE has been better studied in cases of aneurysmal subarachnoid hemorrhage (aSAH).
Neurocardiogenic damage has been also described in various neurological and neurosurgical pathologies, with the most significant studies being performed in patients with aSAH. The resulting cardiomyopathy is known as tako-tsubo or apical ballooning syndrome. Its identification was facilitated by the routine use of echocardiography, which allows its non-invasive diagnosis and a more detailed study of its incidence and evolution.
The biomedical literature regarding pulmonary and cardiac damage related to severe acute cerebral diseases usually differentiates NPE from neurogenic cardiomyopathy even if these complications can frequently coexist in the same patient. For didactical reasons, we will maintain this division in this Chapter, specifying when the possible interaction between cardiac and pulmonary diseases can influence therapeutic decisions in a considerable way.

86.2 Neurogenic Pulmonary Edema

86.2.1 Causes and Incidence

NPE consists of an increase in interstitial and alveolar liquid which occurs as a direct consequence of an acute damage of the central nervous system. It can occur as a complication of every acute event that affects the brain, the brainstem or the spinal cord at cervical level. Its causes include, among the others, aSAH, traumatic brain of cervical spinal cord injury, cerebral or cerebellar intraparenchymal hemorrhages, ischemic stroke, encephalitis and status epilepticus [1]. Intracranial hemorrhages in general, and aSAH in particular, are the most frequent causes.
Data about NPE incidence in patients with aSAH differs accross studies. This occurs due to the different criteria used for its definition and because of the different populations analyzed. While evidence of pulmonary edema has been demonstrated in more than 70% of fatal cases of aSAH studied with necropsy, the incidence is between 8% and 23% when clinical criteria are considered [1-5]. It is more frequent in patients with severe clinical presentations (Hunt and Hess grades IV and V), or with extensive bleeding (Fish-

er grades 3 and 4) and it is possible that the risk of this complication is greater after rupture of posterior circulation aneurysms [1,3].

86.2.2 Pathophysiology

Traditionally, it is postulated that NPE may be a consequence of an excessive adrenergic discharge which leads to pulmonary vasoconstriction and a rapid increase in pulmonary capillary hydrostatic pressure. The resulting pulmonary and systemic vasoconstriction would cause an transitory but dramatic increase in hydrostatic pressure in the capillary vessels of the pulmonary circulation, causing an alteration in the Starling force and consequently leading to fluid leakage into the alveolar space [6,7].
Undoubtedly, other physiopathological pathways mechanisms may be involved, such as pulmonary capillary vessel damage and activation of the inflammatory response, with consequent increase of the permeability of the hemato-alveolar barrier. This may explain the high protein content in the alveolar fluid observed in experimental models of NPE and in patients with this complication [6,8]. The endothelial damage of pulmonary capillary vessels can be caused by the increase in hydrostatic pressure described, by a direct effect of sympathetic hyperstimulation, or by an acute inflammatory response related to the cerebral damage.

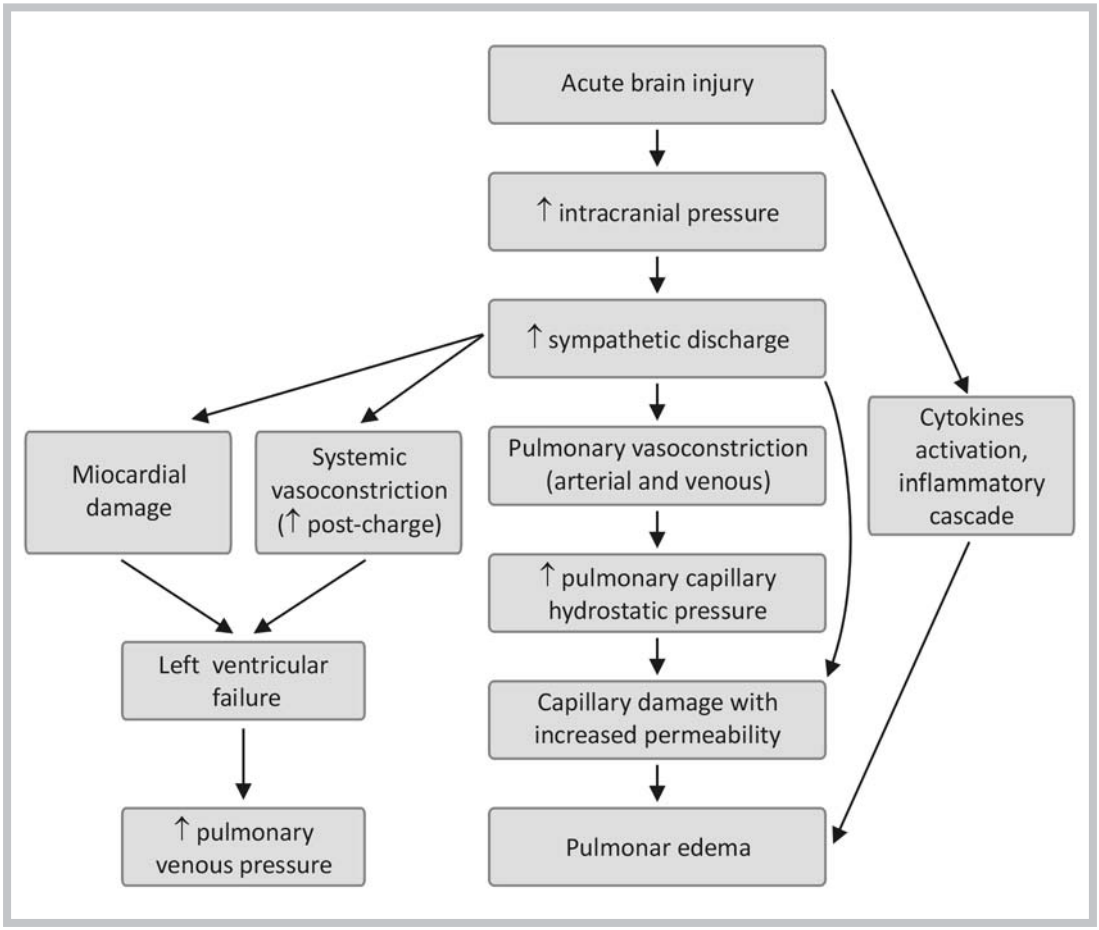

Figure 86.1. Pathophysiology of neurogenic pulmonary edema.

Another element that can contribute to the NPE is the degree of cardiac dysfunction from left ventricular failure. The sudden increase in left ventricular pressure related to the dramatic rise in afterload caused by adrenergically-induced arteiral hypertension can exacerbate the pulmonary hypertension and produce more alveolar edema [9]. In my experience, it can be difficult to discriminate between the two components, neurogenic and cardiogenic, of acute pulmonary edema in neurocritical patients.
Figure 86.1 summarizes the basic concepts regarding NPE physiopathology.

86.2.3 Diagnosis

There are no pathognomic signs which allow the identification of NPE. Its semiology is similar to all the other cases of acute pulmonary edema (dyspnea, hypoxemia, crackles on pulmonary auscultation), but signs of left ventricular failure are frequently absent (absence of cardiac gallop).
Chest films show bilateral pulmonary opacities, corresponding to an increase of interstitial and alveolar liquid (Figure 86.2). Pulmonary infiltrates can resolve rapidly with adequate therapeutic management. In the absence of coexisting cardiac injury, the electrocardiogram does not show major changes and central venous pressure is normal. Although it would be expected to find highly elevated pulmonary capillary wedge pressure, it is not so uncommon to find those pressures within relatively normal range [5]. This is probably due to the fact that the increase in pulmonary wedge pressure is severe but temporary. As a consequence, the pressure can be normalized by the moment the pulmonary hemodynamic measures become available.
The differential diagnosis should include, as in all the patients with acute hypoxemia, ventilator-associated pneumonia, aspiration pneumonitis, atelectasis, acute pulmonary embolism and cardiogenic edema from acute cardiac failure [2,4].
Furthermore it is useful to keep in mind that some hypoxic patients during the acute phase of aSAH can show relatively normal findings on chest X-ray, but this does not exclude the possibility of a of ventilation-perfusion mismatch caused by an increase of intrapulmonary liquid [5]. Once that the other causes of hypoxemia have been excluded, it is appropriate to consider these cases of cryptogenic hypoxemia as possible less severe cases of NPE.

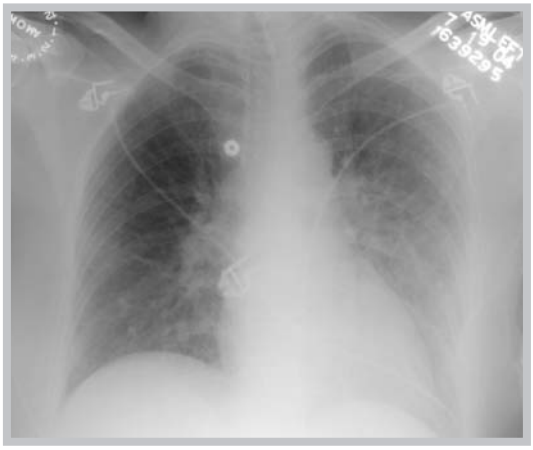

Figure 86.2. **Chest X-ray findings in a case of neurogenic pulmonary edema.**

86.2.4 Treatment

The treatment of NPE is based on the control of the acute neurological disease, with special attention to the reduction of intracranial pressure, and on providing ventilation support to improve hypoxemia [1].
Even if pulmonary complication can be fatal, the majority of deaths in these cases occur as a consequence of the primary cerebral injury. Serial assessment of neurological status and, when indicated, continuous monitoring of intracranial pressure and cerebral perfusion pressure are essential to treat these patients effectively.

Temporary endotracheal intubation and sedation are usually recommended. Some less severe cases can be managed with non-invasive ventilation, but the high levels of positive end-expiratory pressure (PEEP) necessary to treat the hypoxemia may not be well tolerated when are administered via BiPAP mask. Usually PEEP values between 10 and 15 mmHg should be used in cases of severe or moderate NPE. In general, these levels do not compromise cerebral perfusion [10], but the effect of PEEP in the intracranial and cerebral perfusion pressures should be evaluated in each single case. Hyperventilation can be necessary to achieve a fast control of the intracranial hypertension, but prolonged hyperventilation and hypocapnia (PCO_2 <30 mmHg) should be avoided because the resulting cerebral vasoconstriction can cause ischemia. On the other side, permissive hypercapnia, which can be considered an adequate ventilation technique in other cases, is not indicated in the majority of patients with NPE because it can result in worsening of the intracranial hypertension. Ventilation in prone position can be a particularly advantageous option in some patients, and in my opinion should only be performed in patients with severe, refractory hypoxemia [11]. Undoubtedly, these patients should be adequately monitored to ensure that intracranial pressure does not increase when the patient is placed in prone position. The administration of nitric oxide by inhalation should be considered with caution before being prescribed, because its use can increase the risk of hemorrhagic by compromising platelets function.

In patients with intracranial hypertension and NPE, the use of mannitol should be preferred to the administration of hypertonic saline solutions. To decrease the intracranial pressure, the induction of serum hyperosmolarity can accelerate the resolution of pulmonary edema [12]. Pharmacological neuromuscular paralysis can be useful to attain a better control of the intracranial pressure and may be necessary to optimize ventilation and oxygenation. Decompressive craniectomy is a valid option in refractory cases.

The hemodynamic therapy should be ideally guided by echocardiography and, sometimes, pulmonary catheterism. In most cases, bedside echocardiography obviates the need for pulmonary catheterism. When cardiac function is compromised, the use of inotropic drugs can be efficacious. Dobutamine, milrinone, and dopamine (in moderate doses) are valid options. Depending on the systemic arterial pressure, vasodilator drugs (e.g. nicardipine or clonidine), or less frequently vasoconstrictors (e.g. norepinephrine) may be necessary. It is recommended to avoid the use of beta-blockers in all the cases where there is evidence or suspicion of severe heart failure. However, in less severe cases I tend to favor the use of moderate doses of a beta-blocker to prevent additional adrenergically-induce myocardiac injury. Diuretics, such as furosemide, can be used to decrease the preload and they can be administered in combination with mannitol. Once hypoxemia has been corrected, it is very important to remember that in patients with aSAH it is neither necessary nor recommended to maintain the intravascular space contracted, due to the negative effects of hypovolemia on the risk of cerebral ischemia from vasospasm [2]. Once the NPE has resolved, there is no contraindication in these patients for the induction of hemodynamic augmentation therapy (induced hypertension and moderate hypervolemia) if they develop symptomatic vasospasm.

86.2.5 Prognosis

The occurrence of NPE has been associated with worsened functional prognosis, particularly in patients with aSAH [1-3]. This association may be explained by the greater severity of the primary neurological insult in those patients who develop MSE as a complication. Patients with NPE or other acute oxygenation problems often need more prolonged hospitalization in the intensive care unit [5]. However, NPE is eminently treatable and it usually resolves within 24-48 hours with adequate therapy [1].

86.3 Neurogenic Acute Cardiomiopathy

86.3.1 Features, Causes and Incidence

Different cardiac derangements can occur in association with cerebral diseases, including electrocardiographic changes, elevation of cardiac enzymes and transient left ventricular dysfunction. While the majority of these canges are not specific, there is a characteristic form of neurogenic cardiomyopathy known as tako-tsubo or apical ballooning syndrome [13]. This cardiac disorder is usually caused by acute physiological (e.g. in the case of intracranial hemorrhages) or emotional (e.g. "voodoo death") stressors, hence the alternative denomination of "stress-induced cardiomyopathy" [14].

The most frequent electrocardiographic changes are seen during repolarization: T waves inversion (known as cerebral T waves), increase of the QTc interval, and appearance of U waves (Figure 86.3).

ST segment elevation can be confused with acute myocardial ischemia. Tansient Q waves that do not follow the standard evolution of ischemic cases can occur, but are less frequent. These changes were initially described in patients with aSAH and these are the patients in whom they are most often observed in clinical practice. On the basis of the criteria used to define them, the incidence of EGC abnormalities reported in different studies varies, but it is usually accepted that they occur in 40-70% of aSAH cases [13]. The incidence is lower, but nonetheless elevated (15-40%), in patients with ischemic stroke [13].

Cardiac arrhythmias are frequent too. Benign arrhythmias are most common, but fatal arrhythmias can occur. The spectrum of possible arrhythmias includes atrial or ventricular extrasystole, supraventricular tachycardia, torsade de pointes and ventricular tachycardia or ventricular fibrillation [13,15]. In ischemic strokes, the compromise of the insula increases the risk of ventricular arrhythmias and sudden death [16,17]. Whether the side of insular involvement affects this risk is still under discussion [16,17].

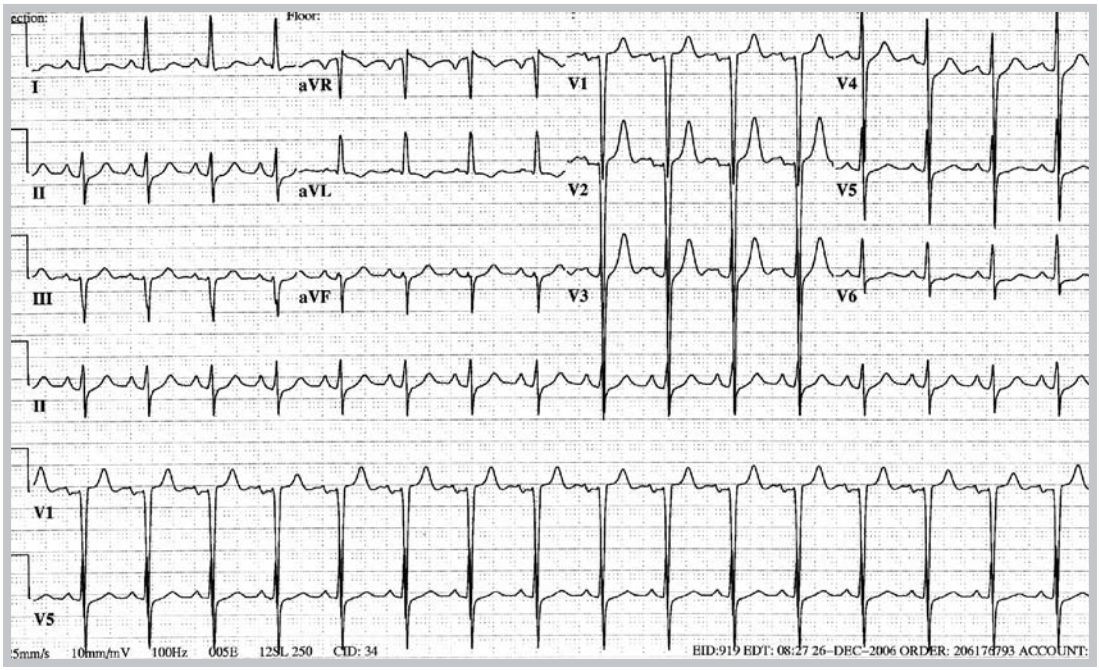

Figure 86.3. Example of electrocardiographic changes in a patient with subarachnoid hemorrhage.

Elevation of cardiac enzymes is frequent in patients with cerebrovascular events, especially if they are severe. Elevated cardiac enzymes can also be seen in patients with seizures, encephalitis, or brain trauma. The levels of both CK-MB and troponin can increase [13,18]. Characteristically they reach a peak during the first day and start declining over the following 1 to 4 days. They correlate with electrocardiographic and echocardiographic changes, but not with coronary disease [19]. Blood levels of brain natriuretic peptide (BNP) are usually increased in patients with electrocardiographic abnormalities [20].

Neurogenic cardiomyopathy can exhibit characteristic echocardiographic features. Regional abnormalities in ventricular motility do not respect the distribution of one coronary artery. Most often involve the apical and septal ventricular segments become akinetic or hypokinetic with relative preservation or hyperkinesis of the basal segments [21]. The resulting appearance of the heart on the ventriculogram explains why this condition has been named tako-tsubo cardiomyopathy ("Tako-tsubo" is the Japanese name for octopus traps that fishermen still use to catch octopus) or apical ballooning syndrome. Yet, atypical echocardiographic patterns can also occur [22]. This kind of cardiomyopathy is more frequent in post-menopausal women suffering of severe aSAH [14,19,23]. In patients with ischemic stroke, this pathology is much more frequent in women with stroke and insular damage [24]. Ejection fraction of the left ventricle decreases suddenly after the cerebral event, but returns to normal over the following 4 weeks [13,14,23]. It can be associated with acute pulmonary edema and can require hemodynamic support.

86.3.2 Pathophysiology

Acute neurogenic cardiomyopathy is thought to be caused by the injury of myocardial fibers and terminal nerves due to a massive sympathetic discharge [13,14,25,26]. This pathophysiological explanation is supported by the reports of apical ballooning in after infusion of cathecolamines [27]. In patients with SAH-related cardiac dysfunction a state of sympathetic denervation with normal myocardial perfusion has been demonstrated [25]. The pathological correlate is contraction band necrosis (also known as myofibrillary degeneration or coagulative myocytolysis) that occurs in proximity of sympathetic nerve terminals and does not respect the boundaries of coronary artery territories [13].

86.3.3 Diagnostic Evaluation

All patients with acute cerebral injuries should be managed in intensive care units, ideally dedicated units with neurological expertise, and be kept on cardiac telemetry. The initial evaluation should include an electrocardiogram, a chest X-ray and cardiac enzymes in all the cases, and a transthoracic electrocardiogram in patients with pulmonary edema, hypotension, or other manifestations of cardiac dysfunction. Furthermore it is prudent to perform an echocardiogram in postmenopausal women with severe aSAH even if there are no signs of cardiac failure, because these patients are at high risk of developing stress-induced cardiomyopathy. In patients with echocardiographic changes compatible with neurogenic cardiomyopathy, it is not necessary to evaluate the coronary circulation. In these cases it is advisable to repeat an echocardiogram after 1-2 weeks to reassess the ventricular function. Pulmonary catheterization is only necessary in cases of refractory shock. Figure 86.4 highlights a diagnostic algorithm to be considered when acute neurocardiogenic injury is suspected.

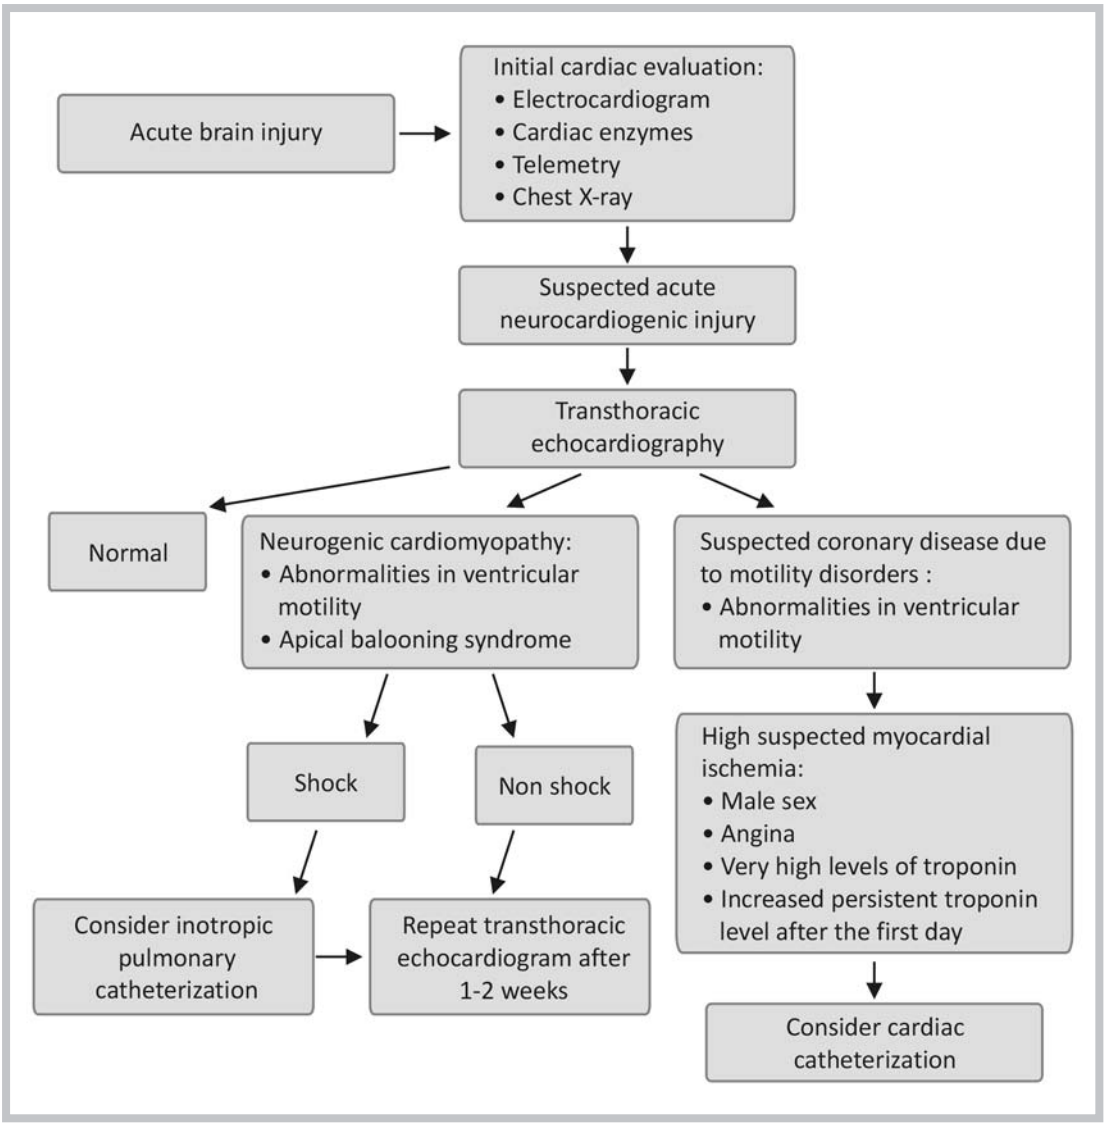

Figure 86.4. **Evaluation and management of patients with suspected acute neurogenic cardiomyopathy. Modified from [14].**

86.3.4 Treatment

The main tenets of treatment of acute neurogenic cardiomyopathy are hemodynamic support and cardiac rhythm monitoring. It is preferable to use inotropic drugs instead of pure vasopressors in case of hypotension. Diuretics such as furosemide are necessary when cardiogenic pulmonary edema is present. Arrhythmias should be treated as in other cases. In patients with prolonged QTc interval it is particularly important to avoid or correct any degree of hypokalemia and hypomagnesemia. In patients with aSAH and vasospasm who still have depressed cardiac function, therapeutic options include inotropic drugs, insertion of an intra-aortic balloon pump, and intra-arterial techniques, such as angioplasty or selective infusion of calcium channel blockers [13,14].

The prophylactic use of beta-blockers in patients at high risk of acute neurogenic cardiomyopathy can be useful, but more studies are needed before it can be recommended.

86.3.5 Prognosis

Although the cardiac dysfunction is reversible [28], most studies have shown that the presence of elevated troponin levels and electrocardiographic changes are associated with worse prognosis in patients with aSAH, intraparenchymal hemorrhage and ischemic stroke [18,29,30]. Available data is insufficient to determine if this correlation could be a direct consequence of cardiac damage or a surrogate marker of more severe acute brain disease.

87 Acute Hydrocephalus in the Neurointensive Care Unit: Etiology, Diagnosis and Treatment

Ricardo Carhuapoma [1]

[1] Associate Professor of Neurology, Neurosurgery and Anesthesiology & Critical Care Medicine, The Johns Hopkins Hospital, Baltimore, USA

87.1 Introduction

This chapter describes the etiology, diagnosis and management of acute hydrocephalus, a common cause of neurological impairment and intracranial hypertension in neurocritical patients. Various disease entities may lead to hydrocephalus. Special emphasis will be devoted to the use of intraventricular catheters or drains in the management of acute hydrocephalus, as well as the use of catheters or lumbar drain. Complications from their use will also be discussed. A brief review of the intracranial hypertension syndrome is given.

87.2 Intracranial Hypertension

The intracranial hypertension syndrome comprises a variety of disease entities. The neurological diseases making up this syndrome may originate in the brain parenchyma or abnormalities in cerebrospinal fluid flow or cerebral blood volume (Table 87.1).
The clinical manifestations of intracranial hypertension are not specific. The etiology of this syndrome has a broad differential diagnosis. Diagnosis is based mainly on suggestive symptoms and signs (see next section), together with brain imaging studies including computed axial tomography (CAT) and cerebral magnetic resonance imaging (MRI). In patients with a level of consciousness of <9 on the Glasgow Coma scale (GCS), invasive monitoring of intracranial pressure is justified. The ideal tool to monitor the pressure is an intraventricular catheter (when the lateral ventricles are dilated enough for appropriate catheter insertion). The use of such catheters facilitates intracranial pressure measuring and relieves pressure by draining cerebrospinal fluid (CSF).

Brain parenchyma	Hematoma, tumour, brain abscess, brain edema
Cerebrospinal fluid	Hydrocephalus
Cerebral blood volume	Hypertensive encephalopathy, cerebral vasodilatation secondary to systemic hypotension, fever, dehydration in patients with abnormal brain compliance

Table 87.1. **Neurological diseases making up intracranial hypertension syndrome.**

87.3 Acute Hydrocephalus

The hydrocephalus syndrome is characterized by an increase in CSF volume. Two groups of causes of hydrocephalus are distinguished: 1) increased production of CSF and 2) reduced reabsorption or obstruction of normal CSF flow. In neurological/

Obstructive hydrocephalus	• Tumours
	• Primary intraventricular hemorrhage:
	  ▪ Hypertensive hemorrhage
	  ▪ Primary vascular abnormality
	• Secondary intraventricular hemorrhage:
	  ▪ Trauma
	  ▪ Subarachnoid hemorrhage
	  ▪ Parenchymal hemorrhage with ventricular extension (Figure 87.1)

Communicating hydrocephalus	• Suppurative meningitis • Subarachnoid hemorrhage (subacute/chronic) • Intraventricular hemorrhage (subacute/chronic)

Table 87.2. **Types of hydrocephalus.**

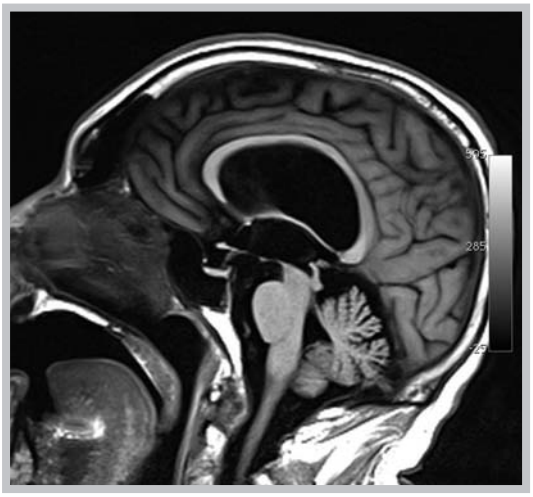

Figure 87.2. **MRI (sagittal section) of patients with hydrocephalus associated with aqueduct stenosis.**

neurosurgical intensive care, acute hydrocephalus is most often caused by a reduction in reabsorption of CSF or an acute obstruction of normal CSF circulation.

The clinical presentation is not specific; characteristic symptoms and signs include: elevated intracranial pressure, reduced consciousness, nausea and vomiting, occasional signs of meningeal irritation due to mechanical traction of the meninges. In advanced stages, lower limb motor weakness with pyramidal signs is frequently found on neurological examination. Papilledema is common in advanced stages. Although the syndrome of intracranial hypertension is simple to identify and familiar to most medical professionals in neuroscience, it is frequently superimposed over an underlying cause: subarachnoid hemorrhage, intracerebral hemorrhage, midline shift with "trapped ventricles", and brain tumours among others. Seeking the causes of this complication in high-risk patients presenting with an unexplained decrease in consciousness is therefore essential. The degree of risk is stratified according to risk factors. Imaging studies such as CT of the brain are needed to confirm the diagnosis. Nuclear magnetic resonance (NMR) is the most appropriate study for obtaining a more accurate anatomical definition (Figure 87.2). Additionally, although of limited use, scales such as the bi-caudate index (size of the frontal caudate ventricles divided by the diameter of the skull at that level) can provide objective values for monitoring patients.

87.4 Treatment

In addition to treating the underlying disease, the emergency treatment of acute hydrocephalus syndrome involves placement of an external ventricular drain (EVD [1,2] via ventriculostomy or intraventricular catheters (IVC).

The most common indication for catheter insertion is a reduced level of consciousness in patients with a radiographic diagnosis of acute hydrocephalus. A description of techniques for external ventricular drainage is beyond the scope of this chapter. The reader is referred to the references listed at the end of this chapter. In general, after insertion of the IVC, the necessary connections are completed (Figures 87.3 and 87.4).

The IVC is connected to a 3-way valve. One line is connected to the drainage chamber, the second to the IVC, and the third to a pressure transducer. Intracranial pressure (ICP) can only be measured after closing the valve to drain the chambers. This will produce a single column of liquid in contact with the membrane transduction.

Management of the IVC will vary depending on the etiology of acute hydrocephalus; however, some general principles are valid and deserve to be discussed:

- The use of an external ventricular drain for acute hydrocephalus is an emergency procedure and can potentially prevent permanent loss of neurological function. However, it is a temporary measure until definitive treatment is identified and instituted.
- The initial goal of ventriculoperitoneal shunting (VPS) is to control intracranial hypertension. However, excessive drainage of CSF should be avoided for the following reasons:
  - Superior cerebellar herniation syndrome [3]. Cerebellar tissue can be pulled along a caudorostral vector, compressing the structures related to the anatomy of consciousness (rostral brainstem and thalamus). This complication ensues from a pressure differential between the different ventricular structures.
  - Re-bleeding from re-rupture of vascular malformations such as aneurysms, arteriovenous malformations, or hypertensive bleeding; this results in a sharp reduction in

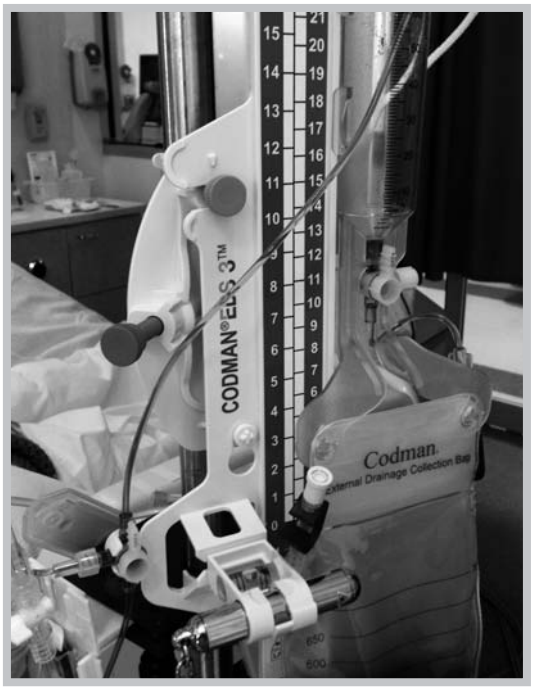

Figure 87.3. Ventricular drainage system.

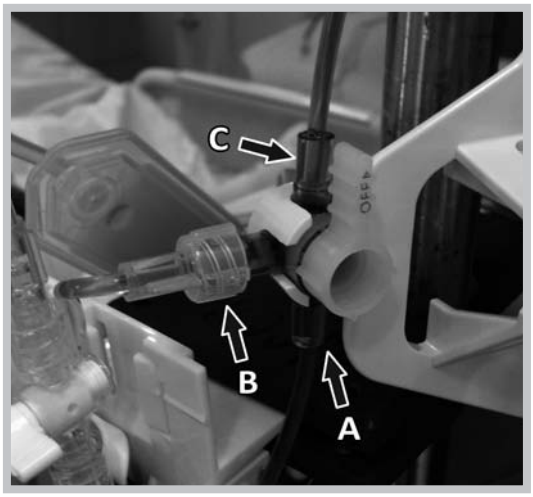

Figure 87.4. Three-way valve with the patient connected (A) to the transducer (B) and the reservoir (C).

transmural pressure due to the hemostatic mechanism that serves for acute or "buffering".

- If the cause of acute hydrocephalus requires surgery (e.g., brain tumour), such treatment should be instituted when the patient has been stabilized. If the cause of acute hydrocephalus requires acute surgical procedures, EVD management varies depending on the natural history of the underlying disease. Once it is determined that the patient requires chronic artificial CSF drainage, a ventricular shunt system will be inserted.

87.5 Intraventricular Catheter Management

In general, the decision to begin discontinuing VPS depends on the following variables:

- Stable neurologic patient.
- Normalization of intracranial pressure.
- Reasonable expectation of normalization of CSF physiology and anatomy, based on the patient's clinical course and knowledge of the natural history of the underlying disease.
- Neurological examination to monitor clinically appropriate response to the discontinuation process.

Once the patient meets these requirements, the "pop-off", or the elevation of the reservoir chamber of the ventriculostomy system, is gradually elevated. Generally, when the pop-off is low (<10 mmHg), CSF drainage may be high (>200 cc/24 h). Pop-off elevations of 5 mmHg every 24 hours is a common practice. The neurological examination, intracranial pressure (ICP) and volume of CSF drained in 24 hours will be taken into consideration. If the neurologic examination and ICP remain stable, the pop-off should be raised every 24 hours to 15-20 mmHg.

At these levels, if drainage is <200 cc/24 h in association with normal ICP values and the neurological examination is stable, pop-off elevations of up to 20 mmHg are recommended. At this level, the drain is clamped, and the neurological examination and ICP are monitored for 24 hours. If these parameters are stable, the drain can be removed. A brain CT study is recommended before removing the drainage system. This recommendation is justified if there is a need to compare ventricular size before and after removing the IVC in case of future clinical deterioration.

If during this process the patient demonstrates neurological impairment, the pop-off must be reduced or the IVC must be reopened. Other causes of encephalopathy should be studied concomitantly, such as metabolic processes, fever, subclinical seizures, and so on. CT can help determine the cause of deterioration. Clinical response to ventricular drainage in this scenario is, however, essential to determine its cause.

87.6 Management of the Catheter or Lumbar Drain

A lumbar drain is a catheter inserted under aseptic conditions in the intervertebral space (L4-L5). The technique involves the use of a Tuohy needle through which the drain is inserted cephalic into the spinal subarachnoid space. This type of CSF drainage is feasible only in cases of communicating hydrocephalus or when elevated ICP is diffuse, in the absence of pressure gradients between cranial compartments. Subsequent management, following the principles described above in the management of IVCs, depends on the

underlying disease [4,5]. This kind of management of acute hydrocephalus or intracranial hypertension (below), though limited to certain diseases, is interesting because it is less invasive than IVC and the implicit risk of brain damage, especially bleeding. The risk of infection persists for the duration of use of these drains.

87.7 Complications

Infections:

- Prophylactic antibiotic therapy is restricted to a dose of antibiotics with activity against Gram-positive bacteria before insertion of ventriculostomy drains impregnated with antibiotics [6].
- Parenchymal hemorrhage in the ventricular drain tract.
- Subdural hematoma, a complication of excessive drainage of CSF.

88 Chronic Subdural Hematoma: A Forgotten Entity in Neurocritical Care

Daniel Agustín Godoy [1]; Rubén Horacio Manzi [2]

[1] Neurocritical Care Unit. Sanatorio Pasteur. Intensive Care Unit, Hospital ''San Juan Bautista'', Catamarca, Argentina
[2] Neurosurgical Department and Medical Director. Sanatorio Pasteur, Catamarca, Argentina

88.1 Introduction

The first description of this entity dates back to 1857 when Virchow termed it "internal hemorrhagic pachymeningitis". Years later, he established the relationship between trauma of subdural veins or "bridging veins'' and the onset of chronic subdural hematoma (CSDH), then named "subdural hemorrhagic cyst". Since then, trauma has been recognized as one of the major risk factors for the development of CSDH.
Classically, CSDH has been considered benign. In our experience, this assumption is far from reality because CSDH can cause various complications with a mortality that, in some recent studies, has been estimated to be 15%. Current opinion in the neurosurgical community considers hematoma evacuation essential in the treatment of symptomatic patients. Opinions differ, however, on other therapeutic options, including the most convenient surgical technique, approach of recurrences or peri-operative management.

88.2 Definition

Chronic subdural hematoma (CSDH) is a subdural blood accumulation surrounded by a newly formed membrane located between the dura mater and the arachnoid space. Generally it manifests clinically 3 weeks after a triggering event that can be or not evident or identifiable. Subacute subdural hematoma develops between 3 and 20 days after the precipitating event. Its form of presentation, clinical features, and treatment are similar to those of CSDH.

88.3 Epidemiology and Risk Factors

The incidence of CSDH is near to 1.7 per 100,000 individuals per year. Mean age at presentation is 63 years. Its incidence is 7 times higher after age 70 years and is expected to increase with longer life expectancy. Age is one of the most important risk factors because the aging process brings two changes related to the development of CSDH. On the one hand, the increased fragility of the bridging veins make them more susceptible to rupture even after minor trauma and on the other side there is a remarkable increase in the subdural space available for the accumulation of collections due to generalized cerebral atrophy. A history of trauma can usually be elicited in 50-70% of cases. Often, such

trauma was minor and in many casesa history of accidental fall, without a direct impact to the head is present. Approximately one quarter of patients is under anticoagulation treatment and 5-10% have a history of epilepsy or alcohol abuse.
Table 88.1 lists predisposing factors for the development of CSDH.

- Age
- Head trauma
- Epilepsy
- Alcohol
- Hemorragic diathesis/coagulopathy
- Oral anticoagulant therapy
- Antiplatelet therapy
- Hemodialysis
- Intracranial hypotension (lumbar puncture, cerebrospinal fluid [CSF] derivations or shunts)

Table 88.1. Risk factors.

88.4 Pathophysiology

From an anatomopathological point of view, within 24 hours after the accumulation of blood in the subdural space, caused by either trauma or another factor, the hematoma is invaded by fibrin and fibroblasts originating from the dura mater. One week later, a membrane forms on the external surface of the hematoma and increases progressively, allowing fibroblasts to invade the hematoma, with the development of a thin internal membrane. The latter process ends after 3 weeks. The hematoma is then liquefied by phagocyte activity and can follow two paths:

- Spontaneous absorption of the hematoma, thus solving the problem, or
- Progressive growth of the hematoma, resulting in CSDH.

Two hypotheses try to explain the growth of hematoma. In 1932 Gardner, studying experimental models, postulated the osmotic theory, based on the premise that fluid from plasma of neoformation vessels of the dural surface or CSF is attracted into the subdural space through osmotic gradient created by the breakdown of blood products of the acute hematoma. This phenomenon is facilitated by the semipermeable nature of the subdural hematoma membrane. This theory was later confirmed by the studies of Zollinger and Gross. In an experimental study, Glover et al. showed that corticosteroids decrease the permeability of the CSDH membrane to proteins, thus decreasing the size of hematoma. Nevertheless, some evidence exists to refute this theory. Gitlin analysed the total ratios between albumin, gammaglobulins and proteins in the subdural liquid and the plasma and found that the concentrations were remarkably greater in the subdural fluid. This fact cannot be attributed to the lysis of erythrocytes because of the lack of these proteins, suggesting that albumin comes from the newly formed vessels of the membrane of the subdural hematoma.
Additionally, Rabe et al. highlighted that albumin marked with iodium^{131}, administered intravenously, appears quickly in the subdural collection. Weir compared the osmolality of the subdural hematoma fluid, venous blood, and cerebrospinal fluid and found no significant difference between them.
The most widely accepted theory sustains that “bleeding recurrence” is the main reason for hematoma growth. Magnetic resonance imaging (MRI) or computed tomography (CT) show different densities of the hematoma. Clots of different ages, consistencies and stages are often encountered at surgery.
This theory was reinforced by Ito et al. who infused red cells marked with 51 Cr-labelled and studied their concentration in a fluid obtained during craniotomy performed between 6 and 24 hours later. They estimated that new hemorrhages contributed on average to 6.7% of the hematoma content. The authors also proposed that hematoma has a high fibrinolytic activity that contributes even more to the increase in its size.
Several anatomopathology studies have explained this aspect better, demonstrating structural alterations in the capillaries of the membranes of the hematoma that can

favour the continuous passage of small amounts of blood towards the interior of the hematoma (Figure 88.1).

Recent studies have demonstrated that the hematoma content is characterized by elevated levels of cytokines and endothelium-derived growth factors that can contribute to the formation and development of membranes, and considerable amounts of inflammation mediators and fibrinolytic factors that can concur in the genesis of hematoma. Therefore, it seems that the hematoma itself is responsible for its chronic evolution.

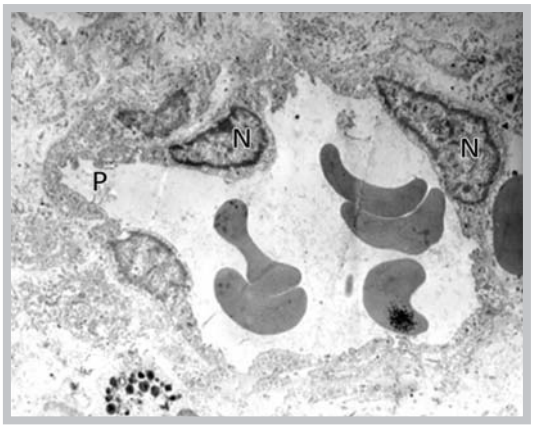

Figure 88.1. **Electronic microscopy showing the external membrane of a chronic subdural hematoma. An ample hair light (l) with erythrocytes is visible within its interior (EC), a thin layer of endothelial cells rests on a discontinuous basal membrane (X 5000).**
N = nucleus
P = protrusion

Since CSDH develops in the atrophic brains of adults of advanced age, the intracerebral pressure (ICP) usually remains within normal limits or rises slightly. Positron emission tomography (PET) studies that evaluated changes in metabolism and cerebral blood flow (CBF) are contradictory. Ikeda found a local reduction in CBF in hemiparetic patients. Ishikawa demonstrated an increase in cerebral oxygen extraction in the hemisphere adjacent to the hematoma, accompanied by a marked reduction in CBF and cerebral metabolic oxygen rate ($CMRO_2$) mainly in the frontal and temporal lobes and in the basal ganglia.

Recently, Yamada et al. observed a small bilateral reduction in CBF and $CMRO_2$, while oxygen extraction, cerebral blood volume, and cerebrovascular reactivity remained stable. All the altered variables stabilized within 4 weeks after hematoma evacuation. This period is shorter (average 3 days), in patients in which the symptoms reverse.

88.5 Clinical Features

The diagnosis of CSDH requires a high degree of suspicion. Due to its multiple forms of presentation, it is known as “the great imitator”. The commonest onset form is an altered mental state (50-70%). Delirium, confusional states, psychotic symptoms or alterations in behaviour are some of the symptoms that often can lead to the wrong diagnosis of psychiatric diseases or dementia.

In less than half of cases consciousness is impaired, varying from confusion to coma. Near to 60% of patients present with focal neurological deficits characterized by a location contralateral to the hematoma, slow evolution, and fluctuations (appearance and disappearance). Sometimes the symptoms are similar to those of a brain tumour patient with signs of elevated ICP such as migraine, vomiting and hemiparesis. Convulsions are infrequent, except in patients with a history of previous seizures. If they do occur, they are almost always associated with large collections. Other manifestations, although less common, include: gait and position disturbances, ataxia, akinesia, rigidity or extrapyramidal syndromes. In some cases, the hemiparesis may be ipsilateral to the hematoma; this can be explained by displacement and compression of the brainstem against contralateral tentorium.

88.6 Role of Neuroimaging Studies in Diagnosis

The neuroimage of election is CT scan because it is not invasive, it is rapid and low cost; in addition, it also allows the evaluation of other intracranial structures. CSDH has a dynamic nature, therefore requires considering this aspect due to the characteristics of the collection change with the time. During acute phase, the hematoma is hyperdense in relation to cerebral parenchyma due to the presence of fresh blood.

In 40% of acute cases, the density can be mixed with hypodense areas. This finding could be due to the fact that bleeding is so recent that part of the blood is not yet coagulated or because of the presence of CSF originating from the arachnoids.

With time, lysis of the collection takes place, so that the hematoma becomes as dense as the cerebral tissue (isodensity). In the chronic phase, beyond the third week, the collection begins to be reabsorbed, so that the hematoma acquires a hypodense aspect. Nevertheless, remembering the concepts explained in the paragraph on pathophysiolo-

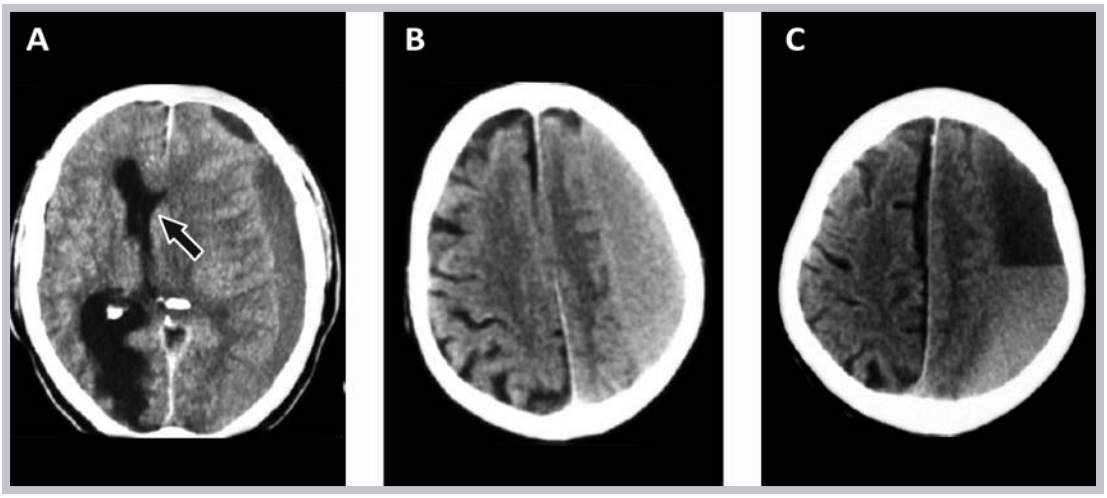

Figure 88.2. (A). Hypodense subdural hematoma with marked midline shift (arrow). (B). Isodense hematoma. (C). Hematoma with mixed density.

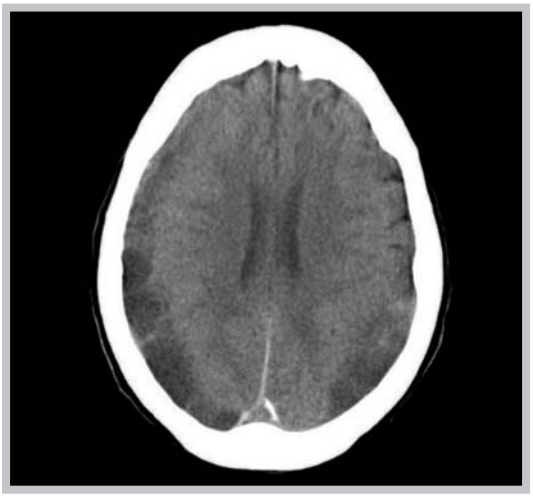

Figure 88.3. Bilateral subdural hematoma with isodense areas.

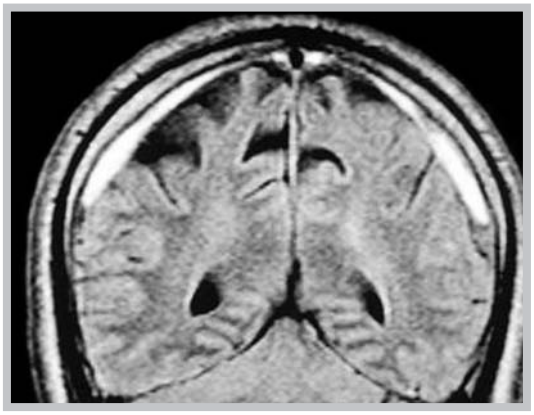

Figure 88.4. T1-weighted image of CSDH.

gy, continuous microhemorrhages can produce sometimes a collection with heterogeneous aspect sometimes with mixed areas with different densities due to precipitation of fresh blood in the declivities (Figure 88.2).

Generally, identifying a hematoma is easier when it appears as a hyperdense. The difficulties arise with isodense collections. In such cases, mainly in non trained eyes, it's very important the analysis of other structures, such as the median line, lateral ventricles and the sulcus between cerebral circumvolutions which often are displaced, compressed or absent, respectively. Another source of confusion is the finding of isodense images after recent trauma. This can be related to very low hemoglobin levels. Bilateral hematomas, usually don't produce midline shift, but may lead to medial compression of both ventricles, resulting in a narrow, elongated ventricle that can suggest a diagnosis of isodense hematoma (Figure 88.3). In such cases, misdiagnosis may be avoided by injecting contrast material, that reinforce internal membrane of the hematoma, cortical sulcus and vessels.

MRI can be especially useful in patients with isodense hematoma without impairment of other cerebral structures or in those cases with hematoma localized at the vertex, the base of the skull or posterior fossa. In addition, MRI allows the identification of small or transversally oriented collections. CSDH is hyperdense on T1 and T2 sequences, reflecting acute bleeding within a chronic collection. On T1 images it can be isodense (Figure 88.4).

88.7 Treatment

88.7.1 Surgery

Chronic subdural chronic hematoma is a surgical emergency, although conservative treatment has been successful in some cases. There is nearly unanimous agreement among neurosurgeons that hematoma evacuation is the gold standard mainly in symptomatic cases or when the thickness of the collection is >1 cm (on the tomograph scale); nevertheless, consensus on the surgical technique is lacking. Two recent surveys in Canada and the United Kingdom support this affirmation. Different options exist. Here we will list them, without entering into a detailed description.

- Twist-drill craniotomy. If the drainage orifice is small and drainage is not left, the index of recurrence is increased.
- Burr hole trephination (two or three), for which irrigates normal saline solution and causing the washing of the collection, until the collection is washed out, giving the brain time to re-expand. A closed drainage system can be left, but some still prefer the technique of "last points".
- Conventional osteoplastic craniotomy, with extirpation of the external membrane of hematoma. Deep membrane is not extirpated, because is attached to the brain and may damage it.
- Neuroendoscopic treatment
- Terphination, making a great hole, through which washing is introduced.

Data from evidence-based medicine do not allow to establish standard treatment guidelines for the surgical treatment of CSDH. Neither trials nor information exist that demonstrate which type of management is better, even if some recommendations are possible; all have a low level of evidence (C):

- Both burr hole trephination and twist-drill craniotomy are safe methods.
- Burr hole trephination has a better treatment/complication ratio and lower recurrence rates than twist-drill craniotomy.

- Conventional osteoplastic craniotomy and burr hole trephination have lower recurrence rates.
- Closed drainage systems reduce the risk of recurrence without increasing the risk of other complications.

88.7.2 Neurointensive Care

Although the treatment of CSDH is generally surgical, almost 20% of cases can resolve spontaneously, principally due to a collections of lower size. If one decides to wait, it is essential to closely monitor the state of consciousness, performing neuroimaging (CT or MR) at the minimum sign of neurological deterioration. Perioperative management doesn't differ from the management of other neurocritical illnesses, except for some controversial aspects that we will analyze below.

Position of the Head: 0 or 30 Degrees?

In medicine in general, and intensive care in particular, there are dogmas that are handed down from generation to generation, even with the lack of solid scientific evidence. One of these controversial topics is how the head should be maintained after CSDH evacuation. Several opinions among neurosurgeons exist. Some advocate a horizontal (0 degrees) head position, others an elevated position, and still others suggest alternating the positions throughout the day. Advocates of the horizontal position base their rationale on "physical reasons", because, in theory, this position diminishes the potential space (which can be increased by the cerebral atrophy that accompanying ageing) where hematoma could develop. In addition, horizontal position annuls the effect of the gravity, improves cerebral perfusion and favours cerebral expansion due to vigorous transmission of arterial compression waves within cerebral parenchyma,. Finally, the horizontal position theoretically improves the drainage of subdural collections.

Some neurosurgeons systematically elevate the head to 30 degrees. It is well known, and it has been previously discussed in other chapters of this book, that elevating the head favours the reduction of intracerebral pressure (ICP), facilitating the venous drainage of the brain. Additionally, remember that two theories try to explain the growth of subdural hematoma: the osmotic theory and the theory of recurrent bleeding. Both these components disappear, at least hypothetically, when the head is elevated because the necessary pressure gradient for the development of the osmotic theory diminishes and the action of gravity decreases the intraluminal pressure from the neoformation vessels of the external membrane of the hematoma that originate recurrent bleeding. Other no less important reasons support the choice for head elevation. Gastrointestinal system of the neurocritically ill patients does not work correctly, becoming paralyzed or slowed down due to cerebral damage or side effects of the drugs commonly administered (e.g., morphine, fentanyl, diphenylhydantoin, noradrenaline, etc.). In addition, the use of acid blockers such as omeprazole and lanzoprazole, or blockers of the acid secretion of the stomach like ranitidine, elevate the pH, thus favouring the growth of microorganisms, mainly Gram-negative species. Also, the lower oesophageal sphincter, whose main function is to prevent gastric reflux, doesn't work properly. All these aspects can augment the risk of continuous microaspirations, which is one of the main risk factors in the pathogenesis of ventilation-associated pneumonia. This risk remarkably decreases when the head of the bed is raised to 30 degrees or more.

In conclusion, there is no consensus on head position during the postoperative period. Nakajima reported that the rate of recurrence is the same for both positions, whereas Miele et al. found no differences in the rate of expansion or in the recurrence of hematoma.

Corticosteroid Therapy: Yes or No?

Anecdotal series, with a small number of patients, or single case reports suggest a favourable effect of corticosteroid therapy in conservative treatment. The rationale for the use of corticosteroids in CSDH lies in its capacity to decrease the permeability and its antiangiogenic properties over the subdural clot membrane, both mechanisms derived from experimental studies and very few clinical studies. Data obtained from a retrospective series suggests that dexamethasone (4 mg every 8 hours) is at least a feasible and safe option in the management of CSDH, however, no evidence for their efficacy exists since the studies were not validated in large-scale populations or in randomized controlled trials.

Anticonvulsants

Seizures as presentation form of CSDH are rare with reported rates around 6%. During postsurgical period the data reported are contradictory. The incidence of seizures appears to be inversely related to the population size. In a small series of 50 subjects, the estimated incidence was 32%, whereas the average rate was 3 and 0.3% in two studies involving 568 and 1439 patients, respectively. Since all the reported studies were retrospective, the systematic use of anticonvulsants cannot be recommended. We use anticonvulsants agents in the following circumstances:

- History of epilepsy.
- Previous utilization of anticonvulsants drugs.
- Convulsions as a presenting form of CSDH.

If the patient is already efficaciously treated with anticonvulsants, the same therapeutic scheme should be continued.

Antibiotics

Although most neurosurgeons or neurointensivists prescribe antibiotics, the best timing, dosage, administration route and therapeutic options are still unclear. From an infectious point of view, the wounds produced by techniques to evacuate CSDH are considered “clean” because they do not produce trauma, tissue damage, potentially do not invade or penetrate contaminated systems such as the digestive, respiratory or genitourinary. If the conditions of surgical asepsis are followed, the use of IV cephazoline 1 g during induction of anesthesia in a single dose is recommended.

88.7.3 Postsurgical Complications

Despite ongoing advances in surgical techniques, postsurgical outcome has remained unchanged. The main reasons for deterioration during the postoperative period are complications associated with hematoma evacuation. This is the reason for which the intensivist must learn to recognize them early for take all necessary measures for their quick and favourable resolution.

The complications rate is >20%, with **recurrence of hematoma** the most frequent one. The incidence of recurrences is 8-45% depending on the series analyzed, and the main risk factors are patient age and the anatomical characteristics of the collection and the membrane. It is often difficult to differentiate between the residual liquid of the surgery and the liquid caused by re-accumulation of the hematoma from recurrent bleeding. This last possibility must always be taken into consideration especially in patients who do not improve or deteriorate during the postsurgical period. In such cases, the drainage debit should be monitored, paying attention to the occurrence of abrupt increases or decreases. If any of the described situations occur quickly, a CT must be performed to reveal the presence of mixed or elevated density collections.

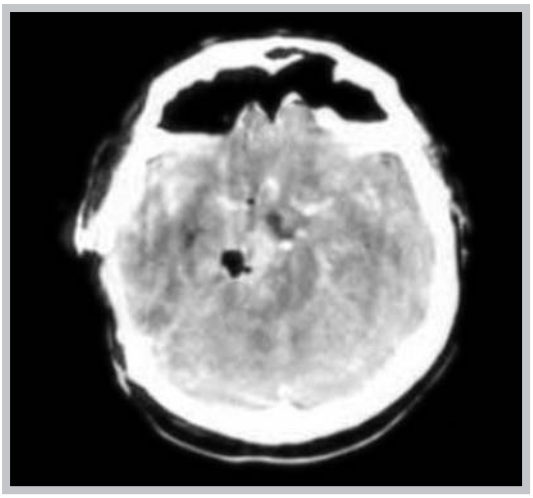

Figure 88.5. **Hypertensive pneumoencephalus in the anterolateral region of the frontal lobes with cerebral edema.**

Occasionally, in approximately 8% of cases, **air is entrapped in the subdural space**. This is favoured by the slow re-expansion of an atrophic brain, chronically compressed by hematoma. Air accumulation can be prevented by maintaining the head horizontal, irrigating the cavity with saline solution to promote slow drainage together with residual hematoma. Nevertheless, and even with preventive measures, the entrapped air can sometimes increase the pressure, causing mass effect and neurologic deterioration. Another important factor that contributes to mass effect is that the volume of the entrapped air increases as the body temperature rises. When entrapped air provoke mass effe, this situation is referred as **hypertensive pneumoencephalus**; this risk should always be taken into consideration because it is a surgical emergency that requires immediate intervention (Figure 88.5).

A lethal complication, fortunately rare, is the development of **intracerebral hemorrhage** (Figure 88.6). McKissock in 1960 was the first to describe a patient who deteriorated suddenly and died after hematoma evacuation. The autopsy revealed bleeding in the brainstem. Since this report, other reports and case series have been published. The reported incidence is around 4-5%. Several theories have attempted to explain this phenomenon but the most consistent one is that the sudden decompression following evacuation of the hematoma is related to a significant increase in cortical cerebral blood flow in blood vessels that have lost their autoregulation. This hypothesis is not sufficient to explain the bleeding that occurs distant from the surgical site, so other factors must be considered, such as coagulopathy, hypertension, amyloid angiopathy, direct damage to the vasculature as a result of displacement, etc.

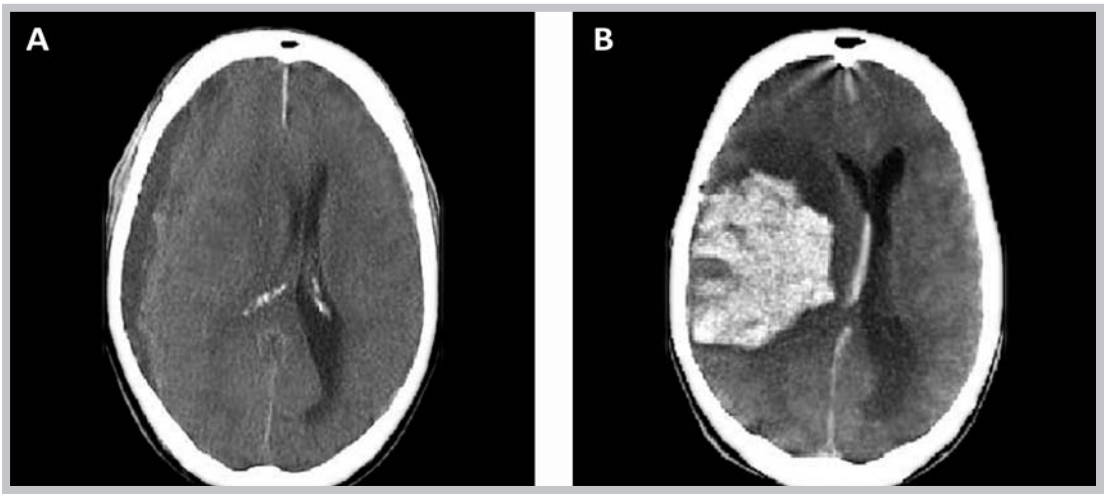

Figure 88.6. **Intracerebral hematoma after evacuation of a hypodense CSDH.**

In the first three days after surgery, the intracranial hypertension syndrome can occasionally occur; its substrate is cerebral edema. This does not usually cause major problems because the standard measures for the management of elevated ICP are normally sufficient to handle this situation.
Other postsurgical complications (approximately 10% of cases) are reversible delirium, or confusional state caused by intracranial hypotension or the onset of seizures.
Other complications are infections, which, although rare, cover a wide spectrum from wound infection to subdural empyema. They are described in detail in another chapter of this book.

88.8 Prognosis

Several predictors of outcome has been described. The preoperative state of consciousness has been found to be of greater significance in different case series. Markwalder devised a scale that allows classifying the degree of clinical deterioration. Multiple CT findings can be associated with preoperative conditions and postoperative recovery of the state of consciousness, including: degree of cerebral atrophy, presence of hydrocephalus, pneumoencephalus, levels of sedimentation, and hematoma density. Interestingly, there is no relationship between hematoma volume, degree of impaired consciousness and/or outcome.

Grade	Description
0	Neurologically normal
1	Alert and orientated: absence of mild symptoms such as headache, or mild neurological deficit such as reflex asymmetry
2	Drowsy or disorientated, or variable neurological deficit such as hemiparesis
3	Stuporous, but responding appropriately to noxious stimuli, several focal signs such as hemiplegia
4	Comatose with absent motor responses to painful stimuli, decerebrate or decorticate posturing

Table 88.2. Markwalder Scale.

There is no consensus on the influence of age on prognosis. Since CSDH mainly affects the elderly, it is unclear whether age *per se* or the presence of concomitant comorbidities are the true prognostic factors.
The reported mortality is 0-38% depending on the population studied, with an average of 16%. Approximately 75% of patients return to their previous activities and 15% remain with severe disabilities.

88.9 Conclusions

Erroneously considered benign, CSDH is a disease of the elderly. Trauma is the most frequent etiology, but there is a trigger event in half of cases. Clinically, it can take various forms and can mimic many other situations or neurological disorders. Computed tomography is the complementary method of choice for diagnosis and monitoring of this patient group. The state of consciousness is key to predicting prognosis. It is a surgical emergency, with a postoperative complications rate of up to 20%. Morbidity and mortality are directly related to age; nevertheless, outcome is very good when CSDH is not underestimated and is managed in a multidisciplinary approach.

89 Intoxication With Central Nervous System Depressant Agents

Claudia Analía González [1], **Roxana Andrea Bertrand** [1]

[1] Unit of Toxicology and Pharmacovigilance. Hospital Municipal de Agudos "Dr. Leónidas Lucero", Bahía Blanca, Argentina

89.1 Introduction

Patients with CNS depressant intoxication often constitute a toxicological emergency. The most common cause of intoxication in adults is attempted suicide, followed by accidental causes, mainly in children.

Given the severity of the emergency that this type of drug can cause, it is critical to correctly evaluate the problem, with adequate patient interview, physical examination and complementary methods. The aim is to reach a presumptive diagnosis, understanding the most likely etiology and start specific treatments immediately.

This chapter provides a practical guide to the management of patients entering an emergency department intoxicated with central nervous system (CNS) depressant agents.

89.2 Development

When patients with altered state of consciousness enter the emergency department, we should always consider possible exposure to CNS depressant agents because this condition requires rapid diagnosis and treatment.

- Alcohol
- Benzodiazepines
- Barbiturates
- Opioids
- Phenothiazines
- Butyrophenones
- Anticonvulsants
- Tricyclic antidepressants
- Others
- Antihypertensives (beta-blockers)
- Calcium channel blockers
- Digitalis
- Vinyl chloride
- Methaqualone
- Chloral hydrate

Table 89.1. Main drugs with CNS depressant activity.

Questions	Answers
What did you take?	Identification of the generic name of the substance involved, the composition of the product containing it, and its presentation
How much did you take?	Evaluates the extent of intoxication in order to start immediately the appropriate treatment
When?	It's the latency time: the time of ingestion to the time patient presents at hospital or onset of symptoms
How?	Evaluates the administration route of the poison
Where?	Know where it happened (it helps when you do not know what the patient has taken)
Why?	To better understand the intoxication

Table 89.2. Questions for the diagnosis of intoxication.

Many various drugs have CNS depressant activity (Table 89.1); therefore, family history of the patient is extremely relevant because it can yield data on the medication administered to the patients, their availability, and so on. All these aspects are useful in the analysis of intoxication cases (Table 89.2).

Few signs and symptoms are special features and, on the contrary, are often similar to those presented by other diseases such as infectious disease, stroke, coma, etc. A thorough physical examination is essential to search for meaningful data (Table 89.3).

Toxicological screenings are limited and not always available in all emergency departments; therefore, available laboratory tests should be performed, such as acid-base status, electrolytes, glucose, urea, white blood cell count, hematocrit, creatine, lactic acid, anion gap, and urine sediment.

The electrocardiogram (ECG) is an inexpensive, quick means to obtain objective information on intoxication etiology and severity. Rarely will ECG alone provide guidance to establish a precise etiologic diagnosis; however, together with findings from history, epidemiology, vital signs, characteristics of the skin, eyes and peristalsis, the ECG has a fundamental diagnostic value. CNS depressants can cause rhythm disturbances in cardiac conduction, often with PR interval prolongation, QRS widening, QT prolongation, and atrial and ventricular arrhythmias.

The physical examination will disclose signs that can help in the diagnosis: vital functions (blood pressure, heart rate, pulse), skin and mucosa colour, smell of the expired air and the vomit or clothes, body temperature, and breathing pattern.

Patients intoxicated with CNS depressants may have different levels of altered consciousness. This is of great clinical importance, because it represents the key point to understand whether the clinical features are related to a structural cause (stroke or subdural hematoma) or to a toxic/metabolic cause (intake of psychiatric drugs, opioids,

Clinical features	Suspected substance	
Miosis, bradycardia, nystagmus, ataxia, coma, hypoglycemia, hypothermia, ethyl breath	Alcohol	
Muscle hypotonia, drowsiness, stupor, coma, seizures, cardiorespiratory depression, hyporeflexia, ataxia, hypothermia	Benzodiazepins	
Nystagmus, somnolence, cardiorespiratory depression, hypotension, slurred speech, hypotonia, ataxia, dysarthria, hypothermia, miosis, flaccid coma	Barbiturates	
Sensory depression, bradypnoea, coma, seizures, spasticity, hyperreflexia, bradycardia, constipation, hypotension, hypothermia, miosis	Opioids	
Arrhythmias, hypotension, hypothermia, sensory impairment, oculocephalic crisis spasmodic torticollis, hypertonia, myoclonus, ataxia, orolingual dyskinesia	Phenothiazines	
Convulsions, sensory depression, extrapyramidal symptoms, anticholinergic symptoms, arrhythmias, hypotension, hypothermia	Butyrophenones	
Hypotension, hypothermia, tremor, hyperreflexia, dysarthria, coma, convulsions, sensory depression, anticholinergic symptoms, arrhythmias	Tricyclic antidepressants	
Nausea, vomiting, myoclonus, mydriasis dysarthria, nystagmus, ataxia, diplopia, blurred vision, respiratory depression	Carbamazepine	Anticonvulsants
Arrhythmias, hypotension, nausea, vomiting, seizures, tremors, nystagmus, vertigo, mydriasis, dysarthria mental confusion, ataxia diplopia, blurred vision	Phenytoin	

Table 89.3. **Clinical signs of CNS depressant intoxication.**

Manifestations	Toxic/metabolic coma	Structural coma
Pupils	Not modified	Modified
Oculocephalic manoeuvre	Maintained	Altered
Papilledema	Rare	Frequent
Motor system	Usually not compromised	Usually compromised
Vital signs	Highly altered	Not highly altered

Table 89.4. **Differences between "structural" and "toxic/metabolic" manifestations of coma.**

hydrocarbons, alcohol, hyperosmolar coma). Therefore, a quick and easy way to orient toward the etiology is to analyze three parameters: pupils, equal and reactive to light; eye position at rest and response to challenging manoeuvres; motor response to painful stimuli. In disorders caused by CNS depressants the first function affected is usually breathing followed by pupillary reflexes. In contrast, pupillary reflexes are altered earlier when the disorder is due to a structural cause (Table 89.4).

89.3 Treatment of the Most Frequent Types of Intoxication With CNS Depressants

Prompt treatment of clinical picture caused by the toxic agent and successful patient management are key to management. Evaluation will follow the ABCD scheme:

- **A**: Airway management, ensuring airway patency and preventing aspiration.
- **B**: Breathing, evaluating respiratory function and adequate ventilation.
- **C**: Circulatory control, restoring or maintaining hemodynamic status.
- **D**: Neurological assessment, followed by measures to prevent absorption of toxic mechanisms, promote elimination of the substance involved, and antagonize the toxic effect of the substance, if possible using specific antagonists.

89.3.1 Preventing Absorption of the Toxic Agent

Gastric Decontamination

If there was an oral intake and the dose has a potential toxicity, vomiting should be induced or gastric lavage performed within the first 2 hours after the accident for liquid and toxic, and within 6 hours for solids, provided that the patient is conscious.

Vomiting

Vomiting is caused by pharyngeal stimulation or administration of syrup of ipecac (15-30 ml in adults and 15 ml in children), followed by approximately 250 ml of water. If this treatment is not effective within 20 minutes, it should be repeated by stimulating the jaws. If vomiting fails, gastric lavage should be performed in order to decontaminate and prevent the absorption of ipecac. This treatment should not be performed in children <6 months of age or in patients in coma or with convulsions. We do not use this method, because evidence for its use is controversial.

Gastric Lavage

A nasogastric tube of the largest possible diameter should be used. The patient is placed in the Trendelenburg position with the head turned to the left, while inserting the na-

sogastric tube. First, the stomach contents should be allowed to flow spontaneously. Then normal saline solution or water should be administered (volume ≤10-15 ml/ kg in children and 200 to 400 ml in adults), repeating lavage cycles until the instilled liquid is equal to the removed one. The liquid should never be introduced under pressure never exceeding the capacity of the stomach, which would otherwise cause opening of the pylorus and rapid passage of toxic substances into the duodenum. The lavage liquid extracted will be collected in wide mouth jars for analysis and forensic toxicology.
Gastric lavage may be performed at any age and even in unconscious patients after tracheal intubation and airway protection.

Administration of Absorbent Substances

Activated carbon, also called activated charcoal, acts by adsorption to form non-absorbable macromolecules. The dosage is 15-30 g in children and 50-100 g in adults, dissolved in 100-150 ml of water or a carbonated drink.
For toxic enterohepatic circulation, activated charcoal, which may start up to 12 hours after ingestion, is indicated in multiple doses, every 4 hours at a dose of 0.50 g/kg, followed by administration of a cathartic. This is contraindicated in case of paralysis, obstruction or perforation of the ileus or in comatose patients without airway protection.

Facilitate Elimination

Intestinal decontamination. Once the toxic agent is adsorbed, its passage through the digestive tract should be accelerated by the administration of purgatives. The most commonly used is milk of magnesia (magnesium hydroxide solution 8%). The dosage is 13-30 ml in children and 60 ml in adults every 4 hours, until the colour of coal deposition. Other cathartics used are sodium sulphate or magnesium: 30 g in 250 ml of water for adults, with a maximum of three doses, and 70%sorbitol solution, 50-70 ml every 4 hours.
Oleose purgatives, solbitol and salite solutions are not recommended for pediatric use because of the risk of causing severe electrolyte alterations. The administration of cathartics is contraindicated in patients <1 year of age or in patients with diarrhoea, evidence of intestinal obstruction, bleeding, perforated viscus or peritonitis, electrolyte alterations, dietary sodium restriction, and renal failure for magnesium sulphate.

Purification Methods

The vast majority of toxins are eliminated with the urine. Adequate hydration ensures normal elimination mechanisms.
Forced diuresis promotes the elimination a copious flow of urine (5-10 ml/min or 500 ml/h) through the provision of sufficient fluids intravenously, and, depending on the pKa of the toxic agent, at changing urinary pH by the administration of alkalizing substances such as sodium bicarbonate (1-2 mEq kg in dextrose solution 5%) in order to raise the urinary pH to 7.5-8, or acidifying substances such as chloride ammonium or sometimes ascorbic acid (the latter are currently under review for their high risk/benefit ratio).
Other methods that can be used in specific cases include: peritoneal dialysis, hemodialysis, hemoperfusion, exchange transfusion, and plasmapheresis.

89.3.2 Benzodiazepine Intoxication

Treatment:
- Perform ABCD.
- Keep the patient under observation for at least 8 hours, then evaluate if he/she is conscious and if his/her psychiatric condition is stable.

- Suspend oral administration.
- Endotracheal intubation, according to neurological status, before starting decontamination of the gastrointestinal tract.
- Supplemental oxygen according to patient's condition.
- If the patient is conscious, vomiting can be induced.
- Gastric lavage 2 hours after ingestion, with saline solution (200 ml in adults, 10 ml/kg in children) until liquid runs clear.
- Activated charcoal can be started up to 4 hours after ingestion, 1 g/kg in 100-150 ml of water or carbonated drinks.
- Administer saline cathartic: The cathartic should be administered after the first dose of charcoal and repeated within 4 hours at the same dose if no catharsis is obtained, taking care not to repeat the carbon until an effective catharsis is obtained.
- The known antidote for benzodiazepines is flumazenil. Its use is recommended in cases of coma and respiratory depression secondary to the use of benzodiazepines. Flumazenil administration may involve risks for patients with hypotension, arrhythmias or hemodynamic instability; furthermore, it can cause seizures in patients with a history of epilepsy, increased intracranial pressure, concomitant ingestion of tricyclic antidepressants, anticonvulsants or cocaine, and benzodiazepine withdrawal syndrome in addicted patients. The use of flumazenil is unnecessary in most cases and can be associated with high risks, so it should be restricted to selected cases. Its effect begins within 1-2 minutes after the first dose and persists for 1-5 hours, depending on dose and type of benzodiazepine involved. The initial dose is 0.2 mg IV (0.01 mg/kg for children), and if no response is obtained, 0.3 mg bolus (up to a maximum of 3 mg in adults and 1 mg in children) can be administered.
- Psychiatric evaluation in cases of suicide.

89.3.3 Phenothiazine Intoxication

Treatment:

- Perform ABCD.
- Vomiting can be induced If the patient is conscious.
- Gastric lavage with saline 200 ml in adults 10 ml/kg in children until liquid runs clear.
- Administer activated charcoal 1 g/kg in 100-150 ml of water or carbonated drinks.
- Administer saline purgatives.
- If extrapyramidal symptoms are present, administer biperiden 0.04 mg/kg IM every 30 min until response (maximum 4 doses). An alternative is to administer diphenhydramine 1 mg/kg IM or IV (max 50 mg).
- In case of seizures, administer diazepam 5-10 mg IV (children: 0.2-0.5 mg/kg); if necessary, add a loading dose of diphenylhydantoin.
- Specific treatment is required in case of cardiac arrhythmias.

89.3.4 Anticonvulsants Intoxication (Phenytoin, Carbamazepine, Valproic Acid)

Treatment:

- Perform ABCD.
- Hospitalize the patient.
- Continuous monitoring for 24 hours
- Suspend oral administration

- Vomiting can be induced if the patient is conscious.
- Gastric lavage with saline 200 ml in adults 10 ml/kg in children until liquid runs clear.
- Administer activated charcoal starting 12 hours after ingestion, 1 g/kg in 100-150 ml of water every 6 h for 48 h or until recovery of consciousness. Closely monitor the state of ileus, because of the anticholinergic effects of the drug.
- Provide cathartic. The cathartic should be administered after the first dose of charcoal and repeated at the same dose if no bowel movement is observed within 4 h, taking care not to repeat the activated carbon until an effective catharsis is obtained.
- In case of seizures or agitation, benzodiazepines (diazepam 5 mg in adults, 0.1-0.3 mg/kg in children) or phenobarbital (15 mg/kg maintenance dose 5 mg/kg) should be administered. Do not administer drugs such as phenytoin or antipsychotics such as haloperidol and group I antiarrhythmics, which increase the risk of cardiac toxicity and decrease the threshold of seizure.
- Specific treatment for cardiac arrhythmias is required.
- Psychiatric evaluation in cases of attempted suicide.

89.3.5 Barbiturate Intoxication

Treatment:

- Perform ABCD
- Gastric lavage and induced vomiting should be performed if the patient is conscious. If sensory depression exists, endotracheal intubation prior to gastric lavage should be done, considering that aspiration is a cause of high mortality.
- Activated charcoal should be administered every 4 h, followed by saline purgatives.
- Monitor cardiovascular status, with special control of blood pressure and eventual shock treatment.
- Serial controls of the internal environment.
- Alkalinize urine with sodium bicarbonate.
- Force diuresis.
- If the dose of barbiturate is very high or there is kidney failure, peritoneal dialysis or hemodialysis should be performed.

89.3.6 Tricyclic Antidepressant Intoxication

Treatment:

- Perform ABC.
- Perform continuous cardiac monitoring and ECG.
- Vomiting can be induced if the patient is conscious.
- Gastric lavage with 0.9% saline solution, until the stomach contents are cleared out (after intubation if consciousness is impaired).
- In this particular case, administer a cathartic (5 ml/kg oral mannitol) before activated carbon because reduced peristalsis can lead to intestinal obstruction. If mannitol is not available, magnesium sulphate should be administered (30 g in adults and 250 mg/kg in children). If in the following 4 h the effect is not obtained, an additional dose of cathartic should be administered.
- Once you have verified the presence of peristalsis, administer activated carbon (1 g/kg in 100-150 ml of water by nasogastric tube), repeating the administration every 6 h for 4 doses, verifying that catharsis is obtained before the second dose. Keep in mind that these drugs have enterohepatic circulation, so carbon administration must be repeated serially for 24 and 48 h.

- Management of seizures with benzodiazepines, diazepam 5-10 mg IV (children dose 0.2-0.5 mg/kg). Do not use phenytoin because it causes sodium channel blocker poisoning.
- If agitation is present, sedation with benzodiazepines is possible. The use of antipsychotics such as haloperidol is associated with an increased risk of cardiac toxicity and reduced seizure threshold.
- Specific treatment in cardiac arrhythmias is required.

89.3.7 Intoxication With Opioids And Their Derivatives

Decontamination of the gastrointestinal tract is performed in cases of oral overdose. It is not useful in cases of intravenous or inhaled ingestion.
Treatment:

- Perform ABCD.
- Naloxone is administered at a dose of 0.4-2 mg up to 10 mg IV.
- Due to the drug's short half-life, continuous infusion at a rate of 0.4-0.8 mg/h should be administered to prevent recurrence of symptoms. In children the dose is 0.01 mg IV, repeated every 2 to 3 min up to 2 mg total.
- Do not induce vomiting because of risk of aspiration or seizures.
- Gastric lavage with saline 200 ml until liquid runs clear (in children 10 ml/kg).
- Activated charcoal 1 g/kg in 100-150 ml of water by nasogastric tube.
- Magnesium sulphate at normal doses.
- If seizures are present, administer diazepam (0.2-0.5 mg/kg). If seizures are uncontrollable or recur, consider the use of phenytoin.
- If hypotension is present, administer intravenous fluids.
- Naloxone may be associated with pulmonary edema, thus requiring mechanical ventilation and positive end-expiratory pressure (PEEP).

89.3.8 Ethanol Intoxication

In a patient with a history of ingesting ethyl alcohol, the presence of other diseases should be checked, such as head or spinal cord trauma, postictal states, infections, or drug intoxication.
Treatment:

- Perform ABCD: The patient intoxicated with ethyl alcohol should be managed on the basis of the clinical state of intoxication and the presence of respiratory, metabolic, gastrointestinal or traumatic complications. In such cases, the patient should be hospitalized or referred to a higher level of care.
- Maintain body heat by physical means.
- If agitation is present, haloperidol should be administered in adults (5 mg per h in adults and 0.01-0.1 mg/kg in children; maximum dose 0.5 mg total).
- Aspiration of gastric contents through a nasogastric tube after intubation is indicated in patients entering an extremely intoxicated comatose state after acute and massive intake of ethanol.
- The use of activated charcoal is indicated when there is the suspicion of co-ingestion of other substances that can be absorbed by activated carbon.
- Administer 100 mg of thiamine IV slowly to patients suspected of alcoholism or malnutrition to prevent or treat Wernicke-Korsakoff syndrome.
- In patients with hypoglycemia, dextrose 0.25-0.5 g/kg IV should be administrated, with periodic monitoring of blood glucose, in the absence of hypoglycemia the patient can be hydrated with normal saline solution.

- If vomiting is present, administer metoclopramide at standard doses.
- In alcoholic patients with hypomagnesemia, magnesium sulphate 2 g IV should be administered.
- Hypokalemia and hypophosphatemia should be corrected.
- 11.In patients with hepatic encephalopathy, lactulose 30 ml per os should be administered.
- In patients with high clinical or radiological suspicion of aspiration, broad-spectrum antibiotics (clindamycin or ampicillin + ceftriaxone sulbactan) should be administered.
- In patients with severe ethanol intoxication, hemodialysis can be performed, although in most cases it is unnecessary.

90 Study and Treatment of Neurological Compromise in Collagenopathies and Vasculitis of the Central Nervous System

María Cristina Zurrú [1]

[1] Chairman of Cerebrovascular Department, Hospital Italiano, Buenos Aires, Argentina

90.1 Introduction

Vasculitis is a clinical entity and pathology caused by inflammation of the blood vessel walls. It affects the small, medium and large vessels, as well as a number of organs, which results in the diversity of its clinical manifestations. Vasculitiis may be primary to the CNS or secondary to different systemic diseases such as collagenopathies, infectious processes, tumours, drugs, etc. An overview of the types of vasculitis affecting the CNS is given in Table 90.1.

90.2 Clinical Presentation

Patients with systemic vasculitis of the CNS initially present with general symptoms such as fever, myalgias, arthralgias and asthenia, together with those related to organs pref-

		Granulomatous	Non-granulomatous
Isolated vasculitis of the CNS		Large vessels	Medium and small vessels
Systemic vasculitis affecting the CNS	Primary	Large vessels (aorta and branches) Medium vessels (visceral vessels) Small vessels	Temporal arteritis Takayasu disease Nodous polyarteritis Kawasaki disease Wegener's disease Schönlein-Henoch purpura Churg-Strauss syndrome Polyangiitis
	Secondary	Viral, bacterial and mycotic infections Collagen diseases (SLE, Sjögren syndrome, Behçet disease, sclerodermia, dermatomyositis) Drugs: amphetamines, cocaine, oral anticonceptives Tumours: leukemia, lymphoma and glioma	

Table 90.1 Classification of vasculitis.

Temporal arteritis	Granulomatous arteritis of the aorta and its branches that mostly affects the external carotid. Thickening is often observed with signs of pain and tumefaction of the temporal artery. It usually affects patients older than 50 years and is frequently associated with rheumatic polymyalgia. Anemia, increased erythrosedimentation rate and alkaline phosphatase are frequent in the laboratory
Takayasu arteritis	Granulomatous inflammation of the aorta and its branches. It generally affects women between 20 and 40 years of age. The clinical picture depends on the involved branches of the aorta, which may present with hemispheric ischemic symptoms, subclavian steal syndrome, lower limb claudication, renal or mesenteric ischemia
Kawasaki disease	Arteritis affecting the small, medium and large vessels associated with mucocutaneous lymph node syndrome. The coronary arteries are frequently involved, causing aneurysms. This disease was described only in patients up to 20 years old
Wegener's granulomatosis	Granulomatous inflammation affecting the respiratory tract and necrotizing vasculitis of the small, medium and large vessels. In the CNS it usually presents with ischemic phenomena. It is often accompanied by necrotizing glomerulonephritis
Churg-Strauss syndrome	Granulomatous inflammation with abundant eosinophils affecting the respiratory tract and necrotizing vasculitis of the small and medium vessels. A respiratory illness characterized by bronchospasms and hypereosinophilia is frequently present

Table 90.2. **Clinical characteristics of the main types of vasculitis affecting the CNS.**

erentially involved in a particular type of vasculitis; for example, purpura, subcutaneous nodules, pneumonitis, nephropathy, etc. Neurological manifestations include: headache, convulsions, signs of focal compromise, cognitive deterioration, altered state of consciousness, involuntary movements, and cranial nerve deficits. The main clinical features of primary and secondary vasculitis affecting the CNS are listed in Table 90.2.

90.3 Complementary Studies

Laboratory findings in vasculitis may be nonspecific and related to the systemic inflammatory response, as in anemia, leukocytosis or leukopenia, elevated C reactive protein, accelerated erythrosedimentation rate, increased fibrinogen, etc. The most frequent alterations related to the involvement of specific organs include: increased blood urea nitrogen (BUN), creatinine, proteinuria and hepatic enzymes. A complementary serum study may provide information concerning the pathogenesis of the disease. The presence of hypocomplementemia is strongly suggestive of a disease mediated by immunocomplexes, such as systemic lupus erythematosus (SLE). The main autoantibodies present in the different vasculitis syndromes are mentioned in Table 90.3.
The electroencephalogram (EEG) is nonspecific and the findings may only be observed in the presence of slow waves or

Antibodies	Vasculitic syndrome
Antinuclear antibodies	Systemic lupus erythematosus Sjögren syndrome Mixed connective tissue disease Dermatomyositis
Anti DNA	Systemic lupus erythematosus
Anti Sm	Systemic lupus erythematosus
Anti P	Systemic lupus erythematosus
Antineutrophil cytoplasmic antibody (ANCA)	
C-ANCA	Wegener's disease
P-ANCA	Microscopic polyangiitis Churg-Strauss syndrome
Anticardiolipin antibodies	Antiphospholipidic syndrome

Table 90.3. **Antibodies and vasculitis syndromes.**

isolated spike waves or generalized in patients presenting with clinical convulsions.

Computed tomography (CT) offers little return for the study of vasculitis in the CNS, with a sensitivity of <50% in the detection of lesions. Magnetic resonance imaging (MRI) seems to be more useful, although its sensitivity and specificity are unknown. Vascular lesions in these patients tend to be multiple and with a hemorrhagic component. Diffusion sequences and T_2-weighted gradient echo are useful for the visualization of hemispherical strokes, as well as those in the trunk or cerebellum (Figure 90.1).

Angiography is useful in the detection of lesions in medium and large vessels. However, when smaller sized branches are affected, and generally with distal compromise of the middle cerebral artery, digital angiography is the method of choice, with a sensitivity and specificity of 50% for the detection of characteristic lesions in the shape of rosary beads (Figure 90.2).

In systemic vasculitis with repercussions in the CNS, the involvement of different organs generally allows for diagnosis, while in primary vasculitis of the CNS cerebral biopsy and leptomeninges are considered the gold standard by most authors. The lack of clinical signs with the high specificity and low efficiency of complementary studies would require a cerebral biopsy when a diagnosis of primary vasculitis of the CNS is suspected.

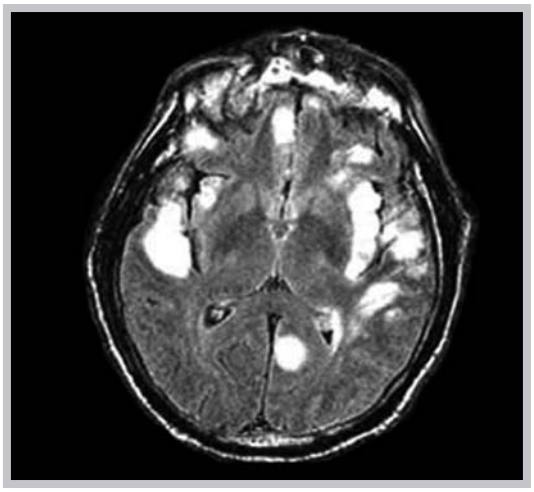

Figure 90.1. Magnetic resonance imaging with multiple lesions hyperintensitive in diffusion-weighted, sequences.

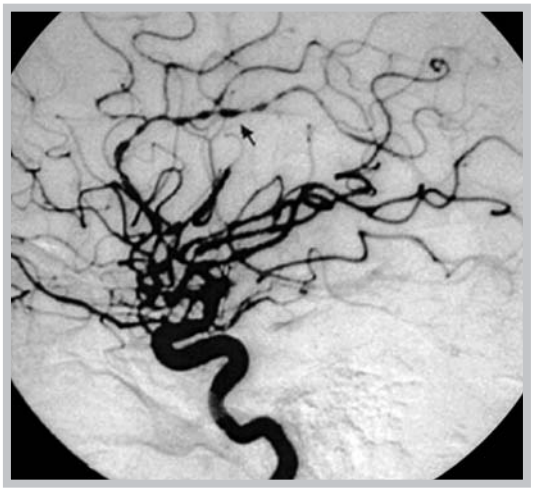

Figure 90.2. Digital angiography with lesions in the shape of rosary beads (arrow).

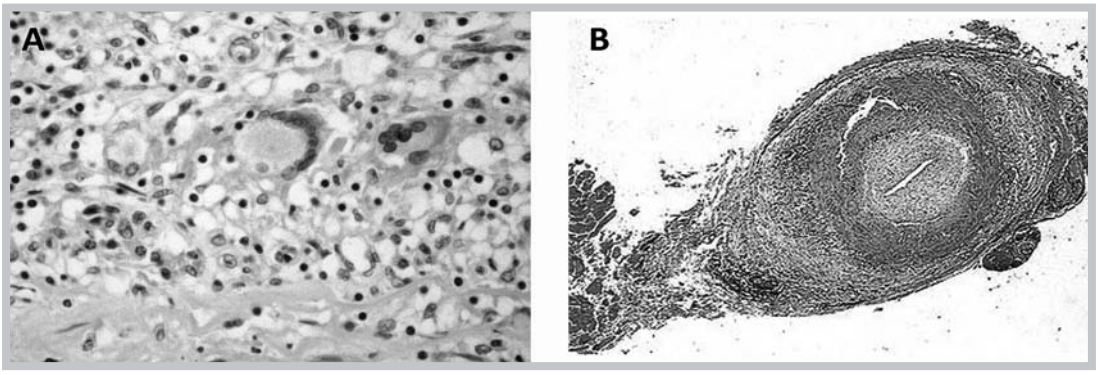

Figure 90.3. Two different patterns of vasculitis: necrotizing granulomatsis in large vessels and nongranulomatosis lymphocitic vasculitis of the small vessels.

In a study by Alrawi et al. only 36% of patients suspected with vasculitis of the CNS were anatomopathogically confirmed, while the remaining 64% had either another disease or the biopsy was not diagnostic. Two patterns have been described in vasculitis: necrotizing granulomatosis in large vessels and nongranulomatous lymphocytic vasculitis of the small vessels (Figure 90.3).

90.4 Pathogenesis

Different immunological mechanisms that are not mutually exclusive are involved in the pathogenesis of the inflammation and damage of the vascular wall. The most common is caused by the formation of immune complexes, as in serum disease. Attachment of immunocomplexes to the vascular wall induces adherence and activation of the complement cascade, with immune amplification through the release of cytokines, the consequent expression of adhesion molecules in their membranes, and the release of their lysosomal products, with damage to the endothelium and other components of the vascular wall. Other mechanisms involved in vascular damage include: anticellular endothelial and antilysosomal antibodies and the creation of a cellular type of immune response with the formation of granulomas.

90.5 Differential Diagnosis

It is worth noting here that there are illnesses that are not classically considered as vasculitis but that share anatomopathological features with it, such as:

- Severe hemorrhagic encephalomyelitis with perivenular inflammatory infiltrates, such as in demyelinating diseases and vascular wall necrosis.
- Reversible posterior leukoencephalopathy where there is an opening of the narrow endothelial unions due to toxic or secondary hemodynamic changes.
- Inflammatory changes in atherothrombotic disease.

The main differential diagnoses of vasculitis of the CNS are summarized in Table 90.4. Figure 90.4. reports a flow-chart for the management of these patients.

Metabolic diseases	• Mitochondriopathies • Organic aciduria
Ischemic lesions	• Hemoglobinopathies • Antiphospholipidic Syndrome • Hemodynamic stroke • Cardioembolic stroke • Venous stroke
Demyelinating inflammatory lesions	• Multiple sclerosis • Sarcoidosis • Subacute sclerosing panencephalitis • Acute hemorrhagic encephalomyelitis • Acute dissemimated encephalomyelitis
Infectious lesions	• Cerebritis • Granuloma • AIDS
Tumoural lesions	• Langerhans cell hystiocytosis • Primary lymphoma of CNS
Non-inflammatory vasculopathies	• Moya Moya Syndrome • Fibromuscular dysplasia • Reversible posterior leukoencephalopathies

Table 90.4. Differential diagnosis of CNS vasculitis.

90.6 Treatment

The medical profile of isolated vasculitis of the CNS or in a systemic context, once infectious tumoural and toxic causes are

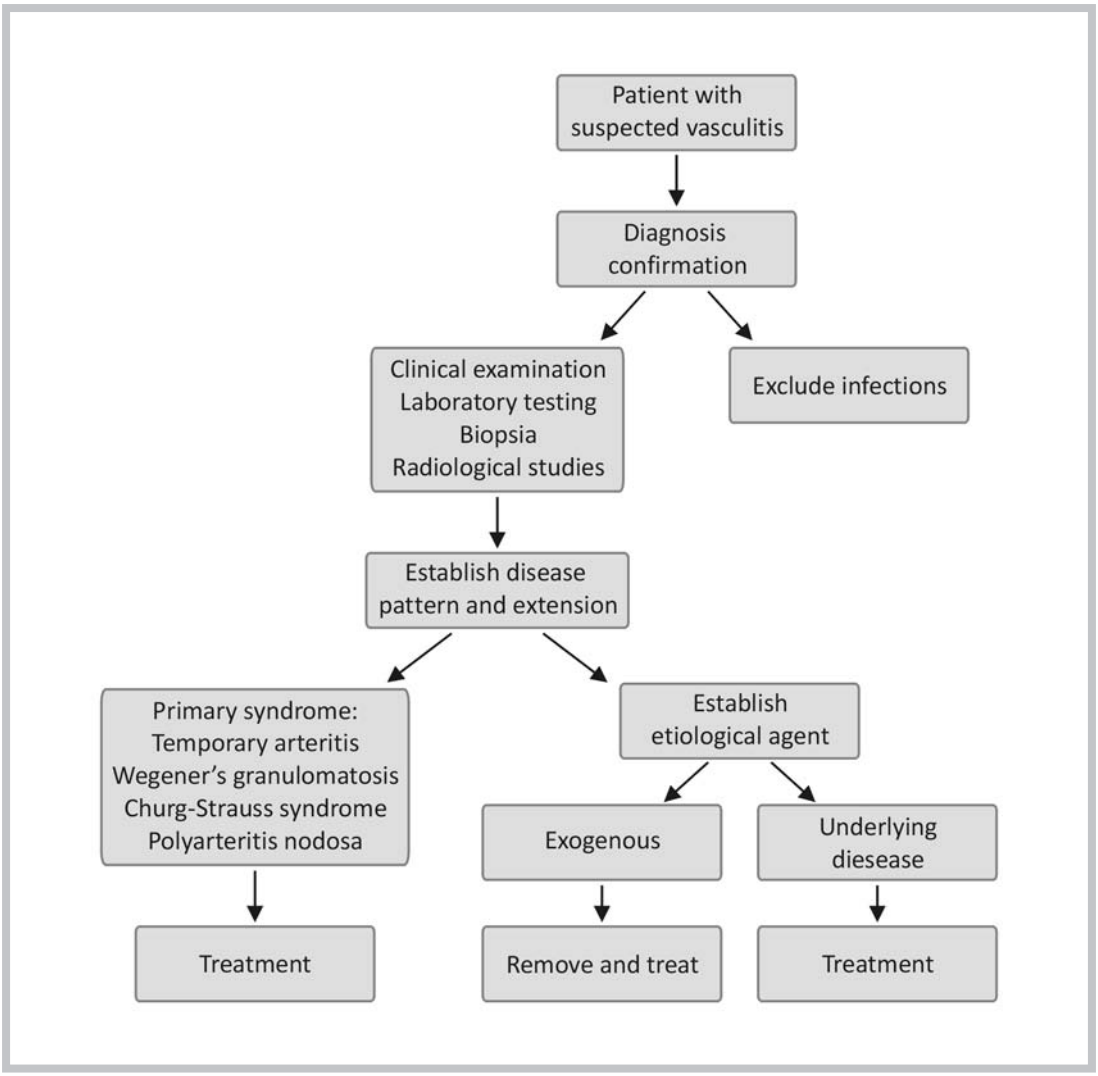

Figure 90.4. **Flow chart for the management of a patient with suspected vasculitis.**

ruled out, requires rapid immunosupressive treatment. In isolated vasculitis of the CNS, there is little experience, as only isolated cases have been reported. Pulsed methyprednisolone therapy may be initiated; when there is no favourable clinical response, treatment with intravenous cyclophosphamide can be initiated. In Kawasaki disease, intravenous administration of standard human gamma globulin has been widely accepted, in a single dose of 3 g/kg within the first 10 to 12 days of onset of the illness. This reduces the incidence of coronary complications. Schönlein-Henoch purpura generally requires no treatment and is self-limited in time.

When CNS involvement is significant, pulsed methylprednisolone therapy may be used. Necrotizing vasculitis, such as systemic panarteritis, Wegener's granulomatosis, the Churg-Strauss syndrome and Takayasu arteritis usually require the administration of combined corticoids and immunodepressants. In systemic vasculitis a certain degree of effectiveness with biological drugs, such as etanercept, inflixomab and rituximab recently been reported. The therapeutic use of antithrombotics is controversial, although certain groups use aspirin in patients at risk of thromboembolic phenomena.

91 Management of Acute Movement Disorders

M. Elena Erro Aguirre [1]

[1] Neurology Department. Complejo Hospitalario de Navarra, Spain

91.1 Introduction

This chapter describes the main acute movement disorders, their clinical manifestations, causes and treatment. Drugs represent the most frequent etiologic factor and are the cause of the neuroleptic malignant syndrome and serotoninergic syndrome. A section of this chapter is devoted to emergencies secondary to Parkinson's disease, including the parkinsonism hyperpyrexia syndrome, acute psychosis and the emergencies derived from deep brain stimulators.

	Rigidity	Parkinsonism	Dystonia	Chorea-balism
Drugs	Neuroleptic malignant syndrome Serotonin syndrome	Parkinsonism-hyperpyrexia (See Table 91.2)	Acute dystonia caused by neuroleptic drugs	Phenytoin, carbamazepine, tricyclic antidepressants, estrogens, cocaine, baclofen, trazodone, anticholinergics
Degenerative diseases			Laryngeal dystonia in multisystem atrophy	Parkinson's disease
Idiopathic			Laryngeal dystonia in adduction, status dystonicus	
Infections	Rabies, tetanus	Mycoplasma, encephalitis lethargica	Encephalitis lethargica, retropharyngeal abscess	
Toxic agents	Strychnine	See Table 91.6		
Metabolic disease	Hypocalcemia	Central pontine and extrapontine myelinolysis		Hypoglycemia Hyperglycemia
Autoimmune diseases	Stiff man syndrome		Anti-NMDAR encephalitis	Sydenham chorea Antiphospholipid syndrome Lupus erythematosus Hashimoto's encephalopathy Paraneoplastic syndrome
Psychiatric diseases	Lethal catatonia		Pseudo-dystonia	
Hereditary diseases	Hyperekplexia, malignant hyperthermia	Dystonia Parkinsonism with rapid onset		
Diseases in children			Atlantoaxial subluxation	

Table 91.1. **Major presentations of acute movement disorders and their causes.**

Movement	Drug (frequent)	Drug (non frequent)
Chorea	L-Dopa	Phenytoin, carbamazepine, tricyclic antidepressants, estrogens, cocaine, baclofen, trazodone, anticholinergics
Myoclonus	SSRIs	Tricyclic antidepressants, lithium, MAO-I, carbamazepine, penicillin and cephalosporins, cocaine, opioids, amantadine, bromocriptine
Tremor	Neuroleptics, valproate, alcohol, sympathomimetics	Opiates, immunosuppressants, OAD, antibiotics and antivirals, anticonvulsants, antiarrhythmics, corticosteroids, amiodarone, thyroxine
Dystonia	Neuroleptics and L-Dopa	Dopamine agonists, phenytoin, carbamazepine, SSRIs, tricyclic antidepressants, cocaine
Parkinsonism	Neuroleptics	Flunarizine, cinnarizine, tricyclic antidepressants, tacrine, carbamazepine, phenytoin, valproate, lamotrigine, MPTP

Table 91.2. **Drug-induced acute movement disorders.**
MAO-I = monoamine oxidase inhibitors
MPTP = 1-methyl-4-phenyl-1.2.3.6-tetrahydropyridine
OAD = oral antidiabetics
SSRIs = selective serotonin reuptake inhibitors

Acute parkinsonism, various forms of acute dystonia, chorea, myoclonus acute ballism are also described. Finally, a section on movement disorders presenting as a stroke is provided.
Movement disorders requiring emergency care comprise neurological diseases with an acute or subacute onset in which the predominant clinical presentation is movement disorder, and in which an error in diagnosis or treatment can lead to significant morbidity and even mortality [1,2]. They account for a small percentage of urgent neurological consultations and may have very different etiologies (Table 91.1), among which are those secondary to drugs (Table 91.2). They can be classified according to the presenting signs and symptoms: rigidity, parkinsonism, dystonia, chorea or ballism and myoclonus.

91.2 Syndromes Presenting With Stiffness

Stiffness is the presenting symptom of neuroleptic malignant syndrome, serotonin syndrome, malignant hyperthermia, stiff-person syndrome, and lethal catatonia (Table 91.3). Other diseases can also manifest with rigidity, including infectious diseases such as tetanus or rabies, strychnine poisoning, hypocalcemia, and inherited diseases such as hyperekplexia.

91.2.1 Neuroleptic Malignant Syndrome

The neuroleptic malignant syndrome (NMS) is induced by drugs exerting an antidopaminergic effect, in particular the classic neuroleptics such as haloperidol or chlorpromazine. NMS can also be caused by an antiemetic such as methoclopramide and antihistamines such as promethazine [3,4]. It occurs in 0.2% of cases after the administration of atypical antipsychotics (olanzapine, clozapine, risperidone, quetiapine, and aripiprazole).
Its occurrence may be favored by the co-administration of lithium to any of the listed drugs. It is more common in young men using slow-release preparations and is favoured by dehydration. This is an idiosyncratic reaction that occurs within a few weeks after the start of the treatment or after an increase in the dosage; it is characterized by severe

Process	Serotonin syndrome	Neuroleptic malignant syndrome	Acute akinesia syndrome – hyperpyrexia	Malignant hyperthermia	Lethal catatonia
Medication	Serotoninergic drugs	Dopaminergic antagonists	Suspension of dopaminergic drugs	Inhalatory anesthesia	
Onset time	<12 h	1-3 days	1-3 days	0.5-25 h	1-3 days
Constants	Hypertension, tachycardia, tachypnoea, hyperthermia (>41.1°C)	Hypertension, tachycardia, tachypnoea, hyperthermia (>41.1°C)	Hypertension, tachycardia, tachypnoea, hyperthermia (>40°C)	Hypertension, tachycardia, tachypnoea, hyperthermia (>46°C)	Hypertension, tachycardia, tachypnoea, hyperthermia (>40°C)
Pupils	Midriasis	Normal	Normal	Normal	Normal
Skin	Diaphoresis	Pallor, diaphoresis	Anhidrosis	Spotted, diaphoresis	Diaphoresis
Intestinal motility	Increased	Normal or decreased	Decreased	Decreased	Normal or decreased
Muscle tone	Increased, especially in lower limbs	Lead pipe stiffness	Increased, plus severe akinesia	Rigidity like "rigor mortis"	Increased with catatonic signs and akinetic mutism
Reflexes	Hypereflexia, clonus	Hyporeflexia	Normal	Hyporeflexia	Normal
Mental state	Agitation, coma	Stupor, coma, mutism	Confusion, stupor, coma	Agitation	Stupor, coma, mutism

Table 91.3. **Major clinical features of different processes that occur with stiffness.**

Process	Specific treatment	Standard treatment
Serotonin syndrome	• Cyproheptadine, starting dose 12 mg followed by 2 mg/2h • Chlorpromazine 50-100 mg IV	• Suspend precipitating drug • Administration of intravenous fluids • Cool body with physical measures • Monitor urine output and treat renal failure (dialysis), if any • Treat acidosis, if any • Institute life-support measures with a respirator, if necessary
Neuroleptic malignant syndrome	• NGT dopamine agonists (bromocriptine, amantadine or levodopa) • Apomorphine SC or rotigotine SC • Dantrolene 25-80 mg/8 h	
Acute akinesia syndrome – hyperpyrexia	• NGT dopamine agonists (bromocriptine, amantadine or levodopa) • Apomorphine SC or rotigotine SC • Dantrolene 25-80 mg/8 h • Treatment of intercurrent infections	
Malignant hyperthermia	• Hyperventilate with oxygen 100% • Dantrolene 2.5 mg/kg bolus, then repeat 2 mg/kg every 5 min after infusion 1-2 mg/kg/h • Treat hypercalcemia and arrhythmia	
Lethal catatonia	• Lorazepam IV • Daily ECT (10 sessions)	

Table 91.4. **Treatment of various processes that occur with stiffness.**

ECT = electroconvulsive therapy

NGT = nasogastric tube

SC = subcutaneous

muscle rigidity, altered level of consciousness and dysautonomia, with fever, sweating, tachycardia, tachypnoea, and fluctuations in blood pressure.
Some studies show an elevation in creatine kinase (CK) as a result of rhabdomyolysis caused by stiffness and which can lead to renal failure secondary to myoglobinuria.
There are two pathophysiological hypotheses: a central mechanism that blocks dopamine in the striatum (stiffness) and hypothalamus (dysautonomia), and a peripheral mechanism that alters muscle fibre contractility due to alterations of the membrane of the sarcoplasmic reticulum.
Treatment consists of suspending neuroleptics (Table 91.4), general life-support measures (hydration and mechanical ventilation if necessary), administration of dopaminergic drugs such as bromocriptine at a starting dose of 2.5 mg/8 h orally (nasogastric tube) and increasing it to 5 mg/8 h after 2 days. Subcutaneous apomorphine or transdermal rotigotine patches may also be administered. Dantrolene at a starting dose of 25 mg/24 h with further increases to 25 mg/12 h or 1-10 mg/kg intravenously may be used in severe disease. Electroconvulsive therapy should be considered in psychotic patients. If untreated, the mortality rate is estimated to reach 20% and the causes of death are pulmonary embolism, aspiration pneumonia and renal failure.

91.2.2 Serotonin Syndrome

The serotonin syndrome is a potentially life-threatening adverse drug reaction that may occur following serotonin-acting drug administration. It has an incidence of approximately 14-16% of patients taking overdoses of selective serotonin reuptake inhibitors (SSRIs), but it may also occur after the use of other drugs with serotonergic action (Table 91.5).
It is clinically characterized (Table 91.3) by altered mental status (delirium, anxiety, hypervigilance, akathisia), autonomic hyperactivity (diarrhoea, sweating, tachycardia, hyperthermia, mydriasis) and neuromuscular disorders (myoclonus, tremor, hyperreflexia, rigidity). The onset of symptoms is usually rapid, occurring within minutes to hours after taking the medication. Laboratory findings consist of metabolic acidosis, rhabdomyolysis, increased CK, kidney failure, and even disseminated intravascular coagulopathy (DIC) [5]. Idiopathic serotonin syndrome is not a reaction but rather a predictable consequence of excess serotonergic activity of the serotonin receptors of the central nervous system (CNS) and peripheral nervous system, resulting from drug abuse interactions or voluntary ingestion as a suicide attempt. The activation of 5-HT2A receptors contributes mainly to the manifestations of the serotonin syndrome. Treatment (Table 91.4) consists of removing the precipitat-

Class	Drug
Serotonin reuptake inhibitors	SSRIs, tricyclic antidepressants, dextromethorphan, dextroamphetamine, cocaine, meperidine, opioids (except morphine)
Serotonin metabolism Inhibitors	MAO-B Inhibitors (selegiline), MAO-I antidepressants
Agents that increase serotonin synthesis	L-tryptophan
Agents favouring the release of serotonin	MDMA (ecstasy), amphetamines, cocaine, fenfluracina
Serotonergic agonists	Sumatriptan, ergotamine, buspirone
Agents favouring nonspecific serotonergic activity	Lithium, electroconvulsive therapy

Table 91.5. Drugs that can cause the serotonin syndrome.
MAO-I = monoamine oxidase inhibitors
MAO-B = monoamine oxidase B
MDMA = 3,4-methylenedioxymethamphetamine
SSRIs = selective serotonin reuptake inhibitors

ing agent, life support, control of agitation, hyperthermia and autonomic instability. In some cases, discontinuation of the offending medication or medications, and offering supportive measures are sufficient to resolve symptoms within 24 hours. In other cases, other measures, such as benzodiazepine administration, should be added. Physical restraint should be avoided because it can cause rapid clinical deterioration. In moderately and severe cases, 5-HT2A antagonists such as cyproheptadine should be administered at a starting dose of 4-8 mg orally, followed by a maintenance dose of up to 8 mg/6 h. It can be administered only orally and by nasogastric tube. When hyperthermia is >41ºC, neuromuscular paralysis with nondepolarizing agents and tracheal intubation may be required. Antipyretics have no role in the management of hyperthermia since it is not the hypothalamus that is involved but rather the muscle activity. Succinylcholine should be avoided because of the risk of arrhythmia, together with the hypercalcemia that occurs with rhabdomyolysis. Drugs such as bromocriptine, propranolol or dantrolene are not recommended.

91.2.3 Malignant Hyperthermia

This serious disease with a genetic component is an autosomal dominant disorder with variable penetrance due to a mutation of the ryanodine receptor on the long arm of chromosome 19 [6]. Mutations of this receptor cause an alteration in calcium homeostasis, with an increase in muscular calcium and sustained muscle contraction which, in turn, leads to a state of hypermetabolism with lactic acidosis, hypercapnia and hyperthermia. It is triggered by inhaled halogenated anesthetics and depolarizing muscle relaxants. Clinical manifestations (Table 91.3) may appear in the operating room or several hours after anesthesia. The most common early sign is tachycardia, followed by muscle rigidity, masseter spasm, and tachypnoea. Metabolic and respiratory acidosis also develop. Elevated temperature is a late sign, together with arrhythmias, cyanosis, hypotension, hyperkalemia and rhabdomyolysis. Treatment (Table 91.4) consists in hyperventilating the patient with 100% oxygen, administering dantrolene (2.5 mg/kg bolus every 5 min followed by 1-2 mg/kg/h infusion), reducing body temperature with physical measures, treating the acidosis with sodium bicarbonate, monitoring urine output, and treating arrhythmias.

91.2.4 Lethal Catatonia

This syndrome has various causes and usually occurs in the context of psychiatric illness; it may be triggered by nervous system infections, hyperthyroidism, lupus, toxic, trauma, etc. It usually occurs in young people and its relationship with NMS is unclear. It's characterized by insomnia, anorexia, catatonic motor excitation, confusion, dysautonomia (sweating, tachycardia and changes in blood pressure), hallucinations, echolalia, echopraxia, stare, fixed postures, mutism, rigidity, intense and high fever (Table 91.3). It has been speculated that its physiopathology is related to an involvement of dopaminergic transmission. Treatment consists of life support with intravenous lorazepam; electroconvulsive therapy is the treatment of choice(Table 91.4) [3].

91.2.5 Stiff Person Syndrome

This syndrome can have an acute or subacute onset and is characterized by the appearance of pain and muscles spasm of the lumbar paraspinal, abdominal and lower ex-

tremities, resulting in an exaggerated lumbar lordosis, which can cause fractures, joint subluxations or abdominal hernia. It is associated with generalized hyperreflexia. Contractures can occur spontaneously or after auditory or sensory triggers and disappears during sleep. Neurophysiological studies suggest that it is a central continuous motor activity. It is accepted that there is an idiopathic paraneoplastic variant of stiff person syndrome (SPS), another variant is associated with focal encephalitis, and a syndrome of rigid limbs. At least half of patients have antibodies against glutamic acid decarboxylase (GAD) and anti-gephyrin antibodies. The efficacy of intravenous immunoglobulin therapy has been demonstrated in some forms of SPS [7].

91.3 Emergency in Parkinson's Disease (PD)

91.3.1 Parkinsonism-hyperpyrexia Syndrome (PHS)

Also called malignant syndrome or NMS-like syndrome, it occurs in patients with long-standing Parkinson's disease admitted to hospital for surgery or intercurrent process that involve a significant reduction in antiparkinsonian medication. It can also occur in other akinetic-rigid syndromes other than PD. It's characterized by the sudden onset of extreme akinesia with increased body temperature (Table 3). Other clinical manifestations that may occur spontaneously are stiffness, decreased level of consciousness (from light drowsiness to coma), autonomic alteration with tachycardia, fluctuating blood pressure, lack of perspiration, ileus, or vocal cord paralysis. In addition, there is an elevation of CK secondary to rhabdomyolysis and that can lead to renal failure. Disseminated intravascular coagulation (DIC) is the most serious complication and carries a high mortality. Not all patients show all clinical signs [8].
Diagnosis is based on clinical manifestations. In addition to levodopa dose reduction, other triggers may be the change in one agonist for another, infection, elevated environmental temperature (heat stroke) causing dehydration, or changes in the distribution of levodopa due to changes in nutrition (i.e., initiation of enteral nutrition). Sometimes a sudden decline occurs as a consequence of antiparkinsonian treatment suspension (the so called "superoff effect"). Underlying the pathophysiology may be acute dopaminergic hypotransmission in the hypothalamus, nigrostriatal system and mesocortical dopamine system. There is also an individual susceptibility. Post-mortem studies have found hypothalamic necrosis.
Treatment consists in its early detection and the administration of fluids (2500-3000 ml/24 h) with electrolytes and glucose, vitamin B1, physical and pharmacological measures against hyperthermia, treating infection if diagnosed, and antiparkinsonian treatment reinstated as soon as possible by nasogastric tube if there are problems with swallowing (Table 4). Bromocriptine, amantadine or apomorphine injection can also be used. If the stiffness is severe, it may be necessary to use dantrolene at doses of 80 mg/day intravenously.

91.3.2 Acute Psychosis

Clinical manifestations of psychosis in PD consists of visual hallucinations, often stereotyped, and persecutory or jealousy delirium. Hallucinations and delirium can be accompanied by intense agitation, confusion and sleep disturbances which alter the quality of life of patients and their caregivers. Psychosis is related to antiparkinsonian treat-

ment. Its onset is not only due to dopaminergic dysfunction but also other neurochemical changes. It has been suggested that hallucinations are due to early mesolimbocortical receptor hypersensitivity not purely related to the degeneration of serotonergic or cholinergic mechanisms [9].
When acute psychosis is suspected, triggers such as infections and metabolic or structural brain processes should be investigated. If psychotic symptoms are mild, you should try to simplify the treatment by reducing or suspending antiparkinsonian drugs added to levodopa, such as amantadine, selegiline, dopamine agonists and catechol O-methyltransferase (COMT) inhibitors. If, despite these changes, the symptoms persist, it may be necessary to reduce levodopa, and, if this is not enough, atypical neuroleptics such as clozapine, quetiapine, or aripiprazole should be administered. Cholinesterase inhibitors have proved effective in cases of PD with dementia. As a therapeutic alternative to neuroleptics, ondansetron, and 5HT3 antagonist have been also proposed.

91.3.3 Emergencies in Patients With Deep Brain Stimulators

Deep brain stimulation is a therapeutic alternative in selected patients with PD. This treatment may cause complications leading to emergency complications that the general neurologist should be familiar with; however, the patient should be referred to a specialized centre in these circumstances [10].
Among the surgical delayed complications we can list deep vein thrombosis and pulmonary thromboembolism, together with any surgical procedure involving prolonged bed rest. In addition, local infections can occur because of: accumulation of serous fluid in the surgical bag housing the stimulator; problems with the implanted material such as electrode displacement or breakage, or cable infection or necrosis in the subcutaneous track. Additionally, the generator may be disconnected because of inadvertent contact with a strong magnetic field, thus producing a sudden worsening of parkinsonian symptoms. This can also happen if the neurostimulator batteries are depleted (they typically last about 5 years). In both cases, in which a negative effect induced by a recent change in the parameters of the neurostimulator is suspected, consultation with neurologists expert in the management of its programming system will be necessary.
Complications consequent to brain stimulation are the appearance of choreic or ballistic movement disorders due to stimulation of the subthalamic nucleus. Psychiatric disorders may also occur, such as apathy or cognitive impairment, anhedonia, euphoria or hypomania, which have been associated with stimulation of the medial and ventral areas of the subthalamic nucleus. The stimulation of neighbouring fibres of the internal capsule can produce pseudobulbar symptoms, such as dysphagia, dysarthria and inappropriate crying.
The neurostimulator produces electrical interference with the electrocardiogram (ECG), the electroencephalogram (EEG), and metallic interference with computed tomography (CT). These effects should be considered when a patient with a neurostimulator enters the emergency room for other medical problems.

91.4 Acute Parkinsonism

The incidence of acute parkinsonism is very rare. It may be caused by infectious agents such as mycoplasma or drugs such as amphotericin B. Metabolic disorders such as central pontine or extrapontine myelinolysis can produce acute parkinsonism. This dis-

- Methanol
- Cyanide
- Herbicides: rotenone and paraquat
- Heroin
- Manganese
- Mercury
- Carbon monoxide
- MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine)
- Plants of the *Annonacea* family, especially *Annona muricata* (corossol, soursop)

Table 91.6. **Toxic agents that can cause parkinsonism.**

ease occurs as a result of osmotic alterations (e.g., in the context of correction of hyponatremia secondary to hyperemesis) and can be found by magnetic resonance imaging (MRI) of cranial hyperintense lesions in the striatum that can be reversed, together with parkinsonism. There is a rare hereditary disease with linkage in a region of chromosome 19, called dystonia-parkinsonism, in which symptoms may occur acutely or subacutely with parkinsonism and dystonia of orofacial muscles. The onset of parkinsonism by accidental consumption or addiction to various drugs is documented in the literature (Table 91.6) [11].

Lethargic encephalitis occurred in epidemics in the early 20th century as encephalitis with involvement of the basal ganglia, mainly producing parkinsonism and psychiatric and sleep disorders. In recent decades, there have also been reports of encephalitis whose pathophysiology is poorly understood. There is no clear evidence of infectious agents invading the nervous system, although lymphocytosis is found in the oligoclonal bands of cerebrospinal fluid. MRI findings may not show alterations or signal changes in the midbrain and basal ganglia. In recent cases, steroids have been used with good clinical response, with complete recovery of the patients in many cases [2].

91.5 Acute Dystonia

91.5.1 Drug-induced Dystonias

Within this group, the most frequent cause of consultation in the emergency department are the dystonias secondary to drugs. Young people often develop this disease during the first hours or days after taking drugs such as antipsychotic dopamine antagonists (haloperidol) or antiemetics (clebopride or metoclopramide), antidepressants, SSRIs, norepinephrine or cocaine. They can also appear after the use of atypical antipsychotics [12].

Other drugs such as rivastigmine or interferon alfa-2b may occasionally cause acute dystonic reactions. The clinical manifestations usually consist of focal craniocervical dystonia, which often occurs in the form of torticollis, but can be as trismus, lingual protrusion, oculogyric crises, pharyngeal or laryngeal dystonia, blepharospasm and even axial and limb dystonia. It occurs in 30-40% of young psychotics who started treatment with antipsychotics. It seems to be dose-related. AIDS patients with immunodeficiencies are at higher risk. In such patients, dystonic reactions have been reported after treatment with other drugs such as intravenous immunoglobulins. Treatment consists of intravenous anticholinergic drugs such as Akineton® (biperiden) 5 mg IV or IM or Cogentin® (benztropine) 1-2 mg; the dose may be repeated if symptoms do not improve; it is appropriate to continue the treatment a few days then orally.

91.5.2 Acute Laryngeal Dystonia

Another reason for urgent consultation is acute laryngeal dystonia or Gerhardt's syndrome, a sporadic idiopathic dystonia in which a laryngeal spasm occurs by dystonia in

adduction of the vocal cords during inspiration, with the potential risk of airway obstruction. The clinical manifestation is a respiratory stridor that yields to sleep. This rare entity is confirmed by fibroscopy and treatment involves the injection of botulinum toxin into the thyroarytenoid muscle [2].
Patients with multiple system atrophy may also present with stridor caused by altered abduction of the vocal cords due to dystonic spasms of the thyroarytenoid muscles (adductors), abductor muscle weakness and neurogenic posterior cricoarytenoid muscle atrophy. This serious symptom can cause sudden death. Treatment consists of applying continuous positive airway pressure (CPAP) (non-invasive passive ventilation), botulinum toxin or tracheostomy.

91.5.3 Dystonic Storm

Dystonic storm (or status dystonicus) is a serious emergency that can occur in patients with primary or secondary dystonia. The symptom is the appearance of severe dystonic spasms involving painful generalized hyperthermia, rhabdomyolysis with the risk of acute renal failure, anarthria, respiratory failure and dysphagia with the risk of pneumonia by bronchoaspiration. Status dystonicus shares many aspects with status epilepticus. Precipitating factors may be the same for both: trauma, surgery, infection, fever and rapid introduction or withdrawal of a drug. The optimal treatment strategy is still unclear. Only in rare cases are oral medications (haloperidol, tetrabenazine and pimozide) effective. Midazolam and short-acting and short half-life benzodiazepines can be used as first-line therapy (30-100 mg/kg/h). If they fail, propofol (0.3-3.0 mg/kg/h) can be administered.The general therapeutic measures consist of hydration to prevent acute renal failure,analgesia, ECG monitoring, respiratory monitoring and admission to the intensive care unit, if necessary. As in status epilepticus, general anesthesia is sometimes necessary, and neuromuscular blockade by curaring agents. infusion of intrathecal baclofen or functional surgery may be needed in patients with degenerative diseases [13].

91.5.4 Anti-NMDAR Encephalitis

The encephalitis associated against the N-methyl-D-aspartate receptor (NMDAR) is a multistage illness that progresses from psychosis, memory and language deficits, seizures, catatonic features associated with abnormal movements and autonomic and breathing instability [14]. Oro-lingual-facial dyskinesias are the most characteristic abnormal movements but other types might occur simultaneously or alternate with limb and trunk choreoathetosis, oculogyric crisis, dystonia, rigidity and even opisthotonic postures. Autonomic manifestations include hyperthermia, tachycardia or bradycardia, hypertension or hypotension, hypersalivation, urinary incontinence and erectile dysfunction. Hypoventilation requiring ventilatory support may occur. Seizures develop at early stages of the disease that may overlap with abnormal movements. Antibodies against NMDAR have a pathogenic role as they cause a reversible decrease of synaptic NMDAR. This disorder predominantly affects children and young adults and it can occur associated or not to a tumour (usually an ovarian teratoma). Treatment consists of tumour resection, if it is present, and immunotherapy (corticosteroids, intravenous immunoglobulinor plasma exchange). Sometimes a second line treatment with cyclophosphamide or rituximab is necessary. More than 75% of all patients have a substantial recovery.

91.5.5 Pseudo-dystonic Emergency

Sometimes an atlantoaxial subluxation or a retropharyngeal abscess in children may presented as a stiff neck which can also occur in cases of spinal cord and posterior fossa tumours. Among these emergencies, we may include psychogenic movement disorders that usually consist of motley and flowery movements that have an acute onset. It is important to consider this diagnosis to avoid unnecessary examinations, but the differential diagnosis can sometimes be difficult and the patient should be kept under observation.

91.6 Acute Chorea-Ballism

Ballism and chorea are part of the same spectrum of motor impairment. Proximal ballism may be associated with chorea in the distal extremity and can transform into chorea. Ballism or chorea with acute presentation are usually due to structural lesions of the nervous system which are usually ischemic but sometimes related to other processes of different nature (infections, autoimmune diseases, hypoglycemia or other metabolic disorders) [2]. Chorea may be the manifestation of a paraneoplastic disease and its acute or subacute onset may be the reason for visiting the emergency room. It's generally accompanied by other symptoms of encephalopathy, and imaging tests findings are usually characterized by signal changes in the basal ganglia. It is associated with lung carcinoma, small cell lung carcinoma and anti-Hu or anti-CV2 syndrome.

91.7 Myoclonus

Myoclonus or asterixis is the clinical manifestation of metabolic encephalopathy of liver failure or kidney failure. Myoclonus may be part of serotonin syndrome. Opiate intoxication and their withdrawal can be accompanied by myoclonus. Treatment with lithium, tricyclic antidepressants, imipenem and cefuroxime may cause cortical action myoclonus. Focal brain lesions of various etiologies (infectious, vascular, etc.) can cause focal myoclonus [15].

91.8 Movement Disorders in Stroke

The presentation of stroke as a movement disorder is rare and occurs in 1% of cases. The most common movement disorder secondary to stroke is hemiballism hemichorea, followed by hemidystonia. Ischemic lesions affecting the globus pallidus or the midbrain may cause acute parkinsonism, stroke of the putamen may cause dystonia, and stroke in the subthalamic or caudate nucleus usually presents with chorea-ballism. Thalamic infarcts may produce different movement disorders depending on the thalamic nuclei involved. Damage to the ventral anterior nuclei can cause myoclonic dystonia (Figure 91.1) and a "thalamic hand", with isolated dystonic posture with pseudo-ataxic movements after injury in the ventral intermediate nucleus (VIM) and ventral posterior nucleus, respectively, and postural and action tremor after injury to the VIM, and impaired thalamocortical connectivity. The most common etiology of strokes that occur with a movement disorder is small vessel disease, but the possibility of a cardioembol-

Figure 91.1. **Sequence of photographs showing involuntary movements in a patient with acute thalamic stroke, with flexion and external rotation of the lower limbs and eversion of both feet (myoclonic dystonia).**

ic origin in thalamic infarcts should be considered. Most of these movement disorders that appear in the acute phase are transient and resolve spontaneously within the first days or weeks.

Involuntary motor phenomena with varied presentation have been reported in ischemic lesions of the brainstem. They can range from small amplitude movements similar to myoclonus to shaking of the limbs and even the trunk, which are often intermittent and can be triggered by painful stimuli. Their frequency is unknown, but they usually occur in extensive lesions of the brainstem usually related to acute basilar occlusion [16]. The pathophysiology is uncertain and the most likely is the corticospinal tract ischemia. Recognition of these movements, and consequent measures for quick diagnosis and treatment, are important because they may suggest the formation of a basilar occlusion.

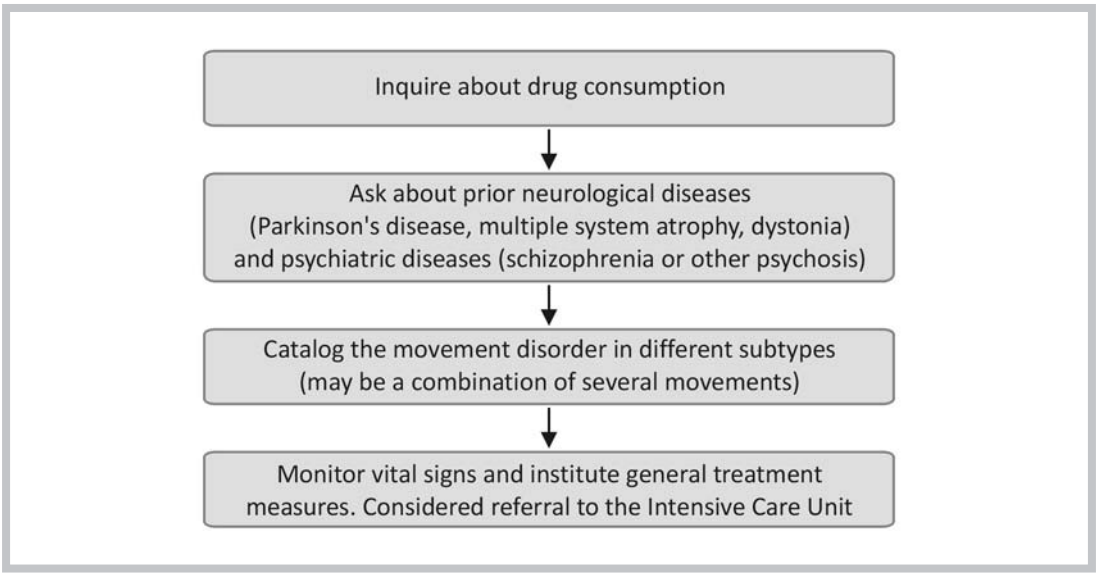

Figure 91.2. **Algorithm for emergency management of acute movement disorders.**

91.9 Conclusions

In patients accessing the emergency room with a movement disorder of acute onset, clinical manifestations and etiology may be various. In such cases we must evaluate the autonomic disorders that may accompany the clinical features and establish the therapeutic measures that can sometimes require ICU admission (Figure 91.2).

92.1 Introduction

Currently, there is a worldwide trend to create specialized intensive care units (ICU). According to two reports (2001 and 2006) by the Royal College of Physicians of London, intensive care management of patients suffering from stroke (cerebrovascular accident [CVA]) appears to reduce hospitalization, degree of sequelae and mortality [1]. In Brazil, especially in private health services and large cities, it is not uncommon to find within the same hospital highly specialized facilities for the care of cardiac, surgical, and transplant patients. And among who benefit most from this segmentation are neurological patients. A neurological ICU may be operated within a general ICU or at a separate location. What defines it is not the physical space but rather the technology resources available for monitoring and treating diseases of the brain, coupled with human resources specialized in neurointensive care [2], including the physiotherapist.

Until recently, neurological disorders in the acute phase were treated with a passive therapy. The patients were kept alive but sedated, with treatment aimed solely to maintain clinical stability until the disorder spontaneously regressed. With the advent of scientific and technological medicine, therapy has become more active: neurological changes and blood metabolism are rigorously monitored so that early intervention can be instituted and undesired consequences avoided or minimized [3]. A typical example is thrombolytic therapy in ischemic stroke.

Worldwide, although neurological diseases are not a leading cause of mortality, the incidence of stroke and traumatic brain injury (TBI) is increasing as is the number of survivors with disabilities.

From a functional standpoint, neurological patients, such as those recovering from TBI, have severe limitations that significantly impair their quality of life, in addition to the psychosocial and financial burden on both the family and society [4]. The clinical manifestation of nervous system diseases is closely related to the site or sites of injury and their respective extension [5]. Therefore, it is essential to understand the nature and complexity of the entire nervous system in relation to the interventions by the multidisciplinary team member to ensure that such treatment is safe, effective and not harmful. The physiotherapist has an important role in the intensive care of the neurologically ill owing to the risk of respiratory complications, the frequent need for mechanical ventilator assistance, and the presence of motor deficits, among others. The physiotherapist plays an active part in assisting patients; this work requires continuous training and improvement, as well as collaboration with doctors, nurses, nutritionists and other team members.

Preventing complications, restoring function and improving the neurological functional status of patients in order to achieve the greatest degree of independence are among the goals of physical therapy in neurointensive care. The rehabilitation process begins

in the ICU and views the patient as a whole individual, taking an approach that does not isolate the neurological system, but rather integrates it with other systems, adjust treatment to the course of illness and recovery to obtain better results.
Hence, it is not advisable for the therapist to work solely according to a protocol. This does not mean ignoring treatment protocols; protocols are important for guiding a group of professionals in the conduct of day-to-day treatment, avoiding hasty decisions and therapeutic abuse. On the other hand, neurointensive physiotherapy, treatment and pre-defined goals can ignore the fluctuating clinical conditions commonly described by patients in the acute neurological phase which requires a more refined therapeutic approach.
Some studies report that respiratory physiotherapy in critically ill patients can bring about undesirable consequences, such as impaired oxygen transport resulting from the adverse effects on venous return, cardiac output and systemic blood pressure. In theory, respiratory physiotherapy applied to the patient's chest, increases intrathoracic pressure [7,8]. This, in turn, leads to decreased venous return, and both can impair cardiac filling, resulting in increased intracranial pressure [9,10]. On the other hand, cardiovascular effects are indeed observed in hypovolemic patients, and the possible temporary increase in intracranial pressure is not reflected in brain injury when cerebral autoregulation is preserved. In practice, physiotherapy and motor rehabilitation need to be informed by the monitoring of brain energy metabolism, for example, as tools to guide the intensity, duration and type of interventions that can be applied to the patient at a given moment.
There are still few studies in neurointensive physiotherapy that add to scientifically based evidence. This does not diminish the importance of physical therapy or that it is not practiced; instead, clinical trials in this segment are lacking. In general, scientific research investigating the technical resources and the activities of the physical therapist in neurointensive care require more rigorous methodological design. We need measures of the expressive point of view of monitoring neurological status and the sample size, as in any study design, with the aim to improve physiological outcomes and clinical outcomes such as achieving a lower incidence of pneumonia, shorter duration of mechanical ventilation and hospitalization, among others.
Thus, in the following pages we will discuss physical therapy in acute-stage neurological patients hospitalized in an ICU.
Finally, there is a popular saying in neurointensive care that says: «If you cannot help, at least do not hinder.» In other words, there is little or nothing you can do to reverse the damage from the primary neurological injury, but incorrect therapeutic management of neurological patients in the acute phase may worsen secondary injury, increasing the degree of disability.

92.2 Neurointensive Vision for Physical Therapy

92.2.1 Characteristics of Neurointensive Patients

The most frequent reasons for admission to a neurointensive ICU are: head trauma, stroke, spinal cord trauma, brain surgery (mainly tumour resection and clamping of aneurysms), among others.
The clinical picture is often characterized by prolonged hospitalization and mechanical ventilation, frequent need for tracheostomy due to immobility and bed restriction. This condition is usually associated with pulmonary complications.
In this context, the appropriate management and support of physical therapy will include: assessment of dysfunction, monitoring, and neurointensive physiotherapy.

Assessment of Dysfunction and Monitoring

The importance of evaluation and monitoring of dysfunctional neurointensive patients resides in the early detection of clinical abnormalities which can be reversed before permanent sequelae ensue. The neurological workup is usually extensive and thorough. In the ICU, the assessment should be rapid and encompass level and content of consciousness, pupil assessment and motor response patterns (muscle tone, reflexes and strength), as well as adequate monitoring of cerebral blood flow and metabolism.

Monitoring of respiratory function will examine the rates of gas exchange and respiratory mechanics (Table 92.1), facilitate the evaluation of pulmonary complications such as hypoxemia and hypercapnia. Both may increase the damage to the airway adjacent to primary lesions, the so-called twilight zone of brain injury.

Oxygenation	• Oxygen saturation (arterial and peripheral) and the ratio of partial pressure of oxygen over the fraction of inspired oxygen (PaO_2/FiO_2) • Pulse oximetry
Ventilation	• Partial pressure of carbon dioxide • Capnography
Mechanical breathing	• Compliance • Lung resistance • Intrinsic PEEP (particularly when the minute ventilation as a therapeutic strategy needs to be increased)

Table 92.1. **Evaluation of gas exchange and respiratory mechanisms in neurointensive care.**

During assessment, the physical therapist will observe the chest and monitor radiological changes, which will guide the diagnosis and monitoring of potential lung disorders, besides the need for physical therapy interventions.

Assessment of cardiovascular function will check for heart rate (HR) and mean arterial pressure (MAP). Continuous electrocardiography (ECG) can identify common cardiac arrhythmias in acute neuropathy [12], and changes in MAP can be correlated to intracranial hypertension. In some acute situations, physical therapy may be contraindicated.

In emergency situations, evaluation is performed concurrently with the basic manoeuvres recommended for the initial treatment of neurological and neurosurgical patients. The team must be integrated and well-trained in order to preserve life. Therapeutic priorities follow the sequence: A – Airway maintenance; B – collateral ventilation/oxygenation; C – circulation; and D – the deficit. Also, further investigation should be performed as soon as possible.

In the neurological workup, the therapist must be properly trained to assess the following parameters.

Parameter	Response observed	Score
Eye opening	Spontaneous eye opening	4
	Verbal stimuli	3
	Painful stimuli	2
	Missing	1
Best verbal response	Oriented	5
	Confused	4
	Profanity	3
	Incomprehensible sounds	2
	Missing	1
Best motor response	Obeys commands	6
	Locates painful stimuli	5
	Nonspecific withdrawal	4
	Decortication	3
	Decerebrate	2
	Missing	1

Table 92.2. **Glasgow Coma Scale (GCS). Teasdale and Jennett (1974) [13], subsequently modified by Jennett et al. (1977) [14].**

92.2.2 Content and Level of Consciousness

The level of consciousness is the degree of behavioural warning the individual shows

that can be determined by the level of response given by the patient to external stimuli. The Glasgow Coma Scale (GCS), devised by Teasdale and Jennett in 1974, [13], initially totalled 14 points and was subsequently amended in 1975, with the addition of 1 point for a total of 15 points. It is used to monitor the level of consciousness after TBI according to the following scores: ≤8 (severe coma); 9-12 (moderate coma); and 13-15 (mild coma) (Table 92.2).

Parameter	Score
Anxious, agitated or restless	1
Cooperative accepting ventilation, oriented and peaceful	2
Sleeping, response to discrete auditory and tactile stimuli	3
Sleeping, minimal response to auditory and tactile stimuli	4
Responds only to painful stimuli	5
No response to painful stimuli	6

Table 92.3. Ramsay Sedation Scale [16].

Besides being used to monitor the patient during the acute phase, ECG is also applied as an index of neurological prognosis. This scale has a positive predictive value of 80-90% for assessing prognosis, with 10-20% of patients who may have an incorrect prediction of their prognosis [15].

Frequently been used in the ICU to evaluate the degree of sedation in neurological patients is the Ramsay scale [16] (Table 92.3). The neurophysiologic responses to verbal, visual, tactile, and proprioceptive stimulation depend on the ascending activating reticular formation and cerebral cortex.

Since the contents of consciousness are the sum of all cognitive and affective functions of humans, such as language, praxis, memory and gnosis, they depend on the function of the cerebral cortex [17] and should be evaluated by asking simple questions concerning the patient's orientation in time, place and person. According to the answer, consciousness is classified as directed or disoriented. At first, the patient may respond to questions coherently or be unable to answer even after being prompted. Some clinical conditions such as hypoxemia and hypercapnia aggravate the state of disorientation and should be rectified immediately once detected.

Pupils

Pupillary examination will evaluate pupil diameter, symmetry and light reflexes (Table 92.4); abnormalities in pupillary size and reactivity may be indicative of structural damage extending from the thalamus to the bridge.

Since some pupil changes can alert to the need for urgent therapeutic intervention, they should be monitored several times a day and during physiotherapy. Complications such as intracranial bleeding and cerebral edema may cause increased intracranial pressure and/or brain herniation, resulting in changes of the pupils, which can vary rapidly from isocoria to anisocoria or mydriasis and non-reactivity of one or both pupils. In such situations, early intervention can determine the patient's prognosis.

Parameter	Classification	Characteristics
Diameter	Miotic	<2 mm
	Mydriatic	>5 mm
	Average fixed	4 to 5 mm, fixed in the light
Symmetry	Average fixed	4 to 5 mm, fixed in the light
	Isocoria	Symmetrical
	Anisocoria	Asymmetric
	Discoria	Abnormally
Reactivity	Photoreactive	Contraction on light stimulus
	Non reactive	No reaction to light stimulus

Table 92.4. Pupillary assessment.

Patterns of Motor Response

Brain lesions can produce pathological patterns of motor response; those most frequently observed in the ICU are:

- Decortication: posture of adduction and flexion of the elbow, wrist and finger flexion of the upper limb, as well as hyperextension, plantar flexion and internal rotation of the lower limb. These changes are suggestive of dysfunction in the deep supratentorial regions of the internal capsule.
- Decerebrate: posture of adduction, extension and hyperpronation associated with upper limb extension and plantar flexion of the lower limb, suggestive of high spinal cord injury, above the red nucleus, extending to the diencephalon.
- Paresis: partial inability to perform voluntary movements. It may consist of several deficits, such as loss of selective motor control of balance, righting reactions, primitive reflexes and sensitivity, as well as the presence of abnormal muscle tone.
- Plegia: the total inability to perform voluntary movements, including deficits that can result from injury to the pyramidal tract, extrapyramidal system, cerebral cortex (premotor, primary motor and somatosensory) and the cerebellum. Depending on the extent and severity of injury, the patient presents a clinical picture of paralysis with spasticity, hyperreflexia or hyporeflexia (sagging).

But among the abnormal reflexes, the one most frequently encountered in clinical practice in the ICU is the plantar cutaneous reflex which, when positive (Babinski sign), indicates a loss of pyramidal function which can be transient depending on the patient's condition.

92.2.3 Brain Hemodynamics

Brain hemodynamics is characterized by a balance of the intracranial components (brain tissue, blood and cerebrospinal fluid [CSF]) being able to tolerate small increases in volume without changing intracranial pressure (ICP). Therefore, an increased volume in one or more components will be accompanied by a decrease in others. However, when there is damage that interferes with brain compliance, even minor expansion of the intracranial content can significantly increase ICP, contributing to the loss of cerebral autoregulation.

Monitoring brain hemodynamics includes the evaluation of cerebral metabolic and circulatory function. The coupling of these functions depends on the mechanisms of cerebral autoregulation. Thus, cerebral autoregulation is the brain's ability to maintain blood flow constant regardless of variations in blood pressure, while satisfying the brain's metabolic demands.

The conditions that lead to augmented aerobic metabolism increase the production of carbon dioxide, responsible for vasodilation and appropriate increased microcirculatory cerebral blood flow. In contrast, anaerobic metabolism, concomitant with a reduction in carbon dioxide, mediates vasoconstriction and flow reduction.

Cerebral blood flow can be calculated by the formula: CBF = CPP / CVR (CBF = cerebral blood flow, CPP = cerebral perfusion pressure, CVR = cerebral vascular resistance). The normal CPP range is 60-95 mmHg. For monitoring CPP, Langfitt and colleagues (12) proposed calculating the difference between MAP and ICP, i.e., CPP = MAP – ICP (MAP = mean arterial pressure, ICP = intracranial pressure).

Thus, maintenance of MAP, generally >100 mmHg in adults, helps to ensure adequate CPP. The parameter of normal peak is <10 mmHg in adults, whereas peaks ≥20 mmHg characterize intracranial hypertension (ICH).

The adequacy of cerebral blood flow to meet metabolic demand can be used to monitor cerebral of oxygen extraction (CEO_2).This represents the true and most important parameter of proportionality between CBF and oxygen consumption. CEO_2 is understood as the difference between oxygen supply and consumption, estimated in clinical practice, the difference between the arterial and venous saturation of oxygen (the latter is obtained from the jugular bulb catheter). Normal values for CEO_2 are 33% for adults, with a range of variation of approximately 24 to 42%. Values above and below normal represent hyper-or low flow in cerebral oxygen consumption, respectively.
These notions of brain hemodynamics guide the team in physiotherapy management and clinical or surgical treatment which require the coupling of neurological function, cardiovascular and respiratory diseases.

92.3 Physical Therapy

92.3.1 Respiratory Therapy

Techniques and Resources of Respiratory Therapy

Respiratory therapy aims to minimize the retention of endobronchial secretions and maximize ventilation and oxygenation (18). When performed during mechanical ventilation, respiratory therapy helps to adjust ventilation parameters, weaning and extubation. The use of noninvasive mechanical ventilation is increasingly reported in the literature [19].
Respiratory complications are more frequent in neurocritically ill patients: pneumonia, acute respiratory failure, neurogenic pulmonary edema and atelectasis [20]. Under these conditions, physiotherapy techniques use protective strategies of mechanical ventilation to minimize the symptoms and degree of lung injury [21,22].
Respiratory therapy may promote a temporary rise in intrathoracic pressure and consequent reflex in cerebral hemodynamics and intracranial pressure [9]. Therefore, patients should be approached with special care for each of the techniques applied at the time of therapy.

Bronchial Hygiene

Chest physiotherapy is included most ICU treatment protocols in the developing countries. Its role is quite varied, depending on location and tradition of service, level of education, training and experience, and especially the patient characteristics.
In some ICUs the physical therapist will evaluate and monitor all patients daily while in others, the service is performed only upon request. This helps to determine the character of its action, intervention and outcomes.
The features and therapeutic techniques in respiratory therapy include the following.

Stimulation of Cough

Stimulation of cough is a common technique to treat respiratory complications resulting from the accumulation of secretions, especially in patients with cognitive impairment (no response to verbal commands) and those with high spinal cord injury, in whom paralysis of the trunk and abdomen muscles reduces the ability to generate effective cough. In such patients, there is a close relationship between motor level and peak expiratory flow during cough [23]. Jaeger and colleagues [24] studied the efficacy of three methods of cough stimulation in patients with high spinal cord injury. The methods in-

volved coughing without manual assistance, with assistance from the therapist, and abdominal electrical stimulation. The effectiveness of the technique was measured by peak expiratory flow. Electrical stimulation-induced cough was more effective than manually assisted cough; however, abdominal electrical stimulation is not a common practice in the ICU.

Inducing coughing is undesirable in patients with increased intracranial pressure. It is contraindicated because it leads to an increase in intrathoracic pressure, decreasing venous return, thereby increasing cerebral blood flow. However, when cerebral autoregulation is preserved, intracranial pressure returns to normal levels immediately after the procedure, demonstrating adequate compliance of the nervous system. Under such conditions, cough can be used as a resource during bronchial hygiene therapy.

Endotracheal Suction

A constant concern in neurological patients is the aspiration of pulmonary secretions because this can negatively affect the cerebrovascular status by increasing intracranial pressure. Therefore, brain damage can ensue not only from the primary trauma but also secondarily to reduced oxygen to the brain as a result of cerebral edema, ischemia and increased intracranial pressure.

Tracheal aspiration refers to the effective removal of endotracheal secretions, aseptically through a suction system. Airway access for the procedure can be achieved by two methods or systems: open and closed. The first is the most widespread and routinely used in clinical practice. It involves disconnecting the patient from mechanical ventilation for the aseptic introduction of a the probe for aspiration. The second system refers to a multi-use probe enclosed in a plastic cover which is connected to an endotracheal tube and ventilator circuit, allowing aspiration without interrupting mechanical ventilation.

Considering the secondary respiratory complications of neurointensive patients in the acute phase, the closed system seems to be more advantageous as it allows continuation of mechanical ventilation and maintenance of positive end-expiratory pressure (PEEP), thus reducing the partial pressure of oxygen in arterial blood (PaO_2) and increased partial pressure of carbon dioxide in arterial blood ($PaCO_2$) and minimizing the risk of contamination and respiratory infections.

With either system it is recommended that the patient be adequately sedated to avoid psychomotor agitation and be properly positioned (supine rise from 35 to 40°). There is no consensus in the literature on performing this procedure in the presence of impaired cerebral compliance. Some authors suggest the use of lidocaine diluted in 0.9% saline solution directly into the tracheal tube or intravenously administered [25,26].

Bruyas (1981) and Thiesen and colleagues (2005) [9,27], at the time of endotracheal aspiration, reported a significant increase in ICP due to stimulation of the cough reflex, which increases intrathoracic pressure and therefore decreases venous return, interfering directly with brain metabolism. Some authors have recommended adequate sedation combined with topical anesthesia and neuromuscular blockers in order to avoid psychomotor agitation and stimulation of the cough reflex, and thus effects on ICP and CPP and MAP [25,28-30].

The aspiration time should not exceed 15 / 2 to prevent hypoxemia; the suction pressure should not exceed 120 mmHg or the suction flow rate 16 l/min to avoid mucosal trauma. Intratracheal instillation of 0.9% saline solution, while feeding, can be used with caution to thin thick bronchial secretions and plugs, as saline instillation may trigger a reflex cough and Valsalva manoeuvre, significantly increasing the ICP [31].

Aspiration should be performed only when pulmonary auscultation reveals rales, the mechanical ventilator display indicates increased peak inspiratory, deterioration of oxygenation demonstrated by a drop in oxygen saturation, and when the movement of se-

cretions is audible during respiration. The technique should not be performed at regular intervals because the risk of routine aspiration outweigh its benefits [31].

Despite its being a widely used procedure in neurological patients, endotracheal suctioning is associated with complications including, hypoxemia, changes in partial pressure of carbon dioxide, tracheal mucosal injury, increased intracranial pressure, hypertension, bradycardia and arrhythmias. It can also result in damage to the mucosa and mucociliary system, which is usually operator-dependent, the amount of pressure used, and the establishment of this procedure as a routine [32].

Another study suggested that hyperventilation and hyperoxygenation performed before tracheal aspiration can avoid significant changes in cerebral hemodynamics [33]. Hypoxemia is one of the most significant complications in neurological patients, since the magnitude of the decline of PaO_2 and oxygen saturation (SaO_2) and increased partial pressure of carbon dioxide ($PaCO_2$) can trigger bradycardia, coronary vasoconstriction and supply blood to the tissues, causing cerebral ischemia, worsening the prognosis.

There is consensus [34,35] that additional oxygen can be administered in ventilated neurological patients during tracheal aspiration procedures.

Conventional Manoeuvres

Conventional physical therapy manoeuvres include compression, vibration, locking and unlocking chest manoeuvres, postural drainage, tapping and ventilatory patterns. These manoeuvres can also be used in neurological patients. However, some care must be observed.

In the study by Thiesen et al. [9] effects were observed of conventional physiotherapy manoeuvres on cerebral perfusion pressure and intracranial pressure in head-injured patients, with peaks of up to 30 mmHg. The authors concluded that the manoeuvres did not significantly affect cerebral perfusion pressure. Of the manoeuvres studied, tracheal aspiration led to an evident increase in ICP, which returned to baseline 1 minute after the procedure. It is understood that in patients with preserved cerebral autoregulation, the return of ICP to baseline values is rapid, without generating unwanted effects in CPP, so that tracheal aspiration can be performed if necessary.

Chest physiotherapy manoeuvres tend to increase intrathoracic pressure by increasing lung volume. They are indicated in the treatment of alveolar collapse because elevated $PaCO_2$ causes vasodilation, with a consequent increase in cerebral blood flow and ICP. Therefore, in situations where alveolar collapse is accompanied by hypercapnia, one of the benefits of chest manoeuvres is to reduce $PaCO_2$.

Thoracic Manoeuvres

Manoeuvres of manual chest physiotherapy (chest compression, locking and unlocking manoeuvres, thoracic breathing pattern, directed or contralateral) for the reversal of alveolar collapse tend to increase intrathoracic pressure by increasing lung volume and warrant caution in these patients. Often the failure is responsible for the increased intracranial pressure owing to increased $PaCO_2$, which is responsible for vasodilation and the consequent increase in cerebral blood flow. Therefore, the increase in lung volume resulting from re-expansion manoeuvres may be beneficial in treating alveolar collapse by reducing $PaCO_2$, even if some degree of intracranial hypertension is generated, especially when cerebral autoregulation is preserved.

Alveolar Recruitment

Alveolar recruitment has been indicated for the treatment of alveolar collapse observed in the acute respiratory distress syndrome (ARDS), where hypercapnia can be tolerated.

In patients with neurological injury alone, the ventilation strategy will differ from those previously mentioned because it seeks to achieve greater control of the amounts of CO_2 in arterial blood. Therefore, in patients with concomitant brain injury and severe respiratory failure there is a conflict in the therapeutic principles that guide ventilatory support. Studies investigating with the effect of positive end-expiratory pressure (PEEP) on ICP have been inconsistent [10,36-38]. Shapiro and Marshall [38] reported increased ICP after using 4-8 cmH_2O PEEP and decreased CPP in 50% of cases. In contrast, Frost [36] observed no peaks with the use of high PEEP.

Importantly, another study found a significant reduction in CPP during PEEP only in patients with low central venous pressure (CVP), suggesting the deleterious effect of hypovolemia during ventilation with PEEP [37]. Some authors have suggested that PEEP may cause a significant increase in ICP only in patients with low-compliance brains [38-40].

For these reasons, it is of fundamental importance to join the efforts of the multidisciplinary team in therapeutic decision making, taking into account the risk-benefit ratio for patients where hypoxia is a major risk factor for complications after injury or brain surgery.

Despite the many studies, mostly experimental, on alveolar recruitment manoeuvres, few clinical trials have investigated the effects of these manoeuvres in acute respiratory failure in neurological patients. Studies by Huynh and Wolf [41,42] concluded that PEEP of up to 15 cmH_2O did not lead to a drop in CPP nor an increase in ICP in patients after neurosurgery.

In another study evaluating 43 patients after severe neurological injury with respiratory failure and undergoing recruitment manoeuvres using pressures up to 60 cmH_2O for 30 seconds, there was a deterioration in cerebral hemodynamics, with increased ICP and decreased CPP. Since the authors noted an improvement in blood oxygenation, they recommended routine use of this manoeuvre.

Muscle Training

Recent studies have addressed the complications of mechanical ventilation in the short term, such as reducing the mass and contractile properties of respiratory muscles. In a study by Capdevila and colleagues [44], 48 hours of mechanical ventilation were sufficient to reduce respiratory muscle strength by around 20 to 30%, the ability to generate strength, fatigue resistance and atrophy of type IIa and IIb fibres of the respiratory muscles in rats. Also, Hering and colleagues [45], in a study in pigs with oleic acid-induced lung injury, found that mechanical ventilation in 80% of cases reduced blood flow to respiratory muscles in comparison to spontaneous breathing, despite improvement of the oxygenation index.

These factors contribute to our understanding that suppression of spontaneous breathing during mechanical ventilation in patients with primary or secondary neuromuscular disorders adversely affects respiratory muscle activity, impairing the removal of ventilatory support.

In this case, the muscle training has a key role in the permanent removal of mechanical ventilation [46]. Stiller and Huff [47] reported that training the muscles of the neck and upper chest in ventilator-dependent quadriplegic patients may improve the vital capacity and allow the ventilator to be disconnected for longer periods.

The use of abdominal weight and load resistance muscle training in 11 patients with complete cervical lesion showed significant differences in forced vital capacity, maximum voluntary ventilation, and maximal inspiratory pressure. However, there was no difference between the two techniques studied by Derrickson and colleagues [48].

In other neuromuscular disorders, muscle training can also improve strength and endurance, as reported by McCool and Tzelepis [49]. The authors reviewed seven studies on

muscle training, involving a total of 75 patients whose training regimen included the use of inspiratory resistance load and isocapnic hyperpnoea. The patients with lower neuromuscular disorders showed significant increases in muscle strength and endurance. Patients with more severe disorders were retainers of carbon dioxide, where there was little change in muscle strength or endurance. No adverse effects were reported in these patients.

Besides the effects on the performance of respiratory muscles, muscle training appears to improve lung function and reduce dyspnoea, as in cases of myasthenia gravis and multiple sclerosis [50]. In such patients, we observed a reduction in periods of pulmonary exacerbation, improved exercise tolerance, cough effective, and less need for mechanical ventilation. In addition, the type of tracheal access must be considered because these patients remain under prolonged mechanical ventilation. Some studies comparing very early tracheostomy intubation with mechanical ventilation reported that tracheostomy assists in weaning from mechanical ventilation and decreases the incidence of infections due to easier suctioning the airways, and generates greater degree of comfort, better mobility, communication and power for the patient [18].

92.3.2 Motor Assessment

Recommended instruments for the assessment of neurological patients in the ICU.

The aims of physiotherapy assessment and intervention in neurological and neurosurgical patients in the ICU are to detect and identify complications, making a detailed assessment of the degree of function and weaknesses. Standardization of physiotherapy assessment and intervention in neurological and neurosurgical patients supports decision making in line with the best scientific evidence and available resources.

Objective clinical assessment will require reliable and valid scales that are appropriate to what we want to measure, that establish a baseline before starting treatment, and that allow us to record the degree and duration of response to treatment. Evaluation includes careful measurement, accompanied by judicious assessment of the results, which will help to create an appropriate intervention plan and permit its modification according to the patient's specific needs.

The goal of rehabilitation is to reduce the level of disability, reaching the maximum of functional independence, participation and integration in social and economic life. To measure the achievement of these objectives, rehabilitation must have assessment tools to objectively quantify the level of disability which a patient presents at a given time and to measure changes that occur prospectively in rehabilitation treatment. The use of rating scales helps to prioritize areas where we must act in the planning of rehabilitation and then allows us to compare the effectiveness and efficiency of treatments.

Physiotherapy assessment and intervention in critically ill patients is aimed at early identification of deficits secondary to the injury, providing timely interventions to existing or emerging gaps, preventing or reducing the risk of further complications, and promoting well-being to facilitate recovery in relation to mobility, health, and preservation of the patient's social role.

Prolonged immobilization, lack of active movement, impaired sensation and proprioception, and altered level of consciousness lead to deficits in aerobic capacity, muscle performance, joint mobility, and integumentary and sensory integrity, which must be identified and treated early to ensure the quality of care and the necessary continuity of care during all phases of the disease.

The American Physical Therapy Association (APTA) [51] has recommended specific criteria for intervention and monitoring the use of testing and measurement.

Deficit	Tests and measures
Impaired aerobic capacity	• Cardiovascular symptoms and signs • Pulmonary symptoms and signs • Evaluation of physiological response to postural changes • Brain monitoring
Impaired respiratory muscle performance	• Maximum static pressures (PI_{max} and PE_{max}) • Nasal pressure sigh
Impaired muscle performance	• Strength, endurance and muscle strength in functional activities
Impaired joint mobility	• Goniometry
Impaired alertness/attention and cognition	• Glasgow Coma scale (GCS) • Rancho Los Amigos Levels of Cognitive Functioning (LOCF) • Mini Mental test
Impaired integumentary integrity	• Braden scale
Impaired ventilation	• Auscultation • Arterial blood gases • Pulse oximetry • Capnography • Pulmonary symptoms (dyspnea)
Impaired breathing	• Breathing pattern • Cough • Assessment of dyspnoea • Phonation • Auscultation • Parameters of mechanical ventilatory support
Impaired gas exchange	• Arterial blood gases • Pulse oximetry
Deficits in integrity reflexes	• Tendon reflexes • Ashworth Scale (muscle tone)

Table 92.5. **Tests and measures to evaluate the most common deficits in neurological patients in the ICU.**

Tests and measures are essential resources for evaluation; they identify deficits, functional limitations and disability, allowing the selection of interventions and the documentation of changes in patient status so that the scope of outcomes which are the endpoints of the intervention can be indicated.

In the ICU, tests and measures should be selected and applied according to the patient's clinical condition, so that dynamic process deficits and limitations can be interpreted and identified. Depending on the state of consciousness, the tests can measure clinical and hemodynamic status and deficits (Table 92.5).

Some authors recommend evaluating the effectiveness of rehabilitation using scales such as the Cognitive Functioning Scale, the Rancho Los Amigos Scale, the Barthel Index, the Mini Mental Test, and the Disability Rating Scale (DRS) [52,53].

Scales for assessing functionality at the beginning and end of rehabilitation intervention that may demonstrate its effectiveness include the scales described below.

Rancho Los Amigos Scale

The **Rancho Los Amigos scale (Levels of Cognitive Functioning Scale [LOCF])** measures the level of patient response and functional capacity. Its name comes from the rehabilitation hospital where it was created, the Rancho Los Amigos in California. The LOCF scale is based on the patient's reaction to external stimuli and to the environment. The scale consists of eight different levels, and each patient will progress through the levels

with starts and stops, progress and plateaus. Irdesel et al. [54] investigated in 30 patients with head trauma admitted to the ICU of the School of Medicine, University of Uludag, complications observed during a rehabilitation program in the acute phase, its relationship with functional status, and the factors that influence rehabilitation outcome. The rehabilitation program consisted of postural rehabilitation, joint mobility exercises and breathing exercises. All patients were assessed with the scales of the Functional Independence Measure (FIM) and the LOCF upon entering the ICU and at discharge. Improvement was measured in terms of functional outcomes and levels of disability. The most frequent complications were pneumonia (46.7%), atelectasis (43.3%), anemia (40%), and meningitis (30%). The authors found that levels of functionality decreased with an increasing number of complications and concluded that rehabilitation plays an important role in the recovery of patients with head trauma and that the reduction in the incidence of complications and improved levels of functionality can be achieved with rehabilitation programs. They suggested the need for long-term studies with a large number of patients to obtain accurate data on factors associated with rehabilitation outcomes.
The following is a brief summary of the components of the LOCF:

- Level 1. No response: The patient is apparently in a deep sleep and there is no response to stimuli.
- Level 2. Generalized Response: The patient does not react consistently and without purpose to the stimulus. The answer is not specific and is delayed.
- Level 3. Localized Response: The patient responds to a particular stimulus but not consistently, can follow simple commands, but is slowed. He or she can be aware of their body, because it reacts to situations of discomfort, with a response to some people but not others.
- Level 4. Confused and agitated response: The patient has greater activity but the ability to process information is severely affected; demonstrates strange and purposeless behaviour, incoherent and/or inappropriate speech. Euphoric or hostile. Selective attention is nonexistent. The patient requires maximum assistance in self-care.
- Level 5. Unclear, inappropriate, not stirred: The patient appears alert and responds to simple commands; has appropriate responses to complex orders; is alert to the environment, with a high degree of distractibility and is unable to focus attention on specific tasks; uses poor language; has important memory impairment, lack of initiative to perform tasks without direction; can perform self-care activities with assistance.
- Level 6. Unclear, appropriate: The patient has goal-directed behaviours under external guidance, follows simple commands and remembers tasks related to self-care and responds appropriately to situations.
- Level 7. Automatic response, appropriate: The patient is independent in protected environments and needs supervision in the community.
- Level 8. Replies with purpose, appropriate: The patient is alert and able to integrate past and present events. Although there are consequences for cognitive-behaviour and functioning in the community.

Functional Independence Measure scale

This global ordinal scale for functional assessment (mobility and self-care) is useful in making decisions about the effectiveness of interventions. Several studies have used the FIM to investigate treatment outcome in self-care, transfers (mobility) and locomotion [55-57].
The FIM uses a 7-point ordinal scale to rate 18 items describing 6 functional areas. The scores measure the weight of care required, wherein high FIM scores represent high lev-

els of independence. Four of these areas: self care, sphincter control, mobility and locomotion factors are measured with 13 items and include motor function. The other two areas, social cognition and communication, are measured with 5 items and relate to the cognitive sphere. The total FIM score is obtained by adding up the scores for the 18 items (Table 92.6).

Level	Description
1	Total assistance; subject contributes <25% of the effort or is unable to do the task
2	Maximal assistance; subject provides less than half of the effort (25-49%)
3	Moderate assistance; subject still performs 50-74% of the task
4	Minimal assistance; subject requires hands-on help only (performs >75% of the task)
5	Supervision
6	Modified independence, subject requires use of a device but no physical help
7	Complete independence

Table 92.6. **Functional Independence Measure (FIM) Scale.**

Barthel Index

The Barthel Index (BI) is a measure of the level of independence in activities of daily living (ADL) [1]. It is the best known, studied and internationally disseminated scale for the assessment of ADLs. ADLs are a set of primary activities of the individual, aimed at self-care and mobility, which provide elementary autonomy and independence and allow the person to live without needing continued assistance from others; these include such activities as eating, bowel control, toileting, dressing, bathing, transferring.

The Barthel Index evaluates 10 areas of ADLs (eating, transferring between the chair and bed, grooming, toileting, bathing, moving, climbing stairs, dressing and undressing, bowel and urine control).

Level	Description
0-20	Total dependence
21 60	Severe dependence
61-90	Moderate dependence
91-99	Slight dependence
100	Independence

Table 92.7. **Barthel Index.**

The total score ranges between 0 and 100, where zero indicates total dependence in ADLs and 100 indicates mobility and independence. The interpretation suggested by Shah et al. (1989) on the BI score is described in Table 92.7.

The Barthel Index is the gold standard test for measuring ADLs; its conceptual validity has enabled studies to demonstrate its predictive ability in relation to duration of hospitalization, overall functional outcome, and the ability to live and participate in the community.

Disability Rating Scale (DRS)

The DRS was designed for assessing patients with moderate or severe TBI (Table 92.8).

The DRS total score ranges from 0 (no disability) to 29 (extreme vegetative state), so the lower the score, the better the patient's functional status [58].

One of the advantages of the DRS is that it allows tracking an individual in a coma until his or her return to the community. The first three items in the order of the DRS ("eye opening", "communication skills"

Level of disability	Score
None	0
Light	1
Partial	2-3
Moderate	4-6
Moderately severe	7-11
Serious	12-16
Very severe	17-21
Severe	22-24
Vegetative state	25-29

Table 92.8. **Disability Rating Scale.**

and “motor response”) are a slight modification of the Glasgow Coma Scale (GCS) [13] and reflect the level of impairment. The cognitive abilities “Food”, “Toilet” and “Go potty” reflect the level of disability, as a “level of functioning.”

92.3.3 Effects of Prolonged Bed Rest

Beyond dispute are the deleterious effects of prolonged bed rest for patients in critical condition. Physical deconditioning and alterations in various systems, secondary to prolonged immobilization in bed are common problems in mechanically ventilated patients with acute respiratory failure, contributing to prolonged hospital stay.

Prolonged immobilization, systemic inflammatory response, poor nutritional status, and the frequent use of drugs such as neuromuscular blockers and corticosteroids contribute to the development of debilitating diseases and neuromuscular disorders. Patients exposed to prolonged periods of immobility often experience pain and changes in mood, compromising their functional capacity [59].

Nava and Ambrosina [60] reported that prolonged bed rest results in decreased muscle mass and muscle capacity for aerobic work; they also noted that patients may progress to polyneuropathy or myopathy of critically ill patients, causing major muscular weakness in approximately 95% of patients up to 5 years during follow-up. The effects of prolonged bed rest in critically ill patients have dramatic effects on the functionality and quality of life related to health. Critically ill patients remain in the supine position for long periods of time, whereas healthy humans change their position approximately every 11.6 minutes during sleep, a phenomenon described as minimum physiological requirement for mobility. Prolonged bed rest can give rise to deleterious effects in the cardiovascular/pulmonary, integumentary, skeletal muscle and others despite repositioning every 2 h [61]. In the ICU, the patient remains for long periods of bed rest, where inactivity and immobility themselves have deleterious physiological effects, including atelectasis, pressure ulcers and increased susceptibility to aspiration and pneumonia.

Prolonged bed rest and immobility predispose to collapse of the peripheral units, resulting in decreased lung volume. The literature reports atelectasis as a common respiratory complication in neurological or neurosurgical patients, associated with low lung volumes, prolonged standing, inadequate cough and accumulation of secretions. The effect of immobility is greater in the elderly and patients with chronic diseases, including congestive heart failure and chronic obstructive pulmonary disease [62]. Some studies report the occurrence of polyneuropathy of critical patients in more than 50% of patients requiring mechanical ventilatory support for more than 7 days [63-65].

Since 1944, the effects of prolonged bed rest have been documented, including bone decalcification, muscle atrophy, dizziness and even fainting when patients start some light activity after prolonged periods of rest [66]. An editorial published in *The Lancet* in 1969 highlighted the damaging effect that prolonged bed rest has on the mechanisms that maintain circulatory homeostasis when passing to the standing position, suggesting that the root causes of an increased tendency toward motion sickness as seen in tilt table tests were insufficient venous return and, consequently, inadequate ventricular diastolic filling and decreased muscle tone, which was consistent with the work of Levine and Lown [67]. The editorial also specified that «the consequences of symptomatic postural hypotension (weakness, instability and tendency to dizziness in orthostatic position) are not specific to a particular disease and are experienced by many patients and healthy individuals after short periods of bed rest».

Table 92.9 illustrates the effects of prolonged bed rest [68]. Recently there has been a growing interest in initiating early mobilization of ICU patients under mechanical venti-

lation. Research in this field is still emerging, but studies indicate that early mobilization in critically ill patients is safe, feasible and associated with short-term benefits. Despite the theoretical advantages that physical therapy offers to address this problem, the evidence is not very strong, yet, in regards to the benefits of early initiation of physical therapy in the ICU [69].

Needham [70] conducted a systematic review of 24 studies involving ICU patients hospitalized with sepsis, prolonged mechanical ventilation and multiple organ failure. The author reported that 46% of 1421 patients in one study had neuromuscular dysfunction associated with prolonged use of mechanical ventilation and longer ICU stays. The review also cited numerous studies, highlighting the physical changes caused by prolonged bed rest, such as loss of muscle strength and changes in heart function. The researcher also based his comments and observations on his experience with patients in the medical ICU at Johns Hopkins Hospital, which has developed a rehabilitation program for ICU patients. The review concluded that the routine use of sedation and prolonged bed rest in ICU patients could cause prolonged residual neuromuscular complications and significant physical impairment of function and quality of life long after leaving the hospital.

Muscular system	• Muscle atrophy • Muscle weakness • Decreased tolerance to exercise • Insulin resistance • Decreased ATP • Decreased protein synthesis • Orthostatic hypotension • Phlebothrombosis
Skeletal system	• Osteoporosis, joint ankylosis, fibrosis
Musculoskeletal system	• Increased resting heart rate • Decreased stroke volume • Cardiac muscle atrophy
Respiratory system	• Decreased vital capacity • Decrease in maximal voluntary ventilation • Altered cough mechanism
Gastrointestinal system	• Constipation • Anorexia
Genitourinary system	• Decreased glomerular filtration • Increased diuresis • Hypercalciuria
Endocrine system	• Glucose intolerance • Altered circadian rhythm • Decreased parathyroid hormone • Increased plasma renin activity • Increased secretion of aldosterone
Metabolism and nutrition	• Increased excretion of nitrogen • Increased excretion of calcium • Increased excretion of phosphorus
Integumentary system	• Pressure ulcers • Edema • Subcutaneous bursitis
Psychosocial	• Depression • Decreased functional capacity

Table 92.9. **Effects of prolonged bed rest.**

Porta et al. [71] conducted a prospective study in 66 patients with respiratory failure and requiring ventilatory assistance for more than 48 or 96 hours. The study compared the effects of implementing a physical therapy program with the effects of general training of upper limb support, which consisted of ergometer cycle training. The study confirmed the benefits of physical therapy in critically ill patients and showed that adding upper limb exercise increases exercise tolerance and reduces dyspnoea and fatigue.

Hodgin et al. [69], in their study surveyed 984 U.S. physical therapists in order to determine the use of physical therapy in the recovery of critically ill patients. The authors concluded that in the United States, physical therapy is performed in ICU patients during recovery from serious illness, however, the frequency and type of physiotherapy varies significantly based on the type of hospital and clinical setting, and 87% of interventions involved stroke patients.

Korupolu et al. [72] reviewed important aspects to consider in the early mobilization of ICU patients, including safety, feasibility, potential benefits, possible obstacles, and resources. The article also highlighted the future directions for this field, including research and potential adjunctive interventions to improve neuromuscular performance resulting from prolonged bed rest after major diseases.

Below are some strategies in evidence-based interventions and the recommendations and conclusions the studies made regarding the effect of prolonged bed rest in neurointensive patients.

Continuous Rotational Therapy

In the supine patient, the abdominal contents push the diaphragm cephalad, resulting in decreased functional residual capacity, with alveolar collapse in dependent areas. Regardless of the mechanisms involved, hypoxia causes atelectasis and hypoventilation, creating a vicious cycle that complicates the clinical course.

Among the intervention strategies to prevent and/or treat atelectasis and pneumonia associated with prolonged bed rest is continuous rotational therapy (CRT) or kinetic therapy and positioning. CTR refers to the use of specialized beds that rotate the patient on its longitudinal axis to a maximum angle of 60 degrees to each side continuously; the slower rotation speed prevents the stimulation of the vestibular apparatus. CRT prevents the closure of dependent airways, reduction of lung compliance, atelectasis, accumulation of lung secretions and secondary infection [73] to these complications.

CTR can be achieved by using a rotational platform bed (movement therapy) or a bed mattress with compartments that inflate and deflate beds (oscillatory) [74].

Some authors have examined the beneficial effects of rotational therapy. Waldmann et al. [75] conducted a meta-analysis to analyze the effect of rotational therapy in the prevention and/or treatment of respiratory complications in critically ill patients. From their search of the literature published between 1987 and 2004 they analyzed 15 studies which reported on the types of beds but very little about the rotation parameters, for example, grade, pause time, and the amount of time per day; however, the meta-analysis suggested that rotational therapy decreases the incidence of pneumonia but has no effect on the duration of mechanical ventilation.

Powers et al. [76] suggested performing rotational therapy with rotation of 40 degrees or more for at least 18 hours a day. The article mentioned that the most suitable patients for rotational therapy present oxygenation index, PaO_2/FiO_2 (P/F ratio) <300 mmHg, FiO_2 >0.5 or PEEP >10 cmH_2O and patients at risk of developing the acute respiratory distress syndrome (ARDS) (septic shock, multisystem organ failure, trauma, and aspiration). The exclusion criteria in the study were the use of rotational therapy in patients without ventilatory support, except for those with spinal cord injury, patients with agitation refractive to sedation, patients incompatible with the specifications of the bed, patients

with uncontrollable diarrhoea and postoperative cardiac surgery. Criteria for discontinuing CTR were: a significant improvement in the P/F ratio, FiO_2 <0.4, increased mobility, uncontrolled shaking, extubation, and ability to walk, patients not more than 5 days on CRT, and patients who could not tolerate CTR for 18 h/day.

Culpepper Swadener et al. [77] investigated the impact of CRT in patients considered at high risk for pulmonary complications, using a tool that predicts patients at risk of nosocomial pneumonia. The tool comprises a list of 12 items, each assigned a score of 1, where 5 indicates that the patient is at high risk for developing pneumonia. Patients who received CRT were divided into two groups: one group started early CRT (n=49) and the other group received late CRT. The results of the study showed that early initiation of CRT, within 48 hours when the patient meets the criteria defined for treatment, significantly reduced the need for care and the total cost of ICU stay. The study excluded neurological patients requiring high FiO_2 for short periods of time to increase cerebral oxygenation, and not by lung involvement. Patients with unstable spinal cord injury, long bone fractures requiring traction, and some patients with head and neck boards were not considered for CRT.

Although the CTR is not used in our unit, it should be considered as a useful tool in the prevention and treatment of pulmonary complications; however, this implies extensive knowledge of the technology, development of a clinical protocol by professionals, and its application on the basis of a judicious assessment to define the correct indication.

Positioning

Positioning is the use of body position as a technique for specific treatment in the ICU. It can be used for physiological purposes: to optimize oxygen transport, increase lung volume, decrease breathing effort, minimize cardiac work, improve mucociliary clearance, and improve ventilation/perfusion [78]. Due to its immediate and direct effect on oxygen transport, therapeutic positioning can be considered a noninvasive intervention that promotes arterial oxygenation. Routine mobilization of critically ill patients at least every 2 hours has become a standard of care. However, there is not an objective assessment regarding compliance with this standard on a regular basis.

Krishnagopalan et al. [79] conducted an observational, longitudinal prospective study to determine whether ICU patients were repositioned every 2 hours. The results showed that, on average, 49.3% of the observed time, patient position was unchanged for more than 2 hours. Only 2 of 74 patients (2.7%) had their position changed every 2 hours. The authors concluded that most patients did not receive critical position changes every 2 hours, which warranted a reassessment of the care of critically ill patients.

Although repositioning critically ill patients seems logical, little data that supports its clinical effectiveness have been published.

In critically ill patients, physical therapists who perform positioning consider the need for selecting and applying specific body positions based on evaluation, chest radiography, and hemodynamics of the patient, always seeking physiological improvement.

The choice of positioning (sitting, lateral, prone, bipedal), time and frequency are the result of clinical reasoning, based on the evaluation of factors contributing to cardiopulmonary failure and response to intervention.

In patients with acute brain injury, special consideration must be taken such as keeping the head and neck properly aligned to promote venous return and/or monitor the position chosen so that it does not interfere with brain monitoring. Depending on hemodynamic conditions and the state of consciousness, the patient's progress and goals of the intervention, several positions can be used.

In critically ill patients, the orthostatic and/or sitting position is used to improve lung volume, reduce breathing effort, and decrease the risk of aspiration. The sitting position restores ventilation-dependent lung regions, preventing intra-abdominal pressure interfering with lung volumes.

The supine position helps improve ventilation/perfusion, redistributes alveolar edema, and improves functional residual capacity in patients with ARDS.

The lateral decubitus position improves the ventilation-perfusion relationship in patients with unilateral disease. Stiller et al. [80] compared various physiotherapy techniques in patients with acute lobar atelectasis, and concluded that with the involved side up and the bed in a horizontal position atelectasis improved when hyperinflation was combined with secretion suction, which was checked radiologically. Thomas et al. [81] conducted a survey of physiotherapists and nurses in three Australian ICUs and inquired about the rationale, objectives, type, frequency, duration, positioning used, and the perception of risks that may hinder implementation of effective positioning. Fifty-nine (83%) of the respondents agreed that there was an accepted norm in relation to the duration of 2 hours in position changes in ventilated patients. Of these respondents, 51 (86%) agreed that this standard is only met "over 50% of the time" by 34 (47%) ICUs. The study concluded that physiotherapists and nurses are aware of the practice of evidence-based positioning according to the indications and the potential risk factors, but it also recognized that educational strategies are needed to improve the type and frequency of positioning in the ICU.

Compression Stockings

In ICU patients, factors such as prolonged standing and/or intraoperative vasodilation can reduce blood flow in the veins and cause venous stasis. Among the factors contributing to the development of venous thromboembolism is damage to the vessel wall, reducing blood flow velocity, and increased blood coagulability known as Virchow's triad [82]. Endothelial vasodilation can overstretch the tunica media and cause damage to the innermost layers. In the presence of venous stasis, these lesions attract activated platelets, clotting factors and other thrombogenic damaged tissues. The interaction of these factors, coupled with trauma and immobility, increase the risk of blood clots in the venous system. This disorder usually occurs in the deep veins of the legs, called deep vein thrombosis (DVT).

Given this situation, there are a number of proposals for prophylaxis, including anticoagulants such as low-molecular-weight heparin and mechanical methods such as compression stockings and intermittent pneumatic compression devices, which are instruments that generate intermittent uniform or graded forces to facilitate emptying of the veins.

The combination of anticoagulant and mechanical methods to prevent DVT has been shown to have additive effect in patients undergoing elective abdominal surgery, coronary artery bypass surgery, and neurosurgery [83].

The effectiveness of early ambulation and lower limb exercises in preventing DVT has not been fully proved, although it is generally believed that the stasis caused by prolonged bed rest plays a key role in the pathogenesis of thrombosis [84]. The simplest method of prevention is early ambulation for muscle contraction in the leg muscles to minimize venous stasis.

The most common mechanical methods in routine use to eliminate venous stasis are graduated elastic compression stockings (GECS) and intermittent pneumatic compression (IPC) with boots or leggings. Compression stockings exert pressure on the applied areas, enabling the venous valves (responsible for proper circulation) to close again and work correctly.

Compression stockings prevent DVT by acting on three etiologic factors: venous stasis, vascular damage and coagulation. External compression reduces the cross-sectional area of the leg and increases blood flow velocity in both the superficial and deeper veins. This increase in blood velocity and decrease in venous stasis reduce the risk of thrombus formation by compressing the dilated vein walls, reducing local contact time and concentration of coagulation agents. Graduated compression stockings are designed to exert greater compression at the ankle (about 18 mmHg) than in the thighs (8 mmHg) to create a pressure gradient favouring venous return.

There are few reports on the use of compression stockings specifically in neurointensive patients; however, given the reported benefits, this prophylactic measure is commonly used in ICU patients with factors risk for DVT.

There are no absolute contraindications to the use of compression stockings. Relative contraindications and risks are associated with skin conditions (burns, skin lesions, presence of orthopedic devices), the presence of peripheral arterial disease or peripheral neuropathy. Excessive pressure exerted by an improper stocking or edema may decrease skin blood flow, causing problems in tissue oxygenation.

It is necessary to take into account some considerations for the appropriate use of compression stockings:

- Select the proper size and height according to the manufacturer's recommendations.
- Evaluate the skin conditions.
- Assess perfusion.
- Monitor leg edema.
- Check that there are no folds that can restrict blood flow.
- Remove the stocking and monitor the skin condition. Although there is no evidence on the optimal frequency to provide skin care, expert opinion suggests that it should be done at least once a day.
- Family and/or caregiver education on the indications for stockings, proper placement, skin care and the need to monitor and control edema.

Still undefined is the length of compression stockings. Thigh-length stockings are more difficult to place, more expensive and less tolerated than knee stockings; however, most studies have been conducted using long stockings.

Some authors suggest and confirm the benefits of applying graduated pressure to activate venous outflow. Graduated pressure is defined as the application of different pressure levels, applying higher pressure to the ankle and lower pressure to the most proximal area. Intermittent pneumatic compression (IPC) provides intermittent inflation that prevents venous stasis in the leg and appears to stimulate the endogenous fibrinolytic system. Sequential compression gradients (e.g., pressure of 20 mmHg on the thigh, 30 mmHg on the calf and 35 mmHg on the ankle, applied sequentially for 12 seconds), produce an increase of 240% in the rate of blood filling in the veins. By way of comparison, single-chamber leggings, inflated to 35 mmHg over the calf for 12 seconds, produce a 180% increase in the venous blood filling rate. Intermittent pneumatic compression with inflatable leggings is seldom used in the ICU, probably it is cumbersome and can only be applied to one patient at a time [85].

Some authors assume that the incorrect application of IPC devices, described in 23% of patients in an ICU and 52% of patients in intermediate care wards, can be a frequent cause of failure in this way to prevent DVT [86].

Complications and side effects of IPC are scarce; they may cause occasional discomfort and should not be used in patients with evidence of peripheral vascular ischemia of the legs.

IPC devices should be applied in the immediate preoperative, intraoperative and early postoperative periods and until the patient is able to walk.

Physiotherapy Intervention Strategies in Neurological and/or Neurosurgical ICU Patients

Rehabilitation in patients with diseases or injuries of the peripheral or central nervous system should be approached as a comprehensive intervention that begins in the acute phase and continues during the period of maximum recovery; early physiotherapy intervention in the ICU is widely supported by the literature [87].

Franckeviciute et al. [88] suggested considering: tolerance to physical activity, autonomic nervous system condition, hemodynamic changes and states of attention, cognition and perception.

Prolonged immobilization, lack of active movement, impaired sensation and proprioception, and altered level of consciousness among others, cause deficits in aerobic capacity, muscle performance, joint mobility, and integumentary and sensory integrity. These must be identified and treated early to ensure quality of care and ensure adequate monitoring during all phases of the disease.

What follows is physiotherapy interventions on the most common deficiencies in patients with acute brain injury.

Joint mobility and muscle performance can be compromised by prolonged bed rest, causing contractures secondary to altered muscle tone, poor mobility, skin wounds, heterotopic ossification, decreased muscle strength, deep vein thrombosis and other complications.

O'Sullivan et al. [89] proposed physiotherapy interventions in ICU patients, with the results evaluated by the LOCF Scale (Levels of Cognitive Functioning) and taking into account the scale's various different levels (Table 92.10).

There are several approaches to the management of neurological sensorimotor problems, including traditional therapy (passive, active assisted, and active exercise), the compensatory approach (promote overuse of the parts involved to compensate functional loss, facilitation skills, and facilitate normal movement patterns to evaluate progress in function), and models based on new motor control theories (movement emerges from the individual's interaction with the environment and the task), and the technique of mobilizing the nervous system [90].

All approaches will include proper bed positioning with the following objectives:

- Establish basic strategies of movement in bed.
- Promote adequate bronchial hygiene.
- Avoid changes in muscle tone.
- Avoid complications in the integumentary system.
- Promote body symmetry.
- Provide adequate proprioceptive stimuli.
- Promote awareness of the affected side.
- Relieve pain.
- Provide comfort.

In the ICU, in order to ensure proper positioning and promote and maintain proper alignment in bed, the therapist must create educational strategies for the nurse, the caregiver and the patient's family. It is

- Improve functionality and level of alertness
- Reduce the risk of secondary complications
- Improve motor control and postural control
- Increase tolerance to activities and positions
- Improve joint integrity and mobility to promote functionality
- Educating caregivers and family about the diagnosis, intervention, physical therapy, goals and results
- Coordinate care with all team members
- Modulate tone
- Improve strength in the patient
- Maintain integrity and joint mobility
- Reduce the risk of secondary complications
- Increase tolerance for activity
- Educating patients, caregivers and family about the diagnosis, prognosis, intervention in physical therapy and results
- Coordinate care with all team members

Table 92.10. Goals of physiotherapy intervention.

Position	Head	Scapula	Trunk	Superior members	Inferior members
Supine	Midline with slight flexion Roll parallel to head to prevent lateral flexion and rotation	Place a small roll under scapula affected to maintain proper alignment Shoulders levelled at all levels	Symmetrical Pelvis level Place pillow under hips to promote weight-bearing	Shoulder in slight abduction and external rotation Elbow slightly flexed; avoid hyperextension of elbow Forearm pronated Wrist in neutral or slight extension Fingers relaxed and abducted	Knees slightly bent. To do is put a roll in the lower third of the thigh. If the patient has increased tone level adductors and internal rotators of the hip should a pillow should be placed in the middle of both lower limbs Foot or ankle boots or splints
Lateral recumbency on affected side	Place two pillows over head to prevent shortening of neck on affected side and ensure proper alignment	Protraction shoulder with scapula in abduction. Avoid having patient bear weight on shoulder	Trunk line	Place pillow under affected forearm to facilitate hand-eye and hand-hand contact	Place a pillow in the middle of the lower limbs. The affected leg is in slight flexion of hips and knees
Lateral position on the healthy side	Place one pillow over his head to promote proper alignment	Scapula in abduction	Trunk line	Affected upper limb: shoulder in neutral, elbow bent, forearm pronated, wrist and fingers slightly extended, abducted and slightly extended. Supported on a pillow under upper limb	Place pillow in the middle of the lower limbs. Affected leg in slight flexion of hips and knees

Table 92.11. **Proper positioning in bed in patients with acute brain injury.**

generally believed that the supine position exacerbates extensor spasm. According to Davies [91], when this position cannot be avoided, the therapist must develop strategies to minimize undesirable effects, with the use of rolls, pillows and wedges to increase the regularity of movements and stretching of the limbs.

The lateral position can be used to break flexor or extensor synergy [92]. Ways to position the patient supine, lateral decubitus on the healthy side and on the affected side to promote proper alignment and positioning are given in Table 92.11.

Depending on the overall conditions of patient, intervention often focuses on traditional therapy. Intervention strategies in traditional therapy will aim to maintain joint mobility, postural responses that normally modulate the tone and provide adequate proprioceptive stimulus.

To achieve these goals, joint mobility exercises can be performed in bed to prevent contractures, avoid deep vein thrombosis and, possibly, lower muscle tone and promote changes in sensory stimulation.

Joint mobility exercises include passive exercises of the trunk, scapula, pelvis, rib cage, upper limbs and lower limbs. Neck mobility should be done gradually, slowly and within

the short range, preventing flexion with the head bent forward so as to avoid increasing intrathoracic pressure and elevation of ICP.

Scapular and pelvic mobilization can be performed when the patient is using diagonal, lateral, scapular, and pelvic techniques with proprioceptive neuromuscular facilitation (anterior elevation, posterior elevation and subsequent depression, previous depression). The technique of initiating rhythm is used with the aim to improve the ability to initiate movement and to provide proprioceptive stimulation. This technique starts with passive exercise and progresses to active and active-assisted exercises, according to the state of consciousness and cooperation, until the patient has adequately integrated movement.

Mobilization of the upper limbs should begin by mobilizing the shoulder girdle at different levels while paying attention to the mechanics of the glenohumeral joint, otherwise joint pain and joint instability can ensue, leading to shoulder pain or subluxation. Wilches et al. [90] suggest the implementation of such measures as follows:

- Support the shoulder in a position that maintains normal scapulohumeral orientation in bed in patients with hemiplegia; when positioned in lateral recumbency, the affected side should be protected against the scapula from non-weight bearing directly on the shoulder; and when in lateral decubitus on the healthy side, positioning should support the upper member engaged to prevent tensile forces from luxating the shoulder.
- Use the savanna motion to move the patient in bed, avoiding traction on the upper limb.
- Range of joint motion (ROM) exercises should not exceed 90° in flexion and abduction of the shoulder unless there is good rotation of the scapula and external rotation of the humeral head.
- Provide support to the upper limb to counteract gravity in the semisitting or sitting position.

For mobilization of the lower extremities, it is essential to maintain a range of motion of all joints with emphasis on maintaining ankle mobility, which can be limited by changes in muscle tone and effects of gravity that produce shortening of the plantiflexors in the muscles and Achilles tendon. According to Williams and colleagues [93], a shortened muscle and no movement can cause stiffening due to increased tissue inside.

Cameron M et al. [94] investigated in 22 patients the changes associated with contracture formation in a population with stroke (CVA) in the acute phase. The presence of contractures was assessed by quantifying the resting posture, resistance to passive motion and passive range of motion, followed by initial assessment; measurements were taken at 4, 8, 20 and 32 weeks. The group able to perform some functional movement (8/22) improved upper limb function while the group unable to make any functional movement (14/22) suffered changes associated with the onset of wrist contractures. The authors concluded that patients more susceptible to the formation of contractures were those who showed no signs of improvement in early functional recovery (2-4 weeks after the event).

Preserving the integrity of the ankle and foot is very important for maintenance of joint mobility because these joints are essential for carrying out functional activities such as transfers, sitting, positioning in the wheelchair, standing and walking. Integrity can be preserved by sustained muscle stretching (about 30 seconds), with continuity, frequency (at least twice a day), and performing a preset number of repetitions according to patient response to ensure benefits (e.g., 3 sets of 6 repetitions).

Muscle stretching should be performed slowly so as not to create a stretch reflex and inhibit neural response. The effect of long slow stretching is not entirely clear, although it varies depending on how long the muscle stays stretched. It seems that it is influenced

by the neural components of muscle through the Golgi tendon organs and muscle spindles, and the long-term structural components by the number and length of the sarcomeres [95].

Importantly, other strategies, depending on the patient's condition, also facilitate stretching, e.g., mobilization of soft tissues, and techniques including motion sequences to establish relationships between segments, such as the Feldenkrais, and from the Bobath concept, the use of inhibitory reflex positions.

Exercises with the patient out of bed, using a chair or table as support for standing, if the clinical condition allows, can mobilize segments such as the pelvis, ribcage and shoulder girdle, with the patient lying partially and moving only on one plane.

92.3.4 Splints

The effects of prolonged rest, unconsciousness, and an altered muscle tone can increase the risk of muscle contractions. Stokes et al. [92] suggest that a low score on the Glasgow Coma Scale (GSC <9) and signs of decerebration identify patients at risk of developing contractures, such as signs of shortening which do not improve with intervention or the inability to assume the standing position due to the motor impairment secondary to injury.

It is important to assess the degree of motor impairment and establish an appropriate diagnosis to prescribe the use of splints. This represents an economic cost to the family that can be avoided if the patient quickly recovers mobility or appropriate assistance is given when the patient will actually require splints.

Joint integrity can be maintained with bed rolls, pillows, wedges, footboards, hands and ankles specifically engaged when the motor deficit is not very clear, and with splints when the patient has a well-established motor deficit as in those with spinal cord injury (SCI).

Clinical practice guidelines on splinting adults with neurological dysfunction (ACPIN, 1998) [96] identified a lack of research in this area, making it almost impossible to adopt an attitude based on the evidence on the use of splints. Splints allow stretching with little long-term strength. Improperly designed splints can cause pressure ulcers and tissue damage, so it is important that after the application of splints, the therapist assesses proper joint alignment and continuously checks for the presence of pressure zones. The therapist should teach the nursing staff and family and/or caregiver to apply the splints correctly, to identify pressure signs, and the time of use.

The time needed to prevent contractures remains debatable; the literature indicates a range from 30 minutes to 6 hours [97,98].

Prophylactic splints, braces or pressure corrective splints or serials can be used in patients with multiple risk factors as identified above. Barnard et al. [99] reported a reduction in the overall level of spasticity after using splint boots. Robichaud and Agostinucci [100] speculated that this effect could be due to a reduction in the signals from proprioceptive and thermal receptors due to splint placement. They indicated that a total contact brace promotes an even distribution of pressure and heat, reducing the excitability of alpha or gamma motor neurons of the spinal cord.

Pressure splints or inflatable splints [101] can be used in the ICU, taking into account the patient's socioeconomic status and knowledge of the indications, contraindications and benefits thereof.

A pressure splint consists of two orally inflatable plastic sleeves designed for upper and lower limbs. They are used for modular sensory stimulation and muscle tone in the affected side. A correctly placed pressure splint not only helps to reduce spasticity as a passive

instrument but, as a more dynamic aid, it plays an active role in achieving better results. The splint can be placed for applying pressure for a period of at least 20 minutes to 1 hour maximum. Pressure splints can be combined with joint mobility exercises and techniques to modulate muscle tone. The splint applies pressure to the arm by placing the shoulder in external rotation, elbow, wrist and finger extension, and thumb abduction.

Corrective or serial splints are used to increase range of motion in the presence of contractures. Two common designs are cylindrical and gutter serial splints. The advantage of drop-shaped braces is that you can encourage active movement while function is not altered.

A systematic review by Mortenson et al. [102] reported that, the level of evidence available to date does not consider serial splinting as an adjunctive therapy to improve functional mobility. The recommendation for future research should include sensitive measures of levels of function, activity and participation according to the International Classification of Functioning (ICF). However, in this very review it was felt that the use of splints improves passive range of motion and decreases spasticity.

Singer et al. [103] in their descriptive study looked at patients with moderate to severe brain injury (GCS ≤12) and assessed ankle dorsiflexion and muscles activity in plantiflexion. The occurrence of contracture was defined as a maximum passive range of motion ≤0 degrees of dorsiflexion with the knee extended on at least two measurements. The study identified ankle contracture in 40 of the 105 patients. Contraction was determined in 23 patients with a physical therapy program that included stretching and prolonged motor re-education. Additional treatment with splints and botulinum toxin to correct persistent contractures was performed in 26 cases.

Other authors evaluated the use of serial casts in 16 patients to determine the short-term benefit of correction of equinovarus ankle after brain injury and concluded that the use of serial splinting seems to be effective in reducing deformity, at least in the short term.

In the ICU a footboard can be designed to ensure adequate alignment of the feet and hands. They can be created by the physiotherapist or occupational therapist using plaster bandages and then laminated with cotton, ensuring that both the upper and lower limbs remain in functional positions. For the lower limbs it is important to maintain the ankle in a neutral position, while the hand should be positioned to the wrist in slight extension (45°), the thumb and fingers slightly flexed and abducted.

Another alteration that can lead to reduced joint mobility and muscle performance is impaired muscle tone secondary to neurological injury, which will result in a lack of adequate voluntary control of movement and musculoskeletal complications that can alter biomechanical movements, subsequently reducing levels of function and independence. It is believed that therapeutic movement and altering the alignment of body parts are able to indirectly influence muscle tone in other areas. For example, movement of the trunk and shoulder girdle can aid in bending the arm [91,104].

The patient's position should be noted as it can provide an indication of normal, increased (spasticity or rigidity) or decreased (flaccid or hypotonic) muscle tone. Tone is assessed by passive movement of the limbs and trunk through the normal range of motion with the patient relaxed. Among the most frequent alterations is muscle spasticity, a motor disorder characterized by a speed-dependent increase in muscle tone, which can cause pain, limited joint motion and difficulty with care. The early onset of spasticity often causes clubfoot in adults with acquired brain injury and may limit the achievement of rehabilitation goals.

Irdesel et al. [105] in their study reported that spasticity was present in 23.4% (7/27 patients), contracture in 10% (3/27) of those with head trauma admitted to the ICU of the School of Medicine, University of Uludag, after an early rehabilitation program.

There are different techniques recommended by root sensory stimulation that can be used to facilitate or inhibit muscle tone, depending on the stimulus and the way it is applied. For example, ice quickly applied over the muscle facilitates its activation; conversely, it inhibits activation if applied for prolonged periods. The neutral temperature (body) is considered inhibitory for hyperactivity of muscle tone. Vibrations can also be used to facilitate or inhibit muscle activity. High-frequency vibration tend to facilitate muscle activation, whereas low-frequency vibration often inhibits muscle activity. Similarly, a quick stretch facilitates muscle activation due to the stretch reflex, while prolonged stretching (manually or using boots, splints or braces) decreases the levels of activity. A quick touch or tapping also facilitates muscle activation, while slow touches are considered inhibitory.

Techniques that activate joint receptors can also be used to facilitate muscle activation in patients with neurological disorders. One aproximation consists of joint-to-joint compression that can be applied manually or by weight bearing. Technical manual traction applied over a joint can also facilitate muscle activity. Changing the patient's position may also be suggested as a technique to alter muscle and postural tone. The assumption is that placing the patient in certain positions can alter muscle length and postural tone and changes in reflex activity. For example, positioning the patient supine can facilitate extensor tone, while the flexor tone is facilitated when the patient lies prone; placing the patient in lateral position is often used to inhibit the effect of the asymmetric tonic neck reflex (ATNR) and to facilitate bilateral symmetrical neck position [106].

During physiotherapy in patients with acute brain injury, the therapist provides stimulation in various ways. When passive movement activities are carried out in patients who are not under the influence of sedatives and muscle relaxants, the therapist should explain what is being done, so that the execution of the activity fosters the patient orientation. It is important to maintain direct communication, thus orienting the patient in time, place and person, via tactile, auditory and visual stimulation.

Sensory stimulation increases alertness and produces movement. It is assumed that overstimulation can be provided in a controlled manner, with a balance of multisensory stimulation and rest, as well as activation and stimulation of the reticular system resulting in a general increase in alertness.

Stimulation is more effective when administered in short treatment sessions (15 to 30 min). Stimuli should be presented first in an orderly fashion in one or two ways at a time, to prevent overstimulation.

Auditory, visual, olfactory, tactile and vestibular stimulation are all important. According to Ada et al. [107], ICU patients are burdened by high dependency and a plethora of interventions that involve handling and movement. Therefore, it may be necessary to limit sensory stimulation instead of increasing rest periods, for example, by using eye patches to maintain normal daily rhythms. It is important to share with the patient's family and friends the concept of controlled sensory stimulation in promoting recovery.

Later, when the patient's hemodynamic conditions permit and under proper monitoring, stimulation can progress to assisted active exercises, assisted-resistance sets and free sets (with mild resistance held between 3-4 seconds) using different techniques and diagonal neuromuscular facilitation of proprioception in patients with SCI. In patients with hemiplegia different intervention approaches include the Bobath technique, the technique of relearning motor, motor control, Brunnstrom technique, Margaret Johnston, Rood and Perfetti cognitive therapeutic exercises, among others.

The patient and nursing staff should be taught the proper way to mobilize the patient in bed, how to place the patient in the upright sitting position. The activities in the bed should be preceded by some preparation with the patient sitting on the edge of the bed with his or her feet flat on the floor or on a surface to activate the trunk muscles while

sitting or standing, which decreases the base of support and places a greater demand on the muscles, promoting greater functionality and independence in the patient.
During the activities in bed, patients recovering from post-stroke hemiparesis should be taught how to change position from supine to lateral decubitus on the healthy side and the affected side, as well as lateral position on the healthy side and the affected side in the sitting position and vice versa so that they can carry out activities such as half-bridging and bridging exercises that help to facilitate co-contraction around the hip and weight bearing on the limb, thereby increasing the patient's functional independence.
In patients with high spinal cord injury (quadriplegic), the family or caregiver should be taught how to properly use sheet movement and how to make bed transfers. If the patient has a high or low paraplegia, training should start with the acquisition of different positions in bed to achieve functional independence using bed or mat activities as proposed by the proprioceptive neuromuscular facilitation technique.
It is important that patients with neurological disorders start sitting and standing early. The sitting position is essential to maximize therapeutic function, reduce positions held, prevent skin pressure ulcers, maintain joint mobility, decrease pain and promote patient socialization. When the aftermath of the injury is severe, the sitting position can be achieved with a wheelchair adapted to the patient's needs, depending on the type, level and severity of the injury.
Facilitating the adoption of the standing position favours the maintenance of muscle length, reabsorption of calcium, intestinal peristalsis, tone, and modulation of the activation of extensor activity. To be most effective, it must be an action that allows dynamic changes in pitch [108]. Markham [109] and Brown [110] agree that the standing position alters muscle tone through the vestibular system, being an important source of excitatory influence to the extensor muscles.
Bohannon et al. [111] suggest that when taken daily, the standing position can preserve muscle tone and reduce the frequency of spasms, thus maintaining joint range.
The ICU patient may be placed in a standing position if hemodynamic conditions permit, using a stretcher or table and standing or leaning with adequate monitoring.
All possible strategies to prevent the onset or complications of deficits in joint mobility and muscle performance should be guided by clinical reasoning-oriented and achievement of patient function and independence.

92.3.5 Technical Mobilization of the Nervous System

Neural mobilization belongs to a group of techniques that have attracted renewed interest, sparked, among other reasons, the growing body of scientific literature that is reviewing and updating the reliability and validity of these procedures and the involvement of the nervous tissue as a source of pain in pathological processes of the musculoskeletal system.
Mobility is the coupling of the nervous system with mechanical systems that determine the quality and range of motion of the musculoskeletal system. The nervous system, like other somatic structures (muscles, tendons, capsules, etc.), may suffer from disease processes affecting its elasticity and mobility, as well as generating symptoms which manifest themselves often with characteristics similar to those generated by other somatic structures.
Orthopedic manual physical therapy has developed and extended the practice of elongation of the nervous system and various treatment techniques for mobilizing nerve tissue and its adjacent structures.

The nervous system and connective tissue sheaths, like other soft tissues, benefit from mobilization and therapeutic criteria applied by elongation.

Movement in one part of the body causes movement of the nervous system. This fact is used as a tool for the diagnosis and treatment of many orthopedic problems. An injury to any body structure can hamper the nervous system's mobility and elasticity, which are essential features of normal body movement. Butler [112] stated that the clinical consequences of an altered biomechanics of the nervous system are recognized and that many disorders attributed to musculoskeletal sources originate or have a significant component in an adverse natural tension.

The connection between movement of the nervous system and symptoms demonstrated in orthopedic patients can be explained by the fact that the nervous system may suffer physical injury that jeopardizes neural and connective tissues. The disorder can be extradural, intradural or both. The nerve is usually in contact with various tissues, called neural containers or mechanical interfaces adjacent to tissue. Pathological phenomena include bleeding, swelling or scar tissue, or splints and perhaps hypertonic and stiff muscles.

The injury may be in the blood supply to the nerve, the nerve itself or the axoplasmic flow (axonal transport). The nervous system consumes 20% of the oxygen present in the arterial circulation, which is necessary for impulse conduction [113]. An increase of 8% in the normal length of a nerve reduces blood flow, and an increase of 15% will result in the complete occlusion of blood flow [114]. Blood vessels in the spinal cord and peripheral nerves have a length and extra-anatomical organization, responsible for movement and normal blood flow [115].

According to Butler [112], alteration of nerve function begins at pressures of 30-40 mmHg. In a healthy person, the pressure in the carpal tunnel with the wrist joint in neutral position reaches 30 mmHg and 100 mmHg with the wrist in flexion, which suggests that a person with hemiplegic flexor spasticity in the wrist joint will have abnormal pressure on the median nerve. The symptoms often seen in the hemiplegic hand may arise, besides other causes, from impaired axonal transport.

It is possible that some of the physiological changes seen in the hemiplegic person are due to spasticity (mechanical interface) that influences the axonal flow. The axoplasm displays thixotropic properties, meaning that it flows better when kept in motion [116].

The neural mobilization technique involves movements not only in joints and muscles but also in the nervous system. Following surgery, the physiotherapist should include: movement of the distal parts in all movements made during treatment, mobilization of the nerve itself and trunk motion, strengthening movement of the nervous system and influencing the sympathetic chain.

Before starting the intervention it is important to make a proper assessment and take into account the following recommendations:

- Treatment progress and movement should be slow because the nervous system is delicate and superficial in some areas.
- The joints should be kept well aligned during each movement.
- Pay attention to the effect of all movements over the body as a whole.
- Special care must be taken when handling unconscious or insensitive patients.
- Nerve pain may appear after a few hours after the nerve has been irritated.
- It has been shown that the frequent repetition of the Stretch Straight Leg Raise technique (resembling a hamstring stretch with hips flexed and knee extended) even in healthy people can cause symptoms such as headache, nausea and a feeling of floating. One possible explanation may be that the exercise pressor reflex (EPR) moves the sympathetic chain.

Rolf [74], Davies [117,118] and Simionato et al. [119] all described signs of neural tension in the Guillain-Barré syndrome. From the authors' experience it appears that the effect of motion on the nervous system can also be applied to CNS lesions. When studying patients with hemiplegia, spinal cord injury or cerebral palsy, it is often observed that the range of motion of a body part is altered by the passive movement of another distant part of the original motion [117]. According to Davies [118], clinical experience shows that there is a loss of movement of neuraxial and peripheral nerves after head injury. This loss results in abnormal postures, increased resistance to movement and loss of selective movements of the trunk and extremities.

Currently, there are no scientific studies or evidence of the effect of neural mobilization in the treatment of patients in intensive care. Knowledge in these patients is insufficient to explain the physiological effect of treatment; however, considering the proposals of the technique, neural mobilization could be used with caution in patients in the acute neurological phase, as long as the neurological changes are stable, the patient is conscious, and no acute disease process is present. Under constant re-evaluation, passive mobilization of the nervous system may be appropriate in selected patients.

92.4 Prognosis

Despite the care directed to ICU patients, it is observed that neurological lesions can have serious sequelae. Given this situation, research has attempted to determine the factors that affect the clinical course and several therapeutic modalities have been suggested and implemented in some segments of rehabilitation. The vast majority of these studies use the Glasgow Outcome Scale (GOS) created by Jennett and Bond in 1975 [14] to monitor patients according to physical sequelae, cognitive and social measures.

Other factors considered in the prognostic evaluation of these patients include: age, pupillary changes and GCS at hospital admission, type of neurological injury, and complications associated with neurological injury such as intracranial hypertension, pneumonia, hypoxemia, and hypotension pressure among others.

Several published studies have correlated therapy after brain injury with the sequelae presented by patients with TBI throughout its evolution. Early identification of secondary brain injury is essential for patients because it can be prevented or minimized with appropriate therapeutic management, thus reducing its influence on the ultimate prognosis of the individual.

92.5 Types of Sequelae

Consequences of head injury can be classified as physical, behavioural, cognitive and medical [120]. The physical sequelae are proportional to the area affected and the degree of injury, and include paresis/plegia, the deficits following cranial nerve injury, post-traumatic epilepsy and headache, as well as combinations of cerebellar and pyramidal signs and asymmetric pyramidal signs and bilateral extrapyramidal signs.

The behavioural sequel are related to changes in the patient's relationship with the environment after brain injury: the damage resulting from neurological impairment in the cortical area of the brain, brainstem, hypothalamus, thalamus, prefrontal and limbic system. These behavioural changes may result from the primary lesion or arise as a side effect, or even, as an exacerbation of pre-existing personality disorders, which can lead

to poor social adjustment, making it difficult to return to activities of daily living (ADLs) [121].

Cognitive sequelae include changes in memory, especially with regard to pre- and post-trauma conditions, as well as difficulties in maintaining attention and concentration [122].

The medical sequelae include those resulting from metabolic, neuroendocrine, cardiovascular, gastrointestinal, respiratory and blood disorders. Hawk [123,124] noted that pneumonia was present in 59.2% of patients (16/27) and 49% of cases (49/100), respectively. This delayed complication is related to a worse prognosis.

Jennett and Plum [125] also reported two other types of disabilities: 1) a persistent vegetative state characterized by reduced responsiveness when awake with no evidence of cortical function; and 2) the socioeconomic sequelae directly related to the epidemiology of TBI, the largest segment composed of persons in their most productive years of life and who are generally responsible for maintaining their families. Hence, the social and economic burdens are carried by the patients and their families.

Added to these burdens, patients often have symptoms that may persist for weeks or months after injury, such as headache, dizziness and incoordination, even in the absence of physical deficits [126].

Finally, the management of patients has evolved markedly in recent decades, especially in the pre-hospital and ICU settings, with faster and more efficient action to improve survival.

Upon admission, immediate care is considered crucial to minimize damage and improve the prognosis of patients, including complete evaluation with imaging studies such as computed tomography (CT) to diagnose the type of injury and its extent. In a simplified manner, CT findings have been classified as focal lesions or diffuse injury, depending on the area affected and its extent. According to the type and degree of involvement, these lesions can be post-trauma prognostic indicators [127-129]. Another classification of CT was developed by Marshall et al. [130] in order to increase the ability to predict patient outcome after TBI, and which is also used in combination with the Glasgow Outcome Scale (GOS) for the same purpose.

92.6 Prognostic Index

There are several factors that can be considered as an index of prognosis after head injury, including the following.

Age: a factor determining the prognosis; the elderly were found to have the worst prognosis of 122 patients after injury [131,132].

Changes in pupil reactivity and the GCS score at the time of initial evaluation are efficient in determining the prognosis: the lower the GCS score and the longer the time spent in a coma, associated with pupillary changes (anisocoria, decreased or absent reflex to light stimuli), the greater the number of patients with worse outcome, high rate of morbidity and late mortality [128,129,131-135].

Type of injury: considering that CT findings may be predictors of prognosis after TBI, patients with diffuse lesions are more likely to have with a worse prognosis compared to those with focal lesions [134].

Presence of complications observed during hospitalization such as hypotension, hypoxia, intracranial hypertension and pneumonia are described in the literature as indicators of poor prognosis, with high rates of morbidity and mortality for patients after TBI [131,138-142].

Surgical intervention is a therapeutic resource for some complications after brain injury [143]. However, outcome after surgery in relation to prognosis remains controversial [144-146].

Change in memory: the vast majority of patients have memory impairment following neurological injury, particularly after TBI. These changes and their recovery are discussed by Katz and Alexander [122], who report that early diagnosis, age and severity of the trauma are the most influential factors in the recovery of post-traumatic amnesia.

Change in behaviour: there are reports that patients may develop behavioural changes after injury [121,147]. Such changes may interfere with social reintegration and are more often identified by family members than by patients. Novack et al. [148] found that cognitive and memory changes seen after TBI improved greatly after 1 year, and that motor sequelae were most responsible for the limitations of the patients. However, these results were only partially consistent with other studies in which such changes interfered with social reintegration [122,123,129,135-137].

The brain is responsible for many higher functions, including cognitive abilities, thinking, behaviour and motor skills. Therefore, the impact of brain injury in the lives of patients and their families can be devastating, whether personal, social, monetary, or a combination thereof.

With regard to therapeutic perspectives, much has been invested in management and treatment; however, they incur high costs for public and private health services, not all of which guarantee the multidisciplinary care (medical, nursing, physiotherapy, psychotherapy, occupational therapy, etc.) necessary to achieve maximum rehabilitation in each case.

Along this line, Mata et al. [149] conducted a study to assess the quality of life after TBI, and found that the quality of life of TBI patients declined from 96.6% (before injury) to 57.5% during the 2 years after injury. And the fall was correlated with age, severity of injury and quality of life.

92.7 Final Considerations

The improvement in the prognosis of neurological patients, clinical and surgical, in recent years, has been due mainly to advances in intensive care. The widespread use of rigorous clinical monitoring, guiding therapeutic interventions in cardiac and neurological functions, allows the therapist to predict the degree of attention patients require not only in mechanical ventilation, but also in the prevention of respiratory and neuromuscular failure. These precautions minimize pulmonary complications, provide early intervention, and contribute to a better prognosis after brain injury.

93 Nursing Care of the Patient With Acute Brain Injury

Fabiana Ciccioli [1], **Mariana Torre** [2]

[1] UTI Hospital Municipal "Dr Leonidas Lucero", Bahía Blanca, Argentina
[2] UCC Hospital Municipal "Dr Emilio Ferreyra", Necochea, Argentina

93.1 Introduction

In the past 30 years great progress has been made in the treatment and outcomes of brain injury. For example, the overall mortality from severe traumatic brain injury (TBI) fell from 36% in 1980 to almost half in specialized trauma centres in recent years. But the belief that this improved outcome may be due to technological advance alone is not entirely true. Monitoring of intracranial pressure and cerebral oxygenation provides us with more physiological information for making decisions; however, most care measures, rather than modify the results, depend on very simple and common manoeuvres such airway control, prevention of hyperthermia and hypotension, and strict monitoring of blood glucose among others.
Growing scientific evidence supports the fact that specialized units with doctors and nurses trained in neurological/surgical intensive care have a great impact and favourable effect on clinical outcomes [1].

93.2 Pathophysiology of Acute Brain Injury

To understand better what happens during acute injuries of the central nervous system (CNS) we must differentiate between primary and secondary injury.
The **primary insult** or injury is the physical damage that occurs at the moment of injury. This injury is already established at the time of admission to hospital and we can do little about it (Table 93.1).
In contrast, **secondary brain injury** (Table 93.2) involves a series of processes that may have been induced directly or not during the initial injury or may be the result of different situations (often iatrogenic) that occur later. Sometimes the effects associated with secondary injury may have extracerebral origin. Cerebral edema, metabolic disorders, calcium toxicity, cytotoxic injury, inflammation or apopto-

- **Trauma:** contusion, concussion, laceration, intra or extra axial hemorrhage
- **Ischemic:** global (anoxia, cardiac arrest) or regional (vasospasm, thrombosis, embolism)
- **Inflammatory:** meningitis, encephalitis, abscess
- **Compressive:** tumours, edema
- **Metabolic:** encephalopathy (hepatic, renal), drugs, electrolyte disturbances

Table 93.1. Mechanisms of primary insult.

- **Hypoperfusion:** global (intracranial hypertension, significant decrease of mean arterial pressure); regional (vasospasm, edema, hyperventilation)
- **Hypoxia:** systemic hypoxia, regional hypoperfusion, increased oxygen consumption (fever, seizures, etc.)
- **Reperfusion injury:** free radical generation, cytokines, prostaglandins
- **Release of excitatory amino acids:** glutamate, aspartate
- **Electrolyte or acid-base disorders:** hyper-or hyponatremia, acidosis, hyper-or hypoglycemia

Table 93.2. Mechanisms of secondary insult.

sis are examples of processes that are initiated as a result of traumatic injury and evolve over time, with worsening of prognosis.
Other secondary insults can result from alterations in other organ systems. Episodes of hypotension, hypoxia, hyperglycemia, hypercapnia, for example, double and sometimes triple the morbidity and mortality of patients with neurological injuries, regardless of the type of injury or its initial severity.
In general, the initial damage cannot be reversed, whereas secondary injury is often preventable or reversible. In patients with acute brain injury, great care should be focused on avoiding or at least minimizing secondary insults. This is the real challenge for the treatment team.
When analyzing the data objectively, it is clear that the causes of the decline in mortality from trauma in the past 20 years have been the ability to decrease the influence of secondary insults to the injured brain.

93.3 Nursing Care of the Neurocritically Ill Patient

One way to improve team work and quality of care is with the application of standards and protocols. Furthermore, clinical practice guidelines save nursing time. Much has been written on this aspect and on the importance and prevalence of some actions over others; however, there is consensus among experts that written protocols greatly reduce the probability of error, promote the uniqueness of criteria between care team members, and reduce morbidity and mortality rates.
In 2005, Jean Louis Vincent [2] proposed a mnemonic for remembering the most important aspects in the daily care of critically ill patients. These criteria are basic and take on special importance in the neurocritical patient.
FAST HUG. Each letter making up this mnemonic represents an issue that directly influences the evolution and prognosis of the patient, supported by evidence from numerous systematic reviews. Vincent adds that we give our patients “a quick hug at least once a day.”

93.3.1 F: Feeding (Food)

The early onset of enteral nutrition is a key component in the care of critically ill patients as it increases mesenteric blood flow, maintaining intestinal mucosa integrity and promoting gastrointestinal motility and peristalsis. Since the brain is unable to store glucose, its primary source of energy, it depends on a constant supply from the cerebral circulation to maintain basal metabolism. When glucose levels decrease significantly, brain cells become dysfunctional and die.
At the same time, promoting proper bowel function in patients with acute brain injury prevents the increase in intra-abdominal pressure and the consequent increase in intrathoracic pressure and ICP, and reduces the risk of sepsis related to the translocation of intestinal bacteria.
Nutritional replacement should begin at an early stage, i.e., within 24-48 hours after brain injury [3-5]. It takes 2 to 3 days to gradually increase the power to reach the necessary requirements. Patients with TBI should receive all of their caloric requirements at day 7 after brain injury [6]. The enteral is preferable to the parenteral route because of the lower risks for the patient. If gastric feeding is not tolerated within 48 hours post-injury, post-pyloric feeding beyond the ligament of Treitz should be initiated [7]. If enteral feeding is not possible or not tolerated, parenteral nutrition should be started [8]. There is no consensus on continuous or bolus feeding, but the latter method is more physio-

logic and increases the probability of distension of the administered volume. All strategies should be considered to manage the nutrients in the optimal amount (e.g., use of enteral tubes of small caliber, use of gastric residual volume threshold greater or not measuring the same).

93.3.2 A: Analgesia

Pain has a negative impact on physiological and psychological recovery. For this reason, adequate pain treatment is essential in the management of critically ill patients. The neurocritical patient feels pain not only because of the underlying disease but also because of the routine procedures received, for example, changes in decubitus, aspiration of secretions, blood sampling, wound healing, and catheter implantation. Episodes of pain significantly increase ICP. In the awake patient, pain is evaluated on graphic scales (visual analog scale [VAS]), usually consisting of a straight line with "no pain" at one end and "maximum pain" at the other, on which the patient marks the level of pain experienced. For sedated patients, in which analgesia tends to be underutilized, it is important to evaluate the physiological equivalent of somatic pain, for example: facial expression, movement and posture can be clear indicators of pain. Among physiological signs, tachycardia, hypertension, or tachypnoea require adjustment of analgesic dose or its utilization, if not being administered.
Continuous infusion of analgesic drugs or regularly administered doses (extra dose or "bailout" when required) are more effective than bolus doses "as needed", which can lead to time intervals without coverage. The indication "as needed" should be eradicated from our mind. Intravenous administration allows faster, more accurate titration according to the needs of the patient. We must remember the side effects of opioids: respiratory depression, constipation, gastroparesis, hypotension, and hallucinations. Adequate but not excessive analgesia coverage must be provided. Furthermore, the fact that a patient cannot speak does not mean that he or she does not have pain. Overanalgesia is just as undesirable as underanalgesia.

93.3.3 S: Sedation

Both insufficient and excessive sedation may have deleterious effects on patient outcomes. Pain and anxiety can increase or exacerbate secondary brain insult by increasing cerebral oxygen consumption and ICP. In contrast, excessive sedation can cause respiratory depression and hypotension, both of which are associated with pneumonia, prolonged duration on mechanical ventilation and stay in the intensive care unit (ICU).
Two strategies to manage sedoanalgesia in the ICU have been proposed: one entails sedation protocol directed by nurses, and the other daily interruption of sedation. The intent of both strategies is to individualize and optimize the management of sedation (adjust the level of sedation to an individual target), minimize oversedation and its complications by preventing the accumulation of analgesics and sedatives (tachyphylaxis). Although it seems easy to increase the sedative dose to keep the patient adapted, quiet and calm, excessive sedation is associated with serious complications, including the risk of venous thrombosis, reduced intestinal motility, hypotension, reduced oxygen extraction capacity, inhibition of the protective reflexes of the airways, shortness of clearance of secretions, increased risk of polyneuropathy due to immobility, prolonged mechanical ventilation and ICU stay, with increases in hospitalization costs.
Both strategies have been associated with significant reductions in the duration of mechanical ventilation and ICU stay. The daily interruption strategy has additional advan-

Score	Designation	Description	Exploration
+4	Combative	Combative, violent, immediate danger to staff	Observe the patient
+3	Very agitated	Aggressive attempts to withdraw tubes and catheters	
+2	Agitated	Frequent and purposeless movements, "struggle" with the fan	
+1	Restless	Anxious but not aggressive or vigorous movements	
0	Alert and calm		
-1	Somnolent	Not fully alert but remains (≥10 seconds) awake (eyes open and track) to the call	Call the patient by name and say "open your eyes and look at me"
-2	Mild sedation	Wakes up briefly (<10 seconds) to the call with eye tracking	
-3	Moderate sedation	Movement or eye opening to the call (but with eye tracking)	
-4	Deep sedation	No response to the call, but movement or eye opening to physical stimulation	Encourage the patient by shaking his shoulder or rubbing over the sternal region
-5	Unanswered	No response to voice or physical stimuli	

Table 93.3. **Richmond Agitation Sedation Scale (RASS) for the assessment of sedation in critically ill patients.**

tages, including less psychological distress at discharge (post-traumatic stress disorder) and a lower rate of complications related to mechanical ventilation such as pneumonia and venous thromboembolism. The daily suspension sedation protocol is not indicated in all patients, so its appropriateness must be evaluated in each case, for example, sedoanalgesia should not be suspended until a patient in the acute stage of brain injury, with unstable ICP values or curves, low intracranial compliance or hemodynamic instability, is stabilized. Therefore, these situations should be evaluated individually. In such patients, continuous titration of sedation is preferable.

If the patient cannot be ventilated and is receiving the maximum dose of analgesia and sedation, he or she can be assessed with the use of muscle relaxants. Neuromuscular blockade should be used only when strictly necessary and for the shortest time possible.

Objective assessment of sedoanalgesia with a validated measurement scale is recommended. It must be done systematically by trained personnel. In recent years we have developed powerful tools to assess sedation. Assessment scales with high validity and reliability include the MASS, SAS and RASS scoring systems. The Sedation-Agitation Scale (SAS) and Richmond Agitation Sedation Scale (RASS) (Table 93.3*)* are easy to use and remember, which facilitates their acceptance by the ICU staff. While the RASS has the highest sensitivity and specificity, the most important aspect is its regular utilization, making day-to-day adjustments and recording the results.

It is recommended not to use deep sedation (RASS <-2) routinely. Sedation levels will differ for each patient and should be adapted to their condition and time of evolution. As a general rule, we recommend a RASS score between 0 and -2 [9].

93.3.4 T Thromboembolism Prophylaxis

The options for the prevention of deep vein thrombosis (DVT) in neurological/neurosurgical patients include both mechanical and pharmacological interventions.

Mechanical therapy carries fewer risks. Sequential compression devices should be used when heparin is contraindicated [10] or as an adjuvant. We recommend graduated compression stockings or intermittent pneumatic compression stockings, unless a lower extremity injury prevents their use. Their use should be continued until the patient can walk. Studies have found no changes in mean arterial pressure, ICP or central venous pressure (CVP) with the initiation of sequential pneumatic compression devices; however, lower extremity injury may prevent or limit their use. Elastic bandages or stockings have not demonstrated clear advantages in the prophylaxis of DVT. Those that have demonstrated an advantage, albeit with low levels of prevention, are known as graduated compression stockings which compress more in the calf region and less towards the root of the thigh. Any decision regarding the use of these therapies for the prevention of DVT must weigh the efficacy and risks of the proposed intervention. Heparins should be indicated from the third day if there are not contraindications and Low Molecular Weight Heparins (LMWH) are better than unfractionated. The formal recommendation is LMWH and intermittent pneumatic compression stockings.

93.3.5 H: Head (Head Elevation)

Several studies have shown that raising the head to 30-45° from the horizontal plane can reduce the incidence of gastro-oesophageal reflux and nosocomial pneumonia in mechanically ventilated patients. In patients with additional acute brain injury, raising the head from the horizontal to 30° facilitates venous drainage of the brain, decreases ICP, while cerebral perfusion pressure (CPP), cerebral blood flow (CBF) and global or regional cerebral oxygenation are not affected [11]. Elevation of the head of the bed >30 degrees may exacerbate intracranial hypertension if intra-abdominal pressure is elevated, therefore, it's not recommended without contemporaneous ICP monitoring.
Elevating the head of the bed may decrease CPP by decreasing arterial pressure, so patients should be euvolemic before raising the bed.
Despite available evidence and recommendations, this simple strategy does not have the expected response of the critical care team although it is an inexpensive measure.
It is important to remember that we are talking here about the semi-sitting position and not only maintaining the head raised. To reduce the likelihood of gastro-oesophageal reflux, staff must ensure that the entire trunk is inclined. This requires continuous postural corrections because even sedated patients tend to slide toward the foot of the bed. The semi-sitting position should be maintained in all patients unless there are express contraindications (for example, neurocritically ill patients with postoperative subacute or chronic subdural hematoma should be positioned flat in bed).
Moreover, patients should always have the head in a neutral position to prevent rotation to the right or the left and neck hyperflexion and hyperextension, which would otherwise increase ICP due to alterations in venous drainage [12].

93.3.6 U: Stress Ulcer

Although still discussed, proton pump inhibitors IV are recommended, beceuse they not develop tolerance, are easy to administer, produce a costant inhibition of acid secretion for 24 hours, and are well toletated in case of renal dysfunction. They should be used until you can start a good nutrition enteral caloric intake, then should be discontinued. Prevention of stress ulceration is especially important in patients with respiratory failure, clotting abnormalities, under steroid therapy, or with a history of peptic ulcer because of increased risk of developing gastrointestinal bleeding related to stress. All guidelines recommend early enteral nutrition as a cornerstone in the prevention of stress ulceration.

93.3.7 G: Glycemia Control

Elevated blood glucose levels are associated with poor outcome in critically ill patients. This point has also been demonstrated in several acute neurological diseases such as stroke and head injury.
After the publication of a widely cited article by van der Berghe et al. [13] reporting a decrease in morbidity and mortality in surgical ICU patients who received continuous insulin infusion to maintain a blood glucose level between 80 and 110 mg/dl, many critical care units implemented the routine use of this therapeutic approach.
Less clear is the effect this practice has on patients with acute brain injury, especially since only 4% of patients in this study had a primary neurological condition as a reason for ICU admission. In such patients, even an accidental short period of hypoglycemia

Causes of elevated ICP	Actions
Position	• Elevate head of bed 15-30 degrees to promote cerebral venous drainage • Keep head in neutral position. Avoid rotation of head and neck flexion, which otherwise increase ICP and decrease venous drainage • Secure the endotracheal tube in such a way that it does not compress neck veins • Avoid bending over 90°
Movement	• Keep the patient as still as possible but avoid restraints (the struggle to free themselves could inadvertently lead to a Valsalva manoeuvre, which increases ICP) • If you must turn the patient, make a block to keep the head in the neutral position. Tell the patient to exhale while you're turning him/her to avoid the Valsalva manoeuvre
Hypoxia	• Administer oxygen as ordered (The oxygen reduces cerebral blood perfusion by vasoconstriction and thus decreases the PIC, so it is dangerous because it can cause cerebral ischemia) • If you must use an oropharyngeal airway, not immobilized in place. If the patient cannot expel secretions from the throat and mouth by coughing, a Valsalva manoeuvre will be performed. Evaluate the need to maintain the artificial airway frequently
Aspiration	• Do not aspirate the patient unnecessarily • When you need to aspirate, hyperoxygenate (FiO_2 100%) before starting, then quickly aspirate (no more than 10 seconds) and hyperoxygenate again after aspiration
Noise	• Keep the patient's environment as quiet as possible with minimal sensory stimulation • Before repositioning the patient, make sure there is no danger of tripping over monitor cables and equipment • Limit conversations in the patient's room. Whenever possible, talk with nurses, family, doctors, and other people outside the room. • When you need to talk to the patient, do it quietly and calmly. Let the voices of family members be known when communicating with the patient
Pain, discomfort, non therapeutic contact	• Limit painful procedures. For example, insert an intravenous line to obtain blood samples for lab tests rather than perform repeated venipuncture • Avoid any stress on the tubes and fittings • Limit non-therapeutic contacts • Schedule nursing procedures so that the patient can rest without interruption. When you have to touch the patient, do it gently and reassuringly
Fever	• Keep the patient uncovered or use light sheets if necessary • Make all efforts to maintain normothermia

Table 93.4. Actions to prevent an increase in ICP.

could be a serious and dangerous secondary insult. If we lower serum glucose levels, we will restrict the availability of this fuel just when the injured brain needs it most [14]. Although the optimal blood glucose range has not yet been determined, extreme oscillations should be avoided. It's essential to individualize therapy and ongoing monitoring to try to maintain this value stable.

Subcutaneous insulin administration has proved to be unpredictable and less effective than intravenous administration in critically ill patients. One aspect to consider in subcutaneous administration is the low predictability of absorption, even more so in patients with edema, compromised peripheral perfusion or state of shock.

The role of insulin infusion in patients with acute brain injury continues to be investigated. Several protocols have shown satisfactory nurse-led blood glucose control in critical care units.

Since patients with hypoglycemia may have symptoms that mimic an acute stroke, manifesting focal signs, speech disturbances, and cognitive changes, capillary blood glucose monitoring should be a routine practice in patients with impaired awareness.

In addition to the FAST HUG mnemonic, every effort in neurocritical patient care should be focused on the prevention of secondary brain injury due to increased cerebral oxygen consumption and ICP. Some additional considerations and procedures may be performed to prevent increased intracranial pressure (Table 93.4).

93.4 Airway Care

Since hypoxemia worsens the deleterious effects of cerebral ischemia, patients with acute brain injury should be closely monitored to maintain oxygen saturation >95%. According to Traumatic Coma Data Bank (TCDB) results, hypoxemia is associated with increased morbidity and mortality in severe TBI. The most common causes of hypoxia are partial airway obstruction, hypoventilation, aspiration pneumonia, bronchial secretions, and atelectasis. Patients with decreased level of consciousness or signs of brainstem dysfunction are at increased risk of airway compromise because oropharyngeal motility is impaired and there is loss of protective reflexes [15].

Determining a patient's ability to protect the airway is based on the observation of the following clinical parameters: 1) Glasgow Coma Scale score; 2) presence of gag reflex; 3) ability to swallow oral secretions; and 4) presence of signs of airway obstruction.

The **Glasgow Coma Scale** (GCS) has traditionally been used to classify injury severity. Patients with TBI (GCS ≤8) are classified as having severe brain injury, requiring airway instrumentation with placement of an artificial airway to ensure adequate oxygenation and ventilation. Endotracheal intubation should be performed rapidly with manual immobilization of the cervical spine [16]. All patients with TBI should be assumed potential carriers of cervical spine injury and should be immobilized with a rigid collar until proved otherwise.

The **presence of gag reflex** has traditionally been cited as a valid predictor of the patient's ability to protect their airway. However, the **ability to swallow** or remove oral secretions (effective cough mechanism) could be a more reliable parameter. In general, if the patient is able to tolerate placement of an accessory to the airway (e.g., an oropharyngeal cannula), endotracheal intubation is probably required, unless there is a concomitant condition that depresses sensory reflexes but is easily reversible as hypoglycemia or opioid overdose.

The **airway** also needs to be maintained permeable due to the risk of obstruction from the inability to manage copious secretions or anatomic obstruction due to airway ede-

ma or traumatic injury. While it is assumed that the protective reflexes of the airway are nausea and coughing, many authors argue that the gag reflex is also important.
The principal cause of obstruction in patients with sensory impairment is relaxation of the muscles at the base of the tongue which can drop into the hypopharynx. Also, it is important to assess signs of increased breathing effort such as noisy breathing, or snoring, or accessory muscle utilization.
Coma does not represent a loss of response to noxious stimuli; however, loss of this response may precipitate intracranial hypertension and herniation. Therefore, sedoanalgesia should be given properly during airway manipulation whenever possible.
Other important considerations in airway management are:

- **Placement of the tracheal tube**. The tracheal tube should be placed in the middle of the oral cavity, perpendicular to the plane of the face, and properly set to prevent movement. It is recommended to mark the tracheal tube at the time of placement in order to know its depth, taking the dental arch as a landmark reference. This measure adjusts the tube depth in case of displacement. In this regard, it must be remembered that changes in decubitus can displace a tracheal tube up to 2-3 cm.
- **Securing the endotracheal tube**. In the neurocritically ill patient, the standard of care is particularly important since fixing the tube can cause increased ICP due to jugular venous compression, so straps should be fastened gently. It is recommended that tapes are not wound around the entire neck but are applied only to the face or loose enough to pass a finger between the tape and the face. Patients without teeth and with the mouth kept wide open pose a greater challenge in this regard. Migration of the distal end of the tracheal tube into a main bronchus, inadvertent extubation, inadequate ventilation, oxygenation and suctioning, and physical airway injury are some of the consequences of failure to properly stabilize a tracheal tube. The tracheal tube should be anchored whenever necessary to prevent inadvertent extubation and excessive movement.
- **Tracheal tube cuff pressure**. Monitoring the tracheal tube should ensure that the cuff pressure remains <20 mmHg while allowing a safety margin below the tracheal capillary perfusion pressure (25-35 mmHg). It is generally assumed that 25 mmHg is the maximum acceptable value for lateral pressure by the inflated balloon on the tracheal wall. If the patient shows signs of poor perfusion and/or high airway pressures during mechanical ventilation, the pressure value must be reduced. If pressures >25 mmHg are required to provide effective sealing of the airway during positive pressure ventilation, alternative measures should be evaluated: change to a larger tube, a tube with a longer ball, always considering that the tracheal tube may have shifted, in which case it must be repositioned. Less frequently ball puncture may also occur, with leaking of air and pressure or incontinent balloon valve or both. Cuff pressure should be checked at least once a day and after each procedure on the respiratory system (changes in ventilator mode, aspiration of secretions, tracheal tube movements, changes in decubitus). The cuff should be checked immediately after nitrous oxide anesthesia, as the gas diffuses into the cuff, increasing its pressure.
- **Oral cavity hygiene**. All sorts of micro-organisms reside in the mouth and oropharynx and are transmitted to the lungs via microaspiration. This is the main risk factor for pneumonia associated with an artificial airway. The methods currently used for oral hygiene are: gauze moistened with a mouthwash; a toothbrush with soft bristles and toothpaste; diluted hydrogen peroxide and chlorhexidine. It has been shown that dental plaque can be removed with gentle brushing because it removes the bacteria harbouring dental plaque; however, there are reservoirs of bacteria in the mouth that cannot removed by brushing. There is still disagreement about the most effective method to reduce bacterial colonization of the oral cavity. Mouthwashes

containing alcohol can irritate the oral mucosa and should be avoided. In some studies, chlorhexidine reduced the incidence of pneumonia associated with artificial airways but no conclusive recommendations can be made. Therefore, it appears that chemical decontamination with chlorhexidine as a single intervention may be insufficient to significantly reduce the risk of pneumonia, and that the most important method is by mechanical cleaning, eliminating pharyngeal lakes (accumulation of saliva and secretions from the balloon and the tracheal wall) at least every 8 hours. With regard to pharyngeal lakes, which are primarily responsible for microaspiration, numerous studies recommend the use of tracheal tubes with a continuous suction lumen placed at subglottic level. Even simple measures such as the use of abundant water and aspiration of the proximal airway at frequent intervals significantly reduce bacterial load.

- Strongly discouraged is the use of an oropharyngeal cannula in an intubated patient. The cannula is an accessory for maintaining transitory airway permeability and to prevent the patient from biting the tube. If the patient bites on the tube, we must seek the cause. Oropharyngeal cannulas favour the accumulation of secretions and the occurrence of pressure sores in the oral mucosa, lips and gums.
- Oral care is not only part of a standard of care to decrease infection rates but also provides the patient with comfort; oral hygiene and tracheal tube change should done at least once per nursing turn.
- **Tracheobronchial suctioning** (Table 93.5). Bronchial suctioning often results in an increase in ICP, which may be transient or sustained over time and of varying magnitude. Tracheal stimulation during suction catheter insertion induces cough and systemic responses, resulting in an increase in ICP and mean arterial pressure (MAP). By itself, the application of negative pressure during aspiration increases ICP and heart rate. Hyperventilation to decrease $PaCO_2$ can cushion the increase in ICP during aspiration, but since the effect on ischemic brain areas is not known and potentially dangerous it is not advisable. A valid measure to prevent desaturation during suction aspiration is 1-minute preoxygenation with 100% oxygen; each attempt should take no more than 10 seconds. Two entrances into the airway are sufficient to eliminate all secretions in most cases. The use of saline instillation in the airway is absolutely contraindicated. We have seen that saline instillation only increases the fluidity of the proximal secretions. Furthermore, it can drag the biofilm attached to the tracheal tube (with bacteria) into the airway, and can produce profound atelectasis, pneumonia and desaturation with catastrophic effects. It can also trigger the cough reflex, with a concomitant increase in ICP. A carefully designed aspiration protocol can dampen the response of ICP and preserve adequate cerebral oxygenation.

- Oxygenate at 100% one minute before suctioning
- Adequate sedation can help prevent a drop in CPP and increase in ICP by preventing movement and coughing
- Neuromuscular blockers may attenuate an increase in ICP because they prevent elevation of intrapleural pressure caused by coughing; however, due to the harmful effects of prolonged utilization, their use is reserved for specific events rather than routine suction of secretions
- During the manoeuvre, monitor ICP CPP, EKG and SaO_2
- Do not instil the endotracheal tube routinely
- Each pass of the suction catheter should be no more than 10 seconds
- The number of suction passes should be limited to one or two per session
- Although hyperventilation can cushion the increase in ICP in response to aspiration, it can also be harmful. Only use if intracranial hypertension is severe and exhaled CO_2 control ($PaCO_2$) is >28 mmHg

Table 93.5. **Key points of secretion aspiration.**

- **Lidocaine**. Lidocaine is a commonly used drug with local anesthetic and antiarrhythmic properties. In patients with severe TBI it is usually administered intratracheally to prevent increases in ICP during aspiration of secretions. Experimental models of air embolism and focal brain lesions have shown that lidocaine, administered intravenously, can significantly decrease ICP [17,18]. Arbit et al. in experimental models of focal lesion, observed that lidocaine decreased ICP and increased CPP without inducing a significant change in MAP or CBF. However, due to the limited available evidence, lidocaine cannot be recommended as routine practice in neurocritical patient care.

93.5 Respiratory Care

Once the airway is secured and permeable, the next step is to optimize oxygenation and ventilation.

All patients with neurological injuries should have a PaO_2 >80 mmHg, an arterial saturation of O_2 (SaO_2) >95%, and $PaCO_2$ within normal ranges (35-40 mmHg).

Classical definitions of hypoxemia cite values of PO_2 and SaO_2 <60 mmHg and 90%, respectively. The brain has no oxygen reserves, so the values cited below are recommended by experts and utilized in all protocols.

Hyperventilation. Hyperventilation decreases ICP through hypocapnia-induced vasoconstriction, which also decreases CBF. However, since prophylactic hyperventilation has been associated with worse outcomes it is not recommended.

During the first 24 hours after brain injury, CBF may decreased, with the risk of cerebral ischemia with hyperventilation. Nonetheless, there are at least two situations in which hyperventilation may be advisable.

The first is used as a last option in the treatment of refractory intracranial hypertension. Protocols vary as to when therapy should be instituted, but most agree that it should be begun only when all other therapies have failed (sedation, paralysis, pharmacology, CSF drainage, osmolar therapy).

Another indication for hyperventilation is acute neurologic deterioration (pupillary asymmetry, posture, motor), whose cause is known or suspected to be an expanding intracranial mass. In theory, a brief period of hyperventilation can reduce ICP enough to allow the patient to undergo computed tomography (CT) or transfer to the operating theatre for evacuation of hematoma or contusion; however, hyperventilation remains a controversial issue.

Capnography. Continuous quantitative capnography is recommended in mechanical ventilated neurocritical patients. The value of $ETCO_2$ (CO_2 pressure at end expiration) can be derived from the value of $PaCO_2$ and it is a non-invasive and useful tool. The goal is to maintain $ETCO_2$ between 35 and 40 mmHg.

93.6 Hemodynamic Care

Both inhospital and prehospital hypotension have been shown to have deleterious effects on the prognosis of acute brain injury. Even a single episode of hypotension was associated with increased morbidity, and multiple episodes of hypotension in hospital have a strong impact on mortality.

The optimal blood pressure level in such patients depends on the type of neurologic injury. All guidelines define 90 mmHg as the minimum level of systolic arterial pressure (SAP). This issue arises from studies performed in TBI patients in which CPP >60 mmHg was associated with better outcomes. To achieve this goal, SAP must be maintained at ≤90 mmHg. Higher MAP levels remain controversial.

Maintaining an adequate blood volume may require fluid administration (crystalloid or colloid). Avoid administering hypotonic solutions in the early hours of brain injury (e.g., 5% dextrose and Ringer's lactate) because they exacerbate osmotic brain edema and increase ICP.

If the patient has a catheter for ICP monitoring, it is advisable to place an arterial catheter to measure MAP beat by beat, to maintain CPP >60 mmHg, and to prevent cerebral ischemic events.

93.7 Catheter and Tube Care

We recommend the placement of a **nasogastric or orogastric tube** in all patients with acute brain injury, for the evacuation and decompression of gastric contents in order to prevent aspiration, decrease intra-abdominal pressure and relieve pain and discomfort. An orogastric tube is preferred in the traumatized patient who shows signs or suspected basilar skull fracture due to the risk of brain migration. The use of a nasogastric tube is associated with increased nasopharyngeal colonization as it can cause reflux of gastric contents from the stomach, allowing bacterial migration to the upper airway. It's a known risk factor for the development of sinusitis which, in turn, predisposes the patient to develop "intubation-associated pneumonia." For these reasons it is recommended that the probe is placed via the orogastric route. Feeding tubes that are poorly positioned, displaced or coiled in the pharynx, together with enteral nutrition generates a higher risk of aspiration in critically ill patients. A patient with brain injury may decrease gastric emptying due to diminished gastric motility, thus increasing the risk for aspiration. Clinical assessment is ineffective to detect the inadvertent placement of a nasogastric tube in the tracheobronchial tree. The only reliable way to determine with certainty orogastric tube placement is by radiography. The American Association of Critical Care Nurses recommends using a secondary method to confirm the placement of feeding tubes. There is no consensus about what constitutes a high gastric residual volume, what is the frequency and interval of measurement, etc. Although gastric residual volume is not directly correlated with gastric motility, tracking trends in the gastric residual volume may be useful in clinical decision making [19]. The gastric residual should be measured with a 50-60 ml syringe, deposited into sterile collector and reintroduced. This practice is difficult to execute, so it is not recommended as routine measurement of gastric residual, but to carefully evaluate abdominal semiology: abdominal distention, bowel habits, presence of diarrhea or constipation, presence of nausea or vomiting. Some measures have had conflicting results in small series of patients: the use of flexible, small calibre nasogastric tubes in theory reduced the incidence of gastro-oesophageal reflux or microaspiration, and the location of an enteral tube in the jejunum had variable effects on the rate of nutrient intake and the incidence of pneumonia [20].

All intravenous, intra-arterial lines, electrodes, urinary catheter, etc. should be placed so as to avoid unnecessary stress and stimuli. All tubes generate some degree of discomfort, pain and increase cerebral oxygen consumption.

93.8 Positional Care and Environment

During hospitalization in the ICU nursing tasks involve mobilization of patients for bathing, suctioning, changing sheets, etc. It has been reported that ICP increases significantly during routine procedures in the ICU, and although most of these elevations last a few minutes, sometimes they can prolong the duration of intracranial hypertension and secondary injury may ensue [21]. Therefore, one must be alert to monitoring ICP before, during and after the completion of any procedure and evaluate in all circumstances whether to discontinue the activity.

Like all critically ill patients, the neurocritical patient should be mobilized to prevent the complications of immobilization (decubitus lesions, DVT, retention of bronchial secretions, etc.) Rotation causes frequent desaturation, hypotension and a possible increase in ICP, especially in hypovolemic patients. In such cases, the patient should be placed supine, and wait until the parameters stabilize again. We think that while we must protect the brain, we should not forget the cardiac, respiratory, venous, muscular and other organic systems. We should always keep in mind the risks and benefits in each case. Intracranial hypertension refractory to treatment is an absolute contraindication to lateralization of such patients.

Our goal is save the patient's life with adequate neurological recovery, so that the individual can return to normal life with the least possible sequelae. Also to be borne in mind is the concept of **early rehabilitation** that relies on preventing complications that may arise in the natural history of neurological injury. Limb alignment and passive mobilization should be rigorously maintained. Active exercises of the extremities must be performed as soon as the patient is stable.

Every effort should be undertaken to prevent pressure ulcers. Care should be intensified, especially where there is bone contact with the bed and swollen areas. You can use pillows, air mattresses inflated sequentially, hydrocolloid dressings, silicone sprays, but the use of these or other accessories does not replace patient mobilization. Each unit should be have a protocol in place for pressure ulcer prevention and treatment. One of the essentials to meet this target is proper nutritional support (feeding F).

Another no less important issue is observing the patient's attitude in bed. Does it look comfortable or does the patient require sedoanalgesia due to anxiety, pain, or delirium? There are many measures that can be implemented to avoid patient discomfort. We will ask the family about the position in which the patient usually lies, if there any taste or preference, for example, about the type of pillow the patient uses, or headphones for listening music, etc. Do not forget that patients who wear glasses or hearing aids will need them during hospitalization. Skin contact is very important. Encourage the family to touch and cuddle even if the patient is unconscious. Human contact given by nurses without gloves is desirable. These are all measures that can be very well received and have no influence on infection control.

Give the patient a notion of time, dim the lights and noise at night or allow the use of a clock to help prevent disorientation.

Whenever possible, avoid physical constraints in the agitated patient. These can increase agitation and injury and increase ICP when performing the Valsalva manoeuvre.

Noise in the ICU creates a hostile environment for the patient, with the consequent disturbance of sleep and development of anxiety. Noise in the ICU is produced by alarms, mechanical ventilators, phones and staff conversations. Levels above 80 decibels should be avoided and levels below 35 decibels promote sleep. A complementary measure may be to provide the patient with earplugs to reduce the amount of noise perceived.

The sleep-wake rhythm must be respected as far as possible, trying to get through the night with the least amount of sleep disturbances by procedures, and provide an envi-

ronment with as little light as possible. This should be implemented using a guide to promote the control of noise and a night light in the ICU.
Massage can be an alternative or adjunctive to drug therapy. Back massage for an average of 5-10 minutes or foot massage for 5 minutes can promote relaxation and improve sleep. The combination of acupressure massage has shown the same benefits.
Music therapy can contribute to relaxation and decrease pain. Music can mask the noise. In mechanically ventilated patients, music therapy is associated with a decrease in anxiety, systolic and diastolic blood pressure and heart rate. Because music therapy is an intervention devoid of adverse effects, and has a low cost, it should be considered as a control measure of anxiety and noise in the ICU [22].
Another important and often forgotten item is to inform the patient about their illness and procedures that we will perform. The lack of information or an improper handling of information to the patient augments anxiety. A better understanding of their disease and interventions can improve collaboration and reduce anxiety. It also seems reasonable to avoid inadequate medical or nursing conversations that the patient may overhear.

93.9 Delirium

Patients admitted to the ICU often have an altered state of consciousness, cognition, perception, and time and space disorientation [23]. These conditions are variously described under more than 25 terms: coma, delirium, acute confused state, cognitive dysfunction, acute brain failure, ICU psychosis, encephalopathy, etc. All of them are clinical expressions of a single entity called acute brain dysfunction, a pathophysiological spectrum, which covers three clinical forms: delirium, stupor and coma.
The definition of delirium was set down in the Diagnostic and Statistical Manual of Mental Disorders 4th edition (DSM) of the American Psychiatric Association published in 2000: **altered level of consciousness or cognitive and/or perceptual impairment (disorganized thinking) of acute onset and fluctuating course, accompanied by attention deficit**.
The delirium may precede or follow the onset of stupor and coma. It occurs within hours or days, and is usually reversible. The patient usually shows memory impairment, disorientation, agitation, slurred speech and irrelevant, hallucinations or delusions. The ability to receive, process, store or recall information is compromised.
Delirium has also been associated with an increased risk of complications (decubitus ulcers, pneumonia) and duration of mechanical ventilation. In 2001 published results showed that delirium is an independent risk factor for prolonged ICU stay. In addition, it predisposes survivors to neuropsychological deficits that impair the quality of life and has been shown to generate an increase of 31% or more in hospital costs [20,24,25].
Despite these data, it is recognized as an underdiagnosis in 66-84% of cases. In a survey of 912 doctors between 2001 and 2002 only 5% monitored delirium [20].

93.9.1 Clinical Forms

There may be prodromal symptoms such as anxiety, irritability, and sleep disorders which progress to a frank picture of delirium in 1 to 3 days.
This syndrome is classified according to alertness and psychomotor activity in three ways:

- Hyperactive delirium: the patient is restless, garrulous with disordered and incoherent speech, irritable, agitated, combative, and aggressive and may be a risk to him-

self (tendency to withdraw probes, catheters, and struggle or fall injuries) or other. The literature describes this form as "ICU psychosis" [26].
- Hypoactive delirium: the patient withdraws and has minimal interaction with ICU staff and family, with lethargy, affective flattening, apathy and decreased response to external stimuli. There is often also, as in hyperactive delirium, an altered sleep-wake cycle, temporo-spatial disorientation, difficulty in concentration and memory.
- Mixed delirium with a combination of the two previous types.

93.9.2 Etiology and Pathophysiology

Delirium usually develops in a susceptible patient exposed to one or more triggers.
The predisposing factors are present on admission to hospital and indicate baseline vulnerability to delirium. These include: age >70 years, male gender, referral from an institution, prior cognitive impairment or dementia, history of depression, malnutrition, hearing loss, reduced visual acuity, cerebrovascular events, epilepsy, habitual use of psychoactive medications, history of alcohol abuse or other drug consumption, and coexisting medical conditions such as hypo- or hyperthyroidism, AIDS, neurologic, hepatic, renal and or congestive heart failure (Table 93.6).
Precipitating factors are noxious stimuli or injury related to hospitalization that trigger the onset of delirium, including primary neurological disorders, infection, shock, hypo- or hyperthermia, hypoxia, dehydration, electrolyte abnormalities, surgery, moderate to severe pain, hypoglycemia, exposure to pharmacological agents (opioids, benzodiazepines, anticholinergics, corticosteroids at a dose of 40 mg/day or more of prednisone or equivalent), removal of substances, mechanical ventilation, central venous or bladder catheterization, constipation, urinary bladder overdistension and sleep deprivation.
A recent study [27] reported that the most important risk factors in the ICU were older age, severity of disease, and administered doses of benzodiazepines.
The exact pathophysiological mechanisms involved in the development and progression of delirium are unknown, although a number of avenues of study are being pursued.

CNS disorders	• Head injury • Seizures • Postictal state • Vascular pathology
Metabolic disorders	• Kidney failure • Liver failure • Anemia • Hypoxia • Hypoglycemia • Thiamine deficiency • Endocrinopathies • Water and electrolyte imbalance • Acid-base disorders
Cardiopulmonary disorders	• Myocardial infarction • Congestive heart failure • Arrhythmias • Shock • Respiratory failure
Systemic diseases	• Substance intoxication or withdrawal • Infection • Neoplasms • Severe trauma • Sleep deprivation • Deregulation of temperature • Post-operative

Table 93.6. **Clinical conditions associated with delirium.**

93.9.3 Diagnostic and Monitoring Methods

Delirium is often not recognized or confused with other disorders in over 84% of cases. Failure in the diagnosis may be explained by inadequate assessment of cognitive functions in an uncooperative or mechanically ventilated patient. In addi-

tion, signs that suggest the presence of this syndrome can be subtle or attributed to other causes.

The DSM recommends the Confusion Assessment Method (CAM) in the diagnosis of delirium, although other scales can be used: Intensive Care Delirium Screening Checklist, Delirium Cognitive and Cognitive Test for Delirium Abbreviated scale. The CAM was validated in 2001 for use in ICUs, including patients receiving mechanical ventilation (CAM-ICU). It's effective and can be implemented by minimally trained doctors or nurses.

CAM-ICU assesses four criteria, three of which must be met for a diagnosis of delirium: (A or D) + B + C

where:

- A: Altered level of consciousness.
- B: Acute change or fluctuation in mental status.
- C: Attention deficit.
- D: Disorganized thinking.

When possible, it will be important to identify the baseline cognitive functional status and differentiate chronic cognitive disorders, mainly dementia and oligophrenia. Dementia is established slowly, over weeks or months; it refers to a lack of intellectual skills and is diagnosed when there is an alteration in memory and at least one of the following: aphasia, apraxia, agnosia or disturbance of executive functions. Its evolution can be progressive, stable or reversible, depending on the disease and availability of effective treatments. It is important to note that patients with dementia may also suffer hallucinations. The CAM-ICU has been shown to be valid and reliable even in these patients.

First, use the Richmond Agitation-Sedation Scale (RASS) to assess the level of consciousness. Patients with a score of -4 (stupor) and -5 (coma) cannot be evaluated, and the diagnosis should be reconsidered when it detects a change in this score.

- The first criterion (A) is to confirm the presence of an altered level of consciousness, as evidenced by any nonzero score (0 = alert and calm) on the RASS.
- The second criterion (B) is to confirm that the change in the level of awareness is new (within 24 hours) and/or fluctuating. For example, a patient drowsy until an hour ago (score -1) is now very agitated (score +3). The new level of consciousness is "alert and calm" and therefore meets criterion A, and since has appeared in acute form it also meets criterion B.
- The third criterion (C), attention, is assessed using the Attention Screening Examination (ASE), and can it be visual or auditory, ensuring that the patient understands the task and can hear or see properly.
- The auditory method entails reading a series of ten letters, such as S, A, H, E, V, A, A, R, A, T and asking the patient to pronounce the letter "A". The visual method involves showing an initial series of five figures, and then a new series of ten figures, five new and five interleaved originally filed, and asking the patient to indicate when a figure is repeated. With either method, the test is positive (attention deficit) when the score is <8 (three or more errors). If the patient cannot speak, he or she may respond by raising their hand or nodding their head, making it possible to evaluate also patients under mechanical ventilation.

Group A	Group B
• Can a stone float on water? • Are there fishes in the sea? • Does one kilo weigh more than two kilos? • Can you use a hammer to hit a nail?	• Can a leaf float on water? • Are there elephants in the sea? • Do two kilos weigh more than one kilo? • Can you use a hammer to cut wood?

Table 93.7. Questions (alternating group A and group B).

- The fourth criterion (D) investigates the presence of disorganized or incoherent thinking which may be evidenced by two or more incorrect answers to four questions like the following:

Questions (alternating group A and group B): see Table 93.7.

93.9.4 Treatment

Proper management of delirium involves prevention, early diagnosis and pharmacological treatment. This requires frequent monitoring of all patients admitted to the ICU, mainly those with predisposing factors: age >70 years, prior cognitive impairment, hearing loss, history of alcohol or drug use, neurological disorders, etc.

A major strategy for delirium prevention is to avoid oversedation, stop and re-evaluate daily requirement, and consider the use of short-acting drugs in case of frequent or continuous administration. Clinical guidelines recommend the use of protocols and scales to improve the dosage of sedatives and analgesics by keeping the patient calm and alert with lowest doses of sedative drugs.

These manoeuvres can help us to reorient the patient: promote the sleep-wake cycle, avoid excessive noise and artificial light at night time, minimize pain, encourage physical therapy and early mobilization, early removal of catheters, optimize contact with the family, and promote visual and auditory stimulation, facilitate temporal-spatial orientation through the provision of eyeglasses, clock, calendar, music headset, radio, photographs of close relatives, favourite food or objects. These interventions reduce by up to 40% the incidence of delirium, and should be part of prevention and treatment strategies.

Once delirium has been diagnosed, we will try to minimize or eliminate all potential precipitating factors. It is imperative to reverse shock, hypoxia, dehydration, abnormalities of sodium and glucose, thiamine replacement, identify a distended bladder or other causes of pain, and remove drugs (anticholinergics, corticosteroids) before selecting a specific drug.

Health personnel and family members should maintain a non-confrontational dialogue with the patient, who displays altered opinion and perception, and not to exacerbate or trigger agitation. The most effective way is to listen and respond with attitudes directed to contain general discomfort, showing that he or she is in a safe environment.

Physical restraint may be necessary in cases of severe agitation to prevent the patient from removing catheters, tubes or probes, and to prevent injury to self or to the attending staff. It will always be a temporary measure which will be reassessed frequently while awaiting the action of drug treatment.

93.10 Eye Care

Some 20-42% of patients develop keratopathies during hospitalization in the ICU. If not treated quickly, it can progress to microbial keratitis, corneal ulcers and subsequent loss of vision, all of which can have devastating effects on the subsequent quality of life.

The ocular surface in healthy individuals is protected by natural defence mechanisms such as the bactericidal effect of the tear film, blinking and proper closure of the eyelids. Depression of consciousness, the use of muscle relaxants and sedation in mechanically ventilated patients contributes to a lack of lid closure caused by the decrease in the tonic contraction of the eye muscles (lagophthalmos). Therefore, the lack of protection

mechanisms and the constant exposure of the ocular surface to environmental pathogens put the ICU patient at a high risk for developing keratopathies.
The most widely studied methods for the prevention of keratitis are the application of lubricating drops and ointments, closing the eyes with duct tape, and humidity chambers. The use of swimming goggles and regular moistening of eyelids with gauze soaked in sterile water provides a more effective humidity chamber than the combination of ocular lubricants and placing tape over the lid [28,29], possibly due to the simplicity of implementation and ease of maintenance, because the humidity chambers should not be applied every 2 hours but placed and allowed to stay put, removed for only short periods of time to clean the eyes and evaluate them. With the application of simple protocols, keratopathies can be prevented and the care of coma patients improved.

93.11 Fever

Fever is an independent predictor of poor outcome in TBI. Hyperthermia or fever is commonly encountered in neurocritical patients. According to published reports the incidence varies between 25 and 50%. It is known that the brain is enclosed in a rigid case and has a high metabolic demand and irrigation, at a temperature approximately 1-2°C higher than the rest of the body. So in a patient with fever and neurological injury, the cerebral temperature is higher, with increased brain metabolism. This increased metabolism leads to an increase in CBF, with the subsequent increase in cerebral blood volume, causing ICP to rise.
The use of lower thresholds for treating hyperthermia is recommended in patients with intracranial hypertension, and every effort should be made to maintain body temperature <37.5°C [30].
Temperature control should be a primary mechanism for controlling ICP [31].
Drug treatment should be combined with physical measures to control hyperthermia. The application of ice or cold water directly to the patient's body causes peripheral vasoconstriction, inhibiting the dissipation of body heat and reduction of fever. It also can cause chills and muscle contractions which produce more heat and shock, in turn, generating a catecholaminergic storm and elevated ICP This situation can be resolved with profound sedoanalgesia.
The most effective cooling method is by combining convection and evaporation. This is achieved by spraying the patient with warm water or placing a sheet saturated with warm water over the patient and using a fan to promote evaporation.
After 60 minutes, at which time the body temperature should have decreased; the patient should be dried and the sheets changed so as not to cause other injuries. This manoeuvre should be performed as often as necessary until the temperature is reduced [32,33].

93.12 Intracranial Pressure Monitoring

The most common types of monitoring are with an intraventricular catheter or an intraparenchymal optic fibre sensor. The intraparenchymal sensor does not pose major challenges for measurement, whereas the intraventricular catheter requires highly trained personnel. That is why we refer to this method in detail.

93.12.1 Calibration of the Intraventricular System

The transducer must be set to zero of atmospheric environment and the ICP device re-calibrated according to the specifications of each team once per shift and each time the patient is mobilized.
According to U.S. National Institute of Health (NIH) guidelines, the pressure transducer of an intraventricular catheter should be located at the height of the patient's face (i.e., the foramen of Monro) at the level of the external auditory meatus or lateral canthus. Other sources say that it should be placed at the midpoint between the lateral canthus and the tragus of the ear. The important thing is that the transducer should always be in the same point. It is therefore good practice to mark the anatomic place of localization.

Intraventricular System Maintenance and General Care

- It is essential to adopt strict aseptic technique during manoeuvres of CSF drainage and sampling. We recommend closed drainage systems, always keeping the set open to the pressure transducer for continuous monitoring, only opening it when we wish to perform therapeutic drainage. Maintain the cleanliness of the system.
- The insertion site must be clean, dry and occlusive. The frequency and type of healing can vary. In general, minimum care should be performed once a day and any time the site is wet or dirty. If the gauze is moist with leaking CSF, this must be reported as it can be a sign of a leak in the system.
- Secure the catheter to the site. It is preferable to place a bandage with a brimmed hat for maximum safety of catheter fixation. A catheter that moves or is dislodged will lead to greater morbidity, increased risk of infection and higher costs.
- The U.S. Centers for Disease Control and Prevention (CDC) advises against the application of antibiotic ointment on the site of insertion of the ventriculostomy.
- It is advisable to carry out cytochemical and bacteriological examination of the CSF in all cases after the third day of monitoring. Order tests for determining lactic acid levels in CSF (levels >4 mmol/l are highly suspicious of meningitis in neurosurgical patients).
- Perform therapeutic drainage if the displayed value does not represent the true ICP after opening the system.
- In case of decompressive craniotomy or CSF loss, monitored ICP values will not reflect the severity of cerebral edema.
- Movements or changes in patient position must be taken into account and the system re-calibrated by adjusting the height again.
- Do not perform excessive drainage, as this manoeuvre can provoke ventricular collapse and, eventually, intraventricular hemorrhage ex vacuo) or reflux (to the patient's ventricular system, with the risk of infection of the CNS).
- The collection bag should be emptied when three-quarters full or more than 24 hours has elapsed without any casting. The stopcock should be disinfected and sterile gloves used to maintain cleanliness of site drainage.
- The volume of CSF drainage should be recorded. Alert the physician when the rate exceeds 20 ml/h.
- Record characteristics of the CSF (appearance and colour). Opacification heralds the possibility of infection.
- Do not secure the catheter to the bed to measure ICP as this will interfere with patient mobilization.
- Do not instil any fluid through the catheter or try to permeate the occlusion by applying pressure.
- Do not re-insert a catheter that has become dislodged.

93.13 CSF Sampling

CSF samples should be obtained from the port of the stopcock closest to the patient. First, you must disinfect the top of the stopcock with alcohol iodine for one minute. For this manoeuvre you should use an aseptic technique, sterile gloves and mask. After donning the sterile gloves, open the system and place the top of the stopcock on sterile gauze. The time to take the sample should not be more than 3 minutes. Sending the CSF collection bag directly to the laboratory for culture may be an alternative to sampling. Physicochemical analysis is then ordered for Gram staining and culture, glucose and lactic acid (>4 mg% suspected postoperative bacterial infection) determinations. Clinical suspicion is warranted. Note the presence of fever and/or neurological deterioration not attributable to other causes.

93.14 Measurement of ICP

With a ventriculostomy, ICP can be measured by connecting a transducer to the drainage system or to the same catheter used to drain CSF. To measure through the catheter, once the system has been calibrated (at the level of the Monro aqueduct), the catheter must be raised until there is a "short" column of liquid in the drainage system. The point where the liquid column is short is the level of ICP, it and can be estimated with a ruler in cmH_2O. Divide this value by 1.36 to obtain the value in mmHg.
Each time the bed is raised or lowered the system has to be re-set to zero to prevent emptying of the ventricles or reflux of CSF into the ventricles.
Measurement of ICP with a transducer is preferable since it avoids handling of the liquid column and enables constant assessment of the ICP value and shape of the curve.

93.15 CSF Drainage

The Monro-Kellie hypothesis states that if one of the components of intracranial content increases, the others must decrease to maintain ICP stable. Therefore, a decrease in one of the three components will reduce ICP. In 1960, Lundberg showed that ICP decreases if we remove CSF through ventriculostomy. The withdrawal of only 3 ml of CSF decreased ICP by 10.1% relative to baseline. CSF drainage protocols include "time-dependent" (leave the drain open for 5 minutes, then close), "volume-dependent" (drain 5 ml and then close) and continuous drainage (leave the system open all the time but close it at intervals to read the ICP).
With a ventriculostomy we need to know the height at which we should place the drain. The height of the chamber determines whether the CSF will drain to the outside or not. A chamber with high CSF pressure that exceeds the pressure of the height of the liquid column allows the fluid to exit freely. A chamber with low pressure (lower than the height of the liquid column) will not permit CSF drainage. In conclusion, CSF drains only if the pressure in the ventricles exceeds the pressure in the liquid column. Therefore, the cmH_2O (ICP) must be specifically recorded as the threshold for drainage.
Two situations should be distinguished:

- **Control of intracranial hypertension (ICH)**. The catheters used for controlling ICH should be kept closed and opened only to control ICH (a first level measure),

monitoring the amount drained by hours: 20 ml/h is the limit, beyond which there is the risk of ventricular collapse. On the other hand, opening of drainage should be provided against a positive pressure that will be achieved by raising the drip chamber above the zero level, as many inches as specified by the neurosurgeon.

- **Control of hydrocephalus**. If the control catheters for hydrocephalus of various origin are left permanently open, draining against a preset pressure will be adjusted according to ventricular size given by computed tomography (CT) and the patient's clinical condition. The measure of ICP in these cases is less important and is recorded every hour [34].

93.16 Intraventricular System Dysfunction

- **System blockage or malfunction**. Contact the attending neurosurgeon; do not instil any solution through the catheter without prior consultation with him. A cranial CT scan should be obtained to check the current position of the catheter (this serves to mark the position of any catheter movement during transfer for imaging studies). In the context of subarachnoid hemorrhage (SAH), the dysfunction may be due to obstruction by clots (sometimes true plugs at the intraventricular blood level). There is recent experience with the infusion of fibrinolytics through the catheter to improve outcomes, allowing better control of ICP.
- **Section or rupture of the catheter**. The catheter should be clamped proximally and evaluated together with the attending neurosurgeon and according to the patient's clinical condition.
- **Opening the sterile system**. Consider the system useless if a leak or disconnection occurs. Close the stopcock closest to the patient to occlude CSF drainage and report immediately. Replace the system using an aseptic technique.
- **Damped wave**. Note the presence of bubbles or leaking connections. If you see bubbles, close the port that communicates with the patient in the three-way stopcock closest to the head and flush the system with sterile saline solution from the same key to the collection bag. Always use aseptic technique: antisepsis 3 minutes for the stopcock, sterile gloves and mask.

93.17 Transfers of Patients With ICP Monitoring

Intra- or interhospital transfers are a risky practice because they may adversely affect the results, generating secondary injury. They should only be performed when the patient is adequately resuscitated and hemodynamically stable. It involves trained personnel and adequate monitoring, at least EKG monitoring and pulse oximetry. The ICP measurement equipment must be open and closed only when the patient is transferred to another table or bed. You should always calibrate the system at the level of the foramen of Monro, regardless of the position of the bed or couch.

Avoid manual hyperventilation and **always** carry supplemental oxygen. It is desirable that during transfer the patient receives the same drug infusion as in the referring service in order to maintain intracranial hemodynamics. All patients must travel accompanied by a doctor, nurse and orderly.

93.18 Continuing Neurological Assessment

Although neurological assessment is part of the physical exam, a complete neurological assessment is beyond the scope of this chapter. We will only refer to continuous neurological monitoring by the nurses in the ICU.

The primary objective of neurological assessment is to detect any changes early during hospitalization and to avoid overlooking a new brain injury or deterioration. It is important to remember that neurological deterioration often occurs unnoticed, and time to treatment will determine its subsequent evolution. So the more frequently you perform neurological evaluation, the faster the diagnosis and treatment and the better the evolution of these patients.

The causes of neurological impairment are not only neurological injury but also response to metabolic disorders, intoxication, and hemodynamic deterioration. It is important to remember that poisoning can occur in parallel with brain injury and that it is dangerous to attribute to alcohol or drugs changes in mental status without imaging. Focal deficits should never be attributed to intoxication.

Initial assessment of the level of consciousness is critical for evaluating pupillary response and motor function. A more complete neurological examination should be performed as part of tertiary assessment.

93.18.1 Level of Consciousness. Glasgow Coma Scale (GCS)

The GCS is the universally accepted scale for assessing consciousness. It is simple and can be performed quickly and repeatedly, it is widely understood and is recommended by many guidelines and protocols. The GCS is not a neurological examination in itself (motor evaluation only reflects the best response) and should not be substituted for such.

Originally developed to monitor the progress of the patient with acute TBI, it is now considered a useful tool to assess all patients at potential risk of neurological impairment, regardless of their primary pathology.

The motor component of the GCS (more than the sum of the total score) has been shown to be an equal or better predictor of outcome in patients with brain injury.

Despite the scale's apparent simplicity, misunderstandings can occur in its application. "Quick and easy to use" does not denote insignificance. In practice, although staff is trained to mark the correct box on the assessment sheet, few nurses appreciate the mechanism underlying the valuation, which can prompt appropriate action when the patient's condition changes. It is not uncommon that a change in the patient's neurological status is not detected early, which could save lives or prevent future brain insults [35].

You should record what you see, avoiding the temptation to adjust the information to the clinical history data. Another potential error is to not encourage patients sufficiently to obtain a true reflection of their neurological response.

Conditions for assessing the GCS. Always obtain and record the best response and apply the scale once the patient is stabilized, without evidence of cardiorespiratory instability (hypotension, hypoxemia, hypercapnia). Once the patient is adequately ventilated and oxygenated, only then can the GCS be applied. We must rule out toxic (alcohol, drugs), CNS depressants and metabolic disorders (hypoglycemia, hyponatremia, etc.) before and after performing evaluation with the scale.

How to assess the best eye response. Evaluation with the GCS begins by observing the patient. You should speak in a normal tone and, if necessary, gradually increase the vol-

ume of your voice. If no response is obtained, you can touch or gently shake the patient's shoulder. If there is no response to this manoeuvre, a deeper stimulus is required. Evaluation of the ocular peripheral stimulus is preferred because a central stimulus will cause the patient to close his eyes and wince, which is not the answer we are trying to elicit. Before applying any stimulus, it is essential to explain to the patient and family exactly what will be done and why, apologizing in advance for the pain you are going to cause (even if the patient is unconscious). Peripheral stimulus is delivered by applying pressure with a pen on the lateral aspect of the second or third finger near the nail, rotating the point of stimulation at each assessment. Pain should be applied gradually for a maximum of 10 seconds. A second opinion should be obtained if the expected response is not elicited. In some cases a nociceptive stimulus is applied to the finger nail bed or pressure on the sternum (rubbing it injures the tissues), but these stimuli can generate residual pain.

Important points to consider:

- If the patient's eyes are closed as a result of edema or facial fractures, 1 point is assigned to the general sum and this should be recorded as "NV" (no value), "E" (edema) or the letter that the team agrees on and knows. In such cases an accurate assessment of the patient's arousal level is impossible to make.
- One point must be subtracted if the patient's eyes are closed because he is sleeping. A common mistake is "eye opening to the call" when the patient is physiologically asleep instead of being depressed.

How to assess the best verbal response. Ask the patient about who he is where and why, the present year and month. If these questions are answered satisfactorily, the patient is oriented.

If any of these questions are answered incorrectly, the situation is unclear. If the patient was recently transferred from another hospital, he or she will have an understandable degree of disorientation; nonetheless, a subtle disorientation may be an early indicator of neurological impairment. Typically, patients who do, deteriorate with time, place and people, in that order.

Important points to consider:

- If the patient is unable to respond due to the presence of a tracheostomy or tracheal tube, 1 point is assigned in the overall sum and should be recorded on the form with a letter "T" (tracheal tube) or the letter that the group should agree on and learn.
- If the patient has dysphasia, this must be recorded with the letter "D" (dysphasia).
- A reliable baseline observational record is the most important element of the GCS and allows early identification of signs of deterioration. For this reason, each operator must apply the same stimulus in the same way and examine each patient in the same way.
- A criticism of GCS is that patients cannot be adequately assessed if they have difficulty in communicating related to age (cannot be used in children under age 5 years), language (do not understand the same language), or any pre-existing condition that may affect speech and learning difficulties or stroke. It is important not to try to adapt, change the form or write to try to "fit it" to the patient. Information obtained from the family, such as the patient's preferred name or details of any previous deficits, may be important for a reliable assessment.

How to assess the best motor response. To be sure that the patient obeys orders, ask him to perform various movements, for example, sticking out the tongue, raising the eyebrows, showing the teeth or raising the thumb. If you are prompted to "squeeze the hand", this also entails releasing it to discontinue a primitive grasp reflex. It is good practice for the patient to obey two different commands, so that one is sure that at least he can obey the same command twice.

Supraorbital pressure	Supraorbital pressure was identified as the "gold standard" but should only be used when you have trained staff to implement it properly. Just below the arc of the eyebrow, there is a small notch through which a branch of the facial nerve runs. The operator's hands rest on the patient's head and the surface of the thumb or knuckle is placed on the supraorbital rim below the eyebrow. The pressure should be gradually increased for up to 30 seconds. This is contraindicated if there is damage or orbital fracture of the skull base (in which case the pressure on the trapezius is an alternative)
Pressure on the margin of the jaw	Pressure is applied to the angle of the jaw. The surface of the thumb rests on the curve of the junction of the maxilla and mandible and the pressure is gradually increased for a maximum of 30 seconds
Pressure on the trapezius	The trapezius muscle extends across the back of the shoulders from the middle of the neck. Keep the muscle between the thumb and index finger and apply gradually increased pressure for a maximum of 30 seconds. The trapezius muscle has motor and sensory components and no risk of causing a spinal reflex to stimulation

Table 93.8. **Implementing central nociceptive stimuli**.

Apply a central nociceptive stimulus to assess the response to pain. It should only be applied if the patient does not respond to verbal commands and it need not be applied if the patient is oriented, for example, when trying to withdraw an oxygen mask or a nasogastric tube.

To classify as a "location", the patient must move his hand toward the point of the stimulus, putting his hand to his chin, crossing the midline, coordinated in an obvious attempt to remove the cause of pain. It is useful to start with the arms in a flexed position of 30° to minimize any abnormality when assessing abnormal flexion or extension.

The National Neuroscience Benchmarking Group recognizes three methods for applying a central painful stimulus: supraorbital pressure; the pressure in the angle of the jaw; and the pressure on the trapezius muscle (Table 93.8). Other methods of applying central stimulus are not recommended because they can only generate a peripheral reflex response.

The answer "taken the pain" is obtained from a central painful stimulus, when the patient bends his arm above the elbow flexion as a reflection of normal, but fails to locate the source of pain.

Abnormal bending, also known as decorticate posture, can be recognized because it is a slower response to painful stimuli. The patient flexes the upper arm and wrist separately. Sometimes the thumbs are placed between the toes.

Abnormal extension or decerebrate posture is characterized by extension of the upper limbs and internal rotation of the shoulder and wrist. Sometimes the legs are also in extension, with the feet pointing downwards.

If there is no motor response, we must ensure that an appropriate stimulus is applied. A patient cannot respond due to illness or injury local (e.g., spinal trauma).

Important points to consider:

- Always record the best answer of the upper limbs by using a central painful stimulus: when assessing motor response the brain is being measured and not the answer cord. A spinal reflex can cause a sudden bending of the limbs and can occur even when brain death has been certified.
- Operators should be aware of their own nonverbal behaviour, since the patient may simply imitate what they see, leading to misinterpretation.

The level of consciousness is the most sensitive indicator of neurological impairment. Unless the patient receives sedatives or anesthetics, with the GCS it may be possible to identify deterioration before changes occur in the pupils or in vital signs.

When communicating the GCS score, it should be done in terms of its individual components, e.g., O3, V2, M4, indicating that the patient opens his eyes to speech, a verbal response is incomprehensible, and flexes to painful stimulation.
A decline of 1 point in motor response or 2 points in the total GCS score is clinically significant and should be reported immediately. To ensure consistency, the same member of the staff should conduct the assessment in a work shift. On delivery, the incoming shift nurse should compare the recorded with new GCS scores. Without such continuity, subtle changes may be overlooked.
Patients often give subtle clues of deterioration, such as being less communicative, with slow responses, and these are particularly related to changes in behaviour. Be aware of these changes and note them on the medical chart.
Lack of confidence in completing the registration can be influenced by previous assessments. Always ask a colleague to revaluate if you are unsure of the procedure. GCS should not be used in isolation. Instead, it should be used in conjunction with other aspects of neurological assessment and pupillary reactivity, the response of members, etc.

93.18.2 Pupils

This procedure should assess the size, symmetry and reactivity to light of both pupils. Any change in these parameters is a late sign of increased ICP. It must be remembered that pupillary reactivity is the only way to monitor the neurological status of a sedated patient. A unilaterally dilated pupil, either slow or fast, is an indicator that the swelling or bruising is getting worse and is compressing the oculomotor cranial nerve through the foramen magnum.
Pupillary asymmetry, loss of reactivity to light or unilateral or bilateral dilatation should raise the suspicion of brain herniation until proven otherwise. It must be remembered that some patients may have a pre-existing eye condition that causes a unilateral dilated pupil, like a waterfall or localized injury; however, although a traumatic optic neuropathy can cause a unilateral pupil to be dilated and not reactive, the presence of local orbital trauma should not be overlooked as an intracranial lesion.

Procedure	Basis
Inform the patient, whether conscious or not, about who will look into his eyes with a light and explain the procedure	Helps reduce anxiety. Ensure, as far as possible, that the patient consents and understands the procedure
Reduce the light overhead or ceiling to observe pupillary reactivity	Provides a better view of the eyes and reaction to light stimulation
Wash your hands thoroughly	Prevents contamination of the eyes and reduces the risk of infection
Keep the patient's eyes open and observe the size, shape and symmetry of the pupils	Normal pupils are round, usually centralized and have a diameter of 1.5-6.0 mm
Keep one eye open and move the light from the outside to the pupil. This should cause rapid pupillary constriction (direct response to light)	To assess pupil reactivity to light. A normal response indicates no injury or pressure on the third cranial or trunk regulating pupillary reactivity
Record any unusual movements such as nystagmus gaze deviation	To assess cranial nerve damage
Repeat the test in the opposite eye	To assess the equality of the reaction and ensure that all areas are working properly

Table 93.9. **Guidelines for the assessment of pupillary reactivity to light.**

Before pupillary signs of cerebral herniation, immediate efforts should be made to reduce ICP while performing diagnostic studies. Urgent intervention at this time can make a significant difference in patient outcome.

Table 93.9 provides a guide for the assessment of pupillary reactivity to light and the basics of the procedure.

Important points to consider:

- If both eyes are closed due to high orbital edema, record this with the letter "E" (edema)
- Rapid pupillary reactivity is recorded as "+" or "R" (reactive). Nonreactive pupils as "-" or "NR" (not reactive) and slow pupils as "L". Each service must formally record the acronym.
- Use a small pen-type flashlight not an ophthalmoscope.
- Slight differences in pupil size may be normal.
- It is not uncommon for healthy people to have different sized pupils.
- Very small pupils (1-2 mm) may suggest the use of opiates, benzodiazepines or barbiturates.
- The use of eye drops such as atropine can dilate the pupils.

93.19 Motor System

Although the GCS only assesses the response of the best extremity, it is necessary to conduct a comprehensive assessment. Hemiparesis, monoparesis, quadriparesis or paraparesis may reflect intracranial or spinal injury and these are not mutually exclusive. Evaluation of the response of extremities provides details on the geographical distribution of the injury and it is an important consideration when performing full neurologic assessment. Each extremity should be valued separately. Ask the patient to hold his arms out in front of him, then look signs of weakness or deviation of the limb. Rate the legs by asking the patient to push his feet toward the evaluator or lift his legs off the bed and keep them bent. In patients unresponsive to a verbal call, a nociceptive stimulus should be applied to a distal region of both legs and arms. If you notice "withdrawal" of the limb, nociceptive stimulation should be performed in a central location to differentiate "withdrawal" from "localization". The response of "localization" (motor response of 5 points) is reached when a limb crosses the midline to the contralateral stimulus or when the arm is raised above the jaw to a stimulus such as supraorbital pressure.

93.20 Vital Signs

The final warning is the triad or Cushing reflex, a classic set of signs and symptoms that indicate that IC is dangerously high and the patient is at risk of life-threatening cerebral herniation. This reflex is a very late sign and is characterized by hypertension, bradycardia and irregular breathing.

Hypertension. The patient typically has high systolic pressure combined with a pulse pressure (wide difference between systolic and diastolic). This causes systemic vasoconstriction and hypertension.

Bradycardia. The heart rate can drop to 35-50 beats per minute. This allows each systole to pump more blood at higher pressure, forcing the entrance of blood to the brain during the peak systolic blood pressure.

Irregular breathing. The pressure on the respiratory centre on the lower and upper spine causes deterioration of the respiratory pattern. The following patterns can be seen:

- Cheyne-Stokes.
- Hyperventilation which removes carbon dioxide, and cerebral vessels constrict in an attempt to reduce ICP.
- Breathing in clusters: periods of rapid, irregular and noisy breathing alternating with periods of apnea.

93.21 Frequency of Evaluation

The 2003 NICE Guidelines recommend that patients with TBI admitted to an emergency department with a GCS score <15 must be observed hourly to determine whether the score improve. Patients admitted with GCS of 15 points must be evaluated every half hour for 2 hours, every hour for 4 hours and every 2 hours thereafter.

Although this is a useful guide in clinical areas, the neurological condition usually dictates the frequency of observations, and any adverse change in the patient's condition is an indicator to increase the frequency of observations.

The quality of observation is as important as quantity. Discontinuation of neurologic assessment depends on the individual clinical trial, but it is reasonable to suspend it when the patient has been stable for a couple of days and the initial condition has been resolved.

93.22 Conclusions

Neurocritically ill patients account for a growing fraction of ICU admissions due to the changing sociocultural characteristics of the population and new technologies that allow more interventions in high-risk patients.

The treatment of these patients is based primarily on preventing secondary injury and treating the complications that may arise during the course of the illness. A multidisciplinary team must be able to work together, with clear objectives and protocols to provide the best care for our patients.

94 Outcome Rating Scales in Neuroinsensivism

Gustavo Petroni [1], Silvia Lujan [1], Carlos Rondina [1]
[1] Intensive Care Unit. Hospital de Emergencias Dr Clemente Álvarez. Rosario, Argentina

94.1 Introduction

An important aspect as the classification and initial assessment of brain injury is the accurate evaluation of the results. The effectiveness of many interventions during the acute care will depend on the evaluation of the results.
When evaluating results we must consider not only physical but also cognitive, mental, and social disabilities. Many of the survivors have deficits (neurological and/or cognitive) that interfere with quality of life.
Rating scales are useful tools to attempt to quantify outcomes in a reliable and accurate way in patients who have suffered neurological injury.
Then we'll describe the most used.

94.2 Outcome Rating Scales

94.2.1 GOS (Glasgow Outcome Scale)

It is still the most used outcome rating scale to evaluate neurological injuries (traumatic and non-traumatic). It assesses general social skills (or dependence) of the patients, taking into account the combined effect of mental and neurological deficit [1]. It determines the independency of a person in the society and the return to the previous life style. Different studies have shown that it is a reliable scale and easily used by different observers.
The GOS includes five categories:

1. Death.
2. Vegetative state(VS): patients can not interact with the environment, they do not respond.
3. Severe disability: patients are able to follow orders, they can not live independently.
4. Moderate disability: patients can live independently, they can not return to work or school.
5. Good recovery: patients are able to return to work or school.

For statistical purposes, the GOS can be dichotomized in Poor outcomes (Dead, VS, severe disability) and Good outcomes (mild disability and good recovery). The GOS allows comparing results of patients treated with different treatments protocols or in different sites. One of the main criticisms is that its simplicity makes it relatively insensitive to changes in recovery that are not enough to make a change in the category.

94.2.2 GOS-E (Glasgow Outcome Scale Extended)

The GOS-E was developed to address the limitations of the original GOS due to the lack of a structured interview.

1. Dead.
2. Vegetative state.
3. Lower severe disability.
4. Upper severe disability
5. Lower moderate disability.
6. Upper moderate disability.
7. Lower good recovery.
8. Upper good recovery.

The structured interview has improved the classification reliability. It has demonstrated to be more sensitive than GOS to changes in patients with mild and moderate Traumatic Brain Injury (TBI).

The interview can be administered to the patient, to a family member, or to any other person who can provide information. The GOS-E is not considered an instrument of self perception, evaluators must give a score to each item based on the most accurate information available, regardless the source.

94.2.3 DRS (Disability Rating Scale)

It is a scale that allows to measure with precision general functional changes (disabilities and impairments) in the recovery process. It was developed and proved in patients with severe and moderate TBI in the rehabilitation environment.

Scores range from 0 (without disability) to maximum score of 29 (vegetative state).

The DRS assesses 8 items: The first three items ("eye opening", "communication" and "motor response") are a modification of the Glasgow Coma Scale and reflects the worsening degree.

The cognitive capacity for self-care activities like "feeding", " hygiene" and "cleanliness" shows the level of disability.

The " functioning level" and " employability" reflect impairment degree and are based on the capacity and not in performance (dependency and social adaptation).

It is one of the best scales to evaluate outcomes in patients with moderate TBI.

Advantages: proved reliability and validity, useful in a great variety of patients, data can be obtained from patients or family, can be done by phone or either by medical records revision, and not requires a great experience of the evaluator.

The ease of administration and the brevity of the scale are the most important reasons for its popularity (15 minutes).

Disadvantages*:* One of its limitations is its relative insensitivity to minor injuries (mild TBI) and its inability to reflect subtle but often significant changes, within a specified window of recovery. It does not measure changes in a short period of time.

94.2.4 FIM (Functional Independence Measure)

It was developed to solve the generalized lack of data of outcome in rehabilitation [2].

It's a basic indicator of the severity of the disability, it evaluates what the person does with the impairment whatever its diagnosis or disability is.

It is an ordinal scale of 18 items including: self care independence, sphincter control, transfers, locomotion, communication, and social-cognitive state.

Scores range from one to seven: a score of seven in a FIM item is categorized as "complete independence", while a score of one means "total assistance" (performs less than 25% of the task). Scores under six require another person for supervision or assistance.

By summing the scores for each item, the possible total scoring ranges go from 18 (lowest) to 126 (highest).
It is very useful for the evaluation of progress during rehabilitation. It is the most widely used functional evaluation measure in rehabilitation. Limitations are that their reliability depends on training and certification of assessors.

94.2.5 Rancho Los Amigos Scale (Level of Cognitive Functioning Scale)

It assesses cognitive function in patients after coma [3]. Allows planning the treatment and following up of recovery. Classifies patients into eight levels:

- I: No response.
- II: Generalized response.
- III: Localized response.
- IV: Confused, exited.
- V: Confused, not exited.
- VI: Confused, appropriate.
- VII: Automatic, appropriate.
- VIII: Deliberate, appropriate.

The level assigned provides a clear description of patient behavior and may be used to develop specific treatment interventions.
Does not require the collaboration of the patient, can be classified based on the observation and response to the environment.
Not attempts to predict long-term improvements. Rapid progresses are usually the first weeks and then they stabilize at levels VI or VII.

94.2.6 Barthel Index

Despite great personal and social impact of stroke, the best method to evaluate results, it is not clear.
One of the most used scales is the Barthel Index; it measures the ability of the person for the accomplishment of ten basic activities of daily living, obtaining a quantitative estimation of the dependence degree of the subject. Includes: eating, transferring from chair to bed, self-cleanliness, toileting, bathing/showering, moving (walking on smooth or wheelchair), going up/down stairs, dressing/undressing, bowels and bladder control. The activities are valued differently, assigning a value of 0, 5, 10 or 15 points. The global range can vary between 0 (completely dependent) and 100 (completely independent) It's an easy measure to apply, with a high degree of reliability and validity, can detect changes, easy to interpret, and its use does not cause discomfort.
Disadvantage: it does not evaluate language, so patients can be evaluated with good recovery despite having aphasia.

94.2.7 Neuropsycological Tests

Even though diagnostic imaging such as MRI, CT, PET or SPECT may show damage to the structural integrity of the brain, blood flow or metabolism, it cannot measure the loss of memory or the ability to maintain attention. Neuropsychological tests assess these deficiencies of cognitive functioning. The tests consist of pencil and paper tasks, verbal tasks, structured and unstructured interviews, and construction tasks.

Area	Tests
Verbal fluency	Verbal Fluency Test (letters, animals, actions)
Higher cognitive functions	Color Trail Test 2
Speed of information processing	Color Trail Test 1/Digits and Symbols/Symbol searching
Working memory	WMS-III Spatial Span/PASAT 50
Learning and Memory	Verbal learning test/Brief visuspatial memory test
Fine motor coordination	Grooved Pegboard Test

Table 94.1 **Some of the most widely used neuropsychological test and the areas involved.**

They are used to analyze and interpret patients' responses to cognitive tasks by comparison with a normal sample. These samples are usually composed of large groups of people with similar characteristics to the patient examined (age, education and cultural training) and the results are expressed in percentiles. It allows to infer what the patient is able to do in his environment on the basis of how he does a set of tasks in relation to how others do these tasks in the population.

Although many patients may not be capable of performing all neuropsychological tests at 6 months, it is recommended that the examiner attempts to perform each test, discontinue them according to the criteria and document why the test was not completed (e.g. aphasia, motor problems, etc.).

Table 64.1 details some of the most widely used neuropsychological test and the areas involved.

94.3 Conclusions

The selection of the functional outcome scale used is based on clinical relevance, reliability and sensitivity to changes.

The reliability indicates the extent to which the scales are reproducible, so that the results obtained allow us to conclude that the assessments made by observers were reliable and therefore the measures to apply. There are some factors associated with patients, observers or with the own scales that can influence the variation of the measurements.

Trained examiners should carry out assessments and periodic re-trainings should be performed to minimize inter-observer variability.

The global results assessment (functional and neuropsychological) provides a better understanding of the behavior of the individual so that the Interdisciplinary Treatment Team may use individual advantages and compensate for limitations in cognitive function associated with brain injury.

95 Concepts and Management of Brain Death and Management of Potential Organ Donation

Claudio García Alfaro [1], **José María Domínguez Roldán** [1],
Juan Villar Gallardo [1], **Pedro Ignacio Jiménez González** [1]

[1] Critical Care and Emergency Department Unit. Hospital Universitario Virgen del Rocío, Seville, Spain

95.1 Part I. Concepts and Management of Brain Death

95.1.1 Introduction

Even though before the Modern Era the death of a person was considered unequivocal when related to corporal signs (rigidity, lividity and the beginning of putrefaction), the development of medical concepts have changed this. In the context of the creation of intensive care units (ICUs) and with the development of cardiopulmonary reanimation techniques, concepts about the death of a person have been modified, and now can be related to organs like the heart or lungs. All this leads to the concept of death related to the only essential organ to life: the brain.
Another problem is how to determine the moment of death in patients with severe brain lesions who have previously experienced variable periods of unconsciousness.

95.1.2 Brain Death Concept

Until the 20th century, the concept of death was related to cardiorespiratory arrest. However, in 19th century, with Virchow's tissue theory, death was considered a process in which different organs and tissues (with a different vital potential) progressively ceased to function. This concept is still strongly accepted and is the origin of the requirement for waiting 24 hours before the burial of the cadaver.
It was in 1968, during the 22nd World Medical Association Meeting, that a declaration about death was elaborated, actualized in later meetings, establishing the responsibility and competence of physicians in the diagnosis and determination of the moment of death.
There are currently three main concepts of brain death: global death, brainstem death, and neocortical death. However, the first two are the most prevalent.
Brainstem death was developed following the criteria established in 1976 in the Conference of Medical Council and their Faculties of the United Kingdom, developing the definition in the document entitled the United Kingdom Code. It is based on the fact that brain death is established when there are lesions in the brainstem with a loss of function. In this case, it is sufficient to perform a clinical examination to make the diagnosis.
Global brain death, a more widespread concept, considers brain death as the summation of brainstem death and neocortical or telencephalon death, i.e., the complete absence of all encephalon and brainstem functions.

Arousal (capacity of consciousness) with loss of awareness (content of consciousness) is considered neocortical death and so the diagnosis should be based on the clinical demonstration of absence of content of consciousness (awareness).

Brain Death Diagnosis

Brain death diagnosis is based on the principle that a patient suffers an irreversible lesion. Therefore, it is essential to know the mechanism of cerebral damage, without which it would be impossible to establish the irreversibility of the process. Determining the irreversibility of the process before performing a clinical diagnosis is mandatory to eliminate the existence of possible factors which could simulate brain death or have an impact on a clinical examination.

Before a diagnosis of brain death can be established, it is mandatory that a patient presents with:

- Absence of systemic arterial hypotension. Systemic arterial hypotension can decrease cerebral blood flow, so blood pressure must be normalized prior to the clinical examination, being coherent with age and medical history.
- Absence of hypothermia. Accidental or induced hypothermia leads to a general decrease in brain activity and can even alter brainstem reflexes if the body temperature is <28°C. The situation must be reversed and the patient must be explored with a body temperature >32°C.
- Absence of effects of neuro-depressant drugs, muscle relaxants and anticholinergics which can mask brain death signs. Among the most frequently used drugs in the ICU is midazolam (benzodiazepine), with a half-life of 1.8-6.4 hours (average, 3 hours). In patients with renal dysfunction this could be more prolonged and may remain for 24 hours. In patients who received benzodiazepines it could be useful to employ antagonist drugs such as flumazenil (dosage of 0.2 mg per minute, with a maximum dosage of 2 mg). Thiopental is another widely used drug, very soluble in fat tissues and low grade of ionization, which allows it to pass easily through the blood-brain barrier. It has a half-life of 3-8 hours after a single injection, but it can be prolonged for 27 hours when administered by continuous intravenous perfusion. As a general rule, authors propose that clinical examination for brain death diagnosis must be postponed until the half-life has elapsed by four times.

Clinical Diagnosis

This diagnosis shows the absence of brainstem function through the absence of reflexes of a given anatomical region. There must be bilateral findings, following a detailed protocol with the next steps.

Absence of direct and consensual pupillary reflex. This is performed with stimulation of a powerful light source, observing in normal conditions pupillary contraction. The pupils can appear round, oval or disc-shaped, medium size or mydriatic, from 4 to 9 mm, and unresponsive to light. There must always be an absence of a consensual reflex. The afferent pathway starts at the retina, continues via the optical nerve until the geniculate ganglion, connecting bilaterally with the Edinger-Westphal nucleus (mesencephalon). The efferent pathway is the parasympathetic portion of the III cranial nerve until the iris muscle constricts. Some drugs (anticholinergics: tricyclics, atropine and adrenergic drugs) produce paralytic mydriasis. So an atropine test must not be done before exploring the pupillary reflex.

Absence of oculocephalic reflex. Exploration is done keeping the eyelids open with the index fingers and thumbs, holding the head with both hands, and moving the head horizontally from left to right (or vice versa) in rapid succession. If a reflex is present, it is

observed by conjugated ocular deviation opposite to the head movement, returning to the initial position with a temporal lag. In brain death, with the reflex absent, the eyes do not move and follow the head movement. Always exclude unstable cervical spine lesions before exploring this reflex because it could produce spinal lesions which could lead to cardiac or hemodynamic instability due to the suddenness of the motion. The afferent pathway starts at the semicircular channels in the middle ear, continuing via the VIII cranial nerve (statoacoustic) until the vestibular nucleus (bulb-pontine level), continuing by the medial longitudinal fasciculus and reticular parapontine formation, interconnecting with the efferent pathway, that is the III and IV cranial nerves.

Absence of corneal reflex. Corneal stimulation is performed using sterile gauze (having previously gently opened the upper eyelids with the fingers), observing a palpable contraction and tearing in a live patient, and an absence of response in brain death. The afferent pathway is the ophthalmic branch (first branch of the trigeminal nerve) which leads to its sensory nucleus and determines a bulb-pontine level of prosecution. The efferent pathway is through the III and VII cranial nerves.

Absence of oculovestibular reflex. This is explored with the head elevated to 30°. A volume of 50 ml saline is injected at 4°C into the ear canal, while maintaining the patient's eyes open for 1 minute. In normal conditions, nystagmus is observed with slow components towards the irrigated ear and a fast corrector cortical component in the opposite direction. It is advisable to wait at least 5 minutes before exploring the contralateral reflex. Nystagmus is regular and rhythmic, and lasts <2-3 minutes. In brain death there is no ocular movement. The afferent pathway is the semicircular lymph channels, continuing via the VIII cranial nerve until the medial longitudinal fasciculum and reticular pontine formation. The efferent pathways are the III, IV and VI cranial nerves.

Absence of nauseous reflex. The soft palate, uvula and oropharynx are stimulated using a wooden tongue depressor. A nauseous reflex is observed in normal conditions and no response in brain death. The afferent pathway is through the IX cranial nerve, connected to the ambiguous nucleus and determining the afferent by the X cranial nerve.

Absence of cough reflex. This is explored by introducing a probe through a nasotracheal tube or tracheostomy to produce tracheal stimulation; in normal conditions cough production is observed and no response in the case of brain death.

Absence of response to atropine. The atropine test explores the activity of the X cranial nerve and its brainstem reflexes. Physiological response consists of increasing the cardiac rate by 10% of the basal cardiac rate after injection of 0.04 mg/kg of atropine sulphate intravenously. In brain death there is no response. It must be administered through a vein not shared by any amine which could have a positive chronotropic effect.

Absence of oculocardiac reflex. Normal response (Ascher's sign) consists of decreasing cardiac rate by 10% and decreasing blood pressure by 35% after applying pressure on the eyeballs. There is no response in brain death. The afferent pathway is the V cranial nerve; the prosecution centre is the nucleus of the V cranial nerve at the bulb level. The efferent pathway is through the X cranial nerve.

Absence of spontaneous breathing demonstrated by the apnea test. Generally, this is the last test because it can generate deleterious systemic and intracranial effects. To perform this test it is recommended that the patient be previously hemodynamically stabilized, with adequate preload, with serum ions and an acid-base balance within the normal range. The respiratory centre is stimulated when the arterial pressure of CO_2 is >60 mmHg or 20 mmHg higher than the usual value (normal arterial pressure, 35-45 mmHg); patients with chronic obstructive pulmonary disease (COPD) often present compensated respiratory acidosis with CO_2 >45 mmHg. Arterial pressure of CO_2 increases 2.5-3 minutes per minute in apnea, so the apnea test must be prolonged until the $PaCO_2$ is >60 mmHg or >20 mmHg higher than the usual value.

Steps to perform this test:

- An initial sample to know the basal CO_2 arterial pressure.
- Period of apnea:
  - The classical way is to disconnect the patient from the ventilator, introducing a probe with an oxygen flow of 6 l/min through an endotracheal tube. The time is calculated to allow the increase in CO_2 >60 mmHg or 20 mmHg higher than the usual value (2.5-3 mmHg for each minute in apnea). A second sample must be drawn to check if the CO_2 values are previously indicated.
  - In respiratorally unstable patients in which it would be impossible to maintain disconnection from the ventilator for a prolonged period, and/or with risk of pulmonary collapse, another technique can be performed: using the ventilator with spontaneous ventilation mode with positive end-expiratory pressure (PEEP) but without support pressure and triggering by pressure (not by flow to avoid auto-cycling) in ventilators where it is possible to disconnect the safety ventilation mode. In older ventilators, the inspiratory branch can be disconnected and connected to a T-tube with oxygen 6 l/min, with a PEEP safety valve in the expiratory branch.
- In all cases CO_2 arterial pressure after 5-8 minutes (approximately) must be achieved and after maintaining an upper level of 60 mmHg or 20 mmHg higher than the basal value. Furthermore, the patient cannot have any respiratory movements.

Absence of spontaneous or provoked facial or muscle movements. No spontaneous facial movement (neither spontaneous nor induced) can be observed in a brain dead patient. No spontaneous or painful facial movement or anywhere in the rest of the body. However, the presence of spinal motor activity does not preclude the diagnosis of death. The presence of plantar cutaneous reflexes, priapism and some complex movements (for example, the Lazarus sign) and no spontaneous facial movement (spontaneous or induced) can be observed in a brain dead patient.

Brain death in children has specific connotations in children under 2 years of age. It is noteworthy that the presence of spinal reflexes is more frequent than in adults. Observation periods are different and more prolonged than in older patients:

- Less than 2 months. The observation time before certifying death is 48 hours. Clinical signs must be explored, such as suction reflex and search reflex. It is recommended to have two flat electroencephalograms (EEGs).
- From 2 months to 1 year. The observation time is 24 hours, the absence of reflexes mentioned above, and two flat EEGs.
- From 1 to 2 years. The observation period is 12 hours. When the mechanism of brain damage is ischemic-anoxia, it is recommended to maintain a period of observation for at least for 24 hours.
- It is important to note that the apnea test takes less time than in older patients because the CO_2 arterial pressure increases faster than in adults (4.2-5.3 mmHg per minute).

Instrumental Diagnosis

Prior to commencing, it is necessary to perform a clinical diagnosis. In clinical diagnosis, certain requirements must be met (hemodynamic stability, etc.). It is important to highlight that instrumental diagnosis is not enough to make a diagnosis but complements the clinical diagnosis. There are tests to explore bioelectric functions (EEG) and to explore cerebral blood flow (cerebral angiography, gammagraphy, transcranial Doppler sonography).

Electroencephalogram is one of the oldest techniques in the diagnosis of brain death. It is based on the demonstration of the absence of bioelectrical brain activity. It was pro-

moted by Harvard Medical School. The American Society of Clinical Neurophysiology set the following requirements for diagnosis:

- A minimum of 8 electrodes must be employed (a complete set in frontal, temporal, occipital and parietal regions).
- Impedance between electrodes from 100 to 10000 Ù.
- Distance between electrodes at least 10 cm.
- Increase in sensitivity must be 7 at <2 mV and the recording must be at least of 30 minutes duration.
- The filtering system has to be adequate to diagnose EEG silence.
- Extensive monitoring of EEG, electrocardiogram (ECG), respiratory, etc.
- There must be no electrical response after somatosensory, visual or auditory stimuli.
- The recording must be performed by skilled personnel.

One of the limitations of this technique is interference from neuro-depressant drugs, barbiturates. Levels of 40 ug/ml are correlated to burst-suppression, and an upper limit of 70 ug/ml is correlated with a flat EEG. So it necessary to determine serum levels as diagnosis capacity can be influenced.

Multimodal evoked potentials. Combined somatosensory and auditory potentials are very useful. Report the integrity of conduction pathways or place of lesion at the peripheral level. Evoked responses which show the bulb as upper prosecution levels are compatible with brain death. This diagnosis is compatible with the following patterns:

- Auditory evoked potentials of bilateral flat brainstem, bilateral or unilateral isolated wave I and unilateral or bilateral isolated waves I and II.
- Somatosensory evoked potentials of short latency for stimulation of the median nerve: P15, N20 and P25 absence, and cortical potentials more overdue in the cephalic-cephalic derivation. Presence of the components P9, P13, Nm (Nm is the derivation cephalic-no cephalic) and presence of the potential of Erb.
- Evoked potentials and electroretinography with persistence of retinal activity and absence of visual cortical evoked potentials.

Transcranial Doppler sonography (TDS). The usefulness of TDS in the diagnosis of brain death is based on the demonstration of an absence of cerebral blood flow in the arteries of the cranial base. The test must include exploration of anterior cranial base circulation (middle cerebral artery and anterior cerebral artery) and posterior cranial base circulation (basilar artery and vertebral arteries). TDS has the advantage that it can be performed at the bedside and can be repeated as often as necessary. Furthermore, records can describe the progressive process of cessation of cerebral circulation through the decrease in diastolic velocity of blood flow, determining four patterns: diastole-systole separation; diastolic reversion or reverberant flow; systolic spikes; and complete disappearance of the sonographic signal. In late patterns in which obtaining signals is impossible, it must be sure that the flow records of the extracranial arteries are adequate, and comparing it with the flow at the intracranial level. Alternative windows can be used such as the orbital to observe whether there is residual flow in the carotids at the carotid siphon. A document by the Task Force Group on Cerebral Death of Neurology determined that in cases in which intracranial flow cannot be recorded, it must be done on the extracranial arteries. This can create the problem of having to perform sonographic diagnosis of cerebral circulatory arrest in patients with decompressive craniectomy, in those with ventricular drainage, or in infants with open fontanels. In such cases it is necessary to perform an EEG or multimodal evoked potentials.

Cerebral angiography. Another option in the exploration of cerebral circulation to establish the diagnosis of cerebral circulatory arrest is cerebral angiography which includes anterior and posterior intracranial circulation. Here are some described patterns of circulatory arrest seen in brain death:

- Total arrest of arterial contrast without vein filling and retrograde disappearance.
- Detention of arterial circulation at the level of the Circle of Willis.
- Extreme slowing down of arteriovenous circulation: more than 15 seconds is considered incompatible with cerebral function.

Like other cerebral perfusion studies, their main limitations are low blood pressure, open fontanels in newborns, large fractures of the vault or skull base, internal or external drainage of cerebrospinal fluid or emissary veins.

Cerebral perfusion studies with isotopes. The study of cerebral perfusion can be done with I 123 IMP and Tc 99 HMPAO, the latter of which has more benefit. There are two phases: the first is angiogammagraphic to appreciate the cerebral flow and the second phase with static images at 5-10 minutes with anterior, right and left lateral protections which disclose parenchymal retention. In cases of brain death, isotopes are not observed in either the perfusion phase or the retention phase.

95.1.3 Communication of Brain Death to the Family

It is very important to develop communication skills for giving information on brain death and its premonitory processes. Communication with the family in the final stages of life is related to the temporal development of the disease, the family's educational level, empathy between the medical staff and the patient's family, family and physician adaptation to situations of crisis and cause of death. Health professionals must help these families understand and accept brain death as they do for families of dying patients in asystole. This may occasionally be complicated for some because it can be complex to understand if the process and information about death are not well explained. This is especially difficult when the family observes that the heart is still beating and the chest is moving because of the mechanical ventilator. This visual aspect may be unsettling for the family, preventing them from grieving in a normal manner. It does not have the same impact when death occurs in situations where the duration of the illness is prolonged and a relationship of trust has been established between the care team and the family. In instances of sudden illness, accidental or fatal, fulminant progression to death, the time needed for adaption to and acceptance of imminent death and a trusting relationship between family members and the doctor is lacking. The medical and nursing staff need to show empathy to the families and provide them with information appropriate to their cultural level. It is important to avoid the use of technical language incomprehensible to the family which may generate mistrust in this relationship. In many cases, family members will inevitably experience a state of crisis. This is defined as traumatic life crisis in a temporary state of greater or lesser duration that leads to disorder and disorganization, characterized mainly by the individual's inability to cope with unforeseen, uncontrolled or unexpected situations. The person is temporarily unable to adequately resolve current problems or address situations or process information. This may be delineated in a series of stages:

- Initially, a reaction to the external event and an increase in tension due to the inability of the person to deal with the specific circumstances.
- Mobilization of other personal resources that reduce the external threat.
- Successfully deal with the adverse situation.
- Redefine the problem as well as others.

The inability to activate some of these strategies can lead to personal disorganization and a state of confusion and disorientation, resulting in psychological mechanisms of denial or intrusion (intrusion means to have feelings of pain, impact images, nightmares,

etc.) that require accompaniment and support to address, integrate and overcome the incident.

Intrusion leads to penetration processes which express, identify and disseminate thoughts, feelings and images of the crisis experienced. It involves defining the problem, making decisions or learning new solutions to mobilize personal resources, reduce unpleasant effects, etc.

This leads to the final stage of complete integration of the crisis in the life of the individual. The crisis may result in an improvement in rationalizing the pain or a worsening in which misconduct can be set from depressive states of the subject.

After communicating death to family members, the first support must be quick and short. Grief reactions may be varied, and psychological responses may include numbness or intense emotional release, sometimes unaware of what happened or showing semi-automatic conduct. For those showing inhibition, lethargy or denial of feelings, the individual may try to separate emotionally from the reality of death. In other people, the reaction is flight or liberation of movement; these are less structured and may be admitted as long as it does not endanger other people or are of a destructive nature. It is important to control the number of people who initially receive this information, because a range of reactions can appear contemporaneously and may be uncontrollable. Hence, there is a need to select as much as possible those who should receive the initial information. The domain of verbal communication skills, active listening, clarification of any issues that may be confusing for understanding the process which has led to this final outcome, summary of information, reflections of feelings and the appropriate management of silences are a priority.

Nonverbal communication must be maintained appropriately, so that spatial positioning is utilised with an attitude of interest, leaning towards the family and not losing eye contact with them. It is important to use a caring tone of voice that should be serene, firm and sufficiently clear, without doubt in clarifying the situation. Occasionally, subtle physical contact may be needed to comfort the family to help them overcome the situation and it can be the first support received by the family. Sometimes these contacts are rejected by the family, in which case we have to change our approach immediately.

When imparting information about brain death, the situation must be handled with care because it may influence personal reactions. In this time of a crisis for the family, future memories will be influenced by the environment in which the news was reported. It must be ensured that the number of family members is limited and they must be the closest relatives. Sometimes the circle can be extended according to the patient's personal circumstances (many children), while anticipating the risk of having less control over possible adverse reactions.

The family has to be notified, if possible, by a physician knowledgeable about the critical situation, opening the possibility of a future unfavourable evolution and placing it in position to progressively accept the death process. After giving the information, the physician should guide the conversation while the body is in the hospital. If the deceased is an organ donor, there is the responsibility to inform the family in an appropriate place and give the necessary support during the waiting time until surgery. If the deceased is not an organ donor, the physician must offer adequate information about where and whom they have to enquire regarding the removal of the body until they leave the hospital.

Communication about the time of death and the organ request must be clearly differentiated. The latter phase must be made by transplant coordinators, as they have adequate prior preparation, with counselling courses and specific training in such situations. Also, depending on particular reactions, the family will need a period of reflection which should not be prolonged, sometimes being a supportive response prior to donation.

95.1.4 Ethical and Management Problems of ICU Admission of Patients With Brain Death

New management and ethical issues are described about managing ICU beds. Basic principles of modern bioethics in order of importance regard: autonomy, non-malfeasance, justice and beneficence. These principles are basic, mandatory and distinct.

Autonomy refers to the evaluation of the opinions and choices of individuals, whether competent or not causing clear harm to others. An action is considered independent when it is taken through the process of informed consent. In cases of unconscious or deceased patients, if there is a written will, it must be consulted, and if the deceased made no living will, the physicians have to attend to the wishes expressed in this life by those who lived with him.

Non-malfeasance must be applied by all physicians because contraindicated procedures cannot be performed without a patient's consent. It is based on the principle of *primum non nocere*.

Justice is to give every man according to his own rights or impartiality in the distribution of risks and benefits. It is imposed by the central government.

Beneficence is the act of maximizing potential benefits and minimizing risks.

A patient is guided by the principle of autonomy. The figure of the doctor has two sides, i.e., those who perform their professional practice in public medicine as being responsible for the patient and administrative management representative, who must apply the principles of non-malfeasance, justice and beneficence. In countries where the media is private, the principles will be non-malfeasance, followed by beneficence (because patients pay for their own treatment) and ultimately justice. In the public sphere, where waiting lists have a specific weight, the principle of justice by the central administration is mandatory. These three principles (non-malfeasance, beneficence and autonomy) are related to an individual's good, whereas justice is related to common good. Common good is always more important than individual good, and this is the reason why there is a certain hierarchy between these principles. These principles were put in place by the Belmont Report, based on the terminology devised by David Ross, becoming a fundamental outline of bioethics from the bioethics book by Beauchamp and Childress entitled *Principles of Biomedical Ethics*, published in 1979.

ICU admission criteria were broadened in 1983 in the First Consensus Conference on Critical Care Medicine. The U.S. National Institutes of Health stated they had to extend the indications. In 1999 the ACCCM and SCCM published admission and discharge criteria based on a list of specific diseases or conditions which, by their nature, determine appropriate admissions to ICUs, resolution criteria and ICU discharge. Everything is conveniently issued in the journal Critical Care Medicine-ICU care of patients in brain death, admission of patients who will progress inevitably to brain death, or those which have already been diagnosed for care and maintenance in order to be donors is now a fact, and needs a rationale analysis.

In recent years, a set of criteria has been established for ICU admission. These criteria are organized by order of importance, but more and more organ donors are candidates for ICU admission. One of the main reasons for ICU admission is to manage changes in the internal medium and the preservation of organs, in order to ensure the future of multiple recipients who may benefit from functioning organs.

This raises the ethical question of whether admission of a brain-dead patient to an ICU is an appropriate action. On the one hand, it could be considered a positive aspect for patients who could benefit from organ donation. On the other, it could be considered a futile and unjustifiable form of therapy.

95.1.5 Key Concepts

- The more widely extended criterion is global brain death, which considers brain death as an addition of brainstem death and neocortical death. Global brain death implies not only permanent cessation of all consciousness functions but also cessation of integrated brain functions, as well as cessation of all brainstem functions.
- For the diagnosis of brain death, the patient must meet certain pre-requirements: absence of systemic arterial hypotension, absence of hypothermia, and absence of neuro-depressant drug effects, muscular blockers and anticholinergics, these being circumstances and drugs which can mask signs of brain death.
- Diagnosis must include the demonstration of cessation of all reflex activity of the brainstem: direct and consensual pupillary, oculocephalic, corneal, oculovestibular reflexes, absence of spontaneous or provoked facial or muscle movements, nauseous reflex, cough reflex, response to atropine, and the apnea test. Complementary instrumental tests are also useful: EEG, multimodal evoked potentials, TDS, cerebral angiography, and perfusion studies with isotopes.
- Communication of the end of life to the family requires training and an accurate technique for special care: presentation of the medical staff; progressive giving of information; clear management of information with low emotional content and special attention to non-verbal communication, favouring empathy, expression and identifying the family's immediate needs and to offer help if needed.
- A patient is guided by the autonomy principle, a physician by non-malfeasance and beneficence, and the family and others by the justice principle. Non-malfeasance, beneficence and autonomy are related to the individual good, whereas justice is related to the common good. More and more organ donors are candidates for ICU admission to improve care and organ optimization for transplant to multiple recipients who can benefit from optimised organs. Saving costs is established by the preservation of quality of the donated organs and the long-term benefit to minimize health problems in the post-transplant period.

95.2 Part II. Management of Potential Organ Donation

95.2.1 Introduction

Although there is a growing need for transplantable organs due to longer waiting lists, we found a disparity between the number of potential organ donors and those who actually donate organs. For designed strategies to be effective and successful there must be awareness, acceptance and opportunity to convey the message to the population. Today, we are reaching the limits of donation: donor type profiles are changing as is the profile of the patients admitted to our units, with a shift of the prototype of young healthy trauma patients to elderly patients affected predominantly by vascular disease. Whatever the trend, it is mandatory to recover viable organs and provide the recipients with the highest quality and probability of optimal outcomes. Therefore, after a brain death diagnosis, donation is requested from the patient's family members, the surgical teams are coordinated, and the receiver hospital is alerted. This strategy may take from 4 to 24 hours. Currently, this time period can be shortened with proper management.
Considering the setting, the time element is highly important, given that it is increasingly common to find donors meeting extended criteria as donors. The latter concept is understood as the number of donors whose organs were thought to be associated with an

increased risk of poor graft function or primary failure or transmission of diseases from the donor. Traditionally, these were older donors, fatty livers, positive serology for hepatitis C or B, central nervous system tumours, and postcardiac arrest donors. However, this concept has changed with the increasing experience of transplant groups, leading to improved outcomes even with organs from donors with the characteristics mentioned above.

Similarly, cold ischemia time should be as tight as possible to ensure good graft function after transplantation. It has been shown that preservation at a temperature between 0 and 4°C results in less cell damage and that the use of special solutions, according to the organ preserved (Euro-Collins, Belzer and the University of Wisconsin), can prolong preservation time, for example: 2 days for the liver, 3 days for the kidneys and pancreas, and 12 hours for the heart. As far as possible, we seek to limit the maximum time for these procedures as the success of graft viability is inversely proportional to the time of preservation.

Also very important is knowing the pathophysiology of the events that occur gradually, as well as the management of hemodynamics, renal function, arrhythmias, protective ventilation, and maintenance of temperature, electrolyte and endocrine balance. Also essential is having a written protocol for managing these patients for the successful preservation of transplantable organs.

95.2.2 Pathophysiology of Brain Death

Death is an irreversible process that can be slowed down by the administration of substances that the body fails to produce. In brain death, after the loss of brain function, including the brainstem and medulla oblongata, there is a massive release of catecholamines which produces extreme tachycardia and hypertension; the duration is variable although limited. This period is critical because it can generate deleterious arrhythmias, destabilizing a previously stable heart disease; at the same time it can precipitate left ventricular failure and acute pulmonary edema or myocardial ischemia by increasing blood pressure.

Once the above phenomena have been mitigated or passed, we can see sudden hypotension that can manifest itself in a multifactorial form. Shock is a consequence of the loss of neurogenic activity, inducing the release of the adrenergic reserve. The loss of fluid by diuresis secondary to the release by the hypothalamic-pituitary axis, hypovolemia due to the traumatic process itself or the use of diuretics, can influence the intensity of the hypotensive response. Another factor that can contribute to arterial hypotension is heart failure (cardiogenic shock) from the action of the adrenergic wave generated at this time.

Tachyarrhythmias and bradyarrhythmias arise in the context of ventricular dysfunction in up to 30% of cases of brain death. Approximately 18% of the patients are young and without previous cardiac abnormalities. These abnormalities are secondary to hemodynamic and neurohormonal disorders that occur during brain lock, i.e., neurogenic myocardial stunning or ischemia. Other causes include hypothermia or electrolyte disturbances (hypocalcemia, hypokalemia, acidosis). Not all clinical pictures are reversible (myocardial stunning), but a great majority are, so this is the basis for waiting several hours until the organs can be extracted, otherwise testing the myocardial reserve with dopamine and troponin I determination are recommended.

Central or pulmonary hypoxemia is frequent after brain death. We must actively protect the lungs, adopting strategies similar to those proposed by the American and European Thoracic and Intensive Care Societies, as defined in the Consensus Statement of 1994.

The proposal is to initiate lung-protective ventilation without generating excessive volumes or pressures harmful for the body. On the other hand, decreased metabolism after brain death produces a drop in CO_2 generation and levels. This facilitates ventilation with lower tidal volumes than in subjects of equal body weight. We must avoid generating atelectasis and prevent infections developing from the accumulation of secretions. Also, we will avoid excessive fluid intake or maintaining high blood pressure with exogenous amines because they can potentially trigger acute pulmonary edema and loss of organs.
The lack of neuroendocrine control is expressed especially in water and electrolyte balance; for example, diabetes insipidus secondary to hypothalamic or neurohypophyseal dysfunction (supraoptic and paraventricular nuclei). Diuretic losses can reach 3-4 cc/kg/h, exceptionally 6 cc/kg/h, so we have to constantly monitor volemia status in addition to replacing lost fluids in order to avoid hypovolemia. Another aspect that we will consider is the loss of hypothalamic regulation of the thyroid and adrenal axis and its direct impact on carbohydrate metabolism. This tends to be altered mainly for two reasons: 1) indiscriminate administration of hypotonic fluids (dextrose 5%) to reduce hyperosmolality due to the lack of ADH and 2) utilization of strict blood glucose control regimens that, as recently published, put some organs at risk. Hormones such as triiodothyronine produced in the anterior hypothalamic area also help to maintain hemodynamic stability.
The destruction of the nuclei in the preoptic area of the anterior hypothalamus alters temperature regulation, increasing hypothermia in most cases. Temperatures <35°C are correctable and temperatures <34°C generate ECG abnormalities such as QRS widening, QT lengthening and Osborn J waves, all of which are frequent events. Although brain death does not produce hypothermia or hyperthermia, some authors postulate that if hyperthermia is present, one explanation might be an underlying infection, but the body temperature can increase when pituitary hormone levels do not decrease, even when the absence of cerebral blood flow by arteriography is established.
Problems in homeostasis and coagulopathy secondary to the release of fibrinolytic agents can originate in the last phase. This may be accompanied by anemia due to hemorrhage or hemodilution. We must not allow hematocrit levels to fall <30%.

95.2.3 Monitoring the Organ Donor Patient

We previously mentioned the serious pathophysiological changes that occur in the process of brain death. In order to monitor its progression, we will monitor the donor. There are minimum requirements that must be met to ensure the success of the process.
Hemodynamic monitoring should include: continuous ECG (arrhythmia monitoring) with a central venous catheter will allow us to determine central venous pressure (blood volume control); the catheter also should allow fluid infusion. Blood pressure can be determined invasively with an arterial catheter, especially when the patient requires vasoactive drugs. Another recommendation is to determine hourly diuresis (Figure 95.1).
Complex monitoring with Swan-Ganz catheters (currently not used) or pulse-induced contour cardiac output (PiCCO) (widely used) affords advantages if they have been inserted beforehand or if you want to optimize the management of these donors in cases of severe or mixed hemodynamic instability (Figure 95.2).
Continuous temperature measurement with external systems is sufficient, although internal probes can be used to measure core temperature.
Another control is to closely monitor lung function: pulse oximetry ensures continuous oxygenation in these circumstances. PET CO_2 is no longer necessary as brain protective ventilation has been stopped.

It is also important to monitor laboratory parameters such as glucose, lactate, and blood count values that not only detect blood loss but also hemodilution and coagulopathy. Also important is the determination of blood group, isogroups and Rh factor because blood may occasionally be needed. Determining electrolytes in blood and urine and blood gases is essential for monitoring the internal environment and preventing acid-base deficiencies or excesses that may impair graft viability. Specific parameters in re-

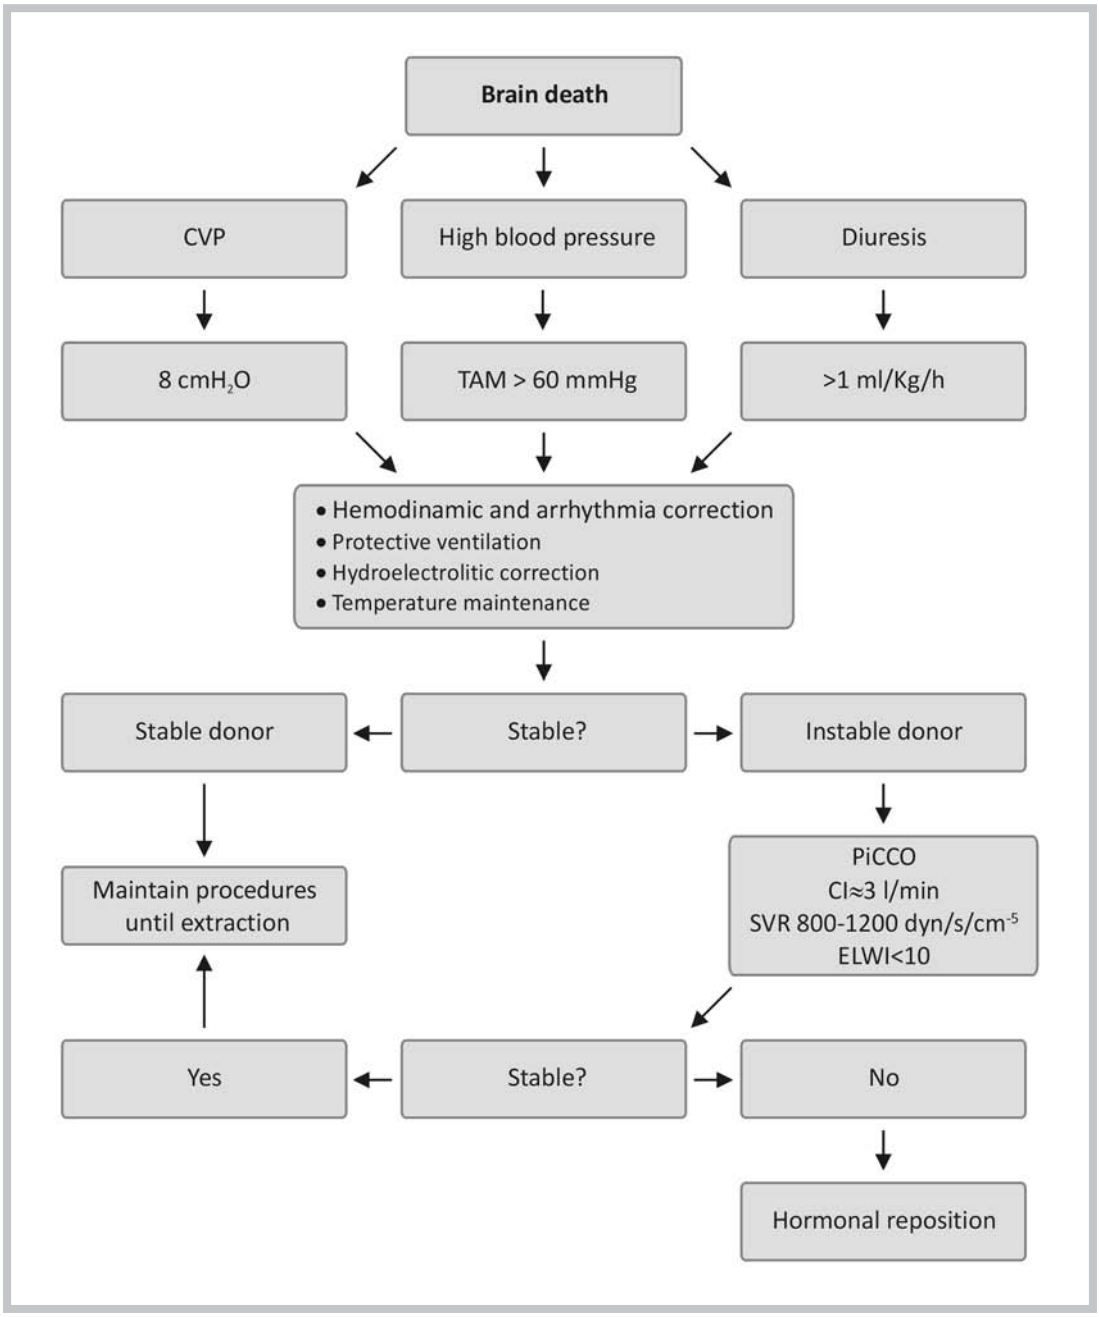

Figure 95.1. **General approach for the management of organ donor.**

lation to different organs are expressed in profiles: liver, kidney, with the calculation of creatinine clearance, the pancreatic profile and the cardiac profile.
When changes are happening quickly, serial determinations by decentralized basic acute care services are key to achieve donor stabilization before transfer to the operating room.

95.2.4 Management of Organ Systems

Hemodynamic Control

This is certainly the most important element to ensure good viability of organs for transplantation. Hemodynamic disorders subsequent to brain death are related to neurogenic shock that determines the loss of vascular resistance and causes relative hypovolemia, but also it can also be the result of polyuria due to diabetes insipidus.
Finally, the administration of hypertonic solutions (mannitol or hypertonic saline) for the treatment of intracranial hypertension can induce excessive diuresis. This situation triggers hypernatremic dehydration in most cases, unless the physician is aware of the changes occurring in the donor.

	Drug/substance	Half-life	Bolus	Perfusion
Hemodinamics	Esmolol	8 minutes	250 µg/kg in 1 min.	25-50 µg/kg/min
	Labetalol	4 hours	50 mg in 2 min	1-2 mg/min
	Urapidil	4.7 hours	25-50 mg in 20 sec	2 mg/min
	Vasopresin	19-20 minutes	1U	0.01-0.03 U/min
Antiarrhythmics	Dopamine	2 minutes	-	5-10 µg/kg/min
	Adrenaline	2 minutes	-	0.1-1 µg/kg/min
	Isoproterenol	5 minutes	-	2-10 µg/kg/min
Hormones	Desmopressin		-	0.03-0.15 µg/kg
	Triiodothyronine (T3)		4 µg	3 µg/h
	Tyrosine (T4)		20 µg	10 µg/h
	Methylprednisolone		15 mg/kg/day	

Table 95.1. **Dosage and half-life of drugs and hormones in the management of donor organs.**

Not recommended is the treatment of the Cushing effect that precedes the final hypotensive phase since it is difficult to handle and because there is little or no pharmacological response. The ultrashort agent beta-blocker esmolol decreases the hypertensive and arrhythmogenic response. It is preferred when associated with tachyarrhythmias. Labetalol (alpha and beta-blocker) has a longer half-life and poor implementation. Another option s is hypotensive agents in patients with brain pathology, for example, alpha-blockers with controlled duration (e.g., urapidil) since they don't affect cardiac rhythm or mask the bradycardia secondary to uncal herniation (Table 95.1). Despite the usually very transient crisis, drug administration may compromise hemodynamic stability, so further hypotension is the rule.

For the hypotensive phase, fluid administration is the first choice, guided by patient monitoring. Provide all necessary actions to maintain central venous pressure between 10 and 12 cmH_2O. In most cases vasoactive amines will be needed. The type of fluids to infuse should be related to the patient's osmolar state.

In cases of hypernatremia, we must administer hypotonic solutions such as dextrose (dextrose 5%) or hyposaline (0.45%) to adjust serum sodium. In the remaining cases, we use isotonic saline (0.9%) or Ringer's lactate, adding as a regular basis colloids in a proportion of 1:3.

It is not uncommon in blood pressure management to administer amines, including norepinephrine (preferable) or dopamine up to 10-12 μg/kg/min. We adhere to these dose schedules to avoid causing tissue damage especially in the heart. In chest trauma with proven cardiac contusion, inotropes such as dobutamine up to 15 μg/kg/min as the maximum dose may be necessary, while taking care not to cause excessive vasodilation, which reduces diuresis. It may be necessary at times to use a combination of vasoactive drugs to prevent the deleterious effects of hypotension especially in the elderly, where the kidney is perfused at high pressure, to ensure that urine flow is maintained >100 ml/h. Adrenaline 0.1 μg/kg/min may be a viable alternative to excessive norepinephrine requirements in addition to improving hepatic blood flow. The administration of corticosteroids, thyroid hormones or vasopressin, which now is increasingly in disuse, can achieve hemodynamic stabilization in some cases (Table 95.1).

Vasopressin at a vasopressor dose (1-2 IU/h) in conjunction with other amines increases resistance in a similar way as used in acute spinal cord injury.

Before transferring the patient to the operating room for organ removal, the surgical team should be informed of amine requirements.

Control of Arrhythmias

The brain-dead organ donor is very susceptible to develop brady- or tachyarrhythmias, atrial or ventricular in origin, as well as different degrees of heart conduction blocks.

Bradyarrhythmias are generally self-limiting, reversible, and do not require treatment; however, if you do need a pharmacological agent, the choice is dopamine at beta-dose; and if no response is obtained, epinephrine or isoproterenol may be tried. Rarely, the need for temporary pacemaker implant may be considered (Table 95.1).

For **tachyarrhythmias** and other conduction abnormalities, after ruling out etiological causes of cardiac or extracardiac origin, amiodarone should be considered the treatment of choice. Up to 10% of donors may have cardiac arrest in which cardiopulmonary resuscitation (CPR) can be performed according to international standards, except for the use of atropine due to central denervation of the heart muscle since brain death prevents the heart from responding to this drug. If CPR is unsuccessful and the donor remains in cardiac arrest, he or she can be transferred immediately to the operating room under breathing bag-assisted breathing and chest compressions for the removal of or-

gans suitable for donation; in hospitals with implemented protocols heart-beating donation should be applied immediately.

Respiratory Control

In the brain-dead patient, hypoxemia of any origin should be avoided and the lungs must be protected by so-called "protective ventilation", especially if the patient is younger than 50 years of age, with no history of smoking or bronchopulmonary diseases that exclude the likelihood of organ donation. The hyperoxia test to check gas exchange values will be made by ventilation with oxygen at 100% and PEEP of 5 cmH_2O for 5 minutes reaching a PaO_2 >300 mmHg. If this test confirms good gas exchange, mechanical ventilation will be <3 days, and we can confirm the possibility by measuring chest circumference and chest radiology without infiltrates: all such parameters can help to predict a successful lung transplant and exitus care in preserving the lungs.

PEEP (cmH_2O)	FiO_2 (%)
5-10	60
10-15	80
15-20	100

Table 95.2. PEEP and FiO_2 values.

Protective ventilation entails limiting tidal volumes, so that the machine is set to 6 ml/kg with FiO_2 necessary to maintain pulse oximetry ≥95%, generally 50% or lower to decrease the possibility of oxygen toxicity. This objective will be sufficient to maintain optimal function. The PEEP is set at 5 cmH_2O and peak inspiratory pressures are kept ≤30 cmH_2O.

Since metabolic needs decrease in the donor brain-dead patient, CO_2 should be not a problem. It is not uncommon that donors are hyperventilated, so serial blood samples should be taken every 4 hours during the time of preservation.

In atelectasis, the recommendations of the Acute Respiratory Distress Syndrome (ARDS) Network Working Group should be followed, handling PEEP according to the inspiratory fraction of oxygen (Table 95.2).

These values should not be exceeded; if peak pressures are >45 cmH_2O during recruitment, controlled pressure ventilation will be necessary.

The excessive positive fluid balance will be controlled with diuretics; this is not usually frequent unless treated with donors with suboptimal pathology control or without organic reserve. In young people there is often a loss of water due to endocrine disruption. Such patients should be managed with PiCCO for volume management.

Decreased tidal volume can also produce atelectasis. This occurs due to a loss of volume of the alveoli and subsequent collapse. Re-expansion with the standard apnea test can provoke atelectrauma. This forces us to introduce PEEP regularly. If the lungs prove sensitive, we can apply the variant T-tube and PEEP valve or, if the patient is on an adapted ventilator, spontaneous breathing modes such as continuous positive airway pressure (CPAP) to the lung can be induced. Aspirations of secretions should be done carefully with an aseptic technique without depressurizing the system in closed suction systems.

In patients who had suffered significant bronchoreactivity, high doses of steroids or beta adrenergic drugs can be given to solve the problems of mast cell degranulation and precipitation of the crisis. However, the use of steroids and adenine-vasopressin agents implies restricting the volume of fluid to infuse.

The administration of prophylactic antibiotics is mandatory, especially in donors eligible for lung transplant or who remain >48 hours in the ICU. Cultures at an early stage should be obtained, and broad-spectrum antibiotics administered such as amoxicillin-clavulanate, cephalosporins, quinolones, or those that have been formalized in the ICU in relation to the prevalent flora.

Endocrine Control

A wide range of changes in hormonal pathways occur after brain death. The brain is a great central controller, principally localized in the hypothalamus.

Diabetes Insipidus

Vascular ischemia secondary to circulatory arrest in the context of cerebral herniation and intracranial hypertension results in the destruction of the hypothalamus and the axis that regulates the secretion of ADH released from the neurohypophysis. Biphasic and triphasic patterns that may occur in surgical patients or in patients with Sheehan syndromes are not often encountered, where within about 6 hours all hormone traces disappear, although the presence of the symptoms can be manifest with ADH levels of 10-90% of the normal range. The result is hypotonic polyuria with a urine output of 4 ml/kg/h, urine density <1005, hyponatremia, plasma hyperosmolality, usually >300 mOsm/kg and urinary osmolality <300 mOsm/kg. This water loss not only carries away sodium but also provokes the loss of potassium, magnesium, phosphorus and calcium. All these alterations must be corrected.

If urine output is >5-7 ml/kg/h and electrolyte control is difficult to achieve, treatment with vasopressin analogues is necessary. This can be given as vasopressin or desmopressin, the latter is now the treatment of choice because of its excellent action and almost no pressor action. Desmopressin has an antidiuretic action 2000 times more potent than vasopressin and its action is 3 to 5 times longer. The administration can be intranasal, intramuscular or intravenous. Vasopressin is only indicated in the presence of severe hypotension resistant to treatment with fluids or amines. The desmopressin dose varies between 0.03 to 0.15 µg/kg titrated to maintain urine output between 2 and 3 ml/kg. Usually, the pharmaceutical presentation is 1-ml vials containing 4 µg of desmopressin. Nasal instillation drops are used in the treatment of chronic deficits.

The undesirable effect is mainly water intoxication. Hours after desmopressin administration there is a dramatic reduction in diuresis which can result in severe dilutional hyponatremia with hemodynamic overload, leading to heart failure. If vasopressin is used, vasoconstriction is a potentially dangerous side effect because it can trigger severe bronchospasm and ischemia of various territories including the myocardium, splanchnic and renal peripheral areas among others.

Glucose Metabolism

The adrenergic and metabolic crisis that ensues after brain death leads to moderate hyperglycemia which can sometimes become severe due to other reasons such as: administration of catecholamines to maintain blood pressure, administration of glucose to maintain normal osmolarity or decrease serum sodium, hypothermia; the use of steroids is another factor involved. Some studies have failed to demonstrate a lack of insulin production in potential donors: the levels may be low, normal or increased.

The major pathophysiological consequences of hyperglycemia are metabolic acidosis, ketosis, hyperosmolarity (of the extracellular environment that leads to intracellular dehydration) and electrolyte changes. Furthermore, hyperglycemia causes osmotic diuresis with polyuria and urinary loss of water and electrolytes contributing to hypovolemia and therefore hemodynamic instability. We must initiate rapid intravenous insulin treatment by continuous infusion to maintain blood glucose between 150 and 200 mg/dl. Some studies have reported a negative action on pancreatic beta cells, so they should be closely monitored in pancreas donors.

The treatment with short-action insulin is indicated and, if necessary, will be maintained with continuous infusion for better control. The control in cases of instability must be done frequently, and if pumps are used to maintain dosing schedules the recommended target is between 80 and 150 mg/dl. Infusion will be administered according to the

protocols in place in the ICU; glucose levels >200 mg/dl should be maintained with 2 to 7 units of insulin per hour.

Alterations of the Hypothalamic-Pituitary-Adrenal and Thyroid Systems

It has been observed in studies by Novitzky, Schrader and Jeevanandam that levels of triiodothyronine (T3), tyrosine (T4) and cortisol are reduced after brain death. Although the levels of thyroid stimulating hormone (TSH), prolactin, growth hormone and luteotrophic (LSH) do not vary over baseline, the decrease in peripheral hormonal levels at 6 hours after brain death triggers a chain of events: high-energy phosphate depletion, increased lactate and free fatty acids that signal the change from aerobic to anaerobic metabolism, and mitochondrial failure. However, some studies showed that after the administration of TRH, TSH increases slightly, suggesting a preserved partial flow after the cessation of cerebral blood flow. All these phenomena result in organ deterioration (e.g., heart and kidneys).

Some authors have reported that the decrease in thyroid hormones detected after brain death is accompanied by a fall in cortisol and insulin levels which can occur in other pathological conditions such as head trauma, severe sepsis, burns, and the so-called sick euthyroid syndrome. This syndrome is characterized by lower T3, accompanied by high levels of rT3; tyrosine (T4) may be normal, high or low, showing a defect in the conversion of T4 to T3 in the periphery, while maintaining normal levels of TSH, so the hormonal profile is configured as a criterion to establish euthyroidism.

It is important to note that alterations in heart rate, bradyarrhythmias resistant to medication or hypotension refractory to inotropes can be treated with thyroid hormone or corticosteroid replacement. Replacement therapy can be initiated as follows: intravenous bolus of 4 μg of T3, continued with an infusion of 3 μg/h. The alternative is T4 which requires a bolus 5 times larger and then continuous infusion of 10 μg/h in conjunction with steroids: bolus of 15 mg/kg methylprednisolone which can be repeated daily while maintaining hydrocortisone, which has a very short duration: 2 hours of efficient action after a dose of 100 mg of the drug, so the administration must be repeated (Table 95.1).

Electrolyte Control

One of the changes immediately after brain death is secondary endocrine failure. Alterations derived from the loss of regulation of the hypothalamic-pituitary axis must be monitored closely. Such alterations usually occur almost immediately. The loss of free water in the urine carries an increased loss of potassium which, unless properly replaced, can generate severe and life-threatening disturbances with critical implications principally for the heart and the potential loss of the donor. To avoid this complication, serial determinations are performed. If the potassium concentrations fall below critical values, replace immediately with the necessary amount of milliequivalents.

It is not unusual at times and in relation to hormonal correction to find hyperkalemia which also may occur secondary to cytolysis due to long-term maintenance or renal failure and metabolic acidosis. In such cases, the levels may rise quickly and unexpectedly. Hemolytic states, occasionally subsequent to blood transfusion, can increase potassium levels and require urgent treatment. Other causes of hypokalemia include: administration of glucose and insulin to facilitate potassium entry into the cell, 1 mol sodium bicarbonate infusion, beta-stimulants, calcium gluconate and loop diuretics such as furosemide.

Serum sodium disorders are very common: hypernatremia is especially frequent usually multifactorial in origin.

It's very common to find hypernatremia prior to brain-death diagnosis, principally due to the treatment of intracranial hypertension with sodiumHypertonic solutions. In cas-

es it is a result of diabetes insipidus with concomitant contraction of blood volume. This alteration is especially harmful for liver function and may compromise subsequent graft take. The treatment is with hypotonic infusions such as dextrose or hyposaline solutions. Hyponatremia is less frequent but can ensue from inadequate intake, inappropriate correction of hormonal disorders, gastrointestinal losses or kidney failure. Treatment is based on fluid restriction and isotonic saline administration with serial laboratory monitoring.
Less frequent are alterations in magnesium, which often occur with refractory hypokalemia, both preventable with the administration of magnesium in conjunction with phosphate to preserve cell membrane integrity.

Temperature Control

The progressive destruction of the hypothalamus leads to a loss of body temperature in relationship to the external environment, with the patient becoming a poikilotherm donor. We must therefore prevent the dispersion of heat by mean of heating systems and fluid replacement. Hypothermia can generate hemodynamic instability, cardiac arrhythmias, renal and coagulation alterations and deviation of the dissociation curve of hemoglobin to the left.
Infused solutions, as well as ventilation gases, should be heated with humidifiers and inspired gas heaters, thermal electric blankets, all directed to maintain a core temperature of 35°C.
Hyperpyrexia should be avoided; in patients who had infections we must ensure negative cultures, negative screening for emboligenic foci from the heart and other locations, and adequate antibiotic treatment before authorizing organ donation.

Hematological Control

The origin of hematological disturbances is multifactorial: it may be due to severe blood loss in multiple trauma, previous transfusions with citrated blood, hypothermia and the continued release of large amounts of tissue fibrinolytic factors, as well as severe skull base trauma, multiple fractures internal organ (liver) injuries, major pelvic fractures or severe leg damage. Furthermore, ischemic-necrotic tissues can release great amounts of thromboplastin. There may also be non-specific abnormalities due to disseminated intravascular coagulopathy. Treatment is based on the administration of plasma and platelets and packed red cells if the hematocrit is <30% for kidney donors or 35% for multiorgan donors.

Renal Function

It is necessary to maintain an hourly urine output of 1 ml/kg in adult patients and 2 ml/kg in children. Polyuria, (urine output >3-4 ml/kg) can perpetuate a situation of hypovolemia due to diabetes insipidus or hyperglycemia.
If the donor is oliguric, with urine output <0.5 ml/kg/h despite maintaining adequate blood pressure and appropriate central venous pressure, administration of diuretics will be necessary. The most frequently used include furosemide at doses of 20-60 mg and intravenous mannitol at doses of 0.25-0.50 g/kg.

Specific Corneal Care

Exclusion criteria for cornea donation are the same as general criteria. We should specifically take care of the donor's eyes, trying to keep them moist and properly occluded. Periodically, lubricants, artificial tear solutions, antibiotic drops of tobramycin or gentamicin should be administrated. Occasionally, corneal epithelial alterations should be minimized with the administration of local cold.

95.2.5 Tests and Special Care for Organ Donation. Diagnostic Determinations in Intensive Care

General diagnostic tests are performed to monitor potential donors; however, to evaluate different viscera we must follow a series of requirements as described below. A general test is the determination of blood count and blood group with Rh factor and investigation of isogroups, which have been obtained by previous requirements. In addition, immunological compatibility between donor and recipient is necessary for heart, liver and lung transplants, as is determining serology. Determination of the type (typing) by extracting lymph nodes is not usually done in the ICU, but is now performed in the operating room.

Monitoring and Special Tests for Lung Donation

Previous care is essential to avoiding volutrauma and barotrauma in mechanically ventilated patients. Indispensable is serial monitoring of blood gases. Assessment will include previous infections, history of smoking, drugs, chemotherapy or radiotherapy, and evaluation of previous occupational risks.

Determination of specific laboratory profiles and arterial blood gases, pH, partial pressure of O_2, CO_2, and serum bicarbonate must be monitored every 4 hours. Before a patient can be considered as a potential lung donor, it is imperative to measure PaO_2 >300 mmHg after the administration of 100% oxygen for 15 minutes with a PEEP of 5 cmH_2O.

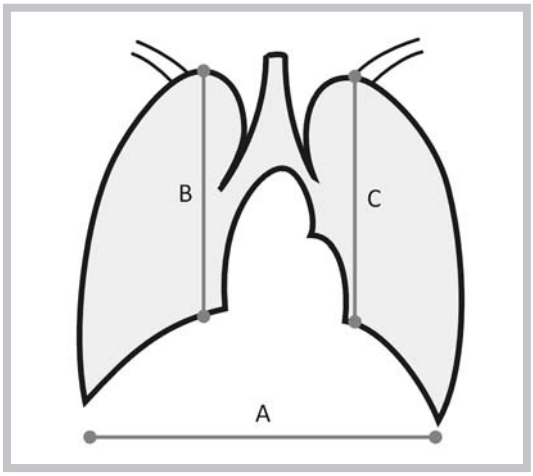

Figure 95.3. **Measures to determine the suitability between donor and recipient: dome-lung apex axis (B and C) and the largest thoracic diameter measured between both costophrenic sinuses (A).**

Chest radiography is important for lung assessment. Check for the presence of pneumonia, neurogenic or cardiogenic pulmonary edema, pneumothorax or hemothorax, which are highly prevalent in patients with severe head injuries under mechanical ventilation. Anthropometric assessment will include measurement of body weight, height, waist circumference and chest circumference. Lung transplantation also requires measurement of the diaphragmatic dome-lung apex axis (B and C) and the largest thoracic diameter measured between both costophrenic sinuses (A) (Figure 95.3).

Monitoring and Special Tests for Heart Donation

It is essential to anticipate an adrenergic storm, which is not dangerous for the heart and will not provoke heart failure. Just as in the lung donor, we must search for salient events in the medical history and risk factors. An ECG is essential.

Determination of specific cardiac laboratory profiles: levels of CPK, CK-MB, troponin to assess possible heart damage, especially in cases of chest trauma, cardiac arrest and cardiac massage.

ECG is mandatory and as is coronary angiography in patients over 45 years of age, so we can assist the donor as quickly as possible.

Monitoring and Special Tests for Liver Donation

Complete and detailed medical history and determination of risk factors for liver disease.

Determination of the hepatic profile: levels of GOT, GPT, GGT, total and direct bilirubin, glucose, electrolytes and clotting times, prothrombin time, partial thromboplastin time and INR. Alterations in these enzymes may indicate chronic liver disease, hepatic necrosis secondary to tissue hypoperfusion due to complications arising from maintenance of hemodynamic status. Also important is the search for tumour markers such as alpha-fetoprotein associated with hepatocellular carcinomas and germ cell tumours.

Abdominal ultrasound.

Monitoring and Special Tests for Kidney Donation

Detailed clinical history and risk behaviours.

Renal profile by laboratory determinations should include: complete urinalysis, proteinuria, blood urea and creatinine.

Also indispensable is determination of chorionic gonadotropin (HCG) to search for choriocarcinoma, germ cell tumours (ovary and testicles), and tumours with ectopic secretion of HGH such as urinary bladder. Prostate specific antigen (PSA) as a marker of prostate cancer, has significance when the values are >10 mg/l.

Ultrasound assessment of the kidneys and excretory pathways.

Monitoring and Special Tests for Pancreatic Activity

Clinical history and risk behaviours are a common step to other organs, focusing on smoking habits, history of gallstones, and alcohol consumption.

The specific pancreatic profile for the laboratory includes: blood glucose and serum amylase and lipase, especially for assessing the viability of the pancreas for transplantation. Lipase levels are not usually affected by brain death, but blood glucose and amylase >10 mg/l are.

Ultrasonography of the pancreatic area; computed tomography (CT) is mandatory if there are any abnormalities in the parenchyma or their excretory pathways.

Key Concepts

- It is important to know the pathophysiological changes that occur in the body once the brain has lost control. Taking these changes into account helps us to determine its specific value and facilitate the treatment of deviations in homeostasis. However, there are many aspects that are yet to be determined and clarified in observational studies.
- We perform a minimum of diagnostic tests and monitoring of variables; the complexity to reach stabilization can be as intense as the maintenance of a living patient.
- The management of control systems of the donor requires not only hemodynamic management with fluids or amines, but also cardiac control after adrenergic discharge. Beta blocking drugs are generally not necessary.
- Implement lung protective ventilation with low lung volumes and PEEP.
- Endocrine and electrolyte disturbances are one of the fundamental problems: hypernatremia, hyperosmolarity and potassium imbalances. Thyroid hormone levels often behave as in sick euthyroid patients. Diabetes insipidus and hypocortisolism can be effectively treated with hormone replacement: vasopressin, desmopressin, T3 or T4, hydrocortisone or methylprednisolone.
- Hypothermia is common, although occasional hyperthermia is present, which is difficult to explain but almost always associated with infection prior to brain death.

- It's very important to preserve hourly diuresis in adults at 2 ml/kg/h and 1 ml/kg/h in children.
- The brain-dead patient may develop blood disorders of varying severity.
- It is always possible to donate corneas.
- We will know the tests to be performed to assess different organs because they sometimes require specific examination when unstable donors are transferred out of the ICU.

96 Reporting Neurocritical Patient's Status to the Family

Eduardo Marcos [1], Gustavo De Salvo [2], Gustavo Piñero [3]

[2] Deputy Head of Service, Therapy for Acute Hospital Municipal "Dr. Leonidas Lucero", Universidad Nacional del Sur, Bahia Blanca, Argentina
[3] Neurointensivist Coordinator, Therapy for Acute Hospital Municipal "Dr. Leonidas Lucero", Universidad Nacional del Sur, Bahia Blanca, Argentina

96.1 Introduction

Neurocritical illness, a group of life-threatening diseases of the brain and spinal cord, is associated with poor prognosis or slow recovery, disability or chronic medical complications. The most common include: cerebral hemorrhage, ischemic stroke, head injury, seizures, and infections such as meningitis. Mortality from these diseases has declined in parallel with the intensity of care received, whereas morbidity has risen with the growing number of patients surviving with sequelae, deterioration in quality of life, and mounting social and health costs in the treatment of neurocritical injury and its aftermath.

Communicating information about diagnosis, treatment or prognosis carries a significant emotional burden for both the team attending the patient and their families. Often this communication is imparted in public places (hall information) or at inappropriate times (request for informed consent), augmenting anxiety, uncertainty, and sometimes distrust toward the treating team. Clearly conveying information about the patient's progress and demonstrating a willingness to answer questions can help to reassure the families and establish confidence.

The intensive care unit (ICU) team must be trained to inform family members about the patient's condition and to allow time them time to accept this "news."

In the doctor-patient relationship, "giving bad news" refers to situations where a feeling of hopelessness predominates, along with a sense of threat to the person's physical and mental well being, a risk to their lifestyle or where the message involves making important personal decisions. Bad news can sometimes be associated with a less "severe" diagnosis such as a temporary disability, the administration of traumatic or painful treatment, or even something that for the attending staff seems banal but comes at an inopportune time, for example, surgery a week before a daughter's wedding or informing a professional athlete fully recovered from a head injury that he or she may perhaps never be able to compete again, and so on.

In such situations, the family plays a central role as the majority of neurocritically ill patients are at different stages of neurological impairment or coma and are unable to understand any information. Subsequently, family members will be called to intervene in the decision-making process because they are usually the ones who best know the patient's preferences and desires. However, these are the same families who are anguished by the threat of imminent death of their loved one. So what we must keep in mind is that, because the family is at an emotional loss, they will barely understand the unpredictability of the course of the illness or treatment outcome.

One of the main ways to reduce the risk of medical litigation is through constant communication among the treating team members, openness to dialogue, and providing accurate information across the entire therapeutic process.
About half of the families of patients in intensive care experience difficulties in communicating with their doctors. This shortcoming can be resolved by answering three questions:

- Which are the common mistakes?
- What do you expect from the family behind the door?
- How should bad news be communicated in the ICU?

96.2 Which Are the Common Mistakes?

The family is relegated to a minor role that is usually overlooked in medical reasoning. After we define the diagnosis, after planning a strategy, often (only much later) someone on the team asks: "And how much does the family know...?" Meanwhile, the family has been suffering from the uncertainty of having their loved one in an ICU. This uncertainty always generates worry and fear, especially when the patient is young and unexpectedly ill. Added to this is the changing and unforeseeable course of intensive care patients. This gives rise to legitimate concerns, "But if he/she walked into the hospital... How can he/she be so serious now?" or "The doctor told me that yesterday he/she was better... How can it worsen so suddenly?"
The ICU is bewilderingly complex: differences in care protocols, routines, attitudes and conduct, diverse visiting hours and staff change from shift to shift. These changes are often seen by the family out in the waiting room as an inconsistency that arouses the suspicion that such inconsistencies can reoccur in other even more important areas of care, for example, the use of analgesics or antibiotics.
In this context it is important to ensure that communication is smooth, consistent and honest with the closest family members. This is achieved by speaking clearly, without jargon. For example, instead of saying "oliguric", you can say "urinating little"; instead of saying "has a pump failure", you can say "his heart is weak". It takes training to handle this basic language with ease in front of family members.
Also, another group of people (friends, doctors, etc.) may also request information.
Many families have one or two spontaneous leaders who are important to identify because their status (age, educational level, profession) can exert a decisive influence on the family. Part of the success of the interview relies on how we communicate with such heads of the family. To keep the information consistent and uniform, the same doctor who writes the report should speak with the family. This information should be imparted calmly, ensuring there is privacy to talk and listen in comfort. There should be no excuses or exceptions for delaying information. Waiting rooms are filled with tension and anxiety grows the longer the delay in receiving news. On the caregiver's side, being punctual expresses respect and consideration for the family. The report will necessarily include the family's needs and the complexity of the patient's situation.
When we refer to the diagnosis, we should express ourselves with honesty and common sense, supported by our knowledge to predict the outcome in critically ill patients. It is appropriate to set short-term goals ("We want to improve your ability to breathe... And then find the cause of respiratory distress."). Once we have defined the plan, it is good practice to make it known and also report alternative plans: this alleviates anxiety and builds confidence within the team. The diagnosis should be adequately detailed and supported by additional studies, which can often be useful to illustrate the structural damage the patient has sustained and present it in a way the family can understand.

All team members must be trained to report consistently, even after hours if necessary, on all changes that occur, including interventions such as intubation, chest tube placement, tracheostomy, and they should be reported to the family prior to the procedure. Omissions in this respect are a source of conflict or loss of confidence.
Nursing staff should be involved in the reports since nurses can help to answer specific questions and collect complaints or opinions from family members. The report must include daily nursing notes to complement the medical report. This allows for documenting information on certain topics such as sleep quality, care of pressure sores, food and mood in a more thorough and timely manner. Nursing notes will support the reports with personal information and impressions gathered in the waiting room.

96.3 What Does the Family Outside the ICU Door Expect?

- Expect respect for personal values, beliefs, preferences and needs. Most family members feel anonymous; making the effort to call them by name has a high value.
- Expect integrated and qualified care which we must ensure is happening. One way is to answer all questions clearly and without hesitation.
- Expect accurate information; if the news is not good it should at least be truthful.
- Expect emotional support given by a health professional who treats them as such; this means that the professional will provide status reports of the patient but also listen to their fears, respect their beliefs, and use words as a therapeutic gesture in the full context of care.

96.4 How Can I Give Bad News?

At the initial interview with the family, the members are anxious and tense. As mentioned above, "bad news" has at least one target component (depending on the severity of the bad news) and a subjective component that depends upon several other factors such as the time when information is given, the psychosocial context, the age of the patient, family and personal obligations, previous experience of illness, values and beliefs, and so on.
The current literature supports the idea that families prefer care professionals who speak with a normal voice – not aggressive or dismissive or superior – and allow the family to ask questions and express their feelings through sincere dialogue.
Studies have shown that learning communication skills can have a positive impact on both the giver and the receiver of bad news. To facilitate this task, a six-step protocol described by Baile and Buckman is given below. Although intended for patients and families of cancer patients, it is highly useful and can be adapted to the management of information from relatives of intensive care patients.

96.5 Steps of Management

96.5.1 Step 1: Preparing the Report

Assemble a detailed review of medical records and confirm the diagnosis, either presumptive or definitive. Establish a mindset of what you want to report, and that it will

be done in a private place without interruptions. Start the interview with a greeting and introductions of the family group, and then invite them to sit down.

96.5.2 Step 2: Discovering What the Family Members Know

Most often the patient will be absent from the report due to illness or coma or under sedation-analgesia and mechanical ventilation. It may be helpful to ask family members: "What do you know already about what is going on?" This question will tell us how much the family group knows about the processes involving the patient; however, the stress of the situation or degree of disruption often does not allow family members to express themselves properly. Seize this stage to assess the cultural level of the family and the emotional weight bearing on the illness event. Depending on their educational level, families may have distorted ideas or confusing opinions. Knowing this in advance will help us to reinforce points in the report that are inaccurate or misleading.

96.5.3 Step 3: Recognizing How Much You Want to Know

The objective at this stage is to match the information you give to what you want to know. Questions like "Do you want me to tell you how the operation will be", "Is there someone you would like me to tell related to what's going on?" This can only be done if the patient is awake and able to process the information that we provide.
In reporting to the family we must take into account that:

- Many families mount a defence mechanism to minimize painful truth or request that you repeat certain topics in the hope that the adverse news may be amended. It is essential that the information supplied to them is clear, firm and true, without creating false expectations.
- Wider access to medical information through magazines, television or the Internet ideally provides for a better understanding of the situation their family member is in; however, this information can be confusing: experimental therapies under investigation or quasi-miraculous cures touting treatments known from the evidence to be ineffective. Such misinformation must be counteracted with the conviction that the treatment the patient is receiving is appropriate, averting useless discussions that lead nowhere.

By the same token, we must be open to the possibility that the family expresses the wish for a second opinion or consultation. Often this is the result of pressure from the family or the fear of losing a loved one. Providing access to a second opinion will help the family to lessen the emotional burden and increase confidence in the treatment team. If we act by applying scientific medical criteria and principles of bioethics, a second opinion can bring more satisfaction than ingratitude.

96.5.4 Step 4: Communicating Information to Families

During critical care it is useful to know the gap between the patient's or family's expectations raised by the actions of the treatment team and the effective enforcement of those expectations. The greater the gap between expectations and reality, the greater the emotional stress on the family, the greater the feeling of dissatisfaction and the lower the degree of communication.
Use simple language appropriate to the family's intellectual and cultural level.

Information can be imparted all at once or divided into smaller topics, making it more effective to improve understanding on the part of the family. We should start with general issues before focusing on more complicated topics or problems that are difficult to communicate, and then lead into a possible prognosis. Before talking about an adverse prognosis, we should begin with an introductory sentence, "We fear that the course is not what we expected". This will relieve the emotional impact of the bad news to come. Avoid using technical terminology; instead, be clear and understandable, leaving space between sentences to allow emotions to flow, be honest and always maintain good eye contact with family members. When imparting vital information it will be important to repeat it several times throughout the report, so that it is better perceived by the family. Throughout the report we will also need to check how much the family has understood of what we have said.

96.5.5 Step 5: Responding to the Family's Reactions

The impact on the family of bad news can be chaotic if given haphazardly. Humour is inappropriate during the report since it can be mistaken by the family. Avoid discussing long-term scenarios and predictions when short-term goals could be more realistic. Assure the family that you will keep them informed continuously of the situation as it changes and that their questions will be answered in future reports.
Patients and their families react to receiving a diagnosis in different ways. An effective way to counter overreaction is to provide an empathetic response. A typical empathetic response comprises 4 stages:

- Try to identify the main emotion that overwhelms the patient and their family.
- If the diagnosis is met with silence, ask how they feel.
- If it is the patient who receives the "bad news" and move physically closer if you can touch their arm or hand. Tell them that their reactions are understandable.
- Allow enough time for the patient to freely express their feelings and emotions.

96.5.6 Step 6: Designing a Treatment Plan

One of the main factors that causes distress in the relatives of ICU patients is uncertainty. It must be handled in a clear, sensible, subtle and delicate manner, explaining that the therapeutic goals are modest, short-term, not miraculous or immediate cures, and that the outcome will ultimately depend on the dynamics of myriad factors that will influence every forecast (avoid creating unfounded expectations of clinical improvement). The objectives at this stage are to show the family that the treatment team is concerned about their ill family member, that a treatment plan is being followed, that if the results are not those expected, there are alternative plans that will be initiated started without delay, and that many decisions will be shared (request to conduct early tracheotomy).
All therapeutic interventions should be mentioned, including urgent intubation, placement of catheters or drainage tubes, mechanical ventilation, surgery and other procedures. They should be communicated and explained clearly and in as much detail as necessary; not doing so invites conflict and no end of ethical, moral and medicolegal contention.
This takes into account the following aspects:

- If the patient asks about his prognosis, provide him or her with a realistic hope.
- Always consider the views of patients and their families.
- Explain and justify the tests and treatments planned.
- Develop alternative plans.

Often, the gravity of the situation or the management of urgency does not allow enough time to follow through with all these initial steps; nonetheless, "emergency" does not justify "misinformation." Once the urgent actions have been taken and the patient's condition and family so permit, the report must provide adequate, detailed and updated information. Do not terminate a family interview leaving the main topics to be covered by the report to the family.

Providing a flow of information on the relationship between the health team, patient and family is one of the most complex and important challenges we face daily. Often communication skills are not taught in academic undergraduate or graduate courses, so it becomes a matter of individual training.

Proper notification of relatives is a therapeutic moment that can lay the basis for a smooth flow of communication, permitting the family to work with the treatment team toward a common goal for the patient's benefit. We must remember that the family and the patient go through different emotional states and that families will express their own needs, fears and worries about their loved one's condition and care. If we can capture these fears and alleviate them, if we can explain the most likely prognosis, treatment options, in brief, if we support the family, we are supporting the patient.

97 Ethical Considerations in the Neuro-Intensive Care Unit

Donald W. Marion [1]

[1] Senior Clinical Consultant, The Defense and Veterans Brain Injury Center, Rockville, Maryland, USA

97.1 Introduction

Decisions to withhold or withdraw life-sustaining care are some of the most difficult and ethically challenging decisions made by physicians and family members in the intensive care unit (ICU), primarily because the patient will likely die within hours after making the decision so there will be little or no opportunity to change your mind. Such decisions typically are made for comatose patients, or those with rapidly progressive and incurable medical disorders such as metastatic cancer, or end-stage cardiac or pulmonary disease. Less frequently they involve withdrawal of life-support therapies for alert patients with steadily progressive diseases for which there currently is no effective treatment, such as Parkinson's disease or amyotrophic lateral sclerosis. Ethical questions revolve around issues of autonomy, confidentiality, futility of treatment, surrogate decision-making, the best-interest principle, and the withholding and withdrawal of treatment (Table 97.1). Respect for patient autonomy and dignity are fundamental ethical components of end-of-life decision making. The overarching ethical principle is that treatment of the patient should not simply prolong the process of dying, and should meaningfully incorporate patient and family concerns about the quality and dignity of life. For example, cardiopulmonary resuscitation of the terminal cancer patient is considered by most as a violation of the dignity of the irremediably ill.

Treatment of the patient with terminal illness should change from "critical care" to "palliative care", or from a reductionist approach to a more humanistic approach. Most patients, families, and health care providers believe that such palliative care should be home-based and focused on ameliorating patient symptoms through minimally invasive means, rather than hospital-based acute care which has as its primary focus to extend life through invasive approaches. But in the U.S. critically ill patients for whom no effective therapy exists are routinely transferred to the ICU without end-of-life discussions. Rady et al. examined the end-of-life care of 156 such patients, none of whom had discussions of palliation or end-of-life care as an alternative treatment prior to transfer to the ICU [1]. The authors concluded that the quality of end-of-life care was substantially disrupted as a result of their admission to the ICU and the intensity of invasive care associated with that transfer. Lack of clinical experience, knowledge, and competency with end-of-life care influenced admission of patients to the ICU regardless of poor prognosis. The rate of progression of the disease also influences recommendations for acuity of care. In one large study, those with end-stage COPD were 3 times more likely than those with lung cancer to be institutionalized in a long term care setting or receive long-term home care dur-

ing the last 12 months of life, whereas those with lung cancer, a much more rapidly progressive disease, were more likely to be hospitalized in an acute care hospital during that time [2].

The medical certainty of the physician's prediction of futility of further treatment, and ability to clearly communicate that certainty to the patient and/or family members, are critical components of the end-of-life decision making process. For many diseases, such as severe traumatic brain injury, massive stroke, or metastatic cancer, the terminal nature of the disease is clear. But for other diseases, such as gradually progressive dementias and chronic pulmonary or cardiac diseases, it may not be, and instead the disease may result in a slowly deteriorating quality of life and gradual loss of independence. In one Swiss study, disagreement between nurses and doctors was frequent with respect to the doctor's judgment of futility of medical interventions [3]. In general, nurses were more pessimistic but were also more often correct than doctors in predicting which patients would die. In that study of 521 ICU patients, it was apparent that the future quality of life could not be reliably predicted either by doctors or nurses. With advancing technology, there now is a computerized decision-support tool, the Acute Physiological and Chronic Health Evaluation III (APACHE III), which predicts the probability that a patient will die. APACHE III already is being used in several California hospitals to "prove to payers that healthcare resources are being used effectively and efficiently", but the APACHE data is not routinely shared with patients or surrogate decision makers [4].

97.2 End-of-life Decision-making

In the U.S., the concept of end-of-life decision making arose more than 50 years ago out of the acceptance of "brain death" as a criterion for permitting comatose patients who meet specific objective medical criteria to be considered "dead" for the purposes of ventilator withdrawal and organ transplantation. In parallel with the transplantation issue, a firm consensus has emerged in U.S. law and ethics that patients have a virtually unlimited right to refuse any unwanted medical treatment, even if necessary for life itself. Indeed, one of the two most important factors for perceived quality of death experiences is not having cardiopulmonary resuscitation during the last 8 hours of life, the other being having someone present at the moment of death [5]. And because they are trained to aggressively treat and attempt to cure disease, physicians generally tend to be less inclined toward hospice care or quality-of-life considerations. Because of advances in technology that have influenced a more aggressive approach of medical professionals to end-of-life care, physicians often offer medical interventions when such interventions may not be necessary, or may not significantly alter the quality of life. However, some recent studies suggest a change in this tradition. In one survey of 118 community-dwelling persons 65 or older with advanced disease, 58% of those with a desire to receive highly intensive intervention to treat their underlying disease received only symptomatic treatment [6]. This study, at least, suggested that many "terminal" patients were receiving less aggressive care than they were willing to undergo.

The hospice and palliative care movements have been instrumental in increasing the understanding of end-of-life care, and in providing patients alternatives to dying in the hospital. The most significant barrier in coordinating and providing end-of-life care is inadequate communication, and at present only 25% of patients who would be eligible for hospice actually enter hospice programs. Early discussion of prognosis and end-of-life care options can help facilitate earlier entry into hospice and palliative care programs. But the reality is often very different, and a survey of 29 cancer nurse specialists found

that interventions in the acute setting are typically driven by a preoccupation with treatment, routine practice, and negative perceptions of palliative care [7]. All of these factors can shape clinical decision-making and prevent patients and their families from fully participating in clinical decision-making at the end-of-life. But it is clear that the implementation of a formal palliative care protocol can improve the quality of care provided to patients dying in an acute care setting. In one prospective study, the implementation of such a program resulted in a significant increase in the number of symptoms documented, and the number of care plans recorded [8]. Opioid medication availability increased from 57% to 83%, and do-not-resuscitate orders increased from 62% to 85%. And these improvements in the delivery of palliative care did not result in an increase in the mortality rate in the ICU, suggesting that they were not simply medical interventions intended to hasten death.

The effect of race and cultural background on end-of-life decision-making has been examined, and at least one U.S.study of 9,076 patients hospitalized with illnesses associated with an average 6-month mortality of 50% did not find that race was associated with decisions to withhold or withdraw ventilator support or dialysis, or to withhold major surgery. However, another U.S.study found that patients with access to a private attending physician were significantly less likely to undergo the active withdrawal of life-sustaining therapies than were patients who did not have a private attending, despite having similar predicted mortality rates by Acute Physiology and Chronic Health Evaluation II scores [9]. That study also found that the patients who did not have a private physician had significantly shorter hospital and ICU lengths of stay, a shorter duration of mechanical ventilation, and fewer total hospital costs and charges. Since access to private physicians is directly related to the patient's economic status, these findings suggest that, in the U.S. at least, socio-economic status can be an important factor in determining the quality of end-of-life care a patient will receive. In addition, the quality of care at the end of life is strongly correlated with where patients die. Both patient and health care system variables effect access to the most common venues of death, such as hospice facilities, acute care hospitals, nursing homes, or the patient's own home. And studies of patients' care and treatment preferences at the end of life suggest that they prefer comfort more than life-extension, wish to participate in decision-making, and wish to die at home.

To be sure, the effectiveness of palliative care programs in promoting end-of-life decision-making is closely associated with the certainty of the prognosis. For example, with patients who have advanced dementia it can be difficult for a palliative care team to influence the care the patients receive in the acute hospital setting because there often is prognostic uncertainty, difficulty assessing the patient's comfort level, and biases among the decision makers. In addition, the likelihood that the terminally ill patient may have access to, or take advantage of, palliative care may be related to their age. Studies suggest that elderly patients with terminal illnesses are much more likely to receive palliative care prior to death, while patients younger than 50 years are more likely to be admitted to acute care hospitals and receive invasive life-support measures.

97.3 Advanced Directives

Advanced directives were devised as a means of expressing the individual's refusal to live in deep unconsciousness with no chance for recovery. Most believe that advanced directives should be respected because they comprise the patient's autonomous decision concerning life-sustaining treatment and death with dignity. The vast majority of patients who die in acute care hospitals, nursing homes, or hospice facilities have "do-

not-resuscitate" orders in place, indicating that the health care providers and family members have been anticipating their death. In a study of 64 patients aged 55 and older who were admitted to an ICU after injury and subsequently died, 23.4% had written advanced directives available [10]. Those with advanced directives were much more likely to have withdrawal of life-sustaining therapies prior to death than were those without such directives.

However, the implementation of Advanced Directives is often complicated by uncertainties of prognosis. It is not always clear, especially in the case of trauma or stroke, if a brain injury will cause a permanent vegetative state or if that patient can in fact regain consciousness. Moreover, preferences for life-sustaining treatment are dependent on the context in which they are made, and individuals may express different treatment preferences when they are healthy than when they are ill. For example, in one study of 88 individuals 65 or older, who were hospitalized for 48 hours or more, the subjects reported less of a desire to receive life-sustaining treatment, and particularly cardiopulmonary resuscitation or artificial nutrition and hydration, when surveyed 14 days after discharge from the hospital than they did prior to their hospitalization [11].

The decision of a patient or patient's family for a "do-not-resuscitate" (DNR) order clearly has important implications for the care the patient subsequently receives. In one retrospective cohort study of 174 moribund patients, those who did not have DNR orders received significantly more inotropic agents, dialysis, and mechanical ventilation at the time of death compared with those who did [12]. Conversely, DNR patients received a 5-fold larger cumulative dose of morphine during their final 12 hours of life. In one study of 270 patients with spontaneous intracerebral hemorrhage, outcomes for those with early (<24 hours from presentation) DNR orders were compared to outcomes for those without such orders [13]. After adjustment for age, gender, ethnicity, Glasgow Coma Scale score, hemorrhage volume, and presence of intraventricular hemorrhage, there still was a 2-fold increase in the likelihood of death for the 34% of patients with an early DNR order. And in a study of nearly 5,000 patients admitted to 11 different hospitals with acute heart failure from 1995-2000, it was found that patients with DNR orders were less likely to have had their left ventricular function assessed, or to receive renin-angiotensin system blockade, anticoagulation, or nonpharmacologic interventions compared with those without DNR orders [14]. Thus, the designation of a patient as "DNR" led to a markedly lower use of quality assurance measures in patients with heart failure.

Patients with dementia also are more likely to have DNR orders and receive less aggressive medical care toward the end of their lives. In a retrospective study of 94,100 patients aged 67 or older, the likelihood of being admitted to the ICU, or receiving ventilatory assistance, cardiac catheterization, pulmonary artery monitor, or dialysis during the last 30 days of their life was compared for patients with and without dementia. Compared to those without dementia, the 31,654 patients with dementia were significantly less likely to receive any of these five aggressive medical therapies at the end of life [15].

In addition, there can be significant differences in the interpretation of hospital resuscitation policies, and of what DNR decisions mean in relation to the practical care of patients. One report from Ireland cited confusion in translating policy into practice as contributing to communication difficulties in initiating, documenting, and implementing cardiopulmonary resuscitation decisions [16]. In this regard, one interesting and potentially challenging problem is the temporary suspension of DNR orders during the perioperative period for surgery that is recommended to resolve a treatable problem or improve quality of life. The alert patient, or family members of comatose patients, are especially disturbed when they realize that the procedure involves the temporary placement of an endotracheal tube and mechanical ventilation because this intervention is so emblematic of the prolongation of life that they are trying to avoid. Such cases often re-

quire detailed discussions with the patient or family member in order to convince them of the need for the procedure, or that the procedure will be beneficial to the patient and is not just meant to prolong life. A trusting relationship between the treating physician and patient or patient's family is essential under these circumstances.

97.4 Withholding or Withdrawal of Treatment

Withholding or withdrawing of life-support practices vary between countries, ICUs, and individuals depending on cultural and religious backgrounds, family and peer pressures, and local practices. But such decisions must always respect four key ethical principles: beneficence, nonmaleficence, autonomy, and distributive justice [17] (Table 97.2). It is incumbent on healthcare providers to be sure that families and the dying patient never feel abandoned, and nurses and doctors should make it very clear that *care* is not being withheld or withdrawn, only unnecessary medical interventions. Unfortunately, decisions to withhold or withdraw treatment are often not given sufficient attention by healthcare providers, and studies suggest that physicians need to do a better job communicating with family members about the various ramifications of these decisions. In one study of 102 elderly patients with terminal diseases admitted to two acute care hospitals in Spain for terminal care, relatives or other primary care givers were questioned about various aspects of the care being provided [18]. The relatives felt that the medical information they were given was accurate in only 67.6% of cases. Control of medical symptoms was considered good in 55%, but there was a perception that pain persisted in 14%, and 45% of patients had uncontrolled dyspnea. Predicting outcomes for critically ill patients is an important aspect of discussions with families in the ICU, but such predictions also can bias the care that ICU physicians may provide, or at least recommend. In one study, mechanical ventilation, inotropes or vasopressors, and dialysis, were significantly more likely to be withdrawn if the physician predicted a less than 10% probability of survival for the patient [19]. Indeed, such predictions were found to more powerfully predict ICU mortality than illness severity, evolving or resolving organ dysfunction, and use of inotropes or vasopressors.

Discontinuation of the mechanical ventilator, and removal of the endotracheal tube, are the most common ways in which life support systems are removed from a patient for whom no further treatment would be of benefit. Patients may be judged to be "symptomatic" during the process of extubation, and require sedation with either a benzodiazepine or opioid medication. In one study of 22 ICU patients, sedative or analgesic medications were given to 75% of the patients during withholding or withdrawal of life support [20]. The recorded reason for administering the medications was to decrease pain in 88%, decrease anxiety in 85%, decrease air hunger in 76%, to comfort families in 82%, and to hasten death in 39%. But in no instance was hastening death the only reason cited for administering the sedative or analgesic. During the 24 hours prior to withholding or withdrawing of life-support, average doses of diazepam were 2.2 mg/h, and of morphine were 3.3 mg/h. After withholding or withdrawal of life-support significantly higher doses of the medications were administered, with average doses of diazepam of 9.8 mg/h, and morphine sulfate 11.2 mg/h. In one Canadian study, the family members of 206 ICU patients who had mechanical ventilation discontinued prior to death were interviewed regarding

- Beneficence
- Non maleficence
- Autonomy
- Distributive justice

Table 97.2. **Key considerations for withholding or withdrawal of care [17].**

their perceptions of the comfort of their loved-one prior to death [21]. All patients were sedated following withdrawal of mechanical ventilation, with the most common medication being morphine (119 pts), followed by midazolam and lorazepam. In 91% of the cases, family members reported that their loved-one was totally, very, or mostly comfortable at the time of death.

Family members should be prepared for a possible delay in the patient's death following extubation, and it should not be suggested that death will necessarily occur immediately. In one study of 32 non-brain-dead patients who were terminally extubated, 25% died within an hour of extubation but one third of the patients survived for 24 hours or more, and the median survival following extubation was 7.5 hours [22]. Moreover, removal of the endotracheal tube often is associated with excessive respiratory secretions that can cause a distressing stridor which may lead relatives to believe the patient is choking and suffering. This "death rattle" is most commonly reported in patients dying from pulmonary malignancies, primary brain tumors, and brain metastases, and predicts death within 48 hours in 75% of patients. A group in the Netherlands has developed a medical protocol that they claim is effective in eliminating the death rattle [23]. Six hours before extubation, enteral feeding is stopped and parenteral fluids are reduced. Overhydrated patients are dehydrated with furosemide. Sedatives, opiods, and methylprednisolone are administered, and butylscopolamine is given 30 minutes before extubation. As a result of this treatment, the authors claim that the terminal extubation process is calm, and not associated with respiratory stridor or undo distress of the patient's family. However, terminal restlessness, or the unsettled behaviors and delirium that occurs in a substantial proportion of patients during the last few days of life, may sometimes be due to some of these same medications. Treatment induced delirium or restlessness has been associated with opioids, antisecretory agents, anxiolytics, antidepressants, antipsychotics, antiepileptics, steroids, and nonsteroidal anti-inflammatory drugs.

Withholding or withdrawal of the feeding tube is considered by most to be the single most controversial and ethically challenging decision for both family members and treating physicians. For example, a survey of Japanese physicians revealed that while most were comfortable withholding mechanical ventilatory assistance, the majority felt that tube feeding should actually be initiated in patients with terminal illness [24]. In fact, half of those surveyed did not even view tube feeding as "life-sustaining treatment". However, when it is clear that death is imminent, and particularly when the patient is obtunded, the provision of nutrition and hydration is usually considered futile. And while the primary concern has been that withholding of these fluids is cruel and causes the patient to suffer, experienced palliative care doctors and nurses have actually found that terminal dehydration appears to lessen suffering for dying patients [25]. These experts have found that medically assisted nutrition and hydration at the end of life rarely benefits patients, and as long as adequate mouth care is given, patients do not suffer.

97.5 Surrogate Decision Makers

Family members or other next of kin are often called upon to help make decisions about withholding or withdrawing life-support for patients with terminal, untreatable diseases who are cognitively impaired or unconscious. Their decision-making ability or confidence is largely related to the level of trust they have in the information being provided by the treating physician, but often times very little trust exists. This may be because many of these patients present following sudden, catastrophic events such as stroke or trauma, and there is little time for family members to establish a trusting relationship

with the healthcare providers. Zier et al. interviewed 50 surrogate decision-makers of critically ill patients in the intensive care units of a public hospital, a tertiary care hospital, and a veteran's hospital in San Francisco [26]. All but 6 of the 50 surrogates had doubts about the treating physician's ability to prognosticate the outcome of the patient. The primary reasons for this doubt were a belief that God could alter the course of the illness or that predicting the future is inherently uncertain, prior experiences where physician's prognostications were inaccurate, and other experiences with prognostication during the patient's intensive care unit stay (Table 97.3).

Some of the most important factors leading to a belief in the physician's prognosis were receiving similar prognostic information from multiple physicians, and prior experiences where they received accurate prognostic information. In another survey of 81 surrogate decision makers at a large county hospital, nearly half of the family members indicated that they had a poor understanding of the nature of their family member's illness [27]. The primary reasons for this were that the surrogate decision makers were not given enough time to speak with the healthcare providers, or that the explanations they were given were too complicated. In their observations of 51 physician-family conferences in which there were deliberations about major end-of-life treatment decisions, White and colleagues found that physicians tend to focus on discussions about the anticipated functional status or quality of life of the patient [28]. The educational level of the family, as well as the degree of physician-family conflict about withdrawing life support, were independently associated with the extent of prognostic information offered by the physician.

The critical aspects of physician communications with family members was examined in a Seattle study of four different hospitals [29]. Fifty-one ICU family conferences in which withholding or withdrawing life support was discussed were audio taped and evaluated. From these analyses, three types of clinician statements were found to be associated with increased family satisfaction: 1) assurances that the patient will not be abandoned before death, 2) assurances that the patient will be comfortable and will not suffer, and 3) support for family's decisions about end-of-life care, including support for the family's decision to withdraw, or not to withdraw, life-support (Table 97.4). Another survey of 48 family members was done to identify critical psychosocial supports and areas of conflict for family members one year after decisions to withdraw or withhold life-sustaining therapy [30]. That study found that many families perceived conflict during end-of-life treatment discussion in the ICU that centered on the communication and behavior of staff. Pastoral care and prior discussions of treatment preferences were sources of psychosocial support. Private family con-

- A belief that God can alter the course of the illness
- A belief that predicting the future is inherently uncertain
- Prior experiences where physician's prognostications were inaccurate
- Other negative experiences with prognostication during the patient's ICU stay
- Not provided enough time to speak with the physicians
- The information provided was too complicated, not understandable

Table 97.3. **Typical causes for mistrust between family members and ICU physicians [26,27].**

- Assurances that the patient will not be abandoned before death
- Assurances that the patient will be comfortable and will not suffer
- Support for the family's decisions about end-of-life care, including support for the family's decision to withdraw, or not to withdraw, life-support
- Availability of pastoral care
- Prior discussions of treatment preferences
- Availability of private family conference rooms
- Lenient ICU visitation policies

Table 97.4. **Strategies most likely to engender trust and satisfaction with end-of-life decision making among family members [29,30].**

ference rooms and lenient visitation policies in the ICU were considered especially important.

Limerick interviewed 17 surrogate decision makers in a large Texas hospital system and developed a model for how typical surrogates make decisions for withholding and withdrawing of life-sustaining measures [31]. He described: a **personal domain**, in which the surrogate rallies family support, evaluates the patient's past and present condition, and views past and future quality of life; the **ICU environment domain**, characterized as chasing doctors, developing relationships with the healthcare team, and confirming probable medical outcomes, and the **decision domain**, characterized by the surrogate arriving at a new belief, getting alone to make the decision, and communicating the decision.

Decisions to withdrawal life support treatment are sometimes made without surrogate input, particularly if family members are not present or are difficult to contact. In other cases, physicians or the healthcare system itself may unilaterally require withholding or withdrawing futile medical interventions because of limited resources (financial and physical). The state of Texas passed the Texas Advance Directives Act in 1999, one provision of which allows a health care facility to discontinue life-sustaining treatment against the wishes of the patient or the guardian ten days after giving written notice if the continuation of life-sustaining treatment is considered medically inappropriate by the treating medical team. If they follow all the provisions of the Act, physicians and the hospital are provided legal immunity from prosecution. When there are disagreements between health care providers and surrogate decision makers, such disputes occasionally are settled in court. A review of such cases in Australia reveals three legal criteria for withholding or withdrawing treatment that have been incorporated in that country's common law: 1) present and future quality of life, 2) futility of present treatment, and 3) burdens versus benefits of present and future treatment and its discontinuance [32]. In a review of critically ill adults from 7 different hospitals in the U.S., 30 of 451 deaths in ICUs occurred after a withdrawal of life-support systems that was ordered by treating physicians without the input of a surrogate decision maker [33]. Most of these withdrawal of life-support decisions were also made without institutional or judicial review, and in a manner inconsistent with the American College of Physicians guidelines for judicial review. Other studies have shown that there are dramatic geographic variations in the prevalence of these unilateral decisions for withdrawal of life-sustaining therapies, and there is evidence that this variation may be driven more by physician attitudes and biases than by factors such as patient preferences or cultural differences. In one large public hospital, decisions to limit life support for 16% of patients who were admitted to the medical ICU, and lacked both decision-making capacity and a surrogate decision-maker, were made independently by the treating physicians and without judicial or institutional review [34]. The majority of these patients were white males older than 64 years.

97.6 Physician's Responsibilities

Improved communication between physicians and family members of critically ill patients can decrease the prolongation of dying in the ICU, but physicians frequently miss opportunities to listen and respond to family members, acknowledge and address emotions, and pursue key principles of medical ethics and palliative care. This includes the exploration of patient preferences, explanation of surrogate decision-making, and affirmation of non-abandonment. It is not always apparent how well physicians do with regard to communication and education of patients and family members. Comprehensive documentation of end-of-life care is lacking in many U.S.medical records, and one study

found that only 10% of the medical records of patients who died after withdrawal of care had documentation of physician participation in the decision making process [35].
In communicating with patients or their surrogates about withholding or withdrawing care, doctors typically withhold information about interventions that are judged too futile to offer. Thus, they retain greater decision-making burden and power, and face weaker obligations to secure consent from patients and proxies. Physician bias clearly has an overarching impact on decisions for withholding or withdrawing care for critically ill patients. In a Canadian study of 851 ICU patients receiving mechanical ventilation, the strongest determinants of the withdrawal of ventilation were the physician's perception that the patient preferred not to use life support, and the physician's prediction of a low likelihood of survival in the intensive care unit, but not the severity of illness and organ dysfunction as assessed on objective scales [36]. A large survey of 1000 generalist and subspecialist internists from Delaware found that respondents were least likely to withhold or withdraw treatment in those who were nonterminally ill, and in alert patients [37]. They were more likely to withhold or withdraw treatment from those with terminal illnesses, dementia or coma. In addition, respondents were most comfortable withholding or withdrawing dialysis and ventilators, and least comfortable withholding or withdrawing feeding tubes and antibiotics. This study clearly found that a large proportion of physicians may be unwilling to adhere to some patients' wishes to withhold or withdraw life-sustaining treatment, especially when they included withdrawing enteral nutrition, and that the clinical scenario and type of treatment are likely to affect the physician's decisions.
In one U.S.hospital, "Q Methodology" was used to locate and describe subjective influences on physicians for end-of-life medical decision making [38]. Second-order factor analysis on seventeen viewpoints used by physicians in four hypothetical urgent decision cases revealed that physicians were guided by patient-focused beneficence, a patient- and surrogate-focused perspective that included risk avoidance, and the best interest of the patient guided by ethical values. Economic impact on the physician, expediency in resolution of the situation, and the expense of medical treatment, were not found to be influential determinants in that particular study. From an ethical and medico-legal perspective, others have specifically emphasized three key issues: the distinction between allowing patients to die in accordance with their wishes versus causing them to die; the fine line between respecting a patient's wish to die with dignity and control versus the risk of subsequent allegations of euthanasia or physician-assisted suicide; and the adjunctive use of medications that simultaneously provide comfort but also may hasten death, such as high doses of morphine.
There is considerable debate about the use of "terminal sedation", with some arguing that this represents physician-assisted suicide or euthanasia, while others believe such treatment is good medical care aimed at reducing the consciousness of a terminal patient in order to relieve distress. In some cases it is used as a measure of last resort, when all other measures to reduce pain and suffering have failed. But in other cases, such as the patient who is brain dead, high doses of opioids may be used to calm the patient and hasten death, and in those cases some have labeled the practice as "slow" or "backdoor" euthanasia. However, in one survey of family members of patients who died after withdrawal of life support, the perception of over 90% of 196 respondents was that their loved-one was either totally, very, or mostly comfortable during the hours prior to death, and this undoubtedly was due to the administration of sedatives such as morphine, midazolam, or lorazepam during and after withdrawal of life support measures [21].
The principle, or doctrine, of "Double Effect" is a set of ethical criteria for evaluating the permissibility of acting when one's otherwise legitimate act, such as relieving pain with

• The nature of the act is itself good, or at least morally neutral • The agent intends the good effect and not the bad, either as a means to the good or as an end in itself • The good effect outweighs the bad effect in circumstances sufficiently grave to justify causing the bad effect, and the agent exercises due diligence to minimize harm

Table 97.5. **Criteria that justify the doctrine of Double Effect.**

opioid analgesics, will also cause an effect that one would normally be obliged to avoid, such as death. Criteria that some suggest make Double Effect treatment justifiable include: 1) the nature of the act is itself good, or at least morally neutral; 2) the agent intends the good effect and not the bad, either as a means to the good or as an end itself; and 3) the good effect outweighs the bad effect in circumstances sufficiently grave to justify causing the bad effect, and the agent exercises due diligence to minimize the harm (Table 97.5).

During the 1990s, physician-assisted suicide received massive media coverage when Dr. Jack Kevorkian wrote about his interventions with at least 130 patients, and especially when he allowed the U.S. television news magazine "60 Minutes" to film an ALS patient administering lethal doses of medication to himself. In 1991 the State of Michigan revoked Dr. Kevorkian's medical license, and he was convicted of second-degree murder and imprisoned from 1999 to 2007. However, U.S. sentiment about physician-assisted suicide is gradually evolving. In 1997, after an extended Court battle, the state of Oregon's "Death with Dignity Act" went into effect and essentially legalized physician-assisted suicide in that state. Similar legislation exists in The Netherlands. Justice requires that we should allow assisted death for patients with terminal illness where no curative therapy exists, and when the steady progression of the disease is physically and emotionally devastating. The compassionate argument is that the patient has a right not to suffer or have constant pain. From a legal perspective, the argument revolves around individual liberty versus state interests. Though society has a strong interest in preserving life, that interest lessens when a person is terminally ill and has a strong desire to end their life. A complete prohibition on assisted death can be viewed as excessively limiting personal liberty. The opposing argument is that physician-assisted suicide is immoral, and disregards the sanctity of life and our religious and secular traditions against taking human life. There also is a clear potential for abuse. For example, certain groups of people, lacking access to care and support, may be persuaded to undergo assisted suicide, or the procedure may become a cost-containment strategy. It is clear that for physician-assisted suicide to be both legal and ethical, there must be a great deal of trust between the patient and the physician. The system as a whole must be constantly vigilant that voluntary, active assistance in dying never becomes involuntary.

Germane to this issue is an ethical analysis of the removal of implanted cardiac pacemakers or cardio-defibrillator devices at the patients' or surrogate's request. Ethicists at the Mayo Clinic reviewed 6 such cases treated at their hospital, and determined that granting terminally ill patients' requests to withdraw unwanted medical support is legal and ethical [39]. Death after removal of the implanted cardiac pacemaker or cardio-defibrillator device was considered due to the patient's underlying pathology, and not the same as physician-assisted suicide or euthanasia.

97.7 The Role of Religion

Organized religions, and various religious beliefs, play an important role in shaping the way most patients and family members think about end-of-life decision-making. While

there are too many different religions to chronicle the relevant teachings of each, the recommendations of some of the most common religions are of interest and provide insight into the common themes. Specific directives of the Roman Catholic Church were articulated by Pope John Paul II in his address to the participants at the International Congress on Life-Sustaining Treatments and Vegetative State: Scientific Advances and Ethical Dilemmas, presented on March 20, 2004. In that address he clearly stated that the removal of feeding tubes from people in vegetative states is immoral, and that no judgment on their quality of life could justify such "euthanasia by omission." The Pope said even the medical terminology being used, such as persistent vegetative state, was degrading, and that no matter how sick a person was, "he is and will always be a man, never becoming a 'vegetable' or 'animal.'" "Providing food and water to such patients should be considered natural, ordinary and proportional care – not artificial medical intervention." As such, it is morally obligatory to continue such care. Since no one knows when a patient in a vegetative state might awaken, […] we cannot ethically justify the abandonment or the interruption of minimal care for the patient, including food and water. "If this is knowingly and deliberately carried out, this would result in a true euthanasia by omission," he said.

To be sure, this papal allocution has not been universally embraced by all Catholic groups, some of whom see the statement as inferring that the average Catholic patient is incapable of making proper judgments about their own care [40]. In most protestant communities, the decrees of the Pope as described above are considered somewhat out of step, and inconsistent with the concepts of the right of self determination and death with dignity. As a result, and as will be seen in the next section regarding international differences in end-of-life decision making, there are significant differences in the way some northern Europeans view withholding and withdrawal of care as compared to those in the south, and particularly the Italians.

The worldwide emergence of religious fundamentalism, and the associated vitalistic view about the sanctity of life, may result in a significant reversion to older, more conservative rules about withdrawal of life support decisions, particularly in the Middle East and Asia [41]. But while this may be a trend for the future, it is not currently observed in all of these countries. For example, in the predominantly Muslim country of Pakistan, one survey of 137 physicians and nurses from 3 separate hospitals did find that while 28% considered it their responsibility to sustain life at all costs, even for a DNR patient, only 8% gave religious beliefs as their reason [42]. Moreover, 85% of respondents recognized "brain death" as a legitimate medical diagnosis.

97.8 International Differences in End-of-life Decision Making

There are significant differences between countries regarding end-of-life medical practices. In some cases this is related to the predominant religion of the country, but in others there also are important non-religious influences. The findings of a large prospective investigation of end-of-life decisions in 37 European intensive care units located in 17 European countries (the EURELD Project) were recently published. The study found that physicians from Switzerland and Sweden were most likely to withhold or withdraw treatment with the intention of hastening the end of life, while those from Denmark and Belgium were least likely [43]. In addition, 73% of all participants frequently admitted patients with no hope of survival [44]. While 80% felt that DNR orders should be applied for such patients, only 58% did so, and there was a wide varia-

tion between countries – DNR orders were recorded in only 8% of cases in Italy, but in 91% of cases in the Netherlands. Moreover, physicians in the countries of southern Europe were less likely than those in the north to apply DNR orders, withhold treatment, and to discuss such issues with the patients and their families. According to the survey, withholding of life-sustaining therapy was much more common than withdrawal of therapy, the reverse of what has been reported for U.S. ICUs. Forty percent of respondents reported that they would deliberately administer large doses of drugs until death ensued. The survey also revealed that ICU admissions were frequently limited by the availability of beds, and this was most pronounced in southern European countries and in the United Kingdom.

In some European countries there also is an increased focus on emergency department end-of-life decision making. One French study reported a series of cases where the decision to withhold or withdraw treatment was actually made in the prehospital setting by emergency physicians [45]. Perceived imminent death due to multiple trauma, chronic disease with severe heart failure, or post anoxic coma, were the most common reasons for withholding or withdrawing life-sustaining treatment in that study, and 79% of these patients died before reaching the hospital. In another French study of 14,875 patients, 119 had decisions to withhold or withdraw life-support made in the emergency department [46]. The mean age of the patients was 75 years, and most had underlying chronic cardiopulmonary disease or metastatic cancer. Life sustaining measures were withdrawn in 37% and withheld in 63%. The median time interval from the decision to death was 16 hours, though at least one patient survived for 140 days. The family was involved in the decision-making process in 72% of patients. In the French ICU, decisions to forgo life-sustaining therapy rarely involve the patient's perception of his or her quality of life, and in a study of 105 patients, the decision to withhold life-sustaining therapy considered the patient's wishes or religious values in only 15% of cases [47]. The advice of the medical team was the most important factor considered in 95.3% of cases. However, a study of end-of-life decision making in a French pediatric ICU suggests much more involvement of family members of dying children, and in that study parents' opinions regarding life-sustaining treatment were obtained in 72.1% of cases [48].

In Spain, the treating ICU physician plays a very active role in decisions to withdraw or withhold care. In one study of 6 adult ICUs, the proposal to withhold or withdraw life support was initiated by physicians in 92.9% of cases [49]. The patient's family was not involved in the decision to withhold or withdraw life support therapy in 28.3%, and patient's advanced directives, where patient's had expressed their wish to decline life-prolonging therapy prior to ICU admission, were present in only 9%. Germany has specific legislation that requires a physician to seek permission for end-of-life decisions from a formally legitimized guardian, and that individual is then legally required to seek permission from a Court of Guardianship before end-of-life medical decisions are made in those cases where the patient is not competent to make their own decisions. But the vast majority of surrogate decisions on incompetent patients are actually not covered by legally valid consent because neither the legal nor the medical systems in Germany are capable of coping with the volume of cases if consent for end-of-life withholding or withdrawal of care were always requested according to legal regulations. In the Netherlands, a large national survey revealed that a nontreatment decision was made in 30% of all deaths in 1995 [50]. Artificial nutrition, hydration, and antibiotics were the treatments most frequently foregone. Thus, in most cases the treatment withheld did not involve high-technology treatment. In 17% of cases, the nontreatment decision was made without being discussed with the patient or the patient's relatives, and without knowledge of the patient's wishes.

Compared with the European countries, withdrawal of care is much less common than withholding of care in Israel. In one study of end-of-life care, 91% of discussions with family members revolved around withholding of care but only 9% were about withdrawal of existing life-support measures [51]. No patient underwent active shortening of the dying process, 69% of patients actually had treatment withheld, and only 5% underwent withdrawal of treatment. In most Israeli clinics, withdrawal of treatment is limited to those diagnosed with brain death, and in one study, no patient had antibiotics, nutrition, or fluids withheld or withdrawn [52]. The reluctance to withdraw treatment also was seen in Lebanon, where a survey of one ICU revealed that among those who died, the decision had been made to withhold life-sustaining therapies in 38%, but to withdraw therapies in only 7% [53].

End-of-life procedures in Argentina are very conservative, perhaps due to a strong Roman Catholic religious influence. In one study of 16 pediatric intensive care units, most children underwent cardio-pulmonary resuscitation before death, and active withdrawal of life-support treatment was rare [54]. DNR orders were present in 16%, and life-sustaining care was withheld in 20%, of those who died. In a major teaching hospital in Hong Kong, of 490 patients who died in the intensive care unit, limitation of life support occurred in 58.8% [55]. Relatives or patients requested limitation of life support in 11%, though the family and/or patient concurred with limitation of life support in 95% of the cases. Therapy was withheld in 31%, and withdrawn in 28%, of the deaths.

In the U.S., withdrawal or withholding of care decisions were associated with approximately 50% of ICU deaths [56]. Withdrawal of life-support was 4 times more common than withholding of life-sustaining therapies in those with a poor prognosis. In patients admitted to one large U.S. ICU with severe neurologic illness, the role of the severity of the illness, healthcare system issues, and social factors were assessed to determine their impact on the decision to withhold or withdraw care [57]. In that study of more than 2000 patients, decisions to withdraw mechanical ventilation were based primarily on the severity of the acute neurologic condition and age. Marital status, premorbid functional status, attending status (private vs. academic), and type of health insurance were not associated with decisions to withdraw ventilation. African-American patients, and those who had had surgery, were less likely to have mechanical ventilatory support withdrawn.

97.9 Unique Pediatric Issues

There is no more ethically and emotionally laden challenge than that of end-of-life decision making for terminally ill infants and young children. Many parents are devastated to the point of being dysfunctional, while others are just emotionally numbed, by the thought of losing their child. Thus, it often is extremely difficult for physicians to discuss withholding and withdrawal of care with these parents. Factors that influence parents in their decisions to withhold or withdraw life-sustaining therapy for their terminally ill child include previous experience with death and end-of-life decision making for others, their personal observations of their child's suffering, their perceptions of their child's will to survive, their need to protect and advocate for their child, and their family's financial resources and concerns regarding life-long care (Table 97.6) There also are racial differences in the likelihood that withdrawal or withholding of care recommendations will be accepted, and they appear to involve such factors as mistrust, religiosity, and perceived discrimination. A study comparing acceptance of withdrawal/withholding of care recommendations between African-American and white parents of

- Previous experience with death and end-of-life decision making for others
- Personal observations of their child's suffering
- Perceptions of their child's will to survive
- The need to protect and advocate for their child
- The family's financial resources, especially with regard to life-long care

Table 97.6. **Issues that are most important to parents in their decisions to withhold or withdraw life-sustaining therapy for their terminally ill child.**

moribund infants found that approached families of white infants agreed to limit life-sustaining medical treatment 80% of the time compared to 62% of families of African-American infants [58]. During the past 2 decades there does appear to be improved communication between parents and healthcare providers leading to a greater acceptance of end-of-life decision making, and at least one study has found that withholding of care, and particularly CPR, has became more common in the pediatric and neonatal ICU [59].

Infants and children with gradually progressive terminal diseases, such as certain inborn errors of metabolism or aggressive malignancies, present particularly difficult ethical challenges. Acute caregivers frequently struggle with feelings that they are saving children that should not be saved, or, conversely, that they are giving up on children too soon. Because most of these children have complex medical problems, they are usually cared for at major University hospitals by multiple caregivers, and studies suggest that there can be significant interdisciplinary differences in biases, knowledge, and beliefs, especially between nurses and doctors, with regard to withholding or withdrawing of life-sustaining therapies. For example, in one study of 781 clinicians working in a pediatric ICU, twice as many nurses as attending physicians felt that they were saving children who should not be saved [60].

When life-sustaining treatment is withdrawn from infants or young children, the decision to do so usually occurs after a prolonged ICU stay of 20-30 days [61]. Most life-sustaining treatments are withdrawn simultaneously rather than stepwise. Perhaps more so than with adults, the neurologic status of the sick child has become a focal point for end-of-life decision-making, and a consulting neurologist, working with the critically ill children and their families, is often a key figure in determining diagnoses and prognoses.

97.10 Conclusions and Key Concepts

The most important aspect of end-of-life decision making in the ICU and elsewhere is communication between the physician and patient, or family members if the patient is cognitively impaired or comatose. Physicians must be sensitive to the emotional needs of these individuals, and to their level of understanding of the complex medical issues related to withdrawal or withholding of care. It is important to clearly relate the degree of certainty with which the physician is able to make the prognosis of death, and the futility of treatment, in terms that the patient and/or family can understand. It should be clearly explained that while death may be postponed by the addition or continuation of certain life-sustaining medical interventions, withholding or withdrawal of those interventions should not be viewed as the cause of the patient's death. Rather, the underlying disease is the cause of their death. In addition, it must always be emphasized that a high quality care will continue to be provided to the patient even after the withholding or withdrawing of specific and futile life-sustaining therapies. The administration of sedatives or narcotics after extubation of the patient can help relieve the patient's distress or pain, but also demonstrates to family members the continued involvement of their healthcare team.
